Not mentioned in either notification was that Dominion had rapidly developed a software change, apparently in response to our findings, that had begun the EAC certification process on October 4 (+43 days) as part of Democracy Suite 5.17 [58]. EAC offers a rapid review process for "minor" changes, which can be used to quickly provide security patches [59], but Dominion did not utilize this process. Instead, it rolled the change into a major update, necessitating a lengthy review that was not complete until March 16, 2023 (+206 days).

Although 5.17 is said to incorporate an "[i]mproved pseudo random number algorithm" (Section 5.1), the user manual for this version contains new guidance advising officials to "remove the RecordId information" "[i]f the Cast Vote Record Export is going to be shared" [20, p. 97]. This suggests that the new PRNG may not fully address the flaw. If removal of the record ID field is indeed warranted under 5.17, this guidance seems dangerously incomplete; it does not mention removal of the "CvrNumber" field from CSV-style CVRs or the "ImageMask" field from JSON-style CVRs, that ballot image filenames must be sanitized, or that records must be randomly shuffled (Section 5.2). Moreover, it is unclear why Dominion has left removal of the record ID field to end-users instead of performing it programmatically.

6.4 Disclosure Outcomes

Our disclosure's strategy of directing contact through state-level election offices proved less than fully effective, as officials did not always propagate information they received to the affected local jurisdictions. Only two states asked us follow-up questions or reported back to us about their mitigation plans. Though some states and localities applied appropriate defensive measures, jurisdictions in at least Alaska, California, and Georgia published vulnerable data in November 2022.

The city of San Francisco provides an illustrative example. It uses Dominion tabulators to count precinct-voted ballots and has published ballot-level data in every election since at least 2019. If the city continued to follow its ordinary procedures, tens of thousands of voters' privacy would be at risk. Our October 10 notification to California's Chief of Elections explicitly named San Francisco as an affected jurisdiction, yet the state neglected to inform the city [52].

On November 8—the day of the general election—San Francisco began publishing new vulnerable data to its elections website. We quickly attempted to contact the city's Department of Elections via its website and Twitter, but we received no response, and San Francisco posted even greater volumes of vulnerable data over the next several days. The city only began to address the problem months later, after we wrote to the San Francisco Elections Commission [28], which conducted its own technical investigation of the issue [32].

Even after San Francisco had completed its investigation, issues persisted into the city's March 2024 primary, 16 months after our initial disclosure. In that election, which again used a vulnerable version of the Dominion software, the city redacted the "RecordId" field from published CVRs, but it neglected to redact the "ImageMask" field, which contains a copy of the record ID. It also failed to remove the record IDs from ballot image filenames. These incomplete redactions happen to exactly match Dominion's guidance from the 5.17 user manual, but unfortunately they leave DVSorder fully exploitable.

Other states likewise continue to be vulnerable. One example is Georgia, which uses vulnerable scanners state-wide and requires ballot-level data to be published by law. The Georgia Secretary of State announced in 2023 that he would defer upgrading to 5.17 until after the 2024 presidential election, more than two years after our public disclosure, citing the cost and logistical complexity of deployment [61]. To our knowledge, the state has yet to issue any guidance on sanitizing ballot-level data, and Georgia counties have published vulnerable datasets as recently as May 2024.

On the other hand, our disclosures prompted effective action in at least some jurisdictions. Minnesota's Secretary of State, for example, said in a statement that his office was "working directly with the counties that use the impacted machines to ensure they are aware of the vulnerability and mitigation measures" [40]. The state subsequently amended its election law to allow jurisdictions to withhold ballot-level data from public release if it was "likely to facilitate associating votes with particular voters, such as showing the order in which the votes were cast" [25]. Several other states, including Michigan, have completed deployment of Dominion's updated software, which may remediate the vulnerability.

6.5 Effects on Public Trust

Making DVSorder public appears to have triggered little mis- or dis-information. Researchers at the University of Washington found in the wake of our public disclosure that nearly every high-engagement post about DVSorder retained our wording that it was a *privacy flaw*, and that conspiracy theories that referenced the issue gained little traction [12]. As noted above, we intentionally emphasized the privacy nature of the vulnerability, and these findings suggest that our strategy was successful at mitigating risks to public trust. This outcome suggests that public communication concerning election vulnerabilities, if appropriately clear and precise, can be constructive and responsible even in an age of disinformation.

In a reflection of the partisan politics that have infected the topic of election security, our findings were reported only by right-wing media outlets. This is unfortunate, as all voters deserve to be accurately informed about the risks elections face and steps officials take—or fail to take—to defend them.

7 Related Work

We are far from the first researchers to draw attention to the threat of ballot-ordering attacks. While DVSorder is unusual in that it can be discovered and exploited using only public information, it follows in a long series of vulnerabilities in voting systems from around the world over the past two decades.

7.1 Past Ballot-Ordering Flaws

Many examples of ballot-ordering flaws exist in the literature. We survey some of the more notable examples below:

Diebold AccuVote TS (2004) As part of the first academic security review of a deployed electronic voting machine, Kohno et al. discovered that the AccuVote TS assigned ballot serial numbers using an LCG that was seeded in a predictable manner, allowing the CVRs to be unshuffled [34]. It is remarkable that the Dominion machines we studied had such a similar design flaw nearly 20 years after scientists first warned of the danger of using an LCG to generate ballot identifiers.

Diebold AccuVote TSX (2007) Calandrino et al. found that Diebold had implemented a new PRNG in response to the findings above, but the generator was still not securely seeded, allowing the order of ballots to be recovered [11, Issue 5.2.21].

Sequoia AVC Edge (2007) In an examination of the AVC Edge, Blaze et al. found that it shuffled ballots into only ten possible orders. An attacker with access to the raw data could determine the seed and fully unshuffle the ballots [8, §4.4.8].

ES&S iVotronic (2007) Blaze et al. discovered that the iVotronic's internal data structures were insufficiently randomized, allowing a partial ordering to be determined from the raw files [7, §7.2.15–16]. Moreover, individual audit trail printouts contained a bar code that included the time the ballot was cast, allowing the order to be fully reconstructed.

Hart eSlate and eScan (2007) Inguva et al. analyzed eSlate and eScan machines, which they found used a poorly randomized data structure for CVR storage, allowing ballots to be recovered in voted order from the raw data files [31, Issue 25].

Sequoia AVC Advantage (2008) Appel et al. found that the AVC Advantage shuffled its ballot storage using a 32-bit seed that could be extracted by poll workers [3, §49].

Scytl Pnyx.core (2008) Clarkson et al. found that remote voting software developed by Scytl relied on an LCG for ballot shuffling [14, §4.3.4.1]. They reported that it used the C standard library's `rand()` function, which is notoriously insecure, and had a bug that resulted in a seed of 8 bits instead of the intended 32, allowing votes to be unshuffled with ease.

India (2010) Wolchok et al. demonstrated that paperless electronic voting machines used nationwide in India stored votes internally in the order they were cast [63]. Given brief physical access to the machine, ballots could be extracted in voted order by connecting a device to the memory chip.

Brazil (2014) Aranha et al. discovered that voting machines used throughout Brazil relied on the C `rand()` function to shuffle ballots [4]. This generator was seeded with the current time in seconds when the software was initialized, which usually occurred between 7 and 8 AM on the day of the election. The seed space thus included only 3600 possible values. Moreover, the machine printed the time it was initialized on a paper poll tape, publicly revealing the exact value of the seed.

Australia (2018) Wilson-Brown discovered that, since 2001, the voting technology used by the Australian Capital Territory *did not shuffle ballots* before they were published online [62]. The election authority dismissed the vulnerability as "purely theoretical" [30], and as of 2020 it had not been fixed [55].

Dominion ICP (2021) In a court-authorized examination, Halderman and Springall found that ICP scanners record ballot images to their removable memory cards in the order they were cast, and, by default, unencrypted [29, §11.2]. Election workers with access to the cards could exploit this to recover the ballots in voted order, even if DVSorder was corrected.

That these errors have occurred time and again for 20 years suggests a persistent failure by vendors and regulators to safeguard voter privacy. Even after this long line of research, ballot-ordering flaws appear not to be recognized within the election sector as important vulnerabilities, despite being a low-risk exploit accessible even to unsophisticated attackers and despite increasing public availability of ballot-level data.

7.2 Other Ballot Secrecy Risks

Protecting privacy in ballot-level data requires more than just concealing the order of casting. Voters who are bribed or coerced can reveal which ballots are theirs by marking them in a distinctive fashion [9], by entering a unique name as a write-in candidate, or by selecting a specific pattern of choices in down-ballot contests [47]. Some voters find themselves in very small anonymity sets: in the U.S., voting districts at different levels sometimes intersect such that only one or a few voters cast ballots with a particular set of contests, and voters with disabilities often use ballot-marking devices that print ballots that appear different from ones marked by hand [36]. Other, more exotic attacks—such as techniques for automatically fingerprinting ballots based on natural imperfections in the paper surface [13] or on voters' individual marking styles [10]—may provide additional avenues for deanonymization.

8 Discussion

DVSorder points to systemic gaps in the design and regulation of election technology with regard to voter privacy. It also provides a case study of challenges to effective vulnerability disclosure and mitigation within the election sector. We discuss these issues below and offer recommendations.

8.1 Design, Certification, and Testing for Privacy

That ballot-ordering vulnerabilities continue to persist indicates an ongoing inattentiveness to voter privacy by voting system developers and regulators. Privacy-conscious system design should have prevented the introduction of these flaws, and privacy-conscious security review should have uncovered them before they placed voters at risk.

Much responsibility falls on the election system vendors. DVSorder resulted from Dominion's use of a class of pseudorandom number generator that was known to be insecure

since the 1970s [50]. The company's attempts at obfuscation suggest that it knew the approach was unsound but was unwilling to apply sufficient resources or expertise to implement a correct solution. Responsibility also falls on state and federal testing authorities, who repeatedly passed the vulnerable Dominion systems, even though the vulnerability should have been readily apparent in a source code review.

U.S. Federal Standards One reason that such problems have been overlooked during system certification is that testing standards are insufficient. In the U.S., the most important regulatory standards for election equipment are the Voluntary Voting System Guidelines (VVSG), a set of criteria maintained by the EAC. Though compliance is not federally mandated, many states require it [43]. Equipment is tested against these standards by private entities called Voting System Test Laboratories (VSTLs) that are accredited by the EAC.

While the EAC guidelines include a number of provisions related to voter privacy, they are evidently ineffective. For example, VVSG 1.0 provides that "[t]he voting process shall preclude anyone else from determining the content of a voter's ballot, without the voter's cooperation" [57, §3]. The affected Dominion equipment is certified to this standard, and despite its plain language, EAC representatives have informed us that they have not found the equipment to be in violation.

A recently adopted revised standard, VVSG 2.0, adds more specific privacy requirements among many other changes. It provides that "[t]he voting system must not contain data or metadata associated with the CVR and ballot image files that can be used to determine the order in which ballots votes [sic] are cast" [56, §10.2.2-B]. Though such a provision would seem to squarely address DVSorder, it is still possible that affected systems could be certified under the new requirements. This is because VSTLs test systems against a predefined set of "test assertions", which serve as a checklist for determining whether or not the system meets the VVSG's requirements. There is no test assertion that requires a VSTL to assess compliance with this provision [16], so a nonconforming system could still be certified under current testing procedure.

Recommendations Voting system vendors should incorporate a focus on security and privacy throughout the product development cycle, as is best practice in the broader technology industry. Vendors should design systems to be secure against a threat model that includes deanonymization attacks, and they should rigorously test their systems for success against that model, whether through in-house or by engaging qualified penetration-testing firms.

Likewise, federal and state regulators should place greater value on privacy. In particular, the EAC should ensure that VSTLs test for all privacy-related requirements in VVSG 2.0. While such open-ended requirements can be difficult to reduce to checklist or "test assertion" form, many problems like DVSorder could be uncovered if the agency required VSTLs to perform a privacy-focused source code review [16].

8.2 Challenges to Effective Disclosure

When vulnerabilities slip through certification and are discovered in live election systems, mitigation requires getting timely, accurate, and actionable information to all responsible parties, which potentially include hundreds or thousands of local jurisdictions. Challenges in conducting this complex communication can delay remediation and increase risk.

During disclosure of DVSorder (Section 6), we were surprised that CISA and EAC did not provide effective assistance. Neither agency helped to coordinate disclosure or even to broker communication between us and state officials. We were also surprised to learn that neither federal agency has the ability to comprehensively identify (much less contact) the U.S. localities affected by a particular voting system vulnerability.

Some state-level authorities did not convey our disclosure to localities. This leaves local officials reliant on their system vendors for information about vulnerabilities in their products. Unfortunately, Dominion chose not to cooperate with us and issued guidance that was incomplete and misleading. As a result of these challenges, many localities did not know they were vulnerable even after we publicly announced the flaw.

Adding to the confusion, when states and localities did receive notifications about the flaw, those notifications were inconsistent. Dominion and the EAC issued separate advisories without coordinating with us that characterized the problem in different and incomplete ways. Faced with conflicting statements about the problem coming from researchers, the federal government, and the system vendor, election officials were left to puzzle out what to do for themselves.

Recommendations The federal government should establish a coordinated vulnerability disclosure program that reliably serves as a clearinghouse for election system vulnerability disclosures. An existing program, such as CISA's, could serve this role if it had the resources and mandate to assist in cases such as DVSorder. Vendors and federal authorities should coordinate with researchers who identify vulnerabilities in order to ensure that communication about the problems is accurate and consistent. State-level election agencies should establish a uniform contact method for reporting security disclosures (perhaps coordinated by a body such as NASED). Vendors like Dominion should accept responsibility for vulnerabilities in their products. By working cooperatively with third-parties who report such problems, vendors can convey more accurate information to localities and better facilitate mitigation.

8.3 Challenges to Effective Patching

Communication is only half the battle. Once state and local entities know about a vulnerability, they need to take effective steps to mitigate it. Often one of the most important mitigations is deploying software updates. This can be logistically challenging when it involves many thousands of systems operated by localities across a state, since election equipment is typically not connected to the Internet and updates must be installed manually by a technician. Unfortunately, as DVS-

order illustrates, the election sector's approach to vulnerability management lags far behind enterprise best practice.

From the time we disclosed the problem to Dominion, it took almost seven months before a software update to address it was developed and federally certified. Even after the update was available, some jurisdictions stated that they would need years to deploy it, and others have no plans to do so. Now, almost two years after our disclosure, states such as California and Georgia are still using vulnerable system versions.

Past election system vulnerabilities have seen even worse response times. For example, in 2007, researchers publicly disclosed buffer overflows and numerous other flaws in a paperless voting machine called the Diebold AccuVote TSX [11], but Georgia used the machines state-wide for 12 more years *without ever patching them* [26]. States will need to significantly mature their vulnerability management practices to match the rapid response times that are expected in industry and other areas of critical infrastructure.

Recommendations Voting system vendors should work to make software fixes available more quickly, and make them easier to deploy, by producing focused patches for security issues rather than incorporating them into major updates. Vendors should also commit to back-porting security fixes to all in-service versions of their products.

States and localities should build capacity to implement election software updates and other mitigations quickly. One potentially effective approach would be to plan and budget for deploying such updates on an annual cycle. This would maintain institutional familiarity with the logistics, which would also help ensure that emergency fixes could be deployed rapidly before an election if necessary.

The costs of keeping up-to-date with security patches vary dramatically with the style of election technology. States like Georgia that require all in-person voters to use computer ballot-marking devices will need to update and maintain many times as many units of equipment as states where most voters mark ballots by hand. States should consider and price-in these costs when selecting a voting system.

The EAC could encourage timely patching under its existing regulatory authority by withdrawing certification from versions of election systems that lack important security fixes. This would encourage vendors to rapidly develop security patches and prompt many jurisdictions to apply the patches so as to maintain compliance with state law.

9 Conclusion

Researchers have uncovered ballot-ordering vulnerabilities at a steady cadence for more than two decades, but DVSorder is a particularly concerning instance of such a flaw. It allows unsophisticated and passive attackers to learn how individuals vote without risk of being detected, and it comes at a time when more ballot-level data is public than ever before.

Jurisdictions that use affected equipment should ensure that their systems are patched to eliminate the flaw, and, until then, that their ballot-level data is properly sanitized before publication. Unfortunately, some states and localities have yet to implement these steps and continue to release vulnerable data today, nearly two years after our disclosure.

DVSorder should be a wake-up call that the election sector needs to take voter privacy more seriously. How is it possible that in 2022, a leading voting system vendor thought shuffling ballots with an LCG was appropriate? Why didn't this raise red flags with regulators during any one of their dozen certification reviews? Why can't jurisdictions as large as Georgia or as sophisticated as San Francisco manage to address the problem even after they know about it? If the right to a secret ballot is to mean anything, actors across the election technology space must do their part to protect it.

A Mathematics of the PRNG

The generator used by Dominion has interesting properties that do not appear to have been discussed in prior literature.

A.1 Mathematically Equivalent Generators

We describe the Dominion ICP generator as follows, where s defines the substitution rule and p defines the permutation rule. For convenience, let m denote 1000000.

$$x_{n+1} = x_n + 864803 \mod m,$$

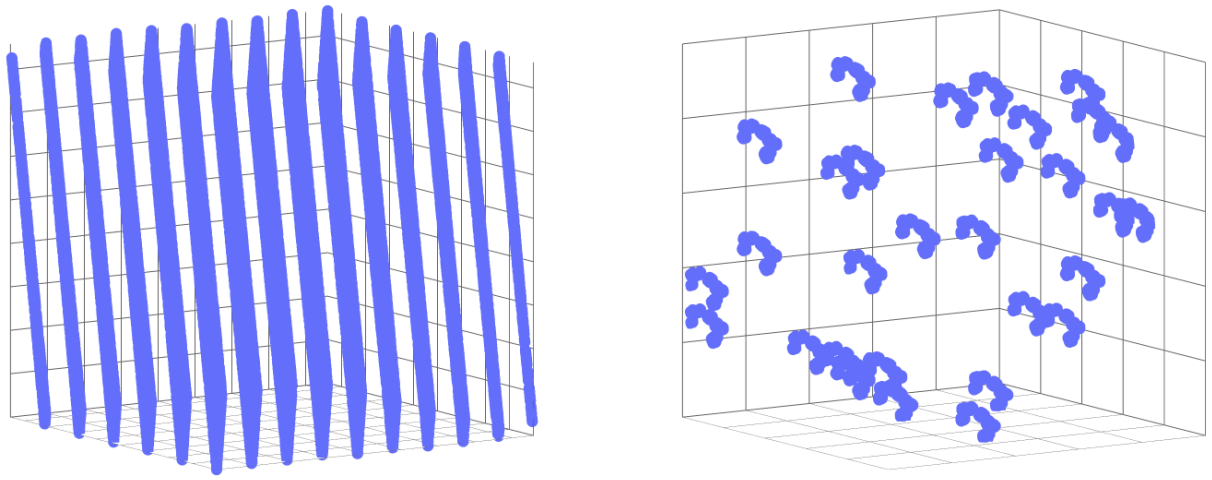
$$s_x = [5,0,8,3,2,6,1,9,4,7], \quad p = [2,6,1,5,3,4].$$

This is mathematically equivalent to the following generator:

$$y_{n+1} = y_n + 135197 \mod m,$$

$$s_y = [7,4,9,1,6,2,3,8,0,5], \quad p = [2,6,1,5,3,4].$$

To understand why these generators produce equivalent cycles, observe that $864803 + 135197 \equiv 0 \mod m$. This means that $x_n + y_n \equiv x_{n+1} + y_{n+1} \mod m$. Choose without loss of generality initial states $x_0 = 0$ and $y_0 = m-1$. By induction $x_n + y_n \equiv m-1 \mod m$ for all n, and because $x_n + y_n$ must be in range $[0, 2m-1]$, we know $x_n + y_n = m-1$.



We rewrite this equation as $x_n = 999999 - y_n$. Observe that on a digit-by-digit level this means x_n has a 0 wherever y_n has a 9, x_n has a 1 wherever y_n has an 8, and so on. Observe also that our substitution rules s_x and s_y are reversed relative to each other, so that a 0 in x_n becomes a 5 in the generator's output and a 9 in y_n likewise becomes a 5, etc. This means that for all x_n and y_n, the generators' output would be the same.

The existence of a complementary generator can be generalized to any LCG which uses a multiplicative term of 1, a substitution rule, and a modulus that is the power of that substitution rule's base. We need only that $b_x + b_y = m$ and that s_x and s_y are reversed relative to one another.

A.2 Graphical Analysis

Linear congruential generators are known to produce output such that when consecutive terms are plotted as three-dimensional points—i.e., points in the form (x_n, x_{n+1}, x_{n+2})—these points are not uniformly distributed but instead fall into planes [38]. The so-called "spectral test" measures the relative strength of a linear congruential generator by the distance between these planes [35], and it is not uncommon to use a graphical representation of these points to provide some degree of intuition of a generator's relative strength.

The Dominion PRNG's output, when graphed, does not fall into planes; the substitution cipher and digital permutation destroy this pattern. The resulting pattern still appears highly non-random, however, and to our knowledge has not been discussed in the literature. Figure 9 depicts a typical LCG's output compared to that of the PRNG from the ICP scanner.

(a) Typical LCG (RANDU)

(b) Dominion's Obfuscated LCG

Figure 9: Unlike typical LCGs, Dominion's does not produce output that falls into planes, but other highly nonrandom patterns still result.

Navigating the Privacy Compliance Maze: Understanding Risks with Privacy-Configurable Mobile SDKs

Abstract

The rise of privacy laws like GDPR and CCPA has made privacy compliance a requirement for mobile apps. Yet, achieving it is difficult due to the apps' use of third-party SDKs with opaque data practices. Recently, to assist apps in complying with privacy laws, many leading third-party SDKs have started providing privacy APIs for configuring the SDK's data practices. Nevertheless, the extent to which such a paradigm, referred to as *privacy-configurable SDKs* (or PICO *SDK*s), truly enhances app privacy compliance remains unclear to the community.

This question can only be answered through a systematic measurement study, which is nontrivial and requires in-depth analysis of the implementation of privacy APIs in PICO *SDK*s, as well as the way they are utilized, sometimes through a "wrapper" SDK that encapsulates other SDKs. To address this challenge, we developed PICOSCAN, a privacy risk analysis framework targeting Android, one of the most common mobile platforms. PICOSCAN automatically analyzes the code of both apps and SDKs to detect practices that potentially invade user privacy. Applying PICOSCAN to 65 most popular PICO *SDK*s and over 48,000 Google Play apps, we uncovered significant privacy risks in today's Android ecosystem. A large number of them fail to correctly utilize privacy APIs as prescribed, and even when these APIs are used, they often do not align with user privacy preferences. Moreover, our study reveals that many wrapper SDKs do not accurately convey privacy configurations to the SDKs they encapsulate, resulting in compliance risks. Our findings expose systematic failures in the design, implementation, and usage of PICO *SDK*s, highlighting the urgent need for more effective solutions to enhance the privacy assurance of Android apps. We will open-source the framework and make the data produced by this study publicly available.

1 Introduction

With the emergence of privacy laws and regulations such as GDPR and CCPA, concerns have been shifted to their compliance, especially for today's mobile apps. A key challenge in mobile privacy compliance is that mobile SDKs' data practices are often unclear to apps, yet privacy laws hold app developers accountable [36, 68, 80, 83]. Recently, to help apps comply with privacy laws and regulations, many SDKs provide mechanisms, particularly privacy APIs, for apps to configure the SDK's data practices (e.g., on *data collection*, *sharing*, or *selling*) to comply with privacy laws. For instance, for compliance with the Children's Online Privacy Protection Rule (COPPA), AppLovin's SDK [22], which is an ad network, offers the privacy API `setIsAgeRestrictedUser`. Once this API is invoked by an app, the SDK will refrain from collecting and processing any data from the current (child) user [15]. While different SDKs support various privacy APIs for apps to configure their compliance with specific laws, such a paradigm, dubbed *privacy-configurable SDKs* (or PICO *SDK*s), has been implemented by a large portion of top SDKs and is widely used in apps on the Android platform.

Emerging privacy risks with PICO SDKs. The PICO *SDK*s are supposed to improve privacy assurance for Android apps. However, our preliminary study reveals subtle privacy compliance risks in (1) how apps use the privacy configuration APIs (or capabilities), and (2) how PICO *SDK*s implement and fulfill the expected compliance. Essentially, the PICO *SDK*s and their adoption bring a variety of general and novel privacy compliance risks, collectively called *privacy-configuration compliance risks* or PICO *risk*s in our research. While observations of noncompliance related to SDKs have been reported before [51, 71], to the best of our knowledge, there has been no systematic, large-scale study on the PICO *risk*s to understand the fundamental causes of the problem.

Particularly, we found that configuring privacy compliance through PICO *SDK* can be more complicated than expected. An app often uses multiple PICO *SDK*s (e.g., for serving ads, analytics, and social networks) and is supposed to properly configure relevant privacy APIs of all these PICO *SDK*s. A PICO *SDK*, such as the ads network SDK AppLovin, internally wraps and uses ads from other ads network SDKs, such as *Google AdMob* and *Unity Ads*, which are also PICO *SDK*s

*The two lead authors contributed equally to this work.
†Corresponding authors: Xueqiang Wang, Luyi Xing

with privacy APIs. These PICO *SDK*s wrapped by AppLovin are transitive dependencies of the app and we call AppLovin a PICO *wrapper*. The wrappers and the SDKs they wrap form complicated delegation relations in privacy configurations: once the app configures specific compliance requirements for the wrapper (e.g., age restriction), the wrapper is supposed to faithfully propagate the privacy configurations to all PICO *SDK*s it encapsulates. This can easily go wrong, leading to privacy risks. Specifically, in the absence of standards, not all (wrapped) PICO *SDK*s support the same sets of regulations, and for the same regulations, they may not even come with the same levels of support. Privacy violations have actually occurred, for example, when an app configures AppLovin for GDPR compliance, while such a configuration cannot be propagated to the wrapped SDK Google AdMob, due to the latter's partial support for GDPR. In the paper, we present detailed case studies and measurements of PICO *risk*s (§ 6), together with nine different types of PICO *risk*s (§ 4).

Detecting privacy risks with PICO *SDK*s. We developed PICOSCAN, an automatic privacy risk analysis framework, to detect PICO *risk*s in real apps on Android, one of the most common mobile platforms. This is based on a set of PICO privacy principles we summarized for different roles in the PICO ecosystem, i.e., the host app, PICO *SDK* and PICO *wrapper* (§ 3.3). PICOSCAN leverages a PICO *usage inspector* to analyze the use of PICO *SDK*s in the apps to determine whether the use violates the app-related principles. It also utilizes a PICO *SDK inspector* to check whether individual and wrapper PICO *SDK* implementations uphold applicable privacy principles. These two components were developed to mainly perform static analysis, with supplemental dynamic analysis to support PICO *risk* detection for specific PICO privacy principles (§ 4).

Measurement of PICO *risk*s in the wild. To understand the compliance risks associated with PICO *SDK*s in the wild, we built a PICO *SDK* metadata database named PICO METADB. This database comprises 65 of the most popular PICO *SDK*s on the Android platform, covering three major categories: 43 ad SDKs, 20 analytics SDKs, and 2 social network SDKs. Running PICOSCAN on 48,305 Google Play apps (downloaded in October, 2023), our measurement results indicate that despite the enhanced privacy configurability, PICO *SDK*s and their use in the wild are far from being compliant, and privacy risks can occur at every step of SDK integration and be introduced by every role in the PICO *SDK* ecosystem. Overall, among 24,844 apps in our dataset that integrate PICO *SDK*s, 7,880 apps (31.7%) are found to contain at least one PICO *risk*. Specifically, 31.5% apps fail to invoke privacy APIs in the first place, leaving privacy configurations of PICO *SDK*s unattended. The risk is substantial considering that over 43.1% PICO *SDK*s include privacy-invading default configurations that allow the collection and processing of user personal data. Even for apps that invoke privacy APIs, they are likely to configure the APIs in a way inconsistent with users' preferences, e.g., 259 apps either hard-code privacy APIs with data-enabling values directly, or set privacy APIs in conflict with user privacy preferences. Further, we found that there are numerous privacy risks even for the apps that perfectly configure privacy APIs, due to the erroneous implementations in PICO *SDK*s and PICO *wrapper*s. For example, 16 PICO *SDK*s that cover 14,869 apps have ambiguous consent configurations such that they still collect user personal data even when privacy APIs are invoked to decline the consent. Things become even more complicated for PICO *wrapper*: 12 PICO *wrapper*s (54.5% out of 22) are found to not relay privacy configurations to the PICO *SDK*s they encapsulate.

These findings shed new light on PICO *SDK*s, leading to better understanding about their privacy assurance. First, with the modularization of app development using closed-source components from diverse parties, developers require enhanced tooling, including privacy-configurable SDKs, to maintain consistent privacy promises across all app components. However, this study demonstrates that this goal may not be easily achieved solely relying on configurability. *Inconsistent privacy configurations* may arise from various development flaws (e.g., missing or erroneous configurations), and unfulfilled responsibilities by PICO *wrapper*s (e.g., broken relay). Second, the design and use pattern of PICO *SDK*s tend to expose app users to privacy risks. Third, misimplementation and misinterpretation are common in PICO *SDK*s, possibly due to the absence of systematic review and proper standards. Based on our findings, we provide suggestions to key stakeholders, such as developers of apps and PICO *SDK*s, as well as policy makers and law enforcement agencies, with the hope of helping end-users obtain genuine privacy assurance when using Android apps (§ 7).

Contributions. We summarize the contributions as follows:

- We present a systematic study of privacy risks for the use and implementation of privacy-configurable SDKs (PICO *SDK*) on Android, and identified a range of general, novel privacy compliance risks, collectively called PICO *risk*s.
- We developed PICOSCAN, a compliance risk analysis framework to automatically identify PICO *risk*s in Android apps and PICO *SDK*s. We will fully release the source code.
- We performed a large-scale study of PICO *risk* with over 48 thousand Google Play apps and 65 popular PICO *SDK*s. This reveals that PICO *SDK*s, though created for privacy compliance, often fail to provide expected privacy assurance.

2 Background

Privacy configuration capabilities supported by third-party SDKs. The mobile SDK ecosystem has evolved significantly, with many SDKs now offering dedicated "*advanced privacy settings*" documents (such as [29]) to assist app developers in achieving privacy compliance. These documents often contain three types of information: legal and privacy disclosure, app-level privacy configurations, and user-level privacy configurations. Legal and privacy disclosure outlines privacy policies describing how an SDK processes and shares infor-

mation, along with methods for end users to exercise privacy rights (e.g., through data subject access request). App-level privacy configurations enable app developers to customize SDK usage and functionality mostly from the server side (e.g., via SDK dashboard), such as specifying data points for an analytics SDK. These configurations apply to all end-users of an app. User-level privacy configurations enable app developers to customize privacy exposure for each end-user. This study focuses on user-level privacy configurations.

Privacy Configurable (PICO) SDKs. To support user-level configurations, third-party SDKs may offer a set of predefined privacy APIs. We refer to such SDKs as privacy-configurable SDKs (PICO *SDK*s). The privacy APIs of PICO *SDK*s may control various data practices, such as data collection, sharing, and selling, in compliance with privacy laws (e.g., GDPR). When using a PICO *SDK*, an app often invokes its initialization API to configure global SDK options. For example, an ads SDK initializes the ads unit ID before requesting ads from backend ad networks. PICO *SDK* privacy APIs are typically invoked alongside the SDK initialization APIs to ensure that privacy configurations are picked up early on by SDKs.

3 Overview of PICO *SDK*s

3.1 Status Quo of PICO *SDK*s

Landscape of PICO *SDK*s. Privacy APIs of PICO *SDK*s aim to help apps fulfill requirements of a range of privacy laws, regulations, and industry standards, such as GDPR [26], COPPA [25], US states' consumer privacy acts [27, 46, 75, 76], China's Personal Information Protection Law (PIPL) [30], and CARU Advertising Guidelines [24]. We conducted a survey to understand the privacy laws supported by popular Android SDKs. Specifically, we gathered a list of 203 most popular SDKs (ranked by AppBrain [4], a service providing Android market statistics) including 137 Ads SDKs, 41 Analytics SDKs, and 25 Social Network SDKs. We focus on the three SDK categories since they were known to involve privacy practices [65, 67, 86]. We asked two security researchers to find API documents for the popular SDKs, and then cross check and combine their results. In total, we found API documents for 91 of the 203 SDKs. From the documents, we searched privacy APIs based on keywords including "`privacy`", "`compliance`", "`regulations`" and names of specific laws. The most commonly supported laws are GDPR (61 SDKs), CCPA (39 SDKs), and COPPA (34 SDKs), spanning a total of 65 PICO *SDK*s. We provide a detailed list of privacy laws and regulations along with the number of SDKs that offer privacy APIs to ensure compliance online [17].

Scope of research. Based on the survey, our study focuses on the support of three laws (GDPR, CCPA, COPPA) by the 65 PICO *SDK*s (see PICO METADB in Section 4.4). We study how effectively their privacy APIs support privacy compliance and whether apps have used them properly to achieve expected compliance goals. Notably, although each privacy law defines a range of privacy-related requirements, we specifically focus on the following requirements for each law, which are most commonly supported by the privacy APIs. We documented all 191 privacy APIs in a database (§ 4.4) and have released them at [17].

• *GDPR compliance with consent requirements.* Based on GDPR, PICO *SDK*s (as data controllers) should establish a legal basis for processing personal data, in most cases by obtaining users' consent. Hence, many PICO *SDK*s have provided privacy APIs with parameters that allow app developers to specify users' consent status, thereby enabling the PICO *SDK*s to administer private data processing according to the consent status. An example is Vungle [79], an ad network SDK which offers an API `setGDPRStatus`. By passing in a `false` parameter value, an app that integrates Vungle can instruct Vungle to avoid collecting a range of personal data restricted by GDPR, such as Android ID and advertising ID.

• *CCPA compliance with the right to opt-out.* Under CCPA, PICO *SDK*s may not have to obtain explicit user consent for data collection (although businesses must provide clear and conspicuous privacy notice). Rather, CCPA requires that end users who are California residents be able to opt-out of data sharing and selling from businesses. To fulfill such a privacy right, PICO *SDK*s commonly provide a privacy API for apps to specify end users' choices of "`opt-in`" or "`opt-out`", based on which the PICO *SDK*s restrict the sharing and trading of user data. For example, the Vungle SDK has an API `setCCPAStatus` to capture users' "`opt-out`" status.

• *COPPA compliance and protection for children users.* COPPA limits the collection and use of children's personal data, except with explicit and verifiable consent from parents. Other laws such as GDPR and CCPA also have corresponding restrictions for processing children's personal data. For compliance, a most common practice we observed from PICO *SDK*s is to provide a privacy API that allows apps specify whether the current user is under age restriction (being a child). The PICO *SDK*s will then refrain from collecting data from the child users. For example, the Vungle SDK provides a privacy API (`setCOPPAStatus`) that takes a boolean parameter to indicate whether the current app user is a child or not.

3.2 Motivating Example

We show real examples of PICO *risk*s in Figure 1. `CallApp` [60][1] is a popular app that has over 100 million downloads on Google Play. It offers attractive security features for users, such as detecting caller identity, and blocking spams. The app, for maximized monetization, implemented in-app ads bidding that selectively displays ads from multiple ads networks using their SDKs, such as `Google AdMob`, `AppLovin`, and `Facebook Audience Network`. Offerings of these ads SDKs include showing

[1] The app is subject to all three privacy laws. It is available to users in the EU and CA. It also collects users' date of birth and permits children to use it.

personalized ads based on users' personal data (e.g., user and device identifiers, and demographic information, etc.). Most of the ads SDKs are PICO *SDK*s, providing privacy APIs for apps to configure them in accordance with applicable privacy laws, such that the apps as a whole can be compliant. Upon analyzing the CallApp app, we found that both the in-app use and internal implementations of PICO *SDK*s are complicated, resulting in several types of subtle privacy compliance risks in Android apps that were unknown, or at least less known before.

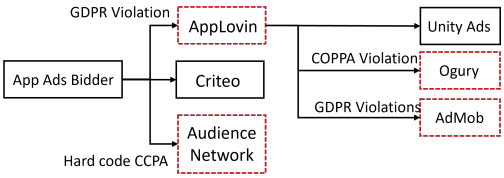

Figure 1: PICO SDKs in the CallApp

First, the app intends to be GDPR-compliant by calling AppLovin SDK's privacy API `setHasUserConsent` with an argument of either `true` or `false`, depending on the user choice. AppLovin itself will not collect or use personal data for delivering personalized ads without user consent (GDPR compliance). However, the AppLovin SDK not only delivers ads from its own ads network, but also internally wraps and bids ads from other ads SDKs, such as *IronSource*, *Vungle*, *Google AdMob*, and *Unity Ads*, etc. These SDKs wrapped by AppLovin are transitive dependencies of the app and we call AppLovin a wrapper SDK or PICO *wrapper*. The expectation is that, once the app urges a PICO *wrapper* like AppLovin for GDPR-compliance, it should propagate the compliance requirement to all ads SDKs it internally uses (by calling their privacy APIs for GDPR). We find that the expectation fails to be fulfilled for key challenges: (1) Not all wrapped ads SDKs support compliance configurations evenly. Google AdMob, for example, partially supports GDPR configuration: after a PICO *wrapper* passes along "not consent" to AdMob's privacy API, AdMob will not deliver personalized ads but will always collect user data including device/user identifiers [1,2]. Failing to account for the different levels of support for the same law among PICO *SDK*s results in compliance risks for the app. (2) Not all PICO *SDK*s used by a PICO *wrapper* support the same laws. For example, the Yandex SDK and Kidoz SDK have not supported privacy configurations for CCPA, and both of them can be used by the wrapper AppLovin.

Second, with many PICO *SDK*s used in an app, their host app or PICO *wrapper* might not configure compliance APIs of all PICO *SDK*s, or configure them in a correct manner. Ogury, for example, is an ads SDK supporting COPPA configuration. However, AppLovin does not call Ogury's COPPA API `applyChildPrivacy`, although AppLovin did call COPPA configuration APIs of all other ads SDKs it wrapped. Also, for CCPA compliance, when the user is a California resident, the app is supposed to invoke CCPA APIs in PICO *SDK*s to communicate the user's opt-out status for data sharing/sale. Although the app uses the Facebook Audience Network (SDK) to deliver ads, it uses a hard-coded "`opt-in`" option when configuring Facebook SDK's CCPA API `setDataProcessingOptions`, posing a violation to users who choose "`opt-out`".

Further, although many PICO *SDK*s feature privacy APIs that support multiple laws, their default configurations (without privacy API calls by the app) do not comply with privacy laws. For example, the InMobi SDK [28] by default does not comply with COPPA unless the app calls the `setIsAgeRestricted` API with an argument value `true`.

3.3 PICO Privacy Principles

We cannot evaluate privacy compliance risks without specific privacy principles tailored for PICO *SDK*s. This section, based on the motivating example (§ 3.2), summarizes a set of such principles for different roles in the PICO ecosystem, i.e., the host app, PICO *SDK* and PICO *wrapper*.

Privacy principles for apps using PICO *SDK*s. Privacy APIs in PICO *SDK*s are designed to meet the key privacy objective of returning privacy control to end users (in alignment with the expectations reported in prior studies [42,51,64,73]). Hence, it is crucial that apps integrating PICO *SDK*s configure the privacy APIs correctly and effectively based on the actual privacy preferences of end users.

> *Principle #1 (Complete, User-controlled Privacy Configuration)*: Apps should ensure complete, correct privacy configurations of all PICO *SDK*s in accordance with user preferences.

Privacy principles for PICO *SDK*s. Similar to the principle of "*secure by default*" [49], which requires automatic enabling of security measures without user intervention, the principle of "*privacy by default*" has become common sense among privacy practitioners [37,52,58] and is also part of privacy laws [44,48].

> *Principle #2 (Privacy by Default)*: PICO *SDK*s should have default configurations that protect user privacy.

Individual PICO *SDK*s offer privacy APIs for enabling apps using them to manage PICO *SDK* privacy practices. Hence, it is natural to mandate that privacy APIs to effectively fulfill all promised privacy compliance without ambiguity, akin to the "*complete mediation*" security principle by Saltzer and Schroeder [72].

> *Principle #3 (Nonambiguous, Fulfilled Privacy Compliance)*: PICO *SDK*s should fulfill all promised privacy compliance once relevant privacy APIs are configured; the promise (for the compliance effect of privacy API configurations) should be nonambiguous.

Privacy principles for PICO *wrapper*s. As demonstrated in § 3.2, when using PICO *wrapper*s (one that encapsulates other PICO *SDK*s), the underlying PICO *SDK*s are not exposed to

apps directly. Instead, their privacy APIs are configured by the PICO *wrapper*s, similar to the delegation design pattern [56]. Therefore, it is the responsibility of the PICO *wrapper*s to properly propagate (or forward) privacy configurations of the app to all internal PICO *SDK*s.

Notably, a PICO *wrapper* itself is usually a PICO *SDK* by providing privacy compliance APIs (e.g., AppLovin in Figure 1) and thus should follow principles of PICO *SDK*s.

Principle #4 (Complete Privacy Delegation): PICO *wrapper*s should fully propagate app's compliance configurations to all internal PICO *SDK*s in use.

Discussion. The principles are not direct adoption of prior general principles, and they are contextualized to PICO *SDK*s. Consequently, the principles will guide the identification of PICO *risk*s in real apps and SDKs (§ 4), although they may not be exhaustive. For example, given that data practices extend into PICO *SDK* backends, it becomes necessary to establish privacy principles that apply to these backends. We leave further exploration of those principles for future research.

4 Analyzing PICO Risks

PICO *risk*s occur when apps, PICO *SDK*s, or PICO *wrapper*s violate the above privacy principles (§ 3.3). In this section, we introduce PICOSCAN, an automatic analysis framework to detect PICO *risk*s.

Overview. Figure 2 shows the overview of PICOSCAN, including the techniques and tools used in it. PICOSCAN takes Android apps as input and identifies PICO *risk*s in two aspects: (1) whether and how the apps use PICO *SDK*s, and (2) how PICO *SDK*s and PICO *wrapper*s implement their privacy APIs to meet the expected privacy compliance, with two main components, i.e., PICO *usage inspector* (*PUI*) and PICO *SDK inspector* (*PSI*), respectively.

PUI first identifies the usage of PICO *SDK*s in the apps through static analysis, which involves searching for package names of PICO *SDK*s and invocations of their privacy APIs. This is enabled by a PICO SDK metadata database (PICO METADB) that we built from the 203 most popular mobile SDKs listed on AppBrain [4]. The database contains various useful information for the analysis (as we will detail in § 4.4), such as the package names of PICO *SDK*s, API signatures, etc. For each privacy API invocation found in the apps, *PUI* further identifies whether the invocation is made by the app code or by a PICO *wrapper*. In the case of the former, *PUI* applies app-specific principles (Principle #1) to detect privacy risks (§ 3.3) related to app code invoking the privacy API. For the latter, PICOSCAN leverages *PSI* to detect privacy risks based on wrapper-specific principles (Principle #4). *PSI* further inspects the implementation behind the privacy APIs of PICO *SDK*s and identifies privacy risks based on PICO *SDK* related principles (Principle #2 and #3). Note that *PSI* analyzes the PICO *SDK*s and PICO *wrapper*s that are already compiled into the apps as an alternative to analyzing separate SDKs, since some SDKs are not publicly available, e.g., Amazon mobile ads SDK [21] is invitation-only.

Directly applying high-level principles in code-level detection is difficult. Thus, we developed a set of more specific, fine-grained technical patterns of PICO *risk*s, called PICO *Violation Patterns* (*PVP*s), corresponding to each principle (Table 1). *PUI* and *PSI* scan for the occurrences of the PVPs in the app code, the code of PICO *SDK*s and PICO *wrapper* hosted in the apps, and report them as PICO *risk*s. PICOSCAN is mainly built on static analysis and is supplemented by dynamic analysis for the scan of certain *PVP*s. For example, under Principle #2, to identify the default compliance status of PICO *SDK*s (e.g., `true` or `false` for age-restricted data collection), we leverage static analysis to identify specific variables that store the compliance value and then use dynamic analysis to find the exact default value (detailed in § 4.2.2). Figure 2 outlines the static and dynamic analysis techniques and tools adopted for different *PVP*s. We will elaborate on the choice of these techniques in the latter part of this section.

Table 1: PICO Violation Patterns (PVPs)

Role	Privacy Principle	PVP
App	#1: Complete, user-controlled privacy configuration	#1: Missing configuration #2: Configuration disregarding or inconsistent with user privacy preferences #3: Erroneous configuration
PICO SDK	#2: Privacy by default	#4: Privacy-invading by default
	#3: Nonambiguous, fulfilled privacy compliance	#5: Ambiguous consent configuration #6: Ineffective configuration
PICO Wrapper	#4: Complete privacy delegation	#7: Uneven privacy support #8: Broken privacy delegation #9: Conditional propagation

4.1 PICO Usage Inspector (PUI)

4.1.1 Identifying PICO Usage from Apps

To determine whether an app uses PICO *SDK*s, including whether privacy APIs are invoked and whether they are invoked by first-party code (app code) or third-party code (PICO *wrapper*s), *PUI* builds a global call graph for the app and traverses all the edges to identify reachable methods that match PICO *SDK* initialization APIs, as defined in the PICO METADB. It then determines the parties using the PICO *SDK*s by comparing the caller of the initialization APIs to the package names of the main app or any other SDKs. The identification of PICO *wrapper*s is slightly difficult, SDKs often lack clear disclosure about whether they are wrappers for other SDKs. In this study, we identify PICO *wrapper*s by uncovering inter-SDK connections on an app's call graph. Specifically, for each discovered PICO *SDK* initialization API on the call graph, we explore the subgraph rooted in this API to locate the initialization APIs of another SDK. This relationship, where the initialization API of one SDK leads to that of another, is a clear indicator that the former SDK functions as a wrapper for the latter SDK.

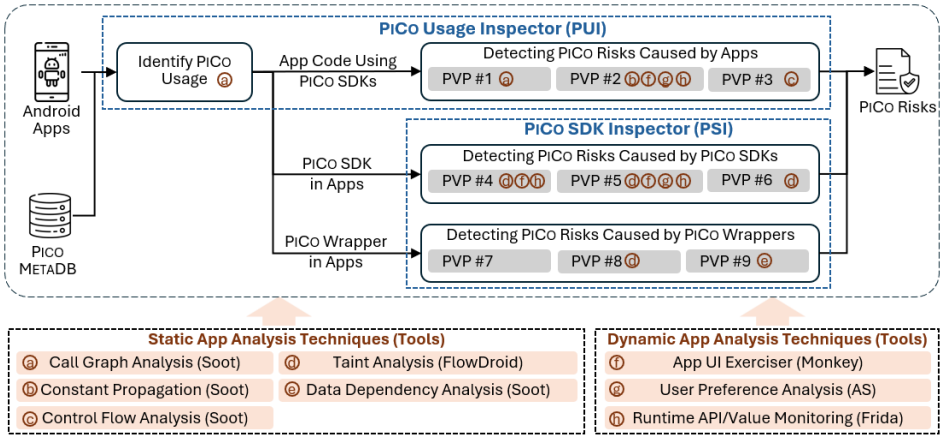

Figure 2: Overview of PiCoScan

4.1.2 Patterns of PiCo Risks Caused by Apps

Under the privacy principles governing apps (Principle #1), we focus on three *PVP*s whose presence in the first-party code indicates risks associated with the app's use of privacy APIs (or configuration capabilities) of PiCo *SDK*s. In general, apps using PiCo *SDK*s are expected to configure the privacy APIs of PiCo *SDK*s correctly, adhering to (1) the API definition and programming requirements, and (2) users' privacy preferences typically collected through app UIs, such as whether they consent to data collection (see Figure 7 in the Appendix for an example). We elaborate on the *PVP*s as follows.

Missing configurations (*PVP* #1). Apps using a PiCo *SDK* but failing to configure the privacy compliance of the SDK by invoking its privacy APIs indicate a PiCo *risk*. An app often uses multiple PiCo *SDK*s but may not configure all of them. An example is the "Copy My Data" (`com.mediamushroom.copymydata`) app [59], which leverages the IronSource SDK to show ads but does not invoke any of the IronSource privacy APIs.

Configurations disregarding or inconsistent with user privacy preferences (*PVP* #2). Apps are expected to capture user privacy preferences and communicate them to PiCo *SDK*s by properly invoking the PiCo *SDK*s' privacy APIs. However, they might fail to capture user privacy preferences or, if they do, they may fail to use the proper parameter values when invoking the privacy APIs. A special situation within this pattern is when an app uses hard-coded parameter values (e.g., `consent: true`) to configure privacy APIs – an issue happened in many apps. Concerning COPPA compliance, for example, the "SuperLozzi" (`com.ltlk.z7`) app, a play-and-earn app with over one million downloads on Google Play, collects the user's date of birth. However, the app calls AppLovin's COPPA API `setIsAgeRestrictedUser` with a hard-coded parameter value of "`false`", which disables AppLovin's COPPA compliance even when the user is a child (see measurements in § 6.2).

Erroneous configurations (*PVP* #3). Even if apps configure the necessary privacy APIs with the correct parameters that reflect user preferences, their configurations may not effectively achieve the desired compliance. This happens when the use of privacy APIs fails to meet the programming requirements specified for using these APIs. For example, the "Solitaire King" (`com.solitaire.king.card.creative.wuliu`) app incorporates the PiCo *SDK* AppLovin to display ads and configures multiple SDK privacy APIs related to CCPA, GDPR, and COPPA. However, AppLovin requires its initialization function, `initializeSdk`, to be invoked after configuring its privacy APIs. Unfortunately, this requirement was not followed by many apps, rendering their privacy configurations ineffective.

4.1.3 Detecting PiCo Risks Caused by Apps

To detect missing configurations (*PVP* #1), *PUI* traverses the apps' call graphs to find out whether the apps initialize and use a PiCo *SDK* but do not call any of their privacy APIs.

For *PVP* #2, we detect the inconsistencies between privacy configurations and the user's privacy preferences using dynamic analysis. Specifically, *PUI* launches the apps under analysis, exercises their UIs, and utilizes accessibility service (AS) APIs [20] to monitor the rendered app UIs. *PUI* identifies privacy consent dialogs that request user consent for data collection and usage (Figure 7 in the Appendix). This is done by matching a set of common privacy-related keywords in the texts of consent dialogs, i.e., via regex matching "`^.*(?:privacy policy|collect your|i agree|your consent).*$`". *PUI* leverages AS APIs to automatically click the button on consent dialogs to decline the consent request, by matching keywords such as "`no`", "`decline`", "`cancel`", "`not now`" or "`disagree`". Meanwhile, *PUI* instruments and monitors runtime parameter values of PiCo *SDK* privacy APIs, in particular those indicating "`true`" or "`false`" for user consent, and "`opt-in`" or "`opt-out`" for data sharing and sale. Since the consent request has been declined, runtime values indicating a "`true`" for user consent or "`opt-in`" represent privacy risks related to *PVP* #2. *PUI* uses Frida [8] for monitoring runtime values. In case that privacy consent dialogs are not observed, *PUI* performs

constant propagation on the interprocedural control-flow graph (ICFG) of the apps to determine whether the parameters of privacy APIs are constants (i.e., hard-coded).

Under *PVP* #3, *PUI* checks whether invoking individual privacy APIs must occur before or after invoking other APIs of the PICO *SDK*s. In our study, the ordering requirements were extracted from SDK documents and recorded in the PICO METADB (14 privacy APIs from eight PICO *SDK*s require specific orders, see Appendix 9). Using the PICO METADB, *PUI* checks the app code and API calls along the control flows to identify misordered API invocations.

4.2 PICO SDK Inspector (PSI) for PICO *SDK*s

PSI analyzes individual PICO *SDK*s to check violations to related principles (principles #2 and #3 in § 3.3), focusing specifically on three PVPs as elaborated below.

4.2.1 Patterns of PICO Risks Caused by PICO *SDK*s

Privacy-invading by default (*PVP* #4). The PICO Principle #2 requires that individual PICO *SDK*s come with a default configuration in compliance with related privacy regulations. However, this is not true for many PICO *SDK*s. Take, for example, the SDK of InMobi [28], a mobile marketing platform specializing in personalized ads. The InMobi SDK will stop collecting certain personal information (such as *advertising ID*) and notify its server to comply with COPPA for the current user only after the host app calls the `setIsAgeRestricted` API with a `true` parameter value. If the above API is not called, InMobi defaults to assuming that all app users are adults, to whom COPPA does not apply, and thus allows for the collection of personal data for user profiling and serving personalized ads. Privacy-invasive default configurations like these are found in many popular PICO *SDK*s (see measurements in § 6.3).

Ambiguous consent configuration (*PVP* #5). At the core of many privacy regulations is a requirement for user consent before processing personal data. For example, GDPR requires that data controllers (apps or SDK providers) must obtain user consent for the collection and use of personal data, including the use for serving personalized ads [26]. Under this requirement, the `requestConsentInfoUpdate` API of AdMob is used to help apps collect user consent "*to use your personal data for personalized ads*" (by showing a consent dialog developed by the SDK, Figure 6), and apply the user consent status for the SDK's operation. While not all PICO *SDK*s come with built-in consent dialogs, they commonly provide APIs for apps to specify the user's consent (`true` or `false`), such as for personalized ads [39]. However, the intended compliance effects of the consent status can be ambiguous: for configurations of `consent: false`, it is unclear whether the SDKs will not collect user personal data, or they will still collect user data but just do not use the data for specific purposes such as serving personalized ads. Our study of real PICO *SDK*s showed that such an ambiguity is indeed underlined by different compliance effects among PICO *SDK*s, resulting in privacy risks: for example, the AdMob SDK always collects user identifiers such as *adid* and *ip address* regardless of the consent status configured by the API; in contrast, Kochava will disable the data collection being more compliant.

Ineffective configuration (*PVP* #6). When apps correctly configure privacy APIs, the PICO *SDK*s are expected to achieve the compliance goals. Problems arise when the PICO *SDK*s have implementation mistakes that render privacy APIs ineffective. For example, the MyTarget SDK offers a GDPR API `setUserConsent` to support the configuration of user consent for data collection. Behind the API, the user consent status is passed along and stored in an SDK internal variable `isConsent`. In the SDK implementation, every collection of device identifiers, such as Google and Huawei ad IDs, occurs after inspecting the variable. Such a variable (referred to as IPSVs in PICOSCAN's detection, § 4.2.2), essentially records the configured consent status, which is important information governing the SDK's privacy practices. However, in the MyTarget SDK implementation, the `isConsent` variable can be modified by other unexpected program paths, specifically from the SDK's CCPA API `setCcpaUserConsent`. Any consent status configured for CCPA will overwrite that of GDPR, silently rendering the GDPR configuration ineffective. This overwriting causes problems in cases where the apps integrating the SDKs need to ensure compliance with both GDPR and CCPA, e.g., when an app must protect users who are California residents while the app itself operates as an EU-based business.

4.2.2 Detecting PICO Risks Caused by PICO *SDK*s

Detecting default privacy-invading configurations (*PVP* #4). To assess whether the privacy configurations of a PICO *SDK* are privacy-invading by default, we developed a method in *PSI* to model the implementation of the PICO *SDK*'s configurations. Specifically, our observation is that once a privacy API is invoked with certain parameters (called privacy parameters), a PICO *SDK* usually stores the values of the parameters (e.g., whether the user is a child) as internal states in local variables, such as class or instance fields. We refer to such variables storing privacy parameter values as *internal privacy state variables* or IPSVs. Further privacy practices of the PICO *SDK*, such as invocations of system APIs to collect personal data, will be governed by checking the IPSV values. In the InMobi SDK, for example, the data flow behind its COPPA API `setIsAgeRestricted` shows that the privacy parameter `isAgeRestricted` is eventually stored in an IPSV, i.e., `<com.inmobi.media.ea: Boolean c>`. In multiple SDK functions that attempt to collect user personal data, it first checks the IPSV to determine whether the collection should proceed. Notably, while the privacy parameter can be stored in various locations, including in shared preferences [31] for persistence, it is often loaded into the IPSV for the SDK to easily access it in different functions.

Based on the above observation, *PSI* first performs static taint analysis on the apps to identify the IPSVs corresponding to the SDK's privacy parameters. This analysis is then complemented by dynamic analysis to identify the runtime values of these IPSVs using Frida [8]. If the runtime values of the IPSVs match the values enabling data collection, sharing or selling as recorded in the PICO METADB, *PSI* reports a PICO *risk* corresponding to PVP #4. More specifically, to identify IPSVs, we use privacy APIs' parameters as sources and find program variables to which the parameter values are propagated (within the SDK code). Considering that the values may be propagated to some intermediate variables, *PSI* filters out those with different types from the privacy parameters and those local variables internal to a method; *PSI* specifically retains variables used in a condition check that acts as a guard for user personal data collection.

Identifying ambiguous consents (*PVP* #5). To detect *PVP* #5, *PSI* identifies the collection of personal data in the SDK code even after configuring `consent: false` in the invocation of privacy APIs. The first step uses static analysis: *PSI* identifies code locations that access personal data. This is done by checking invocations of a list of system APIs (compiled from prior work [70, 87]) that access device and user data (e.g., device identifiers, advertising identifiers, and location). Similar to prior work [40], the static analysis also finds out the program paths in the SDK that transmit the user data to the Internet. Next, *PSI* runs the app and uses `consent: false` to configure the privacy APIs of PICO *SDK*s. This is done using dynamic instrumentation that manipulates related privacy parameters upon the app's invocation of privacy APIs. *PSI* reports privacy risks if it finds that the program paths that collect and transmit user data are executed at runtime (by inspecting call stack traces), even under `consent: false` configurations of the privacy APIs.

Identifying ineffective configurations (*PVP* #6). The presence of multiple program paths manipulating common IPSVs related to privacy APIs is an indicator of potentially ineffective configurations. Therefore, we detect them by checking whether other public APIs of a PICO *SDK* can cause changes to the IPSVs of any of its privacy APIs. For this purpose, we extract the set of IPSVs, S_{IPSV}, for each privacy API of a PICO *SDK*. Next, we perform static taint analysis to collect all internal variables affected by other public APIs of the same PICO *SDK*, i.e., S_v. We cross-compare the S_{IPSV} and S_v to identify whether the IPSVs of the privacy API are manipulated by other program paths. Using this method, we can detect ineffective configurations in other 8 PICO *SDK*s besides MyTarget, such as Appodeal, and BidMachine (see measurements in §6.3).

4.3 PICO SDK Inspector for PICO *wrapper*

The PICO *wrapper* SDKs are special PICO *SDK*s that provide privacy APIs to apps and are expected to fully and correctly propagate apps' privacy configurations to their wrapped PICO *SDK*s. This requirement is instrumental considering that the wrapped PICO *SDK*s are transitive dependencies of the apps, which are often unknown and inaccessible for app developers to configure. Under the Principle #4, PICOSCAN focuses on three patterns of violations related to PICO *wrapper*s.

4.3.1 Patterns of PICO Risks Caused by PICO *wrapper*s

Uneven privacy support (*PVP* #7). In the absence of standards for PICO *SDK*s, individual PICO *SDK*s may support different sets of laws and regulations, and for the same regulations, they may not even come with the same levels of support. For example, PICO *wrapper*s Appodeal [38] and AppLovin [47] provided privacy APIs for GDPR compliance. Meanwhile, they both wrapped Meta Audience Network [7], SDK of another ads network, to help serve ads. Notably, Meta Audience Network has not provided privacy APIs to configure GDPR compliance. This can directly lead to privacy risks with GDPR in real apps. For example, when the app `com.solutions.class11dkg` configures Appodeal with "`consent: false`" for data collection based on the user's privacy preference, Appodeal cannot propagate the configuration to Meta Audience Network, which actually collects user data and serve ads in the app regardless of user's consent, posing a risk.

Broken privacy delegation (*PVP* #8). Even when the PICO *wrapper* uses an individual PICO *SDK* that has aligned privacy law support, it is possible that the PICO *wrapper* fails to fully propagate the app's privacy configurations to the corresponding APIs of the individual PICO *SDK*. For example, AppLovin (PICO *wrapper*) internally uses the Facebook Audience Network (PICO *SDK*) for serving ads. The AppLovin SDK has a CCPA API `setDoNotSell`, that enables app users to opt out of data sharing/sale using a `true` parameter. However, the AppLovin SDK does not use such a parameter or related information to invoke the Facebook CCPA API `AdSettings.setDataProcessingOptions`, leading to a privacy risk.

Conditional propagation (*PVP* #9). A variant of the broken delegation is the presence of extra conditions imposed by the wrapper that blocks propagation of privacy configurations. An example is the PICO *wrapper* Admost and its wrapped SDK Unity Ads. Both SDKs have a GDPR related API to configure user consent for data collection, i.e., `AdMostConfiguration.setUserConsent`, and `MetaData.set` respectively. Based on user choices, when the host app configures Admost with the user's consent status for collecting personal data, Admost will only conditionally propagate the consent status to Unity Ads. When Admost considers the user's IP address is not within EU countries (thus may not be subject to GDPR), it will configure Unity Ads with a "`consent: true`". This happens even if (1) the user does not consent to data collection or (2) the app intends to configure the PICO *wrapper* not to collect user data. Such a design pattern is problematic: (1) it can violate the app's compliance expectation and privacy goal; (2) using IP addresses to determine whether the user is subject to GDPR is not reliable [6, 12].

Further, such a practice violates Unity Ads' privacy goals for users: Unity Ads noted that "*Consent extends beyond GDPR and should be applied in any region*" [77].

4.3.2 Detecting PiCo Risks Caused by PiCo *wrapper*s

PUI detects *PVP* #7 by comparing privacy APIs and different privacy laws supported by the wrapper and its internal PiCo *SDK*s. Such information has been recorded in the PiCo MetaDB (see PiCo MetaDB in § 4.4). For *PVP* #8, *PSI* adopted static taint analysis to check whether the privacy parameters in the wrapper's privacy APIs are propagated through program paths to parameters of internal PiCo *SDK*s' privacy APIs. *PUI* considers that such program paths may come with condition checks before invocations of the internal PiCo *SDK*'s privacy APIs. To identify improper conditions that restrict the privacy propagation (*PVP* #9), we leverage an approach based on the data dependency of the conditions being checked, inspired by prior studies that detect hidden operations [84] or logic bombs [88]. Specifically, *PSI* performs backward data dependency analysis for a condition variable. If its value is independent of a privacy parameter (those in the wrapper's privacy APIs), this indicates that such a condition can be implicit and unknown to the apps that configure the wrapper's APIs. We consider such a condition to be a violation under *PVP* #9. For example, in identifying the above example involving Admost which imposes an improper condition by checking IP addresses, *PSI* finds that IP addresses is not propagated from any parameters of Admost SDK's APIs.

4.4 PiCo MetaDB

PiCoScan comes with a PiCo MetaDB that stores metadata for 65 PiCo *SDK*s on Android whose privacy APIs support GDPR, CCPA, or COPPA. The 65 PiCo *SDK*s are filtered from 203 popular SDKs (see § 3.1), and cover three major SDK categories: 43 ads SDKs, 20 analytics SDKs, and 2 social network SDKs. Table 2 provides a more detailed breakdown of SDK types and the supported privacy laws.

From the API documents of the PiCo *SDK*s found in § 3.1, we asked the two security researchers to independently identify two types of APIs: privacy configuration APIs and the SDKs' initialization APIs, by searching for keywords, i.e., "`initialize`", "`privacy`", and relevant laws including "`GDPR`", "`COPPA`", "`CCPA`", and "`US State laws`", in the documents. They examined the API descriptions to find indicators (such as "`before`", "`after`", and "`order`") for the invocation order and recorded these invocation order requirements. Afterwards, they reviewed the API arguments to identify which arguments are related to "`consent`", "`opt-out`", and "`children`" (corresponding to three requirements noted in the scope of research in § 3.1). They were then asked to validate each other's findings, resolve any disagreements through discussions, and combine them.

In total, PiCo MetaDB includes 191 privacy APIs and 146 initialization APIs of the 65 PiCo *SDK*s. The privacy APIs include 106 APIs for GDPR compliance provided by 61 SDKs, 47 APIs for CCPA compliance provided by 39 SDKs, and 38 APIs for COPPA compliance provided by 34 SDKs. The PiCo MetaDB recorded metadata of the APIs useful for our analysis, including API signatures (including class names, method names, parameters types), corresponding privacy laws, parameters with privacy semantics and values of compliance (e.g., a `true` parameter indicating child users in a COPPA API `setIsAgeRestricted`), and constraints for the correct use of the APIs (e.g., order of API invocations), etc. We show an example of the metadata for Bytedance APIs in Appendix (Figure 5). For reproducibility, the API documents and the resulting PiCo MetaDB have been released at [17].

Table 2: Distribution of SDKs in PiCo MetaDB

SDK Type	# PiCo *SDK*s Supporting			Subtotal
	GDPR	CCPA	COPPA	
Ads	41	33	29	43
Analytics	20	5	4	20
Social Network	0	1	1	2
Subtotal	61	39	34	65

5 Implementation and Evaluation

5.1 Implementation

The static analysis techniques are mostly implemented with Soot [32], one of the most commonly used frameworks for Java and Android analysis. To achieve better coverage, we built app call graphs using an extensive list of app entries, including all lifecycle functions of the registered app components, as well as app methods that match any of the 879 subsignatures of the system callback methods (as reported in EdgeMiner [45]). We built the Interprocedural Control-Flow Graph (ICFG) in the Soot framework using Heros [16] . On top of the call graph and the ICFG, we implemented techniques for constant propagation, and data dependency analysis. In total, we implemented the static analysis with 4,587 lines of code.

The detection of certain PVPs, i.e., #4, #5, #6, and #8, relies on taint analysis, for which we leveraged FlowDroid [40], a state-of-the-art tool for static taint analysis. Specifically, for PVPs #4 and #6, we used FlowDroid to trace the propagation from privacy API parameters to SDK internal variables (IPSVs) storing the parameter values. A key challenge in directly applying FlowDroid is that it only accepts APIs as taint sources and sinks, rather than specific privacy API parameters. We resolved this issue by adapting FlowDroid's source-sink manager, `AccessPathBasedSourceSinkManager`, to allow any program statement and variables, including API parameters, to serve as a source in taint tracking. Based on that, we executed FlowDroid using the privacy API parameters recorded in PiCo MetaDB as sources and 138 networking and file access APIs collected from prior studies [66, 70, 87] as sinks. Then, we identified the IPSVs by analyzing the propagation of privacy API parameters within PiCo *SDK*s through a

`TaintPropagationHandler`. For PVP #5, we track the exposure of user personal data to the Internet by running FlowDroid with a compiled list of 26 sources and 138 sinks based on prior studies [66, 70, 87]. For PVP #8 (broken privacy delegation), we used the privacy parameters in the PICO *wrapper*'s privacy APIs as sources and the privacy APIs of the encapsulated PICO *SDK*s as sinks. We report a PVP #8 risk if an expected taint path (or information flow) was not observed.

To perform runtime user preference analysis, we monitor the content on app user interfaces by intercepting all window content change events using the accessibility service (AS) event `TYPE_WINDOW_CONTENT_CHANGED`. Upon each event, we enumerate all the UI elements by traversing the tree of `AccessibilityNodeInfo` objects, and tell whether the elements are related to privacy by matching crafted regex (as noted above). We exercise the privacy-related UI elements by issuing automated clicks by `AccessibilityNodeInfo.performAction`. In addition, the runtime value analysis is built upon Frida [8] – one of the most popular app dynamic instrumentation tools for Android. The dynamic analysis is implemented with 804 lines of Java code and 1,094 lines of Python code.

5.2 Evaluation

Groundtruth datasets. To assess the effectiveness of PICOSCAN in detecting PICO *risk*s, we constructed two groundtruth datasets: the app evaluation dataset and the PICO METADB evaluation dataset.

The app evaluation dataset contains 40 randomly selected apps along with their PICO *risk*s related to app-related *PVP*s (#1-#3). We installed these apps on a Pixel 6 device, manually exercised the apps, and used Frida to record the stack traces and parameters of any PICO *SDK* initialization and privacy APIs invoked by the apps [8]. To confirm the PICO *risk*s of these apps, we manually checked the stack traces and parameters based on the definition of the app-related *PVP*s. For example, we flagged *PVP* #1 if a PICO *SDK* initialization API was invoked by the app's first-party code without its privacy APIs. The appearance of any *PVP* in the apps is considered an instance of PICO *risk*, and in total, we identified 14 instances of PICO *risk* across 13 apps.

The PICO *SDK* evaluation dataset includes 10 randomly sampled PICO *SDK*s from the total of 65, with three of them being PICO *wrapper*s. To execute the SDKs, we selected the app with the highest number of downloads among all apps in APPSET that utilize each SDK. We installed, ran, and analyzed these apps containing the PICO *SDK*s using similar techniques as described above. We tailored the manual confirmation process to verify the presence of PICO *risk*s related to PICO *SDK* and PICO *wrapper*. For instance, to detect *PVP* #4, we manually identified methods in the apps that return privacy configurations through reverse-engineering, and then hooked into these methods to retrieve the default configuration." This process, particularly the manual reverse engineering and *PVP* confirmation, was labor-intensive and required two security researchers nine days to complete. In total, we identified 16 instances of PICO *risk* in these apps. Table 3 provides the breakdown of all the *PVP*s in the two groundtruth datasets.

Table 3: Groundtruth datasets

Dataset	*PVP*								
	#1	**#2**	**#3**	**#4**	**#5**	**#6**	**#7**	**#8**	**#9**
App Groundtruth	11	2	1	-	-	-	-	-	-
PICO *SDK* Groundtruth	-	-	-	6	1	1	3	3	2

Evaluation results. We ran PICOSCAN on the apps in the two groundtruth datasets on a computer equipped with two AMD EPYC 7742 processors and 256 GB of memory. On average, each app took 425.7 seconds to finish the analysis. Then, we compared the results with the groundtruth datasets. Overall, PICOSCAN achieves 87.5% precision and 77.8% recall for detecting PICO *risk*s caused by apps, and 85.7% precision and 90.0% recall for detecting PICO *risk*s in PICO *SDK*s and PICO *wrapper*s.

• *False positives*. PICOSCAN reported five false positive PICO *risk*s: two related to PVP #1, two related to PVP #6, and one related to PVP #8. The primary cause of these false positives is the inaccurate and incomplete call graphs generated for the apps. For instance, two apps employ dynamic method dispatching or callbacks when invoking privacy APIs of PICO *SDK*s. PICOSCAN erroneously flagged these two apps with PVP #1 (missing configuration) because static analysis failed to identify the privacy APIs on the call graph, even though they were indeed invoked. Another app was flagged with PVP #8 (broken privacy delegation) because a wrapper SDK failed to call privacy APIs of its underlying PICO *SDK*s. However, upon investigation, we discovered that the reported PICO *wrapper*, Vungle, was not actually a wrapper SDK. PICOSCAN mistakenly identified it as a wrapper due to overestimation in call graph construction, which connected another SDK's initialization API to that of the Vungle SDK. Other false positives were also attributed to the inaccuracies of static analysis.

• *False negatives*. PICOSCAN reported four false negatives, with two related to PVP #1 and two related to PVP #4. The causes are twofold. First, for PVP #1, PICOSCAN failed to identify missing privacy API invocations in Unity3D. Specifically, Unity3D employs the same API for three different laws, with the first API parameter specifying which law. Due to the limitation that PICOSCAN does not differentiate APIs based on parameters, it mistakenly considers privacy APIs for CCPA and COPPA to be invoked, even though the API is intended solely for configuring GDPR. Second, for PVP #4, PICOSCAN detects the default value of privacy APIs by monitoring the values of IPSVs identified through static analysis. However, certain SDKs, such as Ogury, do not utilize IPSVs for storing privacy configurations; rather, they store the configuration directly into persistent storage (i.e., "`IS_CHILD_UNDER_COPPA`" in shared preferences). Consequently, PICOSCAN was unable to determine the default value for the absence of IPSVs.

6 Measurement

For measuring PICO *risk*s in the wild, we collect a set of 48,305 mobile apps (called APPSET) by crawling Google Play [57] using a Go-based crawler [33] in October 2023. Specifically, we collected the package names of all 7,753,757 apps that have ever appeared on Google Play (as recorded by AndroZoo [34]), and randomly shuffled the package names before crawling. We followed the order of the shuffled package names and crawled an app if it was relatively new (updated after January 1, 2020) and available in both the United States (including California) and the EU[2]. Among the apps in the APPSET, at least 827 were expected to comply with COPPA since they are committed to follow the Play Families Policy [9]. We report GDPR and CCPA risks over the entire APPSET, and COPPA risks over the 827 apps.

6.1 Landscape

Usage of PICO *SDK*s. Running *PUI* on the APPSET, we found that 58 PICO *SDK*s in the PICO METADB are actively used by apps in the APPSET, i.e., SDK initialization APIs are reachable from app entry points. These SDKs appear in a total of 24,844 (51.4%) apps, with AdMob appearing in the highest number (14,497) of apps and AppNexus in the lowest number (3) of apps. It is worth noting that not all apps use the most up-to-date SDK version. In particular, 12,480 (50.2%) of the 24,844 apps invoke the legacy version of at least one PICO *SDK* that does not implement the corresponding privacy APIs. Also, we identified a total of 22 PICO *wrapper*s from the apps using any PICO *SDK*, and these PICO *wrapper*s are used by 1,769 apps in the APPSET. Each PICO *wrapper* encapsulates an average of 3.08 SDKs, with *AppLovin* having the maximum number of 13 SDKs in a single app. An app can also use multiple PICO *wrapper*s. For example, `com.zloong.eu.dr.gp` app contains nine PICO *wrapper*s, i.e., *AdMob*, *Ironsource* and *AppLovin*, etc.

Overall PICO *risk*s. Table 4 shows the PICO *risk*s that violate privacy principles for three roles, i.e., apps, PICO *SDK*s, and PICO *wrapper*s. Specifically, at least 7,880 apps (31.7% of 24,844) fail to adhere to the privacy principles for apps and are affected by at least one of PVP #1 to PVP #3. The majority of the apps are affected by PVP #1, missing privacy configuration. Among the PICO *SDK*s in PICO METADB, 36 violate the privacy principles for individual PICO *SDK*s and are affected by at least one of PVP #4 to PVP #6. Most (28) of the 36 PICO *SDK*s use a privacy-invading default value for at least one of their privacy APIs (i.e., PVP #4). Additionally, out of the 22 PICO *wrapper*s, 16 are affected by at least one of PVP #7 to PVP #9, thus violating the complete privacy delegation principle.

6.2 PICO Risks Caused by Apps

Missing privacy configuration (PVP #1). Among the 24,844 apps using any PICO *SDK*, 7,818 (31.5%) missed privacy configurations, i.e., they use PICO *SDK*s but fail to set up their privacy APIs. The top 40 apps with the most missed privacy APIs lack, on average, 15 privacy APIs across at least eight PICO *SDK*s. These apps include very popular ones installed by over 10 million users, such as `com.thinkyeah.smartlockfree`, which lacks 24 privacy API calls in 10 PICO *SDK*s. We also found for 16 PICO *SDK*s, over 50% of the apps using each of them are affected by missing privacy configurations. Notable examples include Criteo (99.2%), Amplitude (94.3%), Bytedance (79.0%), and AppLovin (50.2%).

By examining the distribution of the affected apps and the developer documentations of the 39 affected PICO *SDK*s involving PVP #1, we were able to infer a few potential reasons. First, we found that the way in which PICO *SDK*s present privacy configuration options or APIs to app developers is a potential key factor for missing configurations. A large portion (25 out of 39, 64.1%) of PICO *SDK*s document privacy configuration APIs as advanced and optional features (in contrast to regular steps for SDK integration, see below), up to individual app developers to identify and adopt such advanced features. In contrast, documentations of the other 14 PICO *SDK*s (35.9%) suggest adoption of their privacy APIs as part of the regular steps for integrating the SDKs. Although adoption of their privacy APIs are still not mandatory, they may better encourage apps developers to identify and use privacy APIs. The latter group of PICO *SDK*s is significantly less affected by missing configurations compared to the former group, with a Q3 of 64.3% for the former group (i.e., a quarter of the SDKs have a missing configuration rate of over 64.3%) and a Q3 of 32.9% for the latter group, and average missing configuration rates of 43.2% and 23.8%, respectively. We released the list of the affected PICO *SDK*s in the above two groups, their documents and distribution of the percentage of apps missing privacy configurations for PICO SDKs at the time of our study online [17]. Second, in addition to documents, PICO *SDK*s also provide different levels of tooling for app developers to correctly integrate them. Take the Criteo and AppLovin SDK as an example. AppLovin provides a mediation debugger that help app developers to visually debug problematic integration of the SDKs, including configurations by privacy APIs, while Criteo does not provide similar tooling. This could be one potential reason why apps using AppLovin are much less affected than those using Criteo. Third, from the apps' perspective, it might be the case that more popular apps may have greater resources for privacy related engineering and testing. We noticed that only a small fraction (4.7%) of apps using Criteo had more than 1,000,000 installations, while a larger proportion (27.9%) of apps using AppLovin achieved such a milestone. Overall, although many PICO *SDK*s provide privacy configurability, a substantial number of Android apps have yet to adopt them. Hence, the Android ecosystem could greatly benefit from more effective tools, such as those provided by SDK providers, to ensure developers' adoption of these privacy APIs when integrating PICO *SDK*s.

[2] App availability in the EU is determined by a Spain IP.

Table 4: Overall PICO *risk*s

PICO Risks Caused by Apps			PICO Risks Caused by PICO SDKs			PICO Risks Caused by PICO Wrappers		
PVP	**# Apps**	**# Involved PICO SDKs**	**PVP**	**# PICO SDKs**	**# Affected Apps**	**PVP**	**# PICO Wrappers**	**# Affected Apps**
PVP #1	7,818	39	PVP #4	28	20,201	PVP #7	11	322
PVP #2	259	6	PVP #5	16	14,869	PVP #8	12	232
PVP #3	56	3	PVP #6	8	2,097	PVP #9	3	282
Subtotal	7,880	40	Subtotal	36	20,302	Subtotal	16	591

Notably, we don't have ground truth for what the app developers experienced and what development tools they actually used when integrating PICO SDKs. Hence, we may not judge all reasons why app developers came with PVP #1. However, based on our study, the reasons we discussed above could at least partially cause PVP #1 or make it difficult to avoid in the wild. The similar is true for our causal analysis of other PVPs.

Configuration disregarding or inconsistent with user privacy preference (PVP #2). We found that 259 apps, while invoking privacy APIs, fail to configure the APIs correctly according to user preferences. For example, 248 apps choose to hard-code the parameters of privacy APIs (in six PICO *SDK*s) which allows unexpected data exposure regardless of their preferences. We suspect that this choice is driven by factors such as the revenues and privacy engineering cost. For example, many apps often serve as ad publishers, which rely on data collection and personalized ads features to maximize revenues. Hard-coding privacy APIs allows them to quickly enable such features with minimal privacy engineering efforts.

In addition, around 8.8% apps using PICO *SDK*s are found to collect user privacy preferences through privacy dialogs. We found that 11 of these apps still invoke privacy APIs with parameters that enable data exposure, even when the privacy dialogs are declined. A closer inspection of these apps reveals that such discrepancies may stem from app developers' limited knowledge of privacy compliance. For example, the `socksrevive.plugin.dragon` app displays a privacy consent dialog stating that "*By agreeing you are confirming that you are over the age of 16 and would like to personalize your ad experience*" and asks users to consent by clicking a "*YES, I AGREE*" button. The presence of the dialog indicates that the app developer is at least aware of the importance of requesting privacy consent from users. However, the app only uses the dialog as a gating mechanism for new user registrations but fails to propagate the consent status to any other app components, including mobile ads, such as the BidMachine SDK. This problem potentially suggests that the app developer may assume that their app is privacy-compliant as long as a dialog is provided, without fully understanding the necessity of supporting compliance by configuring each individual component.

Erroneous configuration (PVP #3). We observed that eight PICO *SDK*s, such as AppLovin [23] and Ironsource [29], in the PICO METADB require that privacy APIs and initialization APIs be called in a specific order, which if violated leads to erroneous and invalid privacy configurations. Although the percentage is not high, there are still 56 apps that violate this requirement on three SDKs: AdMob, Ironsource, and Unity Ads. In total, these apps were installed over 20 million times. Given that most apps using these three SDKs meet the requirement, we believe that the issue with the 56 apps is primarily caused by implementation flaws of their developers, considering that all eight of these PICO *SDK*s explicitly noted the order constraints in their documents. We released the list of the eight SDKs and their documents online [17].

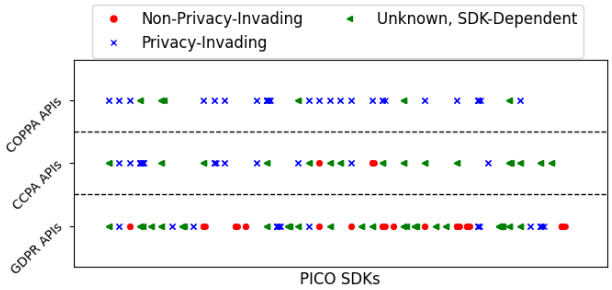

Figure 3: The distribution of default privacy configurations

6.3 PICO Risks Caused by PICO *SDK*s

Privacy-invading by default (PVP #4). Among the 65 PICO *SDK*s, 28 (43.1%) are found to have at least one privacy API with a privacy-invading default configuration, affecting 20,201 apps in APPSET. Figure 3 shows the distribution of the default values of PICO *SDK* privacy APIs.

The privacy-invading default values are not evenly distributed among the privacy APIs for different laws, i.e., the GDPR APIs of eight SDKs, the CCPA APIs of nine SDKs, and the COPPA APIs of 19 SDKs. A potential reason for this disparity could be the varied responsibility models adopted by the PICO *SDK*s, caused by the differing scopes of applicability across different laws. For instance, GDPR, with its broader reach, generally applies to any apps serving individuals within the EU and those based in the EU, while COPPA specifically targets apps serving children under the age of 13 in the US. As a result, many PICO *SDK*s have largely considered GDPR compliance as a baseline requirement, without privacy-invading default values. However, regarding COPPA, SDKs have generally adopted a model where it is the responsibility of app developers to inform SDKs of COPPA's applicability (while, without being informed, the SDK assumes that users are not children and collects their data by default, as described by Unity Ads [19]).

Another observation is that PICO *SDK* developers often do not disclose the default configuration of the privacy

APIs, which goes against the best practices of software configuration [74]. Even more concerning, some SDKs are potentially concealing their default configurations from public scrutiny. An example is the Meta Audience Network SDK. The SDK has a "*limited data use*" (LDU) feature for achieving privacy compliance with US state laws including CCPA. By default, the SDK uses `new String[0]` parameter on its `setDataProcessingOptions` to completely disable LDU. The way that this default parameter is specified is suspicious. Upon initialization, the SDK sets the parameter by reading the `DATA_PROCESSING_OPTIONS_KEY` key from the shared preference. Since LDU has never been configured before, the shared preference will return a *null*, which is then replaced by the SDK with a `new String[0]` value. Interestingly, the above key to access shared preference is obfuscated with a byte-wise XOR encoding by Facebook (in `com.facebook.ads.redexgen.X`), while all the other keys are left intact. This appears uncommon since the only benefit of obfuscating this key, as far as we can imagine, is to make external reviews more challenging to identify the default LDU enablement status.

We want to note that the discovered privacy-invading default values may not fully represent all PICO *SDK*s. In Figure 3, we label many APIs as "*Unknown, SDK-Dependent*" (◀) because the extracted API parameter does not match any value recorded in the PICO METADB. For example, Vungle's COPPA API has a default `COPPA_NOTSET` parameter, which does not match either of the recorded values, i.e., `COPPA_ENABLED` and `COPPA_DISABLED`. While such default values could also invade privacy, we did not report them as PICO *risk*s related to PVP #4.

Ambiguous consent configuration (PVP #5). Sixteen PICO *SDK*s have an ambiguous consent configuration in their privacy APIs, which, even if well configured, fails to stop the collection of user personal data. These PICO *SDK*s lead to unexpected and bypassing privacy exposure to 14,869 apps. One prominent piece of personal data being collected is the advertising ID, a unique ID for advertising. We believe this issue is mainly caused by the lack of standards in implementing privacy APIs. Even though PICO *SDK*s provide seemingly similar privacy APIs (e.g., for collecting user consent), they don't agree on the same privacy assurance.

Ineffective configuration (PVP #6). We identified that eight PICO *SDK*s have at least one privacy API that can become ineffective due to the presence of other program paths that affect its execution. These PICO *SDK*s are integrated by 2,097 apps in APPSET. Interestingly, all the eight PICO *SDK*s, such as MobileFuse and Appodeal, share IPSVs between their GDPR and CCPA APIs. As a result, the GDPR configuration of these PICO *SDK* is affected, e.g., overridden, by their CCPA configurations. The reason for this lies in the fact that, similar to MyTarget, these PICO *SDK*s have CCPA APIs intended to offer essentially the same privacy guarantees as their GDPR APIs, i.e., obtaining user consent for data collection. We believe this is a result of a common misinterpretation of CCPA. In reality, CCPA relies on implied user consent for data collection while requiring options that allow users to opt-out of selling and sharing personal data. Hence, obtaining user consent may not lead to full CCPA compliance, as it does not fulfill the fundamental CCPA requirement regarding opting out of selling and sharing with third parties directly.

6.4 Privacy Risks Caused by PICO *wrapper*s

Uneven privacy support (PVP #7). The support of privacy laws across PICO *SDK*s varies. For example, only 27 (41.5%) of the 65 PICO *SDK*s provide privacy APIs for all three privacy laws. Particularly, 14 out of the 22 PICO *wrapper*s offer APIs for all these laws. However, most of them (11) encapsulate at least one PICO *SDK* that does not provide APIs for all these laws, resulting in uneven privacy support.

Broken privacy delegation (PVP #8). Even with privacy APIs to the same privacy law, 12 wrappers (54.5% out of 22) fail to propagate the privacy configurations into at least one encapsulated PICO *SDK*, resulting in inconsistent privacy configurations in 232 apps. Exploring the documents and design of PICO *SDK*s allows us to make several reasonable guesses. First, the privacy APIs of PICO *SDK*s often appear in the optional "advanced settings" documents. PICO *wrapper*s are not required to configure privacy exposure of PICO *SDK* with these APIs before they can access the main functionality of PICO *SDK*s. As a result, many PICO *wrapper*s may refrain from calling the APIs unless it becomes mandatory. Second, even in the case that PICO *wrapper*s prioritize privacy propagation, their ability to accurately propagate configurations is often challenged by the opacity of other SDKs, and the mismatching semantics of privacy APIs. For instance, Facebook's CCPA API, `AdSettings.setDataProcessingOptions`, implements the "*Limited Data Use*" mode to ensure compliance with state laws such as CCPA, for individuals in California, Colorado, or Connecticut. Unfortunately, this may not be immediately evident to PICO *wrapper*s, which commonly interpret CCPA as "*do not sell/share*" or "*opt-out of selling/sharing*". Therefore, as we suggest in Section 7, adopting standard privacy APIs (e.g., the IAB compliance framework [11]) may help minimize the confusion caused by the custom privacy API implementations of various SDKs.

Conditional propagation (PVP #9). Furthermore, there can be an issue even if there is a path to propagate privacy configurations. For example, three PICO *wrapper*s, i.e., Appodeal, BidMachine, and Admost, have additional conditions such as checking IP geolocation when propagating privacy configurations to wrapped PICO *SDK*s. These conditions affect the propagation of privacy configurations to at least 18 PICO *SDK*s.

In Figure 4, we illustrate the PICO *risk*s that occur between a series of PICO *wrapper*s (left) and PICO *SDK*s (right).

7 Discussion

Disclosure. We reported all the PICO *SDK*s to related vendors including SDK and app developers, which were acknowledged

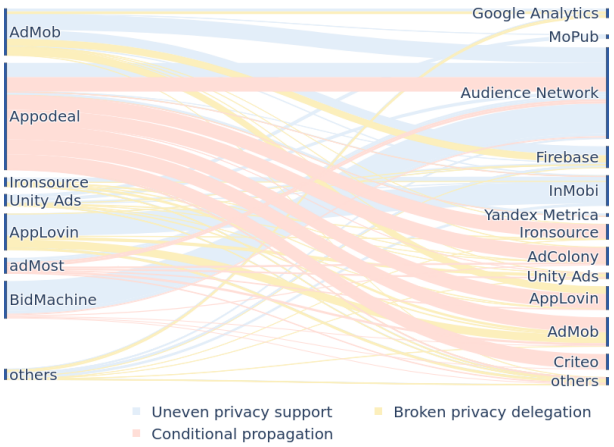

Figure 4: PICO *risk* by PICO *wrapper*s

by some vendors recently. For example, Vungle confirmed and fixed the issues in its latest version 7.3.1; five other SDK vendors appreciated the issues we reported and are investigating them. We will update the vendors' acknowledgement at [17].

Suggestions to stakeholders. Achieving privacy compliance requires collective efforts from multiple involved stakeholders.

• *SDK developers*. Many PICO *risk*s, particularly those associated with PICO *wrapper*s, result from ad hoc, non-standard, and varying implementations of privacy APIs across various SDKs. Therefore, SDK developers may consider adopting standard APIs, such as the IAB framework [11], to offer uniform and interoperable privacy API implementations. Fully integrating the standard APIs is challenging and can take a long time because it requires significant changes to both the client-side and server-side code of PICO *SDK*s, e.g., to fully support IAB signals. As a short-term and interim solution, without overhauling the SDKs' existing code, SDK developers may consider developing adapters on the client-side to parse, propagate, and map standard APIs to the current offerings of privacy APIs. Furthermore, missing configuration is the most common risk in the use of PICO *SDK*s. To mitigate this risk, it may be reasonable for SDK developers to implement a gating mechanism or debugger (as done by AppLovin) that verifies the presence of privacy APIs for each PICO *SDK* integration.

• *App developers*. Apps often incorporate many SDKs, and the privacy configurations of these SDKs can be erroneous and inconsistent. However, in the regular app development lifecycle, there are no review or testing procedures specifically designed to address such errors and inconsistencies. Therefore, app developers may consider implementing dedicated reviews or test cases before delivering their apps to the general public.

• *Privacy law enforcement agencies*. The current PICO *SDK* ecosystem has generally adopted a *confusing responsibility model*, where PICO *SDK*s act as data controllers benefiting from the processing of user-sensitive data, while only the apps (rather than PICO *SDK*s) are exposed to pursuits by law enforcement agencies [53–55]. Hence, PICO *SDK* providers have little motivation to support materialized compliance, such as incorporating privacy-compliant defaults for COPPA. To address this issue, a more effective approach for law enforcement agencies could be to directly perform compliance checks on the implementation of popular PICO *SDK*s, which can also reduce compliance risks for any apps using these SDKs.

Limitation Discussion. We developed common-sense principles and PVPs to model expected practices for using and implementing PICO *SDK*s. Though they cover various types of privacy risks, they are not exhaustive. Other relevant principles and PVPs may exist, which we will explore in future studies. Our PICOSCAN framework primarily relies on static app/SDK analysis, supplemented with dynamic analysis for some PVPs. Due to inherent limitations in processing dynamically loaded or triggered features, the framework's results may not fully reflect app/SDK behavior. This study primarily examines client-side privacy configurations and their implications for privacy. However, apps and SDKs may also use server-side privacy configurations, potentially conflicting with or overriding client-side settings. Analysis of server-side configurations and their interactions with client-side configurations is left for future research.

In addition, this study reported privacy risks that result in technical violations of several privacy principles. However, it is possible that these risks do not actually violate privacy laws. For example, when assessing risks for the CCPA, we assume that all apps available in California are subject to its provisions. In fact, the applicability of the CCPA is contingent upon threshold requirements such as gross annual revenue or the number of California residents whose data are processed. It is likely that the apps we reported on do not meet these requirements, and therefore their privacy risks regarding the CCPA may not constitute actual violations. A similar situation may arise with privacy risks related to the GDPR, especially in cases where the risks manifest in apps that do not use consent as their legal basis. Analyzing these non-technical factors and determining actual violations to privacy laws require the involvement of legal experts and additional non-technical information, which we consider outside the scope of this study. Nevertheless, we firmly believe that identifying privacy risks is highly valuable, as it helps narrow down the analysis of actual violations. Our PICOSCAN implementation identifies PICO *SDK*s and their privacy APIs by matching the package names and API signatures, respectively, as recorded in the PICO METADB. As a result, the implementation is not obfuscation-resistant and cannot cover apps that obfuscate the PICO *SDK* code, and hence the measurement results in § 6 represent only a lower bound of the actual PICO *risk*s.

8 Related Work

Over the past years, a series of prior studies have evaluated the compliance of the privacy policies of mobile apps, and reported incomplete, vague, incorrect, or misleading privacy policies regarding data collection, sharing, and data usage purposes [35, 36, 43, 66, 81, 82, 85]. Similar work also studied

the privacy policies of third-party SDKs [87]. Some other studies analyzed the issues in app consent notices, and reported the data collection and third-party tracking that either without prior consent notices [42, 50, 61–63, 68, 69], or with notices that do not meet the *freely given*, *specific*, *informed* and *unambiguous* requirements of GDPR [41, 61, 62, 64, 69, 78].

Two prior studies [51, 71] are related to our study since they also discussed the privacy configuration issues of third-party SDKs. Specifically, Reyes et al. [71] evaluated the COPPA options by analyzing the traffic generated by child-directed apps and reported that many of the apps fail to set up these options although their users are children. This study, relying on traffic analysis, was unable to attribute the traffic to the app code and identify the actual causes in the code that violate privacy principles, as has been done in our study. Du et al. [51] evaluated inconsistencies between user withdrawal choices and third-party library data collection. This privacy issue can stem from apps failing to configure SDKs for users' data withdrawal (part of PVP #2) or from SDKs failing to fulfill their data withdrawal promises by stopping data collection (part of PVP #5). However, PVP #2 and #5 in our study are more general, covering more privacy rights beyond withdrawal (or opt-out), such as user consent and child privacy rights. Particularly, compared to both related studies, we comprehensively studied the PiCo *SDK* ecosystem and developed several privacy principles that enable the analysis of a broad range of privacy risks. These risks are represented by nine distinct violation patterns (PVP #1-#9) and cover different roles in the ecosystem, including apps, PiCo *SDK*s, and PiCo *wrapper*s. Many of these risks arise from the interactions between these components and have not been systematically studied before.

9 Conclusion

In this paper, we conduct the first comprehensive measurement study on the privacy compliance risks of privacy-configurable SDKs (PiCo *SDK*s) and the apps using them. We built a database of 65 popular PiCo *SDK*s and analyzed over 48,000 Google Play apps to assess their adherence to privacy principles, covering both the app developer's code and the SDKs' code. This analysis is facilitated by our development of a compliance risk analysis framework, PiCoScan. Our findings unveil significant privacy risks associated with both app developers and third-party SDKs, highlighting systemic issues that underscore the need for improved privacy practices and configurations in the PiCo *SDK*s' ecosystem.

Appendix A

Privacy API Metadata in PiCo MetaDB. In Figure 5, we use the Bytedance SDK's initialization and COPPA-related privacy API to show what privacy API metadata looks like. Essentially, in a JSON object, we record the API signatures, associated privacy laws ("`apiType`"), and API parameters and their privacy semantics ("`apiSemantic`"), as well as constraints developers need to follow for the correct use of the APIs ("`apiConstraints`"), etc.

```
{
    "Bytedance": {
      "apis": [
        {
          "apiSignature": "<com.bytedance.sdk.openadsdk.
              api.init.PAGSdk: void init(android.content
              .Context,com.bytedance.sdk.openadsdk.api.
              init.PAGConfig,com.bytedance.sdk.openadsdk
              .api.init.PAGSdk$PAGInitCallback)>",
          "apiType": "Init",
          "apiSemantic": {}
        },
        {
          "apiSignature": "<com.bytedance.sdk.openadsdk.
              api.init.PAGConfig: void setChildDirected(
              int)>",
          "apiType": "COPPA",
          "apiSemantic": {
            "parameterIndex": 0,
            "dataDisablingValues": [1],
            "dataEnablingValues": [0]
          }
        }
      ],
      "apiConstraints": [
        {
          "order": ["COPPA", "Init"]
        }
      ]
    }
}
```

Figure 5: Metadata for a privacy API in PiCo MetaDB

Privacy laws and regulations that current PiCo *SDK*s support. We released the results of our comprehensive review of SDK documents online [17]. We report the privacy laws, regulations, or guidelines supported by the most popular PiCo *SDK*s listed on AppBrain, along with the number of SDKs that claim to support compliance with them using PiCo *SDK* privacy APIs. In total, the PiCo *SDK*s collectively support at least 20 privacy laws, regulations, or guidelines, with GDPR, CCPA, and COPPA being the three most supported laws.

Table 5: Constraints on Privacy API Invocations

PiCo *SDK*	Law	# of APIs	Order Constraint
AppLovin	COPPA	1	[COPPA, Init] [23]
Appodeal	COPPA	1	[COPPA, Init] [5]
Ironsource	COPPA	2	[COPPA, Init] [13]
Ironsource	CCPA	2	[CCPA, Init] [13]
Tappx	COPPA	1	[COPPA, Init] [18]
Unity Ads	COPPA	5	[COPPA, Init] [19]
HyperMX	COPPA	1	[COPPA, Init] [10]
Ogury	COPPA	1	[COPPA, Init] [14]
AdMob	GDPR	1	[GDPR, Init] [3]
AdMob	COPPA	1	[COPPA, Init] [3]

Constraints on privacy API invocations. In Table 5, we present the constraints that app developers need to follow to correctly invoke PiCo *SDK* privacy APIs. In total, eight PiCo *SDK*s require privacy APIs and initialization APIs to be called in a fixed order. Particularly, all of them instruct developers to call COPPA APIs before initialization APIs so that the SDKs can prepare child-directed content, such as ads, during the SDK initialization. These constraints cover a total of 14 unique privacy APIs.

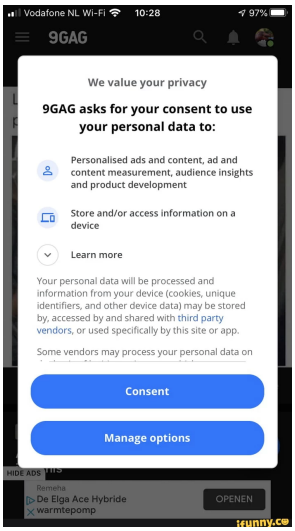

Figure 6: Privacy dialog of the AdMob SDK.

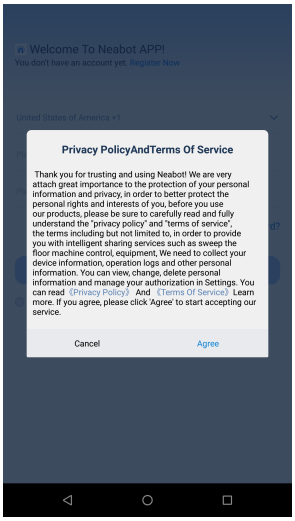

Figure 7: Privacy dialog of `com.jhkj.neabot` app.

Privacy dialogs of real apps and PiCo *SDK*s. In Figure 6, we show the privacy dialog posted by the AdMob SDK in apps that integrate it. This dialog asks users consent to "use your personal data to" offer personalized ads, etc. Figure 7 displays the privacy dialog posted by the first-party code of app `com.jhkj.neabot`, which requests users consent for data collection, etc.

Enabling Developers, Protecting Users: Investigating Harassment and Safety in VR

Abstract

Virtual Reality (VR) has witnessed a rising issue of harassment, prompting the integration of safety controls like muting and blocking in VR applications. However, the lack of standardized safety measures across VR applications hinders their universal effectiveness, especially across contexts like socializing, gaming, and streaming. While prior research has studied safety controls in social VR applications, our user study (n = 27) takes a multi-perspective approach, examining both users' perceptions of safety control usability and effectiveness as well as the challenges that developers face in designing and deploying VR safety controls. We identify challenges VR users face while employing safety controls, such as finding users in crowded virtual spaces to block them. VR users also find controls ineffective in addressing harassment; for instance, they fail to eliminate the harassers' presence from the environment. Further, VR users find the current methods of submitting evidence for reports time-consuming and cumbersome. Improvements desired by users include live moderation and behavior tracking across VR apps; however, developers cite technological, financial, and legal obstacles to implementing such solutions, often due to a lack of awareness and high development costs. We emphasize the importance of establishing technical and legal guidelines to enhance user safety in virtual environments.

1 Introduction

Content Warning: This paper studies harassment in VR. This paper directly quotes participants when necessary, which may contain descriptions of offensive/hateful speech, profanity, and other potentially triggering content.

Virtual Reality (VR) is an emerging technology that enables users to partake in 360-degree virtual experiences using VR head-mounted displays [1–3]. VR offers full-body tracking and synchronous voice chat and has controllers that provide haptic feedback [4], allowing people to interact in newer, more immersive ways compared to traditional social media [5]. While VR presents these novel affordances, it also lowers the bar for unwanted behavior by malicious social actors. The anonymity it provides to users [6, 7], as well as the lack of their physical presence, not only increases the likelihood of harassment but also makes identification of harassers challenging [8]. While online harassment is not a new issue, the unique sense of embodiment and presence that VR enables [5,9], even without haptic technology [10], may amplify certain forms of harassment (e.g., sexual harassment) in virtual spaces.

Harassment in VR is becoming prominent today [11–16], with an abusive incident estimated to occur every seven minutes [17]. VR-based harassment may include virtual violence, virtual groping [18], and haptic sex crimes [19]. To enable users to deal with harassment, VR applications have introduced safety[1] controls such as the personal bubble, power gesture [21], safe zone [22], etc. Targets of VR-based harassment have reported challenges in escaping and reporting problematic users [5], highlighting limitations of existing safety controls. The set of safety controls is not standardized across VR apps, with high variance in functionalities they provide [18], hinting at different usability challenges that may exist for even the same control across VR apps.

To identify gaps in our understanding of harassment controls and better address harassment in VR, it is essential to understand VR safety controls more deeply through the lens of targets subjected to VR-based harassment. First-hand accounts of these targets would elucidate the types of harassing activities that have a lasting impact and how the availability of safety controls, or lack thereof, contributed to these experiences. Further, it would enable understanding the usability and effectiveness of current safety controls and how they may be improved. When users' perspectives are contrasted with those of VR developers, i.e., those involved in the implementation of these features, the combined knowledge will highlight

[1] We consider "safety" in the context of interactions (with users, content, etc.) within the VR environment that threaten a user. We don't consider physical safety implications arising intrinsically from VR hardware (e.g., headset, display), such as flashing lights causing epileptic seizures [19, 20], or injuries arising from careless use of VR (e.g., hitting a wall).

the gaps in practically addressing safety in VR.

Although prior works have identified types of VR-based harassment [5, 18, 23] and availability of safety controls [18] in VR, they have not studied the *effectiveness* of safety controls and reporting mechanisms, nor have they investigated users' perceptions of their *usability* at the time of harassment. We address this research gap by conducting semi-structured interviews with targets (n = 18) of VR-based harassment. We also augment our findings by interviewing (n = 9) VR developers to understand their perceptions on designing and deploying proposed safety features for VR. Specifically, we seek to answer the following research questions:

RQ 1: *How do targets of VR-based harassment perceive the usability and effectiveness of existing safety controls and reporting mechanisms?* We delve into the participants' thought processes behind (not) using safety controls and how such actions contributed to their experience of VR-based harassment.

RQ 2: *What are the expectations and recommendations by targets of VR-based harassment for making VR safer?* We understand what new safety measures our participants desire based on their experiences of VR-based harassment.

RQ 3: *What are VR developers' perceptions of the design and deployment of safety controls?* We understand the challenges VR developers perceive in implementing VR safety controls. Further, we understand developers' views on the feasibility of the safety features desired by targets of VR-based harassment.

We performed a *qualitative analysis* [24] of our participants' responses using open coding [25]. In this paper, we make the following contributions:

- To the best of our knowledge, we are the first to conduct a multi-perspective study on VR safety through the lens of *targets of VR-based harassment* and *VR developers*.
- We identify contexts where existing VR safety controls and moderation practices are non-usable and ineffective. For instance, VR users face usability challenges in finding users in crowded virtual spaces to block them. Safety controls are also ineffective in providing feedback to the harassers.
- We highlight VR users' expectations for making VR safer and contrast them with technical, legal, and financial challenges that VR developers perceive in implementing them. Users desire live moderation in social spaces and want users' behavior to be tracked across VR apps; however, VR developers highlight difficulties in deploying live moderation at scale and the privacy risks in tracking users.
- We use our findings from this multi-perspective study to make recommendations to VR platform owners, app developers, and policymakers for improving safety in VR.

2 Background & Related Work

Online Abuse. Online harassment refers to behaviors that threaten or offend individuals through emails, instant messages, social media, etc. [26, 27]. The ability of users to retain their anonymity [28] exacerbates harassment, and the lack of their physical presence on these platforms makes their identification challenging, causing emotional distress to victims [8].

Table 1: Prominent safety controls available in VR apps.

Safety Control	Function
Mute	Disable voice chat of self, or other users in a VR space
Block	Hide or change the appearance of user(s) in a VR space
Proximity setting	Control the distance at which other users can interact with a user in a VR space
Quick travel	Travel to a different location within a VR app
Safe zone	A user's private space accessible only to that user
Vote kick	Kick a user out of a VR space based on majority vote
Trust rank	Levels of trust assigned to a user

Prior works have extensively studied online abuse in non-VR contexts. Thomas et al. [29] created a taxonomy of types of online hate and harassment, identifying seven classes of attacks, including toxic content, content leakage, and impersonation, based on attackers' intents and capabilities. Of these, toxic content (e.g., bullying, trolling, hate speech) is viewed as the highest priority threat among experts as it incurs significant emotional harm [30]. Additionally, what constitutes toxic content differs across demographics, beliefs, and personal experiences [31]. Researchers have studied technology-based abuse specific to at-risk populations such as youth [32] and sex workers [33–35], as well as how technology facilitates intimate partner abuse and surveillance via mobile [36] and IoT devices [37, 38]. Women, racial/cultural minorities, LGBTQ individuals, and persons with disabilities face more significant risks of online harassment [39, 40].

Safety in VR. VR can act as a medium for harassing activities such as virtual violence, virtual groping [18], and haptic sex crimes [19]. The sense of embodiment and presence facilitated by 3D avatars in VR environments [5, 9], and the ability of some users to feel as though they are their avatars even without haptic technology (termed as *phantom sense*) [10], makes harassment in VR realistic and thus traumatizing. While more female avatars report VR harassment [41], vulnerable populations such as minors face risks of harm through virtual grooming and erotic role-play abuse [42].

VR Apps & Safety Controls. VR apps can be downloaded into standalone or tethered VR headsets [43] through app stores such as Oculus Store [44], Steam VR [45], and Sidequest [46]. While every app has a primary purpose, such as watching movies (e.g., 'BigScreen' [47]) or competitive gaming (e.g., 'Pavlov VR' [48]), many apps have capabilities for multi-user interaction through social spaces and lobbies. Additionally, certain VR apps are primarily meant for social interaction, called Social VR apps (e.g., 'VRChat' [49]).

VR apps have introduced safety controls such as muting, blocking, personal bubble and power gesture [21], personal boundary [50], and safe zone [22] to enable users to deal with harassment. Table 1 describes the most prominent safety con-

trols. Muting may be used either to disable one's own voice such that it cannot be heard by other users or disable other users' voices in a VR environment. "Blocking" — also known as "ghosting" — may make another user's avatar disappear or change its appearance, depending on the implementation. Proximity settings, also referred to as the "space bubble," "personal bubble," or the "personal boundary," enables a user to control the distance at which other users in a VR space can interact with them. "Safe zone" is a user's private space that can be accessed only by the user and may be invoked to "move away" from other users to a safe space. While the "safe zone" teleports the user to a pre-determined location/VR space, "quick travel" can be used to move to other VR spaces within the same app (not just the safe zone). Some apps have custom implementations, like in the power gesture case, which involves "putting your hands together, pulling both triggers and pulling them apart as if you are creating a force field" [21]. Some VR apps have additional safety features such as 'Safety and Trust System' ('VRChat') [51], 'Comfort and Safety' ('RecRoom') [52], etc.

Safety controls may be used proactively (in anticipation of harassment) or reactively (after the harassment incident). Some are inherently used reactively (e.g., blocking, muting) while others (e.g., space bubble) are used proactively [23]. Additionally, VR apps offer ways for reporting harassment, which can be done inside the app, through the headset, or via email to the app developers. While controls like muting and blocking involve only users, reporting involves multiple stakeholders such as users, moderators and automated systems for toxicity detection [53].

Prior work has explored how users engage in social VR [54] and uncovered tensions in specific interactions, such as between children and adults [55, 56]. Moderating sensitive content [57] and reporting users [58] are essential in dealing with inappropriate interactions in VR. Researchers have explored the ethics of acceptable behavior [9, 59], and the influence of body-gender transfer in VR [60].

Freeman et al. [23] interviewed social VR users to understand the new characteristics of harassment emerging in social VR and also investigated users' strategies and recommendations to mitigate harassment. Blackwell et al. [5] investigated users' expectations of social norms and moderation practices in VR communities. Zheng et al. [18] analyzed videos of VR activities posted by social VR users to identify types of safety risks in social VR, including virtual violence, abuse, and sexual harassment. Schulenberg et al. [61] explored the (re)purposing of existing social VR features (e.g., boundary settings) for preventing interpersonal harm in VR.

Distinction from Prior Work. While prior works have characterized harassment in VR and touched upon safety controls, they have not studied VR users' thought processes in (not) using specific safety controls or how the (non) usage of controls influenced their experience. To the best of our knowledge, we are the first to investigate the usability and effectiveness of safety controls through the lens of *targets of VR-based harassment*. We further augment our findings with *VR developers'* perspectives on designing and deploying VR safety measures.

3 Methods

We conducted a phased multi-perspective study with 18 targets of VR-based harassment (**Study-I**) and 9 VR developers (**Study-II**). The findings from **Study-I** were used to design parts of **Study-II**. Table 2 details our recruitment and interview procedure for both studies. We further highlight our study design, data analysis methods, and limitations.

3.1 Study Design & Ethical Considerations

For **Study-I**, we advertised the study in VR-specific online forums. Apart from the recruitment platforms specified in Table 2, we circulated our study in forums for women in VR (e.g., Ladies of Population One) to recruit participants representing marginalized groups in tech spaces [62–64]. A few participants we interviewed shared the study with other groups, facilitating snowball sampling [65] (four participants were from groups where we did not directly advertise). We selected a stratified sample of participants for interviews based on their responses to the screening survey (looking at VR usage and harassment types experienced), irrespective of where they obtained the study information.

We consulted a psychology expert during study design[2] [66] and determined to exclude those diagnosed with post-traumatic stress disorder (PTSD) [67] or seeking help for emotional distress. The expert reviewed our interview script and advised us on phrasing sensitive questions without triggering individuals. In our screening survey, we stated that selected participants would be asked about their harassment experience in VR, but also specified that talking about traumatic events can be cathartic [68]. We curated a list of mental health resources in case of emotional distress during the interview, which included links to websites containing details about mental health hotline numbers to institutions such as the Center for Mental Health Services.

During the interview, in order to study usability challenges in VR safety controls, we first collected contextual information: we asked participants to specify the VR apps in which they experienced harassment (we focused on four apps utmost), then probed about their use of safety controls and reporting mechanisms (explaining the terms when necessary) during/after the incident, and finally asked about what they desired for improving VR safety. After the interview, we inquired about the participants' emotional state, and none reported adverse effects. Regardless, we shared mental health resources with all the participants. Participants were given the opportunity to review the interview transcripts; 11 reviewed them, reporting accurate captioning.

[2]We provide all study materials at: **https://doi.org/10.17605/osf.io/c7fks**

Table 2: An overview of methods for **Study-I** (with targets of VR-based harassment) and **Study-II** (with VR developers).

	Study-I	**Study-II**
Recruitment	VR-specific Discord servers, subreddits, Facebook groups	VR-specific LinkedIn groups, subreddits
Inclusion Criteria	Ages 18-64, resident of the US, active user of VR, experienced harassment in VR, not diagnosed with PTSD, not seeking help for emotional distress at the time of the study	Ages 18 and above, resident of the US, VR developer
Screening Questions	Type of harassment experienced in VR (trolling, bullying, etc. presented as a list of categories), VR apps in which harassment was experienced, VR usage	Roles held as VR developer (UI/UX designer, XR gameplay and tools engineer, AR/VR maintenance and support, etc.), details of VR apps currently developing
Demographics Collection	Just before the interview, to minimize sensitive data collection at screening phase (as participants were targets of harassment)	Part of the screening questionnaire
Interviews	18 targets of VR-based harassment, conducted via Zoom from November 2022 to February 2023, lasting 59 min on average	9 VR developers, conducted via Zoom from August 2023 to September 2023, lasting 49 min on average
Participant Distribution	6 female, 1 non-binary, 5 non-cis, and 7 black persons; 3 participants were prominent in certain VR communities (T12, T13, T15). Refer Table 5 Appendix A.1 for more details.	6 professional developers, 2 VR-based researchers, 1 hobby developer, including the founder of a VR game and a doctorate in XR. Refer Table 6 in Appendix A.2 for more details.
Interview Protocol	(1) Describe harassment incident experienced in VR, (2) Use of safety controls, (3) Use of reporting mechanisms, (4) Expectations for enhancing safety in VR	(1) VR development experience, (2) Solving usability challenges in VR safety controls, (3) Challenges in implementing VR safety features, (4) Feasibility of user recommended features

We developed **Study-II** to contrast the findings of **Study-I** with developers' perspectives by identifying developmental challenges and practical solutions. Our screening survey for **Study-II** asked about participants' roles as VR developers, the apps they developed, demographic information, and their LinkedIn profiles to ascertain their fit for the study. Further, the survey had questions about whether participants had developed apps containing features like socializing, multiplayer gaming, learning, or streaming. We tried to prioritize those with experience in social and multiplayer categories (since those categories of apps have more opportunities for harassment) but eventually included others, too.

We started the interviews by asking participants about their VR development experience and their perspective on handling harassment in VR. Then, we asked about the app development pipeline they were involved in and the challenges they perceived in implementing safety features. We also gathered their perspectives on the feasibility of users' desired features. Our protocol also included questions about reporting and moderation. However, none of our participants were content/user moderators thus we could not report related findings. Questions about the developers' experiences of VR-based harassment were not part of the interview protocol, but some participants shared their experiences.

Both **Study-I** and **Study-II** were approved by our Institutional Review Board (IRB). All audio recordings were transcribed and de-identified immediately after the interviews. Participants also had the option to withdraw from the interview at any time.

3.2 Data Collection and Analysis

We hosted the surveys of our study (screening, demographics, compensation) using Qualtrics [69]. We refined our interview protocol by piloting with three participants for **Study-I** and one for **Study-II**. Participants of both studies were given a 20 USD Amazon gift card after they completed the interviews. All the interviews were audio-recorded and transcribed using Whisper [70]. One researcher checked each transcript for accuracy. Two researchers conducted thematic analysis [24, 25] on the interview transcripts by independently coding the transcripts for both studies. For **Study-I**, the transcripts were divided into four sections (harassment incident, use of safety controls, use of reporting, expectations for safer VR). Each section was coded for all transcripts (in batches of five), followed by discussions to generate/update the codebook before moving on to the next. In the case of **Study-II**, the researchers coded two transcripts together to create the initial codebook, and the rest of the transcripts were coded independently (in batches of two) and discussed for updating the codebook. For both studies, multiple discussions were conducted to reach an agreement to generate a codebook. Since our coding process involved multiple iterations and discussions, intercoder reliability was not necessary to be checked [71].

3.3 Limitations

As is typical with interview studies, our recruited sample size was relatively small due to the sensitive topic of study (**Study-I**) and challenges in recruiting VR developers (**Study- II**). While the exclusion criteria for **Study-I** prevented us from interviewing those impacted deeply by VR-based harassment,

Table 3: Harassment incidents reported by the participants of **Study-I**. Each harassment incident is categorized according to taxonomies from prior work on online abuse attacks by Thomas et al. [29] and VR safety risks by Zheng et al. [18].

Harassment Type	Participants	Excerpts from participants
Trolling / Virtual abuse	T3, T4, T7, T8, T10, T13, T14, T15, T16, T17, T18	*"My accent is different than the average American, and most of the players in this game are either American or British, I've had players chase me around calling me f*gg*t or gay or little b*tch the entire match." (T13, Echo VR)*
Profanity / Virtual abuse	T1, T2, T3, T4, T5, T9, T10, T14, T15 T16	*"We're doing a team task or something like that. They just, started saying some inappropriate vulgar things and I didn't really feel comfortable. (T1, Asgard's Wrath)"*
Hate speech / Virtual abuse	T5, T8	*"He would just yell at me. I think he must have had anger management issues or something; he would say random over-the-top vitriolic things. He sounded furious." (T8, Pavlov VR)*
Threats of violence	T16	*"He started saying, 'I am going to gut your mother and skin your family,' kept repeating it over and over. That was a bit scary, like, really unsettling." (T16, Echo VR)*
Bullying / Virtual violence	T3, T7, T8, T9, T11, T13, T14, T15, T17, T18	*"In the game, you get punched in the head, and it stuns you. I've had players chase me around, trying to punch me in the head the entire match." (T13, Echo Arena)*
(Virtual) Sexual harassment	T4, T7, T12, T13	*"There would be a guy that starts to pretend to r*pe me and encourages others. Because there's presence in VR, they're doing this physically to my avatar, putting their avatar's cr*tch in my face, making slurping noises, sucking [my] b**bs." (T12, Echo VR)*
Explicit content	T2, T6, T11	*"Seeing content, I'm not okay with, people not fully dressed." (T6, YouTube VR)*
Virtual crashing	T11	*"I've played it before. Someone had toyed with that game." (T11, House of Terror)*
Virtual trash actions	T14	*"You can high-five each other. You'll see people slap your hand a bunch of times to get the high five. When you don't, they'll just wave in front of your hand." (T14, BigScreen)*
Misuse of safety features	T8	*"Because everybody looks the same, if he found out a specific person was me, he would team kill." (T8, Pavlov VR)*

we minimized risks to participants. To preserve participants' anonymity while sharing sensitive experiences of harassment, we refrained from having identity verification. However, after the interviews, we identified one imposter participant [72] who participated twice, based on the high similarity of responses[3]. For **Study-II**, we required participants to provide their LinkedIn profile during screening and enable their webcams prior to the interview[4]. In **Study-II**, most developers we interviewed were from small teams, which may not exactly represent development experiences for platforms our participants interacted with. However, safety is relevant in all apps, even those developed by smaller teams. Both studies relied on self-reported information from participants, which may be subject to social desirability bias. To address these limitations in future research, participants may be recruited from a broader range of forums, languages, and cultural backgrounds.

[3]We initially conducted 20 interviews and later excluded the imposter participant's data, totaling the number of valid participants to 18.

[4]When one of the participants failed to enable their camera at the start of the interview in Study-II, the researcher did not proceed with the interview.

4 Users' Perceptions on VR Safety

In this section, we describe our findings from **Study-I** (§ 3), outlining results from every part of our interview protocol. In the first section of the interview, we asked participants about the harassment experiences they had in VR apps to contextualize their use of safety controls (§ 4.1). In the second part of the interview, we focused on participants' awareness of safety controls available in VR apps, as well as their perceptions of the usability and effectiveness of safety controls (§ 4.2). In the third part, we studied the effectiveness of reporting mechanisms (§ 4.3). Finally, we asked about their expectations for enhancing safety in VR(§ 4.4). Our participants' diversity (Table 5 in Appendix A.1) enabled us to capture varying perspectives stemming from a wide range of VR experiences.

4.1 Harassment Experienced by Participants

We asked participants to specify the VR apps in which they experienced harassment (Table 5 in Appendix A.1 lists the apps). Overall, we consider 35 participant-app pairs from 18 participants across 4 social VR, 11 gaming VR, and 2 streaming VR apps. We categorized the harassment incidents

Table 4: Sources of harassment identified by participants.

Source	Participants	Excerpts from participants
Gender	T3, T4, T7 T12, T17	*"Oh, come over here, you b*tch, let me do blah, blah, blah. Women shouldn't even be in this game anyway. Why don't you get off and go make me a sandwich". (T12, Echo VR)* *"It was really frustrating, women are made to be some kind of joke in VR." (T17, Echo VR)*
Race	T4, T13, T15, T16	*"I wanted to play a game with another user and the person wasn't interested in playing with me because he was white and I was black." (T4, Beat Saber)*
Avatar attributes	T15, T16, T9, T11	*"One time I was wearing a turban and jeez, a bunch of kids walked up and wouldn't leave me alone. They kept pestering me and asking if I was Arabic, or Muslim. I didn't really know what to do." (T16, RecRoom)* *"The special season avatar, it's like a dog head. There is a cat avatar, like a Panther. If I have those on, I'll be called a furry, a lot." (T15, Echo VR)*
Physical attributes	T8, T13, T17	*"I had a deviated septum, where one part of the nasal passage is smaller than the other. So my voice sounded really nasally, like, the stereotypical nerd voice. People would make fun of me because of that a lot." (T8, VRChat)* *"Someone figured out I was mute and started going off on me making fun of my disability." (T17, VRChat)*

reported by participants according to existing taxonomies on online abuse [29] (trolling, profanity, hate speech, etc.) and VR safety [18] (virtual violence, virtual crashing, virtual sexual harassment, etc.). Table 3 lists example quotes for each type of harassment recounted by our participants. Here, we do not introduce new findings about harassment in VR; rather, we illustrate the different harassment types to set the context for discussing safety features in the following sections.

We identified that most of our participants experienced different forms of toxic content, apart from VR-specific scenarios such as virtual crashing (using tactics or bugs to ruin others' experience) and trash actions (activities typically intended to spoil the experiences of others) [18]. Participants described their experiences as *'annoying'*, *'uncomfortable'*, *'violating'*, and *'jarring'*. Participants reported experiencing harassment based on their *gender* (as in [23, 41]), with five out of six of our female participants reporting gender-based harassment by a male-like avatar. They also reported that *race*, unique *avatar attributes*, and *physical attributes* that helped identify a user's gender [18, 23], contributed to harassment, as illustrated in Table 4.

In summary, although many accounts of VR-based harassment can be categorized as "toxic content" [29], VR amplifies many forms of abuse (e.g., virtual sexual harassment, bullying) due to its immersion and presence [18] when compared to traditional social spaces online. These incidents leave a significant psychological impact, as reported by our participants.

4.2 Perceptions on Safety Controls

After asking about the harassment incident experienced by the participant, we asked them if they were aware of safety controls at the time of harassment and if they used them. Based on their usage, we asked them about the usability and effectiveness of the safety controls they used. The list of safety controls was not picked beforehand; participants came up with controls themselves during the interview.

Awareness of Safety Controls. Of the 35 participant-app pairs considered, in 23 of the cases, participants were aware of at least one safety control at the time of harassment, which included muting (20), blocking (12) and ghosting (4), using safety bubble (3), vote kicking (1), a form of teleportation such as quick travel (2) or changing lobbies (1). In addition, one participant reported using parental guidance in 'YouTube VR' as a safety control. Participants learned about safety controls in a variety of ways. In seven of the cases, they were informed because of a tutorial available on the VR app. In two cases, the nudges in the app ('Echo VR') prompted them to learn about the controls. In three cases, their knowledge was due to contextual information from playing other video games. Participants also discovered the controls by chance, through exploring the app or searching the Internet.

However, the participants who were unaware of safety controls before encountering harassment did not necessarily attempt to learn about them after the incident:

> *"No, absolutely not. I just left it. [Using the app] is like a fun thing for me to do. I can just find another platform to just move on to." (T1, Asgard's Wrath)*

T14 added that learning the safety controls was not worth his time and hinted at an unintuitive design:*"VRChat is a complicated app. I don't know how it works. It's not, to me, user-intuitive. The offenses are so prevalent that it is not worth my time putting in the time to learn".*

Some participants (T4, T11) reported having checked for controls yet did not make changes to their settings. While T4 did not understand the controls, T11 felt that the trauma of his experience was too much for him to continue using VR.

Activation of Safety Controls. Participants used safety controls both proactively and reactively [23], depending on previous experience of harassment and when they learned about

them. Muting was the most predominantly used control (12), followed by blocking (7) and ghosting (3). The use of quick travel, vote kicking, and parental guidance was mentioned by one participant each. Some controls had several flavors based on the context; for instance, "mute" could be "mute self," "mute others," or "mute all."

T5 talked about the dependence of certain VR games (e.g., 'Beat Saber') on external platforms (Discord) and how controls from those platforms need to be used to mute people while playing the VR game: *"Beat Saber is multiplayer, but there's no voice chat in the game. You have to rely on Discord servers to get into a multiplayer lobby with players, [but there] it's mostly 10-year-olds saying [the] N-word."*

Some participants had clear preferences for using one safety control over another. T5 preferred blocking to muting: *"I'm not going to disable the voice chat in-game [Beat Saber] because it's not everyone [who harasses]. It's only a few people, and blocking them usually helps"*. T8 described his preference for vote kicking in 'Pavlov VR':*"You can mute and also vote kick people. You can call a vote, and if it gets enough votes, the person is kicked from the lobby. It is a necessity to hear everything people are saying, so I don't mute."*

Of the 23 cases where participants were aware of the safety controls in the apps, in 19 of them, they were enabled, while in four, they were not. T12 did not use safety controls as she did not think they stopped the harassment:

> *"If you mute or block them, it's not going to stop the harassment. It's just going to stop me from being aware of it. If they stick their cr*tch in my face, others can see that even if I can't." (T12, Echo VR)*

T17 added that safety controls were implemented only in the lobbies and did not stop harassment while playing 'Echo VR'. T8 found that it was faster to leave 'VRChat' than to individually block every offender.

Usability of Safety Controls. Among 23 instances where participants were aware of safety controls and one instance where they learned about them after a harassment incident, in 14 cases, they found the process of enabling the controls to be easy. In four cases, they found it to be cumbersome and challenging. Moreover, individuals' perceptions of ease of use varied considerably for the same set of features in a VR app. For example, T15 felt: *"The in-game [Echo VR] features to mute or ghost are very simple. You bring up your menu and select the individual or choose the easier option to mute or ghost all"*. In contrast, T12, also a long-term user of 'Echo VR,' said:*"There is a block, but it's hard to use because you have to be able to point at the avatar, which is difficult sometimes"*. T16 recalled how it was hard to find the mute button on 'RecRoom' as a new user:

> *"You had to go into some sub-menu, [with] all the people in the lobby listed, and find their name and click on it. The names are not always super easy to see if they're moving around." (T16, RecRoom)*

Participants also noted that specific controls were more usable than others. T8 found it easier to mute himself than to mute others on 'VRChat':*"It's easy to mute yourself. So that's what I ended up doing most of the time. Blocking people isn't necessarily difficult, but not as fast"*.

Effectiveness of Safety Controls. Participants found safety controls to be useful in certain situations, and we find that the effectiveness of safety controls is highly context-dependent. In social VR, users perceive muting to effectively filter out inappropriate comments and overcome verbal disruption. In gaming VR, which shares the culture of trash-talking with other forms of online gaming [73], users state that muting is effective. T16, who muted his offensive team player on 'Echo VR', said:*"Even if the person said horrible things, I assume they still want to win the game. So they're not going to come over and intentionally play badly"*.

Participants used blocking to effectively limit further interaction with the harassers, especially when there were only a few of them to deal with. They also found quick travel to be effective in escaping from the harasser:

> *"They don't know where you're going, so they can't chase you around." (T7, Zenith)*

Ineffectiveness of Safety Controls. Although participants found the use of safety controls effective in a few scenarios, in a vast majority of harassment incidents, they found the controls lacking in several ways. Social VR users felt that safety controls affected social interactions with non-harassers. T16 noted that enabling safety controls *did not provide feedback to the harassers*, and thus did not stop their behavior:

> *"I don't think that the game tells them that I have muted them. So they would have no feedback [that] this person can't hear me." (T16, RecRoom)*

T7 complained that blocking did not remove the harasser from the game and only changed their appearance on 'Orbus'. She added that quick travel disrupted her experience on 'Zenith':*"You're doing something, and you have to stop what you're doing. It's like you're being punished because you're the one being harassed"*. T5, who used 'Beat Saber' and connected to Discord for voice chat, explained how blocking users on the game did not mute them on Discord and had to use the safety controls on multiple platforms: *"Because blocking the person doesn't mute the person on Discord, I'll just mute the person"*. T13 expressed how certain safety controls would affect communication, which was essential in a strategic game like 'Echo VR':*"Muting players during the game makes it harder because it's a team game, and you can't communicate if you're muting people"*. T9 felt that none of the safety controls would be effective as the harasser could simply create a new account on the app: *"If the guy creates another profile, the blocking and muting would be in vain. You'd have to block this new avatar now. Back to square one"*. T13 and T18 also felt that safety controls would not stop the culture of abuse on 'Echo VR':

"They have zero effect on the larger culture of abuse. They're a testament to the failure of the larger structure to have any form of protection or any meaningful way to stop or intervene in whatever negative dynamics are going on." (T18, Echo VR)

T8 explained how safety controls could be misused, as described in Table 3. T14 felt that the use of safety controls could not prevent disruption when a new user joined the room on 'BigScreen':*"If someone new comes in and doesn't have that person blocked, then you'll have someone being like, oh, who is the screecher? And everyone has to be like, it's this person, block them"*. T14 also felt that the safety controls were ineffective in the unique context of 'BigScreen':

"You can pull up the usernames, but it'll be every username sitting in a theater. If you see someone screeching, you can see a microphone going off. But they'll be quiet when they're doing hand slapping. So you can't see who's talking. Sometimes they will get underneath the seats and slap your hand where you can't see their username. So everyone at that point has to stop the movie and find the offensive person." (T14, BigScreen)

Takeaways: Muting is the most used safety control, in line with trolling and profanity, which are reported to be the most dominant types of harassment. Blocking and proximity settings that help mitigate bullying and sexual harassment are the second most frequently used controls. The key usability challenges with safety controls arise when selecting them from a dense hierarchy of menus while identifying the offending user's name from a long list of lengthy usernames (often with many special characters) or pointing at an offending user's avatar in order to take action on them, while they are still moving. Although safety controls provide a temporary escape to the target, they affect communication with non-harassers, fail to provide feedback to harassers upon muting or blocking, do not remove the harasser from the game but merely change their appearance, and could be misused to cause further harassment. Additionally, they fail to prevent others from witnessing the incident and stop further instances of harassment.

4.3 Perceptions on Reporting

After asking about participants' experiences with safety controls, we also asked them about their experiences with using the reporting mechanisms in VR. Reports can be made in-app, via the headset, or through the website, depending on the VR app and platform in question. We were particularly interested in the reporting process as it is a multi-stakeholder process involving not only the users (unlike the rest of the safety controls) but also developers/moderators and, in some cases, automated toxicity detection systems. Since reporting often involves feedback to the reporting/reported users, we investigated participants' satisfaction with the reporting systems in the VR apps they used.

We find that participants only submitted reports in half of the cases. Their failure to report was either due to a lack of reporting mechanisms, knowledge of reporting, or evidence. Some users did not want to spend effort on reporting. In cases where users submitted reports, their ease of reporting was dependent on the type of evidence they needed to provide.

Why Users Do Not Report. Of the 35 cases of harassment, only 16 cases were reported. Several participants did not know how to report. T16 did not know the controls to report and preferred to leave the app ('RecRoom'), while T7 perceived reporting to be difficult and did not want to "mess" with the process of reporting:

"I'm not sure how you report someone in Zenith and also I just didn't feel like messing with it." (T7, Zenith)

T8 and T16 both mentioned that 'Pavlov VR' did not have the feature to report and expressed their lack of faith in the developers to take necessary action. Some users who were new to the app assumed that the process would be cumbersome based on their experience with other apps. For example, T7 recalled her experience using the in-app keyboard on 'Orbus' and assumed that the process would be similar on 'Zenith':

"I'm sure it would be like Orbus, where you have to fill something out in the game on a keyboard. It's really cumbersome to do that. Plus, they were being very annoying, and I didn't want to stay long enough to do it." (T7, Zenith)

In a few cases, participants reported that it did not occur to them to report. Some participants also failed to report as they believed that the existing policies would not consider a certain type of harassment as a violation. For instance, T5 ('Beat Saber') felt: *"You can't do anything against him because he's technically not breaking any rules"*. Several other participants echoed the notion that reporting did not have any effect. T18, who was banned for 24 hours on 'Echo VR' due to a retaliatory report by his harasser, expressed outrage:

"That incensed me even more. I got banned, and it's only for 24 hours. You expect me to experience the negativity, to videotape the negativity, to go out of my way and submit the report to you. And then you're going to kick them out for 24 hours or 48 hours? How much of a punishment is that? That's a total waste of my time." (T18, Echo VR)

In some cases, even when the user knew how to report, they could not because they did not have evidence. T17 said: *"You have to provide footage of the incident, and I didn't"*.

Ease of Reporting. Our participants submitted reports through the in-app button, headset, or an external website affiliated with the VR app. Six participants reported that they found the reporting process to be simple and easy, and we note that in all of these cases, the only information they needed to provide was a description of the incident or choose the type of incident from a drop-down menu.

T7 found using the in-game keyboard on 'Orbus' for reporting cumbersome and frustrating. T17 felt that reporting was

complex as she could not capture everything her harassers said before she started recording. T13 noted that reporting could be difficult for beginners, but it might get easier with practice. T14 added: *"The only reason I know it so well is because I do it so much. I put time into the community, and I'm on all the Facebook and Discord groups. If a new user were to do it, it's not so clear how to report somebody [on Echo VR]. It's not part of the tutorial at all."*

Of the five cases in which the user had to provide a video of the incident, four participants found the process difficult.

> *"Each report takes 15 minutes if you're doing it properly. You have to get off the game, go through your footage, do a small edit of it, and write out the email. Unfortunately that's why many people don't do it." (T15, Echo VR)*

T12 said that reporting could take five minutes to a week and highlighted some challenges with headset-based reporting:

> *"On Quest 2, you click a report button, and you can record a snippet or upload a video. It'll search for the person, and you just send in the report, which is relatively easy. But you can't shorten it. You can't do that in the headset, you need to go to your computer." (T12, Echo VR)*

How Reporting was Handled. For 11 out of 16 reports, participants believed a moderator had processed their reports. In five of these cases, they were automated responses acknowledging the report. In some cases, the participants assumed that an action had been taken when they did not see the harasser's account anymore (T10, 'Second Life') or did not encounter the type of content they reported anymore (T6 and T11, 'YouTube VR'). Four participants received a response specifying whether action was taken.

In nine cases, participants were satisfied with the responses, while in the other two, they were not. T13 felt that the systems were underdeveloped and human resources were lacking:

> *"I reported to Meta, and I got an email saying that it does not breach their terms of service before I got an email saying, 'we will review your complaint'. So, it's not exactly encouraging." (T13, Echo VR)*

T14 added that while he was satisfied with the platform's actions, he expected more from the app developers:*"With Meta, [I'm satisfied]. I think that more things should get action taken than does. But I wish Echo VR, the company, was taking action and didn't just pass it off to Meta"*.

T16, who did not hear back from the moderators of 'Echo VR,' found reporting to be disincentivizing as he had *"no idea whether it's actually doing anything"*. He believed it was essential for the feedback to include what action was taken and what abilities had been restricted or revoked for the harasser. He also suggested not including the harasser's username in the feedback in order to protect their privacy. T2 added that reports should be taken seriously, considering the target's mental health, while T3 wanted moderators to enquire about the well-being of the user who reported.

Takeaways: If users do not report, it may be due to a lack of reporting mechanisms, knowledge of reporting, or evidence. Although users might find reporting easy once they get acquainted with the system, some aspects of existing reporting mechanisms, such as entering text through a keyboard while in VR or capturing video evidence, are cumbersome. Moreover, users expect timely responses to their reports, with feedback on the action taken.

4.4 Users' Expectations for Safer VR

At the end of the interview, we asked participants about their expectations for safer VR experiences. Participants had insightful suggestions for improving safety controls and new ways of tackling harassment in VR.

Live Moderators in VR. Participants indicated a need for real-time assistance in various situations. T11 said: *"There should be a guide, or an assistant to contact in case things go sideways"*. T17 wanted live moderators who were regular users capable of flagging those who violated the terms of service. T15 described moderators as "in-game security guards," while T12 compared them to the police:

> *"99% of the time, most of us don't see a police person. But if we call one because we really need one, they come. If you could just push a button and have a person called to you, [they] can come and assess the situation." (T12)*

T18 expressed outrage at the notion of social spaces without police officers and emphasized the need for social accountability. T15, a leader in a community for VR gamers (*Virtual Reality Party League*), specified actionable ways to promote live moderation with the help of VR community leaders:

> *"Have community leaders be involved in the main social aspects of games. Whether that is community leaders becoming mods or creating community members who want to step up and become mods. On the back end, have it built properly so they are properly trusted and educated on what they're supposed to do [with] their tools." (T15)*

He also suggested offering perks to the moderators or having it as a paid position:*"They might get a hierarchy rank in that development team. They're allowed to go to certain events. And they're really there for the idea of that community growth. Or it could be paid, you have to be on this headset hour by hour to cover this block and we'll pay you the sum amount"*.

Tracking Users' Behaviour. Participants suggested that VR apps and platforms track VR users' behavior. T1 felt that having access to every user's history was paramount, primarily to determine what action should be taken against them: *"When they ascertain that this person has a history of harassment, [they] can give the person a warning first, and if it continues, just block the person completely, and make sure that the person will not have access to the platform again"*. T12's wanted users' behaviors to be tracked such that they had a certain "trust" level in social spaces inside an app:

"It's good to have certain levels where you trust people or give them abilities or access to places, depending on whether they've earned that. If somebody has been reported for harassment, I'd be booting them right back to level one. They should have to earn back the privilege to be 'normal' again." (T12)

T13 expressed that if a user was flagged for being toxic in one VR space, their *"toxicity"* should *"follow from one app to another"*. He felt that transferring repercussions across apps was essential for a fundamental shift in people's online behavior. He added that it had to be implemented at the platform (*"Meta"*) level, with a coalition among popular VR apps:*"The 10 most popular VR MMO games go, we're going to combine efforts and if you get three strikes combined in any of our games, you can't play any of our games anymore"*.

Detect Distress in Users. Some participants wanted their headsets to detect when they were feeling distressed. T11 felt that VR headsets should be sensitive enough to determine when a person needed help: *"It should tell when a person needs help when he or she no longer feels comfortable in the game"*. T3 added that body movements such as rapid blinking of the eyes or sensors in the headset could be used as indicators of distress: *"When I'm distressed, it gets this information and shuts down. If I am talking to you and I start blinking rapidly, it should know this person isn't okay, and slow down things"*.

In-app Interventions. Several participants indicated their preference for having in-app interventions such as disclaimers, warnings, or prompts to inform them before engaging in potentially toxic environments. T2, who encountered offending scenes on 'YouTube VR,' wanted a disclaimer about the contents of a video. T11 suggested the inclusion of a prompt that would ask the user if they wanted to exit an app when harassment was detected:*"If your headset can detect [harassment], there should be a prompt [asking] if you would want to leave the game you are in"*. T8 and T9 wanted features that would warn users before they entered social spaces where they might encounter harassers:

"If somebody is playing in a certain lobby and they'll know you, recognize you, and get angry at you again, I don't think the game should allow you to join it or tell you who is in the lobby before you join it. It should have a disclaimer that says you've tagged this person." (T8)

T9 added that users joining areas with problematic users (e.g., trolls) should get a notification warning them.

Segregation of Users. Participants had concerns about the safety of kids and wanted age-based restrictions for VR usage:

"VR shouldn't be for kids, honestly. Oculus is already requiring apps to remove 13-year-olds on it. I don't think they're going to stop using Oculus; they're just going to create a normal account and start communicating." (T5)

T18 added, *"No children should be allowed to play with adults. Period. There needs to be age segregation, [because] there are adult predators transgressing boundaries of morality"*. T9 echoed the notion of segregation and suggested that the entire app be divided into age brackets:

"There would be a bracket [with] young kids, another intermediate bracket, [with] teenagers. Adults, somebody will have to agree to some terms and conditions. If you're joining this section, know you may experience this and this. In other sections, all of that is banned." (T9)

T14 felt that paid users could be segregated from unpaid users to filter out children:*"It would be cool if I could pay money to only play with people who paid money because it would get rid of a lot of screechers"*. T5, who had negative experiences with child users saying racial slurs and destroying virtual artifacts inside games, wanted adult-only lobbies. He also believed that checking IDs could be a way to enforce this:

"I'm not saying that kids shouldn't be able to enter, just that there should be a way that adults can just stick with each other, maybe like ID check." (T5)

Takeaways: VR users believe that live moderators and age-based segregation would significantly reduce harassment in VR. They also recommend automatic detection of harassment situations and tracking users' toxicity histories across VR apps. Further, they want in-app interventions to inform them of harassers in the vicinity or in VR spaces they enter.

5 Developers' Perceptions on VR Safety

Based on our findings from **Study-I**, we conducted **Study-II** (§ 3) where we interviewed (n = 9) VR developers. We asked them about the feasibility of the safety features desired by our users (§ 5.1), challenges in designing and deploying safety controls (§ 5.2), and ways to improve existing controls (§ 5.3). With professional developers, VR-based researchers, and hobby developers represented by our participants (Table 6 in Appendix A.2), we believe our findings provide an extensive view of the challenges and limitations in this domain.

5.1 Feasibility of User's Expectations

One portion of our interview protocol was about eliciting developers' perceptions of the features desired by the participants of **Study-I**. We started by asking the developers' perspective of what was needed to make VR safer and followed it by presenting the main user-desired features — live moderators in VR, tracking users' behavior, detecting distress in users, in-app interventions, and segregation of users — and asking about their feasibility. Since the segregation of users largely stemmed from users' desire to have an identity or age-based segregation, we asked developers about the feasibility of identity verification.

Live Moderators in VR – Feasibility. Developers largely agreed that having live moderators in every social space was

infeasible due to the human resources required, the financial challenges, and the difficulty in scaling. D8 said: *"That wouldn't be very scalable, especially for teams like mine where we only have three people developing"*. D7 argued that the economic model would not work, with D9 adding: *"a small development studio, [with] six people and 100 servers couldn't fund that many people to do that. Even a big company who could do that, [would] have to fund thousands [of] people to listen in on every conversation that's said"*.

To tackle these issues, D3 suggested leveraging the VR community to ease the burden on human moderation, echoing T15: *"some platforms have community outreach, where respected members of the community can act as deputies of sorts"*. Drawing from his experiences in community management for his VR game, D7 added that live moderation was taxing and could be effective long-term only if moderators were part of a community: *"They have to get something out of the experience in the first place, or it's just something that burns people out"*. D3 advocated using a small, well-trained team to ensure consistent moderation practices. Multiple developers echoed that moderation at scale could be done using AI-based abuse detection but also recognized the inherent technical and privacy challenges:

> *"Is it practical? How will people react to it? These are the questions that we need to be asking because we're already doing voice, but what about content and avatars? When are we going to have models that look at a 3D mesh and identify if there's any perfect content on it?" (D3)*

Tracking Users' Behaviour – Feasibility. Developers argued that tracking users' behavior was feasible from a technical standpoint; however, they did not favor its deployment. D1 pointed out that if a user violated the terms and conditions of a VR community once, it may not be fair to exclude them from other apps, especially if they corrected their behavior. D9 added: *"If you connect every app ever and you're toxic on one app and it now spreads to everything, obviously people wouldn't want that. You could also have silent toxic people that just lower your rating"*. D3 further highlighted the importance of ensuring that users did not get a negative impression of a user before interacting with them: *"I would not put [the rating] in something which is always stuck to your head. But if I made the conscious decision to require more information about [the user], it's present"*.

Developers highlighted potential challenges in implementing this technique. D8 believed that the tracking could happen only at the platform level (such as Meta, Steam, etc.) due to the existence of several VR stores, each using different accounts. D6 added that users must be incentivized to use the same profile on all apps/platforms. However, they also found this solution to be privacy-infringing:

> *"As a user, I don't like to be pervasively tracked by corporations. Whether or not they're providing me tangibly usable tools, they're not trustworthy entities." (D7)*

D2 argued that, while the data could be anonymized if it was used for training an AI model to detect harassment, real-time tracking involved legal challenges. D3 wanted VR companies to be transparent about data collection practices to users: *"Transparency on the company's part is necessary to reaffirm faith in users"*. Despite their thoughts on how this solution compromised users' privacy, developers also perceived the value of tracking users:

> *"It's good to have that unified information. As a developer, I would love to have a jump list of problematic users and an ability to just, at the very least, pre-sort them into [a similar] category of servers." (D7)*

Detect Distress in Users – Feasibility. Our participants agreed that the automatic detection of distress in users to turn off the headset or quit a VR app seemed a good solution but raised concerns about the availability of sufficient input for accurate detection:

> *"We'll have to be able to break down the feasibility in terms of being able to understand when any stress is happening, how to interpret it, in order to implement it." (D2)*

D4 believed there could be many false positives, where emotions such as excitement may be wrongly detected as distress. D6 added that false positives would result in a *"terrible user experience"*. D9 suggested that obtaining feedback from the user upon detecting distress might achieve a good trade-off between model improvement and user experience.

In-app Interventions – Feasibility. The developer participants agreed that having in-app interventions was *feasible* solution. D1 suggested the use of voice-activated commands for interacting with pop-up notifications and encouraged designs with minimal visual interaction:

> *"The less you have to disturb the user in terms of having to do manual input, that's good. You can [use] pop-ups and [they] just [have] to click, that's useful. It can even be voice-activated commands [without the] user having to interact too much with hand controls." (D2)*

Identity Verification – Feasibility. Since our user participants wanted to segregate users based on age or identity verification, we asked the developers about their perspectives on implementing identity verification. They felt that users would not be willing to share official identification as it was invasive, compromised anonymity, and posed risks in cases of data breach while failing to address the problem:

> *"Someone who's someone is immaterial to whether or not they are a problem. Having their government ID is just putting more power in the hands of tech platforms." (D7)*

D1 and D2 suggested the integration of social media profiles to VR accounts; however, such initiatives have received backlash in the past, as described by D9: *"[Meta] were trying to connect everything from Facebook, Instagram, Oculus, and they got in trouble for doing that"*. D2 and D5 recommended

using hardware identifiers or IP addresses to detect a user. D2 suggested third-party verification but also highlighted challenges in complying with different technology laws across countries. D3 shared that some VR clubs required real-life identification to partake in the community:

> *"Some communities have third-party services to check if the person's real. And that can vary. You take a selfie with your ID, let your personal information out. Or it can be a Discord bot that takes a picture of your driver's license, talks to a background checking service." (D3)*

D5 suggested computer vision techniques for face detection to predict a user's age, while D6 recommended using physiological attributes such as movement and posture for inference.

Takeaways: Sustainable live moderation in VR communities may rely on moderators embedded in the community and augmented with AI-based abuse detection. While tracking users would enable VR developers to create a block list of problematic users, it may be limited to a single platform (e.g., Meta, Steam, etc.) and pose legal risks to VR companies. Detecting distress in users requires a thorough evaluation of whether VR systems can access sufficient input for accurate detection. Developers advocate third-party verification for non-invasive user identification and propose in-app interventions.

5.2 Challenges in Designing Safety Controls

Several questions in our interview were about extracting the challenges in the development of safety controls. We asked developers whether and when safety control design appeared in the pipeline of the apps they developed and what, according to them, was hindering the development of effective safety controls in VR apps. We also asked them if they believed an industry standard of VR safety controls could be created and what technical, social, and economic barriers they perceived.

Safety Not A Priority. A majority of our developer participants believed that VR platforms and app developers do not currently prioritize safety. D3 explained that moderation in VR tended to be reactive rather than proactive, as the development efforts would be focused on appealing to the investors and clients. D4 and D8 felt that VR developers usually had small teams and did not have the bandwidth to develop features for safety. D9 added that developers would not implement safety features until their users reported issues:

> *"Companies are very money-first, fix later. [Maybe] this is why it's getting pushed off, and not many people are talking about it or fixing it." (D9)*

Several participants agreed that there was a lack of financial motive to prioritize safety. D7 highlighted the need for tech companies to justify developmental efforts, especially in light of recent economic conditions with mass layoffs: *"the primary challenge is justifying all that development effort when that could be put towards new user acquisition or directly monetizing engagement"*. D7 added that big companies did not stand to lose out monetarily due to the users that stopped using apps due to harassment:

> *"You can always try to acquire new users faster than you are losing older users. If [companies] can compensate for X women who are leaving, and it's just awful being a woman online, period, but have a referral program that gets more teenage boys to recommend the platform, and they get a $3 kickback and that makes their numbers go [up], then [they] don't have a problem." (D7)*

Participants also believed that well-implemented safety controls may limit interactions among users, impact overall app engagement, and disincentivize companies to focus on them:

> *"Platforms wouldn't wanna do that because engagement is easiest to generate via conflict. If you actually allow people to peaceably exist separate from each other, there are repeat logins that people don't end up doing." (D7)*

Lack of Guidelines/Standards. Developers argued that they did not have any guidelines for ensuring safety in VR apps and stressed the importance of creating awareness among developers to design for safety. For instance, D5 shared:

> *"We don't have a list to go through [that] says you should have [these] models in your app for safety. I'm not sure if it's already there. But clearly, it's not in my mind. It would be nice to have clear regulations to follow." (D5)*

When asked about the feasibility of creating an industry-wide standard for VR safety controls, most of our participants foresaw challenges in bringing together the major stakeholders in the ecosystem. D2 felt that effective enforcement of a standard required coordination among all the big companies, while D7 illustrated how companies tended not to cooperate:

> *"Apple goes out of their way to not use any of the same words to describe things. They just announced a VR headset without using the words virtual reality once. It's antithetical for them that there's some collective best way to handle user moderation. It had to be forced by the EU to put a charger on their phone. That tells how much these corporations want to cooperate on anything." (D7)*

D2 illustrated the technical challenges in implementing uniform data collection practices across platforms: *"To implement such a standard, the way data is gathered in application A should be similar to application B. You have to develop [a] middle framework capable of [collecting] this data and parsing it"*. D6 felt that enforcing entities to adhere to standards was hard. D5 believed non-profit organizations could facilitate companies working together.

Practical Challenges. Developers identified several technical and logistical challenges in the design and deployment of effective safety mechanisms for VR. D2 felt, *"it's complicated to prove that someone is harassing you because it's through the internet, you have the VPN, can hide your IP. It's tricky to prove that someone is harassing you"*. D7 stressed the importance of recruiting good moderators for his VR game:

"You need effective moderators. People who are aware of the rules, who see eye to eye to you about what they mean, why they exist, what your goals for the community are, who you wish to include and exclude in that community, and willing to put in the hours being present. They shouldn't just feel like silent overlords because that can build resentment patterns between user bases." (D7)

An inherent challenge about safety controls that developers called out was that they offloaded a lot of responsibility to the user, as users needed to remember the right controls and use them at the time of need. This is further exacerbated by complications in usability testing, specifically in replicating stressful situations to test how usable the tools are:

"The biggest barrier is actually simulating those experiences to see the tools that are actually working." (D8)

D7 also emphasized the complicated interface development work involved in synthetically recreating reality for VR apps.

Compromise Privacy. Most of our participants expressed concerns about using methods that infringed privacy for the sake of safety and questioned the necessity of invasive practices for moderation. D3 said, *"most people are turned off by the idea of [something] constantly monitoring them, possibly storing their conversations on a database somewhere for an extended period of time"*. While discussing ways to collect evidence for reporting, many developers suggested using a video buffer that stored the recording from a specific time period (e.g., the last 10 seconds); however, all of them agreed that it was privacy-violating:

"Say the platform has the recording of everything in the last 24 hours. The user can always go back to see what happened around [them]. So everything will be recorded, but I don't know how that will conflict with privacy." (D5)

Takeaways: VR companies tend not to prioritize safety due to a lack of financial incentives and high development costs. Further, VR developers lack awareness about safety risks in VR and may not have legal or technical guidelines for safety design. Developers also highlight challenges in simulating VR safety risks for user testing of the safety controls and raise questions about balancing privacy with safety.

5.3 Improving Safety in VR

We asked developers about the similarities and differences in dealing with harassment in VR when compared to traditional forms of social media. We then asked them what they perceived to be lacking in safety controls and how they may be improved. We also presented the usability challenges from **Study-I** and asked developers how they would solve them.

Abuse Detection. Most of our developer participants agreed on the challenges involved in moderation at scale and recommended using several abuse detection methods as the first step in the moderation life cycle. D3 believed, *"there's certainly the chore that is the actual implementation, once those systems are in place, they're largely autonomous. I don't need to touch it."*, and explained how word analyzers may be used to identify verbal abuse and notify users:

"Using semantic analyzer, we have been able to identify the intent of what someone is saying. If we identify that as harmful or having foul language, we can give the user a reminder, like, hey, you should be watching your language. If it persists, we can take moderation action." (D3)

D2 added that a common list of bad words may be detected and used to notify relevant users: *"We're thinking of being able to remove some words from the usage of the users"*. For detecting other forms of abuse in a non-invasive manner, D6, a VR-based researcher, proposed the use of logged events:

"I would keep track of user events that can occur, positions of their avatars, the proximity of different avatars. If I have that record, even without video evidence, I would know if they were in proximity, if some user events occurred. If I have the username reported, I can see if they were in those proximity and had the opportunity to interact." (D6)

Effective Grouping of Users. Drawing on his experience running a VR game, D7 shared that effective community management with like-minded users grouped together prevented conflicts, reinforcing users' preferences from **Study-I**:

"One of the bedrocks of sustainable community management is about establishing a set of norms and expectations and creating an environment that funnels those correctly so that you are effectively grouping users together who share expectations. And if they're sharing expectations, you don't get people in conflict [like when] one person thought they were here for X and another thought they were there for Y, and they're now fighting over that." (D7)

Developers further elaborated on interaction filtering and social graph pruning to group users. D7 said: *"I'm in party mode. I hit a button, and it makes my social protocols in terms of who can talk to me, and this becomes broad momentarily because I trust the people running this party. Then I switch to a different virtual space, and I hit a button that changes who can DM me for a private chat, who appears on my screen"*. He added that all connections of specific users should be prevented from ever interacting with another user to effectively cut off problematic social graphs.

Solving Usability Challenges. To solve some of the usability challenges that our participants faced in **Study-I** (pointing at a user in virtual space to block them, choosing a user from a long list of usernames, typing on a keyboard in VR), developers proposed several potential solutions, and generally advocated for designing intuitive controls that felt natural to use. D3 believed that blocking tools needed more granularity, providing the capability to block different aspects of a user, such as *"their voice, avatar, ability to scale, and other atomic elements that users can have fine-tune control over"*. D7 added that users should be able to block other users for

different periods of time: *"you should be able to shut someone up for 10 minutes if they're just being annoying"*.

To effectively identify users for taking action, D4 recommended designing ways to pause the scene and recalled how Meta Horizon Worlds implemented this: *"you just hold up your arm and press a button. It immediately freezes everybody, but you still see other people in the room. If someone is harassing you, you can pause everything, report [or] block them"*. D7 added that the list of users can be accompanied by a snapshot of their avatars:

> *"If that list is difficult to deal with, why is that list not sorted by distance to you physically? Or grouped into sets of bands? You're trying to identify someone like oh it's a guy with a hat and a coat. If you think about the way you would search a physical space in that context and mark people off, effectively modeling that cognitive process as a UI tool is a way to do that." (D7)*

D8 also recommended implementing voice-based memos for actions such as reporting in order to avoid typing in VR.

Creating Awareness among Developers. Three out of nine developers who took part in **Study-II** argued that more awareness was needed among VR developers about harassment issues in VR. D9 expressed that independent developers needed to be made aware of safety issues and provided with the relevant resources for them to adopt a safety-oriented design:

> *"When I was developing, the last thing I was going to add was safety features. So bringing more awareness to the little guys, the small developers, giving them resources that allow them to integrate these things quickly . . . " (D9)*

D8, who was part of a three-member development team, argued, *"if it was a big enough issue, even though we're a small team if it was brought to our attention, probably have a sprint to focus on that, at least one of us"*.

Open-sourced Safety Libraries. Several participants shared that open-sourced libraries available through popular game engines that allowed developers to integrate standard safety controls into their apps would be valuable. D9 said: *"if you had a library you could pull from, easy implementation. Especially if it just works out of the box"*. He further added that if it were open-source, when somebody found a way to break it, the community would be able to fix it. D2 added:

> *"It should be a plug-and-play tool that could be brought to the game engines, and you just drag and drop." (D2)*

D8 pointed out the importance of having well-established requirements in app stores for targeting efforts towards safety: *"If some stores have requirements where your app needs [certain] features to be admitted, that would force all the devs to have at least something to protect its users"*. D1 and D7 stressed that seminars and workshops may be organized for developers to brainstorm on creating such tools. D5 also suggested creating standardized tutorials for VR users, informing them how to protect themselves.

Takeaways: Using word filters and semantic analyzers may aid in abuse detection. Developers recommend implementing extensive controls to limit or allow user interaction in various settings. Granular controls allow users to restrict interaction temporally and spatially address certain limitations of existing safety measures. Seminars and workshops can be conducted to inform developers about VR safety and foster innovation in safety design. Additionally, integrating open-sourced safety-focused libraries with popular game engines can streamline the development of safety controls.

6 Discussion

In this paper, we outlined our findings about VR safety features based on a multi-perspective study with 18 targets of VR-based harassment and 9 VR developers. In this section, we discuss the broader findings from our study and offer recommendations to help VR platform owners, app developers, and policymakers enhance VR user safety.

What's New With VR-based Harassment? Much like various other manifestations of online harassment, VR-based harassment exposes users to harmful content, including bullying, threats of violence, and sexual harassment [29]. While certain forms of harassment may be universally applicable across different mediums, the distinctive features of VR applications give rise to unique manifestations of harassment. For instance, incidents such as virtual sexual harassment, where the harasser positions their avatar's "crotch" on the target's face, and virtual violence, where a harasser can manipulate the target's avatar to cause disorientation, illustrate the specific challenges posed by VR, as outlined in Table 3.

VR parallels other forms of online interaction, such as gaming, so many solutions that apply to the latter (profanity filters, reporting systems, behavioral analytics, etc.) apply to the former. However, implementing the same solutions effectively in VR requires significant redesign to accommodate the three-dimensional and immersive nature of interaction that leads to more traumatizing forms of harassment (e.g., virtual sexual harassment). Further, safety controls are not equally effective across VR contexts, particularly while removing harassers from gaming and streaming settings, highlighting the uniqueness of safety design for VR. Proposed solutions have included robust reporting mechanisms [23], non-player characters as safety companions [18], and consent-based designs [61, 74] for boundary settings. We add to this by identifying ways to improve safety in VR — keeping the bad actors in check while minimizing the load on users and enabling developers to implement these solutions.

Minimizing Load On Users. With the burden for staying safe online currently falling on users [30], the fact that many participants from **Study-I** were unaware of VR safety controls calls for improving user awareness about safety controls. Apart from making the information available in-app as tutorials, nudges to users, and displaying cues in VR in the style

of "Madison Avenue" advertising [75], we also recommend that VR app/platform owners inform users through official websites, app stores, and social media campaigns. However, as our findings highlight, understanding the usage of safety controls is a time investment that VR users must be willing to make. A good design of safety controls should make this learning process seamless and consider particular contexts in which users would employ them, such as gaming or streaming settings. Standardizing the baseline safety controls across the VR ecosystem may help, as participants report that safety controls get easier to use with familiarity.

Stopping Bad Actors. Stopping bad actors requires automated or human-driven identification of bad behavior and enforcement of sufficient, non-biased punitive action. The action may range from warnings and penalties to bans that prevent harassers from returning to the platform [5]. While several ML-based techniques have been developed to detect obscene imagery [76] and abusive language [77], there is a need to direct efforts towards detecting a variety of toxic content from a 3D environment.

Since user reports play a major role in VR moderation, designing usable reporting mechanisms with multi-modal availability is critical. Again, standardizing the reporting features across VR would reduce the burden on users. Effective moderation requires VR apps/platforms to have diverse, well-trained moderators in the community. AI-based moderation techniques [78] may be considered for prompt processing and providing timely feedback to the reporter. Models of norm enforcement such as *responsive regulation* have been identified in the literature [5], where the penalties are proportional to the offense's severity and the perpetrators' intent.

Identifying cases of false reporting and providing constructive feedback to the ones reported for corrective behavior should be an integral component of moderation. Prior work has proposed the inclusion of a "limbo" space where a reported user could be taken to while the moderator provides them feedback about why they were reported [79]. Non-invasive forms of identity verification need to be implemented to prevent toxic users from returning to the platform in case of a permanent ban.

Enabling Developers. A key part of solving the safety problem is enabling VR developers. The design of safety controls requires innovation in usability as they need to be usable in three-dimensional space, in contrast to their counterparts in other online social platforms. As more and more inexperienced developers enter the burgeoning VR industry, awareness is critical to ensure a safety-oriented design of VR apps. Although the VR ecosystem consists of a diverse population of independent developers, gaming companies, and corporations, likely with conflicting priorities [5], technical and legal guidelines mandating standards for safety and data collection practices would ensure cross-platform compliance and reduce the burden on developers. VR-specific regulations for appropriate codes of conduct, tutorials, moderation systems, and the required set of safety features in VR platforms/apps would simplify the design process for developers. Open-source development of VR safety-oriented libraries would add immense value, particularly if integrated into game engines.

Considering Multiple Perspectives. Although VR users and developers had shared opinions in our study, such as using community members for effective moderation, developers expressed more concern about users' privacy compared to users while thinking about safety design for VR. Although users recommended behavioral tracking across VR apps to ensure safety, by implementing these pervasive tracking mechanisms, VR app companies may be subject to legal scrutiny and lose their users' goodwill in cases of false reporting. From **Study-II**, developers had conflicting views on when safety controls needed to be included in the development pipeline for a VR app: some wanted to design them at the start to be in tune with the affordances of the app, while others wanted to focus on the core functionality first. Although developers recommended safety-focused research, they also highlighted the challenges of simulating harassment scenarios for user testing. It is imperative to reflect on these contrasting perspectives to implement solutions that achieve a good balance of safety and privacy with ease of development.

7 Conclusion

Since VR serves as an emulation of the real world, it presents many of the challenges in society, perhaps creating a notion that harassment in VR is a societal problem. However, VR-based harassment is yet another instance where technology facilitates malicious social actors to thrive, similar to social engineering attacks such as phishing or robocalls. Thus, similar to developing solutions for phishing or robocalls, we must engineer robust solutions to address VR-based safety risks. Techniques such as AI-based abuse detection, semi-automated moderation, and identity verification raise questions about users' privacy; therefore, it is vital to identify practical, privacy-preserving solutions that serve VR platforms, developers, and users. To allow for anonymous VR interactions while creating safe spaces, VR apps may create tiered experiences, with some spaces having identity verification and others not. To prevent vulnerable populations such as children from partaking in potentially dangerous VR spaces, users' gait, height, and facial features may be used to run a model on-device to infer their age. Problematic and disruptive users may be removed from other users' views by pruning their social graphs. The onus is on major players in the VR ecosystem to come together to solve the problem of harassment in virtual environments.

Acknowledgments

We are deeply grateful to the VR users and developers who participated in our studies, as well as Dr. Vanessa Volpe, De-

partment of Psychology, North Carolina State University, who helped us refine Study-I. We extend our thanks to Elizabeth Lin, Greg Tystahl, Sathvik Prasad, and Zahra Shiraz for their feedback on the interview protocols. We also thank our anonymous reviewers and shepherd for their constructive and insightful feedback, which helped improve this paper significantly. This material is based upon work supported in parts by a Meta Research gift award. Any opinions, findings, conclusions, or recommendations expressed in this material are those of the authors and do not necessarily reflect the views of Meta Inc.

Abstract

Nowadays, unattended device rental services with cellular IoT controllers, such as e-scooters and EV chargers, are widely deployed in public areas around the world, offering convenient access to users via mobile apps. While differing from traditional smart homes in functionality and implementation, the security of these devices remains largely unexplored. In this work, we conduct a systematic study to uncover security implications in IoT device rental services. By investigating 17 physical devices and 92 IoT apps, we identify multiple design and implementation flaws across a wide range of products, which can lead to severe security consequences, such as forcing all devices offline, remotely controlling all devices, or hijacking all users' accounts of the vendors. The root cause is that rentable IoT devices adopt weak resource identifiers (IDs), and attackers can infer these IDs at scale and exploit access control flaws to manipulate these resources. For instance, rentable IoT products allow authenticated users to find and use any device from the rentable IoT apps via a device serial number, which can be easily inferred by attackers and combined with other vulnerabilities to exploit remote devices on a large scale. To identify these risks, we propose a tool, called IDScope, to automatically detect the weak IDs in apps and assess if these IDs can be abused to scale the exploitation scope of existing access control vulnerabilities. Finally, we identify 57 vulnerabilities in 28 products which can lead to various large-scale exploitation in 24 products and affect millions of users and devices by exploiting three types of weak IDs. The vendors have confirmed our findings and most issues have been mitigated with our assistance.

1 Introduction

The sharing economy [10] is a new trend in cities, providing unattended IoT device rental services to consumers.By integrating cellular Internet of Things (IoT) controllers into useful tools such as e-scooters, chargers, and washing machines, these devices can be rented to users and billed based on their usage duration in an unattended manner. Benefiting from IoT controllers, these devices can be controlled remotely, enabling operators to efficiently manage and monitor large numbers of devices over cellular networks. Users can conveniently rent these devices on a self-service basis via the apps to enhance their travel, entertainment and life experiences. With an increasing number of rentable mobility and charging devices deployed in cities, misuse of these devices can result in serious consequences, such as property damage, and jeopardizing public safety. However, the security implications of these rentable IoT devices remain under-explored [59].

Previous work has demonstrated that smart home devices face significant security challenges in multi-user scenarios [53, 55, 69]. In contrast to traditional smart home devices, where attackers can only affect a limited number of devices [54, 69, 70] belonging to individual owners, IoT device rental scenarios involve a single vendor managing a large number of devices accessible to all users, rendering them more vulnerable to large-scale exploitation. Paid users can rent devices by using the devices' QR codes or serial numbers (SNs). This enables attackers to exploit remote devices via their SNs. For instance, adversaries who can bypass the payment can remotely abuse devices by obtaining their SN. Unfortunately, this security risk is not fully understood by device vendors, as many devices employ short serial numbers to simplify the entry process for users, inadvertently allowing attackers to infer these SNs, thereby facilitating widespread remote attacks across numerous devices. As a result, vulnerabilities in these rentable devices can easily lead to large-scale attacks affecting large numbers of devices and users.

Compared to existing smart home devices, rentable IoT devices require different security analysis and methodologies to address their unique security risks due to their different functionality and implementation. Unlike Wi-Fi-connected smart homes, rentable IoT devices utilize cellular networks, greatly impeding the interception or analysis of device-to-server com-

*The first two authors contributed equally to this paper.

munication. For smart home devices, insider attackers can easily eavesdrop on the traffic [13] and send spoofing requests [56, 67, 69] in smart homes, while targeting rentable IoT devices with 4G/5G cellular networks requires deploying fake base stations and exploiting vulnerabilities in the 4G/5G protocols [32, 65]. The adaptation of cellular networks highlights the need for a dedicated study of new attack strategies on emerging rentable IoT devices. Rather than adopt trigger-action platforms [16, 19, 20] or mobile-as-a-gateway [70] to control IoT devices, rentable IoT devices are directly controlled by their backend services. Existing IoT researches mainly focus on analyzing traditional IoT platforms (such as SmartThings [19, 20] or AWS IoT [35, 67]), which typically use HTTPS or MQTT protocols. Rentable devices usually implement custom backends and protocols that require new analysis methods.

To understand the security of these devices, we conduct a systematic study on real-world IoT device rental services. There are three challenges in efficiently identifying vulnerabilities in both the IoT controller and mobile apps of rentable devices. First, some devices (e.g., chargers) do not use batteries but work with high-voltage household or industrial alternating current (AC). It is dangerous to test or debug these devices to extract their firmware. Second, it is hard to analyze the communication of these devices as they adopt cellular networks and customized protocols. Third, all of these products are closed-source and it is difficult to identify threats such as large-scale off-path attacks that exploit vulnerabilities in multiple components. To address these challenges, we propose a general workflow for studying the devices and apps of these products. First, we partially boot the necessary MCUs of the devices by using jumper wires to provide extra power supply under a safe voltage. Then, we propose a log-based approach to efficiently reverse the protocols of these devices, which capture cellular network traffic in plain text from the cellular processor (CP) log. Finally, we perform black-box API tests to identify vulnerabilities on both the devices and the apps and propose a tool IDScope to effectively assess if these vulnerabilities can large-scale exploit users and devices.

We investigate 17 physical devices and 92 apps of IoT device rental services by reversing the protocols of these devices and apps, re-implementing their protocols, and testing their APIs by impersonating these devices or apps to communicate with their servers. We identify 23 vulnerabilities in 14 devices and 34 vulnerabilities in 23 apps. Meanwhile, we identify multiple products use weak IDs for both their devices and users, which can lead to large-scale remote exploitation via ID enumeration attacks. To assess this threat, we propose a dynamic analysis tool, called IDScope, which can automatically identify the weak IDs, find the appropriate APIs to verify the enumerated IDs, and assess the affected scope (e.g., numbers of devices and users) of existing vulnerabilities. We find that attackers can infer all device serial numbers of 60.9% (56/92) products. 84% (48/57) of the vulnerabilities can lead to large-scale exploitation of 24 rentable IoT products, resulting in large-scale privacy leakage, account hijacking, free device use, or device manipulation. Our findings have been assigned with 18 CVE/CNNVD/NVDB numbers[1] and can affect several popular products (e.g., Teld, StartCharge, YuehuoCX) with more than millions of users and 100K devices.

New Insights. Our study indicates that rentable IoT devices' QR-code (containing the device serial number) can also become an attack surface. This is because (1) paid users can choose any device via the device serial number. However, many rentable IoT devices only verify if a user is paid but do not check which device he/she uses. This may allow unauthorized users to remotely activate or deactivate other users' devices using their serial numbers. (2) The device serial numbers of many products are too short and have obvious patterns (e.g., common prefixes). Therefore, attackers can easily infer the serial numbers of new devices and verify these numbers using the apps' APIs. All they need is a QR code to obtain an initial device serial number. They can then use the app APIs to enumerate more serial numbers. By further exploiting other vulnerabilities (e.g., payment bypass), attackers can accomplish large-scale remote attacks on a product via the apps without touching any real device.

Contributions. Our contributions are as follows:

- We conduct a systematic study to uncover the security implications in rentable IoT devices. Moreover, we propose a general workflow to analyze all kinds of rentable IoT devices. Our approach successfully identifies 57 vulnerabilities affecting 28 real products.
- We find that most rentable IoT devices are severely vulnerable to ID enumeration attacks, which can turn ordinary access control flaws into high-risk attacks to remotely exploit devices at scale.
- We propose a tool dubbed IDScope to automatically detect ID enumeration vulnerabilities on rentable IoT products and show that 84% of the existing vulnerabilities can be exploited to attack all devices or users of several vendors.
- We propose a mitigation solution to prevent ID enumeration attacks and help vendors mitigate these vulnerabilities.

Ethics Consideration. We investigate the security of real-world products crucial to users' daily lives. To minimize impact, testing is limited to our private devices[2] or app accounts, ensuring that both attacker and victim scenarios remain within our private environments, avoiding disruption to vendors or users. To identify large-scale exploitation, we need to confirm if these products' IDs are enumerable. IDScope eliminates the need for brute-forcing all IDs, instead efficiently inferring the valid ID range by sending only a few requests at a very low rate, similar to web crawlers. The IDs we gather do not include private information; for instance, device IDs are visible on devices, and user IDs are simply integers or strings.

[1] We track the vulnerabilities at https://vehicle-security.github.io.

[2] Some devices are also sold to individuals (see § 2.1).

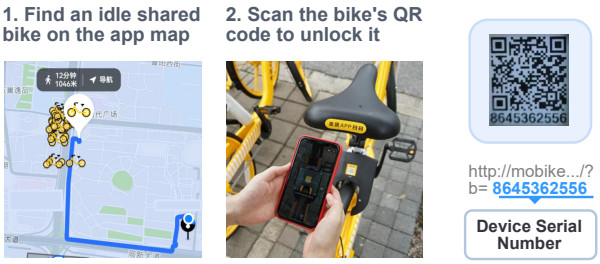

Figure 1: Users can access any device via the app.

During the research, we ensure that all of our approaches comply with the vendor's bug bounty plan [1], do not cause DoS attacks, and do not compromise user privacy.

2 Background

2.1 IoT Device Rental Service

The rise of cellular IoT technologies has popularized IoT device rental services in urban areas, allowing devices to function and be placed anywhere without relying on Wi-Fi or wired connections. As shown in Appendix A, various rental devices operate unmanned in public areas of cities and are managed unattended by cellular IoT controllers.

Cellular IoT Controllers for Rentable Device. The rentable devices are equipped with a cellular IoT controller to receive control commands from the server for manipulating the devices. The cellular IoT controller usually has the following components:

- **4G/5G MCU.** This MCU is dedicated to communicating with the cellular networks. It can also be used to process simple tasks such as data collection or send commands via Usart to control (e.g., turn on/off) physical devices (e.g., laundry machines). Thus, these devices' IoT controllers only contain the cellular MCU.
- **Main MCU (optional).** Some devices need to process complex tasks, such as managing the charging process, and adopt a dedicated MCU for real-time controlling the peripherals (e.g., DAC). We regard this task controlling MCU as the main MCU, as it usually contains the entire control logic of the devices. In devices with a main MCU, the cellular MCU is used in pass-through mode, only forwarding network packets to the server via the cellular network.

Devices Rental. All rentable devices are available to every user. Taking the popular shared bicycle as an example (see Figure 1), users can find idle bicycles on the map of the companion app and they can choose any of these bicycles (step 1). To rent a bicycle, they first need to make an order on the app by scanning the bicycle's QR code (step 2). The app then resolves the QR code's content (e.g., a URL or an ID) and sends requests to the server to remotely activate this device. After users complete the trip, they can lock the bicycle and immobilize the wheels via the apps. The cost is automatically charged on the app.

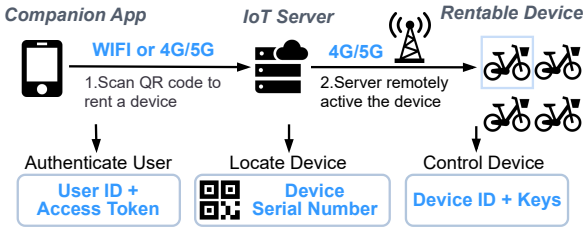

Figure 2: The workflow of device rental service.

Device Management. Mobility devices, such as e-scooters and e-bikes, are predominantly managed by large vendors who operate thousands of these units across various regions. These vendors are responsible for periodic inspections, repairs, and the strategic relocation of devices to meet the demand influenced by population density and usage patterns. In contrast, stationary devices like EV chargers and laundry machines necessitate fixed installations and a continuous power supply. These devices are purchased by individual operators, who own a few devices and strategically position them at their stores, parking facilities, or other suitable locations. This setup allows operators to rent out the devices to customers, neighbors, or others in need, generating profit while leveraging the vendor's backend systems for control and billing.

2.2 ID Enumeration Attacks

ID enumeration attacks [12] involves attackers discovering valid resource identifiers (IDs) on web or app APIs to gain unauthorized access to restricted resources by manipulating or guessing these IDs in URLs or request parameters. We find that rentable IoT devices are particularly vulnerable to ID enumeration attacks as large numbers of users and devices are managed by the same backend. As depicted in Figure 2, when the user scans a QR code to initiate a device rental request, the device's serial number is transmitted to the server. The server then authenticates the user's credentials. Subsequently, it retrieves the corresponding device information based on the provided *device serial number*. Once the target device is identified, the server transmits control commands to it via the cellular network connection. This process involves authenticating multiple resource identifiers (IDs):

- **User ID** is used by the apps to identify various users. Many rentable products automatically assign an increasing number as the user ID for the new user during registration.
- **Device Serial Number** is used by the apps to distinguish devices, which is usually very short (6-9 digits) as users sometimes need to manually enter it into the app when the QR code is abraded by malicious users [3].
- **Device ID** is stored in the firmware and used for device-server authentication. Some devices may reuse the device serial number as the device ID for simplicity.

[3]The shared bicycle market in China used to be highly competitive, resulting in frequent cases of bicycle vandalism.

We find that in multiple rentable products, the enumeration of three types of IDs can lead to severe consequences. First, user ID enumeration can lead to large-scale data breaches or account hijacking, when attackers can compromise access tokens. Second, harvesting device serial numbers can facilitate the large-scale exploitation of remote devices. For instance, if attackers can circumvent payment systems or exploit privilege escalation vulnerabilities [45], they can manipulate all devices identified by the enumerated serial numbers. Furthermore, we have observed that numerous devices share common authentication keys or lack proper device authentication, allowing server connections solely based on device IDs. These vulnerabilities make these devices susceptible to large-scale impersonation attacks using enumerated device IDs. We provide real-world examples of such attacks and illustrate how attackers can remotely exploit users or devices from various vendors in sections § 6.3 and § 6.4.

3 Overview

3.1 Threat Model

We consider rentable IoT devices and their smartphone apps as potential attack targets and focus on remote exploits that do not require attackers to have physical access to the victim devices.The attacker's goal is to use devices for free or do damage to the device (e.g., DoS) or other users (e.g., information stealing, account hijacking). To achieve this goal, they may try to exploit the communication between the devices and the server, or communication between the app and the server to affect the devices or other users. Meanwhile, attackers may try to reverse-engineer and dynamic/static analyze both the device firmware and the apps. After attackers grasp the devices' and apps' credentials and protocols, they may off-path exploit the server APIs by impersonating the devices or apps to send spoofed requests to the server.

Our only assumption is that attackers can analyze both devices and apps. This is reasonable because rentable IoT devices are usually deployed unattended in public spaces, making it easy for attackers to illegally acquire one. Note that they only need one device[4] to explore the firmware and extract the secrets. IoT apps are also publicly available on app markets or can be accessed in WeChat. Attackers can readily manipulate these apps from malicious mobile devices, such as rooted Android phones, using their own accounts.

3.2 Methodology

As shown in Figure 3, we developed a semi-automated workflow to analyze rentable IoT devices. We first combine reverse engineering and black-box API testing to find vulnerabilities in apps or devices. Then, we use IDScope to assess if these

[4]In our study, we use two devices, one acting as the attacker and the other as the victim, to avoid ethical issues.

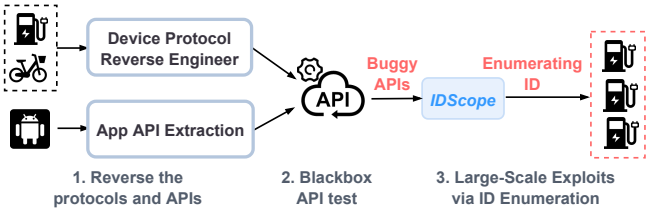

Figure 3: The workflow of identifying large-scale exploitation vulnerabilities in devices and apps of the rentable products.

vulnerabilities can be scaled to remotely exploit more devices at a large scale. The detailed steps are as follows:

S1: Reverse Engineering Protocols and APIs. This step aims to reverse-engineer the APIs and extract the credentials (e.g., crypto keys and access tokens) for further testing these APIs. The companion apps usually use HTTPS and can be easily analyzed via MitM. However, most rentable IoT devices adopt custom binary protocols to communicate with the IoT server. Besides capturing their network traces, we also need to further analyze their firmware to extract the cryptographic algorithms and keys (illustrated in § 4.1).

S2: Black-Box API Testing. In this step, we focus on identifying vulnerabilities that can affect the current devices or app users. We use a semi-automated approach to identify insecure server APIs when they communicate with apps or devices. For the physical devices, we manually check their server connection protocols to verify if the devices are correctly authenticated by the servers. For instance, some devices do not encrypt the messages or do not use unique keys to authenticate different devices. For the companion Apps, we automatically replay the existing requests and substitute the identifier (e.g., `uid`, `Device Serial Number`) fields to check if the server can correctly authenticate and authorize [72] these APIs. By checking the return code, we can identify the vulnerable APIs and then manually check their impacts. The analysis results are illustrated in § 4.2 and § 5.

S3: Large-Scale Exploits via ID Enumeration. Many simple vulnerabilities can be scaled to attack many other devices remotely when attackers can enumerate devices' or Users' IDs. This is because some devices have weak authentications (discussed in § 4) such as sharing the same cryptographic keys, which allows the attackers to large-scale impersonate any device if they know other devices' IDs. The same situation occurs in the apps, as some APIs do not strictly validate the users, and attackers can exploit these vulnerable APIs to misuse devices. We propose IDScope to assess large-scale exploitation of the devices or the apps in § 6.

3.3 Common Weakness in Rentable Products

We systematically study the common vulnerabilities in the design and implementation of IoT device rental services by investigating 17 devices and 92 apps. More than 50 vulnerabilities are identified in the devices or apps, leading to large-scale

Table 1: Common weakness in rental services' IoT devices or apps.

#Products	#	Common Weakness	Security Impacts	#Vul Devices
Device (17, see Table 2)	D1	The log port of cellular chips is unprotected	Intra/Inter-Chip network traffic capture	17 (100%)
	D2	No protection for MCU debug interfaces	Debug and extract the firmware	9 (52.9%)
	D3	Unstripped firmware with log strings	Facilitate protocol analysis	14 (82.4%)
	D4	Insecure authentication implementation	Device impersonate (see Table 3)	8 (47.1%)
	D5	Multiple devices share the same secrets	Device impersonate (see Table 3)	4 (23.5%)
	D6	Device ID is enumerable	Large-Scale device impersonate (see Table 6) *	11 (64.7%)
App (92, see Table 8)	A1	Vulnerable payment implementation	Free device usage (see Table 7)	5 (5.4%)
	A2	Improper permission checks of app APIs	Privacy leakage, Free device usage (see Table 4)	15 (16.3%)
	A3	User ID is enumerable	Large-Scale exploits other users (see Table 7) *	14 (15.2%)
	A4	Device Serial Number (SN) is enumerable	Large-Scale exploits other devices (see Table 7) *	56 (60.9%)

* Without other vulnerabilities, ID enumeration is only a security risk. For large-scale attacks, D6 relies on D4/D5 and A3/A4 relies on A1/A2.

privacy leakage, device manipulation, and free device usages, which are detailed in § 4, § 5, and § 6. We summarize the underlying weaknesses that lead to these vulnerabilities in Table 1.

Weakness in Device Hardware and Firmware (D1-D3). Rentable IoT devices lack detection for hardware tampering via software (**D1**), fail to secure the chips' debug modes (**D2**), and retain log printing code in their release version (**D3**). Although these vulnerabilities cannot lead to direct exploitation, attackers can employ them to dynamically analyze these devices to grasp their communication with the servers for further identifying remote exploitation vulnerabilities.

Weakness in Device-Server Interactions (D4-D6). We identify several devices that use insecure authentication (**D4**) or encryption (**D5**). Devices with these vulnerabilities are only distinguished and authenticated by the server using their unique device identifiers [64, 69]. If the attackers can gain other devices' identifiers, they can impersonate all these devices. We identify several devices' identifiers that can be enumerated by attackers (**D6**), allowing attackers to remotely exploit as many devices as they can enumerate.

Weakness in App-Server Interactions (A1-A4). We find that several companion apps have logic bugs in their payments allowing users to rent the devices without paying (**A1**). Some devices have APIs with improper permission checks, allowing unauthorized access (**A2**). These vulnerabilities can be scaled to all devices when attackers can enumerate (**A3**) all devices' serial numbers (i.e., QR codes). Some products' user IDs can also be enumerated and expand the scope of horizontal privilege escalation to exploit all users (**A4**).

4 Analyzing Vulnerabilities of Devices

4.1 Workflow for Studying Rentable Devices

To investigate device security, it is essential to have physical access to real rentable devices and disassemble their IoT controllers to perform tasks such as connecting jumper wires [24] to chips for network and firmware analysis. However, most rentable devices are owned by vendors or operators (e.g., all Uber e-scooters belong to Uber), making it challenging to acquire devices for research purposes. Fortunately, some devices (e.g., Teld EV-Charger) are available for individual purchase, allowing users to participate in the vendor's IoT rental service and rent out devices for profit. Ideally, our approach requires only two devices for each product, one acting as the attacker and the other as the victim.We buy 16 rentable IoT devices (shown in Table 2) and cooperate with a vendor to gain an extra device (i.e., *Meituan* bicycle).

We employ protocol reverse-engineering and black-box API tests to identify vulnerabilities in rentable IoT devices. As shown in Figure 4, the steps of our workflow are as follow:

S1: Capture Network Traces and Extract Firmware. Many rentable devices (e.g., EV chargers) are unsafe for hardware tampering because they run on high-voltage household (e.g., 220V) or industrial alternating current (AC) power, not batteries. We disassemble these devices and use bench power supplies to partially boot [58] and run the core chips, such as cellular chips and controller chips (e.g., STM32F4, see Table 2). After booting up the system, we can perform further analysis (e.g., dump logs, or debug) by connecting jumper wires to these chips' pin-outs.

We capture the network traces of these devices to reverse engineer [17, 21, 66] their communication protocols.Due to the high cost of hijacking cellular network communications through fake 4G base stations, we chose to capture the internal network traces of cellular chips, which are not encrypted by the SIM card's cryptographic keys. We find that all cellular chips allow developers to enable the debug log via AT commands [3], which enables us to extract the cellular chips' internal payloads from the logs. By exploiting this vulnerability (**D1** in § 3.3), we can capture the network traces of all target devices (see Table 2) from the pinouts of the cellular chips (see Figure 8). However, *Meituan* bicycle is quickly disconnected by their server and we fail to gain enough logs.

For several devices (e.g., Teld, Starcharge), simply capturing their network traces is not enough because the traces cover only a few commands or the messages are encrypted. We need to debug further and analyze the firmware to extract extra commands and retrieve the hard-coded encryption keys.

Table 2: The physical devices studied in this work and their hardware details. (∅: no such module/feature, -: unknown)

As shown in Table 2, 8 devices usually have no firmware protection (**D2** in § 3.3) and we can easily extract or debug their firmware via the JTAG port. Note that many firmware appear to be the debug versions and the plain text log prints are not removed (**D3** in § 3.3). By examining these log strings, we can easily understand the message dispatching approaches in the binary code and get more commands (`CMD` in Table 2). Only 4 devices encrypt their messages, and we successfully crack the encryption of 3 devices. The fail case is *JieDian*, as we are unable to analyze their firmware. We successfully debug 11 devices to facilitate protocol reverse engineering.

S2: Re-implement Protocols and Perform API Tests. In real-world scenarios, impersonating a server and sending spoofed 4G messages to devices over the air is exceedingly difficult, as it necessitates exploiting zero-day vulnerabilities in 4G networks [15, 33, 47]. Consequently, our focus shifts to exploring how adversaries can impersonate valid clients and send malicious messages to servers via alternative network connections.

We develop phantom clients [69] that replicate original devices by using the same protocols and reusing their credentials to reconnect with servers. To achieve this goal, we analyze network traces and firmware (detailed in Appendix B) to dissect protocol message sequences, structures, and encryption, and then reimplement these protocols in Python. To ensure the correctness of our phantom clients, we compare their messages with those of real clients and verify the server responses at each protocol step, confirming their functional equivalence.

We successfully develop phantom clients for 15 devices, while failing for *Meituan* and *JieDian* due to insufficient network traces. We then use black-box API testing to determine whether attackers can manipulate device states through spoofed requests. Similar to AuthScope [72], we begin by identifying and altering critical message fields, such as IDs and commands, to probe server vulnerabilities through unauthorized requests. We then examine server responses and check the status of devices and apps to assess whether these crafted requests can successfully manipulate the states of other devices, which indicates potential remote exploits.

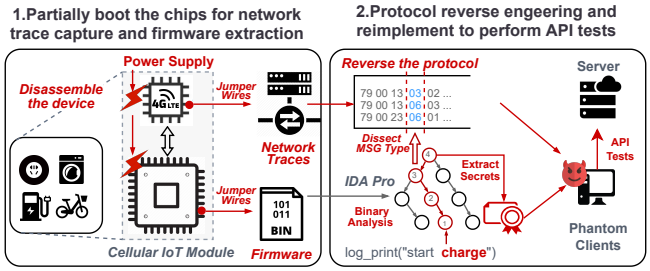

Figure 4: The workflow for studying the rentable IoT device.

4.2 Security Implications in Devices

By testing 15 devices with phantom clients, we identify that 14 devices are vulnerable to device impersonation attacks.

Hazards of Device Impersonation Attacks. The phantom clients can reconnect to the server using the devices' credentials, which can lead to two outcomes: sending spoofed messages to the server to change the devices' states, or replacing the original devices' server connections and preventing them from receiving server messages. With these tactics, we find that 4 devices can be exploited for free use.

(1) Device State Spoofing. Rentable devices typically upload their health states, including cellular signal strength and operational condition (good or faulty), to the server. However, attackers can easily manipulate these states using phantom clients. For example, they can make offline devices appear online, misleading users into paying for unavailable services. Conversely, they can present functional devices as faulty, prompting unnecessary maintenance checks and deterring rentals. We identified 14 devices vulnerable to such state spoofing attacks (shown in Table 3). While some devices attempt to restore their correct states through periodic updates, attackers can override these data more frequently, making the devices continuously display false states. The only exception is *YFLe*, which adds nonce and signature to their messages, and we fail to craft valid messages to change their states.

(2) DoS by Remotely Forcing Devices Offline. For several devices, when we reconnect to the server using the victim device's identifier and credentials, the original devices are forced offline. The server releases the existing connection upon accepting a new connection from the same device. This happens on 5 out of the 15 devices, while the remaining 10 devices maintain both the original connections and the new connections established by our phantom clients. Although the 5 offline devices continue attempting to reconnect to the server, conversely causing the phantom client to disconnect, attackers can persistently attempt to knock the real devices offline, leading to device DoS attacks.

(3) Free Use of Device. Rentable devices are deactivated by server commands; however, attackers can intercept these commands, allowing devices to continue operating beyond the rental period. We identify 3 devices that are vulnerable to this attack. For the *Teld* charger and *QiXin* bicycle, attackers can finalize the rental in the app and then use phantom clients to force the real devices offline. This redirects the device stop commands to the phantom clients instead of the actual devices, enabling free use of the devices. For the *Meituan* bicycle, we can make a local bicycle offline by removing its cellular antenna, which causes the server to process the order as completed normally, but leaves the bicycle unlocked, allowing continued unauthorized use.

For the *AnKong* washing machine, we discovered that clients can publish MQTT messages to each other without restrictions due to the lack of a server MQTT ACL policy [60]. This vulnerability allows attackers to send fake device activation commands to other devices' MQTT topics based on their device IDs. These spoofed messages are then transmitted to the actual devices by the MQTT server, leading to their unauthorized activation. By acquiring device IDs from the devices' QR codes, attackers can freely utilize any device through this attack vector.

Case Study for Attacking Various Devices. All rentable devices share a common architecture managed by their IoT controllers and communicate remotely with the server via a cellular network. However, the analysis and attack details vary across different devices.

(1) Mobility Devices and Stationary Devices. Based on the trust model, existing rentable devices fall into two categories: mobility devices such as e-scooters and e-bikes, which users can take with them, and stationary devices like EV chargers, which are immovable and can only be used at specific locations. Both types of devices offer basic controls for activation and deactivation, and they provide updates on device states, including 4G signal strength (RSSI) and health status. Mobility devices additionally need periodic GPS updates. When devices move outside of approved areas, the server shuts down power, preventing operation beyond designated zones. Attackers may exploit this feature to halt devices using GPS spoofing attacks. Stationary devices are immune to such attacks as they are not restricted by GPS location.

(2) Reverse-Engineering Different Protocols. Except for the 3 devices using MQTT or HTTPS protocols, all others utilize custom binary protocols. Among these devices, EV chargers exhibit a diverse array of commands, including querying the grid status, individual charging channel information (voltage, current, charging status, and energy consumption), controlling the start and stop of charging for specific channels, and exchanging keep-alive messages for both devices and active charging sessions. Each command has a corresponding request and response packet, resulting in a substantial number of distinct command pairs that should be sent in the correct sequence. This extensive command set significantly increases the reverse-engineering effort required for EV charger protocols, making them more difficult to analyze than other devices with simpler protocols, such as e-bicycles and rentable tools, which are typically controlled by simple device start or stop commands. Due to the large number of variable fields in EV charger protocols, extracting and analyzing their firmware from the STM32 MCU is essential to fully understand their protocols.

Note that all of the vulnerabilities discussed in this section can be exploited remotely without touching the physical devices if knowing the victim device's login credentials. Given that many devices share the same hard-coded authentication keys or have no authentication, we further explore the possibility of exploiting more devices on a large scale via ID enumeration attacks in § 6.3.

5 Analyzing Vulnerabilities of Apps

In this section, we perform a semi-automated API black-box test to detect vulnerable app APIs that can exploit other devices or users.

App Collection. We identify IoT companion apps for rentable devices by searching for product names as keywords across various App markets. In China, most devices prefer WeChat mini-programs over native Android or iOS apps, as the convenience of accessing these mini-programs directly within the WeChat platform, which eliminates the need for users to

Table 4: Vulnerabilities in IoT companion apps.

Device Type	Attacking Users		Abusing Devices	
	Privacy Leakage	Account Hijack	Payment Bypass	Manipulate Device
EV Charger	Sunmue, Potevio	Teld		
Charger	LuLuChong, NBLinks ZhouDian			LuLuChong, NBLinks
Mobility	YueHuoCX, YueShiJi GXRongYi	YueHuoCX, YueShiJi GXRongYi,DFPV	QiXin, GO-ON	YueHuoCX, YueShiJi GXRongYi, Hozonauto DFPV, Lime, Helbiz
Tools		AnSheng	HQJL	
Entertainment	BDT		QSMX, Dadaball	

install separate mobile apps. Note that not all of these apps (or mini-programs) can be selected for research since we cannot find valid QR codes for them, which are necessary to rent the devices. As a result, we only find Android apps for 6 Chinese devices. For the devices without mobile apps, we focus on their WeChat mini-programs. We also identify 21 apps that service in countries outside of China, such as Lime e-scooters in the US and Europe. However, we only successfully register for 11 of them. As listed in Appendix A, finally, we get apps for a total of 81 Chinese rentable products (including 75 WeChat mini-programs and 6 Android apps), and 11 iOS apps for Europe/US products.

Analysis Methodology. We focus on identifying payment and API access control vulnerabilities that can result in unauthorized device control or access to other users' resources. We propose a semi-automated approach to test the native Android/iOS apps and WeChat mini-program apps. First, we prepare accounts and login to these apps, which can only be done manually, as rentable IoT apps typically require real-name registration and a deposit before use. While processing the deposit, we manually check if the payment arguments can be manipulated. Then we manually trigger the core logic of the apps by scanning their QR codes and selecting the appropriate UIs to rent and return a physical rentable device. Simultaneously, all requests can be captured by the Burpsuite proxy [2]. After these manual steps, the remaining tasks are black-box API testing, where requests are automatically mutated and replayed in BurpSuite. Specifically, we utilize multiple accounts, with some acting as attackers to gain unauthorized access to the resources of other victim accounts. If the forged requests are accepted by the server (e.g., return HTTP 200), we continue to manually check for access control violations in these APIs. We further validate if these vulnerable APIs can be further exploited by ID enumeration attacks to cause large-scale damage to other devices or users, which is discussed in § 6.4. We discover 34 vulnerabilities in 23 IoT apps, which can be divided into two types based on the victim:

Attacking App Users. As shown in Table 4 (attacking user column), we identify multiple authentications or access control vulnerabilities in mobile apps that allow attackers to steal other users' personal information or hijack others' accounts.

(1) Privacy Leakage. We identified 9 vulnerable IoT apps that leak the users' most sensitive data, such as users' real names, identity card numbers, phone numbers, etc. 8 of the 9 products (excluding *Sunmue*) contain vulnerable APIs that mistakenly return all user fields stored in the same database column, failing to exclude sensitive data from the response, even though not all of these fields are required to be displayed in the UI. Note that *HuoYueCX* E-Bike has added $*$ to mask some sensitive data but still leaks users' home addresses. *Sunmue* provides a super account whose `uid` is 0 and can access all users' orders. By retrieving the order information, we can get other users' phone numbers and vehicle license plate numbers.

(2) Account Hijacking. We identify 6 apps that contain horizontal privilege escalation vulnerabilities, which permit attackers to hijack other user accounts to access devices. For 3 of them, attackers can directly modify the device activation request's *uid* making the charging order to other users' accounts Specifically, *YueHuoCx* possesses a vulnerable API that inadvertently exposes other users' access tokens. For 2 apps, i.e., the *Potevio* EV charger and *DFPV* rentable EV, attackers can steal other users' accounts if they acquire the victim's phone numbers. Similar to previously documented insecurities in face verification system [68], the *Potevio* EV charger app exposes a vulnerable login API that is only locally authenticated with a user's fingerprint or face identification. Once the local biometric authentication is bypassed, attackers can substitute the authenticated phone number with that of the victim, effectively seizing control of the account. The *DFPV* rentable EV app's login API mistakenly returns the SMS one-time password (OTP) [41] to the app and attackers, allowing attackers to gain unauthorized access to any accounts and control them by stealing the SMS verification code. Additionally, *Ankong* app exposes vulnerable device binding APIs, which attackers exploit to elevate their privileges to device administrators using device IDs, thus gaining unfettered access to the devices.

Abusing Devices via Apps. As shown in Table 4 (abusing device column), we identify multiple vulnerabilities that allow attackers to exploit devices via payment bypass or device manipulation APIs.

(1) Payment Bypass for Free Device Usage. We identify 4 apps on WeChat that can manipulate the payment parameters to alter the transaction amounts. For instance, the *QSMX* app, which offers various vehicles, such as the E-Car, E-Boat, and E-Bicycle for sightseeing, enables all orders directly via its WeChat mini-programs. When a user chooses a product, the app communicates the type and associated cost of the product to the server, which then initiates a payment transaction based on the cost data received from the app. By employing Man-in-the-Middle (MitM) attacks, we demonstrate the feasibility of altering payment requests, such as changing ¥10 to ¥0.01, for nearly free renting of these products. This vulnerability also allows attackers to alter the payment of deposits, which can significantly reduce their attack costs. Furthermore, the GO-ON e-scooter iOS app in South America has vulnerabilities in its membership plan API that expose test accounts, allowing free use of any e-scooter.

(2) Manipulating Remote Devices via Apps. We identify 9 apps that can be abused to control remote devices via horizontal privilege escalation. For the 3 e-bikes (includes *HuoYueCX*, *YueShiJi*, and *GXRongYi*) and 2 e-bike chargers (includes *LuLuChong* and *NBLinks*) apps, we can only disable active devices, such as stopping the charging process or immobilizing the bicycles. These apps lack APIs for activating devices, which are instead automatically activated post-payment. Remotely stopping a moving e-bike can cause it to gradually slow down and halt, potentially injuring the user. Note that the remote stop device poses a significantly greater risk to rentable bicycles equipped with locks, as it suddenly locks and immobilizes the bicycles. We can fully control others' devices for the two rentable EV apps, i.e., *Hozonauto* and *DFPV*. Their vehicle control APIs only validate whether the user is valid and whether the vehicle identification number (VIN) is valid, without confirming the user's access to the current vehicle. Attackers can replace the VIN in the requests to activate or deactivate other vehicles illegally.

We identified three vulnerable e-scooter apps operated in Europe/US. The Lime app restricts users to renting or reserving a maximum of five e-scooters via its group ride feature. However, we discovered a vulnerability in the device renting API that allows attackers to bypass this restriction and use more than five scooters. We identified 2 vulnerable trip management APIs in the Helbiz app that enable device manipulation. One allows attackers to retain control over returned devices, and the other permits attackers to alter the state of an unlocked device to locked, while the physical device remains unlocked and usable.

6 Scaling Attack Scope via IDScope

Large numbers of rentable devices in the same type and configuration are deployed and maintained by the same owner, and these devices automatically connect to the vendor's private cloud, which makes them tend to adopt shared keys or weak authentication implementations. As a result, attackers can impersonate these devices and send spoofed requests to the server by manipulating the device ID in vulnerable APIs, leading to large-scale exploitation of users or devices. We propose IDScope to automatically identify and efficiently infer the affected scopes of such large-scale exploitation in the devices and apps of IoT rentable products.

6.1 IDScope Design

Although previous approaches, such as AuthScope [72], can also detect vertical privilege escalation in apps by enumerating resource IDs.Rather than identifying these vulnerabilities, we need to efficiently collect all valid IDs to prove that it is practical for attackers to launch large-scale remote attacks by inferring their device serial number (SN) without getting the

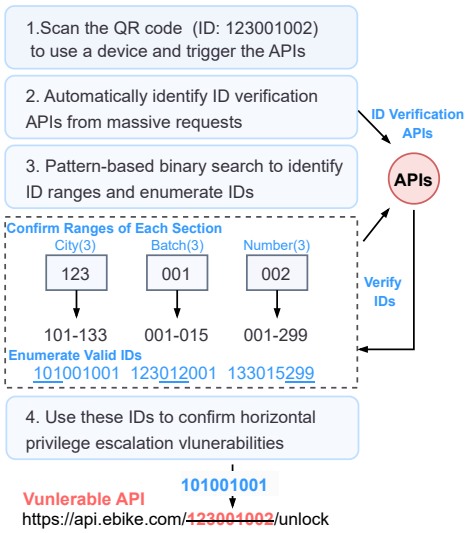

Figure 5: The design of IDScope.

QR code of these devices. However, AuthScope only supports brute-force ID enumeration and is inefficient at inferring IDs.

To fill this gap, we propose an ID enumeration tool called IDScope to quickly infer valid resource IDs (e.g., user ID, device serial number) and assess the affecting scopes of existing authentication, access control, and payment vulnerabilities discussed in § 4.1 and § 5. Figure 5 shows the design of IDScope. The basic idea is to find the ID verification APIs that can validate whether a resource ID is associated with real resources, and validate the guessed ID based on those APIs. It then replaces the IDs in existing requests to visit the vulnerable APIs and check whether the requests with spoofed IDs are accepted by the server. To efficiently guess IDs, IDScope has two key designs:

Automatically Verify Resource IDs. To bootstrap the analysis, we first need to manually scan a QR code to activate and deactivate a device in the rentable IoT apps to trigger device rental requests. By examining these requests, IDScope can automatically identify ID strings and match these strings in various API URLs and parameters. When the ID strings appear in both the payload and response of certain APIs, it means that these APIs may serve as resource verification IDs. We further confirm these APIs by checking keywords (e.g., resource not existing) in their response to exclude the false positive cases. After finding out the ID verification APIs, IDScope can automatically guess new IDs by mutating IDs based on the seed ID (in the QR code) and verifying these IDs using the verification APIs.

Efficiently Enumerating IDs. Since rentable IoT products typically have integer-based resource IDs, employing binary search to guess their ranges is much more efficient than brute-force number enumeration. We observe that device serial numbers often exhibit identifiable patterns, with specific sections representing distinct information. For instance, certain initial digits indicate the device model, while the concluding

Table 5: IDScope's success rate in enumerating different IDs.

#App	Service Area	Device Serial Number		User ID	
		#Enumerable	#Pattern	#Enumerable	#Pattern
81	China	48 (59.2%)	32 (39.5%)	14 (17.3%)	7 (8.6%)
11	Europe/US	8 (72.7%)	6 (54.5%)	- *	1 (9%)

* Fail to enumerate IDs due to not finding ID verification APIs.

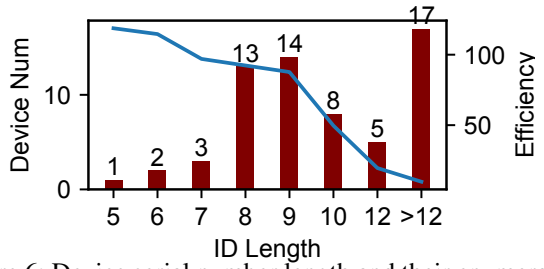

Figure 6: Device serial number length and their enumeration efficiency (how many IDs can be guessed by each search).

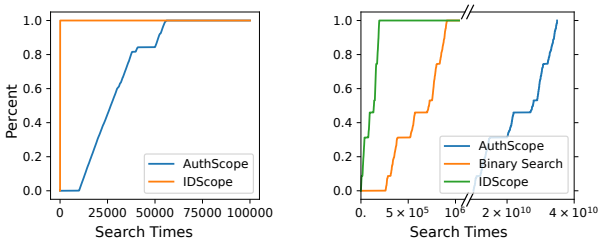
digits denote the serial number. IDScope first tries to identify such patterns and confirm the ranges of each section. Then, it applies binary search on each section. This approach can significantly reduce the search space on pattern strings.



Finally, IDScope verifies whether the existing vulnerable APIs can access the resources with the enumerated IDs. For instance, by replacing the user IDs, IDScope can check if the APIs can access the profiles of other users. APIs with horizontal privilege escalation flaws [45] can potentially be exploited to target all users or devices if attackers can enumerate all IDs. In such cases, rate-limiting measures are ineffective in blocking the attackers, as they can easily switch between different user IDs.

IDScope Implementation. We prototype IDScope as a BurpSuite [2] plugin in about 1200 lines of Python code. Note that IDScope can also work as a standalone Python program to off-path send requests to the servers by reusing the access tokens. IDScope sends multiple requests to quickly infer the valid ranges of ID values. These requests are sent in a single PC at a very slow frequency and do not lead to a DoS attack. We empirically specify several ID patterns and first check whether the ID follows these patterns. For the IDs that do not match any pattern, we cannot use the pattern-based binary search and fall back to the normal binary search.

6.2 The Effectiveness of IDScope

We evaluate the effectiveness and efficiency of IDScope using 75 rentable IoT apps collected in § 5.

Experiment Setup. We run IDScope on real products and ID datasets granted by the vendors. We first check how many rentable IoT apps are successfully processed by IDScope to correctly identify the ID verification APIs and fully enumerate the valid ID ranges of real devices or users. Rather than dump all their device IDs, we get a precise range of these devices as the IDs of these devices are usually continuously incremented.

(a) IDScope vs Brute Force on LuLuChong Dataset (5 digits)

(b) IDScope vs Binary Search on QSMX Dataset (11 digits)

Figure 7: The CDF of enumerated IDs and search times.

IDScope can further precisely verify if each number in this range is a real device. We only do this under the grant of the vendors. Furthermore, we obtain several device ID datasets from the vendors to evaluate the performance of IDScope.

Enumeration Results. As presented in Table 5, IDScope succeeds in enumerating the device serial number (SN) of 56 products, and the rest 36 products' SN are too long and lack discernible patterns, making enumeration impossible. However, some of these apps leak their SN in the map APIs, enabling attackers to easily steal all the device SNs (§ 6.3). Specifically, IDScope successfully identifies the ID patterns for the device serial numbers of 28 products. IDScope successfully enumerates user IDs for 14 products only, as most lack accessible user ID verification APIs, requiring both an access token and the user ID to construct valid requests.

Enumeration Performance. Figure 6 shows the enumeration efficiency of IDScope on products with different ID lengths. Figure 7 shows a comparison of different enumeration approaches. IDScope's pattern-based binary search approach is 4 magnitudes faster than AuthScope's brute-force approach for products with sequential IDs. For IDs longer than 6 (e.g., *QSMX* adopts 11 digits with patterns), AuthScope cannot infer their ranges within a reasonable timeframe. While naive binary search could be employed, it would require sending tens of thousands of requests, taking several hours to complete. IDScope can achieve a performance improvement of 3 to 4 orders of magnitude over naive binary search and is 10 orders of magnitude faster than AuthScope. Consequently, IDScope can identify all devices of a vendor with much fewer requests.

6.3 Scale Device Side Exploits via IDScope

In § 4.2, we identify 14 devices that are vulnerable to device impersonation attacks. Since some of them lack secure authentication and attackers can impersonate them using their device IDs, we further leverage IDScope to validate whether these vulnerabilities can be exploited at scale to attack all devices via ID enumeration attacks.

Large-Scale Obtaining Device ID. We identify two attacks that can lead to large-scale device ID leakage. As shown in

Table 6: Device vulnerabilities that can be exploited at scale.

[1] Besides enumerate IDs, attackers can exploit the super accounts (vertical privilege escalation).
[2] *QiXin*'s device SN cannot be enumerated and is leaked by map API.

Table 2, we can get the ID of every device for 13 products.

(1) Enumerating Weak ID with IDScope (A1). Some devices reuse the device serial numbers (in QR codes) as device IDs in the firmware. We obtain these devices' serial numbers by applying IDScope on their companion apps. These enumerated IDs can be abused to exploit vulnerable APIs.

(2) Exploiting the App API to Leak Device ID (A2). Rentable IoT products need to display the user's nearby devices in their apps. To implement this feature, the server provides device profile retrieval APIs to the app, which fetches nearby devices and displays them on the map using these APIs. We identify multiple vulnerable app APIs that mistakenly return all of a device's fields reading from the databases, including sensitive data like the device ID, while only a few of these fields are actually displayed in the app. By modifying the GPS location, we can abuse these APIs to leak the IDs of all devices.

Remotely Exploiting Devices at Scale. As shown in Table 6, for 13 of the 14 vulnerable devices, attackers can replace the device ID to connect to their server and perform various attacks. These devices use weak authentication, and attackers can easily bypass authentication and authorization and send spoofed requests to affect other devices. Specifically, 3 of them hard-coded common keys in all their devices, and 10 devices do not authenticate the devices. Theoretically, attackers can get all device IDs and remotely exploit any device. For *MeiTuan* bicycle, we fail to reverse their protocol and do not identify any APIs with access control vulnerabilities. *WeiPeng* uses unique keys for each device. As a result, we can only exploit their vulnerabilities on local devices.

6.4 Scale App Side Exploits via IDScope

We adopt IDScope to confirm if the app vulnerabilities discussed in § 5 can lead to the large-scale exploitation of users or devices. The results are shown in Table 7.

User ID enumeration. IDScope succeeds in enumerating all the user IDs of 9 products, which with ID length of 5 to 11. In particular, IDScope can identify the ID pattern of *LuLuChong* and *NBLinks*, which contain common alignment prefixes making it easy to find out all valid user IDs. Using only 7 digits as user IDs seems inadequate for accommodating the increasing number of users in two products. For example, *YueHuoCX* [11] has millions of users but relies on just 7 integers for user identification.

The failed cases include two devices that use the phone number (11-digit) as user IDs, which are inefficient to be enumerated by IDScope. However, for popular products, the phone numbers may still be enumerated, as attackers can get hits by matching the rentable IoT deployment cities with the guessed phone number's registration cities. The other 4 products utilize IDs consisting of 14 to 24 irregular numbers or strings, which can resist the enumeration of IDScope.

Device ID enumeration. IDScope can efficiently guess 15 vulnerable devices' serial numbers and identify their ID patterns. For example, the *QSMX* rentable e-bike/boat uses 9-digit IDs, but they have a pattern of 3-4, where the first 3 digits refer to the city code and the last 4 digits are the device numbers. Attackers can easily infer the valid ranges of these 3-digit sections. The VIN number also has a similar structure [9] that cars of the same vendors only vary in some sections of the whole string. The failed cases (e.g., *QiXin*) are devices that use a long random string containing both numbers and characters.

Large-Scale Exploitation on Users and Devices. For 9 products susceptible to user ID enumeration, attackers can exploit vulnerable APIs using the victim users' IDs, leading to large-scale privacy leakage and unauthorized access to private user data. In addition, five products exhibit account hijacking vulnerabilities, enabling attackers to seize control of user accounts on a large scale. Once these accounts are compromised, attackers are positioned to manipulate associated devices via their serial numbers. For 5 products with payment bypass vulnerabilities and 7 products with device manipulation vulnerabilities, attackers leverage enumerated device SNs to access or rent devices without cost, leading to extensive unauthorized usage. Notably, the `Teld` EV-charger

has another vulnerable API allowing users to be added to a free-charge whitelist, which can be exploited to enable free charging on any device after gaining device SNs from the app's map APIs.

Although the 3 vulnerable e-scooters (discussed in § 5) apps' device SN can all be enumerated, Lime and Helbiz still require attackers to pay for their orders, while GO-ON allows attackers to large-scale unlock all e-scooters for free. Combined with credit card fraud, attackers can unlock unlimited Lime e-scooters and manipulate all devices of Helbiz.

7 Responsible Disclosure and Mitigation

7.1 Responsible Disclosure

From 2022 to 2023, we identify 28 vulnerabilities in 19 apps and 18 vulnerabilities in 11 devices of rentable products. We inform vendors of our findings via email, phone, or WeChat, with communications typically lasting one to two months. All vulnerabilities are confirmed by the vendors, resulting in 15 CVE/CNNVD entries and 3 NVDB entries. The vendors promptly resolve the 28 vulnerabilities in apps. The 18 vulnerabilities on devices are addressed in their new devices but some (e.g., hardcoded keys) remain in their legacy devices.

In 2024, we investigate 6 new Chinese rentable devices (including *AnSheng*, *AnKong*, *WeiPeng*, *YFLe*, and *BDT*) and find 5 vulnerabilities across 3 physical devices and 2 vulnerabilities within two apps from 3 different vendors. To date, only *Ankong* has confirmed its 3 vulnerabilities and we are continuing discussions with the remaining 2 vendors. In addition, for the 11 e-scooter/e-bike operating in other countries, we discovered 4 vulnerabilities in the iOS apps of Lime, GO-ON and Helbiz. We inform the affected vendors of the vulnerabilities via email. They have acknowledged forwarding the information to their technology teams for further confirmation. We track vendor feedback online at https://vehicle-security.github.io.

7.2 Mitigating ID Enumeration Attack

The root cause of ID enumeration attacks is that some APIs lack proper access control, and attackers can illegally access unauthorized resources via the resource ID. Before being detected by the server, they can attack as many devices as possible by large-scale enumerating the resource IDs. It is impossible to eliminate all these vulnerabilities to make ID enumeration harmless. A straightforward way to mitigate this attack is to append random characters to the ID string and increase its length to make it much harder to enumerate. However, some products need to retain a simple ID to make it easier for users to manually type in the ID if the QR code is broken. Also, some resources may use the auto-incrementing fields of the database (e.g. primary key) as IDs, which are expensive to change due to the complexity of the backend. Simply adopting a rate limit is also inadequate as the apps may also frequently invoke these APIs to query devices via their IDs.

To enhance the security of using short digits as IDs, we propose a decoy ID-based solution [37] to quickly detect the ID enumeration attack. The basic idea is to mix the real IDs with fake IDs, and the fake IDs are not actually used by the devices, but can only be accessed by attackers who try to craft requests to enumerate IDs. Apps typically do not access these fake IDs unless users mistakenly input incorrect IDs, which occurs at a very low rate. If a client consistently triggers fake IDs at a high frequency, it strongly indicates the adversaries are attempting to enumerate IDs. The server can then block these clients.

Security Analysis. We assume that attackers can change their IPs and user IDs to bypass the rate limit. The defense goal is to prevent them from exploiting the devices with continuous serial numbers. We choose to shuffle the real IDs and mix them uniformly with the decoy ID. By studying the ID distribution in real products, we notice that the real device numbers are about 5% to 45% of all the ID space. That is, for a 5-digit ID, there can be 5000 (5%) to 45K (45%) consecutive device numbers ranging from 0 to 5000/45000. This allows us to insert 3 to 8 fake IDs in every 10 IDs, which is enough to prevent enumeration in any range of device numbers. By setting a threshold of three fake IDs that a malicious user can trigger, attackers can be detected within 10 enumeration requests.

7.3 Mitigating Other Vulnerabilities

We correspond with multiple vendors via email to facilitate the mitigation of vulnerabilities.

(1) Mitigate Physical Devices' Threats. Local exploits, although limited in scope, typically begin with attackers analyzing the hardware of devices by extracting firmware [24], injecting intra-board messages [3], and creating phantom clients [69]. Such methods require disassembling the devices and exploiting weaknesses in the MCUs [58]. To counter these tactics, vendors are advised to redesign the physical structures of their products to hinder disassembly and reassembly efforts, enhance the security of MCU firmware [5], and integrate anti-tamper mechanisms that can detect any disassembly attempts [57]. One plausible measure to protect MCU firmware involves implementing one-time programmable eFuses [6], which can permanently disable JTAG and SWD interfaces, thus securing the hardware from unauthorized modifications. Additionally, installing hardware that monitors and records the device's internal status [57] can help servers identify hardware tampering or falsified device states. However, these hardware updates can be extremely time-consuming due to the vast number of devices involved, presenting a significant challenge in large-scale implementations. Therefore, we suggest vendors deploy server abnormal detection [43] for frequent invalid requests to identify and ban compromised devices.

Currently, only the *Meituan* shared bicycle uses special physical structures to automatically disconnect devices when they are disassembled.

*(2) Mitigate the Device-Side Remote Threats.*Among 15 remotely exploitable products analyzed, only 2 employed message encryption, sharing keys across devices, while the others lacked encryption or robust authentication methods. Device IDs, often simplistic and predictable, were consistently exposed via app APIs, facilitating potential large-scale attacks [24]. Notably, in our work five of these devices employed easily guessable, sequential IDs, increasing their vulnerability to enumeration attacks.

While some vendors have begun issuing firmware updates since October 2022 to implement unique device passwords, significant challenges persist, especially for products like *LVCC* that lack support for OTA updates. Recommended mitigation strategies include the implementation of TLS for secure communication, the use of unique device passwords, the deployment of session-specific tokens, and the strengthening of ID security measures to enhance overall device-side protection. Although plaintext passwords can still be extracted from firmware, large-scale remote exploitation is impractical as attackers can only access limited local devices.

*(3) Mitigate the App-Side Remote Threats.*Companion apps often handle payment or device control requests, which can be compromised by attackers due to insecure implementations. This includes vulnerable server APIs that fail to properly manage authorization or inadvertently expose sensitive data [72]. Such vulnerabilities pose a risk to a vast number of devices. Vendors have responded swiftly by rectifying these flaws. Furthermore, they are enhancing the security of device IDs by lengthening them, incorporating decoy IDs, and implementing abnormal activity detection systems.

8 Related Work

EV Charger and E-Scooter Security. Our study includes nearly 40% of the devices that are rentable chargers for e-bikes or EVs. We specifically investigate the security vulnerabilities in the firmware and apps of these rentable devices. While previous research has addressed physical layer security [14] and communication security within charging standard protocols [23], these areas are orthogonal to our focus, which centers on issues arising from the shared nature of these devices. Previous work [59] focuses on the privacy issues in e-scooter rental apps, we systematically study the exploitation of their apps and devices.

Enumeration Attacks. Existing works focus on detecting enumeration attacks on cloud environments, usernames, etc. [12,28] Enumeration attacks specifically targeting IoT devices remain unexplored. In our work, we uncover and demonstrate novel types of enumeration attacks that exploit various resource IDs of rentable IoT devices, presenting unique challenges and requiring distinct enumeration strategies tailored to the rentable device context.

IoT Access Control. Multiple users and devices [55,56] can lead to significant authorization and usage coordination challenges in a smart home ecosystem. Kratos+ [54,55] addresses these challenges by implementing a system of partial authorization, which ensures normal operation while mitigating the risks associated with excessive permissions, which not only maintains normal operations but also prevents the risks of excessive permissions that could lead to device tampering. To further enhance the security of the Smart Home System (SHS), Aegis framework [13, 52, 53] supports various network communication protocols and enhances threat detection capabilities. It effectively monitors both encrypted and unencrypted traffic, identifies potential threats from integrated sensors in-home devices, and deploys defensive strategies to mitigate these vulnerabilities. However, it still needs to explore how to adapt these solutions to rentable IoT devices as they have a different backend architecture.

IoT Authentication Security. Existing works [18,34,35,51, 69] mainly focus on the interactions between smart home IoT devices and clouds. rentable IoT devices represent new research problems as they communicate directly with the cloud, while smart home devices may use the companion app [46,70] as gateways or IoT hubs [69] to connect to the IoT cloud. The MITM attacks (e.g., OTA hijack) on smart homes devices [18, 70] cannot be applied to cellular IoT devices as their communication is over the LTE cellular network. Similarly, the large-scale weak authentication found in cellular IoT devices by our study is unlikely to happen in smart homes, which are usually managed separately by users [34,35]. Note that there are also some approaches [26, 64] that propose new mechanisms for securing IoT authentication, which can help to mitigate the weak authentication problem and device impersonation attacks discussed in our work.

IoT Reverse Engineering. Reverse engineering is widely used [18, 62, 69] for researching the risks in closed-source IoT products. Our work focuses on reversing the customized binary protocols of cellular IoT devices. The existing protocol reverse engineering efforts can be divided into two categories: binary analysis based approaches [22,25,42] which dynamically or statically analyze the binary code and memory data of protocol processing, and network message traces based approaches [38,39,66] which distinguish the message types and identify their formats by message cluster and alignment. Only adopting firmware analysis [22] is inadequate for retrieving message formats due to their complex, variable-length parameters. The challenge in reversing cellular IoT device protocols lies in understanding the semantic of all commands, not just clustering messages [66] to identify format, as network traces can only cover a few commands of the devices. We address this problem by analyzing the firmware to extract new commands from the strings of the log print code.

IoT Firmware Security Extensive research efforts are pro-

posed to identify the vulnerabilities [27, 29, 44, 63] or enhance the security in IoT devices [31, 49]. HEAPSTER [29] discovers the vulnerable heap allocators in IoT firmware. DICE [44], P2IM [27], and Jetset [36] improve the firmware rehosting [30] to facilitate the firmware fuzzing test. Our work do not exploit the vulnerabilities in firmware but extract secrets from them. HERA [49] and RapidPatch [31] address the challenge of hotpatching real-time IoT devices for timely bug fixes. These works are orthogonal to our study.

IoT Cloud and Companion App Security. Existing works focus on smart homes' cloud access control security [35, 69] and protocol security [34, 60]. Jia et al. [34] and MPInspector [60] focus on MQTT based IoT devices, while most cellular IoT devices use customized binary protocols. Multiple works [46, 50, 61, 70] choose to study IoT security from the perspective of the companion apps. MaaG [70] identify the vulnerable access controls between IoT devices and their companion apps. BLESCOPE [71] discovers attackers can fingerprint the BLE based IoT devices by obtaining their static UUIDs from the companion apps. DIANE [50] analyzes the companion apps to efficiently generate valid inputs to fuzz IoT firmware. Our study reveals new consequences of large-scale exploiting the users and devices by abusing app APIs.

9 Discussion

We talk to vendors to identify the root causes of their vulnerabilities and learn from their mistakes to establish best practices for securing rentable IoT devices.

The Root Causes of Using Weak IDs and Common Keys. As discussed in § 2, rentable IoT products commonly utilize three resource IDs: the user ID, the device serial number, and the device ID. Vendors choose simple IDs like auto-incrementing user IDs for their easy implementation and human readability, ignoring the security risks, which have been underreported until now. Using common keys is also a trade-off in device manufacturing. The device serial number is often printed on the physical device to allow manual entry, favoring shorter IDs for ease of use. Additionally, because of the large number of devices, to streamline device provisioning and communication processes, vendors often employ common keys across multiple devices and use continuous integers as serial numbers.

Limitation and Future Works. Our work has two primary limitations, and we leave them for future work.

(1) Investigating More IoT Products. Two key factors restrict the number of products studied. First, it is extremely expensive for us to get more devices or apps for research. We can only buy very few devices as a limited number of vendors sell shared IoT devices to individual operators. It is also time-consuming to obtain devices from the vendors by cooperating with them. However, attackers face little hindrance in acquiring these devices, as they can illegally obtain (e.g., steal or rob) a device, given the huge number of devices operating unmanned. Furthermore, accessing the QR codes of rentable IoT apps presents another challenge, as they are typically only available on physical devices deployed across various cities. It is interesting to extensively study all the components of rentable IoT devices, such as EV charger's management website [48] and charging standard [40].

Second, testing rentable IoT products is labor intensive. Many rentable IoT apps adopt real-name registration and need to pay a deposit before use. These processes cannot be automated now. Reverse engineering IoT firmware and Android apps also require sophisticated hacking skills. In the future, we plan to study a wider range of rentable IoT products in a more efficient way.

(2) In-depth Study of the Cellular Network and Chips. We believe that the vulnerabilities outlined in this paper may also be present in other cellular IoT devices. Unfortunately, our attempts to crack the secure boot of cellular MCUs have been unsuccessful, hindering further exploration of their firmware. Additionally, the absence of professional cellular network security analysis tools and environments, which are often costly and must be operated within strictly controlled conditions as mandated by laws in many countries, including China, has limited our ability to delve deeper into cellular network security. This restricts our capability to experiment with and analyze cellular networks safely and legally. If attackers can intercept the 4G/5G cellular network, they can use our vulnerabilities to manipulate multiple physical devices by forging server commands.

10 Conclusion

In this paper, we conduct the first study to introduce the architecture and uncover the security implications of rentable IoT products. By investigating 17 physical devices and 92 IoT apps, we find that rentable IoT devices exhibit multiple common design and implementation vulnerabilities in both their local devices and companion apps. To validate these findings in real products, we first propose a semi-automated approach to test the APIs of rentable IoT devices and apps, successfully identifying 23 vulnerabilities across 14 physical devices and 34 vulnerabilities within 23 apps, which can affect 28 products. Moreover, we also find these devices utilize weak IDs across multiple resources, posing a risk of large-scale exploitation to users or devices. To assess the scope of affected devices, we then propose an automated ID enumeration detection tool, called IDScope, which confirms that 13 devices and 17 apps are vulnerable to large-scale attacks that can affect all users or devices from the same vendor for 24 products. Our work elucidates the root causes of these vulnerabilities, enabling effective vendor mitigation and resulting in 18 CVE/CNNVD/NVDB numbers.

Acknowledgment

We would like to thank our shepherd and the anonymous reviewers for their valuable comments. This work is in part supported by the National Natural Science Foundation of China (62272265, 62132011, and U1936121). Qi Li and Jianwei Zhuge are the corresponding authors of the paper.

A Real World Rentable Cellular IoT Products

Table 8 shows the IoT-based device rental products studied in this work. It falls into four usage categories: charging, mobility, entertainment, and daily tools.

- **Chargers.** With the proliferation of electric vehicles, rentable chargers are emerging in cities for people to charge everywhere. Some leading operators in China such as *Teld* [8], *StartCharge* [7], and *Potevio* [4] have deployed millions of rentable chargers. We also investigate many other rentable charging services, such as rentable power banks for mobile, smart sockets, and battery charging cabinets for electric bicycles.
- **E-Scooter/E-Bicycle/Car.** Compared to traditional rental services, e-scooters, bicycles, and cars have gained popularity due to their convenience. They can meet urban residents' flexible short-distance travel needs as massive unmanned devices are deployed everywhere, and people can rent them anytime in a pay-per-use mode via mobile apps.
- **Entertainment Devices.** Public entertainment devices such as massage chairs, billiards, and Mahjong tables can reduce management costs through IoT-based device rental services. With cellular IoT and companion apps, consumers can self-serve the process of paying, renting, and returning these devices.
- **Tools.** Facilities such as laundry machines and hair dryerss, are frequently used in our daily life. Using cellular IoT, these tools can be deployed and maintained unmanned in hotels or dormitories at low cost.

B Capturing Cellular Chip's Inner Traffic

As shown in Figure 8, we connect jumper wires to the IoT chips for power supply, message trace capture, and debugging. Some devices contains two chips and utilizing a cellular chip to relay messages from the control chip (i.e., main MCU). Their inter-chip traffic can be easily captured by using USB-TTL serial cables to monitor the messages between two chips.

For devices equipped with a single cellular chip, there are no inter-chip messages and the network traces come directly from the cellular chip itself. By enabling the debug log feature on these chips, we can access the unencrypted, raw messages from the cellular process log (CP log). We can efficiently capture these logs and retrieve the internal messages of the cellular chips by attaching jumper wires to the appropriate pinouts.

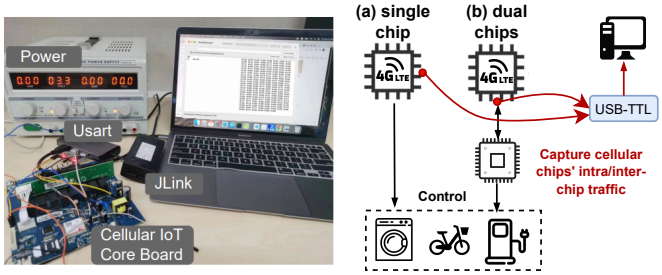

Figure 8: Capture cellular chips' inner traffic by connecting jumper wires to the logging pinouts.

SAIN: Improving ICS Attack Detection Sensitivity via State-Aware Invariants

Abstract

Industrial Control Systems (ICSs) rely on Programmable Logic Controllers (PLCs) to operate within a set of states. The states are composed of variables that determine how sensor data is interpreted, configuration parameters are applied, and actuator commands are issued. Recent works have shown that attackers can manipulate these variables to compromise ICS safety and security. To detect such attacks, previous approaches have leveraged invariants—a set of rules defining the correct behavior of an ICS. However, these invariants suffer from a critical limitation: they are *state-agnostic*. This means they define variable ranges across all possible ICS states, leading to loosely bounded detection thresholds. Unfortunately, attackers can exploit these loose bounds and launch stealthy attacks that evade detection without violating such invariants.

In this paper, we introduce SAIN, an automated method to derive *state-aware* ICS invariants with tighter bounds and enforce them through a PLC-based monitor. SAIN first generates invariant templates by identifying the PLC program states, state transitions, and the inter-dependencies among sensing, actuation, and configuration variables within each state through program analysis. It then partitions the ICS data traces into state-specific sub-traces and quantifies the invariant templates with concrete, tighter bounds, as system-specific knowledge about the subject ICS. Lastly, it enforces the state-aware invariants through a run-time monitor. We evaluate SAIN on a Fischertechnik manufacturing plant and a chemical plant simulator against 17 attacks. SAIN protects the plants, on average, with a false positive rate of 2% and a run-time overhead of 3%.

1 Introduction

Industrial Control Systems (ICS) play a vital role in automating and managing complex industrial processes. Compared to traditional ICS with non-programmable controllers, ICS with Programmable Logic Controllers (PLCs) achieve increased configurability and automation. The PLC program acts as the central processing unit that monitors and governs the entire control process. The execution of a PLC program is based on three categories of variables. (1) The sensing variables are continuously updated with real-time data acquired from the sensors connected to the PLC's input station. (2) The configuration variables encompass a set of parameters that establish the operational characteristics of the ICS. (3) The actuation variables define the control signals transmitted to the PLC's output station connected to the actuators.

Prior research has shown that ICSs are vulnerable to attacks that manipulate the PLC variables without altering the underlying PLC program [8, 10, 38, 43]. These attacks can have disastrous consequences, as evidenced by real-world incidents. For instance, the Stuxnet worm [13] caused extensive damage to centrifuges in a nuclear facility by altering the converter frequency variable from 2 Hz to 1410 Hz. Similarly, the BlackEnergy attack [8] compromised a power system by manipulating circuit breaker variables from 1 to 0, leading to the disconnection of 27 substations.

To detect such ICS attacks, prior work has explored techniques that leverage invariants, which define the relationship between PLC variables and their value bounds [14, 23, 48]. These invariants are typically derived through data mining techniques applied to ICS execution traces that record sensor readings, actuator values, and configuration parameters during the normal operation of an ICS. Another line of work has incorporated the temporal characteristics of an ICS into invariants [3, 27, 52, 53], enabling them to integrate the timing relations between variables to improve attack detection.

Despite their success, we notice that state-of-the-art techniques define an invariant as a property/behavior that must be true *throughout the entire operation* of an ICS and, as a result, some invariants may set loose bounds of variable values to hold throughout the ICS operation. In practice, however, an ICS process is naturally partitioned into a sequence of distinct states (operational phases) to control the physical process in smaller tasks, ensuring that the operation of the ICS in each state is successfully completed before transitioning to the next state. Our key observation is that the

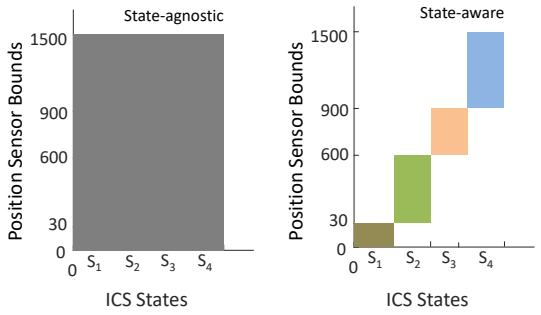

Figure 1: Bounds in state-agnostic vs. state-aware invariants.

value bounds for an invariant may vary depending on the specific ICS state. Figure 1 illustrates this limitation by comparing state-agnostic and state-aware invariants derived from a manufacturing testbed [40]. The state-agnostic approach sets a single, global bound on invariants that is satisfied by all collected ICS traces. Such looser bounds in state-agnostic invariants allow attackers to launch stealthy attacks in certain states. In contrast, the state-aware approach establishes invariants with tighter bounds specific to each ICS state.

To address this problem, we introduce SAIN[1], a framework for deriving and enforcing state-aware invariants with tighter state-aware PLC variable bounds. SAIN consists of four modules: ICS state identification, code-level invariant derivation, invariant quantification, and runtime monitoring. SAIN first conducts static analysis on the PLC program to extract ICS states, state transitions, and the relations among PLC variables (i.e., sensing, configuration, and actuation). It then generates invariant templates that involve the relevant variables for each state, and partitions benign ICS traces into state-specific sub-traces based on the state transitions. Lastly, it leverages an association mining algorithm to numerically instantiate the invariant templates by mining the state-specific sub-traces.

During ICS operation, SAIN enforces the state-aware invariants in the PLC runtime, which executes the process control code and interacts with the I/O modules [33]. Among the PLC runtime functions, only those that are subject to (potentially malicious) remote update of PLC variables are instrumented with the SAIN runtime monitor. As such, the runtime monitor, as a detection agent, is only triggered when the PLC receives a program variable update request from an external entity (e.g., the human-machine interface). This ensures that SAIN runtime monitor guards against external attacks, with minimal impact on the PLC scan cycle time.

We evaluate SAIN on Fischertechnik (FT) [15] (a real miniature manufacturing plant testbed) and a simulated chemical plant [17] against 17 attacks, with real PLC code running on both plants. Our evaluation shows that SAIN detects and prevents all attacks on average with a false positive rate of 2% and run-time overhead of 3%. We compare SAIN's attack detection effectiveness with state-of-the-art ICS invariant-based techniques, Feng et al. [14] and VetPLC [52]. The invariants derived from Feng et al. detect 5/17 attacks, and the temporal invariants derived following VetPLC detect 6/17 attacks.

In summary, we make the following contributions.

- We introduce SAIN, an automated approach for deriving state-aware invariants, as system-specific knowledge, by combining PLC program analysis and trace mining. Compared to their state-agnostic counterparts, state-aware invariants set tighter bounds that enable the detection of stealthy attacks.
- We develop a SAIN runtime monitor, as a detection agent, that leverages state identification signatures to determine the current ICS state and enforces state-aware invariants.
- We demonstrate the effectiveness of SAIN on two ICS testbeds through 17 attacks, including false configuration injection, sensor data manipulation, malicious actuation signals, and physics-aware attacks. SAIN detects all attacks with low runtime overhead.

SAIN source code, attack videos, and traces are available at https://github.com/purseclab/SAIN.

2 Background

Programmable Logic Controller (PLC). The ICS monitors and controls an industrial or manufacturing process. The PLC is the central controller of the ICS, executing the control logic that governs the sensing-control-actuation loop of the process.

The PLC has two key components: the variables and program. PLC program variables fall into three categories: (1) sensing variables that reflect real-time sensor measurements, (2) configuration variables that define operational parameters of the ICS, and (3) actuation variables that carry control commands to physical actuators within the plant. The PLC program defines the control logic, issuing control commands to the physical plant based on real-time sensing variables.

State-driven PLC Program. The nature of ICS leads to the fact that its PLC program reflects and implements the ICS's states and transitions, modeled with a Finite State Machine (FSM) [18,30,53]. Each state in the FSM represents a specific operational phase of the ICS and the corresponding actions it performs. Transitions between states occur based on new events or changes in process variables (e.g., sensor readings or actuator states). The state-driven programming of PLCs naturally aligns with industrial process control. By decomposing the ICS operation into distinct states, the PLC program monitors and executes control logic in a state-specific manner. The FSM model has been widely used for the automated generation, validation, and transformation of PLC code [39,45,54].

PLC Runtime. The PLC runtime is a privileged layer of software that executes the PLC program. Modern PLC runtime

[1]The acronym SAIN stands for "state-aware invariants", with the word *sain* in French meaning "healthy".

```
int main(int argc,char **argv){
    //Creating PLC Variables
    glueVars();
    //Initiating Server Applications
    pthread_create(&interactive_thread, NULL, appThread, NULL);
    //Scan Cycle
    while(run_openplc){
            //Updating Input Variables with Sensor Data
            updateBuffersIn_MB();
            //Execute Control Program
            config_run__(__tick++);
            //Write Output  Variables to Output devices
            updateBuffersOut_MB();}
}
```

Listing 1: Overview of OpenPLC runtime execution flow.

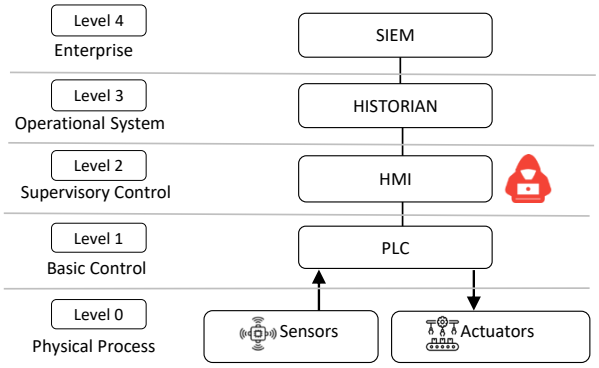

Figure 2: The illustration of ICS operation based on Purdue model and the threat model of SAIN.

also supports the execution of server applications that allow other devices/machines to communicate with the PLC. For example, the Siemens PLC runtime executes a web server [5], while the OpenPLC runtime supports applications to which devices can be connected [2].

Listing 1 shows the control flow of an OpenPLC runtime. The initialization phase establishes the PLC variables and server applications. These variables can be accessed by both the server applications and the PLC control program. The main loop continuously updates the PLC variables with sensor readings, executes the control program, and subsequently sends control commands to the actuators.

3 Threat Model

We describe our threat model using the Purdue Model [50] for ICS security. Purdue Model is a hierarchical model for ICS, as shown in Figure 2. Level 0 implements a network of sensors and actuators interfaced to Level 1, which consists of multiple PLCs. Level 2 implements supervisory entities, such as SCADA and HMI, to control PLCs by sending messages. The messages from Level 2 are served by different server applications in the PLCs. These applications can allow the manipulation of PLC variables, including sensing, configuration, and actuation variables.

We assume the entities above Level 1 can be remotely compromised by the attacker to disrupt ICS operations. The attacker can compromise entities at Level 2 and above using existing mechanisms (e.g., spearphishing to compromise the HMI [31] and by exploiting disabled security functionalities in server applications [11]). Specifically, attackers can remotely access these entities to inject malicious messages into the Level 1 network and manipulate the sensing, configuration, and actuation variables in the PLC. We assume that the Level 0 and 1 network is air-gapped from the Level 2 network. Therefore, entities at Level 2 cannot spoof messages within Level 0 and Level 1 networks. We assume that the attacker cannot manipulate the PLC firmware. Additionally, we assume that the attacker does not have physical access to ICS devices such as sensors, actuators, and PLCs. Consequently, the attacker cannot spoof physical sensor and actuator values. We also assume that the PLC control program correctly implements the ICS states and state transitions, ensuring that the FSM derived from the PLC program is correct. Our threat model aligns with those in the prior work that leverage invariants for ICS security [24, 29, 30].

4 Overview of ICS Attacks and Invariant-Based Defenses

A wide range of attacks are caused by the fact that PLCs are becoming increasingly connected by running server applications (e.g., Web server, MQTT, and OPC-UA). Through these applications, remote operators can access and modify PLC program variables as an operation convenience. Unfortunately, such remote connectivity also enables attacks that remotely manipulate PLC program variables [8, 10, 38, 43]. As a defense, invariant-based techniques have been proposed to detect attacks that violate the invariants.

However, previous approaches define state-agnostic invariants. The lack of ICS state-awareness leads to invariants with loose bounds, within which stealthy attackers can manipulate the variables "under the radar" and evade invariant-based detection. We present a motivating example of a stealthy evasion attack that exploits the loose bounds of the PLC variable values in state-agnostic invariants.

4.1 Motivating Example

We present an attack against the Fischertechnik (FT) manufacturing plant, a PLC-controlled production factory [40] (described in Appendix A). The plant's delivery process is controlled by a PLC program that implements the FSM shown in Figure 3. Each state (S_i) is associated with a set of semantically close actions to be completed. The state transitions (T_i) represent the conditions that must hold for the PLC to advance to the next state.

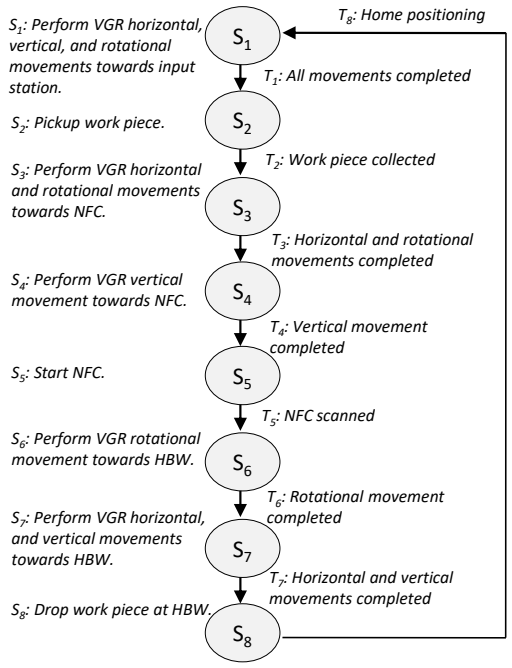

Figure 3: PLC workflow in the FT manufacturing plant. S_i denotes the states, and T_i denotes the transition between states.

Attack Objective. In the delivery process, the attacker's objective is to initiate the vacuum gripper robot (VGR) horizontal movement during state S_6. Yet, the PLC control logic is designed to trigger only the rotational movement in S_6, with the intent of preventing any collision between the VGR and high-bay warehouse (HBW) storage site. Thus, if the attacker can cause the VGR to perform a horizontal movement during S_6, this could potentially damage both the VGR and HBW.

PLC Logic for Controlling VGR Horizontal Movement. The PLC configuration variable "H_TargetPosition" is set based on the VGR's target position, as 600 for HBW and 900 for NFC. To initiate the horizontal movement, the PLC activates the VGR's horizontal actuator "H_StartPositioning." During the horizontal movement, the PLC continuously receives the VGR's current position through sensing variable "H_ActualPositioning." The PLC monitors the value of that variable and compares it to the target position and an offset. Specifically, when the value of "H_ActualPositioning" becomes greater than or equal to [H_TargetPosition - Offset] and less than or equal to [H_TargetPosition + Offset], the PLC stops the VGR's horizontal movement.

Limitations of Previous Defenses. Previous invariant-based approaches [12, 14] usually begin by defining predicates for actuation variables and then deriving the value ranges of the sensing variables for each predicate. For instance, the invariant (I_1) listed below is derived following Feng et al. [14] using Fischertechnik's data traces. I_1 establishes the benign variable value ranges based on traces from the entire plant operation.

Table 1: State-aware invariants to prevent VGR-HBW attack.

State	Invariant
S_1	H_Target = 30 & H_Actual[0-14] → H_Start = ON
S_2	H_Start = OFF
S_3	H_Target = 600 & H_Actual[0-584] → H_Start = ON
S_4	H_Start = OFF
S_5	H_Start = OFF
S_6	H_Start = OFF
S_7	H_Target = 900 & H_Actual[0-884] → H_Start = ON
S_8	H_Start = OFF

However, such ranges turn out to be too loose, allowing a stealthy attacker to carry out the VGR-HBW collision attack. Specifically, the attacker is able to initiate the VGR's horizontal movement during a specific ICS state (S_6) without violating the invariant (I_1).

- I_1: if H_TargetPos[30-900] and H_ActualPos[0-884] then H_Start = ON

The VGR-HBW attack remains undetectable even with temporal invariants due to the absence of a tighter time bound. Invariant I_2 below is extracted following the temporal invariant derivation method in VetPLC [52]. This invariant sets an upper time limit of 7 seconds without considering the specific timing constraints under individual states.

- I_2: if H_TargetPos[30-900] and H_ActualPos[0-884] then H_Start = [ON, 7 sec]

Our Approach. SAIN detects stealthy attacks by generating state-aware invariants with tighter bounds and enforcing them when the PLC receives an external variable update request from the HMI. Table 1 presents the PLC variable bounds for an invariant under different states. Thus, when the attacker initiates the VGR's horizontal movement in S_6, a violation is detected because the VGR's horizontal movement is not allowed in this state.

4.2 Design Goals and Challenges

Our main goal is to defend ICS against stealthy attacks that evade state-agnostic invariants. To this end, we define our design goals as follows:

G1: Generating state-aware invariants with tighter bounds. As detailed in Section 4.1, prior works overlook the ICS states and derive invariants from the entire set of benign ICS traces, resulting in loose PLC variable bounds. However, generating state-aware invariants as system-specific, quantifiable knowledge is challenging because it requires (1) identifying the specific states from a large PLC code that controls multiple interacting components, (2) partitioning the data traces based on the states, and (3) generating and quantitatively concretizing invariants that define the relations between PLC variables under each state separately. Addressing these challenges requires a combination of PLC program analysis and ICS data trace mining.

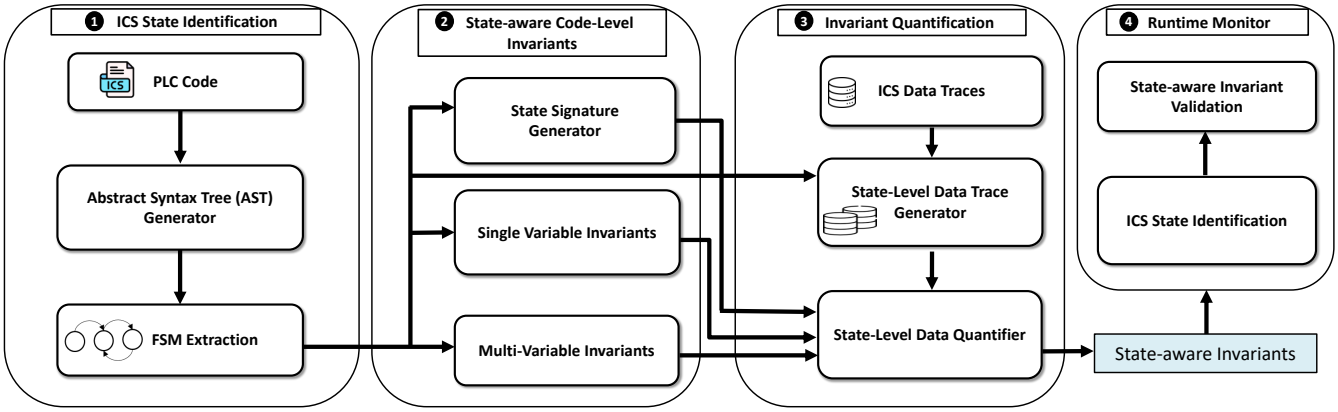

Figure 4: Overview of SAIN architecture.

G2: Monitoring and enforcing invariants at runtime. The state-aware invariants need to be enforced during ICS operations. Here, challenges include dynamically determining the ICS state at runtime and enforcing the associated invariants accordingly. Moreover, the invariant enforcement should incur a low performance overhead to satisfy the ICS's real-time requirements. To address these challenges, we extract the state transition conditions from the PLC code as unique signatures of each state, and use them at runtime to determine the current ICS state. We also develop a PLC runtime monitor that incurs minimal overhead on the PLC scan cycle timing.

5 SAIN Design

We introduce SAIN, an automated framework that generates and enforces state-aware invariants with tighter PLC variable value bounds, derived as system-specific knowledge from both PLC program and traces. Figure 4 presents the overview of SAIN, which is composed of four key stages: (1) ICS state identification, (2) state-specific code-level invariant derivation, (3) invariant quantification, and (4) SAIN runtime.

SAIN first leverages the PLC program to identify the states that are defined and implemented to control ICS operations (❶). SAIN determines the conditions, which include the sensing, configuration, and actuation variables in the PLC, that must hold under each ICS state and converts them into invariant templates (❷). For example, an invariant template defines the relation between specific sensing, configuration, and actuation variables that trigger the VGR's horizontal movement. SAIN then quantifies the invariant templates by leveraging ICS data traces – partitioned by state – to set concrete bound values in the templates (❸). Lastly, to enforce state-aware invariants, SAIN has a runtime monitor that validates PLC invariants upon receiving external requests through the HMI. The runtime monitor identifies the current ICS state and enforces invariants for that state (❹).

5.1 ICS State Identification

SAIN extracts the ICS states from the PLC code through program analysis. These states then guide SAIN's code-level, state-specific invariant derivation (Section 5.2) and invariant quantification (Section 5.3) stages.

Our key observation is that the PLC functions as an FSM, running among predefined states in accordance with the control flow of the PLC program. In fact, PLC programming languages (IEC 61131-3 standard [22]) inherently emphasize state-based control. For example, Structured Control Language (SCL) and Structured Text (ST) allow the creation of FSMs and state-driven logic using a text-based syntax. Sequential Function Chart (SFC) is specifically designed to define and execute state-based control logic, offering a visual representation of states and transitions [54].

Following this observation, to extract ICS states from a PLC program, SAIN first generates an Abstract Syntax Tree (AST) as an intermediate representation of the PLC program. It then builds an FSM model of the PLC code, mapping out the behaviors and transitions of the ICS within and across states.

5.1.1 Abstract Syntax Tree (AST) Generation

SAIN performs parsing to break down the PLC code into individual tokens, and constructs an AST through the Parsing Expression Grammar (PEG) [16]. This grammar acts as a set of rules that guide the parsing process and reflect the control logic structure. The AST is a generalized representation of the PLC program that includes state identifiers, variable dependencies, and control flow relations, enabling SAIN to extract language-independent FSMs.

5.1.2 FSM Extraction

Algorithm 1 outlines SAIN's approach to extracting an FSM from the AST of the PLC code. The algorithm first examines the functional blocks of the PLC control logic (Line 3-4).

Algorithm 1 Finite State Machine (FSM) Construction

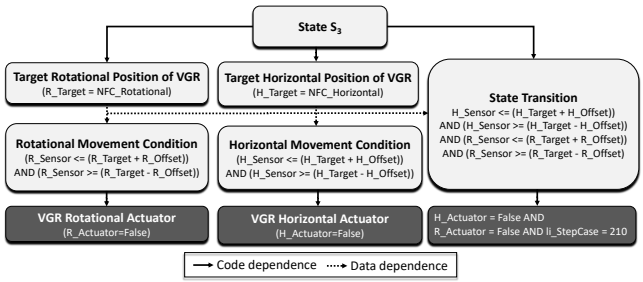
Input: PLC Program
Output: Finite State Machine (FSM)

1: Initialize an empty FSM
2: Convert PLC program to an Abstract Syntax Tree (AST)
3: Extract function blocks from AST
4: **for** each function block **do**
5: **for** each case block in the function block **do**
6: Define a state in the FSM for case block
7: Create control flow graph for case block
8: Create data flow graph for case block
9: Combine control and data flow graphs to form PDG
10: Identify transition conditions from PDG
11: Include the transition conditions as an edge in the FSM
12: **end for**
13: **end for**
14: Return the FSM

Table 2: Illustration of state transition conditions for the delivery process in the FT manufacturing plant.

SS*	DS†	Transition Condition‡
S_1	S_2	H = INPUT, V = INPUT, R = INPUT
S_2	S_3	W = $\surd$
S_3	S_4	H = NFC, R = NFC
S_4	S_5	V = NFC
S_5	S_6	S = $\surd$
S_6	S_7	R = HBW
S_7	S_8	H = HBW, V = HBW

*SS is the source state. †DS is the destination state. ‡H is for horizontal sensor, V is for vertical sensor, R is for rotational sensor, W is for workpiece collected, S is for NFC scan done.



For each functional block, SAIN iterates the case statement blocks (Line 5), constructing a control flow graph for each case (Line 7). The control flow graph represents individual statements as nodes and reflects the program's control flow along its edges. SAIN then constructs a data flow graph by tracing the data dependencies between statements (Line 8). For each case statement, SAIN combines the control and data flow graphs to create the Program Dependency Graph (PDG), including both control and data dependencies (Line 9). Each case block represents a distinct state in the FSM, allowing us to perform state-level program analysis.

For each state, SAIN stores the PDG and a state transition table. The transition table has two fields. The "toState" to record the next state and "condition" to record state transition conditions. SAIN determines the "toState" field by identifying the specific variable(s) that cause the switches between the case statements. It then finds the variables that have control and data dependencies on the "toState" field from the PDG, identifying the state transition conditions (Line 10). SAIN then includes the state in the FSM as a node, and incorporates the transition conditions to the outgoing edges from that node (Line 11). Figure 5 shows the PDG and transition table for state S_3 extracted from Listing 2.

Table 2 shows the state transition conditions that correspond to the FSM depicted in Figure 3. The Source State

```
1  //Horizontal (H) movement towards NFC
2  H_Target := NFC_Horizontal;
3  H_Actuator := TRUE ;
4  IF (H_Sensor <= (H_Target + H_Offset))
5    AND (H_Sensor >= (H_Target - H_Offset)) THEN
6    H_Actuator := FALSE;
7  END_IF;
8
9  //Rotational (R) movement towards NFC
10 R_Target := NFC_Rotational;
11 R_Actuator := TRUE ;
12 IF (R_Sensor <= (R_Target + R_Offset))
13   AND (R_Sensor >= (R_Target - R_Offset)) THEN
14   R_Actuator := FALSE;
15 END_IF;
16
17 IF (H_Sensor <= (H_Target + H_Offset))
18   AND (H_Sensor >= (H_Target - H_Offset))
19   AND (R_Sensor <= (R_Target + R_Offset))
20   AND (R_Sensor >= (R_Target - R_Offset)) THEN
21   H_Actuator := FALSE;
22   R_Actuator := FALSE;
23   #li_StepCase := 210;
24 END_IF;
```

Listing 2: The PLC code of state S_3 shown in Figure 3.

(a) Program Dependency Graph (PDG)

Condition	toState
H_Sensor <= (H_Target + H_Offset)) AND (H_Sensor >= (H_Target - H_Offset)) AND (R_Sensor <= (R_Target + R_Offset)) AND (R_Sensor >= (R_Target - R_Offset) AND H_Actuator = FALSE AND R_Actuator = FALSE	li_StepCase = 210

(b) Transition Table

Figure 5: The program dependency graph and transition table for the state S_3, extracted from Listing 2.

(SS) indicates the state from which the transition condition is verified to move the ICS to the Destination State (DS). For instance, if the ICS is in state S_3, and the horizontal and rotational sensors values indicate the VGR has reached the NFC position, the ICS moves to state S_4.

5.2 State-aware Code-level Invariants

SAIN leverages the FSM of the PLC program to extract each state's distinct properties, which become invariants of that state. From the inter-state characteristics (state transition conditions), we define (1) *state identification signatures* that enable identifying the current ICS state at runtime and (2) *inter-state invariants* that allow checking the validity of state transitions. From the intra-state characteristics (the PLC variables in a specific ICS state), we generate *intra-state invariants* that define the properties/behaviors intrinsic to that state.

Algorithm 2 State Signature Generation

Input: Finite State Machine (FSM)
Output: State Signature Table

1: Initialize an empty State Signatures Table
2: Identify all paths in FSM using Depth-First Search (DFS)
3: **for** each path in the FSM **do**
4: **for** each state in the path **do**
5: Extract transition conditions leading to the state
6: Accumulate conditions into signature
7: **end for**
8: Remove redundant conditions from signature
9: Store the signature in State Signature Table
10: **end for**
11: **return** State Signature Table

Table 3: State signatures of the delivery process states.

State	H	V	R	W	S
S_1	0	0	0		
S_2	Input	Input	Input		
S_3	Input	Input	Input	√	
S_4	NFC	Input	NFC	√	
S_5	NFC	NFC	NFC	√	
S_6	NFC	NFC	NFC	√	√
S_7	NFC	NFC	HBW	√	√
S_8	HBW	HBW	HBW	√	√

H: Horizontal sensor, **V**: Vertical sensor, **R**: Rotation sensor, **W**: Workpiece collected, **S**: NFC scanned.

5.2.1 ICS State Signatures

An ICS state signature consists of a set of PLC variables and the unique values they take for the ICS to transition to that specific state. In the FSM, the transition conditions are designed to create a unique path to a state, guaranteeing that no two states can be reached using the same combination of transition conditions. Therefore, the combination of the transition conditions generates a unique signature for a state.

From the FSM, SAIN collects PLC program variables from the transitions leading to each state and specifies their value or range during that state. By checking these variables during runtime, SAIN determines the current ICS state. Algorithm 2 outlines state signature generation from the FSM. The algorithm first traverses the FSM using the depth-first search method to identify all distinct paths (Line 2). A path is a sequential series of states within the FSM. For each state, SAIN combines the state transition conditions leading to that specific state (Line 5-6). This combination forms a signature that encapsulates the sequence of conditions leading to a state. If there are multiple paths leading to the same state, it generates multiple signatures for that state. SAIN eliminates any repetitive conditions found in the signature, ensuring that each signature is concise and unique (Line 8).

Table 3 presents the state signatures for the delivery process, extracted from the transition conditions in Table 2. Each signature is unique to the corresponding state, e.g., when SAIN observes the signature "H=NFC, V=NFC, R=HBW, W=√, S=√", it determines that the current state is S_7.

5.2.2 Intra-state Invariants

Intra-state invariants are rules that apply to a specific ICS state to maintain its integrity. Each ICS state is programmed to execute specific operations using the sensing, configuration, and actuation variables. If an ICS state deviates from its designated operations at runtime, intra-state invariants are violated.

SAIN derives two types of intra-state invariants: single-variable invariants and multi-variable invariants. A single-variable invariant specifies the allowable value range for an individual variable within a state. For instance, within a state, a configuration variable is restricted to hold only the value "900". A multi-variable invariant involves a set of inter-related sensing, configuration, and actuation variables, along with their respective value ranges, in a state. A multi-variable invariant is composed of two sides. The right side has the actuation variable, and the left side has variables that can impact the actuation variable's value. To determine the actuation variables, SAIN checks if a variable has only incoming edges in the PDG (defined in Section 5.1.2). To determine the variables on the left side of the invariant, SAIN finds all variables with outgoing edges directed toward the actuation variable.

Example. Listing 2 represents a code snippet for the state S_3 of Figure 3. The code segment first initializes the target positions for the VGR's horizontal and rotational movements, represented by variables H_Target and R_Target, respectively. It then sends control signals to the respective actuators. After sending the control signals, it checks the readings from both the horizontal sensor (H_Sensor) and the rotational sensor (R_Sensor). If both the horizontal and rotational sensor readings fall within their respective target ranges, it indicates that the VGR has reached its desired positions for both horizontal and rotational movements. In this case, the code segment sets the corresponding actuators, H_Actuator and R_Actuator, to false. This action deactivates the actuators, stopping further movement and indicating that the desired movements have been performed successfully. From Listing 2, SAIN derives the following intra-state invariants:

- IntraS3$_1$ (For the Horizontal (H) Actuator Start): *If the "H_Sensor" is within the range [H_Sensor_Min, H_Sensor_Max], then "H_Actuator" is TRUE.*
- IntraS3$_2$ (For the Rotational (R) Actuator Start): *If the "R_Sensor" is within the range [R_Sensor_Min, R_Sensor_Max], then "R_Actuator" is TRUE.*
- IntraS3$_3$ (For the Horizontal (H) Actuator Stop): *If the "H_Sensor" is within the range [H_Target - H_Offset, H_Target + H_Offset], then "H_Actuator" is FALSE.*
- IntraS3$_4$ (For the Rotational (R) Actuator Stop): *If the "R_Sensor" is within the range [R_Target - R_Offset, R_Target + R_Offset], then "R_Actuator" is FALSE.*

5.2.3 Inter-state Invariants

Inter-state invariants are rules that indicate valid state transitions. Each state in an ICS is programmed to transition to another state only when certain conditions are satisfied. If a state changes without meeting such conditions, the corresponding inter-state invariant is violated.

SAIN leverages the state transition conditions extracted from the PDG in Section 5.1.2 to derive the inter-state invariants. In contrast to the intra-state invariants that define the ICS properties/behaviors that must be satisfied within a state, inter-state invariants determine the conditions necessary before the ICS can transition to the next state. For instance, in Listing 2, which shows a code snippet for state S_3 from Figure 3, SAIN derives the inter-state invariant defining the transition condition from state S_3 to S_4.

- InterS3$_1$ (Transition from S3 to S4): *If both "H_Sensor" and "R_Sensor" are within their respective target ranges [H_Target-H_Offset, H_Target+H_Offset] and [R_Target-R_Offset, R_Target+R_Offset] and both "H_Actuator" and "R_Actuator" are FALSE, then li_StepCase = 210.*

Intra-state and inter-state invariants complement each other to support state-aware ICS integrity enforcement. Intra-state invariants pertain to the correctness of operations within a state to maintain ICS integrity, whereas inter-state invariants ensure the legitimacy of transitions between ICS states.

5.3 Invariant Quantification

Invariant quantification involves assigning concrete numerical bounds to variables in an invariant template. Invariant templates extracted from the PLC code as described in Section 5.2 may leave their bounds unresolved. SAIN quantifies them using data traces partitioned by state to ensure the bounds are state-aware and hence tighter compared to those in state-agnostic invariants. To this end, SAIN partitions the entire ICS operation traces into state-specific sub-traces, which are then mined to derive concrete variable value bounds.

The system-level ICS data traces encompass all benign operations of the ICS, under all ICS states. SAIN partitions the data traces according to the state transition conditions (derived from the PLC code). The algorithm to partition system-level data traces into state-specific sub-traces involves traversing the traces and comparing the variable values with the state transition conditions. Particularly, the algorithm detects state transitions by identifying the points where the conditions are met and records the corresponding indices in the data traces. From these detected state transition points, the algorithm then partitions the data traces into multiple sub-traces, each corresponding to a specific state.

SAIN then quantifies the "unresolved" invariant templates with state-specific sub-traces using the data mining tool Quantminer [41]. Incorporating the invariant templates (i.e., invariants with unresolved bounds) and the partitioned sub-traces into the data mining process leads to state-aware invariants with concrete, tight PLC variable value bounds. An invariant template is a predicate. For example, a single-variable invariant template may have the form $\# < V < \#$, where V is a variable and # is a numeric value. For a multi-variable invariant, its template defines the relation between sensing, actuation, and configuration variables. The data mining tool then sets the numerical bounds in the invariant templates using the state-specific sub-traces. For instance, the quantified intra-state invariants from Listing 2 are:

- IntraS3$_1$ (For the Horizontal (H) Actuator Start): *If the "H_Sensor" is within the range [0-885], then "H_Actuator" is TRUE.*
- IntraS3$_2$ (For the Rotational (R) Actuator Start): *If the "R_Sensor" is within the range [40-691], then "R_Actuator" is TRUE.*
- IntraS3$_3$ (For the Horizontal (H) Actuator Stop): *If the "H_Sensor" is within the range [890,910], then "H_Actuator" is FALSE.*
- IntraS3$_4$ (For the Rotational (R) Actuator Stop): *If the "R_Sensor" is within the range [695,705], then "R_Actuator" is FALSE.*
- InterS3$_1$ (Common Condition for Both Actuators): *If both "H_Sensor" and "R_Sensor" are within their respective target ranges [890,910] and [695,705] and both "H_Actuator" and "R_Actuator" are FALSE, then li_StepCase = 210.*

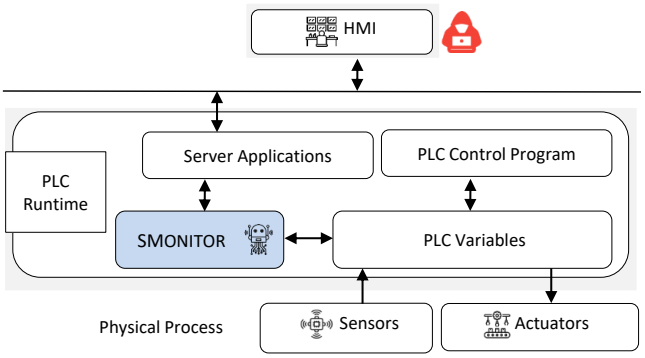


Figure 6: The deployment of SMONITOR in an ICS.

5.4 SAIN Monitor

SAIN enforces the extracted state-aware invariants using a monitoring agent (SMONITOR), implemented within the PLC runtime, which checks external accesses to PLC variables. Figure 6 shows the placement of SMONITOR in an ICS, and Figure 7 illustrates the operation steps of SMONITOR.

For a given server application, SMONITOR first performs use-definition chain analysis to identify the functions that can access PLC variables. After identifying these functions, it instruments the target functions to invoke SMONITOR when the function is called. This allows it to check variable update requests against SAIN's state-aware invariants. To achieve this,

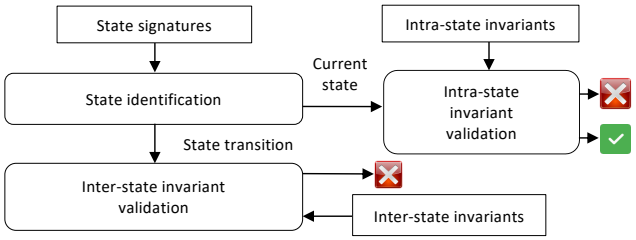

Figure 7: Operation steps of SMONITOR.

Algorithm 3 Run-time ICS State Identification

Input: PLC variables
Output: Current state

1: Load `Signatures` at PLC Runtime startup
2: **for** each `signature` in `Signatures` **do**
3: Compare `signature` with the real-time PLC variables values
4: **if** a `signature` matches the PLC variable values **then**
5: Mark the `signature`'s state as `Current state`
6: **end if**
7: **end for**
8: **return** `Current state`

SMONITOR performs two operations: (1) state identification, and (2) intra-state and inter-state invariant validation.

State Identification. SMONITOR determines the current ICS state by comparing state signatures with current variable values. Algorithm 3 shows the process of identifying an ICS state. State signatures formatted as strings are loaded from the PLC runtime database at the start of the PLC runtime (Line 1). SMONITOR then interprets them through the expression parsing technique [35] and compares them with the real-time PLC variable values (Line 3) to identify the current state of the ICS (Line 5). After identifying the initial state of the ICS, instead of using the state signatures, SMONITOR keeps track of the state transitions to determine the subsequent ICS states. This approach allows it to verify only the specific intra-state and inter-state invariants related to the current state, reducing the number of invariants that need to be checked. Thus, this approach ensures that SMONITOR introduces minimal delays and does not affect the operation of the ICS at runtime.

Intra-State and Inter-State Invariant Validation. For a remote PLC variable update request, SMONITOR leverages the current state to check the intra-state invariants under that state. It first verifies the request against single-variable intra-state invariants. If the request passes this initial check, it then evaluates the variable update request against the multi-variable invariants. For inter-state invariants, SMONITOR checks whether the variable update request causes a state transition by checking whether the updated variable appears in the state transition conditions in the FSM. It then verifies the variable update requests that cause a state transition against the inter-state invariants. If an invariant violation is detected, the monitor denies the variable update request and alerts the operator.

6 Implementation

We implement SAIN in C# with the following components. (1) A static analysis tool that takes the PLC program (ST or SCL) and extracts state identification signatures and intra-/inter-state invariant templates. (2) A data partitioning tool to split system-level data traces into state-specific sub-traces. (3) To quantify invariant templates, we leverage a data mining tool Quantminer [41]. SAIN enhances the data mining process by providing invariant structures and integrating the state-specific sub-traces for mining, allowing us to derive state-aware invariants with tight bounds. (4) A PLC-based monitor, developed in C, compatible with the OpenPLC runtime to check and enforce the state-aware invariants.

7 Evaluation

7.1 Experimental Setup

We evaluate SAIN on two ICS testbeds. The first is the FT manufacturing plant [15], managed by the Unipi PLC [46] equipped with OpenPLC runtime. FT is a suitable evaluation platform as it includes diverse software components, sensors, and actuators with close fidelity to real-world plant operations. The second testbed is the Tennessee Eastman chemical plant simulator [17]. This simulator integrates OpenPLC with an ST application, a Human-Machine Interface (HMI), and the Modbus/TCP protocol. We run SAIN's offline components (i.e., ICS state identification and state-aware invariant generation) on a laptop running Windows 10 (64-bit) and equipped with 16 GB of memory and an Intel(R) Core(TM) i7-8550U processor operating at 3.79 GHz.

Data Trace Collection. We collect data traces (sensing, actuation and configuration variable values) over a 12-day period from ICS plants operating 24/7, through PLC runtime logging mechanisms. For the first ten days, we operated the plants under normal conditions without attacks. We use the traces from the first two days to quantify the invariants and the last eight days to evaluate whether SAIN causes false alarms (i.e., false positives). During the last two days, we perform attacks to evaluate SAIN's attack detection performance. Throughout this period, we constantly log and transfer PLC variable data to a historian server[2].

ICS Attacks Performed. Table 4 presents the 17 attacks we perform on the two ICS testbeds. Our attacks align with our threat model; we exploit the HMI and send malicious variable update requests to the PLC. Our attacks encompass sensor variable manipulation (S), false configuration injection (C), and malicious actuator commands (A). Particularly, in 9 attacks, we manipulate sensor variables; in 11 attacks, we

[2]We make the data traces publicly available to foster future work. https://github.com/purseclab/SAIN.

Table 4: Overview of attacks for SAIN evaluation.

ID	Description	Manipulated* S	A	C	Type†	P
A_1	Start horizontal movement while VGR can just rotate; VGR & HBW collide.		√	√	Intra-State	√
A_2	Rotate the VGR towards the HBW instead of the NFC; the VGR collides with the HBW during NFC operations.			√	Intra-State	√
A_3	Place the MPO robot in a position where only the VGR can work; the VGR and MPO robots collide.	√	√	√	Intra-State	√
A_4	The VGR vacuum turned off during delivery; the workpiece falls at a random location.		√		Intra-State	
A_5	Spoof the VGR rotation sensor to avoid its benign stop; VGR stops at no man's land.	√			Intra-State	√
A_6	VGR relocates to an invalid home position after order completion; a collision occurs for the next order.		√	√	Intra-State	
A_7	Move the MPO robot to an invalid position; safety hazard.	√	√	√	Intra-State	
A_8	Halt the NFC scan operation; the delivery process halts.	√	√	√	Intra-State	
A_9	Send a false signal that the container is available while the VGR waits to drop an item on the conveyor; collision		√		Intra-State	
A_{10}	Continuously manipulate the VGR rotation speed to swing the workpiece; wear and tear of components	√	√	√	Intra-State	
A_{11}	Activate the MPO heating station; safety hazard.	√	√	√	Intra-State	
A_{12}	Rotate VGR to its maximum limit, exceeding the allowable range for normal plant operation; safety hazard.	√	√	√	Intra-State	
A_{13}	Move the HBW robot to a point that is not allowed in normal plant operation; safety hazard.	√	√	√	Intra-State	
A_{14}	Start a new state before finishing the current state; interrupting the planned sequence of activities.			√	Inter-State	
A_{15}	Transition to an unspecified state; stopping the plant operation.			√	Inter-State	
A_{16}	Raise the boiler pressure over the established safety threshold; explosion.			√	Intra-State	
A_{17}	Halt the product development process; decreasing output	√			Intra-State	

*S: sensor, A: actuator, C: configuration, †Intra: Intra-State attack, Inter: inter-state attack. $A_1 - A_{15}$ are attacks against the Fischertechnik manufacturing plant, and $A_{16} - A_{17}$ are attacks against the chemical plant.

manipulate actuator variables; in 13 attacks, we manipulate configuration variables; and in 9 attacks, we manipulate multiple PLC variables (e.g., sensor and actuator variables). These attacks show that stealthy attackers can bypass the loosely bounded invariants and cause damage to the ICS.

We also conduct 4 physics-aware attacks, in which we follow the methodologies outlined in the prior work [19, 28, 47] to minimally manipulate the PLC sensing, configuration, and actuation variables in each scan cycle by closely following the expected physical behavior of the ICS. Our attacks also align with the MITRE ATT&CK techniques for ICS [32], such as Control Manipulation (T831), Unauthorized Command Message (T1047), and Modify Parameter (T817). The MITRE ATT&CK framework for ICS defines adversary tactics, techniques, and procedures used against ICS in the real world. Since our attacks align with the MITRE framework, they can be generalized to other ICS platforms. Our attack vectors are similar to those adopted in prior ICS security efforts [49, 52].

We categorize the attacks performed into two types: intra-state and inter-state. In an intra-state attack, the attacker keeps the ICS in a correct state while manipulating the PLC sensing, configuration, and actuation variables in a way that could result in an unintended action within that current state. In an inter-state attack, an attacker manipulates a PLC program variable to cause either a *premature* or *invalid* state transition within the ICS. A premature state transition occurs when an ICS transitions to the next state before the current state is complete. An invalid transition occurs when an ICS transitions to a state that is not logically sequenced according to the PLC control program's FSM. We implement both types of inter-state attacks to show the generality of SAIN in detecting attacks that cause premature and invalid state transitions.

Research Questions. We evaluate SAIN by focusing on the following research questions:

RQ1 What is the attack detection performance of SAIN?

RQ2 What is the comparison of attack detection performance between SAIN and state-of-the-art methods?

RQ3 How many false positives do SAIN and state-of-the-art methods cause?

RQ4 What is SAIN's state-aware invariant generation time?

RQ5 What is the comparison of the number of validated invariants between SAIN and the state-of-the-art?

RQ6 What is SAIN's runtime performance overhead?

7.2 Effectiveness of SAIN

7.2.1 Attack Detection Performance (RQ1)

SAIN leverages state-aware invariants with tight bounds to detect and mitigate all 17 attacks. These attacks cover intra-state, inter-state, and physics-aware attacks.

In intra-state attacks, the attacker performs an operation that is allowed when considering the overall ICS environment but not in a specific ICS state. For instance, A_1 is an intra-state attack in which the attacker starts the horizontal movement of the VGR. During this attack, the horizontal movement of the VGR remains within the valid system-level bounds but causes the VGR and HBW to collide when it is triggered in a specific ICS state. In the ICS states where this movement is not allowed, SAIN detects this attack as the following invariant is violated: *H_Actuator = False*. As another example, A_{16} is an intra-state attack in which the attacker manipulates the boiler threshold to a level that is prohibited in the overall chemical process. SAIN detects this attack through the single variable invariant *Pressure[55295-55302]*, since the threshold exceeds the limit during the attack.

In inter-state attacks, the attacker manipulates PLC variables to follow an unexpected control-flow path. As an example of a premature state transition attack, A_{14} is an inter-state attack in which the attacker initiates a state transition before the current state, S_3, is completed. As an example of an invalid state transition attack, A_{15} is an inter-state attack in which the attacker initiates a state transition to S_{10}, which is an invalid transition from S_6. Since SAIN derives inter-state invariants from state transition conditions that need to be fulfilled before the transitions to the next state, SAIN detects these attacks.

We present two case studies in Section 7.4 to further detail how SAIN detects an intra-state and an inter-state attack.

In physics-aware attacks, the attacker manipulates the PLC variables with minimal deviation from the benign values. For example, in the attack A_5, the attacker manipulates the VGR's rotational movement sensing variable (*R_Sensor*) close to its benign values, eventually causing a collision between the VGR and HBW. SAIN defines tight upper and lower bounds for the VGR's rotational movement sensing variable for each state (S) as follows.

$$0 \leq S_1 \leq 30 < S_2 \leq 40 < S_3 \leq 705 < S_4, S_5 \leq 720 < S_6 \leq 5350$$

These tight bounds are sensitive even to stealthy manipulation of variable values. Specifically, SAIN detects this attack through the invariant bounds *R_Sensor[0-30]* for state S_1, as the variable's manipulations exceed the upper bounds. The attacker increases the *R_Sensor* value in the benign range of 1.5 to 2.1 at each scan cycle, and SAIN detects this attack when it becomes 30.1 before any damage to the plant.

As another physics-aware attack example, in A_1, the attacker stealthily manipulates the actuator and configuration variables to initiate the VGR's horizontal movement during state S_6. Particularly, the attacker increases the *H_Target* variable from its benign value 900 by 0.1-0.3 in each scan cycle until it reaches 960 and sets the *H_Actuator* variable to True, to cause a collision between the VGR and HBW. For state S_6, SAIN's state-aware invariants specify that *H_Target* must be within the [890-910] range and *H_Actuator* must be False and, therefore, SAIN detects this attack.

7.2.2 Attack Detection Comparison (RQ2)

We compare SAIN with two state-of-the-art ICS invariant generation methods, Feng et al. and VetPLC because they demonstrate better performance in generating comprehensive ICS invariants compared to prior approaches. We reimplemented both of these approaches. To ensure the correctness of our implementations, we extracted invariants from data collected from our testbeds and integrated their invariants within the PLC runtime. We then evaluated their ability to detect ICS attacks in which the attacker performs an operation that is not allowed during the entire ICS operation. Our results indicate that they detect such attacks with high accuracy, consistent with the results reported in their papers.

Table 5 presents the attack detection comparison between SAIN and the state-of-the-art methods. As detailed in Section 7.2.1, SAIN's state-aware invariants detect and mitigate all 17 intra-state and inter-state attacks. In contrast, Feng et al. detects 5/17 (29%) attacks, while VetPLC detects 6/17 (35%) attacks. Both Feng et al. and VetPLC prevent attacks where the invariants derived from system-level data traces are violated. VetPLC, which extracts temporal invariants, is more effective when the attack violates the timing constraints between the PLC variables.

7.2.3 SAIN's False Positive Performance (RQ3)

False positives occur when benign variable updates are flagged as attacks, causing unnecessary alerts. Table 6 presents the false positive rates of SAIN and state-of-the-art invariant derivation methods. For the FT manufacturing plant Feng et al. generates 51% false positives, VetPLC generates 25% false positives, and SAIN generates 2% false positives. For the chemical plant, Feng et al. generates 2% false positives, VetPLC, and SAIN generates 1% false positives.

We observe that false positives in Feng et al. and VetPLC are primarily caused by either the incorrect definition of invariant structures or the underestimation of the invariant data bounds, with the majority resulting from the former issue. For instance, Feng et al. derives its invariant structures solely from data traces, causing it to derive invariants that represent the *correlations* between PLC variables. However, we observe that, especially in the FT manufacturing plant, the correlations between the PLC variables vary based on ICS

Table 7: Average time (hh:mm:ss) to analyze the PLC program of Fischertechnik (FT) and chemical (CP) plants to extract state-aware invariants.

ICS Testbed	AST Construction	FSM Extraction	State Signatures	Invariant Templates	Trace Partitioning	State-aware Invariant Quantification
FT	00:00:17	00:01:30	00:00:45	00:02:25	02:10:00	00:17:00
CP	00:00:01	00:00:09	00:00:04	00:00:11	00:24:00	00:05:00

states. Such variations in correlations across ICS states cause Feng et al. to have high false positives in certain states. For example, FT manufacturing plant traces show a correlation between the VGR horizontal sensor, vertical sensor, and vertical actuator. Feng et al. derives an invariant based on this correlation. However, in state S_8, only the vertical sensor is correlated with the vertical actuator. This causes Feng et al.'s invariant to generate false positives in state S_8.

Additionally, state-agnostic analysis generates conflicting invariants when the occurrence of events varies across different states. For instance, if the order of events is sequential in one state but parallel in another state, an invariant designed for sequential events generates false positives in the other state. In contrast, SAIN does not generate false positives due to incorrect invariant structures because it derives state-aware invariant structures directly from the PLC code that controls the ICS process. Thus, it only generates false positives when it derives invariants with overly tight bounds.

7.3 Performance Evaluation

7.3.1 Invariant Generation Overhead (RQ4)

Table 7 presents the processing time for each stage of SAIN's state-aware invariant generation. We found that SAIN's processing overhead increases with the number of ICS states and the amount of data traces used for invariant quantification. For instance, FSM extraction takes 90 seconds for the FT manufacturing plant and 9 seconds for the chemical plant. As another example, partitioning the data traces takes 2 hours and 25 mins for FT and 17 mins for the chemical plant.

7.3.2 Number of Validated Invariants (RQ5)

Table 8 shows a comparison between SAIN and state-of-the-art methods in terms of the number of invariants validated. For instance, the "Average" column indicates the average number of invariants that are checked in response to a variable update request. SMONITOR, upon receiving a variable update request, only validates the specific set of invariants that are relevant to the updated variable. On average, it validates 5 invariants for the FT manufacturing plant and 3 for the chemical plant. In comparison, Feng et al. validates 134 invariants for the FT manufacturing plant and 11 for the chemical plant, while VetPLC validates 35 invariants for the FT manufacturing plant and 7 for the chemical plant. SAIN validates a smaller number of invariants because it selectively validates invariants according to the current ICS state. Since each ICS state is designed to execute a limited set of operations, it reduces the number of invariant validations.

Table 8: Number of invariants validated for variable updates in the Fischertechnik (FT) and Chemical (CP) plants.

Testbed	Method	Min.	Average	Max.
FT	Feng et al.	43	134	315
	VETPLC	11	35	83
	SAIN	1	5	11
CP	Feng et al.	7	11	27
	VETPLC	3	7	12
	SAIN	1	3	5

Table 9: Scan cycle time (ms) of PLCs controlling Fischertechnik (FT) and Chemical (CP) plants.

ICS Testbed	Normal Cycle Time	Time Limit	Method	Min.	Average	Max.
FT	36	150	Feng et al.	44.46	57.48	84.3
			VETPLC	38.42	43.7	49.26
			SAIN	36.22	37.1	38.42
CP	5	25	Feng et al.	6.54	7.42	10.94
			VETPLC	5.66	6.54	7.64
			SAIN	5.22	5.56	6.10

7.3.3 Runtime Performance Overhead (RQ6)

To assess the impact of SAIN's state-aware monitoring on the Fischertechnik and chemical plants, we measured the variations in PLC scan cycle times in two scenarios.

- Normal Operation: When SMONITOR is inactive.
- SMONITOR: When SMONITOR remains active and checks invariants whenever the PLC receives a variable update request from an external source.

To track the scan cycle time in the PLC runtime, we create variables to record the start and end times of each cycle. We use the CLOCK_MONOTONIC function for precise timing. At the beginning of each cycle, we note the timestamp, let the PLC perform its operations, and then mark the timestamp again at the end. The difference between these two timestamps provides us with the cycle's duration.

Table 9 shows the PLC scan cycle time in both plants during their normal operation, with an active SMONITOR, and the maximum allowed execution time required for the safe operation of the plants. We derive the maximum allowed execution time for each plant from their PLC configurations and developer documentations. Our measurements show that the scan cycle time with SMONITOR for the FT manufacturing plant is 37.1 ms, which slightly differs from the normal operation of 36 ms. The normal operation and SMONITOR monitor scan cycle times for the chemical plant are less than 6 ms. The overall maximum allowed execution time is 150 ms for the FT manufacturing plant and 25 ms for the chemical plant. Therefore, our experiments show that SMONITOR's

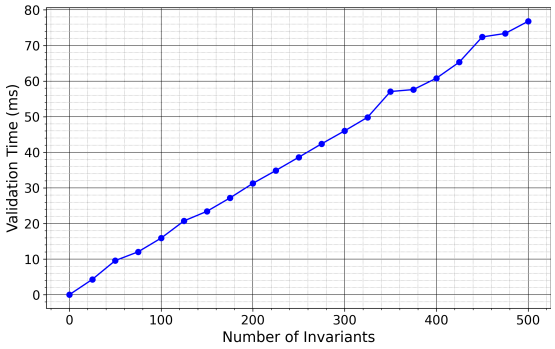

Figure 8: Validation Time vs. No. of Invariants.

runtime performance overhead is minimal and complies with the maximum allowed scan cycle time limits.

To assess the real-world impact of SAIN's runtime overhead, we evaluate the change in invariant validation overhead as the number of invariants increases. Figure 8 shows a linear relationship between the number of invariants and the invariant validation time. Considering that SAIN requires the validation of only a small number of invariants, it remains highly suitable for real-world ICS. Even with 500 invariants, SAIN's invariant validation overhead is below the maximum execution time allowed in the FT manufacturing plant.

7.4 Case Studies

We present two case studies, an intra-state and an inter-state attack, to demonstrate how SAIN's state-aware invariants with tight bounds detect these attacks.

7.4.1 Case Study 1: Intra-State Attack

In attack A_{10}, the attacker constantly increases and decreases the vertical movement speed of the VGR. This speed manipulation over time causes the workpiece hanging from the VGR to swing while the VGR moves.

Stealthiness. Unfortunately, both Feng et al. and VetPLC cannot detect this attack because the attacker remains within the allowed system-level bound ([500-800]) for the VGR's vertical speed, and does not violate the timing between events.

The VGR's vertical speed in normal plant operation varies based on the ICS states. The PLC adjusts the speed to match the specific needs of the ICS process. In some states, the speed increases, while in others it decreases to ensure synchronization within the ICS. Feng et al.'s state-agnostic invariants merge such speed variations into a generic bound, and do not consider that the speed bounds could change when the ICS state changes. Therefore, it fails to detect this attack.

In total, it takes the VGR 10 seconds to reach the HBW with the workpiece during the benign operation of FT. While the attacker modifies the VGR speed, they employ both fast and slow speeds to ensure that the 10-second timing is not violated while the workpiece swings and falls. This ensures that the attack is stealthy against timing-based invariants (e.g., those extracted by VetPLC).

SAIN Detection. To detect this attack, SAIN leverages a tightly bounded invariant regarding the VGR's vertical speed while it carries a workpiece to the HBW.

7.4.2 Case Study 2: Inter-State Attack

In the FT manufacturing plant, the PLC program uses a variable *li_StepCase* to determine which state should be executed. In attack A_{14}, an attacker prematurely sets *li_StepCase* to "210", initiating the next state before the current one is finished. This causes the VGR robot to begin its vertical movement while still completing its horizontal and rotational movements, leading to a collision with the HBW station.

Stealthiness. Unfortunately, both Feng et al. and VetPLC cannot detect this attack due to their state-agnostic invariants. During normal plant operation, the variable *li_StepCase* is set to "210" multiple times in different ICS states. Consequently, the state-agnostic invariant merges the constraints into a single invariant that sets the *li_StepCase* variable to "210". This enables the attacker to manipulate the *li_StepCase* variable before it was supposed to change in its intended state without being detected by the invariants of these works.

SAIN Detection. SAIN detects this attack through a state-aware invariant that ensures *li_StepCase* changes only when the state transition condition is met. As this attack causes the premature state transition, SAIN detects it.

8 Limitations And Discussions

False Positives. SAIN reduces false positive rates compared to state-of-the-art invariant generation methods, yet it still faces the challenge of completely eliminating false positives. As discussed in Section 7.2.3, SAIN false positives occur mainly due to overly tight bounds. This could be addressed by ensuring that the data traces used to quantify invariants are complete. However, collecting complete traces in ICS environments might be challenging due to different environmental conditions and the complexity of capturing diverse ICS processes. We note that this limitation exists in all data-driven approaches in ICS security [14, 30], which may be mitigated by other forms of ICS knowledge/invariants (e.g., formal or natural language specifications by vendors).

Adapting to Code Updates. If the PLC code is updated, SAIN's invariants must be regenerated to adapt to the new control logic. However, in ICS, code updates are infrequent for two main reasons. First, the code running on PLCs is typically stable and well-tested before deployment. Second, the process of updating the PLC code often involves downtime, which could be costly in ICS [7, 42].

Potential Race Conditions. Race conditions in PLCs occur when variable updates depend on the timing or order of execution of multiple code paths that manipulate shared variables. SAIN does not introduce any race conditions into the PLC. Particularly, SAIN's invariants in SMONITOR are employed in code blocks intended for external access to PLC variables and do not involve any write operations on the variables; therefore, it avoids introducing new race conditions.

Potential False Negatives. SAIN validates PLC invariants when it receives external variable update requests via the HMI. An attacker who has physical access to ICS devices such as sensors and actuators can spoof physical sensor and actuator values and bypass SAIN's detection. This limitation is common in ICS security approaches that operate on the PLC or HMI [21, 25]. In future work, we will extend the SAIN runtime monitor to validate sensor-to-PLC and PLC-to-actuator communication with state-aware invariants, under a more advanced threat model.

9 Related Work

We compare SAIN with the prior work in Table 10. For ICS security, several static analysis approaches have been proposed to analyze the PLC code and identify vulnerabilities that may lead to violations of predefined security policies [6, 30, 37]. Yet, the lack of runtime information poses challenges for these approaches, resulting in overapproximations that cause wrongly identified vulnerabilities and underapproximations that cause missed vulnerabilities. For instance, when an attacker manipulates runtime temperature sensor readings, static analysis methods may not detect this attack because they lack real-time sensor data. To address the limitations of static analysis, prior work has explored extracting invariants by mining benign execution traces of a plant through statistical learning techniques [4, 14, 23, 25] and machine learning models [9, 26]. These state-agnostic invariants are derived solely from data traces without explicitly considering the specific states defined in the PLC code. This limitation makes them vulnerable to stealthy evasion attacks, as demonstrated in Section 7.2.

Recent works have proposed temporal invariant mining approaches that capture the temporal dependencies between system events and use event timings as safety requirements [3, 34, 52, 53]. These methods prove highly effective in detecting attacks in which adversaries manipulate the order or timing of events. Yet, some attacks may not involve altering event order or timing. For instance, an attacker can manipulate a robot's speed in such a way that it arrives at its destination on time, but the speed changes cause the robot to drop its payload.

Prior research has also proposed state-aware physics-based attack detection (PBAD) techniques for ICS [19, 47]. These techniques first extract ICS states manually or from data traces. They then model the state-aware physical behavior of the ICS with subspace models and compute runtime residuals, which indicate the deviations between model estimations and real sensor readings. PBAD techniques are highly effective against ICS attacks when the residuals exceed a threshold. Unfortunately, they are less effective against stealthy physics-aware attacks that manipulate the actuator and sensor variables *within* the residuals [20, 36, 44]. In contrast, SAIN derives state-aware invariants for ICS through the combination of program analysis and trace data mining. To achieve this, SAIN extracts an FSM representing the states and state transitions in the ICS through PLC program analysis, and it splits the ICS data traces into state-specific sub-traces and quantifies the invariants with concrete and tighter bounds. Therefore, SAIN complements PBAD techniques by enforcing intra-state invariants with tighter bounds on PLC variables and inter-state invariants that check the validity of state transitions.

10 Conclusions

In this paper, we first show that prior work generates invariants with loose bounds, allowing an attacker to conduct stealthy evasion attacks and avoid detection. We then introduce SAIN, an automated method for generating state-aware ICS invariants with tight bounds that detect such stealthy evasion attacks. SAIN reasons about and enforces the state-aware invariants through a novel PLC-based runtime monitor that detects and mitigates ICS attacks with minimal impact on PLC scan cycle timings. We evaluate SAIN on both Fischertechnik and chemical plants to show its effectiveness in detecting various attacks, including PLC variable manipulation and physics-aware attacks, with minimal runtime performance overhead.

Appendix

A Fischertechnik (FT) Manufacturing Plant

The Fischertechnik (FT) Manufacturing Plant [40] in Figure 9 performs a number of PLC-controlled manufacturing processes. It uses the Siemens S7-1500 PLC and SCL programming language. The same testbed has already been used in other ICS security research efforts [1, 40, 51]. It consists of typical factory components such as a storage and retrieval station, a vacuum gripper robot (VGR), a high-bay warehouse (HBW), a multi-processing station with an oven (MPO), a sorting line with color detection (SLD), an environmental sensor, and a swiveling camera (SSC).

The factory operation is divided into two modes: (1) *Delivery* - A raw workpiece is placed in the input area. When the sensor detects the workpiece, it triggers the VGR to collect it and move it to the NFC reader, where its identification number is read. The VGR then transports the piece to the HBW storage site. (2) *Order* - Users place an order through the dashboard by choosing the desired workpiece. The HBW withdraws the workpiece and positions it for VGR. The VGR transfers the workpiece to the MPO, where it is processed for delivery and finally moved to the delivery location.

Opportunistic Data Flow Integrity for Real-time Cyber-physical Systems Using Worst Case Execution Time Reservation

Yujie Wang, Ao Li, Jinwen Wang, Sanjoy Baruah, Ning Zhang

Washington University in St. Louis

Abstract

With the proliferation of safety-critical real-time systems in our daily life, it is imperative that their security is protected to guarantee their functionalities. To this end, one of the most powerful modern security primitives is the enforcement of data flow integrity. However, the run-time overhead can be prohibitive for real-time cyber-physical systems. On the other hand, due to strong safety requirements on such real-time cyber-physical systems, platforms are often designed with enough reservation such that the system remains real-time even if it is experiencing the worst-case execution time. We conducted a measurement study on eight popular CPS systems and found the worst-case execution time is often at least five times the average run time.

In this paper, we propose opportunistic data flow integrity, OP-DFI, that takes advantage of the system reservation to enforce data flow integrity to the CPS software. To avoid impacting the real-time property, OP-DFI tackles the challenge of slack estimation and run-time policy swapping to take advantage of the extra time in the system opportunistically. To ensure the security protection remains coherent, OP-DFI leverages in-line reference monitors and hardware-assisted features to perform dynamic fine-grained sandboxing. We evaluated OP-DFI on eight real-time CPS. With a worst-case execution time overhead of 2.7%, OP-DFI effectively performs DFI checking on 95.5% of all memory operations and 99.3% of safety-critical control-related memory operations on average.

1 Introduction

Real-time embedded systems play a critical role in modern society, as they are used to control and monitor various safety-critical processes, such as air traffic control, medical operations, and autonomous driving. Besides real-time responsiveness, security of these systems is also essential for safety, where it is widely acknowledged that there is no safety without security [46].

However, due to the constraints on processor speed, the trade-off between performance and security has been a major obstacle in embedded system designs. As a result, to maintain form factor and low cost, security overhead often has to be very small [65]. Overhead from data flow integrity (DFI) ranges from 100% to 200% is often considered prohibitive for most real-time embedded systems.

Real-time Scheduling and Security Opportunities: While there will always be a trade-off between security and performance, there are unique properties in real-time cyber-physical systems offering new opportunities. One key observation comes from the difference between the average execution time and the worst-case execution time (WCET). In real-time systems, the most important property is that all tasks need to complete in a timely manner with no task exceeding its deadline, since there is risk in physical world consequences (such as a plane crashing or a collision with pedestrians). In order to ensure this property, real-time system designers perform schedulability analysis using the WCET of the tasks to ensure all the tasks can complete even in the worst case. However, as the worst case is rare most of the time, the typical runtime of a task is significantly less than its WCET. In our preliminary analysis of eight CPS platforms, the worst case is more than five times of the average case for many tasks. Such difference is often referred to as *slack* in real-time system literature. As a result, after the real-time task finishes its execution, the system often remains idle. Recognizing this opportunity, existing work has explored utilizing such time for additional system checks [25,41] or additional non-critical tasks in mix-criticality systems [36].

OP-DFI: Building on top of the observation that slack opens up new opportunities to improve system security opportunistically, we propose OP-DFI, which takes advantage of slack to perform data flow integrity checks. This allows the deployment of computationally intensive data-flow integrity on real-time embedded platforms without impacting the real-time requirement. Different from existing works that leverage opportunistic execution [25] to perform memory checksum

verification, the targeted security primitive dictates that OP-DFI cannot wait till the task completion and has to be executed as in-line reference monitors for data flow integrity, presenting a fundamentally different set of challenges to meet both the real-time and security requirements.

Technical Challenges and Solutions: The challenges in OP-DFI arise from the need to accurately estimate the amount of slack, formulate a security policy leveraging such slack, and enforce the security policy in runtime.

Challenge 1: Slack Estimation. The key idea behind our slack estimation approach is to leverage program inputs and contexts to eliminate infeasible worst-case execution path (WCEP) for better estimation of slack. However, enumerating all the paths to recalculate the new WCET imposes prohibitive runtime overhead. To address this, path constraints and new WCET are pre-computed and stored in a table. Yet the table can be very large, imposing prohibitive memory overhead. To tackle this, OP-DFI leverages only a small number of constraints at the cost of further under-approximation of slack. To maximize the impact of the limited constraint evaluations, the selection of constraints takes advantage of the predictable nature of CPS and optimizes over the expected input distribution. Furthermore, since slack estimation is under-approximated to ensure real-time requirements are met, this may result in a lack of computation time earlier in the task execution. To tackle this issue, we make the observation that if critical data is isolated, as long as it has not been written, it does not have to be tracked. To minimize runtime overhead, OP-DFI makes use of memory tag extension (MTE) in ARM hardware to perform the hardware-enforced isolation to prevent arbitrary data write, such that it remains possible to turn on DFI for more of these variables. Three sandboxes are maintained, the unprotected variables, the protected variables, and metadata.

Challenge 2: Translating Slack to Security Protection. Effective use of slack for data flow protection requires addressing several technical problems. First, to maximize the security protection of slack, the security policy has to balance between the probability of memory access and the cyber-physical security implications of the memory location to decide if it should be included. At the same time, OP-DFI also has to ensure that the constructed security policy does not violate real-time constraints by estimating its impact to the worst-case execution time. Lastly, OP-DFI also has to ensure that the selected data is indeed protected while leaving the rest of the program unchecked. To tackle this, OP-DFI formulates two properties of security coherence, from both spatial and temporal dimensions. The properties are based on the observation that the data corruption of protected variables can only be achieved by either tampering with their dependencies or by modifying them during the time window when they are not protected.

Challenge 3: Runtime Enforcement of Dynamic Policy. Due to changes in security policy over data flow during runtime, the reference monitor must adapt to new sets of data access rules by using different in-line reference monitors. While conceptually simple, implementing this in the system is very challenging, as the security policy and its enforcement are often accomplished via reference monitors in the form of software instrumentation. Updating the policy would modify the program instrumentation, or the reference monitor needs to have sufficient logic to switch between different security policies. Additionally, dynamically self-modifying the binary is not only problematic from the security perspective but also degrades performance due to cache coherence. To address this problem, OP-DFI trades the space for performance. More specifically, OP-DFI keeps different versions of the same code logic but with different levels of policy protection, and dynamically switches to the code with the desired policy.

Evaluation and Outcome: We implement a prototype of OP-DFI to enforce opportunistic DFI on the AArch64 platform. The prototype includes a slack analyzer for input-based slack estimation, a library for runtime enforcement, a customized compiler for automatic program instrumentation, and an optimization engine for optimal security policy generation. We evaluate the prototype on eight real-time CPS platforms. Compared to regular DFI with 184% WCET expansion, OP-DFI with 2.7% overhead can effectively perform DFI checking on 95.5% of all memory operations and 99.3% of safety-critical control-related memory operations on average. In summary, our contributions are:

- We propose a new security primitive, opportunistic DFI, capable of enforcing data-flow integrity by taking advantage of processor reservation for meeting the worst-case execution time of tasks.
- We tackle several technical challenges to design opportunistic DFI, including runtime estimation of slack, balancing security and real-time in slack utilization, as well as runtime enforcement of dynamic policy.
- We implement a prototype[1] and evaluate it on eight real-time CPS platforms to demonstrate its effectiveness.

2 Background

2.1 Real-time System

Real-time systems execute tasks with precise timing constraints [59–61]. In real-time CPSs [63], tasks are often recurring or periodic workloads, each instance of which must complete by a *deadline*, after which a delayed control signal may cause catastrophic results (e.g., a self-driving car crash). A formal guarantee of timeliness is achieved through *schedulability analysis*, which determines whether each instance of every task can complete within its deadline on the target system.

[1] Source code is available at https://github.com/WUSTL-CSPL/OP-DFI

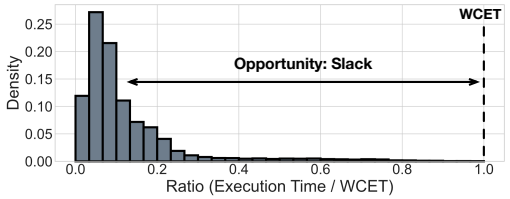

Figure 1: Opportunity in WCET reservation.

To this end, each task's workload is characterized according to its *worst-case execution time* (WCET). Because program execution paths may be input-dependent [37], a common approach to measuring WCET involves statically unrolling loops to derive the longest execution paths [42]. In combination with low-level timing data for basic blocks or functions, each path's execution time may be characterized. The path with the longest execution time, or *worst-case execution path* (WCEP), defines the WCET. Analysis techniques, such as utilization bound tests [39] and response time analysis [31], can then be used to determine the schedulability of a complete task system under the assumption of worst-case execution.

However, individual instances of a task often execute for less than the WCET. This discrepancy is referred to as *dynamic slack*. It can be regarded as the extra computational resource remaining after executing a task instance and can be used on other computations such as security checking [41].

2.2 Software Security

Data Flow Integrity: DFI aims to check whether loaded data is only modified by expected instructions at runtime [18]. Specifically, a software-based DFI mechanism instruments a program to taint bytes written to memory with the corresponding store instruction's ID assigned during compile time. Before any data is loaded from memory at runtime, the reference monitor checks whether the data has been modified by the set of expected instructions, which is obtained through compile-time static analysis.

ARM Memory Tag Extension: ARM Memory Tagging Extension (MTE) [1] is introduced by ARM on the AArch64 platform to provide defense against attacks that try to subvert code to process malicious data. MTE introduces two kinds of 4-bit value tags: address and memory. An *address tag* is stored at the top of each pointer. A *memory tag* is associated with every 16-byte memory region. The address and memory tags will be verified every time an instruction loads or stores data. If two tags are mismatched, a hardware fault will be triggered. Current Linux kernels support configuring whether MTE is enabled on a specific region of memory [2]. MTE also offers user-space instructions for manipulating memory tags. For instance, the instruction `STGP` is a variant of the regular store instruction `STR`. Unlike `STR`, `STGP` stores both the tag and data in memory.

ARM Branch Target Identification: Branch target identification (BTI) aims to mitigate jump-oriented programming (JOP) attacks [5]. With BTI, the targets of indirect branch instructions are enforced to be designated locations, such as the beginning of functions. Therefore, BTI can also be regarded as an efficient but coarse-grained control flow integrity (CFI).

Table 1: WCET reservation on real-time systems

Type	Platform	Hw	Task	# Traces	Ratio (%) (Ave. / WCET)
Drone	PX4 [45]	A53	altitute control	1M	13% (36/275 us)
			navigate	1M	15% (22/141 ms)
	Ardupilot [9]	A53	throttle loop	1M	7.8% (4.0/52.4 us)
			bearing update	1M	5.1% (2.2/43 us)
AV	Turtlebot [53]	A72	laser receive	100K	5.3%(10/187 ms)
			dwa planning	100K	39% (402/1016 ms)
	Autoware [33]	A78	path planning	100K	3.2% (90/2736 ms)
			mission planning	1M	9.9% (28/281 us)
	Jackal [30]	A78	laser handle	1M	14% (109/778 us)
			odometry handle	1M	8.4% (4.6/54.6 ms)
Robot	OpenMani. [48]	A53	trajectory make	3K	28% (4.1/14.2 ms)
			main control	1M	21% (15/70 ms)
	Unitree [54]	A57	fsm control	1M	22% (835/3697 us)
			trottling control	1M	13% (209/1512 us)
	OP3 [48]	A57	walking control	1M	17% (2.8/15.8 ms)
			head control	1M	1.7% (92/5259 us)

3 Motivation

Overhead of Direct Application of DFI: DFI is one of the most powerful tools to defend against advanced attacks, such as data-oriented attacks [17,19]. However, existing DFI implementations often impose an average overhead ranging from 100% to 200% to the program runtime [13, 18]. As a matter of fact, on the eight CPS platforms we studied, DFI leads to an average WCET increase of 184%. To provide a concrete example, *throttle loop* is a safety-critical real-time task within Ardupilot, where full DFI leads to runtime expansion of 125% for WCET. According to the task model from the Ardupilot documentation, the system is no longer schedulable when the overhead is greater than 44%.

Opportunity in Worst Case Execution Time Reservation: While direct application of DFI incurs prohibitive runtime overhead, the difference between WCET and average runtime does provide unique opportunities. To gain a more quantitative understanding of available slack in common safety-critical tasks in existing CPS platforms, we have conducted a measurement study over 16 real-time tasks supporting different CPS functions (navigation, throttle, trajectory, and more) selected from eight most widely studied CPS software across three types of CPS platforms (including drones, autonomous vehicles (AV), and robots) using four different types of processors (ARM A53, A57, A72, and A78). Details of our evaluation setup can be found in Table 1.

Measurement Setup - For each CPS, we select officially released missions to initiate its execution. For drones and autonomous vehicles, the missions involve following a predefined trajectory. For robots, their missions consist of a series of actions, such as standing up, walking, turning around, etc. More details about the concrete set of missions can be found in Appendix C.1. During these missions, we record the ex-

ecution time of two critical tasks. Most tasks are measured and calculated over 1 million loops. Four tasks have fewer traces due to their relatively low task release frequency. The WCET is obtained via aiT TimeWeaver [6], a state-of-the-art timing analysis tool used in the industry. To obtain the WCET of a task, aiT TimeWeaver first unrolls the task's control-flow graph (CFG) into paths based on loop bound information. The tool then leverages Arm CoreSight debugging feature to profile the fine-grained execution time of individual basic blocks. Based on these fragmented timing profiles, it calculates the execution time of the longest path and reports it as WCET.

Observations - As shown in Table 1, the average execution time for different tasks ranges from 1.7% to 39% of WCET, with an average runtime of just 13.9% of the WCET. To understand this from a statistical perspective, Figure 1 shows the distribution of the percentage of task execution time in relation to task WCET. As shown in the figure, 90% of execution time is less than 20% of the WCET. As a result, for a large percentage of the executions, there are ample opportunities to leverage slack to improve the security of the system.

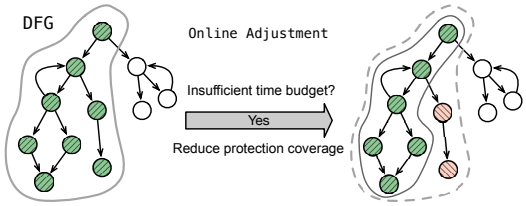

Figure 2: Workflow of opportunistic DFI.

Opportunistic DFI: Due to the large difference between WCET and the average runtime, it leaves a surplus of reserved time in most execution iterations, i.e., slack. However, direct application of existing data flow security primitives also leads to expansion of WCET. To capitalize on this opportunity, we propose a new security primitive, opportunistic DFI, which deploys DFI to perform data-flow checking whenever there is slack. Figure 2 shows the workflow of opportunistic DFI. Specifically, in-line reference monitors, which DFI uses for security checking, are deployed only on a portion of the program such that only a portion of data flows are checked. During execution, slack is monitored to adjust the coverage of DFI. For instance, if the slack is insufficient for the current DFI deployment, it reduces the amount of data flow to check. While the idea is simple, the design has to balance two requirements, timing and security respectively. From a timing perspective, WCET has to remain unaltered. From a security perspective, protection over the data has to be sound when only applied opportunistically over a subset of it. Details of the design are presented in Section 5.

4 Threat Model and System Goal

Threat Model: In this work, we focus on preventing memory corruption, therefore, we follow the common threat model of other DFI works [13, 18, 50, 51], trying to defend against data-oriented attacks [4, 26, 27, 29]. We assume there exists a memory corruption bug in the application software that can be exploited by attackers to read and write memory arbitrarily [3]. Consistent with other works [13, 18, 50, 51], we assume that code injection is prevented using existing memory protection technology such as MMU or MPU, therefore instrumentation cannot be tampered by the attacker. We also make the assumption that it is possible to prevent the instrumentation from being bypassed. This can be realized using software-based CFI implementations [34, 55] or hardware-based methods, such as the BTI feature in ARM [5]. Our design assumes that it's possible to sandbox the program. This sandboxing can be implemented using software-based fault isolation [57] or hardware-based mechanisms, such as ARM MTE [1]. Our implementation leverages the hardware features, ARM BTI and MTE, to enhance efficiency. Additional discussions on how to realize the CFI and sandboxing using a software-only approach are available in Section 11. Although the combination of CFI and sandboxing, such as BTI and MTE, provides powerful protection, the limited granularity of the sandbox still exposes a non-trivial attack surface for data-oriented attacks [44]. Our focus is memory-corruption-based attacks, therefore, hardware attacks [22], side-channel attacks [64], and performance interference attacks [38] are out of our scope. In this work, we focus exclusively on application security, assuming that all privileged software stacks, including the OS, hypervisor, and device firmware, are trusted. Lastly, though DFI is capable of preventing all illegal data flow (i.e data flows that do not follow the known DFG), the goal of OP-DFI is to provide as much data flow protection as possible without violating the real-time constraints, where the quantification of protection can take the form of either the number of read/write instructions or the number of critical variables or memory addresses.

5 OP-DFI Design

While the idea of utilizing slack for security is attractive, making use of such time without impacting the real-time system presents several unique challenges, from estimating the available slack during the execution of the program, to how to apply the slack to ensure data-flow integrity for critical data while maintaining the policy coherence. The system overview is shown in Figure 3.

5.1 On-the-fly Slack Estimation

Slack is defined by the difference between the time it takes to execute a task and its WCET. Such slack is easy to calculate upon the completion of the task, but it is impossible to obtain prior to the completion of the task. On the other hand, to make use of the time for security, the necessary condition is to have an under-approximation of the slack available, such

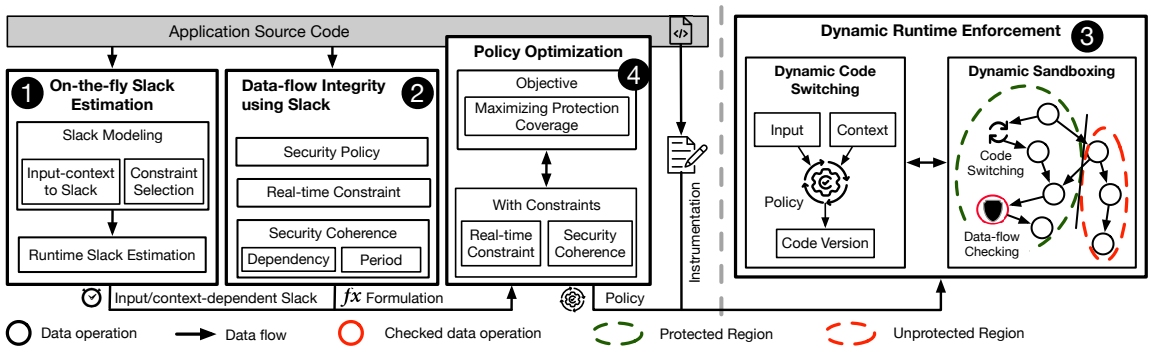

Figure 3: OP-DFI system overview.

that the system timeliness will not be impacted. To do so, we build on top of the observation that the execution time of a task depends on the program inputs (including sensor inputs, external messages, and program memory), assuming performance interference from other processes in the system has already been taken into consideration for the timing profile in the original design. While a subset of inputs are known at the start of the task (referred to as *input*), others will only become available during the execution of the program (referred to as *context*). The key idea behind run-time slack estimation in OP-DFI is that with the input and the known subset of context, then it is possible to prove some of the program paths to be infeasible. If the original WCEP happens to be in the set of infeasible paths, then WCET can be updated to provide a better estimate of the slack.

From Input-context to Slack: OP-DFI first employs symbolic execution to gather symbolic formulas for path constraints (i.e., branch conditions on paths). A subset of the formulas are computed at runtime using both the input and the known subset of context. The result is then considered as an estimate of the execution state. Since the collected formula might only be partially evaluated due to missing context, it is recalculated when more context becomes available, enabling a more accurate state estimation. With the estimated state as an index, the corresponding slack can be looked up from a pre-computed table, which is generated using Algorithm 1. Specifically, for an estimated state, Algorithm 1 checks the feasibility of all paths in the order from longest to shortest, continuing until it encounters a path that cannot be negated. The corresponding slack of that path is then taken as the estimated slack. This estimated slack is an under-approximation of the slack under the current state, as proved in Appendix A.1.

Constraint Selection: Conceptually, contexts can be used to prove that certain paths are infeasible, leading to a better estimate of slack. Therefore, a naive approach would be to insert checkpoints for new slack estimation at every single memory update relevant to the constraint formula. However, directly evaluating the full constraints over all paths incurs significant runtime overhead. An alternative is to encode them into lookup tables, but such a design leads to significant memory overhead and still incurs a non-trivial computational overhead

Algorithm 1: Parametric Estimation of Slack

```
Input: S_Ω                          // constraints eval results
Output: B                           // Worst-case slack estimate
// From long to short path
foreach p_i in Sort({p_1, p_2, ...}) do
    if Infea(p_i, S_Ω) then
        continue                    // Path eliminated
    else
        return WCET − t_i           // Path's slack estimate
```

Note: S_Ω: { $(\omega_0 : r_0)$, $(\omega_1 : r_1)$, ... }, where r_i is the evaluation result for symbolic formula of branch constraints ω_i, and can be true, false or unknown (for missing context). $Infea(p, S_\Omega)$: true if the path condition of p violates S_Ω.

to calculate the table index from memory contexts. As a result, only a subset of constraints can be used. This leads to the problem of which subset should be selected will offer the higher probability of obtaining a better estimate of slack.

A straightforward method to balance overhead is to randomly select a limited number of constraints. However, not all constraints are equally effective. Given that the inputs for CPS typically follow specific distributions, certain path constraints are more frequently effective for path elimination in Algorithm 1. Based on this observation, we employ dynamic profiling to capture the mission-level CPS input distributions, which guides the optimization engine in selecting the constraints that are most effective for the most commonly appearing inputs. The details of the optimization formulation are in Section 5.4. Using this set of constraints, the expected gain in the bounds of slack is optimized over the expected input distribution. This, also in turn, enables more fine-grained code switching and enhances protection. Empirical measurements from our evaluation in Section 8.2 show the proposed method improves slack estimation accuracy by 15.3% on average.

5.2 Data-flow Integrity using Slack

Once an under-approximation of the slack is obtained, it is important to consider how this slack can be used for security. Unlike the conventional data-flow integrity, due to the limited slack, only part of the system can be protected (referred to as

the *protection region* and denoted by θ). Yet this leads to three challenges: 1) From the perspective of security policy, how to select which memory access instructions to instrument, 2) From the timeliness perspective, how to ensure the computational cost of the protection remains within the available slack, and 3) From the perspective of coherency for the protection, how to ensure that the selected data is indeed protected while leaving the rest of the program unchecked?

Security Policy: OP-DFI adopts a security policy π to select the protection target at runtime. The form of π is a mapping function that outputs a set of checked memory operations, θ, based on the estimated execution state S_Ω. This state is calculated using the current input and context, as discussed in Section 5.1. In synthesizing such a policy, there are two factors that govern the selection of memory operations. The first factor is variable usage. Variables not expected to be accessed before the next slack estimation checkpoint are directly included since they do not impact on runtime cost under normal conditions. For variables with uncertain usage, OP-DFI estimates access probability based on input data distribution and prioritizes the variables with higher probabilities. The second factor considers the importance of a variable's security implications, which can be derived from both cyber and physical perspectives. From the cyber aspect, variables that are more depended upon by other variables may be prioritized due to their broader impact. Regarding the physical aspect, variables associated with critical physical meanings could be prioritized. For example, control variables essential to the cyber-physical loop may receive higher priority for protection. To facilitate the selection from physical aspect, OP-DFI enables users to define policies that specify the criticality of variables. These factors are incorporated as weights in the synthesis of the security policy π, details of which will be provided in Section 5.4.

Real-time Constraint: OP-DFI imposes the constraint that, for every possible estimated state S_Ω, the computational cost of the checked memory operations must not exceed its estimated slack. Formally, the constraint is:

$$\forall S_\Omega, \Delta(S_\Omega, \pi) \leq \mathcal{B}(S_\Omega) \tag{1}$$

where $\mathcal{B}(S_\Omega)$ is the slack estimate obtained in Section 5.1. $\Delta(S_\Omega, \pi)$ represents the runtime cost of the checked memory operations, which is overestimated using the highest cost among all potential paths for the estimated state S_Ω.

For each individual potential path associated with the estimated state S_Ω, we quantify the runtime cost induced by a security policy in terms of the number of instructions added to the execution path by the policy. Given the security policy can be updated at each slack estimation checkpoint, the runtime cost of the security policy can be different between different checkpoints. To address this, OP-DFI divides the paths into subpaths at each slack estimation checkpoint and individually quantifies their runtime costs. The detailed derivation of $\Delta(S_\Omega, \pi)$ is discussed in Appendix A.2.

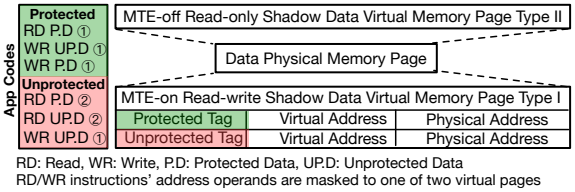

Figure 4: Dynamic sandboxing.

Security Coherence: Recognizing that the data corruption of protected variables can only be achieved by either tampering with their dependencies or by modifying them during the time window when they are not protected, there are two dimensions of security coherence that the policy needs to guarantee. The first dimension concerns the spatial aspect: given that attackers can compromise data through its dependencies, it follows that if a data item is included in the protected region, all its data and control dependencies must also be included. The second dimension focuses on the temporal aspect: given that the protected region can change at slack estimation checkpoints during runtime, attackers could exploit unprotected periods to compromise data. Since predicting the timing of attacks is challenging without additional security measures, effective protection can only be maintained if a variable remains protected throughout the task loop. In other words, the protected region can only shrink during runtime.

5.3 Dynamic Runtime Enforcement

As the protected region is consistently updated at slack estimation checkpoints, this leads to two challenges: 1) How to change the policy enforcement mechanism in the code instrumentation, since data-flow checking is generally enforced by in-line reference monitors via program instrumentation, which is not mutable at runtime. 2) How to ensure the protection remains coherent when protection boundary changes.

Dynamic Code Switching: To adapt the security policy at runtime, one direct method is to perform runtime binary rewriting. However, this approach can significantly degrade performance due to cache coherence issues. OP-DFI addresses this by maintaining multiple versions of code that have the same logic but different levels of protection. It then integrates a code-switching Reference Monitor (RM) into each slack estimation checkpoint to enable real-time switching between these code versions. For the generation of multiple code versions, an intuitive approach would be to create a unique code version for each estimated slack determined in Section 5.1. However, maintaining such a large number of code versions can lead to significant memory overhead. To mitigate this, we limit the number of code versions. Furthermore, when different code versions share the same code regions, we leverage MMU with address alignment to share these common code pages, reducing memory consumption.

To determine the switching target, the RM first re-evaluates the constraint formula using the input and context, and then

outputs the estimated state S_Ω. Subsequently, S_Ω is input into the security policy, which results in the identification of the transfer target. Conceptually, the target code version is usually the one that can provide the highest level of protection within the updated slack budget. Detailed implementation of code switching RMs are in Section 6.

Dynamic Sandboxing: There are two requirements for the second challenge. First, upon boundary changes, the protected data should remain isolated from the unchecked memory operations. Second, the overhead on the boundary change process is minimized.

Sandboxing is a natural solution for achieving the isolation, but its static nature limits its applicability in our scenario. To address this, we propose a novel dynamic sandboxing approach, where the isolation boundary is dynamically adjusted based on changes in the protected region. However, directly implementing dynamic sandboxing is problematic. Traditional sandboxing relies on inline instruction masking to sanitize addresses. Dynamic changes of the protection boundary can incur prohibitive overhead, as they require moving data between sandboxes, thereby violating the second requirement. To handle this issue, our system leverages ARM MTE to facilitate access control. We assign distinct MTE tags to the checked and unchecked code regions. Every time a memory is modified, its memory tag is updated as the tag of the write instruction. Thus, any unauthorized tag write on protected data by unchecked code will eventually be detected during checked read operations, as the stored memory tag is inconsistent with the instruction tags. The advantages of ARM MTE is its support for the `STGP` instruction, which allows data and memory tags to be modified simultaneously. By replacing the `STR` instruction with `STGP`, the need for additional instructions to update memory tags upon protection boundary changes is eliminated, thereby avoiding extra overhead.

Unfortunately, the use of ARM MTE introduces a new challenge: it indistinguishably prevents both read and write operations on protected data from unchecked code. This limitation could disrupt the program's normal execution, as unchecked code may need to read the protected data. To mitigate this issue, we introduce a second virtual page with MTE-off and read-only privilege to enable access, as shown in Figure 4. Lastly, to prevent unchecked write operators from updating the metadata in MTE, an instrumentation is added to enforce a known "unprotected" mask for all those memory write instructions.

5.4 Opportunistic DFI Policy Optimization

From the previous sections, the effectiveness of a security policy is influenced by various factors, including the formation of protected memory operations, the choice of path constraints, and the selection of code versions for different slack. Besides, these factors are subject to multiple constraints, namely real-time constraint, security coherence, and limitations on memory impact. Our goal is to find a security policy that maximizes our security objectives without violating any of the three constraints. To achieve this, we naturally formulate it as an optimization problem.

Security Objective: To quantify the security objectives within the optimization framework, OP-DFI proposes a metric called *coverage score*. A naive approach for calculating this score is to simply count the number of checked memory operations, treating all operations as if they were of equal importance. As discussed in Section 5.2, the security implications of variables can vary, meaning that allocating more of the time budget to more important variables could enhance overall security. Thus, OP-DFI introduces weights for variables to indicate their importance. To identify such importance, sensitivity analysis [10, 62] is a potentially promising solution. To capture the difference in the importance, a weight is added to each operation in the problem formulation. With the weights, the protection coverage score $\mathcal{C}$ for a set of selected path constraints Ω_s and policy π is calculated as the weighted average percentage of checked memory operations:

$$\mathcal{C}(\Omega_s, \pi) = \sum_{x \in X} \Pr(x) * \Big(\sum_{\vartheta \in \pi(S_\Omega(x))} w_\vartheta \Big). \tag{2}$$

Where x represents the input and context, $\Pr(x)$ is the dynamically profiled distribution of x, and $S_\Omega(x)$ signifies the execution state estimated using x. The variable w_ϑ represents the importance weight assigned to a memory operation ϑ with $\sum_\vartheta w_\vartheta = 1$. By default, w_ϑ is set to $\frac{1}{N}$, where N is the total number of memory operations. Additionally, $\pi(S_\Omega(x))$ represents the final set of protected memory operations. It is important to note that the simple formulation above captures only memory operations but not how it relates to critical variable or memory coverage, which is an important direction for our future work.

Optimization: The optimization problem is formulated as finding $(\Omega_s, \pi)^*$ that maximizes $\mathcal{C}(\Omega_s, \pi)$, subject to a set of constraints on Ω_s and π. These constraints consist of limitations on the runtime and memory overhead imposed by Ω_s and π, as well as the requirements on π for security coherence. To solve the optimization problem, we employ a combined approach that leverages the genetic algorithm for its capability in solving non-linear problems, and mixed-integer linear programming for its efficiency. More details on the optimization problem formulation and solving can be found in Appendix A.3 and B.1 respectively.

Even though our evaluation across eight platforms in Section 8 didn't yield any instances where the optimization produced a null policy, a policy protects no memory operations, it remains possible that in extreme cases, the output policy is null. For example, when all variables are mutually dependent, a substantial amount of slack would be needed upfront to protect any individual variable due to its dependencies on others. In these situations, no suitable policies would be available, and OP-DFI would not offer any additional protection.

6 Implementation

A prototype of OP-DFI is built on AArch64, and the implementation mainly contains four parts, including slack analyzer, code switching RM, program instrumentation, and optimization engine. The policy optimization engine is described in Appendix B.1 while others are described below.

Slack Analyzer: To compute path-level slack, timing analysis [24] is conducted. This involves several steps: First, dynamic analysis is used to profile the timing characteristics of various basic blocks. Second, loops are unrolled based on the bounds given in the schedulability analysis of the system. Subsequently, path information and low-level timing data are combined to calculate slack using the industrial-standard timing analysis tool, aiT TimeWeaver [32]. To obtain symbolic formulas for constraints, we utilize a symbolic execution engine based on KLEE [16]. Given that a threshold is set to bound constraint evaluation cost, which also limits the complexity of the constraint formula, the depth of symbolic execution is limited as well, thereby preventing path explosion. With the chosen constraints, slack estimation checkpoints are added at relevant variable updates. Given that the constraints pertain to specific variable updates, each checkpoint uses an update counter to differentiate between multiple updates for the same variable.

Code Switching RM: For efficient determination of the switching target, the switching rules, automatically generated by the optimization engine, are implemented as a precomputed lookup table, where the estimated execution state is utilized as the index. Moreover, to prevent potential attackers from exploiting the system by maliciously jumping to code versions lacking protection, each code version is enclosed within a compartment, achieved by aligning its code addresses to ensure differences only exist in the high bits. A register, which can only be updated by reference monitors, is reserved to store the identifier of the current code version. This identifier is used to conduct address masking on each indirect branch, guaranteeing that the control flow remains confined within the correct compartments at all times.

Program Instrumentation: To enforce hard-coded MTE tags, masking instructions are inserted before both read and write instructions. Similar to the optimization techniques used in static sandboxing [49], repeated masking for registers used in frequent memory accesses, such as stack accesses, can be eliminated. To prevent attackers from directly jumping to the middle of the instrumented code, a coarse-grained CFI mechanism is employed as a fundamental security feature. Specifically, ARM BTI instructions are inserted at each function entry and potential function return address. The return address is further protected with a shadow stack, implemented using a separate MTE tag. Additionally, all metadata is protected with a distinct MTE tag.

7 Case Study

```
void generate_attitude_setpoint (const Quatf &q, ...){
    const float yaw = Eulerf(q).psi();
    _man_yaw_sp = yaw;
    /* . . . */
    // fly towards the direction of (roll, pitch)
    Vector2f v =  Vector2f(_m_control_setpoint.roll *
         _man_tilt_max), _m_control_setpoint.pitch *
         _man_tilt_max);
    Quatf q_sp_rp = AxisAnglef(v(0), v(1), 0.f);
    /* . . . */
    //calculate how much the yaw changes
    const Quatf q_sp_yaw(cosf(_man_yaw_sp / 2.f), 0.f,
         0.f, sinf(_man_yaw_sp / 2.f));
    correctTiltSetpointForYawError(q_sp_rp, q, q_sp_yaw);
     /* . . . */}
```

Variable Set #1: _m_control_setpoint.roll, _m_control_setpoint.pitch, q_sp_rp, _man_titlt_max

Variable Set #3: _man_yaw_sp, q_sp_yaw, yaw

Variable Set #2: q

Listing 1: Code snippet of the case study.

In this case study, OP-DFI is applied to the CPS task *altitude control* of PX4 [45]. Listing 1 shows code snippets taken from the altitude setpoint generation process in the altitude controller, with irrelevant code omitted for simplicity. This process involves a procedure to correct setpoints in the presence of a yaw error. The correction procedure takes three control variables: `q_sp_rp` (pure tilt quaternion that needs correction), `q` (current attitude), and `q_sp_yaw` (pure yaw quaternion). These variables are categorized into inclusive/exclusive sets based on their dependencies, in accordance with the security-coherence constraint. Subsequently, the optimization engine generates the optimal policy to maximize the quantified protection coverage score. The process of constructing the coverage scores is accomplished through Sensitivity Analysis [62]. The variables of configurations with the most substantial influence are given priority for dynamic protection. In our case, the control variable `q_sp_rp` in the altitude controller is identified as more critical than the control variables `q_sp_yaw` and `q` in the context of altitude setpoint corrections, and it is highlighted in red in Listing 1. As a result, memory operations on its dependent variables (set 1) are prioritized for protection by assigning higher optimization weights (ten times larger in our setting) than to other memory operations. With OP-DFI deployed, it achieves a 94.2% protection coverage with just a 2.8% increase in WCET. Compared to regular DFI, the WCET is reduced by 108%.

8 Evaluation

Our evaluation aims to answer the following questions: **(1)** What is the system overhead and provided protection of OP-DFI compared with full DFI? (Section 8.1) **(2)** What are the factors affecting slack estimation? (Section 8.2) **(3)** What is the trade-off between different code versions? (Section 8.3) **(4)** How effective is OP-DFI when facing an adaptive attacker? (Section 8.4).

Evaluation Setup: The evaluation is conducted on eight real-time CPS platforms [9, 30, 33, 45, 48, 53, 54], as shown in Table 2. Among the eight CPS, PX4, Ardupilot, Turtlebot, and OpenManipulator are evaluated in real-world scenarios, while the others are evaluated in simulation mode. We utilized all eight platforms for the evaluation question (1) (Section 8.1),

Table 2: Runtime performance of OP-DFI

CPS	Baseline (ms)				System Runtime Overhead (%)					Reduced WCET	Coverage Score	Protected Ctr.Var.
	Average Runtime		WCET		Average Runtime			WCET

which focuses on macroscopic performance metrics. Subsequently, to answer the evaluation questions (2) - (4) (from Section 8.2 to 8.4), we selected PX4, Turtlebot, and OpenManipulator. These platforms are selected for their real-world settings and represent CPS platforms for drones, autonomous vehicles, and robots, respectively. The evaluated tasks for each CPS (in the order listed in Table 2) are *navigate*, *throttle loop*, *laser receive*, *path planning*, *laser handle*, *main control*, *fsm control*, and *walking control*. The evaluated hardware is Cortex-A53 on Raspberry Pi 3 model B (PX4, Ardupilot, OpenManipulator), Cortex-A57 on Jetson Nano (OP3, Unitree), Cortex-A72 on Raspberry Pi 4 model B (Turtlebot) and Cortex-A78 on Jetson AGX Orin (Autoware, Jackal). For security policy generation, we set the number of code versions, the number of selected path constraints, and the threshold for constraint evaluation cost to 6, 16, and 0.3% of WCET, respectively. We prioritized the protection of control variable-related memory operations by assigning them optimization weights 10 times larger than others. However, for clarity in presenting protection coverage within the program, the coverage scores displayed in this section represent the average percentage of checked memory operations. Moreover, due to the lack of publicly available hardware for ARM MTE and BTI, instruction analogs are employed to assess performance. Regarding WCET measurement, we are utilizing the aiT TimeWeaver [6], a timing analysis tool. Further details regarding the instruction analogs and WCET measurement can be found in Appendix C.1.

8.1 Comparison with Full DFI

To answer evaluation question (1), we measured the offered protection and system overhead, including average runtime, WCET, and memory overhead, under the CPS missions as described in Table 7.

Baseline DFI: The baseline DFI [18] enforces inter-procedure data-flow checking using a read-write table, write-tainting, and read-checking instrumentation. Specifically, the read-write table keeps an entry for each 4-byte word. Each memory write is assigned a 2-byte label and is instrumented to update the table entry with its label when writing, and the memory read is instrumented to check if the memory content has been written by a legitimate memory write according to the result of static analysis.

Runtime Overhead: Both average and WCET overhead of OP-DFI are measured and shown in Table 2.

Average Runtime Overhead - OP-DFI results in an average runtime overhead of 157.5%, attributed to data-flow checking (147.8%), code switching (4.19%), and dynamic sandboxing (5.4%). Among these factors, data-flow checking in OP-DFI is comparable to full DFI (147.8% versus 155.3%) and accounts for the most significant portion of the average runtime overhead due to the abundantly available slack. The dynamic code switching mechanism incurs a runtime cost of 4.1%, attributable to the evaluation of constraint formulas, tracking runtime context, and executing transitions between code versions. Moreover, the overhead incurred by dynamic sandboxing (5.4%) is comparable to static sandboxing, as dynamic sandboxing only requires inserting an address masking instruction before memory operations, akin to certain implementations of the static sandboxing approach.

WCET Overhead - Compared to full DFI, OP-DFI achieves a 181% reduction in WCET overhead. WCET overhead is attributed to the unavoidable code switching (0.4%) and sandboxing (2.3%) instrumentation on WCEP. Conversely, the code instrumented for data-flow checking does not add to the WCET of the original task due to the design of OP-DFI: it only checks when slack is available. Code switching typically induces less WCET overhead than sandboxing. This disparity arises because the cost associated with constraint evaluation, a phase of the code switching process, is restricted by a predefined threshold (0.3% of WCET). In contrast, sandboxing occurs with memory accesses on WCEP. Upon further investigation of code switching, the overhead of some instances slightly exceeds the predefined threshold due to the added complexity of context tracking. However, in Autoware and OpenManipulator, the overhead stays below this threshold. This can be ascribed to two factors: The selected constraints can depend directly on inputs, lowering evaluation costs, and some constraints undergo partial evaluation due to missing runtime contexts on the WCEP.

Memory Overhead: Figure 5 shows the breakdown of memory overhead for each system component. Built on top of baseline DFI, OP-DFI shares a common memory overhead (approximately 50%) with baseline DFI due to the utilization of read-write tables for taint tracking. Moreover, OP-DFI introduces additional memory overhead ranging from 19.2% to 31.7% due to various factors, including code ver-

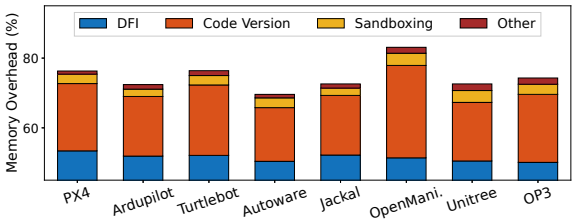

Figure 5: Memory overhead breakdown.

Table 3: Context tracking for slack estimation accuracy

CPS	D. P.	No Ctx	Partial Ctx	Full Ctx
PX4	w	69%	78%	92%
	w.o	53%	65%	
Turtlebot	w	79%	85%	95%
	w.o	58%	73%	
OpenMani.	w	59%	73%	90%
	w.o	41%	61%	

D.P.: dynamic profiling, w: with, w.o: without

sions, sandboxing, and others (such as the pre-computed table for switching target lookup and the shadow stack for return address protection). Among these factors, code versions contribute the most significant overhead, accounting for 18.9% of the memory overhead. The second contributing factor to memory overhead is the sandboxing implemented using MTE, introducing an overhead of 2.7%. This arises because MTE supports isolation only at a 16-byte granularity, necessitating data alignment to accommodate these 16-byte granularity restrictions when adjacent data has different privileges.

Protection Coverage: With a WCET overhead of 2.7%, OP-DFI effectively performs DFI checking on approximately 95.5% of all memory operations and 99.3% of those related to control variables, where the discrepancy arises from the prioritization of control variables during the policy generation phase. Typically, CPS with ample slack (which allows for more resource allocation) and a lower average runtime overhead for DFI operations (thereby consuming fewer computational resources for checks) yield higher coverage scores. Moreover, a greater data and control dependency within a program can reduce the protection coverage. This happens because interdependent data needs to be consolidated into a single set when choosing instrumentation points. As the size of these data sets increases, the granularity of slack utilization becomes coarser, which compromises the protection coverage. For instance, even though OpenManipulator has less available slack (with its average runtime accounting for 21% of WCET) and a higher average DFI runtime cost (120%) compared to Jackal, it achieves better protection coverage. This is attributed to fewer dependencies among its program variables.

8.2 Analysis of Slack Estimation

There are two key factors influencing slack estimation: different levels of context tracking and variations that cannot be captured by inputs a priori.

Table 4: Slack variation

CPS	Mission	Sla. Var.	Est. Acc.	Est. Acc.↑
PX4	takeoff	0.17	77%	2.8%
	flyto	0.19	70%	4.1%
	land	0.25	59%	5.6%
Turtlebot	w.o obstacle	0.08	86%	0.4%
	w obstacle	0.11	72%	3.2%
OpenMani.	grasp	0.27	62%	1.8%
	place	0.29	55%	2.8%
	rotate	0.15	73%	2.2%

Different Levels of Context Tracking: To investigate the impact of varying context levels on slack estimation accuracy, we experimented with three distinct settings: input-only (no context), partial context, and full context. In the input-only setting, the considered inputs are the navigation mode, user command, and position status for PX4; laser data for Turtlebot; and user command, trajectory status, and moving status for OpenManipulator. The partial context represents the program's default configuration, where only a subset of runtime variable updates are automatically selected through optimization. In contrast, the full context involves tracking every branch target encountered during program execution. Table 3 presents the results for the three CPS platforms.

The results indicate that incorporating more context improves the precision of slack estimation. Specifically, when using full context, the accuracy reaches 92%. The residual discrepancy is primarily attributed to inter-process interference. Employing partial context provides an average accuracy increase of 9.6% compared to input-only estimation. Remarkably, for OpenManipulator, the improvement is even more pronounced at 14%. This is because certain loops in its kinematics solver are resource-intensive and heavily dependent on non-input global variables. We also evaluated the effectiveness of dynamic profiling in constraint selection for both input-only and partial context scenarios. The results are indicated in the second column D.P. in Table 3. We observed an average improvement of 15.3% in slack estimation accuracy, underscoring the efficacy of dynamic profiling.

Slack Variation: We further measured slack variation across eight different missions, calculating the normalized difference between the actual slack and the lowest observed slack for the same input. The results, presented in Table 4, show a variation ranging from 0.08 to 0.29, with an average of 0.18. Greater slack variations generally result in reduced slack estimation accuracy because the worst case is assumed for uncertain estimates. To improve slack estimation, one viable approach is to increase the number of path constraints for a more precise execution state estimation, albeit potentially at the expense of performance. By increasing the number of path constraints from the original setting of 16 to 24, we achieved a 2.8% improvement in estimation accuracy.

8.3 Analysis of Code Version

We first evaluated the general protection coverage and runtime performance across different code versions. Then we exam-

Table 5: Properties of different code versions

CPS	Code Version	Ave. Run. Overhead	Cov. Score	Cov. Diff.	Switch Cond.
PX4	highest	118%	1	0.15	>67%
	others	75%	0.83		9%∼67%
	lowest	19%	0.16		<9%
Turtlebot	highest	162%	1	0.21	>75%
	others	116%	0.77		13%∼75%
	lowest	7%	0.09		<13%
OpenMani.	highest	124%	1	0.09	>72%
	others	86%	0.89		16%∼72%
	lowest	5%	0.12		<16%

ined code switching frequency in different missions. Lastly, we manually introduce different numbers of code versions to further explore the trade-offs in selecting such a number during optimization. For the sake of simplifying the discussion, in the rest of this section, we focus on the code versions with the *highest* and *lowest* coverage scores, while grouping all other versions under the category *others*.

Protection Coverage and Overhead: Table 5 presents these two properties as well as the average difference in coverage among different code versions. It is observed that code versions with higher protection coverage generally incur a greater runtime cost due to the increased number of memory operations that need to be checked. This leads to the associated switching condition requiring a larger slack to accommodate the increased runtime cost. Coverage differences among the various code versions are relatively small and even, ranging from 0.09 to 0.21. Notably, even though the code version with the lowest coverage is designed for scenarios with no slack, it can still have a non-zero coverage score (averaging around 0.12 in our evaluation). As long as the memory operations checked in a given code version are not part of the WCEP, these checked data operations will not affect the WCET.

Code Switching: The last column in Table 5 indicates the range of available slack required to switch to a specific code version at the first switch. Among the tested CPSs, Turtlebot has the most stringent switching conditions, requiring more slack due to its higher runtime cost of DFI compared to the other two CPSs. For example, the *highest* code version in Turtlebot requires more than 75% of the WCET as slack to initiate the switch. As for the actual switching frequency, Figure 6 presents both the frequency at which the program switches to a specific version at the first code-switching point

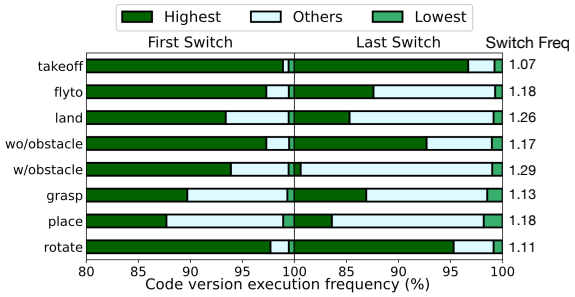

Figure 6: Code switching frequency.

and the frequency at which the program remains on that version after the last switching point. The results indicate that OP-DFI implements proactive protection by maintaining an overly large initial protection region to take advantage of the potential increase in slack while maintaining security coherence. This is illustrated in Figure 6, where the dark green bars in the left subfigure are longer than those in the right subfigure. Moreover, switching primarily occurs at the program's entry point, with the switching frequency in subsequent executions remaining below 0.18, due to the availability of sufficient slack. In approximately 91% of cases, the program eventually switches to the version with the highest coverage for the same reason. Additionally, different missions can result in varying switching frequencies. For instance, the "w obstacle" mission exhibits a higher switching frequency compared to the "w.o obstacle" mission of the same CPS. This difference is due to the presence of randomly occurring obstacles during the mission leading to fluctuations in slack, which cannot be inferred at the program's entry point. Consequently, the updated slack prompts OP-DFI to narrow the protection coverage.

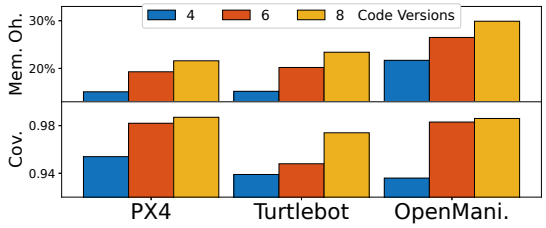

Figure 7: Memory overhead and protection coverage under varying numbers of code versions.

Number of Code Versions: We also investigated the impact of varying the number of code versions. Illustrated in Figure 7, when the number of code versions increases from 4 to 8, the protection coverage experiences a rise of 0.04. However, the memory overhead also witnesses a 7.6% increase. Our results indicate that an increase in the number of code versions leads to improved protection coverage, effectively creating a more fine-grained security policy. It's also noteworthy that the growth in memory overhead is not linear with the number of code versions. This is because different code versions can share the common code pages, and OP-DFI leverages the MMU to map the common physical code pages to multiple code versions, thereby reducing memory overhead.

8.4 Adaptive Attack Analysis

Analysis Principle: While the level of protection provided by OP-DFI is bounded by the available slack, the need to exhaust slack also constrains the attackers on the adversarial input, since the input must satisfy specific path constraints to cause a significant expansion in the task run-time. To gain a more holistic understanding of the practical level of protection for CPS systems, this trade-off is analyzed through the lens of

Table 6: Constraint on control flow and input value

CPS	Est. Slack	Constraint		Cov. Score
		control flow	input value	
PX4	0	27%	0.042%	0.16
	0∼20%	42%	0.73%	0.43
	0∼40%	71%	8.2%	0.75
	0∼80%	87%	15.3%	0.95
Turtlebot	0	24%	0.007%	0.09
	0∼20%	47%	1.6%	0.36
	0∼40%	67%	5.5%	0.73
	0∼80%	84%	14.4%	0.84
OpenMani.	0	22%	0.015%	0.12
	0∼20%	38%	0.063%	0.41
	0∼40%	56%	4.8%	0.71
	0∼80%	90%	27.5%	0.91

the exploitability by an adaptive adversary in this section. Even though the concrete techniques to implement a shellcode could differ from one stance to another, there are often two necessary conditions to successfully exploit a vulnerability in the system, namely, the ability to reach vulnerable functions with attackers' input and the ability to craft the input to trigger the vulnerability upon delivery. Note that even if the input is supplied by the attacker, there can be various logic in the program, such as data sanitization, preventing arbitrary manipulation on such input.

Analysis Approach: The first exploitability metric is adversarial access to the security-sensitive functions, since function calls, like unsafe C library function calls and system calls [11, 20, 23], are frequently used for exploitation. However, not all the function calls matter, only those with adversarial inputs flowing into can be exploited. Thus, only calls to security-sensitive function with adversarial information flows are measured. To provide a quantitative measurement, it is quantified as the percentage of reachable security-sensitive locations, which are defined as calls to security-sensitive functions. The second exploitability metric is the adversary's ability to manipulate the input. To obtain the ranges of possible manipulation, the path constraints from the worst-case execution path are converted to a logic formula that limits the range. To obtain a quantitative measurement, the percentage of the modifiable range over the full range of the input is measured. It is important to note that the measurement for exploitability requires considerations of many subtle details and remains an open research challenge [52]. The two basic metrics measured in this study are merely the first step towards quantitatively understanding the exploitability in the context of OP-DFI, and in the future, we intend to further develop this research.

Analysis Results: The quantitative measurement of the constraints at different slack levels are shown in Table 6. As the results show, in the worst-case scenario where there is no slack, the reachable security-sensitive locations are constrained to 24.3%, and only 0.02% of the program's input value range can be utilized for generating exploits. This limitation arises because, in order to traverse longer paths, the input must satisfy all constraints along these paths, thereby restricting control flow and input value. As the slack level increases, attackers gain greater flexibility to craft exploit payloads and access more security-sensitive locations. However, concurrently, the protection offered by OP-DFI also increases due to the augmented amount of slack (with a coverage score of 0.90 when slack is 80% of WCET), providing enhanced defense. A concrete example can be found in Appendix C.2.

9 Security Analysis

Security of System Implementation. First, attackers may attempt to jump around the instrumented reference monitor to bypass security checking. However, OP-DFI leverages the hardware feature ARM BTI to efficiently enforce a coarse-grained CFI, which ensures the attacker can only jump to the function entries and return to callsites. As a result, all data operations are checked, and the control transfer between code versions can only occur in code switching units given that all indirect jumps are masked into an address range. Second, OP-DFI uses MTE to securely maintain the write protection of data. All data created from the protected region is associated with specific MTE tags, and only the code within the protected region carries these same MTE tags. Any write operations from the unprotected region will alter the original tags of the protected data, which will subsequently be detected when the data is read by the protected region. At runtime, OP-DFI may dynamically reduce the scope of the protected region via code version switches. In the newly activated code version, the MTE tags in the removed region are hardcoded to be different from those in the protected region. Consequently, after such a code version switch, any attempt from the removed region to directly write on the protected data will also be detected. Furthermore, since the removed region has no dependency with the remaining protected region, the sandboxing effectively prevents data corruption from the unprotected region. Lastly, the metadata for OP-DFI and the software-based DFI enforced in the protected region are also protected by ARM MTE. OP-DFI ensures that all MTE tags are hardcoded and reserve specific tags to the metadata, ensuring that only designated RMs can modify it.

Security of Data-flow Protection. Although OP-DFI does not guarantee complete protection for all data flows, its adaptability allows it to optimally secure a desired subset of data. For instance, in the eight platforms we evaluated, OP-DFI can be customized to achieve an average protection coverage of 99.3% for control variables. Furthermore, for variables that are expected to be protected, OP-DFI offers comparable security guarantees as full DFI. Since OP-DFI enforces DFI to check data flows in the protected region, any illegal data flows within the protected region that deviate from DFG can be detected. An attacker may attempt to modify unprotected data to influence the protected data. However, this is not possible because OP-DFI maintains security coherence, taking into account both the dependency and the protection duration of

the protected region. The former ensures that at any given time, the protected region encompasses all data and control dependencies of the protected data. Additionally, the latter ensures that the shrunken protected region, by the end of the task, remains protected throughout the entire iteration period.

Real-time Guarantee. The violation of real-time guarantees can arise from either the overestimation of slack or when the actual enforced DFI exceeds the capability of the estimated slack. For the first case, our slack estimation provides a lower bound for the actual slack, as we proved in Claim 1. Regarding the second case, the DFI enforcement policy is generated under the strict constraints of the slack budget, as outlined in Appendix A.3. Consequently, its actual execution time cannot exceed the capability allotted by the given slack.

10 Related Work

Information Flow Integrity: Among the existing work on DFI, RT-DFI [13] optimizes DFI tag checks to reduce the overhead for real-time systems. KENALI [50] supports partial DFI to only protect selected data. TMDFI [40], HDFI [51], and Trustflow [14] reduce the runtime overhead of DFI but require customized hardware. OP-DFI complements existing work by utilizing slack to minimize WCET overhead. Furthermore, some existing works on CFI take real-time into consideration [21, 47, 58, 65]. However, most of them focus on average runtime efficiency, while OP-DFI focuses on minimizing WCET overhead using slack.

Opportunistic Execution: Opportunistic execution [25, 35, 41] leverages slack to perform additional workloads. For example, [25, 35] utilize slack to execute extra inter-process real-time tasks, which can include security checks [25]. However, [25] is limited to examining program static properties rather than runtime behaviors. On the other hand, [41] employs slack measured by the timer for intra-process online monitoring, albeit requiring customized hardware. OP-DFI complements these works by using slack to assess program runtime behavior without the need for customized hardware.

Parametric WCET: The parametric WCET analysis [7, 8, 12, 15, 28, 43, 56] aims to derive a function that expresses the WCET of a program in terms of its input parameters, software-related factors (e.g., flow constraints), and hardware-related factors (e.g., timing impacts of cache and architecture). However, existing works manly focus on offline analysis.

11 Discussion and Limitation

Extending Optimization Across Multiple Execution Iterations: The current design of OP-DFI focuses on maximizing protection on a single job release. However, for periodical tasks in CPS, there are usually strong temporal dependencies among different real-time tasks or different jobs of the same task. Though such dependency has not been an issue for platforms in our evaluation, it is entirely possible that a large amount of control variables have to be protected in the beginning when slack is not available. A potential mitigation is to use sanitizers to bring the critical control variable back to protection or reset it to the default state, leveraging the physical momentum to mitigate the control impact.

Dependence on Hardware Feature: While OP-DFI utilizes existing hardware features ARM MTE and BTI for runtime enforcement, it is also possible to use software-based fault isolation and software-based CFI to realize the enforcement.

Memory Overhead: The current implementation of OP-DFI incurs a non-negligible memory overhead of 23.1% over that of the full DFI. This increase is largely attributed to the utilization of multiple code versions designed to facilitate changes in security policy enforcement. Although memory usage is already optimized by sharing code pages common to different versions, as the number of code versions increases, the effectiveness of this optimization can diminish because common code regions become more segmented, resulting in fewer 4KB (page-size) common code regions. Several potential mitigation solutions exist. First, more common code pages can be generated by adjusting the code layout during compilation. Second, finer-grained code region sharing can be achieved by decomposing the execution of a code version into the executions of multiple smaller code regions. Then, the sharing of common regions can be realized using trampolines that transit execution among different regions. Lastly, it is possible to trade space expansion with computational overhead by dynamically updating the policy in place.

12 Conclusion

In this paper, we propose a security primitive, opportunistic DFI, to opportunistically perform in-line data-flow checking using the opportunity of slack in real-time systems. To enforce opportunistic DFI, a system OP-DFI is proposed, for which an input/context-dependent slack is constructed, the real-time property and security coherence are modeled, and dynamic runtime enforcement mechanisms are designed. A prototype is implemented on the AArch64 platform and evaluated on eight real-time CPSs.

A Additional Design Details

A.1 Proof of Parametric Slack Estimation

CLAIM 1 Given the constraint evaluation results S_Ω for a set of selected constraints Ω_s, Algorithm 1 provides an under-approximated worst-case slack estimate $\mathcal{B}$ of the program.

Based on the definition of slack: slack = WCET - execution time, we define $\mathcal{W} = WCET - \mathcal{B}$. We then show the equivalence of Claim 1: Algorithm 1 provides an over-approximated worst-case time estimate $\mathcal{W}$ of the program, given the constraint evaluation results S_Ω for a set of selected constraints Ω_s.

Proof. Let $\mathcal{P}$ be the program under analysis, $\mathcal{K}$ be the worst-case execution time analysis tool, $\{p_1, p_2, ..., p_n\}$ be the set of all execution paths for $\mathcal{P}$, $\{t_1, t_2, ..., t_n\}$ be the corresponding (over-approximated) execution time estimates for the paths, and $\{\Omega_1, \Omega_2, ..., \Omega_n\}$ be the corresponding path constraints. Each Ω_i is a constraint statement consisting of the concatenation of the individual branch constraint $\{\omega_i^1, \omega_i^2, ..., \omega_i^j\}$. As previously defined in Algorithm 1, S_Ω represents the results of evaluating the constraints in the set Ω_s, where $\forall \omega_s \in \Omega_s$, $\omega_s \in \{\Omega_1 \cup \Omega_2 \cup \ldots \cup \Omega_n\}$.

We make the assumption that given the program $\mathcal{P}$ and the worst-case analysis tool $\mathcal{K}$, $\mathcal{K}(\mathcal{P}) \rightarrow \{(p_1, t_1), ...(p_n, t_n)\}$, where t_i is the over-approximated estimate of the execution time along p_i. We also assume there exists a logical solver Ψ that can determine whether a path p is feasible or not.

To obtain an over-approximated worst-case time estimate, $\mathcal{K}$ can simply output t_{max}, where $t_{max} = max\{t_1, t_2, ..., t_n\}$. To obtain a tighter bound, some WCET tools also eliminate infeasible paths, therefore the output becomes $t_{max} = max\{t_1, t_2, ..., t_m\}$ where $t_i \in \{t_1, t_2, ..., t_n\}$, $\Psi(p_i) \rightarrow true$. Intuitively, Algorithm 1 goes one step further and eliminates the infeasible paths using the known states in S_Ω. Mathematically, the output is now $t_{max} = max\{t_1, t_2, ..., t_q\}$ where $\forall t_i \in \{t_1, t_2, ..., t_n\}, \Psi(p_i) \rightarrow true \wedge feasible(p_i, r_s)$ for $\forall(\omega_s : r_s) \in S_\Omega, \omega_s \in \Omega_i$. $feasible(p_i, r_s)$ is true either r_s is *unknown* or r_s does not violate the condition of p_i. As a result, among all feasible paths, the algorithm still selects the longest running time, and since this running time estimate is over-approximated, this algorithm still returns an over-approximation of the worst-case execution time.

We can prove this by contradiction. Let t_w be the worst-case time output by Algorithm 1 given $\mathcal{P}$ and S_Ω, with the corresponding worst-case execution path as p_w. Since this is the worst-case execution time, that means for all feasible paths, $\mathcal{F}$, where $\Psi(p_i) \rightarrow true \wedge feasible(p_i, r_s)$ for $\forall(\omega_s : r_s) \in S_\Omega, \omega_s \in \Omega_i$ given the known constraint evaluation results S_Ω, t_w is the largest number in the set, i.e. $\forall t_i \in \mathcal{F}, t_w \geq t_i$. Let p_z be the program execution path that leads to running time estimation of t_z, however $t_z > t_w$. This creates a contradiction between two complementary conditions. If $p_z \in \mathcal{F}$, then it contradicts with the max selector statement where $\forall t_i \in \mathcal{F}, t_w \geq t_i$. If $p_z \notin \mathcal{F}$, then it contradicts either the constraint evaluation results S_Ω or the original path feasibility $\Psi(p_z) \rightarrow true$.

A.2 Quantifying Runtime Cost

To quantify the runtime cost of a specific path, the path is divided into subpaths based on slack estimation checkpoints along its course. However, due to the uncertainty of the estimated execution state related to other paths, we enumerate the complete set of potential intermediate estimated execution states for each subpath. This set is denoted as $S^*(p, S_\Omega) = \{\langle S^{p_{[0]}}, S^{p_{[1]}}, \ldots\rangle\}$, where $S^{p_{[i]}}$ represents a potential intermediate estimated execution state on subpath $p_{[i]}$. Subsequently, the runtime cost for a path given an estimated execution state, denoted as $\Delta(p, S_\Omega|\pi)$, is established as the highest runtime cost among different potential intermediate execution states:

$$\Delta(p, S_\Omega|\pi) = \max_{\langle S^{p_{[0]}}, S^{p_{[1]}}, \ldots\rangle \in S^*(p, S_\Omega)} \sum_{i}^{n} \delta(\pi(S^{p_{[i]}}), p_{[i]}) \quad (3)$$

where $\pi(S^{p_{[i]}})$ represents the set of checked memory operations selected by the security policy with the intermedi-

ate estimated execution state of subpath $p_{[i]}$. Furthermore, $\delta(\pi(S^{p_{[i]}}), p_{[i]})$ is the runtime cost on subpath $p_{[i]}$ arising from the chosen checked memory operations $\pi(S^{p_{[i]}})$, and it can be computed based on instruction count. Finally, the runtime cost under an estimated execution state S_Ω can be obtained as the largest runtime cost among all paths corresponding to that estimated state: $\Delta(S_\Omega, \pi) = \max_{p \in P} \Delta(p, S_\Omega | \pi)$.

A.3 Policy Optimization

Optimization Problem Formulation: According to the definition of a security policy π, it can be parameterized by the checked memory operations across different code versions $\Phi = \{\theta_0, \theta_1, ...\}$, as well as the switching rules utilized at different slack estimation checkpoints $\{\pi_0, \pi_1, ...\}$. The set of selected constraints can be denoted as $\Omega_s = \{\omega_0, \omega_1, ...\}$. The goal of the optimization is to find the optimal parameters that satisfy the specified constraints:

$$
\begin{aligned}
(\Omega_s, \pi)^* = & \arg\max_{\Omega_s, \pi} \mathcal{C}(\Omega_s, \pi) \\
\text{s.t.} \quad & \Delta_\Omega(\Omega_s) \leq \varepsilon_\Omega \\
& \Delta(S_\Omega, \pi) \leq \mathcal{B}(S_\Omega), \text{ for all } S_\Omega \\
& \mathcal{D}(\theta) = \theta, \text{ for all } \theta \in \Phi \\
& \pi(S) \supseteq \pi(S'), \text{ for all } (S, S') \in \mathcal{S}^*. \\
& |\Omega_s| = N_\Omega \\
& |\Theta| = N_\Theta
\end{aligned}
\tag{4}
$$

where $\Delta_\Omega(\Omega_s)$ is the evaluation cost of the constraint formula (which can be obtained through the instruction count of the formula) and is bounded by a threshold ε_Ω; $\mathcal{D}(\theta)$ is the dependency of θ; (S, S') is the estimated execution state before and after the transition, and $\mathcal{S}^*$ is the set of all possible transitions; $|\Omega_s|$ is the number of selected constraints where constraints with the same formula are deemed identical, and it is set to N_Ω; $|\Phi|$ is the number of code versions and is set to N_Φ.

The first constraint bounds the evaluation cost of the constraint formula. The second constraint pertains to the real-time requirement, ensuring that the runtime cost of checked memory operations remains within the available slack. The third and fourth constraints relate to security coherence, ensuring that the code version includes all necessary dependencies and can only shrink following each code switch. The fifth constraint limits the table size to $O(2^{N_\Omega})$ entries, and the sixth constraint restricts the number of code versions.

B Additional Details on Implementation

B.1 Optimization Engine

In order to generate the optimal parameters, the search space is initially reduced to facilitate optimization. Considering that the evaluation cost of selected constraints is bounded, constraints with intricate symbolic formulas can be excluded from the search space. Additionally, by leveraging the security-coherence constraint, the code version must encompass all dependencies, and the switching rule exclusively transitions to versions with fewer checked memory operations, resulting in a further reduction of the search space.

Subsequently, the optimal parameters can be approximately determined through the utilization of Mixed-Integer Linear Programming (MILP) and Genetic Algorithm. To elaborate, the initial optimization parameters of the genetic algorithm are first set. Specifically, since high slack estimation usually provides more opportunities for protection, the initial parameters for selected constraints are set as the set of constraints that can yield the highest average estimated slack. After establishing the initial search state, the genetic algorithm iteratively performs the following steps: it mutates the selected constraints, and after each mutation, MILP is employed to facilitate the search for the corresponding optimal switching rules and code versions. This iterative process continues until convergence is achieved or timeouts.

C Additional Details on Evaluation

C.1 Evaluation Setup

Testing mission used in evaluation: Table 7 lists all the missions employed to test the eight CPS platforms in this paper. These missions encompass trajectories or sequences of actions. For drones and autonomous vehicles, the CPS platforms are tasked with executing circular trajectory missions. The robotic arm (OpenManipulator) is assigned the duty of repeatedly performing actions involving object grasping, rotation, and placement. Similarly, the quadruped robot (Unitree) and humanoid (OP3) are required to cyclically complete tasks such as standing up, walking, turning around, and sitting down. An asterisk (*) in the table denotes that the official repository does not provide specific test missions; instead, it offers simulated scenes. As a result, we manually curated the missions using the provided scenes.

Table 7: Testing missions

	Mission Type	Mission Name
PX4	Trajectory	FW_mission_1.plan
Ardupilot		copter_mission.txt
Turtlebot		turtlebot3_house*
Autoware		nishishinjuku_autoware_map*
Jackal		agriculture_world*
Unitree	Actions	stairs*
OP3		walking demo
OpenMani.		pick and place demo

Instruction Analogs: Given that the prototype utilizes

the hardware features ARM MTE and BTI, to the best of our knowledge, there are no publicly available development boards that support ARM MTE and BTI at the time of writing. Consequently, instruction analogs are employed to assess performance. Instruction analogs are a series of instructions that consume similar CPU cycles and memory footprint but do not perform actual checks [44]. According to the description, considering the negligible overhead of MTE and BTI, we use regular memory operations to simulate MTE-specific memory operations. For example, we analog an MTE-specific store instruction (`STGP`) with a regular store instruction (`STR`). Additionally, we analog a BTI instruction as an exclusive-or (`EOR`) instruction.

WCET Meaurement: We utilize the aiT TimeWeaver [6], a timing analysis tool, for WCET measurement. This tool can take CoreSight ETM trace packets as inputs to obtain architectural-level timing information. Among the four boards, only Jetson Nano (Cortex-A57) and Jetson AGX Orin (Cortex-A78) support Coresight ETM, while we were unable to find the CoreSight ETM supporting documentation for the other two, Raspberry Pi 3 (Cortex-A53) and Raspberry Pi 4 (Cortex-A72). To conduct WCET measurement on the Cortex-A53 and Cortex-A72 cores, we thus utilize the Cortex-A53 and Cortex-A72 cores available on the Juno Development Board, where CoreSight ETM is available. This serves as an alternative method to obtain architectural-level timing information for the Cortex-A53 and Cortex-A72 processors.

C.2 Adaptive Attack Evaluation

An Example of Constraint on Input Value: To justify the reasonableness of our metric — which involves constraints on the input value range — we refer to a real-world example from PX4 for clarification. Listing 2 shows a scenario where the adaptive attacker is unable to simultaneously push the task onto the worst-case execution path and trigger the exploit. The code snippet is taken from the `mavlink_receiver.cpp` file in the PX4 project, with irrelevant code omitted for simplicity.

The function `handle_message_statustext()` (on line 01) is responsible for parsing the input messages regarding system status and then publishing the parsed information as logs if necessary (the condition is on line 05). At the outset of this function, line 03 invokes `memcpy()` to copy the content of `msg` to a local variable `statustext`. Initially, length checking exists before the copy to prevent out-of-bounds writes. For the attack demonstration, we replaced this with an unsafe version on line 04, allowing the attacker to craft a large `msg` to trigger a buffer overflow, a preliminary step in exploiting the system. Concretely, the attacker needs to create an exploit payload that is long enough to overwrite data beyond the buffer size of `statustext`. However, such a crafted exploit payload cannot trigger the WCEP (line 06) and thus cannot lead OP-DFI to predict WCET. The reason is that the WCEP depends on a `true` return value from the function `should_publish_current()`. However, if `statustext` is overwritten, this function will always return `false`. This is because the function `should_publish_current()`, on line 09, inspects the content of `statustext`. If `statustext` contains no `\0`, the task will return `false`, preventing the task from entering the WCEP. In summary, to steer the task onto the WCEP, the input value must remain within the value limited by the size of `statustext`. Adhering to this constraint prevents the triggering of a buffer overflow, not to mention successful exploitation.

```
01  void handle_message_statustext(mavlink_message_t *msg) { /*Attacker's input*/
-02     uint8_t len = msg->len < STATUSTEXT_LEN? msg->len : STATUSTEXT_LEN;
-03     memcpy(statustext, _MAV_PAYLOAD(msg), len);
+04     memcpy(statustext, _MAV_PAYLOAD(msg), msg->len);
05     if (_mavlink_statustext_handler.should_publish_current(statustext)) {
06         _log_message_pub.publish(_mavlink_statustext.log_message()); /* WCET Path */
       }
   }

07  bool should_publish_current(const mavlink_statustext_t &msg_statustext,...) {
08     /* . . . */
09     const bool found_zero_termination =
strnlen(msg_statustext.text, sizeof(msg_statustext.text)) < sizeof(msg_statustext.text);
       /* False for oversize input */
10     if (found_zero_termination) {
11       return true; /* Need to be true for worst-case execution path */
12     } else {
13         return false;}}
```

Listing 2: Example of constraint on input value.

In general, the constraints imposed by the WCEP always restrict the search space during payload generation. Hence, we leverage these restrictions to quantify the trade-off an attacker faces when attempting to both trigger the WCEP and launch an exploit.

C.3 Comparison to CFI

Table 8: Comparison to CFI

System	Information Flow Checking		Runtime Overhead	
	data flow	control flow	average	WCET
RECFISH [58]	0	100%	25%, 30%	-
Kage [21]	0	100%	6.1%	5.1%
CFI CaRE [47]	0	100%	13%∼513%	-
Silhouette [65]	0	100%	3.1%	2.8%
OP-DFI	96.6%	100%	137%	2.6%

Table 8 contrasts OP-DFI with CFI works tailored to real-time systems [21, 47, 58, 65]. We evaluated [21, 65] on STM32L475 and STM32F469 respectively, while using the reported numbers for others due to lack of source code access. The results indicate that OP-DFI incurs a higher average runtime overhead (135%) due to its comprehensive protection for both control and data flow (96.6% of memory operations and 100% of control transfers are checked) for stronger protection. Regarding the WCET overhead, which is more critical as it directly affects the hardware requirements, OP-DFI (2.6%) is comparable to that of the listed CFIs (3.9%).

On Bridging the Gap between Control Flow Integrity and Attestation Schemes

Mahmoud Ammar, Ahmed Abdelraoof, and Silviu Vlasceanu

Abstract

Control-flow hijacking attacks remain a significant challenge in software security. Several means of protection and detection have been proposed but gaps still exist. To address such gaps, leading processor manufacturers have introduced new extensions in their latest-generation architectures, such as Pointer Authentication (PA) and Branch Target Identification (BTI) technologies in the ARMv8.5-A processor architecture. However, simply enabling these technologies would offer only limited security guarantees without trustworthy evidence of runtime integrity.

To bridge this gap, we propose CFA+, a practical hardware-assisted control flow attestation mechanism with prevention capabilities. CFA+ leverages ARMv8.5-A's BTI security extension in combination with selective software instrumentation to enable lightweight always-on monitoring of the execution state without the need for maintaining in-memory control flow logs. The hybrid policy of CFA+ enables immediate prevention or quick detection of control-flow violations while providing trustworthy evidence of runtime integrity. CFA+ offers strong security guarantees for complex software stacks while maintaining high efficiency and scalability. Evaluation results demonstrate that CFA+ incurs an average runtime overhead of less than 3% when applied to various benchmark applications, including the SPEC CPU2006 suite and nginx.

1 Introduction

Despite advancements in system security, the foundation of most software stacks still depends on unsafe programming languages like C and C++ for their flexibility and performance benefits. However, these languages necessitate manual memory management, which often results in programming errors and memory corruption vulnerabilities, leaving software vulnerable to exploitation by adversaries. While traditional code injection attacks have been largely mitigated through the deployment of defenses like Data Execution Prevention (DEP) [72] and static Remote Attestation ($\mathcal{R}$A) approaches [34, 86], control flow hijacking attacks, such as Return-Oriented Programming (ROP) [53] and Jump-Oriented Programming (JOP) [57], have gained popularity as effective alternatives for determined adversaries. These attacks exploit memory corruption vulnerabilities, such as buffer overflows and use-after-free bugs, to achieve malicious objectives, exemplified by privilege escalation. Adversaries accomplish this by manipulating a program's control flow through the execution of carefully selected code snippets, known as gadgets. ROP attacks are characterized by chaining a sequence of gadgets, each ending with a return (`ret`) instruction. On the other hand, JOP attacks construct chains of gadgets on forward edges by targeting code fragments that end with indirect `jump` or `call` instructions.

Problem Statement. Over the past two decades, researchers have extensively studied Control Flow Integrity (CFI) schemes, which aim to mitigate control flow hijacking attacks by protecting both forward [13, 14, 17, 18, 35, 36] and backward [14, 18, 24, 36, 88] edges through enforcing various policies that must be respected during runtime. However, despite these efforts, such attacks continue to persist [19, 28, 33, 47, 58], highlighting the inherent limitations of enforcement-only solutions. These limitations arise from various factors, including the complex nature of target software [62], compatibility issues [60], and unbalanced trade-offs between security and performance [45]. Additionally, implementation mistakes represent a significant avenue for adversaries to exploit, bypassing detection by CFI defenses, which primarily operate at a local level [58, 62]. The concept of local detection within these mechanisms does not provide external evidence that could offer valuable insights into the execution flow of the target application, creating uncertainties regarding the current state of runtime integrity.

This, in turn, has motivated the design and implementation of Control Flow Attestation (CFA) mechanisms, which have emerged as a promising approach for providing external evidence of runtime integrity. As such, they offer crucial insights and enable remote detection of control flow violations [21, 22, 27, 56, 63]. The key idea behind CFA is the remote verification of the runtime integrity status of a target device/application, referred to as the prover ($\mathcal{P}$rv), by an external trusted entity known as the verifier ($\mathcal{V}$rf). To ensure

trustworthy guarantees, $\mathcal{P}$rv is typically equipped with a trust anchor to preserve the authenticity of collected execution traces that comprise the attestation report. This report is regularly or upon request transmitted to $\mathcal{V}$rf for verification.

However, despite the growing demand for verifying the runtime integrity of complex applications [21], the majority of existing CFA mechanisms are primarily designed for and limited to simple embedded systems [12, 22, 27, 56, 65]. Porting such solutions to tackle complex software stacks is hindered by several limiting factors. These include significant runtime overhead, insufficient scalability, and compatibility issues arising from intrusive hardware modifications.

While a few CFA proposals have been developed to tackle complex software [21, 63], they still encounter performance and scalability challenges, as discussed in Section 3.2. Furthermore, these schemes primarily focus on remote attack detection, which typically occurs late. Considering the broader attack surface in complex software, early detection, similar to local CFI mechanisms, is preferable whenever feasible but without compromising the advantages of external evidence. Unfortunately, activating separate CFI and CFA mechanisms would impose significant performance overhead, rendering it impractical for various real-world applications.

In particular, existing CFA schemes have largely overlooked the potential benefits of incorporating elements from CFI mechanisms. Such integration has the potential to enhance performance, accelerate attack detection, and achieve greater scalability. This oversight has resulted in impractical solutions that struggle with performance and scalability challenges. Remarkably, the potential synergies between CFI and CFA approaches have not been extensively investigated, highlighting the significance of exploring this overlooked avenue to mitigate control flow hijacking attacks.

Contribution. We take a first step to address the aforementioned limitations by proposing CFA+, a hybrid runtime defense approach that combines the strengths of CFI and CFA approaches by offering both control flow attestation and prevention capabilities for complex user-space applications. Unlike traditional CFA mechanisms, CFA+ takes a different approach to attest runtime integrity without explicit monitoring and logging of execution traces or relying on costly and non-scalable verification procedures. The key idea of CFA+ is to offer implicit monitoring of the execution state through incorporating CFI building blocks in its design, prioritizing prevention (i.e. local detection) over remote detection, while always providing trustworthy evidence of runtime integrity. For this purpose, CFA+ reserves two general purpose registers, referred to as State Register (SR) and Reference Register (RR), which are leveraged to implicitly maintain awareness of execution integrity. To achieve so, CFA+ generates unique identifiers (IDs) for selected forward-edge control transfer instruction, depending on a pre-generated function-level Control Flow Graph (CFG). It then selectively instruments these instructions, to encode (before executing a `call` instruction) and decode (after returning from a callee function), via XOR operations, SR with the corresponding ID. This creates a two-way execution-dependent function-call chain in SR, which can be used to assess runtime integrity without the need for in-memory history logs. Additionally, RR is employed to protect native code from vulnerabilities in shared libraries. To mitigate ROP attacks when backwarding (executing `ret`), CFA+ applies a lightweight masking mechanism by XORing return addresses being pushed to or popped from the stack with SR, enabling quick detection of corrupted return addresses.

To prevent bypassing the inlined instrumentation instructions and enhance prevention capabilities, CFA+ leverages the Branch Target Identification (BTI) feature, a security extension introduced as a CFI technology in the ARMv8.5-A architecture [6]. BTI restricts the possible targets for indirect branch instructions based on designated *landing pad* instructions. This ensures that indirect branches, including `ret`, can only target landing pads, triggering a hardware-based exception otherwise. The integration of BTI forms the core of CFA+'s hybrid policy, enabling immediate prevention of non-BTI-compliant control flow violations or quick remote detection of sophisticated ones. Furthermore, CFA+ incorporates an efficient $\mathcal{V}$rf functionality based on SAT solvers. By considering the generated CFG and a minimal attestation report (including SR, RR, and Program Counter (PC) register values) as inputs, the SAT solver-based $\mathcal{V}$rf could detect control flow violations by identifying inconsistencies in SR and RR with respect to the execution context.

We evaluate CFA+ using various benchmarks, including the C benchmarks of the SPEC CPU2006 suite and the nginx web server. Evaluation results demonstrate that CFA+ introduces an average runtime overhead of no more than 3% on $\mathcal{P}$rv, with an average increase in binary size by 22%. Additionally, the verification process of attestation reports takes only a few seconds when executed on a laptop-class machine

In summary, this paper presents several contributions:

- It introduces CFA+, an elegant hybrid control flow verification mechanism that efficiently combines runtime attestation and enforcement capabilities in a single design. CFA+ targets complex user-space software stacks at a large scale while incorporating a lightweight verifier functionality based on SAT solvers.
- It sheds light on the strengths and weaknesses of ARMv8.5-A's Branch Target Identification (BTI) technology, integrating it as a CFI cornerstone within the CFA+ design to enhance its precision and granularity.
- It provides extensive performance evaluation, demonstrating superior advantages of CFA+ over existing state-of-the-art CFA and CFI mechanisms.

Scope. This work primarily focuses on C applications for simplicity, with the intention of discussing its applicability to embedded applications based on the ARMv8.1-M architecture. Extension to C++ applications, where particularly vtables should be handled, is left as future work.

2 Background

2.1 Fundamentals of ARMv8-A Architecture

ARMv8-A (also known as AArch64 or ARM64) is the first ARM architecture that supports a 64-bit address space, 64-bit wide registers and pointers, and 64-bit arithmetic operations, utilizing a 32-bit fixed-length instruction set, called A64 [5]. The architecture includes 31 64-bit general-purpose registers (GPRs), denoted as `x0` – `x30`. Additionally, there are special-purpose registers (SPRs) such as the stack pointer (`SP`) and the program counter (`PC`). While the `PC` is not directly accessible as a GPR, it can be implicitly read by `PC`-relative address compute instructions.

ARMv8 ABI. The Application Binary Interface (ABI) defines the guidelines for executing code, including calling conventions and register usage. One aspect of the ABI focuses on GPRs, which also might serve special purposes. For instance, `x30` functions as the link register (`LR`), responsible for retaining the return address following a function call. As described in Section 4, CFA+ reserves two GPRs to ensure proper functionality without introducing compatibility issues.

2.2 Branch Target Identification (BTI)

BTI is a hardware feature introduced in the ARMv8.5-A and ARMv8.1-M processor architectures [4,6]. It provides enhanced protection against control flow violations by offering landing pad instructions, which prevent the execution of unintended target instructions when a vulnerable indirect branch is executed. When BTI is enabled, the processor restricts indirect branch instructions to target only memory addresses that contain landing pads, which act as entry points to guarded memory blocks. Otherwise, a hardware-level exception is triggered, as depicted in the left half of Figure 1.

The encoding of landing pads looks like `bti <target>`, where `<target>` represents the assembler encoding of the type of the indirect branch instruction that is allowed to target such a landing pad. The ARMv8.5-A-based processor can distinguish between indirect `jump` and `call` instructions. Therefore, `<target>` can be one of three valid values, which are: `c` for indirect function `calls`, `j` for indirect `jumps`, and `jc` for all indirect branches. This distinction would reduce the number of possible JOP gadgets as shown in the right half of Figure 1. Notable is that return (`ret`) instructions represent

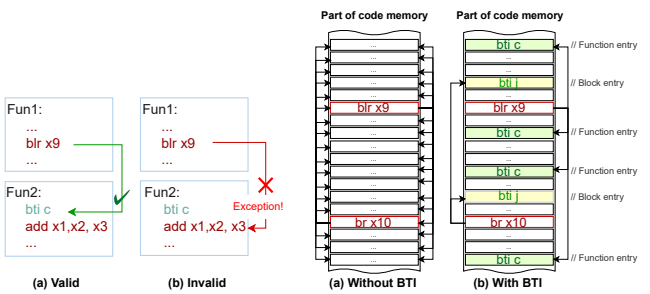

Figure 1: Possible valid targets by a vulnerable indirect call (`BLR`) or jump (`BR`) instruction in the presence or lack of BTI.

a form of indirect `jumps`, which transform the control to the caller function by jumping to the loaded address in the link register (`LR`). Therefore, their possible valid targets can be restricted by inserting `bti j` after each `call` instruction. Yet, BTI alone offers only coarse-grained security guarantees.

3 Motivation & Related Work

3.1 Control Flow Integrity (CFI)

CFI is a principled approach that restricts all indirect branch instructions to adhere to a statically determined control flow graph (CFG) [36]. In general, CFI solutions insert inline reference monitors (checks) before indirect branch instructions, whose transfer targets could be compromised, to enforce that such instructions only jump to legitimate targets at runtime [14, 17, 18, 35, 59, 61, 74, 75]. The effectiveness of CFI mechanisms is strongly tied to the precision of the generated CFG and the enforced policy [45]. Consequently, CFI techniques are broadly categorized as coarse-grained or fine-grained. The former is simpler and less computationally expensive, favoring performance over security. The latter is more effective in detecting control flow violations as it inserts checks at a more granular level, imposing a higher performance overhead. CCFIR [18] is one of the early coarse-grained techniques that categorizes valid target addresses into three sets, each can be approached by only one type of indirect control transfer (ICT) instructions, i.e., `returns`, indirect `calls`, or indirect `jumps`. While this approach reduces the attack surface (by acting as a software-based BTI), the number of potential gadgets that an adversary could exploit in complex applications is still quite large.

Several other coarse-grained CFI techniques have followed, which aimed at improving the accuracy of the enforced policy, without increasing the performance overhead [38, 59, 71]. However, bypassing such techniques has been demonstrated in various attacks [15, 19, 33, 46]. Therefore, a variety of fine-grained CFI approaches have been proposed [14, 17, 35, 74, 75]. Yet, the vast majority of them have not been widely adopted by industry due to their impact on performance. The few others that have been supported in mainstream compilers, e.g., LLVM CFI [17], are not comprehensive enough to completely prevent control flow violations [47, 52] or suffer from compatibility issues with some applications [60].

The accommodation of context-insensitive policies significantly contributes to the gaps present in CFI solutions [26, 47, 62]. Despite recent advancements, context-sensitive CFI schemes [11, 42, 43, 51] often suffer from limitations such as high performance overhead, compatibility issues, or false positives, which raise doubts about their ability to provide strong security guarantees [45, 60]. Additionally, the presence of implementation mistakes introduces additional hidden vulnerabilities that undermine the security of these approaches [62]. Consequently, the lack of external trustworthy evidence regarding the execution flow of the target application poses challenges in accurately assessing its runtime integrity status.

3.2 Control Flow Attestation (CFA)

CFA is a security service that enables a trusted party, i.e., verifier ($\mathcal{V}$rf), to verify the runtime integrity status of a prover ($\mathcal{P}$rv) application running on a remote device [56]. Unlike CFI, CFA offers a distinct approach to identifying control flow violations by leveraging insights derived from external evidence obtained remotely. To this end, $\mathcal{P}$rv is instructed to build an authenticated log, referred to as CF_{report}, which contains pointers for all ICT instructions that have been executed since the last attestation operation. $\mathcal{V}$rf will eventually receive CF_{report} to verify the integrity of the execution state and detect potential control flow violations. CF_{report} is commonly constructed by relying on software instrumentation [56], customized hardware [22], or a combination thereof [27]. C-FLAT [56] is the first to introduce CFA. It proposes a software-based instrumentation technique to collect and log execution traces, relying on ARM TrustZone to securely store and authenticate the collected measurements, before reporting to $\mathcal{V}$rf. The main disadvantage of C-FLAT is the high-performance overhead due to frequent context switching to the TrustZone when executing any ICT instruction. As a follow-up, various CFA schemes with different assumptions and guarantees have been proposed [12, 16, 22, 27, 65]. Unfortunately, these schemes are mainly designed for simple bare-metal embedded software. Attempting to port such designs to complex user-space applications would either be infeasible or result in excessive performance overhead.

ScaRR [21] and ReCFA [63] are the only two CFA schemes that are aimed at handling complex software. In their essence, they still follow the traditional CFA approach of explicitly tracking and logging the execution order of ICT instructions. To handle complex software, they leverage various optimization techniques, such as skipping safe ICT instructions, compressing logs, and fragmenting paths into smaller parts. While both schemes address some of the shortcomings in other CFA designs, they remain limited due to some fundamental issues:

- **High runtime overhead** on $\mathcal{P}$rv: ReCFA incurs an average runtime overhead of 42.3% when applied to some benchmarks. ScaRR incurs a higher overhead than ReCFA due to its design, which depends on frequent context switching between the kernel and user modes. This overhead is not acceptable in real-world scenarios.
- **Limited scalability**: This implies different limitations on both $\mathcal{P}$rv and $\mathcal{V}$rf, which are summarized as follows:
  - **The potential of Denial of Service**: Having several CFA-enabled $\mathcal{P}$rv applications running on the same device and continuously sending $\text{CF}_{reports}$ to $\mathcal{V}$rf, as in ScaRR [21], might impact the availability of the device as this would consume a significant portion of the network bandwidth.
  - **Costly verification**: The design of both ReCFA and ScaRR requires a continuous and open-ended verification process of all executed control flow events by any $\mathcal{P}$rv application. This approach is neither scalable nor efficient since the occurrence of attacks is typically an exceptional case
- **Feasibility Concerns**: The design of both schemes overlooks the compatibility with static $\mathcal{R}$A mechanisms in the sense that the reported results are not anchored in the same Root of Trust (RoT). This oversight not only complicates the attestation process but also raises concerns about the provided security guarantees. This is particularly crucial when aiming to ensure integrity through relying on some form of confidentiality, as is the case with ReCFA, which employs the Intel Memory Protection Keys (MPK) technology as a RoT [54], despite the reported limitations and security flaws [50].

3.3 BTI & Friends

Several hardware extensions have been recently supported in processor architectures to mitigate control flow hijacking attacks. For instance, the ARMv8.5-A architecture supports Pointer Authentication (PA), Memory Tagging Extensions (MTE), and BTI [7]. Notably, Apple has integrated the PA feature in several products [3], while Google has enabled MTE in their latest Pixel phones [2]. Furthermore, Academia has proposed various defenses, leveraging PA [23, 24, 55] as well as MTE [48]. Nevertheless, certain measures have been bypassed due to serious design flaws [9, 30, 62, 64].

On the other hand, BTI can be bypassed by a simple buffer overflow vulnerability, as visualized in Figure 2, where: (i) the `else` branch of the `main` function is entered and the `processInput` function is invoked (*ln.* 8 and 21), (ii) a buffer overflow vulnerability is triggered and overwrites the correct return address inside the `processInput` function stack frame (*ln.* 3), and (iii) returning inside the `if` statement body, where only privileged users are allowed to enter, without violating the BTI-enforced protection (*ln.* 4 and 13). Although Figure 2 demonstrates a ROP-like attack by manipulating backward edges, the same also applies to forward ones. Furthermore, the naive activation of BTI does not block control flow bending attacks [47]. Nevertheless, contrary to PA and MTE, BTI has the advantage of being simple and secret-independent, which are important features when leveraged in security designs.

```
1  void executePrivilege(void){
2    /*function that executes some syscalls, e.g., execv()*/
3  }
4
5  void processInput(char *arg[]){
6    /* a function that has a stack buffer overflow
7       vulnerability that let's the attacker
8       to control the next return instruction's target */
9    ...
10   return;
11 }
12
13 int main(int argc, char *argv[]){
14   ...
15   if(priviliged){
16     getPermissions();
17     ...
18     executePrivilege(...);
19   }
20   else
21   {
22     processInput(argv);
23     ...
24   }
25   ...
26 }
```

(a) Sample C code with a buffer overflow vulnerability.

```
1  processInput:          // @processInput
2      bti  c
3  /* buffer overflow vulnerability */
4      ret
5  main:                  // @main
6      bti  c
7    ...
8      tbnz   w8, #0, .LBB1_2
9      b      .LBB1_1
10 .LBB1_1:               // %if.then
11     ldr    x0, [sp, #16]
12     bl     getPermissions
13     bti  j
14     adrp   x0, .L.str
15     add    x0, x0, :lo12:.L.str
16     bl     executePrivilege
17     bti  j
18     b      .LBB1_3
19 .LBB1_2:               // %if.else
20     ldr    x0, [sp, #16]
21     bl     processInput
22     bti  j
23     b      .LBB1_3
24 .LBB1_3:               // %if.end
25     ...
26     ret
```

(b) BTI-enabled assembly for ARMv8.5-A translated from (a).

Figure 2: A BTI-bypassable control flow violation Example.

4 CFA+

Goal. The primary objective of CFA+ is to bridge the existing gap between control flow integrity and attestation schemes. While these schemes diverge in various aspects, CFA+ specifically aims to provide both local and remote detection capabilities within a single, efficient, and scalable design.

Overview. CFA+ employs selective software instrumentation to implicitly monitor the execution flow and provide basic detection capabilities, while it depends on BTI as a principled CFI foundation to extend the detection capabilities and ensure proper execution of inlined instrumentation instructions. In contrast to traditional CFA approaches that often suffer from extensive measurement collection and reporting mechanisms, CFA+ utilizes `XOR` operations to encode and decode data in two dedicated registers, enabling implicit monitoring and the preservation of relevant state data during runtime. If a violation is detected, the application will optionally be terminated and the values of these two registers in addition to the `PC` register are logged in an append-only log file stored in non-volatile memory, e.g., a hard disk. The updated hash value of this file is always anchored in a RoT to verify its integrity when necessary. When required, $\mathcal{V}$rf interacts with an attestation agent (ATTEST_{agent}), which a user-space process, to obtain a signed CF_{report} for all active CFA+-enabled $\mathcal{P}$rv-s. Subsequently, the runtime integrity status of each $\mathcal{P}$rv is verified based on the received CF_{report}.

4.1 Threat Model & Assumptions

We consider a powerful adversary ($\mathcal{A}$dv) attempting to achieve arbitrary code execution on a potentially flawed but benign application by exploiting memory corruption vulnerabilities to hijack the control flow. We assume a BTI-enabled hardware architecture, specifically ARMv8.5-A or higher versions. Moreover, we assume that the underlying OS kernel and hardware are trusted, providing the user space with essential protection features such as $\mathbf{W} \oplus \mathbf{X}$ [78]. It is worth noting that the kernel should not store any user-level registers in user-accessible memory during context switches, which is the case in major OS kernels. Finally, we consider a $\mathcal{P}$rv device equipped with a root of trust (RoT) like a Trusted Platform Module (TPM) [68] or ARM TrustZone [80]. Non-control data attacks, side channels, and physical attacks are beyond the scope of our threat model, which aligns with state-of-the-art CFI [14, 17, 25, 39, 42] and CFA schemes [21, 63].

4.2 CFA+ Terminology

The following terms are used to simplify describing CFA+:

- **State Register (SR) and Reference Register (RR)**: Two GPRs exclusively reserved for CFA+, which are utilized for maintaining relevant runtime state information.
- **Call Identifier (ID)**: A distinctive hard-coded value assigned to each `call` instruction. It undergoes two `XOR` operations with `SR`: (i) before executing the `call` to encode `SR`, and (ii) after the `call` to decode `SR` and restore its original value.

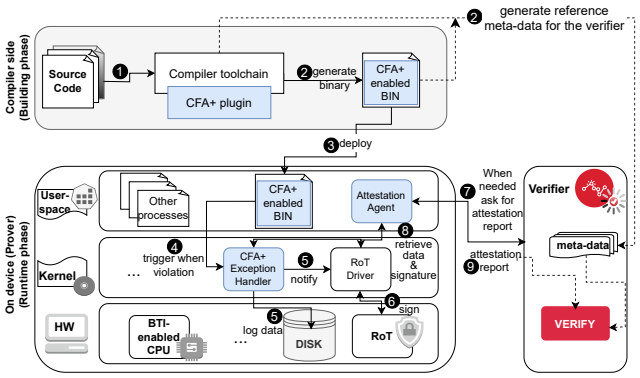

Figure 3: An overview of the entire attestation architecture of CFA+ (Blue/Red components are added to support CFA+).

4.3 System Overview

An overview of the CFA+ architecture is depicted in Figure 3. During compilation, CFA+ employs a series of analysis and transformation passes (visualized as CFA+ plugin), to harden the target software with its instrumentation. The details of this phase are discussed in Section 4.4. On the BTI-enabled $\mathcal{P}$rv device, the kernel loads a custom kernel module, known as CFA+ Exception Handler ($\text{EH}_{\text{CFA+}}$), which performs certain actions once triggered by a BTI violation. These actions include logging essential attestation data and communicating with the onboard RoT to sign the updated log. The ATTEST_{agent} process, responsible for sending and receiving attestation-related messages, can be implemented as an extension of any attestation agent used for static $\mathcal{R}$A. For instance, in the Linux kernel, the Integrity Measurement Architecture (IMA) [86] enables static $\mathcal{R}$A through an attestation agent that can be adapted to support CFA+ with minor modifications. Whenever needed, $\mathcal{V}$rf initiates the attestation procedure to verify the runtime integrity of all CFA+-enabled user-space applications running on a target $\mathcal{P}$rv. Further details on the attestation process are provided in Section 4.5.

4.4 Compiler Instrumentation

4.4.1 Target Instructions

To detect control flow violations, CFA+ needs to instrument all ICT instructions, which can be divided into two categories: forward-edge instructions, i.e., indirect `calls` and `jumps`, and backward-edge instructions, i.e., `returns`. Abstractly speaking, `ret` instructions can also be considered as a form of indirect `jumps`, given that, in the AArch64 architecture, returning from any non-leaf function means: (i) the return address is loaded from the stack into `LR`, and (ii) `ret` is then executed through jumping to the address in `LR`. Therefore, one of the key principles of CFA+ is to bind the genuineness of stack-saved return addresses to the correct value of `SR`. This can be achieved by instrumenting direct `call` instructions to non-leaf functions.

On the other hand, indirect `jumps` are mainly generated from switch statements that are translated to jump tables by compilers. These tables are usually read-only, bound-checked,

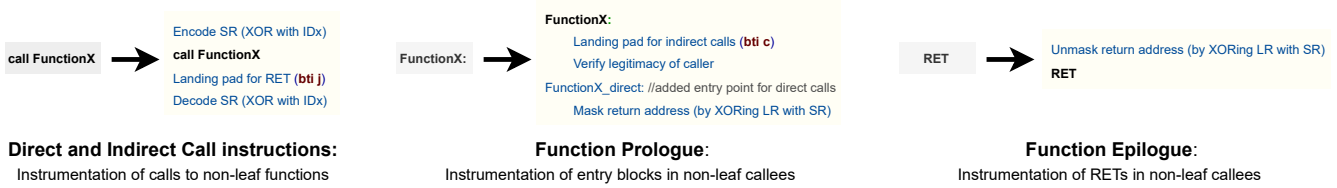

Figure 4: Illustration of CFA+ instrumentation in the basic form.

and have entries targeting addresses within the same function body. Therefore, the vast majority of CFI schemes pay attention to indirect `calls`, considering that indirect `jumps` are protected by default [28]. CFA+ follows the same principle but also adds some flags, i.e., `-fno-jump-tables`, in the compilation pipeline to disable the generation of these tables. While such a configuration might slightly increase the runtime overhead, it has the advantage of not only eliminating some JOP gadgets but also protecting against some microarchitectural attacks [49]. This is considered one of the main countermeasures to mitigate such attacks in the Linux kernel [20] and in some CFI mechanisms, e.g., RAP [87].

As such, CFA+ targets instrumenting indirect `call` and `ret` instructions, in addition to some direct `calls` as a way to map forward- and backward-edges and stay context-aware.

4.4.2 Basic Form of Instrumentation

CFA+ relies on two main pillars: (i) software instrumentation, and (ii) BTI. Figure 4 illustrates the positioning of these pillars, considering a basic form of instrumentation, where CFA+ targets instrumenting three types of code elements:

- **Call Instructions**: This includes all indirect `calls` in addition to the direct ones that invoke non-leaf functions. A unique ID is generated for each selected instruction, which is used to encode and decode `SR`. A landing pad for `ret` instructions (`bti j`) is inserted after each `call`.
- **Function Prologue**: Each candidate function for indirect `calls` is guarded with `bti c`, followed by a block of instructions to verify the legitimacy of the caller instruction. A new label (an entry point), is added for direct `calls` targeting the corresponding function to skip non-relevant instrumentation instructions. The return address of each non-leaf callee function is masked with `SR` (i.e., `LR` = `LR` ⊕ `SR`) before being saved in the stack.
- **Function Epilogue**: This entails unmasking the return address by XORing with `SR` again before executing `ret`.

4.4.3 Detailed Working Mechanism

The following steps are performed during compilation:

1. CFA+ generates a function-level CFG for any target application. Considering the example application in Figure 5 (A), the resulting CFG is shown in Figure 5 (B). To resolve indirect `calls`, CFA+ borrows the static analysis mechanism of TyPro [35], which is based on type propagation. This approach would allow for identifying the minimal, yet over-approximated, set of possible targets for each indirect `call` at compile-time without introducing compatibility issues.

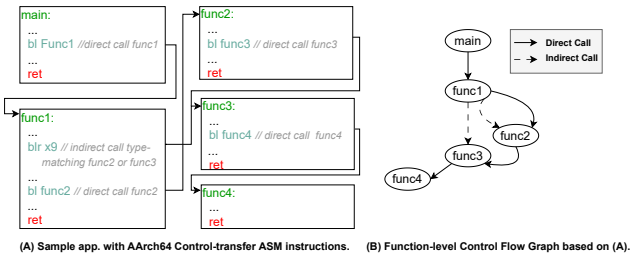

Figure 5: Illustration of function-level CFG.

2. CFA+ extracts the strongly connected components in the constructed CFG [76] and sorts them topologically [67]. It then traverses the CFG to analyze each function and extract relevant information, such as the function type (e.g., leaf, external, etc.), direct callers, number and type of indirect calls, the set of callees and their types, etc.
3. Based on type propagation analysis, CFA+ tracks the origin of each indirect `call` and constructs equivalence classes (ECs) accordingly. Each candidate function for an indirect `call` joins the corresponding EC. Partially overlapping ECs remain disjoint to maintain a high level of precision. Each EC is then carefully assigned a 48-bit unique identifier (ID_{EC}) as multiples of 2 to distinguish individual bits as much as possible.
4. Considering the above analysis, CFA+ visits each function according to its topological order and generates a 64-bit unique ID for each `call` instruction (e.g., using a hash function). The ID generation process for indirect `calls` considers generating only a unique 16-bit value, which when combined with the corresponding ID_{EC}, the resulted combination represents the real unique ID for any indirect `call`. A key property to maintain is that XORing any ID with one or more IDs in the same path should result in a unique value at the program level. Maintaining this requirement is feasible even in many complex applications, given the entropy of 64 bits. Considering that the return addresses of leaf functions are not stored in memory, their corresponding direct `call` instructions are skipped from ID generation or additional instrumentation, except for adding landing pads.
5. To instrument target `calls`, CFA+ reserves two GPRs (`SR` and `RR`) for its exclusive use, which are initialized to zero in the `main` function. Listing 4.1 showcases the base control-transfer instructions of three functions (`func1`, `func2`, and `func3`) from the ones shown in Figure 5. Listing 4.2 depicts the instrumentation of `func1`'s `call` instructions, where each `call` is preceded by an encod-

```
1  func1:                          ; non-root caller
2      ...                         ; start of func1 prologue
3      str x30, [sp,-16]!          ; saving (pushing) LR value on the stack
4      ...                         ; end of func1 prologue
5      blr x9                      ; indirect call type-matching with func2 and func3
6      ...
7      bl func2                    ; direct call to func2
8      ...
9      ...                         ; start of func1 epilogue
10     ldr x30, [sp], 16           ; restoring (popping) the value of LR
11     ...                         ; end of func1 epilogue
12     ret
13 func2:                          ; non-leaf callee
14     ...                         ; func2 prologue
15     ...
16     ...                         ; func2 epilogue
17     ret
18 func3:                          ; non-leaf callee

12     eor x28, x28, x15           ; decoding - via XORing- SR(i.e. x28) using x15
13     ...
14     ldr x15, =IDy               ; loading the ID of this (in-)direct call instruction into x15
15     eor x28, x28, x15           ; encoding - via XORing- SR(i.e. x28) using x15
16     bl func2_direct             ; direct call to func2
17     bti j                       ; landing pad for RET instructions
18     ldr x15, =IDy               ; loading ID once again into a corruptible register, i.e., x15
19     eor x28, x28, x15           ; decoding - via XORing- SR(i.e. x28) using x15
20     ...
21     ...                         ; start of func1 epilogue
22     ldr x30, [sp], 8            ; restoring (popping) the value of LR
23     eor x30, x30, x28           ; unmasking the value of LR (x30) by XORing again with SR (x28)
24     ...
25     ret
```

Listing 4.2: CFA+ instrumentation of `func1` (cf. Figure 4).

ing `XOR` instruction of `SR` (cf. *ln.* 8 and 15), and followed by a `ret`-specific landing pad along with a decoding `XOR` instruction of `SR` (cf. *ln.* 10-12 and 17-19).

6. To detect tampering with spilled return addresses, non-leaf functions that are not candidates for any indirect `call` simply have their prologue and epilogue instrumented with a single encoding and decoding `XOR` instruction, respectively. For instance, in Listing 4.2, `func1`'s return address, which is in `LR` (`x30`), is masked (i.e., `XORed`) using `SR` before saving it in the stack memory (cf. *ln.* 3). The retrieved address is unmasked again before returning the control back to the caller function (cf. *ln.* 23). Malicious tampering with the stored address would yield a corrupted one when unmasked, which would trigger a BTI violation.
7. The prologue of any function that might be invoked indirectly is divided into two parts. The upper part is the main entry point for indirect `calls`, which starts with a landing pad, i.e., `bti c` (cf. *ln.* 2 in Listing 4.3 and Listing 4.4), followed by a block of instructions to validate the legitimacy of the indirect `call` instruction. The lower part starts with a symbol, introduced by CFA+, that has the same visibility as the corresponding function to act as an entry point for direct `calls` (which are rewritten accordingly in caller functions), skipping the execution of irrelevant instrumentation instructions (cf. *ln.* 8 in Listing 4.3 and *ln.* 7 in Listing 4.4). If the target function is a member in one EC and is targeted by one indirect `call`, the verification procedure is simple, where only the ID of the indirect `call` instruction is checked (cf. *ln.* 3-6 in Listing 4.4). If the expected ID is verified, the execution proceeds normally, bypassing the trap instruction. Otherwise, a BTI violation is triggered by indirectly jumping to an invalid random address (i.e., performing an indirect `call` to the middle of an arbitrary function using the value in `LR` (`x30`). Assuming that `func2` can be targeted by more than one indirect `call` instruction, CFA+ generates, during the analysis phase, a `mask` value, which will be used to verify the legitimacy of the indirect `call` instruction. This per-function value is generated by ORing the IDs of all legitimate indirect `call` instructions to the underlying function. Performing a bitwise AND operation between the resulted `mask` and ID of the indirect `call` instruction should yield the same ID as a correct result (cf. *ln.* 3-7 in Listing 4.3). Given the way of generating IDs for indirect `calls`, bypassing this check by non-legitimate `calls` is difficult and would eventually be detected if happened.
8. To detect malicious tampering, the return addresses of indirectly called functions are also masked and unmasked in certain places as described in point 6 (cf. *ln.* 9 and 15 in Listing 4.3 and *ln.* 8 and 14 in Listing 4.4).

Corner Cases. The previous discussion did not delve into scenarios such as `setjmp/longjmp`, where non-traditional control flow transfers may occur, leading to a return to an unexpected location. While cases like `setjmp/longjmp` are considered unsafe and have become rare in production software, our approach has the potential to support them by modifying the relevant stack unwinding library in the underlying compiler (e.g., LLVM-Libunwind [69] in the LLVM/Clang compiler). The concept involves saving a copy of `SR` on the stack whenever the return address in `LR` is stored there. Upon reloading `LR`, the copy of `SR` would be discarded. During stack unwinding for exceptional circumstances, each intermediate stack frame between the current stack pointer and the target stack pointer needs to be traversed to restore each stored copy of `SR` and perform an `XOR` operation with the current value. This serves as an alternative approach to the typical `SR` decoding method. In this particular case, even if

```
1  func2:                                  ; non-leaf callee; belong to more than one EQ
2      bti c                               ; landing pad for indirect calls; start of func2 prologue
3      ldr x27, =mask                      ; load the identified mask value into RR (i.e., x27)
4      and x27, x27, x15                   ; a bitwise AND between the mask (in x27) and the ID (in x15)
5      cmp x27, x15                        ; compare the result in x27 with the ID in x15
6      b.eq func2_direct                   ; if equal, execute the rest of the prologue normally
7      blr x30                             ; otherwise, raise an exception by jumping to an invalid address in LR
8  func2_direct:
9      eor x30, x30, x28                   ; masking (XORing) the value of LR (x30) using SR (x28)
10     str x30, [sp,-8]!                   ; saving (pushing) LR value on the stack
11     ...                                 ; rest of func2 prologue
12     ...
13     ...                                 ; start of func2 epilogue
14     ldr x30, [sp], 8                    ; restoring (popping) the value of LR
15     eor x30, x30, x28                   ; unmasking the value of LR (x30) by XORing again with SR (x28)
16     ret
```

Listing 4.3: CFA+ instrumentation of `func2` (cf. Figure 4).

malicious tampering occurs with the copies of `SR`, it would not compromise the security of CFA+, as it would result in an inconsistent `SR` value in the target location, which would eventually be detected.

4.4.4 Handling Shared Libraries

The previous discussion aligns well with statically compiled software. However, complex applications usually rely on shared libraries, which can be used by any process running on the same device. In general, handling shared libraries in runtime defenses is a challenge by itself, which is not considered by many defenses, including the recent ones that depend on Pointer Authentication (PA) [23]. Therefore, CFA+ proposes a lightweight protection approach for shared libraries that brings two main advantages. First, it maintains compatibility with legacy software stacks. Second, it shields native CFA+-enabled software from exploitable vulnerabilities in shared code. To achieve so, CFA+ requires compiling shared code with extra flags that would do the following:[1]

- Reserve `SR` and `RR` to ensure they remain uncorrupted by any instruction in shared code. For instance, to exclude the `x27` and `x28` registers from the register allocation phase in the LLVM/Clang compiler, the following flags should be added to the compilation pipeline: `-ffixed-x27 -ffixed-x28`.
- Emit `bti c` instructions at the start of any address-taken function. Additionally, after each `call` instruction, emit `bti j` instructions.

This lightweight instrumentation provides coarse-grained protection to shared libraries without introducing compatibility issues with legacy code, as the added landing pads will be interpreted as `NOPs` for any non-BTI-enabled code.

On the $\mathcal{P}$rv side, the instrumentation of `calls` to external functions in shared libraries is illustrated in Listing 4.5. The main difference, compared to the instrumentation of `calls` to native functions, is that `SR` is backed up in `RR` before executing the encoding `XOR` and `call` instructions (cf. *ln.* 3-4), and it is immediately verified after executing the decoding

[1]We note that CFA+ considers the Procedure Linkage Table/Global Offset Table (PLT/GOT) entries protected using the available security features in compilers or kernels, such as Relocation Read-Only (RELO) [82].

```
1  func3:                                  ; non-leaf callee; belong to one EQ
2      bti c                               ; landing pad for indirect calls; start of func3 prologue
3      ldr x27, =IDx                       ; load the expected ID into RR (i.e., x27)
4      cmp x27, x15                        ; compre the value in x27 with the value in x15 (loaded by the caller)
5      b.eq func3_direct                   ; if equal, execute the rest of the prologue normally
6      blr x30                             ; otherwise, raise an exception by jumping to an invalid address in LR
7  func3_direct:
8      eor x30, x30, x28                   ; masking (XORing) the value of LR (x30) using SR (x28)
9      str x30, [sp,-8]!                   ; saving (pushing) LR value on the stack
10     ...                                 ; rest of func3 prologue
11     ...
12     ...
13     ldr x30, [sp], 8                    ; restoring (popping) the value of LR
14     eor x30, x30, x28                   ; unmasking the value of LR (x30) by XORing again with SR (x28)
15     ret
```

Listing 4.4: CFA+ instrumentation of `func3` (cf. Figure 4).

```
1  funcX:                                  ; non-leaf callee
2      ...
3      mov x27, x28                        ; Saving (backing up) the value of SR (x28) into RR (x27)
4      eor x28, x28, #0x17E8               ; encoding - via XORing- SR(i.e. x28) using a unique bitmask (ID)
5      bl printf
6      bti j                               ; landing pad for RET instructions
7      eor x28, x28, #0x17E8               ; decoding - via XORing- SR(i.e. x28) using same bitmask (ID)
8      cmp x28, x27                        ; Check whether RR (x27) is equal to SR (x28) as expected
9      b.eq funcX_printf_1                 ; If equal, execute normally by skipping the EH_CFA+ triggering instr.
10     blr x30                             ; otherwise, raise an exception by jumping to an invalid address in LR
11 funcX_printf_1:
12     ...
13     ret
```

Listing 4.5: CFA+ instrumentation of a call to external func.

`XOR` instruction (cf. *ln.* 6-10). Given that each `call` instruction has a unique ID, returning to a different location than the expected one would be immediately prevented due to the mismatch between `SR` and `RR` values.

As can be seen in Listing 4.5, the instrumentation of `calls` to external functions is further optimized, where `XOR` instructions operate directly on immediate values. Thus, extra `load` instructions to load the hard-coded IDs are no longer needed. A crucial aspect in the ARMv8 architecture is that logical instructions, e.g., `XOR`, accept specific 13-bit bitmask immediate values as a third operand, which each would map to a 64-bit unique value when the instruction is executed [5]. This mechanism can generate 5,334 unique 64-bit values. For instance, the shown bitmask `0x17EB` would be translated to a 64-bit ID equal to `0xFFFFFFFE000003FF`. Leveraging these pattern-based generated values as IDs would yield many collisions in terms of getting the same `SR` value in different locations. This will not be the case for `call` instructions to external functions, given that `SR` will not be updated by these external callees and it will be immediately checked upon return.

4.5 Runtime Attestation & Verification

CFA+ not only prioritizes prevention over remote detection but also reduces the frequency of $\mathcal{V}$rf-$\mathcal{P}$rv interaction, as signs of violations can be inferred at any time from `SR` and `RR`.

Attestation Procedure. The instrumented $\mathcal{P}$rv application is expected to run normally. When a BTI violation is triggered, control will be transferred to $\text{EH}_{\text{CFA+}}$, which maintains a central append-only log file for all $\mathcal{P}$rv-s. This log file is stored

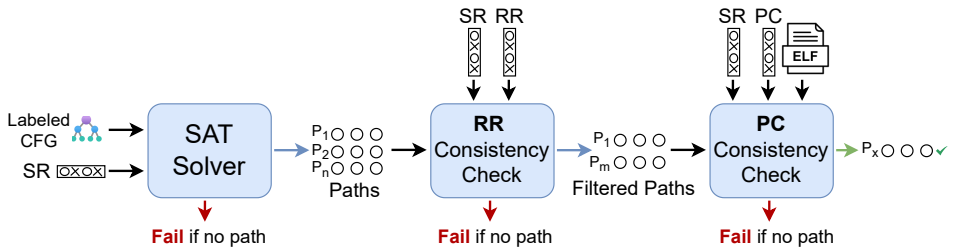

Figure 6: Illustration of the verification procedure of CFA+.

in non-volatile writable memory, such as a hard disk. EH_{CFA+} will then add a new record in the log file, trigger the RoT to sign the hash value of the updated version of it, and optionally terminate or restart the victim $\mathcal{P}$rv. The record will contain (i) the $\mathcal{P}$rv process name and ID, (ii) IMA measurement (if exists), which is the hash value of the $\mathcal{P}$rv binary image when loaded, (iii) the values of SR, RR, and PC, and (iv) a binary flag indicating whether this record is added due to a violation (1 means a violation, and 0 otherwise). When necessary, $\mathcal{V}$rf asks $ATTEST_{agent}$ to send CF_{report} for all CFA+-enabled $\mathcal{P}$rv applications running on the same device. Taking into account the potential compromise of certain $\mathcal{P}$rv-s, which may result in a violation of the expected control flow without local detection (i.e., no BTI violation), $ATTEST_{agent}$ instructs EH_{CFA+} to record the most recent execution status of all active $\mathcal{P}$rv-s. EH_{CFA+} will then create an information record for each $\mathcal{P}$rv, indicating the latest values of SR, RR, and PC, while setting the binary flag to 0 to indicate its inclusion for attestation purposes only. Eventually, $\mathcal{V}$rf will receive a signed CF_{report} from $ATTEST_{agent}$, which mainly consists of the log-file records in addition to the RoT signature.

Verification Procedure. After successfully verifying the integrity of CF_{report}, $\mathcal{V}$rf can verify the runtime integrity status of any $\mathcal{P}$rv in the log file. $\mathcal{P}$rv-s with records indicating violations are considered compromised without verification. For other $\mathcal{P}$rv-s, $\mathcal{V}$rf does the verification by checking the consistency of the reported register values w.r.t. the legitimate control flow of the corresponding CFG, as depicted in Figure 6. Given that the idea of CFA+ is to dynamically label the CFG edges depending on the execution context, where SR always holds the label of the last visited edge by PC, one way to verify the control flow integrity is to extract the related path and check the consistency of the reported values, e.g., the value of SR should equal to the XOR operation of all IDs starting from the root function until reaching the last ICT instruction executed by PC. To achieve so, $\mathcal{V}$rf turns the path(s) extraction process into a Boolean satisfiability problem, to be solved by a SAT solver. The input to the SAT solver would be (i) the CFG of the corresponding $\mathcal{P}$rv, represented as a complex data structure that contains all the needed information about caller and callee functions along with the associated IDs of related `call` instructions, and (ii) the reported SR value. Despite the low probability of having collisions (as we discuss later), the SR value is expected to be seen in more than one part of the program. Thus, the SAT solver can be configured to output all possible root-anchored paths that would lead to such a value.[2] If eventually no path is found, the $\mathcal{P}$rv is regarded as compromised due to the illegitimate SR value. If a path or more are found, the following checks are performed to further verify the execution integrity:

- For each path, $\mathcal{V}$rf checks the consistency of RR, which should have limited values compared to SR, as follows:
  - If the last assignment to RR was made before a call to a function in a shared library, then the correct value of RR should equal to the reported value of SR (potentially XORed with intermediate IDs if SR is updated in a further different location).
  - If the last assignment to RR was made due to an indirect `call`, then the RR value would be the ID of that `call` instruction or the result of XORing this ID with the corresponding `mask` in the callee.

  If the above checks fail for all paths, a control flow violation is likely the cause and thus the corresponding $\mathcal{P}$rv is considered compromised.
- After passing the aforementioned checks, $\mathcal{V}$rf proceeds to verify the consistency of SR with the value of PC for each validated path. To accomplish this, $\mathcal{V}$rf needs to access the Executable and Linking Format (ELF) file associated with the corresponding $\mathcal{P}$rv. This access allows $\mathcal{V}$rf to examine whether PC points to an instruction within one of the functions that constitute the underlying path. This verification step can still be easily conducted despite the potential activation of Address Space Layout Randomization (ASLR) at runtime, which randomizes the base address but leaves the lower part of PC unchanged. If at least one valid path is found, $\mathcal{V}$rf concludes that $\mathcal{P}$rv is benign.

5 Implementation

CFA+ prototype consists of three parts: (i) the compiler toolchain, (ii) the helper software modules on $\mathcal{P}$rv, and (iii) the $\mathcal{V}$rf framework. On the compiler side, CFA+ is implemented as a set of in-tree analysis and transformation passes that extend the LLVM 15.0 compiler framework. The analysis pass is implemented in the LLVM Intermediate representation (IR) layer at the `Module` level. The transformation pass is realized at the `Machine Function` level and implemented in the

[2] The details of the constructed Boolean formulas and variables are described in Appendix A.

Table 1: CFA+ implementation details.

Component	Language	LoC	Description
Compiler Toolchain			
Analysis Pass	C++	1876	CFG and ID generation
Transformation Pass	C++	1419	Instrumenting target code elements
Modifications to sources	C++, cmake	15	Modifying related LLVM sources
$\mathcal{P}$rv			
Kernel Module (EH_{CFA+})	C	738	Handling BTI violations and logging data
Attestation Agent (userspace)	Rust	746	Receiving and sending attestation data
$\mathcal{V}$rf			
SAT-based verification	Python	639	Verifying reported register values
Communication Server	Rust	1153	communication purposes
Automation Scripts	Bash	312	Automating the verification process

AArch64 backend. The LLVM Linker (LLD) is used to enable Link Time Optimization (LTO) [70], which is a requirement for CFA+. On the $\mathcal{P}$rv side, EH_{CFA+} is implemented as a kernel module on top of the ARM kernel v5.11, extending the default handler of BTI instructions. Furthermore, $ATTEST_{agent}$ is implemented as a user-space process that provides not only support for CFA+ but also for any $\mathcal{R}$A scheme that depends on IMA [86], which is the de-facto standard for static attestation in the Linux kernel. To maintain further compatibility with IMA, we leverage the TPM as a RoT, where a different Platform Configuration Register (PCR) is used to store the hash value of CF_{report}. On the $\mathcal{V}$rf side, we build on top of the open-source SAT solver from Google Optimization tools (aka OR-Tools [66]) for verification. The noise protocol framework is used for secure communication between $\mathcal{V}$rf and $\mathcal{P}$rv [1]. The Concise Binary Object Representation (CBOR) is used as an efficient data serialization format that produces small message sizes, which is recommended by the Trusted Computing Group (TCG) specifications [89].

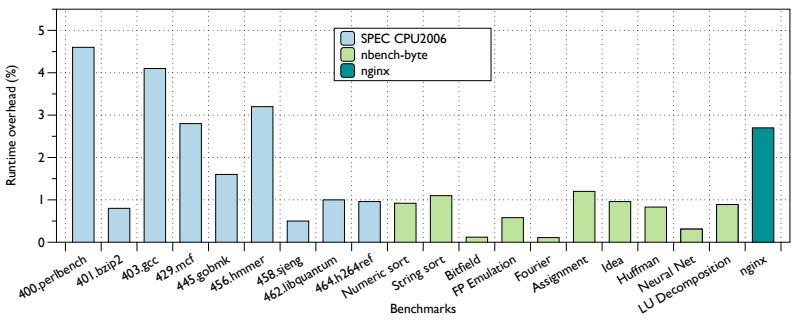
The current prototype for the entire CFA+ architecture consists of 6898 Lines of Code (LoC), excluding libraries. Further details about each component are provided in Table 1.

6 Evaluation

Goal. We evaluate CFA+ in terms of performance overhead, security, and compatibility.

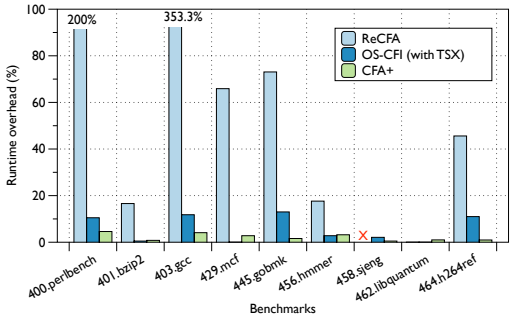
Methodology. To the best of our knowledge, until the time of writing this paper, the Apple M2 and M3 MacBook devices are the only commercially available hardware that has support for BTI. Yet, the support of Apple devices in the mainstream Linux kernel is still a work in progress [79]. While Asahi Linux is making faster progress in this direction, the support of the BTI feature is not there yet [83]. Therefore, we use the QEMU 5.2.0 emulator for our evaluation, which has support for BTI [81]. We note that the obtained results are expected to be higher on QEMU compared to real systems due to the emulation of certain instructions in software. We run QEMU on a machine that supports the ARMv8.2 architecture (i.e., Kunpeng 920-3226 processor with 32-core ARMv8.2 CPUs operating at 2.6GHz, accompanied with 128GB of DDR4 memory), running Ubuntu 20.04.5 LTS AArch64. This will further reduce the emulation impact on performance as QEMU will take advantage of the native support of all instructions by the host system and will only emulate the landing pad ones.

Compilation flags. CFA+ introduces the `-cfaplus` compiler flag to harden the target software. `x27` and `x28` registers have been used as `RR` and `SR` respectively, which can be reserved by adding the `-ffixed-x27` and `-ffixed-28` flags to the compilation pipeline. Finally, our target benchmarks are compiled with `-O2` optimization flag.



Benchmarks. The following benchmarks are considered:

- SPEC CPU2006 (C only) [85]: We run each benchmark for 5 iterations, considering the `ref` (real) dataset.
- nbench-byte [90]: We run each test for 200 iterations, adopting the same methodology followed in state-of-the-art (SOTA) runtime defenses [23].
- nginx v1.22.1 [73]: We use the `wrk` benchmarking client [91], running on the host machine, to continuously request a static 4KB HTML page for 30 seconds.



6.1 Performance Overhead

Runtime overhead on $\mathcal{P}$rv. Figure 7a illustrates the runtime overhead of CFA+ on the selected benchmarks. The highest observed overhead 4.6% occurs in the `400.perlbench` application, while the lowest overhead of approximately 0.12% is recorded in the `Fourier` application. The `SPEC CPU2006` benchmarks exhibit 2.2% overhead on average, whereas for the `nbench-byte` and `nginx` benchmarks, the average overhead is 0.7% and 2.7% respectively. Considering all benchmarks, the overall average runtime overhead of CFA+ amounts to 1.5%. We note that the primary factor contributing to the runtime overhead of CFA+ is the ratio and type of `call` instructions compared to the total number of instructions, as well as the frequency of executing them. For instance, according to the statistics shown in Table 4, the `call` instructions in the `nbench-byte` benchmark account for 5% of the total number of instructions, with the majority being `calls` to external functions that do not require CFA+ related load (memory access) instructions as part of the `call` instrumentation. Conversely, while the `400.perlbench` benchmark shares the same ratio of `call` instructions, a smaller fraction consists of direct `calls` to external functions, where the instrumentation is optimized. Moreover, the number of indirect `calls` and candidate functions for such `calls` is higher in `400.perlbench`, resulting in the execution of more CFA+ related instructions.

While achieving an objective comparison is challenging due to variations in systems and other factors, Figure 7b presents a comparison of the runtime overhead of CFA+ with two representative SOTA CFA and CFI schemes, namely ReCFA [63] and OS-CFI [43], considering the common benchmarks used in evaluation. The reported results are just for demonstrating impact, which show that CFA+ outperforms ReCFA by several orders of magnitude, highlighting the performance advantage of its non-traditional design in attesting runtime integrity. Additionally, CFA+ does not suffer from compatibility issues encountered in ReCFA, such as the case with the `458.sjeng` application. On the other hand, although the average runtime overhead of CFA+ is 5x faster than OS-CFI, OS-CFI exhibits better performance in certain appli-

nbench-byte	651432	666180	2.26%
nginx	780283	962427	23.34%
Average			22.06%

cations like `401.bzip2` and `429.mcf`, where indirect `call` instructions are minimal or non-existent. We note that OS-CFI focuses solely on forward-edge protection.

Overall, CFA+ demonstrates superior performance compared to many coarse- and fine-grained CFI schemes, while providing stronger security guarantees [14, 17, 18, 25, 59, 61]. However, it is essential to acknowledge that there is no one-size-fits-all solution, as specific application-dependent factors may favor other schemes for individual benchmarks.

Compile-time overhead. To assess the additional compilation time introduced by CFA+ passes, we employed the LLVM command-line option `-time-passes`. Table 2 presents the normalized compilation time (in seconds) for selected benchmarks, comparing runs with and without CFA+, and highlighting the analysis pass duration. On average, the compile-time overhead of CFA+ remains below 1.5%. Notably, the nbench-byte benchmark is excluded as it exhibits negligible overhead.

Binary Size Overhead. While many CFI and CFA schemes struggle to balance the trade-off between security and performance, the design of CFA+ prioritizes both features, albeit with increased binary size overhead. Table 3 demonstrates the size of the `.text` section, which contains all instructions, including CFA+ instrumentation instructions and hard-coded IDs. ELF binaries' precise sizes (in bytes) were measured using the `size` command in the Linux kernel. The `456.hmmer` benchmark exhibits the highest binary size overhead, amounting to 48.44%. However, in more complex applications like `403.gcc` and `400.perlbench`, this overhead is reduced by at least 10%, resulting in 38.69% and 34.28% respectively. The `nbench-byte` benchmark demonstrates the lowest overhead, with only 2.26% increase in binary size. The average binary size overhead across all benchmarks is approximately 22%.

The binary size overhead is influenced by various factors, with the ratio of `call` instructions to the total number of instructions being particularly significant, along with their distribution across functions. Table 4 provides detailed statistics on the selected benchmarks, showing that the `456.hmmer` benchmark exhibits the highest ratio of call instructions at 9% of the total instruction count. This indicates the addition of at least 5 extra 4-byte instructions as pre- and post-call instrumentation, along with 8 bytes as a hard-coded unique ID for each `call` instruction. While this explains the significant binary size overhead observed in certain applications, it is worth noting that, by excluding certain outlier cases, e.g., the `456.hmmer` benchmark, the average binary size overhead of CFA+ remains comparable to other forward-edge CFI schemes, such as LLVM-CFI (up to 23.21% code increase) and FineIBT (up to 19.05% code increase) [13].

Verification speed. The speed of the verification process is primarily determined by the performance of the SAT solver module, which has a dominant impact. To evaluate it, $\mathcal{V}$rf was configured to attest each benchmark 50 times during execution. The reported register values were then offloaded to the SAT solver for path(s) extraction, which ran on a laptop equipped with an Intel Core i7-1185G7 3GHz CPU, and 16GB of DDR4 RAM, running Ubuntu 20.04.5. Figure 8 depicts the minimum, average, and maximum time (in seconds)

Table 4: Statistics about the various benchmarks that are tested with CFA+.

		Functions						Instructions						
	Benchmark	Total Number	External Functions	Leaf Functions	Candidates to Indirect Calls	Direct-only Called Functions	Indirect-only Called Functions	Total Number	Number of Calls	Direct Calls	Indirect Calls	Calls to External Functions	Calls to Leaf Functions	Number of RETs

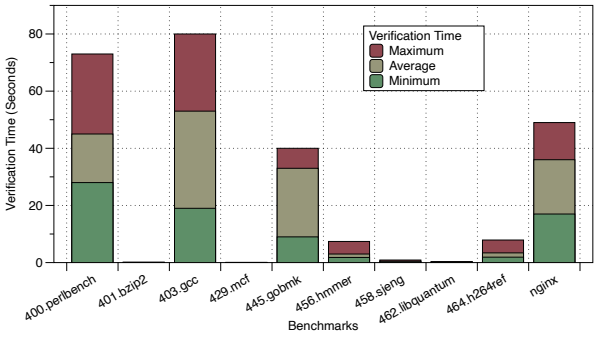

Figure 8: Insight on the speed of the SAT-based verification.

required to find the first path confirming the reported values. While most applications took only fractions of a second, complex applications like `403.gcc` took up to 80 seconds to find the matching path. On average, the verification process was completed in less than half a minute in most cases.

6.2 Security Evaluation

The security of CFA+ relies on five pillars:

- **Transparency.** CFA+ is inherently transparent as it does not rely on any confidential data, rendering it immune to a wide range of attacks, including certain side-channels.
- **Register-level atomicity.** CFA+ is not susceptible to race conditions in multi-threaded applications, where the intermediate values of the inline reference monitors can be manipulated while residing in memory. The values of the inline reference monitors of CFA+ are protected by design as they never leave the `SR` and `RR` registers, which are not shared among threads.
- **Strong collision resistance.** The entropy source to maintain collision-free `SR` values based on the generated IDs is 64 bits, which is big enough to achieve this property. For small and mid-sized applications, all potential values of `SR` can be checked during compile-time, where custom IDs can be regenerated in case of detecting a collision. This check is hard to perform for big and complex applications. Nevertheless, we note that the biggest application, i.e., `403.gcc`, we encountered has around 2^{59} unique paths. This means that the probability of having collisions is $(\frac{1}{2^{64}-2^{59}}) \approx 3\%$, which is low and unlikely to yield sufficient gadgets to launch an attack that complies with BTI instructions and eventually bypasses CFA+.
- **Resilience.** The hybrid design of CFA+ renders it highly resilient against sophisticated attacks. For instance, consider the scenario where `SR` is `XORed` (encoded) with a `call`'s ID before its execution to invoke an intermediate function. Within this function, the return address is masked and saved on the stack. Tampering with this address, such as overwriting it, would result in one of two cases upon unmasking: (i) targeting a non-landing pad location and thus immediately triggering EH_{CFA+}, or (ii) leading to an arbitrary landing pad with a different ID, resulting in an inconsistent `SR` value. This inconsistency can lead to either (i) quick detection and prevention of the attack if the `SR` value is used to unmask previously masked return addresses along the execution path, or (ii) eventual detection by $\mathcal{V}$rf during attestation and verification. $\mathcal{V}$rf can determine that either (i) no legitimate path could have the reported `SR` value, or (ii) there are inconsistencies between `SR` and `PC`, indicating that `SR` appears in the wrong path. A similar approach is employed during the verification process to detect control flow bending attacks [47].
- **Shielded execution.** As discussed in Section 4.4.4, CFA+ does not allow vulnerable shared code to return to a different location as this would be immediately detected and prevented due to mismatch values between `SR` and `RR`. This shields native code from exploitable vulnerabilities in shared code.

6.2.1 Experimental Security Evaluation

Limited short gadgets. The incorporation of BTI in CFA+ design significantly reduces the number of short gadgets, which are the most common ones in real-world attacks [31]. This further complicates any adversarial attempts to exploit potential collisions in complex applications. For instance, we leveraged capstone 5.0 [10] and Ropper 1.13.8 [84] to filter

Table 5: Number of potential gadgets w.r.t. CFA+

Benchmark	Number of ROP gadgets (Up to 6 instructions long)		Number of JOP gadgets (Up to 6 instructions long)	
	Without CFA+	With CFA+	Without CFA+	With CFA+
400.perlbench	932	0	461	0
401.bzip2	9	0	19	0
403.gcc	1791	0	2456	0
429.mcf	12	0	1	0
445.gobmk	473	0	548	0
456.hmmer	86	0	116	0
458.sjeng	37	0	6	0
462.libquantum	19	0	1	0
464.h264ref	193	0	113	0

out all potentially useful ROP and JOP gadgets that are up to 6-instruction long in the SPEC CPU2006 suite. We did not record any gadget in CFA+ enabled applications compared to their unprotected versions. Table 5 shows the impact of CFA+ on the number of available gadgets.

Real World Exploits. Although it is hard to reproduce CVEs, especially for the AArch64 architecture, we managed to reproduce CVE-2013-2028. It is a stack-based buffer overflow vulnerability (triggered via an integer underflow), which affects `nginx 1.3.9`, allowing for a ROP attack that causes a denial of service and arbitrary code execution. We were able to reproduce this CVE on the AArch64 architecture and illegally execute the `execve` system call in the absence of CFA+. Although the entire nginx binary did not have the encoding of the syscall `SVC #0` instruction, i.e., 0x010000d4, we directed the `ngx_execute_proc` function to perform `execve` on our behalf as part of the exploit. When running the recompiled version of nginx with CFA+ enabled, this attack is immediately prevented, due to attempting to jump to a corrupted address that when unmasked, resulted in an invalid target. We further performed a deliberate follow-up attestation that concluded the compromise of the corresponding $\mathcal{P}$rv after observing the related record in CF_{report}.

6.3 Compatibility.

Functional correctness CFA+ successfully maintains the functionality of all the benchmarks under consideration, as it does not cause any execution failures or unexpected results that would prevent performance numbers from being reported by the evaluation frameworks. Additionally, the borrowed type propagation analysis mechanism from Typro [35] ensures compatibility with potential valid targets for indirect `calls`. This stands in contrast to other approaches, such as LLVM-CFI [17] and ReCFA [63], which are incompatible with at least one application in the SPEC CPU2006 suite.

Impact of instrumented shared libraries on legacy code. Considering that the evaluation frameworks we employed utilize static linking for objective performance measurement reporting, we aimed to investigate the impact of instrumented shared libraries on legacy code in terms of compatibility and runtime overhead. To achieve this, we made modifications to the evaluation scripts of the SPEC CPU2006 benchmark suite, enabling dynamic linking against a custom `GLIBC` that we pre-compiled with instrumentation, as described in Section 4.4.4. By comparing the runtime of each application using this modified dynamic linking configuration to the default static linking configuration, we observed a negligible overhead, averaging at 0.03%. These results not only confirm the absence of compatibility issues but also demonstrate the functional correctness of our approach.

7 Discussion

Precision of CFA+. CFA+ exhibits a precision that is on par with other CFA schemes [21, 63], despite generating a CFG at the function-level and primarily instrumenting `call` instructions. The need for generating a CFG at a lower level, e.g., the basic-block level, only arises when indirect `jump` instructions are a concern, which is not the case for CFA+. As discussed in Section 4.4.1, CFA+ adopts a recommended practice of disabling the generation of jump tables, where most indirect `jump` instructions typically reside [87]. This proactive measure reduces the number of JOP gadgets and provides protection against specific microarchitectural attacks [20].

Nevertheless, even in rare scenarios where the compiler emits indirect `jump` instructions for optimization purposes, the number of such instructions and their legitimate targets remain limited. The CFA+ compiler toolchain will then ensure the generation of relevant landing pads, particularly `bti j`, to handle these cases appropriately. Based on the results presented in Table 5, these instructions are unlikely to form useful gadgets. Furthermore, they cannot target other valid landing pads designed for `ret` instructions (i.e., the `call`-preceded ones), as triggering such landing pads means executing subsequent instrumentation instructions that introduce arbitrary updates to `SR`. This inconsistency would have a cascading effect on the entire invocation chain, violating its integrity. This violation would eventually be detected, as elaborated in Section 6.2.

CFA+ vs other defenses. As discussed in Section 3, while the current CFA and CFI schemes vary in their designs and security guarantees, CFA+ stands out as the first solution to combine the advantages offered by both approaches. Table 6 and Table 7 compare CFA+ with the most relevant CFA and CFI techniques respectively. In addition to its distinguishing prevention capabilities, Table 6 shows that CFA+ is the only attestation scheme that handles complex software stacks with minimal runtime and network overhead. Furthermore, it is the only scheme that performs attestation at scale, where the status of many $\mathcal{P}$rv applications is reported in one compact report and verified smoothly. Please note that the CFA schemes reported in the upper part of Table 6 are included for illustrative purposes and are not directly comparable to CFA+ as they primarily focus on embedded software. Table 7 highlights CFA+'s superiority over relevant CFI schemes, as it is the only one that covers forward and backward edges, while providing trustworthy evidence of runtime integrity. We note that FineIBT [13] introduces an optimized

and hardware-assisted version of LLVM-CFI [17], leveraging Indirect Branch Tracking (IBT), which is Intel counterpart of ARM BTI [88]. IBT is part of Intel's control flow Enforcement Technology (CET) where hardware-assisted shadow stack is available as well [88]. Therefore, the contribution of FineIBT is limited to protecting indirect forward edges, without providing any evidence of runtime integrity.

Compatibility with $\mathcal{RA}$. CFA+ prioritizes seamless integration with static $\mathcal{RA}$ approaches. It not only utilizes and shares the same RoT with IMA [86] but also follows a similar design for maintaining attestation reports. In particular, likewise IMA, CFA+ maintains a unified log file for all events, with its hash value stored in a designated PCR register within the TPM. When required, $\mathcal{V}$rf can obtain the two signed log files in one attestation request.

Integration with Pointer Authentication (PA). PA is a hardware security feature introduced in the ARMv8.3 architecture, which aims at ensuring pointers integrity with cryptographic primitives [7]. To achieve this, new instructions are added to sign and verify pointers. The computed cryptographic hash, known as Pointer Authentication Code (PAC), is stored in the unused upper bits of 64-bit pointers. Mainstream compilers like LLVM/Clang and GCC now include support for signing return addresses using PA by adding the `-mbranch-protection=pac-ret` flag.

CFA+ proposes a lighter-weight alternative for signing and verifying return addresses using `XOR` instructions. Nevertheless, the current design and implementation of CFA+ are fully compatible with PA. When the `-mbranch-protection=pac-ret` flag is added to the compiler pipeline, the transformation pass of CFA+ relies on it for return address integrity. As a result, CFA+ emits fewer instrumentation instructions accordingly.

Based on experimental evaluations, incorporating PA as a primary component in the CFA+ design offers an average reduction of approximately 2% in binary size overhead. However, we did not consider so for two key reasons. First, PA instructions introduce additional runtime overhead. Reports indicate that executing 7 `XOR` instructions can be 0.15% faster than executing 1 PA instruction [40]. Considering that signing and verifying a `ret` instruction requires at least two PA instructions, the worst-case scenario of CFA+ would be faster with 7 additional non-cryptographic instructions (2 pre-call, 1 `bti c`, 4 post-call) executed within a `call-ret` edge. Furthermore, recent research concludes that signing `ret` instructions with PA could result in an average runtime overhead of 3% [24], with extreme outlier cases reaching a runtime overhead of 17% [77]. As previously discussed, CFA+ could effectively protect both backward and forward edges with a comparable average runtime overhead. Second, PA relies on confidential data, such as secrets, which exposes it to a wider range of attack surfaces including various side channels [9, 30, 64]. In contrast, the current design of CFA+ is transparent, i.e., secret-independent, resulting in a smaller attack surface.

Applicability to embedded software. The ARMv8.1-M architecture has recently introduced ISA extensions that add support for BTI and PA [4]. ARM Cortex-M85 and ARM Cortex-M52 are examples of microcontroller units (MCUs) that incorporate these security features [8]. The CFA+ design is applicable to these MCUs with two minor modifications. First, unlike the A-profile processors, `ret` instructions in these MCUs do not adhere to the restrictions imposed by landing pads. However, this can be overcome by replacing each `ret` instruction with its equivalent form (i.e., `br LR`) that can be restricted by landing pads. Second, in many scenarios, these MCUs operate in a bare-metal execution mode, where there is no trusted kernel available to implement $\text{EH}_{\text{CFA+}}$ as part of it. In such cases, $\text{EH}_{\text{CFA+}}$ can be implemented within an integrity-protected memory area, utilizing the available TrustZone for isolation, or even as pure software, similar to the approach taken in PISTIS [37]. It's worth noting that the CFA+ design is not limited to the TPM as the RoT. Other RoTs can be utilized, as their primary purpose is to sign the attestation report and store the cryptographic hash of its records.

Non-control-data Attacks. C-FLAT [56] and other CFA proposals, such as OAT [65], have expanded their threat models to cover certain non-control-data attacks [32]. While addressing these attacks served as one of the primary motivations for the development of CFA mechanisms [56], the

underlying assumptions of the proposed defenses may only be applicable to simple specialized embedded software, which C-FLAT and OAT, among others, target. For instance, C-FLAT relies on recording all executed inputs and including them in the attestation report for verification, whereas OAT requires manual efforts to annotate critical data variables. These assumptions may not hold for general-purpose complex software, which CFA+ aims to address. Nonetheless, CFA+'s threat model encompasses control flow bending attacks, which is the relevant generalization of non-control-data attacks that manipulate control data [47]. As previously discussed, the detection of these attacks relies only on identifying inconsistencies between `SR` and `PC` values. We note that CFA+ has the potential to leverage other architectural features to cover non-control-data attacks. For instance, it could utilize PA to enforce data-flow integrity, as proposed by RSTI [41]. Further exploration of these possibilities is left for future research.

Limitations of CFA+. One limitation of CFA+ is its reliance on reserving two registers, which can pose compatibility issues for software that utilizes inline assembly and relies on these registers. For these cases, CFA+ would terminate the compilation process, indicating the potential compatibility issue. Additionally, the binary size overhead associated with CFA+ may not be acceptable in certain scenarios or applications. To address this limitation, CFA+ could benefit from several compiler optimization techniques that have not been considered so far, including static pruning of instrumentation points, redundant checks eliminations, and instrumentation hoisting (especially for provably safe `call` instructions).

8 Conclusion

This paper presented CFA+, a novel hybrid runtime defense approach that combines the strengths of Control Flow Integrity (CFI) and Control Flow Attestation (CFA) schemes to provide both local and remote detection capabilities in an efficient design. By leveraging the Branch Target Identification (BTI) feature of ARMv8.5 and selective software instrumentation, CFA+ not only enforces a local policy to mitigate control flow hijacking attacks but also enables lightweight always-on monitoring of the execution state without the need for maintaining in-memory control flow logs. To facilitate trustworthy verification, CFA+ encapsulates relevant runtime state information in dedicated registers that can be securely obtained by an external verifier. Furthermore, CFA+ features an efficient design for the verification process of attestation reports, allowing for easy detection of control flow violations. Evaluation results demonstrate that CFA+ achieves high efficiency and scalability, effectively balancing strong security guarantees with performance advantages.

A SAT-based Verification Procedure

As described in Section 4.5, the $\mathcal{V}$rf turns the verification process into a Boolean satisfiability problem, which can be solved by any efficient SAT solver. To this end, the SAT solver would need to determine whether there exists an assignment of truth values to variables in a given logical formula so that such a formula evaluates to True. In the context of CFA+, the SAT problem involves determining whether a valid assignment of truth values to the variables exists in the corresponding CFG, such that the set of connected edges identified in the CFG would correspond to the reported SR value. To solve this, we only need one Boolean variable to mark the taken edges (1 means taken, 0 means not taken).

More formally, a Boolean variable e_{used} is created for each edge e, which is set to 1 if the corresponding edge e is selected. The solver takes the function-level CFG and the reported SR value as inputs and produces a labeled CFG with 0s and 1s. In this labeled CFG, the edges labeled with 1s lead to the specified SR value. Two constraints must be satisfied when assigning these values:

- Connectivity: the selected edges should form a path, i.e., a spanning tree.
- Equity: the XOR value of the ID of these edges should equal to the input SR, which is formalized as

$$XOR(\{e_{\text{ID}} \mid e \in E, e_{used}\}) = \text{SR}$$

We note that the ID in e_{ID} is the ID of the related `call` instruction.

Assuming a collision-free CFG, where only one path would lead to the reported SR value, the first constraint can be met by looking for the Eulerian path, where each edge should be visited only once, and every chosen edge should be reachable from the root vertex (root function). This means that for any vertex (function), except for the root and leaf vertices, the number of incoming edges that are selected should equal to the number of outgoing selected ones. This is formalized in the following formula:

$$\forall v \in V \setminus \{v_{\text{root}}, v_{\text{leaf}}\} : |\{e \in E \mid e_{\text{used}}, e_{\text{caller}} = v\}| = |\{e \in E \mid e_{\text{used}}, e_{\text{callee}} = v\}|$$

The balance mentioned above is not mandatory for the root vertex, which should have an additional outgoing edge, as well as for leaf vertices, each of which should have an additional incoming edge. The following two formulas formalize these statements for the root and leaf vertices, respectively:

$$|\{e \in E \mid e_{used}, e_{caller} = v_{root}\}| = |\{e \in E \mid e_{used}, e_{callee} = v_{root}\}| + 1$$

$$|\{e \in E \mid e_{used}, e_{caller} = v_{leaf}\}| + 1 = |\{e \in E \mid e_{used}, e_{callee} = v_{leaf}\}|$$

The second constraint can be satisfied by formulating individual equations for each of the 64 bits in the ID. This approach allows for grouping the edges based on the XOR value of their respective bit, ensuring alignment with the corresponding counter bit in SR. The formalization of this approach is as follows:

$$\forall bit \in \{1,2,3,\ldots,64\} : XOR(\{e_{used} \mid e \in E, e_{id}^{bit} = 1\}) = \text{SR}^{bit}$$

where x^i denotes i-th bit of x, and x refers to either e or SR.

If the SAT solver successfully finds a solution, the path can be simply recovered using a Depth-First Search (DFS) algorithm.

To address potential collisions and extract multiple paths, additional measures can be taken in the SAT formulation. One approach is to introduce duplicated edges in the CFG to extract more distinct paths. Another approach is to introduce several boolean variables. These variables serve the same goal but target different choices within the CFG, allowing for the exploration of alternative paths. It is important to ensure that the assignment of these variables is not exactly the same across all paths, as this would result in identical paths being extracted.

Windows into the Past: Exploiting Legacy Crypto in Modern OS's Kerberos Implementation

Michal Shagam *Eyal Ronen*

Tel-Aviv University

Abstract

The Kerberos protocol is used by millions of users and network administrators worldwide for secure authentication, key distribution, and access control management to enterprise networks and services. Since its initial public deployment in 1989, the protocol has undergone many revisions to incorporate new cryptographic primitives and improve security. For example, initially based solely on users' passwords and symmetric cryptographic primitives, current implementations also support smartcard-based authentication with asymmetric cryptographic primitives for improved security. However, this iterative revision process has resulted in implementations riddled with legacy crypto primitives and protocol designs.

In this work, we show how we can exploit this legacy crypto to completely break the security of the enterprise network. Firstly, while arguably more secure, smartcard-based authentication uses RSA encryption with the notorious PKCS #1 v1.5 padding scheme. Although the RSA decryption is done securely inside the smartcard, a non-constant time unpadding code runs on the client's CPU. This makes both Windows's and several Linux distributions' implementations vulnerable to the Bleichenbacher attack that can recover cryptographic session tokens. Secondly, we show that the RSA smartcard-based authentication does not provide forward secrecy to the cryptographic tokens that the server provisions to the client. Thirdly, we propose and analyze different algorithmic approaches to minimize the overhead required to handle noisy oracles in the Bleichenbacher attack. This general Bleichenbacher attack analysis may be of independent interest.

Finally, we demonstrate microarchitectural side channel-based end-to-end attacks on the Windows Kerberos implementation. We start by showing how to recover tokens used to encrypt session transferred remote files by Samba. We then show how to amplify the number of decryptions performed with a single user's PIN code input, allowing us to accelerate our attack and recover users' (and admins') credentials before expiration. In addition, we describe a remote attack vector that allows us to perform the attack and generate queries.

1 Introduction

The Kerberos protocol [53, 54] is used for secure authentication and access to remote services over insecure networks. It is based on a centralized approach where a dedicated Key Distribution Center (KDC) server is responsible for user authentication and the distribution of keys. It is used across many operating systems [8, 9, 21, 24, 26, 43, 60, 71] and within many organizations [16, 20, 25] and is therefore a prime target for attacks [12, 39, 69]. Current implementations have added support for asymmetric encryption [72] and smartcard-based authentication [7].

Currently, smartcards [7] are considered a go-to secure authentication tool. Smartcards often embed *two factors* of authentication - something you have, which is the possession of the smartcard itself, and something you know, which is the smartcard pin code. The smartcard integration goal was to enhance the security of the Kerberos protocol [27], removing its reliance on users' passwords, which are a known weak point (e.g., due to users choosing weak passwords, large password breaches, phishing attacks, etc.) [17, 18, 34, 38, 49, 51, 67].

Moreover, as the private keys are stored and used only inside the secure smartcard, one can hope that the authentication process will be more resilient to attacks against the cryptographic implementations, such as Bleichenbacher's padding oracle attack [13]. However, although smartcards may securely perform the RSA decryption calculation, they still rely on the host computer to perform all the delicate handling of the PKCS #1 v1.5 unpadding and verification. Even though the Kerberos protocol does not provide a timing oracle to a network adversary, running the unpadding and verification code on the host machine may make it vulnerable to microarchitectural side-channels-based Bleichenbacher attacks.

In this work, we set out to answer the following question:

Are modern implementations of Kerberos smartcard based authentication secure against padding oracle attacks?

Table 1: Implementation Vulnerability Survey

OS	Kerberos Protocol	Smartcard Interface	Vulnerable
Windows	Security Package	basecsp	both
macOS	Heimdal	OpenSC	both
FreeBSD	Heimdal	OpenSC	both
Ubuntu	MIT	OpenSC	interface
RedHat	MIT	OpenSC	interface
Gentoo	MIT	OpenSC	interface
OpenSuse	MIT	OpenSC	interface
CentOS	MIT	OpenSC	interface
ArchLinux	MIT	OpenSC	interface
Suse	MIT	OpenCryptoki	no [a]

[a] We note that OpenCryptoki did include some non constant-time code that was identified by the tools from [33], but exploiting it using using a micro-architectural side-channel attack is challenging and would probably require a prohibitively large number of queries.

1.1 Our Contribution

Unfortunately, we discovered that all major implementations of RSA [63] smartcard-based Kerberos authentication are vulnerable to padding oracle attacks based on microarchitectural side channels. Moreover, protocols such as Samba [41] rely on Kerberos for authentication and key distribution even though Kerberos does not provide forward secrecy. This combination leads to practical attacks that allow unprivileged machine-in-the-middle (MiTM) adversaries to access restricted files in the network. Finally, by exploiting the lack of a global rate limit on the number of protocol sessions initiated in Windows, we can accelerate our attack to stealthily steal nonexpired users' authentication tokens that allow us to impersonate users and admins in the network and gain access to all of their information and capabilities.

More specifically, our contributions are as follows:

Survey of major RSA smartcard-based Kerberos implementations. We surveyed (using manual inspection of open source code and reverse engineering of close source binaries) the implementations used by the default configuration of Windows, MacOS, and several Linux distributions. The survey included all three major implementations of the Kerberos protocol — Windows' closed-source Security Package and the open-source Heimdal and MIT implementations. Only MIT implemented the required mitigations against Bleichenbacher's attack, and both other implementations include nonconstant-time code that can be exploited. We also surveyed the default smartcard interfaces used — Windows' closed-sourced basecsp, and the open-source OpenSC and OpenCryptoki. Both basecsp and the widely deployed OpenSC contain nonconstant-time code in their implementations of PKCS #1 v1.5 unpadding which make them vulnerable to Bleichenbacher's attack. The summary of our findings can be found in Table 1, where from the 10 operating systems we surveyed, 9 were found to use a vulnerable default configuration, including Windows, MacOS, and Ubuntu.

We note that as a step in the right direction, the recent Windows 11 22H2 versions disabled the use of RSA smartcard authentication in Kerberos (although the vulnerable implementations still remain). However, the currently supported and widely used Windows 10 (70% of Windows computers [57]) and Windows 11 22H1 versions remain vulnerable.

Proof-of-Concept (PoC) of Bleichenbacher Oracle on Windows. We exploited one of vulnerabilities we discovered in Windows to implement a PoC of our micro-architectural side-channel attack and create a Bleichenbacher padding oracle. We then tested and analyzed the accuracy of the oracle.

Handling Noisy Oracles in the Bleichenbacher Attack. Noisy oracles are a significant challenge to Bleichenbacher's attack. Although they are very important in practice, they have only received very limited attention in the literature [15], and the current trivial approach can double the number of required queries [64]. We experimentally explored several methods to improve the soundness of the Bleichenbacher attack and its robustness to noisy oracles. Our novel traceback approach utilizes the statistical properties of the attack. It allows us to minimize the overhead of additional required queries compared to a perfect oracle. While our approach might slightly reduce the overall success rate, it is specifically suitable for cases where we only have a limited time to perform our attack. In this case, only attacks with a small number of queries can succeed in time, so algorithms that require high query overhead to handle noisy oracles (e.g., repeating queries to improve soundness) will cause the attack to fail.

End-to-end attack implementation on Samba's file encryption. To show the practicality of our MiTM attack, we experimentally verified our ability to recover files encrypted using the SMB3 [44] protocol. The SMB3 encryption keys are sent to the client as part of the Kerberos protocol. As neither SMB3 nor Kerberos provides forward secrecy, we can exploit our attack to recover the Kerberos and SMB3 keys transferred in a previous session and recover the content of the encrypted files. This is possible even with a slow attack that may finish long after the target session expires.

Accelerated Stealthy Attack. The main bottleneck in our attack is our ability to cause the client to initiate new protocol sessions, as each initiated session results in a single padding oracle query. In many cases this requires user interaction and pin code entry, and results in only a small number of session initiation attempts that allow for padding oracle queries. This may result in a very slow attack that is potentially user detectable. In order to actively exploit the recovered session token (e.g., to impersonate an admin), our attack needs to finish in less than 10 hours before the session token and ticket expire. To overcome this limitation, we analyzed different user

actions that initiate Kerberos protocol sessions. We found that specific user actions may attempt to initiate a large number of sessions (due to retries) without requiring the user's PIN code. Moreover, we discovered that although there is a limit on the number of failed attempts a single action can initiate, there is no global cap or rate limitation on the total number of protocol sessions. Finally, we show how in some settings, we can remove all requirements for user interaction by remotely initiating the requests from a malicious webpage. The attack is also stealthy as the user sees no notification, and all the resulting messages are handled by our MiTM attacker without interaction with any of the network's servers.

Open Source Kerberos MiTM Attack Framework. Together with the paper, we will release all of the code developed for our attack. This includes the full code of our MiTM framework that can manipulate Kerberos messages, and derive all of the various keys and decrypt the different messages.

1.2 Responsible Disclosure

We started a responsible disclosure process with Microsoft, the maintainers of the Heimdal Kerberos implementation, and the OpenSC maintainers. OpenSC have fully patched their PKCS #1 v1.5 code to be constant-time. We were allocated CVE-BLINDED with a high severity jointly with a disclosure from a concurrent work [33]. Microsoft acknowledged our findings as an Elevation of Privilege attack. They are currently working on a fix which they plan to release in July 2024. Although they don't have access to exact numbers, they estimate that a large number of users use smartcards for Kerberos authentication and are affected by our findings. The Heimdal team has confirmed our findings, and we are waiting for updates regarding their patching plans.

1.3 Structure of the Paper

Section 2 provides background and describes related work. Section 3 presents our threat model, describes our padding oracle, and our survey of vulnerable nonconstant-time code in Kerberos implementations. Section 4 describes our Proof-of-Concept padding oracle implementation, and Section 5 describes a full end-to-end attack on Windows. Section 6 explains how we accelerated our attack, and Section 7 discusses how to efficiently handle noisy oracles in the Bleichenbacher attack and present an active user impersonation attack. Section 8 describes how to optimize the process of finding a session that can be decrypted before it expires. Finally, Section 9 discusses the root causes for our attack and proposes various mitigations.

2 Background

2.1 Kerberos protocol

The Kerberos protocol [53, 54] is a trusted third-party authentication protocol. Initially developed in the late 1980*s*, it is based on the Needham-Schroeder symmetric-key protocol [52] from the 1970*s*, although newer implementations also support key transfer using asymmetric encryption. The protocol is widely used across operating systems [8, 9, 21, 24, 26, 43, 60, 71] and has several widely used implementations including: MIT [47], Heimdal [29, 30], and Microsoft [43]. The Kerberos protocol defines a protocol between three types of entities:

1. Client or principal — this includes the host computer itself and the user
2. Key Distribution Center (KDC) — The third-party trusted server (also known as the domain server) that provides the authentication service.
3. Application service server (Application Server) — A server that provides access to the network resources such as remote files, remote powershell and email server.

We note that some of the Kerberos entities, such as the KDC and the Application Server, are often implemented on the same physical computer.

2.1.1 Tokens in Kerberos

Kerberos uses tokens (which are called tickets) which are provided to the client during authentication, and can be used by the client to prove their identity and permissions to application servers. The tokens contain encrypted information that allows servers in the network to verify the validity of the tokens. The tokens can be used for a limited amount of time, known as a lifetime. After the token expires, the client needs to repeat the authentication process. The default token lifetime on Windows is 10 hours, this can be extended for up to 7 days with a process called ticket renewal [45].

The two main types of tokens used in Kerberos are called Ticket-granting-tickets (TGTs) and Ticket-granting-service (TGSs) sent in the Kerberos protocol messages AS-REP and TGS-REP respectively. The TGT ticket is used by the client to request TGS tickets. The TGS service ticket is then used by the client to gain access to different services on the network.

2.1.2 PKINIT

PKINIT is an extension of the Kerberos version 5 protocol [70] adapting it to support asymmetric encryption and allowing the authentication of clients without relying on (potentially weak or compromised) user passwords. The asymmetric encryption in PKINIT is used to transfer a symmetric key which we refer to as the session token. This session token is then used to derive the rest of the keys used in the remainder of the protocol.

2.1.3 Open Source Kerberos Implementations

The Microsoft Windows implementation of Kerberos is closed-source. The most common open source implementations of Kerberos, which can be used on additional operating systems, are the MIT KRB5 [8, 9, 16, 21, 24, 26, 47, 55, 60, 61, 71] implementation and the Heimdal [23, 29, 65] implementation. The Heimdal [29] Kerberos implementation, in addition to being open-source, was created as an implementation independent of US regulations and export restrictions. Therefore Heimdal [48] was historically used when export restrictions hindered the use of the MIT implementation.

2.1.4 Microsoft Active Directory

For Windows Servers, Active Directory (AD) [42] implements a domain Server, acting as the trusted party KDC, providing authentication and network resources and services including a centralized remote filesystem, remote powershell and outlook email service. The remote filesystem is most commonly implemented using the Samba [41, 44] protocol that relies on the Kerberos protocol for authentication (although some legacy authentication protocols may still be supported).

2.2 Smartcards and Multifactor Authentication

Smartcards [7] are physical devices with integrated chips that can securely store cryptographic certificates used for identification and authentication of users. To prevent the compromise of the private keys, smartcards can usually use them internally to perform cryptographic operations on behalf of the user.

In general, three common factors can be used for authentication: something you know, something you have, and something you are. Multifactor authentication is the use of two or more authentication factors. Possession of the smartcard provides the something you have factor. Smartcards are commonly used with a personal identification number (PIN) limiting the amount of incorrect attempts in order to prevent brute-force attacks which covers the something you know factor as well. Smartcards can also be incorporated with a fingerprint reader that also require biometric authentication (something you are) to use the smartcard.

2.2.1 Kerberos RSA Smartcard-based Authentication

Users can authenticate and log on to a Client using a password or alternatively with a smartcard [7]. When a user logs in or unlocks a Client, they connect the smartcard to the Client, and then the user is prompted for their pin code. The smartcard holds a private key and a public certificate that correspond to the user, and if the PIN is correct, the certificate is sent to the Client who verifies the certificate and username correspond. The client then initiates the Kerberos [27] authentication protocol, while requesting the smartcard to perform the asymmetric cryptographic operations (e.g., RSA decryption and signing) on its behalf.

The Client initiates the Kerberos authentication protocol by sending an AS-REQ message which is a request for a ticket granting ticket. The message includes the user's certificate and is signed by the smartcard.

The Server responds by sending the Client an AS-REP packet that includes the TGT. The AS-REP message includes an RSA ciphertext that encrypts a symmetric key that is used to decrypt the session token allowing the encryption and decryption of the current packet and the rest of the session. This RSA ciphertext is sent to the smartcard for decryption, and it is the main target of our attack. A more detailed description of the key scheme can be found in the protocol technical specification [70].

2.3 Padding Oracle Attacks

Padding schemes are used to encode messages before encryption. After decryption, the resulted plaintext is "unpadded" to recover the original message. The unpadding process usually involves verification of the padding. Code that implements this unpadding and verification process may leak some information about whether the decrypted padded message conforms to a specific padding structure. Attackers can use side-channel attacks to learn this information and exploit it to mount adaptive chosen ciphertext attacks that can recover the plaintext value. Side-channels can include indicative error messages, timing variations, memory access patterns, etc.

2.3.1 RSA padding

Padding schemes are used in many implementations of RSA in order to add semantical security and prevent malleability. We will describe the padding standard PKCS#1 V1.5 [31, 50] which is used for RSA encryption and is vulnerable to chosen ciphertext attacks such as the Bleichenbacher attack [13].

Let (N,e) be an RSA public key, let (N,d) be the corresponding private key, and let ℓ be the length of N (in bytes). The encryption and padding of a message m containing $k \leq \ell - 11$ bytes is performed as follows:

1. First, a random nonzero padding string PS of byte-length $\ell - 3 - k \geq 8$ is chosen.
2. Set m^* to be $\texttt{0x00}||\texttt{0x02}||PS||\texttt{0x00}||m$. Note that the length of m^* is exactly ℓ bytes.
3. Interpret m^* as an integer $0 < m^* < N$ and compute the ciphertext $c = m^{*e} \bmod N$.

The decryption routine computes $m' = c^d \bmod N$ and parses m' as a byte string. It then checks whether m' is padding standard conforming:
$m' = \texttt{0x00}||\texttt{0x02}||PS''||\texttt{0x00}||m''$ where PS'' is a string consisting of at least 8 nonzero bytes. If the message is found to be conforming the decryption routine returns m'' (which will

be equal to $m*$ if the ciphertext was not modified). Otherwise the decryption routine fails.

2.3.2 Bleichenbacher's Attack on PKCS#1 v1.5 Padding

Appendix A provides a high level description of the Bleichenbacher [13] chosen ciphertext padding oracle attack on the padding scheme defined above. The attack allows an attacker to compute a private key operation without knowing the secret private key. The attack relies on the RSA homomorphic property of multiplication.

Attack Prerequisites Bleichenbacher's attack assumes the existence of an oracle BI which given an RSA ciphertext c as input answers whether c decrypts to a PKCS #1 v1.5 conforming message. More formally, let (N,d) be an RSA private key. The oracle BI performs the following for every ciphertext c

$$\mathsf{BI}(c) = \begin{cases} 1 \text{ if } c^d \bmod N \text{ has valid PKCS \#1 v1.5 padding} \\ 0 \text{ otherwise} \end{cases}$$

2.3.3 Bleichenbacher Oracle Notation

In this paper, we follow previous work [11, 64] and consider three different checks that can be performed by an implementation when validating the RSA-decrypted padded plaintext. All of the implementations we surveyed checked that the padded plaintext indeed begins with the expected value of $0x0002$. This check was followed by some combinations of the following checks:

First Check Verifies there is at least one zero byte within the padded plaintext.

Second Check Validates the first 8 bytes of the padding string are nonzero.

Third Check Verifies the length of the unpadded data.

We denote an oracle that performs all three checks as FFF and the most permissive oracle that doesn't perform all three as TTT. An ignored check is denoted with a T.

2.4 Flush+Reload Cache Attack

Microarchitectural side-channel attacks, such as cache side-channel attacks, exploit information leakage from the hardware infrastructure itself. The cache is often a shared resource between users and can be used as a side channel to learn information on another process without authorization or Administrative privileges. Attackers can use this side channel to bypass security mitigations applied on virtual memory since the cache side channel relies on the physical addresses.

Flush+Reload [74] is a side channel technique that allows monitoring of access to memory lines in shared pages. The monitored memory lines are flushed from memory and later the memory line is reloaded. The amount of cycles it takes for the memory line to be reloaded can indicate whether the memory line was in the cache. The attack can be used to target the last level cache, L3, allowing monitoring when the victim and the attacker do not share the same execution core.

2.5 SMB3

The Samba protocol [41] allows the authorized transfer of remote resources, shares, between computers on a network. In previous versions of the Samba protocol, remote files and large resources were transfered as plaintext and an attacker could recover the unencrypted files sent over the network by simply eavesdropping and reconstructing the files.

SMB3 [44] introduced the encrypted transfer option for remote resources. The principal is authenticated and the files are sent via an encrypted session. The encrypted session is created as a Kerberos based encrypted session. The Kerberos session is established and used to send the encrypted SMB3 session token. Therefore if an attacker can decrypt the Kerberos session, they can extract the SMB3 session token and reconstruct the files sent over the encrypted session *thus exploiting the lack of forward secrecy.*

2.6 Related Work

2.6.1 Attacks on Kerberos

Since the Kerberos protocol is used across many operating systems for secure authentication and managing access credentials, it is a prime target for many attacks such as Kerberoasting [39], pass the ticket attacks [69], pass the hash attacks [12], and golden ticket attacks.

There have been several credential dumping attacks on compromised hosts [19]. The attacker gains read access to the memory of the lsass process, Local Security Authority Subsystem Service, and extracts the stored credentials from memory. Microsoft has since implemented several layers of encryption and isolation techniques [46].

A recent related attack on legacy crypto in Kerberos from Google Project Zero [22] showed that the use of legacy cryptography and lack of authentication of parts of the ticket request message allows an attacker to replace the requested encryption key types with a 40-bit RC4 [59] key allowing a bruteforce attack. This allows the adversary to recover and exploit the ticket returned in the response to the request service ticket message.

2.6.2 Attacks on RSA PKCS #1 v1.5

Since the original Bleichenbacher paper [13] there has been a long line of work attacking RSA PKCS #1 v1.5 [11, 28, 36, 40, 73]. For example, the DROWN attack [10] a cross protocol MiTM attack exploiting SSLv2 [58] protocol flaws allowing an attacker to decrypt TLS [59] connections using the RSA key exchange when the same private key was used

for both TLS and SSLv2. The Return Of Bleichenbacher's Oracle Threat, ROBOT [14], a chosen ciphertext attack using different server responses based on whether the padding is conforming, a padding oracle, to sign a message with the private key. The 9 Lives of Bleichenbacher's Cat [64] also exploits microarchitectural side channels and downgrade attacks for several TLS [59] implementations.

In an independent concurrent work, Kario [33] surveyed open-source implementations of PKCS #1 v1.5 decryption using an automated testing approach and have also found that OpenSC has vulnerable non constant-time code. Using their automated tool, OpenCryptoki was also shown to have non constant-time code.

3 Padding Oracles in Kerberos PKINIT

We have conducted a systematic analysis of the security of all major RSA smartcard-based Kerberos implementations in respect to Bleichenbacher's padding oracle attack. In this section we will describe the threat model we assume for our attack and the parts of the protocol we analysed. We will then present some examples of the different types of oracles we found.

3.1 Timing Base Padding Oracles

Unlike the TLS protocol [62], Kerberos does not seem to provide a network adversary with a timing oracle. As explained in section 2.2.1, the RSA ciphertext encrypts a symmetric key that is used to decrypt an authenticated ciphertext included in the same message. If a modified ciphertext results in a plaintext with incorrect padding, the Kerberos protocol will simply discard the message. Moreover, even if a modification of the ciphertext results in a plaintext with correct padding, the resulting symmetric key will be changed, and the symmetric authenticated decryption will fail. This will also cause the Kerberos protocol to discard the message.

Although the amount of time until the message is discarded differs in both cases, there is no externally visible difference in the response, as the client will simply not respond. Moreover, from our experiment, it seems that on Windows, the TCP connection used for the attack is closed independently of the type of error, preventing an oracle based on a lower communication layer such as the ROBOT attack [14]. To conclude, in our experiments, we were not able to find any timing-based oracles. However, as we will show, the code that runs on the client may still be vulnerable to micro-architectural side-channel attacks, which can still allow us to build a padding oracle.

3.2 Threat Model

Our threat model is depicted in Figure 1 and is derived from the Kerberos' main goal of allowing authentication over an insecure network. Thus we assume that all parties that participate in the protocol are honest and not compromised. This includes the servers (i.e., the KDC and various applications service servers), clients, users and smartcards. The users use smartcards to authenticate their clients to the KDC using Kerberos and for the provisioning of tokens and cryptographic keys for secure authenticated communication with the various application service servers (e.g., securely accessing remote files). The goal of our attack is to gain unauthorized access to network resources.

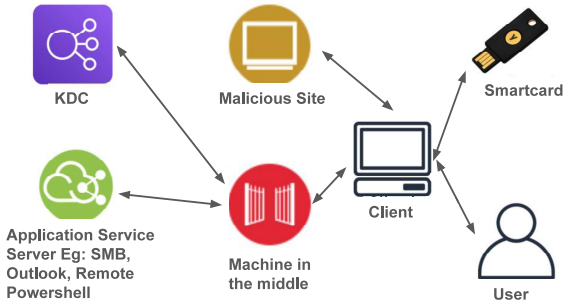

Figure 1: Threat Model Overview - we assume a network with honest servers and an honest user trying to log in using an uncompromised smartcard and client machine. A malicious MiTM is able to intercept and modify packets over the network and to communicate with an *unprivileged* malicious program running on the Client.

As we assume that the network itself is insecure, a MiTM attacker can sniff, intercept, and modify packets sent between the client and the servers (e.g. a compromised router). To allow microarchitectural side channel attacks, we further assume that the honest user's computer, the Client, also runs *unprivileged* malicious code. The code can be an *unprivileged* program that the honest user ran, a program currently running under a *different* user account that is logged on to the same computer, assuming the other user may be compromised or deceived into running our code. Moreover, previous work shows that JavaScript code from a malicious website running inside the user's browser may perform such micro-architectural attacks [35, 37, 56, 66, 68]. Note that for our experiments, we used unprivileged native code running under a different user account. Finally, for our accelerated attack (described in Section 6.2), we further assume that the honest targeted user accesses a malicious website.

Note that we assume that the communication between the client and the smartcard is secure, and that the PIN codes are not compromised.

3.3 Oracle Description

As described in section 2.2.1, our attack focuses on the client's RSA decryption that occurs while handling the Kerberos AS-REP message, specifically the PK-AS-REP message which is part of the Kerberos PKINIT extension. RSA is used as a key encapsulation mechanism (KEM) to encrypt symmetric keys that are required to decrypt the rest of the message and derive the Kerberos session token which we want to recover in our attack.

Following The 9 Lives of Bleichenbacher's Cat [64] paper, we can partition the RSA decryption process in Kerberos to three main stages:

1. **Mathematical Calculation and Data Conversion** — First, the RSA ciphertext is decrypted and the resulting plaintext is converted into a byte array. In our case, this stage runs on the smartcard.
2. **PKCS #1 v1.5 Verification** - The byte array is then checked for conformity to the PKCS #1 v1.5 padding scheme and the padding is removed.
3. **Protocol Level** – If the byte array passes the verification stage, the Kerberos protocol will try to use the resulting plaintext as a 3DES symmetric key. If the resulting plaintext size is equal to the expected key length or padding oracle mitigations were implemented, the resulting key will be used to decrypt the rest of the AS-REP message.

In our attack we need to overcome two main challenges: The first is that we don't have direct access to the smartcard, and thus can't exploit padding oracles in the first stage of the decryption. The second and more significant challenge is that the client does not respond to any failure in the AS-REP decryption process. As the symmetric encryption part of the AS-REP is authenticated, even if PKCS #1 v1.5 validation of the modified RSA plaintext passes, the symmetric decryption will fail and the packet will simply be dropped and ignored. To overcome theses challenges, we searched for nonconstant-time code at the PKCS #1 v1.5 verification and Protocol level stages, that can be targeted using microarchitectural side-channel attacks.

3.4 Nonconstant Time Implementations

We surveyed all three major implementations of the Kerberos protocol — Windows' close-source Security Package and the open-source Heimdal and MIT implementations for nonconstant time code. While MIT properly implemented mitigations against Bleichenbacher's attack, both other implementations include nonconstant-time code that can be exploited for a padding oracle attack. We also surveyed the default smartcard interfaces used — Windows' close-sourced basecsp, and the open-source OpenSC and OpenCryptoki. We found that the most widely used interfaces, basecp and OpenSC include nonconstant-time code. Table 1 shows which packages are uses by default in 10 OSs we surveyed, and that 9 of them use nonconstant-time code, and Table 2 shows the specific oracles we found in each package. We will now describe several examples of nonconstant-time code in Windows which is arguably the most widely used Kerberos implementation. For examples of nonconstant-time decryption in other OSs, see the full version of the paper.

```
1  int VerifyPKCS2Padding(inBuffer, inLen, out){
2  ...
3  if ((*(char *)(inLen - 2 + inBuffer)=='\x02')
4    && (*(char *)(inLen - 1 + inBuffer)=='\0')){
5    pcur = (char *)(inLen + inBuffer);
6    do {
7      if (*pcur == '\0') break;
8      pcur -= 1;
9      inLen -= 1;
10   } while (inLen != 0);
11   int i = 0;
12   if (inLen != 0) {
13     //Allocate output buffer
14     //copy plaintext to output
15     ...
16       return SUCCESS;
17     }
18     ... }
19   }
20   return ERROR;
21 }
```

Listing 1: Simplified Decompiled VerifyPKCS2Padding

3.4.1 PKCS #1 v1.5 Verification Oracles

While the smartcard performs the RSA decryption itself, the padding removal and verification is performed on the Client and implemented in the basecsp smartcard interface which has two vulnerable functions. Listing 1 shows a simplified code of the function **VerifyPKCS2Padding**. It verifies the padding is correct by verifying the first two bytes are `\x00\x02` and that the message contains an additional `\x00` byte to indicate the beginning of the data. The code lines 5 to 18, which search for an additional zero byte, are only performed when the first two padding bytes are correct leading to a TTT type padding oracle. Moreover, the code lines 13 to 16, which copies the buffer, only run if a `\x00` byte was detected, targeting these code lines leads to a different FTT padding oracle.

Listing 2 shows a simplified code of the function **CSPUnpadData**. It calls the **VerifyPKCS2Padding** function on line 3. Only if the padding check and removal is successful then the copy and swap buffer code in lines 5 to 8 runs, leading to an FTT padding oracle.

3.4.2 Protocol Level Oracles

Windows' Security Package does not implement any of the standard mitigations against Bleichenbacher attacks. Listing 3 shows a simplified code of the function **CPImportKey**. The call to function **FIsLegalKeySize** at line 6 is only made if

Table 2: Padding Oracle Summary

Oracle Type	Implementation	Function Name	Nonconstant time code
FTT	Security Package	CPImportKey	Conditional check for plaintext length
FTF	Security Package	CPImportKey	Conditional call to 3DES decryption
TTT	Basecsp	VerifyPKCS2Padding	Conditional search for zero byte
FTT	Basecsp	VerifyPKCS2Padding	Conditional buffer copy
FTT	Basecsp	CSPUnpadData	Conditional buffer copy
FFT	Heimdal	p11_rsa_private_decrypt	Nonconstant time call to interface
FTT	Heimdal	hx509_cms_unenvelope	Conditional check for plaintext length
FTF	Heimdal	hx509_cms_unenvelope	Conditional call to 3DES decryption
FFT	OpenSC	pkcs15_prkey_decrypt	Conditional buffer copy
FFT	OpenSC	sc_pkcs1_strip_02_padding	Conditional buffer copy
-	MIT	pkcs7_decrypt	-
-	OpenCryptoki	-	-

```
1  int CSPUnpadData(inBufferCtx, outLen,  out){
2    ...
3    result = VerifyPKCS2Padding(...);
4    if (result == 0) {
5    //Swap byte order in plaintext
6    //and copy to outBuf
7      ...
8      *out = outBuf;  }
9    ...
10   return result;
11 }
```

Listing 2: Simplified Decompiled CSPUnpadData

```
1  int CPImportKey(csInfo){
2    ...
3    int result = CspUnpadData(csInfo,&len,&out);
4    if (result == SUCCESS){
5      ...
6      int isLegal = FIsLegalKeySize(len,out);
7      if (isLegal){
8        Decrypt_3DES(encData,out,len,&decData);
9        ...
10     }
11   }
12   return SUCCESS;
13 }
```

Listing 3: Simplified Decompiled CPImportKey

function **CspUnpadData** is successful, leading to a FTT oracle. Moreover, the call for 3DES decryption at line 8 only occurs if the resulting plaintext size corresponds to a legal 3DES key size, this leads to a stricter FTF type oracle.

4 Padding Oracle Proof-of-Concept

In this section we will describe our padding oracle PoC on Windows. As described in Section 3, we had the choice of several different oracles to target with a microarchitectural side-channel attack. Such attacks can be relatively noisy, while the Bleichenbacher attack requires a large number of queries and can be very sensitive to errors. This means that we need to take care when we choose our oracle and calibrate our attack.

The oracle which is arguably the easiest to target is the conditional call to 3DES decryption in **CPImportKey** as we can target the actual 3DES decryption process (e.g., access to the 3DES SBOXs tables in memory). As the decryption takes a relatively long time and includes a very large number of repeated memory access, it results in an attack with very high accuracy. However, this is a relatively strict FTF padding oracle as it requires the first zero byte after the padding to be at the specific location corresponding to an accepted 3DES key size. This requirement decreases the probability of getting a conforming plaintext by a factor of 2^{-8}, and significantly increases the total number of queries required by the full attack.

The most permissive oracle that requires the smallest number of total queries is the TTT oracle in **VerifyPKCS2Padding**. However, we found that, both the TTT and FTT oracles in **VerifyPKCS2Padding** are compiled to very short assembly code that co-resides in the same cachelines as other code segments that are not part of the oracles. This resulted in a very low accuracy that was not suitable for our needs.

Finally, we decided to exploit the FTT padding oracle in **CPImportKey**. Although it is stricter, the probability of conforming to it decreases by less than a factor of 2 compared to the more permissive TTT oracle. On the other hand, it is much easier to target with a microarchitectural side-channel attack leading to a much higher accuracy of our attack.

4.1 Experimental Oracle Calibration

In order to verify the existence of the padding oracle on Windows, we created a setup with a Windows domain Server, Windows Server 2019 running Active Directory and a Client

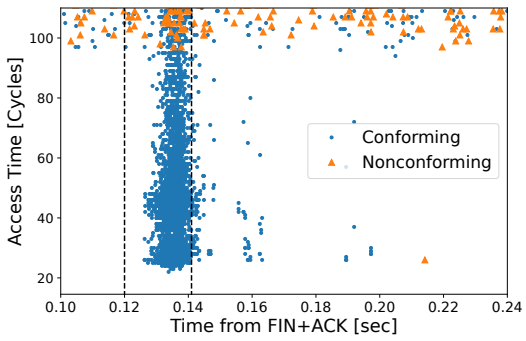

Figure 2: Calibration Hit and Access Time Cycle Count Comparison - A comparison of cache hit patterns of all calibration hits for both message types synchronized using the FIN+ACK packet time reference frame. The time range chosen, between 0.12 and 0.14 seconds after FIN+ACK, is shown by the dashed black lines.

running a Windows 10 operating system with users that can login using smartcards. The setup Client has a dual-core CPU, Core i7-7600U processor. We used a YubiKey USB token based smartcard with 2048-bit RSA key.

We implemented a MiTM attacker (that runs on a separate computer on the same LAN) that can receive AS-REQ messages from the client and respond with AS-REP messages with a modified RSA ciphertext. We implemented *unpriviliged* attack code that runs on the client and uses the Flush+Reload [74] attack to monitor the cacheline that stores the code of the oracle we exploit. Note that the native attack code runs under a different user account than the one we target. The attack code starts its measurement after receiving a command from the MiTM machine and stops after receiving another command from the MiTM machine with a specified delay. The attack code then sends back a trace of all cache hits (where the access time is below a fixed threshold). We tested this setup by sending 4000 AS-REP messages to the client, with interleaved conforming and nonconforming RSA padding. Note that we don't assume clock synchronization between the MiTM attacker and the client, and that network packet handling and processing is asynchronous and may vary in time. We used the network packets to synchronize our attack and align the different traces. We synchronized our attack to the time where the MiTM attacker receives a FIN-ACK packet from the client that confirms the AS-REP message was received.[1]

Figure 2 shows the distribution of the resulting cache hits for messages with conforming and nonconforming RSA padding aligned using the time the FIN+ACK message was received by the MiTM attacker. Although we receive a large number of hits also for nonconforming messages, by using the alignment and restricting ourselves to the specific time range of 0.12 to 0.14 seconds after the FIN+ACK message, we can get a relatively robust signal. Table 3 shows the distribution of hit counts within the above range for single messages. The distribution was calculated from an extensive experiment with ≈ 27000 conforming messages and ≈ 66700 non-conforming messages. Note that we still get some conforming messages with zero hits, and nonconforming messages with one hit.

[1]This TCP FIN+ACK messages are always sent by the network stack and is unrelated to the decryption process. After receiving the FIN+ACK message, the MiTM attacker sends a notification messages to the attack code running on the client machine which is then used to sync the resulting trace.

Table 3: Hit Count Message Distribution

Amount	0	1	2	3	4
conf.	0.07	0.12	0.36	0.36	0.09
nonconf.	0.9984	0.0013	10^{-4}	$3 \cdot 10^{-4}$	$5 \cdot 10^{-5}$

Note that the resulting oracle is still too noisy to be used for a full attack. A straightforward solution is to follow the approach of Ronen et al. [64] and repeat measurements to improve the oracle's accuracy at the cost of a significant overhead in the number of oracle queries required to finish the attack. In the next section, we will assume a reliable padding oracle based on repetitions. In Section 7, we will delve deeper into this problem of noisy oracles and describe and analyze different approaches to handle them more efficiently.

5 End-to-end Attack

We will now describe how we can mount a full end-to-end attack on Kerberos. After validating the existence of a padding oracle, the main remaining challenge for our attack is the requirement for user interaction. The Kerberos authentication protocol can only be initiated by the client as a result of some user action, for example, an attempt by the user to login to the client machine. Such a login attempt will cause the client to initiate a protocol session and to send an AS-REQ message.

In the first stage of the attack, our MiTM attacker can forward the AS-REQ message to the KDC and receive from it the resulting AS-REP message, that includes the RSA ciphertext we want to decrypt (which will allow us to recover the session token). The MiTM can now use the Bleichenbacher attack algorithm to maliciously modify the RSA ciphertext and use the oracle we presented in Section 4. As described in Section 3, due to the validation of the symmetric decryption process, the protocol session will fail even if the RSA plaintext passes the padding verification.

After this first stage, there is no more interaction with the KDC. Each future protocol session initiated by the user will cause the client to send a new AS-REQ message. The MiTM will use the same AS-REP messaged he received from the KDC in the first stage, and will modify the RSA ciphertext according to the Bleichenbacher attack algorithm depending

on the previous result of the oracle query.

After a login attempt, if a protocol session fails, the client will retry to initiate the protocol up to 3 times. If all 3 attempts fail, the user might be alerted that an error has occurred.[2] This means that we can use a single login attempt for up to 3 padding Oracle queries or 2 if we want to let the protocol finish successfully on the last attempt and ensure the stealthiness of the attack. Assuming a full Bleichenbacher attack will require more than 10000 queries, we require more than 5000 login attempts by the user before we are able to decrypt a single session ticket, which could take a very long time period. As the session ticket expires after about 10 hours, it will not be usable anymore.

5.1 Attack on Samba's file encryption

In this attack scenario, the MiTM has monitored and saved packets from a previous or ongoing Kerberos session where the User accessed an application service and data the User was authorized to access was sent over the Kerberos based encrypted session. We specifically target the SMB3 [41] protocol where the User accesses files on a remote filesystem and shared files are transferred over an encrypted session. The goal of the SMB3 protocol is to encrypt and protect the transfer of the remote files so that only authenticated and authorized users can access them. We exploit the fact that neither Kerberos nor SMB3 provide forward secrecy in respect to the Kerberos' long-term RSA keys and encryption. I.e., if we can compromise the RSA keys, or break a specific RSA ciphertext, we can decrypt and recover the sessions' token. Using the session token and the transcript of the protocol we can derive all the encryption keys used in the resulting SMB3 session to decrypt the files sent over the network. Although the corresponding session tokens usually expire after 10 hours by default on Windows, the same long-term RSA keys stored on the smartcard can be used for years without change. This means that as long as our MiTM can record the protocol transcript of a specific session and the SMB3 encrypted files, it can run the attack as long as the user doesn't rotate the long-term keys on the smartcard. In the end of the attack, the recovered session ticket will enable the attacker to decrypt the files.

We have implemented a full end-to-end attack based on the padding oracle described in section 4. We will open source all the code used for the attack, including the full code for the Kerberos and SMB3 key derivation and file decryption. Note that to speed up our experiments, we used the acceleration technique described in Section 6.

[2] E.g., the user might notice some resources are not available.

6 Attack Acceleration

The attack described in Section 5 can take a very long time to finish, and it only allows for a passive decryption of data sent in the past. In this section, we will describe how we can significantly accelerate our attack. In Section 7 we will show how to efficiently use the resulting noisy oracle to allow us to break Kerberos sessions before they expire, and use the recovered tokens to impersonate users in the network.

6.1 Initiation of Kerberos Sessions

As we mentioned before, our attack relies on the client machine attempting to initiate Kerberos sessions. After a user attempts to login and inputs their PIN code, windows will initiate a new Kerberos session, and if it fails, it will retry up to a total of 3 attempts without requesting the user to reenter their PIN code (thus handling temporary connectivity issues). The amount of authentication attempts is part of the domain group policy and can be configured depending on the network requirements (with default value of 3).

The logon process occurs infrequently and can take up to several minutes resulting in a very low query rate. However, we discovered that other user actions can lead to a much higher number of protocol initiation attempts. Moreover, some of them do not require the user to reenter their PIN code. For example, a user attempts to access remote files will initiate a Kerberos authentication attempt without requiring any additional user input.

File permissions are checked after the Kerberos session is established, therefore Kerberos session establishment attempts are generated before permissions are checked. For this reason, the domain user isn't required to have permission to access the shared folder in order for the vector to work.

Although the number of authentication attempts is limited by the group policy, the actual number of attempts per user action is significantly higher. This is presumably because a failure in the authentication, will cause a failure in a higher level code, that will cause it to also retry. Moreover, there is no global limitation on the total number or rate of attempts! The actions can therefore be repeated in order to initiate a large number of sessions at a very fast rate.

Table 4 shows a comparison of the amount of queries generated by different user actions and whether the actions require the PIN input. Generating the authentication requests can be as simple as opening file explorer with one of the recently used files being a file or folder that requires user authentication to access or accessing one of these files in notepad or in the run app.

The rate of generated AS-REQs varies greatly between these sources due to the additional overheads (e.g., user interaction). While runas generates about 4 or 5 queries per minute, the additional actions that do not require reentering the PIN are significantly faster and can reach over 50 queries

Table 4: Action Query Generation Comparison

Process	Session Retries	PIN required
login	∼3	yes
unlock	∼3	yes
First credential use	∼80	yes
runas	∼2	yes
file explorer	∼20	no
more	∼2	no
cat	∼20	no
remote file access in run app	∼70	no
remote file access in notepad	∼80	no

Listing 4: Crafted HTML Example

per minute.

6.2 Remote Access Vector

The actions we surveyed can significantly increase the amount of queries per PIN code entry, however the attack is still highly dependent on the honest user actions and the rate of actions. In order to remove this dependency, we found a remote vector which allows a malicious website to trigger the authentication process without any user interaction, by attempting to access remote files.

As described above, remote file access attempts can trigger the authentication process and generate AS-REQ ticket requests. In contrast to our micro-architectural attack code that can run under a *different* user account, only code running under our target user can trigger these accesses. As we don't want to assume that the target user will run our code, we show how we can trigger these accesses by only requiring the target user to access a malicious website. There are several methods a website can cause the browser to attempt to access remote files, e.g., using an image input, iframe input, or links. In addition, the crafted HTML file can specify an automatic refresh, which causes the browsers to keep sending requests. The example HTML code in Listing 4 demonstrates one of the methods to generate requests. Line 5 accesses a remote file which generates requests and line 3 automatically reloads the html site which causes line 5 to be repeated continuously.

Although these remote file access attempts will fail due to our attack (and, in fact, the files might not exist at all), the attack can remain stealthy since there are many ways to hide the file access errors in the browser. For example, loading an image or an iframe to an unseen location or a very small area on the screen. There is also the option of displaying alternative text when loading fails. This means that the user gets no notification of any error and remains unaware of our stealthy attack. Moreover, the attack can continue running as long as the malicious website's tab is opened. The attack will continue even when the targeted user views another tab, uses another application instead of the browser, or even locks the computer or switches to another Windows user.

In order to determine the practicality of this vector, the three most common browsers were inspected: Google Chrome, Edge (also Chromium based) and Microsoft Internet Explorer. Our attack works on all browsers for HTML files that are locally stored on the machine. The behavior for HTML files retrieved directly from remote websites is different due to different mitigations implemented in order to secure file access. While all three browsers generated queries for local HTML files, Edge and Chrome, both based on Chromium, blocked these attempts for the remote HTML sites. Thus, our attack will work on all browsers if we can cause our user to open a locally stored malicious HTML file (e.g., after downloading it from a malicious website and saving it locally). In addition, even for the case of remote HTML files, there is a vast amount of recent vulnerabilities published [1–6] that can be exploited to implement this remote vector. We thus argue that our remote attack vector is practical as, with high probability, many more similar vulnerabilities still remain.

Even after the acceleration, the overhead required to handle the noisy oracle might prevent us from finishing our attack before the Kerberos session expires. In the next section, we will describe how to reduce the overhead and perform a full end-to-end attack to hijack Kerberos sessions.

7 Bleichenbacher Attack with Noisy Oracles

As was described by Capol [15], the literature on Bleichenbacher attacks mostly focused on perfect oracles without any noise. However, in practice, many oracles are noisy. Ronen et al. [64] handled a noisy oracle by simply repeating each "positive" query multiple times to reduce the false positive rate to a negligible level. This approach is based on the intuition that the attack algorithm can recover from a false negative with some overhead, but a false positive might cause the attack to fail. As the overhead of repeating each false query is larger than the overhead of false negatives, only positive queries are repeated.

The general idea suggested by Ronen et al. [64] is to reduce the false positive rate to a negligible level (false positives should never occur) while paying the price in query overhead due to both repeated queries and the increased false negative rate. We argue that this approach is sub-optimal in both their

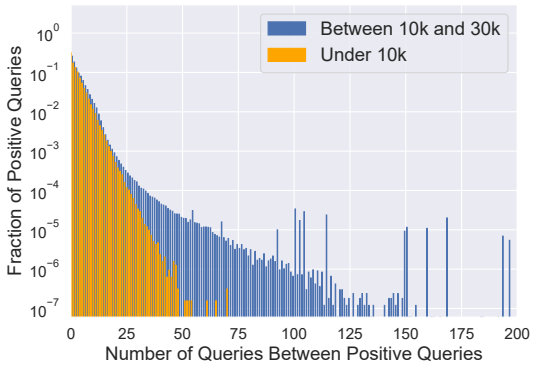

Figure 3: Comparison of the amount of false queries between consecutive positives queries for ciphertexts deciphered in under 10k queries and between 10k and 30k queries (using a perfect oracle

and our settings. In both settings, we want to be able to finish the attack in a limited time period (30 seconds timeout in [64] and 10 hours until ticket expiration in our case). This changes our optimization goals. We don't want to ensure that all attacks succeed (no false positive), but maximize the percentage of attacks that finish successfully below a fixed query number threshold. In Section 5 we show how we can exploit our attack even if we can't finish it in less than 10 hours. However, using the attack acceleration we present in Section 6, an under 10 hours attack becomes practical and minimizing the query overhead becomes significant.

7.1 False Postive Detection

To minimize the query overhead, our novel approach does not try to prevent false positives with costly query retries, but instead we accept a non-negligible false positive rate. If we are able to detect when a false positive occurred, we can instead trace back to a previous correct state of the attack. As we will show, the cost of such a detection and trace back is smaller on average than the cost of reducing the false positive rate.

The main remaining question is how to detect a false positive before the attack finishes. For this, we exploit a statistical property of the attack that is unique to the subset of "fast" messages that can be attacked successfully under our timing constraints before the token expires. We recorded ≈ 40000 RSA ciphertexts generated by the KDC for the AS-REP message. For each ciphertext, we simulated a Bleichenbacher attack with a maximal cutoff threshold of 30000 queries. The attack was able to decrypt ≈ 11500 ($\approx 29\%$) of the ciphertexts in under 30000 queries, and ≈ 3200 ($\approx 8\%$) of the ciphertext in under 10000 queries.

Figure 3 shows the number of false queries between consecutive positive queries. We can see that for the subset of "Under 10k" messages, a sequence of more than 30 consecutive false queries only occurs with a negligible probability, and we don't see any sequences of more than 70 consecutive false queries. Moreover, our experiments showed that if we reach an incorrect state due to a false positive, we will get very long sequences of false queries. This means that we can use such long sequences to detect that a false positive has occurred. Our trace-back algorithm saves the state of the attack for the last 15 positive queries; if a sequence of more than 100 false queries is detected, the algorithm's state is reverted to the earliest saved position. Note that we use conservative numbers to handle multiple false positives.

We developed a low overhead query repetition algorithm tailored to the hit count distribution shown in Table 3. It doesn't require any repetition for the vast majority of both false and negative queries, repeating a query only in a small number of borderline cases. The resulting oracle still has a low but not negligible false positive rate and thus requires our trace-back approach.

Our low overhead repetition algorithm works as follows:

1. A zero hits result is taken as a definite nonconforming query result. It is not repeated. This leads to 7% of false-negative results, but the attack can recover and still works with a slightly larger number of queries.
2. A two hits or more result is taken as a definite conforming query result and is not repeated.
3. A single hit is a borderline result which is repeated up to 3 times:
   (a) If the result of the next query is two hits or more, the repetition stops and the original query is considered conforming.
   (b) If the next query is borderline or 0 hits, we continue to the next query.
4. If no query had two hits or more, the original query is considered nonconforming. This results in a very small number of false-negative results, but again the attack can recover.

Note that our traceback algorithm has one exception. Reverting the first positive query (i.e., the first multiplier found in phase 2 of the attack as described in Appendix A) may require a very large number of additional queries. Thus, for the first positive query, instead of the usual repetition algorithm. As the majority of 5 has only a negligible false positive probability, we never revert it.

7.2 Noisy Oracle Simulation

To test our novel traceback approach, we created a simulated noisy oracle based on the distribution from Table 3. We used this oracle in our simulation to compare our low-overhead traceback approach with two other higher-overhead algorithms. The first is the "double" conservative algorithm that repeats each positive query (hit count > 1) and requires both attempts to be positive to return a positive result. The

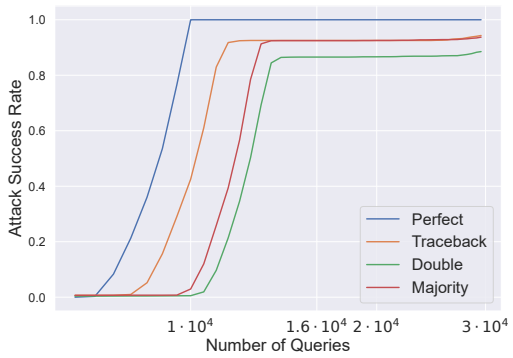

Figure 4: Comparison of noisy oracle handling methods in performed simulation experiment

second is the less conservative "majority" algorithm that, after the first positive query, can attempt up to two more times, requiring a majority of two positives to return a positive result. The "double" algorithm has fewer queries and a lower false positive rate compared to the "majority" at the cost of a higher false negative rate.

Figure 4 shows the results of our simulation comparing the fraction of the attacks that were able to finish successfully with a given number of queries. Note that as we are only interested in "fast" attacks, we limited the simulation to ciphertexts that can be decrypted with less than 10000 queries assuming a *perfect* not noisy oracle, which we also used as our baseline. As we can see, only our traceback-based attack is able to decrypt a non-negligible number of messages in less than 10000 queries with a noisy oracle, reaching a success rate of over 40% of the messages decrypted in less than 10000 queries with a perfect oracle.

7.3 Kerberos Sessions Hijacking

Using our efficient traceback attack to handle the noisy oracle, we were able to exploit the remote vector approach for a full end-to-end attack that allowed us to recover session tokens in less than 6 hours, *before they expire*. The session token can be exploited to gain access to all of the resources and services the user has permission for. For example, if we target an admin user, we can exploit the session token to open a remote powershell with full admin permissions.

We ran our full traceback attack and were able to successfully hijack in less than 10 hours 15 out 17 different session tokens generated by the KDC (taken from the "Under 10k" set). The full experiment results are provided in Appendix B. Using our remote vector, we were able to achieve an average rate of 25.8 queries per minute, which translates to up to 16,000 queries within a 10-hour span. Our trackback approach combined a low false negative rate of 1.74% achieved a very small query overhead. The overhead for most attacks was under 1500, with several attacks having an overhead of ≈ 1000. This is much lower than the minimal overhead of ≈ 2000 incurred by any approach that requires even a single repetition for a positive query to reduce the false positive rate.

8 Optimizing Attack Retires With Early Abort

To hijack a session, we need to be able to finish the attack and decrypt its token before it expires, i.e., in less than 10 hours. The attack we described in Section 7 is able to perform a little over 16000 queries in 10 hours. This means we can only successfully attack tokens whose messages can be decrypted with less than 16000 *noisy* queries. A naive approach to finding such a message would be simply trying to run the full attack with a 16000 queries (ten-hour) limit on a message from a new session. If the attack doesn't finish in time, we retry the attack with a new message from a new session until the attack succeeds.

Assuming $P_{<16k}$ is the probability that a message can be decrypted with less than 16000 *noisy* queries, such an attack is expected to take on average $\frac{1}{P_{<16k}} \cdot 10$ hours. We will now show how to significantly reduce the overall attack time using our early abort method.

8.1 Early Abort Optimization

Our early abort optimization is based on the following insight: There is a strong correlation between the number of queries required to find the first positive query (i.e., to find the first multiplier in phase 2 of the attack as described in Appendix A) and the probability the message can be decrypted with a small number of queries.

Our optimization runs as follows: We run the attack till we reach a threshold of a fixed number of queries, which we denote Q_{th}. If no positive query has been detected, i.e., the first multiplier was not found, we early abort and rerun the attack on a new message. Otherwise, we continue to run the attack until it either succeeds or we reach the $16k$ query limit. If the attack doesn't succeed, we will again try to attack a new message. The value of Q_{th} has a significant effect on the average complexity of the attack. A lower value will allow us to early abort faster, but will increase the probability we will early abort attacks that could have succeeded. We used a simulation to explore the attack complexity with different values of Q_{th}. Note that setting $Q_{th} = 16k$ results in the naive retry approach.

We tested our attack using a simulated noisy oracle over the ≈ 40000 RSA ciphertexts generated by the KDC, running the attack (without early abort) 5 times for each ciphertext. In each run of the attack, we stored the number of queries required to find the first multiplier, and the number of queries required to finish the attack. Using the results, for each value of Q_{th}, we can calculate the following values:

$P_{<16k}(Q_{th})$ — The probability that, for a random ciphertext,

Q_{th}	$P_{<16k}$	$P_{>16k}$	$Q_{<16k}$	n_{msgs}	T_q
200	0.006	0.0000	8657	160	40578
300	0.009	0.0000	8642	109	41267
400	0.012	0.0001	8619	83	41941
500	0.015	0.0002	8666	66	41352
600	0.018	0.0003	8743	55	41822
700	0.020	0.0003	8763	49	42684
1000	0.029	0.0005	8878	34	42854
2000	0.056	0.0015	9217	17	43080
3000	0.083	0.0027	9528	12	43159
16000	0.178	0.0375	11115	5	84949

Table 5: Comparison of Early Abort Based on the First Multiplier

the first multiplier will be found with less than Q_{th} queries and that the attack will succeed with less than $16k$ noisy queries.

$P_{>16k}(Q_{th})$ — The probability that, for a random ciphertext, the first multiplier will be found with less than Q_{th} queries but the attack will require more than $16k$ noisy queries to succeed.

$Q_{<16k}(Q_{th})$ — The average query count to decrypt a random ciphertext, assuming the first multiplier is found with less than Q_{th} queries and that the attack will succeed with less than $16k$ noisy queries.

$n_{msgs}(Q_{th})$ — The average number of random ciphertext we need till we find a ciphertext such that the first multiplier will be found with less than Q_{th} queries and that the attack will succeed with less than $16k$ noisy queries. calculated as:

$$n_{msgs}(Q_{th}) = \frac{1}{P_{<16k}(Q_{th})}$$

$T_q(Q_{th})$ — The expected number of messages required to finish the full attack. It is calculated as:

$$T_q(Q_{th}) = n_{msgs} \cdot (Q_{<16k} \cdot P_{<16k} + 16000 \cdot P_{>16k} + Q_{th} \cdot (1 - P_{<16k} - P_{>16k}))$$

The resulting values as a function of Q_{th} are shown in Table 5. The last row with $Q_{th} = 16000$ is equivalent to the naive approach that simply tries to attack all messages without early abort. Using low Q_{th} values can reduce the total attack time by half compared to the naive approach. We note that for low Q_{th} values (i.e., below 400), the results are slightly noisy due to the low probability of $P_{>16k}(Q_{th})$. For the experimental verification of the attack, we use a conservative value of 600 for Q_{th}.

8.2 Experimental Results

We implemented our early abort attack and experimentally verified it. In our attack we use a Q_{th} with a value of 600.

#	n_{msgs}	T_q	T[hours]	$Q_{<16k}$
1	36	29336	18.4	8309
2	30	26185	16.4	8680
3	29	27023	16.9	9367

Table 6: Experimental results for token recovery using the early abort attack.

Table 6 shows the number of messages (n_{msgs}), total queries (T_q), and total attack time in hours (T[hours]) for each token recovered. It also shows the number of queries required for the successful decryption of the last message ($Q_{<16k}$). We note that the attack seems to be faster than our simulated attack, with a much lower number of messages required before we are able to recover a token. We believe that this might be due to the distribution of errors. In our simulation, we assume uniform and independent error distribution, but in reality, they may occur in bursts. We leave the analysis of the noise distribution and its effect on such attacks for future work.

9 Conclusions

Modernizing operating systems in general, and their security mechanisms in particular, is a difficult task that requires updating cryptographic implementations while trying to maintain backward compatibility. In Kerberos, this process lead to a convoluted combination of modern and legacy cryptographic primitives and designs. Although the Kerberos protocol is critical to the security of countless sensitive networks, and has undergone countless updates, its default configuration for the most security sensitive use cases (that require 2FA) is still vulnerable to an attack published more than 25 years ago.

9.1 The Danger of Legacy Crypto

Our research can highlight the many different ways legacy crypto can be exploited to implement a full end-to-end attak. We will now discuss some of the root causes we identified and how we propose to mitigate them.

Using Nonconstant-time Crypto Legacy Crypto such as the RSA PKCS #1 v1.5 based encryption is notoriously hard to implement securely. In more than 25 years we have seen countless cycles of new attacks and new mitigations (especially but not limited to TLS). While it is possible to use the lessons learnt in TLS and try and implement the decryption with constant-time code, and add the required Bleichenbacher mitigations (as was done in the MIT implementation), we believe this is not the right path to move forward. A better alternative such as ECDSA and ECDH based options are already supported in Kerberos, we should push for complete deprecation of RSA PKCS #1 v1.5.

Unauthenticated Data In our attack we exploited the fact that many parts of Kerberos messages are not authenticated (e.g., to spoof both AS-REP and error messages). This was also exploited in the downgrade attack by Google Project Zero [22]. Although a complete overhaul of Kerberos to include strong authentication might be a challenging task, there are other options to reduce the risk. For example, Kerberos can be used over more modern and vetted protocols such as TLS [32]. Using such options can help prevent attackers from exploiting such vulnerabilities in the Kerberos protocol.

Lack of Forward Secrecy Protocols such as SMB3 rely on Kerberos for authentication and key distribution. To protect the sensitive data of such protocols, Kerberos should ensure forward secrecy. This can be done with a redesign that adds forward secrecy to the protocol, such as incorporating ephemeral Diffie-Hellman key exchange or tunneling the communication using a modern and secure protocol such as TLS (similar to the proposal for Kerberos above). In any case, the security properties of the protocols that rely on Kerberos should be well-defined and communicated to the users.

Unlimited Access to 2FA token Although it is not a weakness by itself, our attack relies on the fact that there is no global rate limit to the number of calls to the smartcard. Although an initial PIN code entry is required, we were able to cause the client machine to use the smartcard to decrypt more than 10000 RSA ciphertexts without any user interaction. This is several orders of magnitude more than what we can expect in a normal operation. Smartcards should provide an option to configure some policy for rate limitations. Moreover, the OS can also force user interaction by limiting the amount of calls to the smartcard before asking the user to reenter their PIN code, this should be implemented using a global counter.

9.2 Further Research

In this work, we provide an efficient algorithm to lower the Bleichenbacher's attack overhead when using noisy oracles. Our algorithm is focused on efficiency in the subset of "fast" attacks that require a relativity low number of queries. This is motivated by time constrained attack scenarios where slower attacks will fail to finish on time in any case. As we have shown, other approaches might improve the success rate when we consider other subsets of messages. We believe that further exploration of the problem space will reveal many more interesting approaches and tradeoffs that can optimize the attack for more real world scenarios.

A Bleichenbacher Attack algorithm

Below is a description of how an attacker can use the Bleichenbacher oracle BI to perform an RSA secret key operation, such as decryption, on c without knowing the secret exponent d. We refer the reader to [13] for a more complete description.

High Level Attack Description Let c be an integer. To compute $m = c^d \bmod N$, the attack proceeds as follows:

Phase 1: Blinding The attacker repeatedly iterates over integers beginning at s_0 and computes $c^* \leftarrow c \cdot s_0^e \bmod N$. The attacker checks if c^* is a conforming ciphertext by evaluating $\mathsf{BI}(c^*)$. When an s_0 is found such that $\mathsf{BI}(c^*) = 1$. The phase ends. This step can be skipped completely if c is already a valid PKCS #1 v1.5 ciphertext in which case $s_0 = 1$.
We note that when the oracle returns a positive result ($\mathsf{BI}(c^*) = 1$) the attacker knows that the corresponding message $m^* = m \cdot s_0 \bmod N$ starts with 0x0002. Thus, it holds that $m \cdot s_0 \bmod N \in [2B, 3B)$ where $B = 2^{8(\ell-2)}$ and ℓ is the length of N in bytes. Finally, the condition of $m \cdot s_0 \bmod N \in [2B, 3B)$ implies that there exists an integer r such that $2B \leq m \cdot s_0 - rN < 3B$, or equivalently:

$$\frac{2B + rN}{s_0} \leq m < \frac{3B + rN}{s_0}.$$

Phase 2: Range Reduction Having established that $\frac{2B+rN}{s_0} \leq m < \frac{3B+rn}{s_0}$, the attacker proceeds to choose a new integer multiplier s, computes $c^* \leftarrow c \cdot s^e \bmod N$ and checks that $\mathsf{BI}(c^*) = 1$. When a suitable s is found, the adversary can further reduce the possible ranges of m, further detailed in [13]. The attack terminates when the possible range of m is reduced to a single candidate.

The original algorithm was published in 1998 and was known as the 'Million Message Attack'. However, since then there have been many optimizations for the attack [11]. In some implementations, not all parts of the padding scheme are verified and the attack can be adapted.

Table 7: Experimental Attack Results

Session	Success	Attack Time (hours)	Total Query	Perfect Oracle Query
1	True	5.44	8422	7203
2	True	4.89	7805	7362
3	True	5.96	9151	7587
4	True	5.64	8787	7713
5	True	5.22	8180	7178

B Session Hijacking Experimental Results

Table 7 shows the experimental results of our full end-to-end session hijacking attack. For each successful attack, we give the attack time, the total queries required for the attack (including repetitions as described in Section 4.1). We also provide a baseline of the number of required queries assuming a perfect oracle. Two attacks were stopped due to errors that prevented them from finishing on time.

Divide and Surrender: Exploiting Variable Division Instruction Timing in HQC Key Recovery Attacks

Lund University, Sweden

Abstract

We uncover a critical side-channel vulnerability in the Hamming Quasi-Cyclic (HQC) round 4 optimized implementation arising due to the use of the modulo operator. In some cases, compilers optimize uses of the modulo operator with compile-time known divisors into constant-time Barrett reductions. However, this optimization is not guaranteed: for example, when a modulo operation is used in a loop the compiler may emit division (`div`) instructions which have variable execution time depending on the numerator. When the numerator depends on secret data, this may yield a timing side-channel. We name vulnerabilities of this kind Divide and Surrender (DaS) vulnerabilities.

For processors supporting Simultaneous Multithreading (SMT) we propose a new approach called DIV-SMT which enables precisely measuring small division timing variations using scheduler and/or execution unit contention. We show that using only 100 such side-channel traces we can build a Plaintext-Checking (PC) oracle with above 90% accuracy. Our approach might also prove applicable to other instances of the DaS vulnerability, such as KyberSlash. We stress that exploitation with DIV-SMT requires co-location of the attacker on the same physical core as the victim.

We then apply our methodology to HQC and present a novel way to recover HQC secret keys faster, achieving an 8-fold decrease in the number of idealized oracle queries when compared to previous approaches. Our new PC oracle attack uses our newly developed Zero Tester method to quickly determine whether an entire block of bits contains only zero-bits. The Zero Tester method enables the DIV-SMT powered attack on HQC-128 to complete in under 2 minutes on our targeted AMD Zen2 machine.

1 Introduction

The rise of quantum computing presents a grave threat to current cryptographic infrastructures, primarily based on problems like factoring and discrete logarithms. Shor's algorithm [55], in particular, significantly compromises these security foundations. In response, the National Institute of Standards and Technology (NIST) initiated a process in 2016 to identify and standardize quantum-resistant public-key cryptographic algorithms, focusing on developing new standards for Key Encapsulation Mechanism (KEM) and digital signatures. This initiative drew a robust response from the cryptographic community and after thorough review and feedback, NIST endorsed CRYSTALS-Kyber [53] as the primary KEM algorithm and CRYSTALS-Dilithium [44], FALCON [48], and SPHINCS+ [37] as key digital signature algorithms. This initiative marks a significant shift towards securing cryptographic practices against emerging quantum computing threats.

One notable aspect of NIST's selection is its emphasis on lattice-based algorithms like CRYSTALS-Kyber, CRYSTALS-Dilithium, and FALCON, reflecting a preference for lattice-based cryptography. However, to ensure a robust cryptographic future, NIST also prioritizes diversity in cryptographic solutions, hence its ongoing round 4 selection process included non-lattice-based KEM algorithms. This phase spotlighted code-based KEMs such as Classic McEliece [7], HQC [4], and BIKE [13], alongside a now broken isogeny-based KEM, SIKE [39]. Among these, the HQC proposal [4,5,14], based on hard decoding problems in coding theory, emerges as a promising candidate [6].

Given HQC's potential for NIST standardization, an immediate and critical focus must be directed towards scrutinizing HQC's security claims. Specifically, secure implementation strategies for HQC on various real-world platforms warrant exhaustive study.

Numerous studies, such as [15, 27–30, 36, 46, 52, 60, 62], have extensively explored HQC's security and implementation aspects, adopting a dynamic attack-and-fix methodology throughout NIST's initial evaluation rounds. The fourth-round HQC submission includes a single implementation claimed to be constant-time, suggesting resilience against timing attacks [40]—a type of attack that leverages variations in execution time to compromise security. As constant-time imple-

mentation is a critical aspect in cryptographic libraries, it is a fascinating research challenge to either validate this security claim or identify a more efficient attack strategy for potent key-recovery attacks.

In our paper, we identify a novel timing side-channel vulnerability in the implementation for HQC, originating from division operations that are not constant-time. This vulnerability enables an efficient key recovery timing attack against the claimed constant-time implementation in the designers' round 4 submission to NIST. This makes HQC one of the few known cases where division instructions are used in a cryptosystem with secret inputs and cause an exploitable timing difference. We call these vulnerabilities instances of the DaS vulnerability. Other instances are a potential fix for the Lucky13 attack [41] and KyberSlash [17, 26]. In KyberSlash similar code structure causes the compiler to emit `div` instructions where constant-time code could have been generated.

Our approach builds on the established PC oracle-based side-channel attacks, creating a PC oracle that verifies if a particular ciphertext c decrypts to a given message m. This type of attack can be traced back to the reaction attack, initially introduced by Hall et al. in 1999 [33]. Furthermore, this attack methodology has found broad applicability in the realm of post-quantum cryptography, as evidenced by works such as [19, 31, 45, 49, 50, 61], and is applicable to various side-channels such as timing, cache timing, power, and electromagnetic radiation, provided the side-channel leakage is sufficient to construct a PC oracle.

We develop the desired PC oracle using a novel side-channel, called DIV-SMT, which originates from integer modulo operations in some SMT processors such as AMD Zen+/Zen2 processors.

On the x86-64 instruction set architecture, implemented by the AMD Zen+/Zen2 processors, the `div` instruction is used to calculate both, the quotient and the modulo of the two operands. Hence, divisions and modulo operations in the source code are usually both compiled to `div` instructions. Compiler optimizations eliminate the `div` instructions in some cases. Specifically, with a divisor known at compile time, the GCC compiler might apply Barrett Reduction [16] as an optimization. However, as we show in Section 4, this optimization is sometimes not performed, even if it would be possible.

In these widely deployed high-end processors, varying numerator and divisor sizes in integer divisions can result in single cycle execution time differences. Exploiting such small timing differences is non-trivial and the `div` instructions only make up a small part of a complete decapsulation in the HQC cryptosystem. Further, advanced CPU features like out-of-order execution can render timing measurement more challenging. Thus, the SMT context becomes crucial here, allowing the attacker and victim threads to run on the same physical core with shared caches, execution units, and schedulers. This setup can create contention on execution units [8] or schedulers [25], enabling an adversary to detect when a co-located program executes a specific instruction, such as a multiplication or a division.

In contrast to these prior works, which attacked non-constant-time ECDSA and RSA implementations by detecting the points in time when specific instructions are executed through a timing side channel, our novel approach infers information about the numerators for the same division instruction. Our attack highlights a serious security risk in the HQC implementation submitted to NIST that claims to be constant-time. The claimed constant-time property is crucial for the safe integration of HQC into real-world libraries.

While avoiding non-constant-time instructions is a standard practice in constant-time implementations, division operations in modern high-end CPUs have previously seen little cryptographic research attention due to the lack of documented vulnerabilities and exploits resulting from their timing behavior. To our knowledge, our research presents the first key-recovery attack that clearly demonstrates the potential of exploiting this vulnerability on current, SMT enabled CPUs. Thus, our methodology of distinguishing different numerators in an SMT environment can offer valuable insights for security assessments beyond attacking HQC.

In December 2023, a vulnerability related to the use of modulo operations, potentially compiling into `div` instructions, was independently identified in the CRYSTALS-Kyber reference implementation by Bernstein [17] and by Tamvada, Kiefer, and Bhargavan [26]. The CRYSTALS-Kyber design team has acknowledged and purportedly rectified this issue. These groups did not present an attack strategy for exploiting this vulnerability in high-end modern CPUs, but their discoveries highlight the broad relevance and impact of our innovative attack methodology in the SMT context, as we deem it likely that our DIV-SMT methodology can also be used to exploit KyberSlash vulnerable implementations of Kyber.

Utilizing the PC oracle derived from the DIV-SMT side-channel, we further advance our research by developing a methodology that significantly reduces the number of PC oracle queries needed to extract HQC's secret key. This new approach holds significance beyond the newly discovered timing attack exploiting the DaS vulnerability for two main reasons. First, it relies on a PC oracle that can be built from various side-channel leakages. This versatility makes it suitable for a broad spectrum of PC oracle-based side-channel attacks on HQC, thus widening its applicability beyond just timing attacks. Second, since interacting with the oracle is often the primary bottleneck in such attacks, optimizing oracle calls is crucial for efficiency in most of real-world attack scenarios.

We introduce a new technique called Zero Tester for efficiently identifying through PC oracle calls whether a consecutive block, referred to as an 'inner block' in HQC's coding scheme, consists solely of zero-bits. Through the integration

Work	Oracle Calls
GHJLNS22 [28]	866 143
SHRWS22 [52]	>50 000
HSCGJ23 [36]	>50 000
SCA-LDPC [32]	10 000
Our Work	1 142

Table 1: Comparison of our attack to previous works. The reported number of idealized oracle calls required for HQC-128 key-recovery is shown.

of this method with a shifting strategy, we have the capacity to pinpoint numerous zero-bit's positions inside the secret vector using few queries. This method significantly increases the speed of full key recovery: Given that the public key already provides n linear equations for the $2n$ unknowns in HQC's secret key, identifying approximately n out of $2n$ unknown zero positions is sufficient.

Summary of Contributions. Our core contributions are:

- We unveil a novel timing side-channel vulnerability in the supposedly constant-time optimized reference implementation of the HQC round 4 submission to NIST, which is an instance of the vulnerability class named Divide and Surrender (DaS).
- We propose a new practical exploitation strategy of division timing variance through the use of DIV-SMT side-channels in SMT processors. By leveraging contention between SMT sibling threads, we detect the execution of specific instructions (`div`) and infer information about the operands processed (specifically, the count of leading zeros in the numerands). This insight lays the groundwork for creating a Plaintext-Checking (PC) oracle, enabling us to execute a key-recovery timing attack.
- We propose a novel key-recovery method for HQC using the PC oracle, significantly reducing the required number of side-channel traces. A detailed comparison with prior studies for HQC-128 key-recovery is presented in Table 1. We conduct extensive simulations to investigate the efficacy of our proposed key-recovery method, employing a simulated PC oracle across different levels of oracle accuracy. Our simulations demonstrate a significant improvement requiring only 11% to 13% of the oracle calls relative to the SCA-LDPC framework presented at ASIACRYPT 2023 [32]. Notably, this gain persists even as the oracle's accuracy decreases to 0.9.
- We demonstrate the practical applicability of our attack through evaluation on an AMD Zen2 CPU. Out of 1000 attacks conducted, three-quarters lead to successful full key recovery, achieving a median attack time of 111 seconds.

The artifact is available at https://github.com/hqc-attack/divide-and-surrender.

Responsible Disclosure. We disclosed the issue to the HQC design team in February 2023. After the release of our first draft, the scheme designers released a patched optimized reference implementation on 2024-02-23 [23]. The designers chose to manually implement the Barrett reductions (cf. Section 6.1) [35]. Furthermore, we disclosed the issue to the PQClean team in March 2023 [9]. We believe our disclosure allowed implementers to implement a presumably constant-time version of the vector sampling algorithm using explicit Barrett reductions.

Outline. The rest of this paper unfolds as follows: Section 2 provides the essential background, covering both the HQC KEM proposal and relevant aspects of CPU architectures. We present our main attack strategies in Section 3. This is followed by the introduction of a novel PC oracle in Section 4, specifically designed to exploit a division timing side-channel to challenge the constant-time claims of an implementation submitted to NIST. Experimental results are reported in Section 5, followed by a comprehensive discussion in Section 6. Section 7 draws conclusions.

2 Preliminaries

In this section, we present some preliminary background on the HQC proposal, CPU Pipelines, and SMT.

Notations. Consider $\mathbb{F}_2$ as the binary finite field, where the operations $+$ and $-$ are equivalent. The Hamming weight of a binary vector is defined as the number of non-zero entries in the vector. In the HQC scheme, we employ a cyclic polynomial ring $\mathcal{R} = \mathbb{F}_2[X]/(X^n - 1)$, where n is an integer in $\mathbb{Z}$. Elements in $\mathcal{R}$ can be alternatively viewed as row vectors in a vector space over $\mathbb{F}_2$. For uniform sampling from a set $\mathcal{S}$, we utilize the notation $\xleftarrow{\$}\mathcal{S}$. Specifically, $\xleftarrow{\$}\mathcal{R}_\omega$ indicates uniform sampling from $\mathcal{R}$ of an element with a Hamming weight of ω.

2.1 HQC

HQC [4], a code-based post-quantum IND-CCA (Indistinguishability under Chosen Ciphertext Attack) secure KEM, leverages the complexity of decoding random quasi-cyclic codes in the Hamming metric for its security. It was proposed as a KEM candidate in the fourth round of the NIST Post-Quantum Cryptography (PQC) standardization [18]. At the conclusion of the fourth round, NIST intended to standardize a single code-based KEM primitive, either HQC or BIKE. Similar to other NIST PQC Public Key Encryption (PKE)/KEM candidates, HQC proposal commences with an IND-CPA (Indistinguishability under Chosen Plaintext Attack) version, termed HQC.CPAPKE, and subsequently introduces an INC-CCA KEM, called HQC.CCAKEM, through a CCA transformation (HQC utilizes the Hofheinz-Hövelmanns-Kiltz (HHK) transformation [34]).

2.1.1 The PKE Version of HQC

The HQC.PKE algorithm comprises three sub-procedures: PKE.KeyGen, PKE.Encrypt, and PKE.Decrypt. Within PKE.KeyGen, the algorithm uniformly samples three polynomial elements—h, x, and y, with x and y maintaining fixed Hamming weights of w. The secret key is designated as (x,y) and the public key as $(h, s = x + h \cdot y)$. PKE.Encrypt begins by initializing the pseudo-random number generator (PRNG) with a seed θ making the sampling process deterministic. Subsequently, the algorithm uniformly samples the polynomials r_1 and r_2 from $\mathcal{R}$, each possessing a Hamming weight of w_r, and e with Hamming weight w_e. The ciphertext c is computed as $c = (u,v)$, where $u = r_1 + h \cdot r_2$ and $v = m\mathbf{G} + s \cdot r_2 + e$. The matrix $\mathbf{G}$ is the generator matrix of the linear code $\mathcal{C}$, which we will describe later. PKE.Decrypt employs a decoder $\mathcal{C}$.Decode$(v - u \cdot y)$, where

$$v - u \cdot y = m\mathbf{G} + s \cdot r_2 + e - (r_1 + h \cdot r_2) \cdot y = m\mathbf{G} + e' \quad (1)$$

$$e' = x \cdot r_2 - r_1 \cdot y + e \quad (2)$$

given that $s = x + h \cdot y$. If the Hamming weight of the error term e' is small (i.e., within the decoding capability of the employed decoder), the decoder could correct such an error, leading to successful decryption.

Beginning with the October 2020 release, HQC transitioned to a design incorporating a decoding strategy that utilizes a concatenated code combining an internal duplicated Reed-Muller (RM) code and an outer Reed-Solomon (RS) code. The resultant code produces a publicly known generator matrix $\mathbf{G} \in \mathbb{F}_2^{k \times n_1 n_2}$, where $k = 8k_1$.

The specifics of the HQC parameters are detailed in Table 2. HQC computations occur within the ambient space $\mathbb{F}_2^n$, with any remaining $n - n_1 n_2$ positions of no value discarded. The concatenated code, $\mathcal{C}$, merges an internal duplicated RM code with an outer RS code. The internal duplicated RM code possesses parameters $[n_2, 8, n_2/2]$, and the outer RS code is defined as $[n_1, k_1, n_1 - k_1 + 1]$.

During the encoding process, a message $m \in \mathbb{F}_{2^8}^{k_1}$ translates into $m_1 \in \mathbb{F}_{2^8}^{n_1}$ by the outer Reed-Solomon code. The internal duplicated Reed-Muller code then encodes each byte $m_{1,i}$ into $\bar{m}_{1,i} \in \mathbb{F}_2^{n_2}$, where $0 \leq i < n_1$. Consequently, we attain $m\mathbf{G} = (\bar{m}_{1,0}, \cdots, \bar{m}_{1,n_1-1})$ with dimension $n_1 n_2$.

To decode $V = v - u \cdot y$, $V \in \mathbb{F}_2^{n_1 n_2}$ is partitioned into n_1 blocks, denoted as $V = (V_0, \cdots, V_{n_1-1})$, with each $V_i \in \mathbb{F}_2^{n_2}$ defined as an 'inner block', where $0 \leq i < n_1$. Each V_i undergoes decoding by the internal duplicated Reed-Muller code into $\bar{V}_i \in \mathbb{F}_2^8$, where $0 \leq i < n_1$. Thereafter, $\bar{V}$ is compiled as a string of $8n_1$ bits, denoted as $(\bar{V}_0, \cdots, \bar{V}_{n_1-1})$. For each $i \in [0, n_1)$, $\bar{V}_i$ is termed an 'internal codeword'. It is observable that $\bar{V}$ is a noisy codeword of the outer Reed-Solomon code, which can be decoded into k_1 elements over $\mathbb{F}_{256}$ and transformed into k_1 message bytes.

Figure 1: HQC.CCAKEM

2.1.2 The KEM Version of HQC

The HQC KEM, depicted in Figure 1, is constructed from the HQC PKE scheme using an HHK transform. Crucially the encryption is now de-randomized and the decapsulation performs a re-encryption step to verify the validity of the ciphertext. Additionally the decapsulation invokes two distinct cryptographic hash functions: $\mathcal{G}$ and $\mathcal{K}$. The seed θ is derived from the message m, the public key and a random 128-bit salt. The seed θ and the inputs that are used to derive it are vital to the exploitation of the scheme, as it determines the side-channel behavior of a ciphertext (cf. Section 4).

2.2 CPU Pipelines

Modern superscalar CPUs execute multiple instructions in parallel [22]. The CPU frontend decodes instructions into micro-ops (µops) and forwards them to the backend via a dedicated dispatch buffer. The CPU backend has multiple execution units, processing µops in parallel. Simple µops, (e.g., additions of two registers) can typically be executed by multiple execution units, whereas more complex µops (e.g., divisions) require a specialized execution unit [12, 38]. The execution units are controlled by one [38] or multiple [10–12] schedulers that retrieve µops from the dispatch buffer and determine which µops are ready for execution, based on their operand dependencies, enabling out-of-order execution. The results of the executed µops become architecturally visible after they retire in the instruction stream order.

	RS-S			Duplicated RM

Table 2: The HQC parameter sets [4]. The base Reed-Muller code is the first-order $[128, 8, 64]$ Reed-Muller code.

2.3 Simultaneous Multithreading (SMT)

CPUs reach their maximum performance if they utilize all execution units simultaneously. Usually, this is not achieved with a single instruction stream. Therefore, many modern CPUs execute multiple instruction streams on the same core, sharing caches, execution units and schedulers. Most Intel and AMD CPUs support two SMT threads on the same core [12, 38]. Some Power10 CPUs can support up to 8 SMT threads per core [2]. While this increases performance, it also enables multiple side channels [57, 58]. Particularly, contention on execution units [8] or schedulers [25] enables an adversary to observe that a co-located program executes a specific machine instruction. This in turn allows an adversary to recover secret keys when attacking non-constant-time ECDSA and RSA implementations [8, 25].

3 New Key-Recovery Attack

In this section, we present a novel key-recovery attack on HQC using a PC oracle. We begin with a general description of the threat model and provide a comprehensive overview of the key recovery process used in such attacks. Following this, we review several existing attacks in detail in this context. Finally, we describe our new method, which efficiently identifies blocks in the secret vector that have a zero Hamming weight.

3.1 The Generic Threat Model

In our study, we investigate a side-channel-assisted chosen-ciphertext attack model targeting HQC's decapsulation algorithm. Here, the attacker crafts ciphertexts and observes side-channel information emanating from the targeted device. This could include timing, cache-timing, or even power and electromagnetic leakages. Our general threat model posits that the attacker can construct a PC oracle $\mathcal{O}^{\rho}_{\text{HQC}}$ from side-channel leakage. This oracle confirms or denies whether $\mathsf{PKE.Decrypt}(sk, c) \stackrel{?}{=} m$, where c represents the ciphertext and m a message vector. This oracle has an accuracy level of ρ, meaning it returns a correct decision with a probability of ρ and an incorrect one with a probability of $1-\rho$. Leveraging such an oracle, our focus shifts to methods for full secret key recovery. We assume that the adversary can choose both the ciphertext and the message.

The above framework outlines our generic threat model. For any specific attack scenario, a more detailed threat model must be articulated, as the adversary's methodology for constructing the PC oracle could vary substantially depending on the concrete attack. For instance, in Section 4.2.1, we elaborate on the threat model pertinent to our newly identified timing attacks originating from division timing side-channels, where both the adversary and the victim need to run in the SMT setting.

3.2 High-Level Overview of Key Recovery

We present an end-to-end description of PC oracle-based attacks on HQC. These attack strategies exploit decoding failures, which leak key information and are detected through a PC oracle built from side-channel leakages. As described in Section 2.1.1, the ciphertext (u, v) is computed using the message m, intermediate random vectors r_1, r_2, e, and public parameters h, s, and $\mathbf{G}$. The attacker strategically assigns values to m, r_1, r_2, and e to engineer ciphertexts (u, v) that exhibit a specific property. These chosen ciphertexts are then submitted to the device for decapsulation, during which the attacker monitors the side-channel leakages to construct the PC oracle.

Since decoding failures leak information about the error contained within a ciphertext, the attacker's task then becomes crafting ciphertexts whose error yields information about the secret key. In particular, since the input to the decoder $\mathcal{C}.\text{Decode}(\cdot)$ is $v - u \cdot y$, the decoding result is linked to the secret vector y, and also to x. via the public h and the relation $s = x + h \cdot y$. Upon determining the decoding outcome—success or failure—via the PC oracle, the attacker can recover the key through methods such as bit-by-bit determination [28], enumerating patterns within an inner RM block [36], or querying sparse parity checks of several bits [32]. These strategies will be elaborated on in Section 3.3.

All of these attack strategies operate under a common assumption. They all presume that the decryption outcome hinges on a single inner block decoding of the RM code. In other words, the attacks have already introduced enough errors to push the outer RS decoding to its boundary for correct decoding. Thus, corrupting a single additional RM block

causes a decoding error of the entire concatenated code construction. This process is an optimization that is not strictly necessary for exploitation, but significantly reduces the number of online queries.

3.3 Relevant Attacks

We briefly review three relevant attacks, each discussed in the following references: [28], [36], and [32].

3.3.1 The Key-Recovery Attack by Guo et al.

Guo et al. [28] propose the following method: the attacker sets r_1, r_2 and e in such a way that the error that the decoder must correct is simply the secret y. This is done by setting r_1 to 1 (the multiplicative identity of R) and both r_2 and e to 0 (the zero vector). The foundational ciphertext is then

$$C_0 = (u, v) = (1, m\mathbf{G}). \tag{3}$$

Passing this ciphertext into PKE.Decrypt reveals that it will run the decoder on $v - u \cdot y$, which simplifies to $m\mathbf{G} - y$. Thus, the decoder receives the encoded message with the error y, which is part of the secret key.

As in all of the following attacks, the attacker then corrupts RM blocks until one more corrupted RM block will lead to a decoding failure in the RS decoder. Then, the attacker focuses on a single inner RM block which they aim to recover. Within this RM block the attacker introduces errors until a decoding failure occurs. Then, they flip each bit to test if it results in a decoding success again. When this happens, the bit was an error-bit with high probability. Since all added vectors are recorded, this method enables a highly probable prediction of a specific bit in the secret y. The strategy comes at the cost of high online query complexity, as each test of the decryption status requires a separate call to the oracle or the PKE.Decrypt procedure with the secret key.

3.3.2 The Two-Phase Attack by Huang et al.

Huang et al. [36] introduced a two-phase key-recovery attack that employs the PC oracle. The attack comprises both online and offline stages. During the online stage, the attacker's objective is to identify a specially crafted, invalid ciphertext $c = (u, v) = (1, v)$ such that adding the secret key's y results in a decoding failure: $\mathcal{C}.\text{Decode}(v + y) \neq \mathcal{C}.\text{Decode}(v)$. The attacker repeated a certain number of attempts to find such a ciphertext. Upon finding a potential candidate, the attacker engaged in educated guessing to discern if a weight-1 pattern explains the decoding behavior. To enhance the likelihood of identifying the correct pattern, the attacker can repeat this procedure. If numerous attempts yield no such ciphertext c, the conclusion is that the inner block has a weight of 0, signifying an all-zero vector block. Thus, this method can determine most of the inner blocks with a bounded weight of 1.

Similarly, the attacker can employ this method to recover the inner blocks of x with weight bounded by 1. Due to the sparsity of the key, a significant number of blocks have weight bounded by 1. Thus, about 50% of the secret positions are recovered. With the public key relation that $x + h \cdot y = s$, the full secret key can be recovered by Gaussian elimination or slight post-processing such as information set decoding.

The primary advantage of this method over the key recovery method from [28] is that when performing educated guess for the value of one inner block of y (or x), only the public decoder of the employed RS RM codes is used, which can be done offline without interaction with the oracle. Thus, the online query complexity can be much lower.

3.3.3 The SCA-LDPC Framework

SCA-LDPC [32] is a generic framework grounded in coding theory for key-recovery chosen-ciphertext side-channel attacks on lattice-based and code-based KEMs using a PC-like oracle. When applied to HQC, this framework significantly reduces query complexity compared to the attacks outlined in [28] and [36].

In contrast to the other attacks, the approach in [32] generates a low-Hamming-weight vector h_l and sets $r_1 = h_l$, while keeping r_2 and e as zero vectors. Consequently, the decryption function takes $v - uy = m\mathbf{G} - h_l \cdot y$ as its input. Unlike the method in [28], which inefficiently recovers only a single y-vector entry per PC oracle call, the SCA-LDPC attack yields more valuable information. This is because each entry in $h_l \cdot y$ is much closer to a uniformly distributed bit, increasing the amount of information gained from each oracle interaction. Further, due to the low-Hamming-weight characteristic of h_l, we can generate a Low-Density Parity-Check (LDPC) code and deploy iterative decoding techniques to effectively recover the sparse secret vector y.

It is worth emphasizing that the attacks from both [36] and [32] leverage the extreme sparsity of HQC's secret key vectors. However, they are based on divergent design principles, making it nontrivial to combine these two attack strategies as per current literature.

3.4 New Method: Zero Testers with Shifting

We next introduce a novel method that tests whether n_2 consecutive bits have weight zero with greater query efficiency. While this approach aligns with the attack described in [36], it diverges in its methods and objectives. Rather than identifying patterns with a bounded weight of 1, our method focuses on efficiently determining blocks with weight zero. We generalize the definition of a block to allow for cyclic shifts of a vector.

Definition 3.1 (Block)**.** A block is a collection of n_2 consecutive bits. Typically blocks are a slice of an element of $\mathcal{R}$. The block may wrap around at the edges — e.g. the last bit, and the first $n_2 - 1$ bits of $x \in \mathcal{R}$ may form a block.

Definition 3.2 (Zero-Block)**.** A zero-block is a block that has zero Hamming weight, i.e. all bits are zero.

The zero-blocks we identify may be at any offset in parts of the secret key's x and y. We are not limited by the RM code's codeword offsets, as we can shift the secret key's components using u and r_2. Specifically, we can craft a ciphertext such that the victim's decoder will correct an error corresponding to shifted versions of x or y.

To construct a ciphertext that contains y shifted by k positions as its error, we can set $r_2 = 0$ and $u = X^k$ and compute v honestly as per the scheme by $v = m\mathbf{G} + s \cdot r_2 + e$. During decapsulation, this will result in $\mathcal{C}$.Decode$(v - u \cdot y)$, where

$$v - u \cdot y = m\mathbf{G} + s \cdot r_2 + e - X^k \cdot y = m\mathbf{G} + e - X^k \cdot y.$$

The error e is then used by the zero-tester method to ascertain information about the first block of this shifted version of y. Analogously, for x, one may set $r_2 = X^k$ and $u = X^k \cdot h$, which results in the computation of

$$v - u \cdot y = m\mathbf{G} + s \cdot X^k + e - X^k \cdot h \cdot y = m\mathbf{G} + x \cdot X^k + e,$$

given that $s = x + h \cdot y$. Both cases result in shifted versions of the secret key becoming the error that the victim's decoder needs to correct. This shifting idea was already introduced in [36]; however, it is made viable through our new zero-testers and we fully develop and implement the idea.

A zero-tester can be used to identify whether a block has weight zero. Zero-testers are errors we add to the ciphertext, such that a decoding failure indicates whether the tested block in the original error of ciphertext can be a zero-block or not — i.e. it indicates whether a block of the secret key has weight zero. To implement this idea we find a sequence of errors (testers) that can be added to the ciphertext's y. The errors e_i are chosen such that adding one or more error bits to them results in a RM decoding failure. This allows efficient testing of whether a block of n_2-bits of the secret key is zero. Using these testers we can perform the attack. The requirement for a single error to detect all possible errors is unsatisfiable since the additional errors could unflip error bits set by the error e. A more reasonable requirement is that each tester should detect a large subset of possible errors induced by the secret key. Since the secret key is sparse the weight of the n_2-bit blocks is typically ≤ 5. Ideally, the union of the sets of secret key errors that the testers detect makes up the vast majority of possible errors that we are likely to encounter. Furthermore, we would like to find the shortest sequence of testers that allows us to detect the whole set of possible errors.

The number of oracle calls our attack requires is highly sensitive to the number of tests required per block. In contrast to other methods, we do not need to search for set-bits - with our zero-testers we can recover n_2 bits with very few queries. Each test requires a single oracle call. For zero-blocks all tests (3 for HQC-128) must be performed to confirm that it does indeed contain no set bits. Since the majority of blocks have a weight larger than 0, we can filter these out early. Only approx. 40% of blocks pass the first stage of the zero-tester in HQC-128. This means for the majority of blocks only a single oracle call needs to be performed. The second stage again only lets 31% of the remaining blocks pass. Thus, even though we use 3 testers for HQC-128, only 1 oracle call is performed per shift for the majority of cases.

The full attack then consists of shifting the respective part of the secret key into a position and performing zero-tests on the first block of the ciphertext. The core procedure of our attack is represented as pseudocode in Figure 2.

3.4.1 Finding Suitable Zero-Testers

Our method of finding a sequence of testers is akin to a mutation fuzzer. We start with random testers of a weight $w_{ini} \in \{\lfloor n_2 \cdot 0.4 \rceil, \ldots, \lfloor n_2 \cdot 0.5 \rceil\}$. Then we perform many mutations on these testers and select the mutation that performs the best. Experimentally we found that mutations that flip 1 or 2 bits yield the best results.

Our evaluation criterion is also probabilistic: we sample a given number of low-weight errors according to the probability distribution of their occurrence in the secret key. This probability distribution can be approximated well using the coefficients of the polynomial given by f:

$$f(x) = ((1-p) + p \cdot x)^{n_2} \tag{4}$$

where $p = \frac{\omega}{n}$. The j^{th} coefficient of f yields the probability that j bits are set in an array of n_2 bits where each bit is i.i.d. with probability p of being set.

After applying a mutation we estimate the success probability of an attack as the probability that the sequence of testers will not fail for the number of queries required by the attack (e.g. 1000). If this estimated attack success probability is greater than 99% we terminate.

If we see no improvement in some iterations of the mutation finding process, we restart the process entirely with newly chosen random errors. This prevents remaining stuck in local optima.

3.5 Selecting Suitable Shifts

During the attack, we shift the secret key to test the weight of different blocks of the key. This raises the question of which of all possible n shifts should be tested first to increase the efficiency of the attack.

3.5.1 Static Shift Selection

A simple approach is to use a fixed sequence of shifts every time we perform the attack. For HQC-128 we used the shifts 0, 192, 92, 297, 238, and 115 plus an offset of bn_2 for the current block $b \in \{0,\dots,n_1-1\}$. These shifts were chosen by greedily picking a shift that performed well in simulation, under the assumption that the previous shifts have already been used to test each block. If these shifts don't suffice we pick random new shifts that have not been tested before.

3.5.2 Dynamic Shift Selection

When performing the attack we obtain new information about the key with each query. Based on the queries performed and their observed responses, we can attempt to search for a shift that will maximize the information gained. One such method could be derived from belief propagation, as the problem shares a similar structure. Once we have an algorithm for estimating the posterior conditional probability distribution of a zero-test for a shift s given the query response pairs observed so far, we could combine it with game tree search algorithms, e.g. a variant of expectimax. This may yield further improved shifts. However, this would come at a significant computational cost, as the branching factor is $n \geq 17669$.

3.5.3 Recoverable Keys and Success Chance

Our attack depends on that there exist sufficiently many zero-blocks in the two parts of the secret key x and y such that we can recover slightly more than 50% of the secret key. This means there may be some keys that cannot be recovered by our attack, since some keys may not have enough zero-blocks. In the simulation we show that for HQC-128 and HQC-256 this is not an issue, and we can recover 98% and 99% of keys respectively, assuming we try all possible shifts exhaustively. For HQC-192 we can only recover approx. 15% of keys, but a large portion of the key can be recovered and be used to reduce the complexity of other attacks.

To obtain the full key in post-processing one can solve the linear equations given by the public key relation $s = \begin{bmatrix} I_n & \mathrm{rot}(h) \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix}$. In practice, the resulting $n \times n$ matrix over $\mathbb{F}_2$ is often not invertible. Thus, one needs to recover additional zero-bits until there is an invertible submatrix. We recover 5 additional bits, which yields a probability of approx. 97% that the $n \times (n-5)$ matrix contains an invertible $(n-5) \times (n-5)$ submatrix. This probability is computed as $p(n,m) = \prod_{i=1}^{m}(1-2^{i-1-n})$ [21], where $m = n-5$.

Choosing fewer than five additional bits tends to decrease the probability of finding an invertible matrix significantly. Conversely, selecting slightly more than five bits, such as increasing the count from 5 to 10, does not markedly enhance this probability since 97% is already quite high. Last, the attack performance suffers if a significantly greater number of additional bits need to be recovered.

Algorithm 1: PC-Oracle Key Recovery Attack

Data: h from the public key, a suitable message m and salt, shifts, zero_testers, and scheme parameters n, n_2, δ
Result: bit_status array: zero-bits in the secret key

```
bit_status_{i,j} ← "Unknown" ∀i ∈ ["X", "Y"], j ∈ {0,...,n−1}
for k ∈ shifts, key_part ∈ ["X", "Y"] do
    if ⋀_{j∈{s−n2+1,...,s}} bit_status_{key_part,j} = "KnownZero" then
        // we already know each bit in this block to be zero
        continue
    end
    classification ← "ZeroBlock"
    for tester ∈ zero_testers do
        set error e with δ = ⌊d_RS/2⌋ RM-code blocks flipped,
         such that the corruption of the first block
         will cause an RS decoder failure.
        set the first block of e to the used tester
        if key_part = "X" then
            r2 ← X^k
            u ← X^k · h
        else if key_part = "Y" then
            r2 ← 0
            u ← X^k
        end
        construct ciphertext c as (u, mG + s·r2 + e, salt)
        if ¬O_HQC(c) then
            classification ← "NonZeroBlock"
            break
        end
    end
    if classification = "ZeroBlock" then
        for j ∈ {s − n2 + 1,...,s} do
            bit_status_{key_part,j} ← "KnownZero"
        end
    end
    if (Σ_{i∈[X,Y]} Σ_{j∈{0,...,n−1}} bit_status_{i,j} = "KnownZero") ≥ n + 5
     then
        return bit_status
    end
end
return bit_status
```

Figure 2: The core of our attack procedure on HQC represented as pseudocode. For brevity we assume that array accesses into bit_status wrap around modulo n.

4 Division Timing Side-Channel

In [28] the authors reveal a timing-side channel stemming from the use of variable-time constant-weight vector sampling. The constant-weight vector sampling is performed as part of the re-encryption step to sample the vectors r_1, r_2, and e. The re-encryption step is part of the decapsulation, as shown in Figure 3. The identified vulnerability was that the sampling process used rejection sampling, which is non-constant-time in the used randomness. The vector sampling process must be constant-time in the used randomness because the randomness depends on the seed θ, which is derived from secret inputs (the message). Leaking any timing information about θ leads to a distinguisher which can be used as a PC oracle. Such a PC oracle completely breaks the cryptosystem leading to full

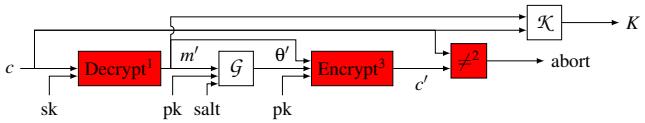

Figure 3: Simplified illustration of HQC decapsulation. Parts with previously identified timing side-channel vulnerabilities are marked in red. Our identified side-channel is in the vector-sampling part of the re-encryption, similar to [28]. It was introduced in the patch to [28]. [1] [46, 60]; [2] [30]; [3] [28].

```
for (size_t i = 0; i < weight; ++i) {
    tmp[i] = i + rand_u32[i] % (PARAM_N - i);
}
```

Figure 4: Vulnerable code snippet generating `div` instructions.

key-recovery.

To remedy the timing side-channel the authors of the scheme implemented a constant-time constant-weight vector sampling algorithm described by Sendrier [54]. This algorithm requires modulo reductions of random numbers, which were derived from the seed θ. Unfortunately, the compiler (gcc v13.1.1) uses division instructions to implement these modulo reductions. Division instructions typically take a variable number of cycles on a CPU, depending on the size of the operands. (cf. Section 4.1). The vulnerable code snippet may be found in Figure 4. We identified the vulnerability through manual analysis of the code's disassembly.

In principle modern compilers have the ability to convert modulo reductions modulo a compile-time known constant into constant-time code using Barrett reductions. This optimization typically occurs when there are single modulo or division operations, that are not within a loop. However, in this case, the compiler does not do so, even when using the `-funroll-all-loops` flag. This flag causes the loop to be unrolled, but the compiler still generates division instructions instead of Barrett reductions.

The timing variation caused by the divisions may be exacerbated if the target system is embedded, and has worse division performance than high-performance x86 microarchitectures. For our analyses and exploitation, we focus on high-performance x86_64 systems, as the vulnerable optimized HQC implementation is written for processors supporting the AVX2 vector instruction-set extension.

4.1 Analyzing Numerator Dependent Division Throughput

To characterize the side-channel leakage that we want to exploit we perform experiments regarding the division throughput on different x86_64 processor microarchitectures.

We measure the throughput of an instruction sequence

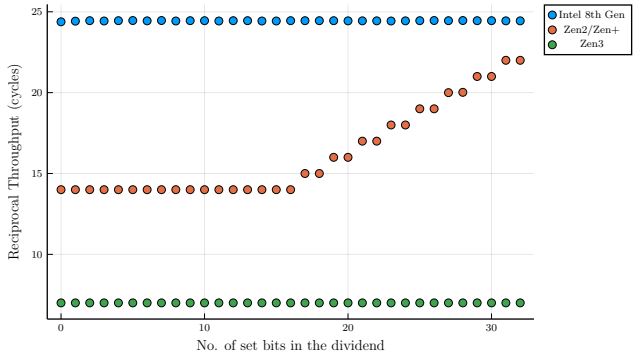

Figure 5: Empirical results of numerator dependent throughput of divisions on different microarchitectures for a fixed divisor (17669). Some high-performance x86 microarchitectures can perform 32-bit divisions by the chosen fixed divisor with numerator-independent throughput, while Zen2 and Zen+ have varying division throughput. Note that we only show the throughput for numerators up to 32-bit and for a fixed divisor, as this is the case most relevant for exploitation of the vulnerability in HQC. We can observe a timing variation on all of the tested architectures if we instead inspect up to 64-bit numerators.

containing a division using nanoBench [3]. The measured instruction sequence is shown in Figure 6.

```
mov r10, 17669 ; divisor
mov rax, numerator
xor rdx, rdx
idiv r10
```

Figure 6: Measured instruction sequence, where numerator is replaced with a concrete numerator.

The instruction sequence was measured on Zen3 (AMD Ryzen 9 5900X), Zen2 (AMD Ryzen 9 3900X), Zen+ (AMD Ryzen 7 3700U) and Intel 8th Gen (Intel i7-8550U). The measured throughput includes not only the division itself but also the preceding instructions. On AMD architectures the `076.00 LsNotHaltedCyc` performance counter was used. On Intel we used `3C.00 CORE_CYCLES`. The benchmark results can be reproduced using the code artifact.

The AMD and Intel optimization manuals are relatively sparse on details regarding latency and throughput of divisions. The AMD optimization manual for the Family 19h line of processors (Zen3, Zen3+, and Zen4) states that: "The hardware integer divider unit has a typical latency of 8 cycles plus 1 cycle for every 9 bits of quotient. The divider allows limited overlap between two consecutive independent divide operations. 'Typical' 64-bit divides allow a throughput of one divide per 8 cycles (where the actual throughput is data dependent)" [11]. For the Family 17h (Zen, Zen+, and Zen2) the

optimization manual states: “The radix-4 hardware integer divider unit can compute 2 bits of results per cycle” [10].

To exploit the variable division runtime we target a Zen2 machine. We choose Zen2 due to the variable division timing even for 32-bit numerators.

Using just timing information on the vector sampling part of the HQC decapsulation on an otherwise idle machine, we are able to distinguish a fast vector sampling from a random one. We obtain an accuracy of up to 80% (both classes represented equally). However, when measuring the execution time of the entire decapsulation, the timing signal becomes too weak for practical exploitation. Even 100 000 timing measurements do not suffice to gain any significant distinguishing advantage.

4.2 DIV-SMT

We introduce DIV-SMT, which enables us to precisely measure only the contribution of the `div` instructions to the timing signal, and filter out noise caused by the other parts of the cryptosystem - less than 2% of the decapsulation runtime is dedicated to the divisions relevant to our attack. Like prior works [8, 25], we use contention among SMT sibling threads to detect the execution of a certain instruction (`div`). In addition and in contrast to these works, we also use contention to infer information about the processed operands (the number of leading zeros in the numerators).

4.2.1 Threat Model

DIV-SMT is relevant to all contexts where the attacker can execute code co-located to the victim. Crucially, the CPU must support SMT and have it enabled. Disabling SMT comes with a typically high but workload-dependent cost [42, 51]. Especially in systems with high SMT thread count like Power10, which sports up to 8 SMT threads per core, it is very desirable to leave SMT enabled. Further, the attacker must not be impeded by scheduling countermeasures such as Linux’s Core Scheduling [1]. Core Scheduling may prevent the attacker from running on the same core as the victim, but also comes with a performance cost. In certain cases, the performance may be worse than with SMT disabled due to the additional scheduling overhead [20].

4.2.2 Side-Channel Measurement

The setup for DIV-SMT is as follows: the attacker runs a thread pinned to the sibling SMT thread of the victim’s thread. For our attack simulation, we also pin the victim’s thread. In more restricted scenarios, the attacker may not have permissions to pin other user’s processes. To counteract this, the attacker may start many DIV-SMT receivers [24]. If possible, these receivers may be pinned to a different physical core to reduce measurement noise.

```rust
fn rdpru32() -> u32 {
    let lo;
    unsafe {
        asm!("rdpru",
            out("eax") lo,
            out("edx") _,
            in("rcx") 1,
        );
    }
    lo
}

let mut i = 0;
while !done_decaps.load(Ordering::SeqCst) && i < len {
    measurements[i] = rdpru32();
    let mut _dividend = 1;
    let mut _remainder: u64 = 0;
    let divisor = 1;
    unsafe {
        asm!(
            ".rept 5",
            "xor edx, edx",
            "div rcx",
            ".endr",
            inout("rax") _dividend,
            inout("rdx") _remainder,
            in("rcx") divisor,
        );
    }
    i += 1;
}
```

Figure 7: Excerpt from the attacking code showing the measurement loop and use of the `rdpru` instruction. In the loop body the `APERF` performance-counter is stored into the measurement array and 5 divisions are executed. The loop continues until either the maximum trace length is reached (in which case the trace is discarded), or the decapsulation has finished.

The attacker executes division instructions in a loop, measures the cycle counter and stores the counter for measurement in an array. For the cycle counter measurement, we use the `rdpru` instruction. The `rdpru` instruction allows us to read the Actual Performance Frequency Clock Counter (`APERF`) performance-counter from user-space which counts the number of cycles executed by the specific core the executing thread is running on [43]. This is opposed to the `rdtsc` instruction which reads a globaö core-frequency-independent timestamp counter. Further, in our experiments, `rdpru` executes faster than `rdtsc` which enables higher temporal resolution in our SMT side-channel traces. An excerpt from the attacking loop code may be found in Figure 7.

When the victim is executing divisions, the execution unit for divisions is busy, and the attacker’s divisions are also slowed down. Slowing the attacker’s divisions down causes an increase in the cycle delta between measurements for the attacker. When the victim does not use the execution unit for divisions, the attacker’s divisions complete at a faster rate

enabling us to filter out parts of the cryptosystem that do not use divisions and are therefore irrelevant to our attack. We use an empirically determined constant threshold to classify whether the sibling SMT thread is performing divisions. We then sum up these division timings to obtain a total division runtime for a single trace. After collecting 100 traces and computing each trace's total division runtime, we compute the median total division runtime. This division runtime is then thresholded to form a classifier.

In principle, we use the contention timing side-channel for two distinct purposes. Similar to e.g. PortSmash [8] and SQUIP [25]), we use the contention side-channel to detect the execution of division instructions. Additionally, and unlike them, we use the side-channel to infer information about the processed operands, an aspect of SMT contention attacks, which, to the best of our knowledge, has not been exploited before.

4.2.3 Practical Exploitation in HQC

For our HQC attack, we compute a threshold using ciphertexts where it is known whether a decoding failure occurs. Such ciphertexts are easy to construct by setting the error to a large or small value. The classifier then determines whether the total division runtime is faster than a random message or not. If it is faster, we know that decoding succeeded.

With the SMT based side-channel, we obtain above 90% accuracy with 100 traces. To further increase the accuracy, we measure the true-positive-rate and true-negative-rate of the classifier, and make a decision based on multiple classifications by computing the probability of a positive or negative class, given the observed classifications. A majority vote could also be used and would likely perform similarly.

Finding suitable zero testers is the most costly part of the attack, which is why we would like to only perform it once. By fixing a single message first we can achieve that goal, since the zero testers depend solely on the first RM codeword.

In the round 4 submission of HQC the public key and salt are added as inputs to derive the seed θ, which in turn determines the generated numerators. The addition of the salt allows us to brute-force a salt, that, together with the fixed message and a given public key, generates suitable numerators. This process is also illustrated in Figure 8. In general, we want to find a salt that minimizes the division runtime of the generated numerators as this will increase the distinguishing capability. In our experiments we brute-force salts for each attack such that we expect a timing difference of at least 55 cycles from a median ciphertext's numerators total division runtime.

4.2.4 Evaluating the Side-Channel

We evaluate how many traces are necessary to classify a ciphertext with a desired accuracy. In Figure 9 we show that

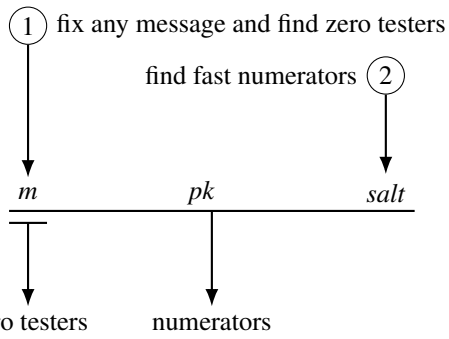

Figure 8: We first choose an arbitrary message for which we intend to find suitable zero testers. Once we've found suitable zero testers for this message we can attack any public key by varying the salt. By changing the salt we change which numerators are generated. These are used during the re-encryption step and leak timing information about the decoded message. We need to distinguish our chosen numerators from random different ones. Therefore, we want to find a salt that generates fast divisions with small numerators.

within our lab environment the number of traces per oracle call could still be halved without a significant drop in the classification accuracy. However, the number of traces required in other noise contexts may deviate significantly.

In Figure 10 we demonstrate the clear difference in the timing distributions of fast and random ciphertexts as observed by the DIV-SMT side-channel.

In Figure 11 we show that the computed division timing of a ciphertext strongly correlates with the timing observed by the DIV-SMT side-channel. For Zen2 the number of cycles per division is estimated as $8 + \lfloor(\lfloor\log_2(q+1)\rfloor + 1)/2\rfloor$, where q is the resulting quotient of the division. This model is derived from the optimization guide [10].

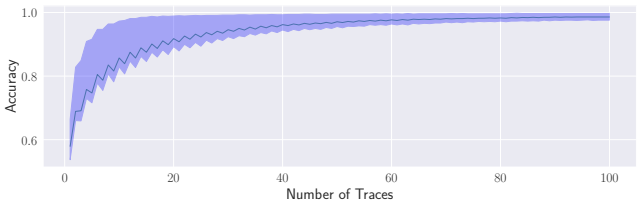

Figure 9: Oracle accuracy over the number of traces used to determine the median division timing. The line represents the median oracle accuracy, while the shaded region represents the 5th and 95th percentile.

5 Experimental Results

In this section, we present the experimental results of our research, organized into two distinct subsections. We begin by

	$O_{HQC}^{perfect}$	O_{HQC}^{iedal}	$O_{HQC}^{0.995}$	$O_{HQC}^{0.95}$	$O_{HQC}^{0.9}$	$O_{HQC}^{0.515}$
SCA-LDPC [32]	9 000	10 000	18 000	35 250	59 500	n/a
Our Work	1 094	1 142	2 246	4 922	6 951	5 728 728
Success Rate	78.00%	77.30%	76.90%	77.10%	76.60%	77.13%

Table 3: Comparison of median oracle calls required in our attack vs. SCA-LDPC. For our attack we additionally show the success rate. Attacks are classified as successful if they managed to recover $n+5$ zero bits from the secret key and no bits were incorrectly identified as a zero bit. These $n+5$ zero bits are sufficient in approx. 97% of cases as discussed in Section 3.5.3.

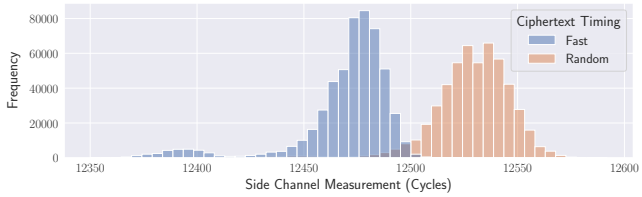

Figure 10: Side-channel measurement for fast and random ciphertexts. Here, fast ciphertexts with a computed division timing deviation of 55 cycles from the median division timing were selected.

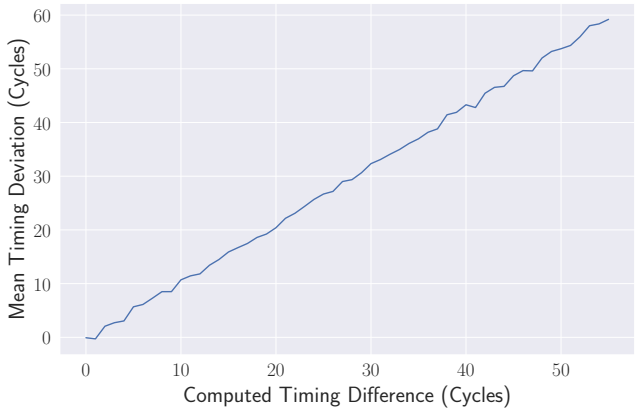

Figure 11: Mean measured difference between the division timing of fast and random messages as measured by the side-channel over the estimated division timing deviation.

showing the simulation results, which illustrate the enhanced performance of our method across a range of oracle accuracies. Subsequently, we present real-world attack results on HQC-128 executed on an AMD Zen2 platform, demonstrating its practical effectiveness and confirming that our simulation findings align with real-world applications.

5.1 Attack Simulation

To provide evidence that our new attack strategy works, we perform attacks using a simulated side-channel oracle. The simulated oracle obtains the true information that is to be leaked and adds oracle accuracy dependent noise to it. The true information in our case is whether the decoder outputs the original message or not. We simulate the attack in 6 different scenarios: perfect, ideal, 0.995, 0.95, 0.9 and 0.515, denoted by $O_{HQC}^{perfect}$, O_{HQC}^{ideal}, $O_{HQC}^{0.995}$, $O_{HQC}^{0.95}$, $O_{HQC}^{0.9}$ and $O_{HQC}^{0.515}$, respectively.

The perfect side-channel scenario is unattainable in practice; this oracle simply reveals the true information—whether the decoder outputs the original message or not. Nonetheless, this concept plays a crucial role in the misuse or key-mismatch attack scenarios [15].

The ideal scenario is relevant to the round 3 implementation of HQC – it is similar to the perfect oracle, except that a message-dependent deterministic failure rate of 0.0058 for decoding failures is simulated. Specifically, when the decoder outputs a message m' different from the original message m there's a chance of 0.0058 that the ideal oracle will output that $m = m'$, even though they are different. This simulates the case where the message m' has the same timing behavior as the message m and is therefore indistinguishable. We use this oracle for the sake of comparison to previous works, as in its current form it no longer applies to the HQC round 4 implementation, since the timing vulnerability discovered in [28] has been patched.

The other oracles build on the ideal oracle and add independently sampled random noise: for an accuracy level of $\rho = 0.995$ there is a $1-\rho = 0.005$ chance that the result will be flipped.

In Figure 12, we show the number of oracle calls the attack requires to complete an attack under different noise conditions. The oracle here is simulated and uses a random number generator to simulate the random failures during a real-world side-channel attack. It can be seen that the distribution has a long tail, which consists of attacks that fail because they cannot find a sufficient number of zero-blocks.

In Table 3, we compare the median number of oracle calls required by our attack versus the SCA-LDPC framework. Our findings indicate a substantial improvement with the new Zero Tester method, which necessitates only 11% to 13% of the oracle calls compared to the SCA-LDPC framework. Notably, this ratio of efficiency gains remains consistent even as the oracle's accuracy decreases to 0.9.

We simulate the performance of the PC oracle at the accu-

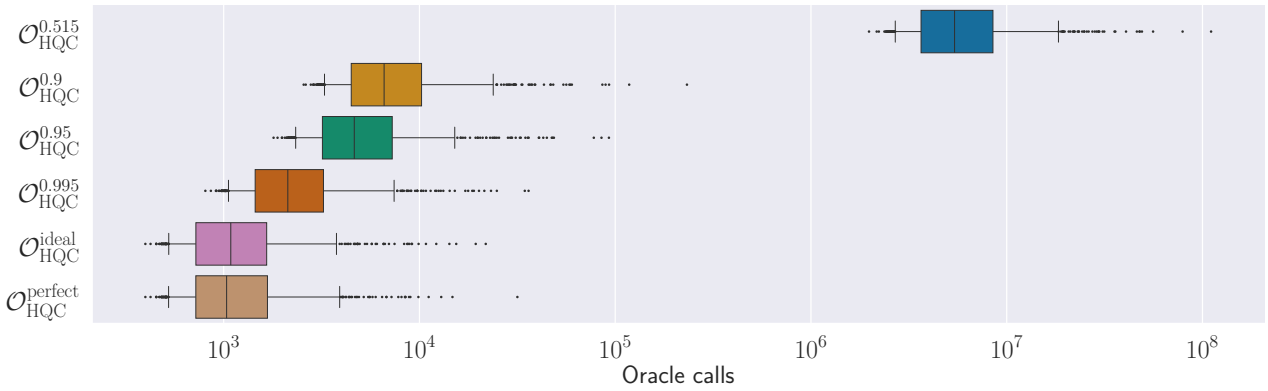

Figure 12: Oracle call requirements for attacking HQC-128 under various oracle accuracies, with whiskers representing the 5th and 95th percentile. We performed 1 000 simulated attacks per oracle accuracy.

racy of 0.515. As noted in [59], this specific accuracy level corresponds to the effectiveness of a Neural Network model in constructing a PC oracle from a masked hardware implementation. For such an oracle $\mathcal{O}^{0.515}_{\mathrm{HQC}}$, estimating the number of oracle calls required by the SCA-LDPC framework is resource-intensive, a task not undertaken in [32]. In contrast, our simulations demonstrate a median requirement of only 5 728 728 oracle calls.

If desired one may reduce the number of oracle calls further by trading it for computation time. Although the trade-off comes with quickly diminishing returns as Information-Set Decoding (ISD) [47,56] comes with high costs. In Table 3, we simulate a success probability ranging between 76% and 78%. Enhancing the success rate is achievable through employing more resource-intensive ISD for post-processing, as opposed to Gaussian Elimination.

5.2 Real-World Attacks in an AMD Zen2 Platform

We performed 1000 attacks using our DIV-SMT side-channel oracle. The targeted machine is a Zen2 machine featuring an AMD Ryzen 7 3700X 8-Core Processor. The attacks ran concurrently on 8 cores, each using 2 SMT threads. 75.3% of the attacks succeeded in recovering $n+5$ zero-bits from the secret key. This success rate comes close to the 76% to 78% success rate that we observe in simulation (cf. Table 3). A median of 465 409 DIV-SMT traces were used to form responses to a median of 2 577 oracle calls in a median attack runtime of 111 seconds. The number of traces includes a median number of 204 180 calibration traces. Using the calibrated threshold the SMT oracle was tested to have an accuracy of 98.8%.

6 Discussions

In this section, we discuss the discovered vulnerability and attack methodology from various perspectives. We first address countermeasures against the DaS vulnerability in HQC. Subsequently, we compare our new key-recovery method to the state-of-the-art SCA-LDPC framework, elucidating the sources of performance improvement. Lastly, we explore the potential limitations of the new Zero Tester method.

6.1 Countermeasures

In addressing the DaS vulnerability within HQC, two main countermeasures emerge:

1. Manually code the necessary Barrett reductions.
2. Use multiplication and bit-shift as in Bit Flipping Key Encapsulation (BIKE)

The HQC design team and the PQClean implementers, after our public disclosure [9], chose the first approach – it stays true to the specification of the scheme. Barrett reductions are a way to compute $a \bmod n$ when n is a known constant in constant-time (the timing is independent of a). Specifically, one computes the quotient $q = a/n$ and then the remainder as $a - qn$. The quotient q is approximated by $q = \lfloor (a+1)m/2^k \rfloor$ for a suitable k and m. Here m is computed as $\lfloor 2^k/n \rfloor$, such that $m/2^k$ is an approximation of $1/n$ and $a+1$ is used instead of a to prevent underestimating the quotient. The floored division by 2^k can be implemented through a bit-shift, which is constant-time on most systems, especially in the shifted operand. For further details we refer to the updated HQC optimized reference implementation.

BIKE replaces the modulo reduction with rounding: Instead of $i + (s_i \mod n - i)$ they compute $i + \lfloor (n-i)s_i/2^{32} \rfloor$. The latter function can be implemented using an integer multiplication and a bit-shift. This function generates the same noticeable bias as the modulo reduction when compared to a uniform distribution. Note that the bias is not a security issue [54].

Variants	P_0	P_1	P_2	P_3	P_4	$P_{\geq 5}$
HQC-128	23.44%	34.38%	24.83%	11.77%	4.12%	1.45%
HQC-192	16.50%	30.00%	27.00%	16.04%	7.07%	3.40%
HQC-256	23.14%	34.06%	24.87%	12.02%	4.32%	1.59%

Table 4: Approximation of the probability that a randomly sampled inner block in the secret vector has a certain Hamming weight [27]. P_i denotes the probability that the block has a Hamming weight of i.

When possible we recommend to use the method used by BIKE as it is easier to implement (especially cross-platform), less error-prone, and most likely faster on most target architectures. We recommend a change in the specification in any case: implementers of the modulo reduction in the specification are likely to make the same mistakes unless additional guidance is given.

6.2 Comparison to SCA-LDPC

The SCA-LDPC framework [32] is a generic framework that can apply not only to code-based schemes but also to lattice-based schemes with a larger alphabet and a denser secret distribution. Our new PC key-recovery method is tied to HQC and exploits the extreme sparsity of the secret vector and the concatenated code construction used in HQC. The latter allows us to check whether blocks of consecutive bits in the secret key have weight 0, and due to the low weight of the secret key, this is often the case.

Our method provides substantial improvements over the SCA-LDPC framework for HQC, mainly for two reasons. Firstly, our approach, which focuses on identifying n zero positions from the $2n$ unknowns, requires extracting less mutual information compared with the SCA-LDPC framework that aims to recover the entire secret vector y or x. Considering the HQC-128 parameter set, the latter must uniquely determine y or x among $\binom{n}{\omega} \approx 2^{623}$ possible configurations. In contrast, by exploiting public key information, our method needs to recover only approx. 129 bits of information. This is roughly estimated by subtracting the entropy associated with a binary vector of dimension n and weight 2ω from the entropy of two binary vectors, each of dimension n and weight ω:

$$\binom{n}{w}^2 / \binom{n}{2w} \approx 2^{129}. \tag{5}$$

Secondly, our method has the potential to extract considerably more information from a single side-channel trace. For instance, in the HQC-128 context with a perfect oracle, the SCA-LDPC framework requires about 9000 oracle calls (cf. Table 3) to gain 623 bits of information. In contrast, simulations indicate that our approach, in its first pass to test the key's 92 RM blocks, expects to recover approximately 8300 zero positions with only 172 oracle calls. This could reduce the number of possible patterns by a factor of approx. 2^{47}.

6.3 Limitations

Lastly, we discuss the limitations of the new Zero Tester method and the potential for improvement. The efficacy of our approach is contingent upon finding long sequences of all-zero entries between two ones in the secret polynomials x and y. The probability that an inner RM block within the secret vector is entirely zero is over 23% for HQC-128 and HQC-256, decreasing to 16.5% for HQC-192, as shown in Table 4. This reduction in likelihood explains the limited applicability of the new method to HQC-192, where it is effective for only about 15% of keys, as discussed in Section 3.5.3. For the remaining keys, the positions recovered are not adequate to achieve full-key recovery using Gaussian Elimination. Resorting to the more computationally demanding ISD algorithms for post-processing could enable the recovery of a greater number of keys. We defer a detailed quantitative analysis of this aspect to future research.

7 Conclusion

In this work, we have identified a novel timing side-channel vulnerability, an instance of the DaS vulnerability class, within the optimized, supposedly constant-time, reference implementation of the HQC round 4 submission to NIST. This vulnerability, characterized by its generic nature as demonstrated by similar issues in cryptographic implementations like KyberSlash, poses a significant security risk. Our proposed DIV-SMT methodology effectively targets this vulnerability on SMT-enabled processors by leveraging contention among SMT sibling threads. This process not only identifies specific instructions but also deduces operand information, thereby establishing a PC oracle distinguisher that enables a key-recovery timing attack.

Additionally, we have introduced a new key recovery approach for HQC leveraging the PC oracle, which significantly lowers the requirement for side-channel traces. Through comprehensive simulations using a simulated PC oracle at various levels of accuracy, coupled with practical attacks executed on an AMD Zen2 CPU, our research confirms both the effectiveness and practical viability of our novel attack strategy.

Abstract

Constant-time implementations are essential to guarantee the security of secret-key operations. According to Jancar et al. [42], most cryptographic developers do not use statistical tests to evaluate their implementations for timing side-channel vulnerabilities. One of the main reasons is their high unreliability due to potential false positives caused by noisy data. In this work, we address this issue and present an improved statistical evaluation methodology with a controlled type-1 error (α) that restricts false positives independently of the noise distribution. Simultaneously, we guarantee statistical power with increasing sample size. With the bounded type-1 error, the user can perform trade-offs between false positives and the size of the side channels they wish to detect. We achieve this by employing an empirical bootstrap that creates a decision rule based on the measured data.

We implement this approach in an open-source tool called RTLF and compare it with three different competitors: *Mona*, *dudect*, and *tlsfuzzer*. We further compare our results to the t-test, a commonly used statistical test for side-channel analysis. To show the applicability of our tool in real cryptographic network scenarios, we performed a quantitative analysis with local timing measurements for CBC Padding Oracle attacks, Bleichenbacher's attack, and the Lucky13 attack in 823 available versions of eleven TLS libraries. Additionally, we performed a qualitative analysis of the most recent version of each library. We find that most libraries were long-time vulnerable to at least one of the considered attacks, with side channels big enough likely to be exploitable in a LAN setting. Through the qualitative analysis based on the results of RTLF, we identified seven vulnerabilities in recent versions.

1 Introduction

Cryptographic algorithms that operate on secret data are prone to side-channel attacks. One primary example are timing side channels, where the algorithm may leak information about the secret data through their execution time. An attacker can exploit this by benchmarking execution times of known and unknown secrets.

Side Channels Are Hard To Prevent Prime examples of timing side channels are conditional branches based on secrets and secret-based memory access, which create timing differences through the CPU cache. To prevent timing side-channel attacks, developers devised different strategies, colloquially known as constant-time programming. These strategies include, for example, the replacement of branches by logical operations to ensure a constant control flow. However, developers often do not mitigate side channels systematically; according to Jancar et al. [42], two out of 20 cryptographic libraries claimed that side-channel attacks were outside their attacker model, and another ten libraries only used best-effort strategies to mitigate them. While there are different tools available to support developers [4, 5, 6, 7, 8, 11, 14, 20, 22, 25, 31, 38, 39, 49, 50, 59, 71, 83, 84, 94, 96, 97, 98, 105], according to Jancar et al. [42], these tools are often perceived as hard to use.

All previously mentioned tools rely on a well-defined leakage model [9, 30, 56] to abstractly reason about the absence of timing side channels. However, accurately modeling real-world leakages is challenging and requires intensive knowledge about underlying software and hardware layers [9]. An example of this is the underlying assumption that the CPU instructions are executed in constant time independently of their operands. This is not always the case as, for example, the `UMUL` instruction on an ARM Cortex-M3 is not constant time. The expectations of the cryptographic community on the underlying hardware keep getting further subverted by attacks like Spectre [47], Meltdown [53], and the recent Hertzbleed [95]. Hertzbleed is especially interesting in this context, as it showed that changes in the CPU frequency may depend on the values used in otherwise identical instructions. Since the CPU frequency directly influences the execution time, an attacker may be able to derive information about a secret parameter based on a timing side channel.

Measurements Are Necessary Given the complex hardware impact on timing behavior and the unreliability of source code tools, *measuring* the timing behavior of a deployed sys-

tem is indispensable. Analysis of the gathered timing samples is offered through tools like *Mona* [75], *dudect* [68], and *tlsfuzzer* [45]. However, timing measurements are often omitted in the development life cycle; according to Jancar et al. [42], five out of 20 libraries only did manual statistical runtime testing.

Statistical Terminology A statistical evaluation can test a hypothesis on two random distributions, for example, to test if a random number generator is good, one tests the hypothesis H_0 that the distribution of its outputs is identical to the uniform distribution. If a statistical test rejects H_0, this means that the outputs of the generator are not uniformly distributed. It is then assumed that hypothesis H_1 holds, which states that the two distributions are different.

In cryptographic timing measurements, we repeatedly measure the execution time of a secret-key operation under two different preconditions P_X and P_Y (e.g., padding is correct vs. padding is incorrect). We thus produce two different statistical samples $x := (x_1, \ldots, x_n)$ and $y := (y_1, \ldots, y_n)$. If there is a statistically significant difference between these two samples, it may be possible to learn, for a randomly chosen ciphertext, if P_X or P_Y holds. To determine if this is the case, we test the null hypothesis, which assumes that the distributions of x and y *are* equal. If H_0 is rejected, this is an indication that the two distributions may not be equal and that there may be a difference. However, since we are working with finite samples, a test of the H_0 hypothesis may fail for two reasons: wrongfully rejecting H_0 (type-1 error, *false positive*) or wrongfully accepting H_0 (type-2 error, *false negative*). The rate of correctly rejecting H_0 is referred to as statistical power (*true positive* rate).

Statistical Guarantees In general, for two unknown distributions D_X and D_Y, it is impossible to give a bound on the type-2 error for a given sample size. This is because these distributions may be arbitrarily close but still different; think of two otherwise identical distributions D_X and $D_{X+\varepsilon}$, where the values for $D_{X+\varepsilon}$ are sampled from D_X, but a small constant value ε is added to each sample. For each sample size n, we can then choose a value ε_n such that H_0 is falsely accepted.

However, it is possible to bound the type-1 error. For parametric distributions, i.e., distributions that can be characterized by a few parameters, such tests are available in standard tools. For example, if the tested distribution is 'close enough' to the normal distribution (which can be characterized by the two parameters *mean* and *variance*), a t-test can be used. Unfortunately, such parametric approaches are inadequate for timing measurements as real-world timing measurements are highly complex and cannot be sufficiently captured through parametric distributions.

There are two research directions for designing statistical tests with a bounded type-1 error rate for non-parametric distributions:

- **Bounded type-1 error for small samples:** Since sampling (not only for timing measurements) comes with a cost, it is desirable to bound the type-1 error already for small samples. This implies that as much information as possible from the samples should be used in the test.
- **Trade-off between type-1 error rate and detection rate:** For a fixed sample size, a lower type-1 error implies a lower detection rate. For example, for a given sample size of two distributions, the mean will nearly always be different; for a low type-1 error, we would make the tolerance interval (or *confidence intervals*) for this difference, which we consider to be attributable to random noise, larger, and would therefore not detect a difference if the mean of the two distributions lies in this interval. This implies that it is desirable to use the desired type-1 error rate as an input parameter to the statistical test and not hardcode it.

Tools like *Mona* [75] and *dudect* [68] aim for low error and good detection rates for small samples, but both error and detection rates have not been quantified. Moreover, we will empirically show in Section 4 that both tools may have low detection rates or unbounded type-1 errors. This leads to our first research question:

> **RQ1: Can statistical techniques be used in the context of the non-parametric distributions of timing measurements to design tests for arbitrary samples, where the type-1 error and detection rate are balanced by an input parameter?**

We answer this question in the affirmative. Any statistical method aims to maximize the detection rate (or minimize the type-2 error) for a prescribed type-1 error. *tlsfuzzer* [45], a recently released tool for timing analyses, already addresses this challenge better than *Mona* and *dudect* but still lacks effectiveness in terms of statistical power. In our approach, we use multiple quantiles to extract as much information as possible from the distributions. In order to guarantee a balance of type-1 error and detection rate, we employ an empirical bootstrap to obtain a reasonable decision rule (i.e., a rule to reject or accept H_0) based on the measurements. Specifically, the derived decision rule does not exhibit excessively conservative behavior, nor does it produce an inflated type-1 error rate (cf. Section 4). Our construction is described in Section 3 and implemented in our tool *R-Time-Leak-Finder (RTLF)*.

Timing Measurements for TLS To evaluate our approach, we chose especially noisy timing side channels – secret data operations in complex real-world TLS implementations. For TLS implementations, various exploitable timing side channels have been published [1, 2, 16, 17, 60, 62, 104, 108], and various fixes have been applied to the source code of the attacked libraries to make them 'more constant time'. These fixes were mostly applied after a vulnerability was discovered and published – the success of these fixes is not documented. This leads to our second research question:

RQ2: Do potential timing side channels still exist in TLS implementations? If not: when have they been fixed, and are these fixes stable?

We answer this research question by performing the first quantitative timing side-channel study on TLS libraries. We tested eleven different libraries, in 823 versions. We considered Bleichenbacher [12], Vaudenay Padding Oracle [92], and Lucky13 attacks [1] which triggered a large body of side-channel research [2, 13, 55, 61, 62, 72, 73, 77, 106] and thus had continuous impact on the tested libraries.

Results in TLS Libraries Our qualitative analysis of the most recent libraries revealed that a significant number of libraries exhibit vulnerabilities that are probably exploitable in a LAN setting. Our approach detected eight potential vulnerabilities across the libraries, seven of which we could manually attribute to specific locations in the source code (cf. Section 7).

Overall, a high number of TLS libraries contained remotely exploitable timing vulnerabilities throughout different versions that are present for very long periods and sometimes still not fixed. Our study shows that throughout its history, TLS is and was in a bad state regarding the analyzed vulnerabilities (cf. Section 6 and Section 8).

Contributions We make the following contributions:

- We propose a non-parametric test based on quantile differences to statistically evaluate timing measurements with a type-1 error bounded by an input parameter α (cf. Section 3.3), which we publish in an open-source tool called RTLF[1].
- We compare RTLF with different competitors by evaluating them based on artificial timing side channels (cf. Section 4)
- We present a large-scale and longitudinal timing evaluation of eleven TLS libraries in 823 versions across three vulnerabilities and discuss the results for OpenSSL in more detail (cf. Section 6 and Section 8).
- We verify our results in the newest version of the analyzed libraries through manual code review. Our tool could detect eight potential attacks, of which we could pinpoint seven to specific locations in the code, resulting in three Vaudenay Padding Oracle vulnerabilities, three Bleichenbacher vulnerabilities, and two Lucky13 vulnerabilities (cf. Section 7).

Responsible Disclosure We contacted the developers of the libraries for which we identified exploitable timing leaks in their most recent version. Mozilla is in the process of patching the reported issues for NSS. The responses from other libraries reflect the results from Jancar et al. [42], that timing side channels are typically not systematically mitigated and are not the highest priority for the developers.

2 Background

Timing attacks were first described by Paul Kocher in the context of private-key operations on smartcards [48]. He showed that if the naive square-and-multiply algorithm is used for exponentiation, the Hamming weight of the exponent can directly be deduced from the execution time; with more sophisticated measurements, the private key itself can be computed. Secret-data-based cache access (a prime example for the more general case of secret data access) also poses a common source for timing differences, as frequently used data will be available faster to a program than less frequently used data.

Attacker Models The attacker's position in relation to the target is important for the exploitability of side channels. The closer the attacker is to the victim, the better the attacker can gather the leaked data. A special attacker model is the *co-located attacker*, where the attacker shares the hardware with the victim, giving the attacker the ability to probe cache lines, allowing for more powerful side-channel attacks like trace attacks. While academically, the co-located attacker model has been intensively studied [18, 19, 23, 65, 107, 108], it is not considered by all implementations. For example, OpenSSL, one of the most prominent cryptographic libraries in the world, updated its security policy in 2019 to exclude side-channel attacks with a co-located attacker from their security model. Such security issues will be mitigated, but not awarded with a CVE anymore. In our paper, we therefore focus on side channels that likely do not require a co-located attacker.

2.1 Transport Layer Security

The Transport Layer Security protocol (TLS) [28, 69] provides confidentiality, authenticity, and integrity of the exchanged data on the underlying transport protocol. To guarantee secure encryption using the record layer, all required cryptographic parameters, such as keys and algorithms, are negotiated through the TLS handshake protocol.

CBC Padding Oracle Attacks In 2002, Vaudenay first introduced the concept of a Cipher Block Chaining (CBC) Padding Oracle attack [92]. The attack relies on a decryption oracle that responds to queries about CBC padding validity. This behavior can be used to execute an adaptive chosen-ciphertext attack. TLS 1.0, 1.1, and 1.2 employ CBC mode in a MAC-then-Pad-then-Encrypt scheme [28], making them potentially vulnerable to these attacks.

Lucky13 In 2013, AlFardan and Paterson discovered Lucky13, the most commonly known timing side-channel attack on the MAC-then-Pad-then-Encrypt scheme in TLS [1]. They showed that certain padding modifications also affect the length of data validated by the MAC algorithm, resulting in a tiny timing side channel that can be exploited to run Padding Oracle attacks.

Bleichenbacher Attacks In 1998, Daniel Bleichenbacher published an adaptive chosen-ciphertext attack on RSA encryption schemes that use PKCS #1 v1.5 padding [12]. For TLS, this attack enables the attacker to recover the *Premaster Secret* of a recorded session and thus decrypt any application data exchanged by the communicating peers. Over time, different types of oracles re-enabled Bleichenbacher's attack. For example, Klima et al. [46] found an oracle resulting from an invalid TLS version in the decrypted ciphertext.

The most recent version TLS 1.3 [69] solves many of these issues by prohibiting RSA PKCS#1 v1.5 and CBC. However, Jager et al. [41] showed that a cross-protocol Bleichenbacher attack is possible against TLS 1.3, if server implementations use the same certificate for previous versions of TLS.

2.2 Statistics

Statistical hypothesis tests are used to derive a quantitative decision based on data $x := (x_1, \ldots, x_n)$ and $y := (y_1, \ldots, y_n)$. They derive a decision to accept or reject the null hypothesis H_0 in favor of an alternative hypothesis H_1 based on a *summary statistic* $S := S(x, y)$, which derives a summarizing quantity based on the data (e.g., mean). Here, $S(\cdot, \cdot)$ is also called the *test statistic*.

Background Usually, a two-sample hypothesis test is constructed in a way that given data x and y, they select H_1 in favor of H_0 if the summary statistic $S(x, y)$ exceeds some threshold c, above which S seems at odds with H_0. Since the data contains some unpredictable randomness, there is always a risk of a false decision *against* or *for* H_0. In statistical terms, rejecting H_0 when it holds true is usually referred to as a type-1 error (*false positive*), while not rejecting the hypothesis H_0, which does not hold true, is called a type-2 error (*false negative*). In this context, α represents the predetermined type-1 error rate that is deemed acceptable. Specifically, we have $\mathbb{P}(S > c | H_0; \text{is true}) \leq \alpha$. The statistical power of a hypothesis test is the probability of rejecting H_0 when H_1 is true (i.e., the probability of a true positive). As the sample size increases, a well-designed hypothesis test should eventually reject H_0 when H_1 is indeed true. In other words, $\lim_{n\to\infty} \mathbb{P}(S > c | H_1; \text{is true}) = 1$. This is an important characterization for the type-2 error, as it is asymptotically negligible in the sample size n.

Bootstrap In a lot of statistical frameworks, the threshold c may be unknown. In such cases, the true theoretical threshold c can be estimated through a procedure known as *bootstrapping*, which is based on a simulation of the test statistic for artificially generated random data with a distribution closely similar to the true but unknown distribution of the data. In this paper, we use a specific resampling strategy that depends on the data set. By repeatedly resampling the data set and imitating the behavior of S given H_0, an empirical estimator c^* for $c := c(1-\alpha)$ can be obtained. More detailed, if we consider a rejection rule of the form $S > c$ and S is resampled exactly B times, we can order the resulting values, $S_1^*, \ldots, S_B^*$ and output the empirical threshold $c^* := S_{(\lfloor (1-\alpha)B \rfloor)}$. In summary, bootstrapping allows one to define a *configurable* threshold. For a more theoretical introduction and statistical guarantees, we refer to [89].

Quantiles The $p-$th quantile is a statistical measure that separates the lowest $p\%$ of the data set from the remaining $(100-p)\%$ of the data. The $p-$th quantile of a continuous real-valued random variable X can be defined by $\mathbb{P}(X \leq q_p) \geq p$ and $\mathbb{P}(X \geq q_p) \leq 1-p$. In other words, the $p-$th quantile is the value $q_p \in \mathbb{R}$ such that $p\%$ of the probability mass is lower or equal to q_p and $(1-p)\%$ larger.

2.3 Timing Measurements

Timing measurements, which capture the real runtime of a system, can be analyzed with statistical techniques to detect timing side channels. However, statistical techniques cannot prove the absence of certain types of side channels but can only make statistical statements. Since statistical techniques operate on actual measurements, they are limited by the ability to perform *accurate* measurements. Additionally, because statistical methods have to execute the code, only a limited number of inputs from the input space can be tested. Choosing inputs that will most likely trigger side-channel vulnerabilities is up to the user of the technique.

That said, a considerable upside of statistical techniques is that they do not require a leakage model as they interact with the system like a remote attacker would. This allows statistical techniques to potentially also find issues that are outside of the expected leakage model of the developer. Statistical methods are independent of the used programming language or hardware, which makes them generally easy to use.

Mona Timing Report[2] [75] is a statistical analysis tool that performs Crossby's box test [24] for a given set of measurements. Unless the user specifies a box, Mona Timing Report will iterate over all percentile boundaries in steps of one percent. Finally, it returns the biggest box where the measurements of two distributions did not intersect. If any box was found, the distributions are assumed to be different. If no box could be found, the distributions are assumed to be the same. Subsequently, we refer to Mona Timing Report as *Mona*.

dudect[3] [68] performs a series of Welch's t-tests [74]. It collects measurements in batches until a difference has been determined. For distributions without a timing difference, *dudect* will never terminate. Based on its first set of measurements, *dudect* determines 100 percentiles, ranging from the fastest 6.7% to the fastest 99.9%, to group future measurements into data sets of increasing size. For each data set, *dudect* conducts a separate t-test as well as a t-test based on all measurements and on the variance of all measurements,

[2] https://github.com/seecurity/mona-timing-report
[3] https://github.com/oreparaz/dudect

resulting in a total of 102 t-tests. Only if the result of one t-test with at least 10,000 data sets exceeds ten, *dudect* assumes that two distributions are different.

tlsfuzzer[4] [45] conducts a series of different statistical tests. For the final decision, four distinct tests are executed, namely the Wilcoxon signed-rank test [103], Sign test [93, Section 15.3], t-test [74], and Friedman test [34]. If any of these tests reveal a statistically significant difference among the distributions, *tlsfuzzer* asserts the presence of a difference. In addition to these tests, *tlsfuzzer* also generates confidence intervals for certain quantities, such as the mean or median, through a bootstrap procedure. However, these are not part of the decision-making process.

3 Methodology

In this work, we propose a new statistical technique based on a combination of quantile estimators with a bootstrap method for detecting subtle timing side channels. This approach allows us to obtain a configurable threshold for the type-1 error that can be used to optimize the analysis towards nuanced side channels or low false positives.

3.1 Trade-Off Between Type-1 Errors and Power

Statistical approaches in tools like *Mona* [75] or *dudect* [68] use static algorithmic methods to decide if H_0 should be accepted or rejected. There are several ways in which this can cause significant problems. For example, if the static decision rule is based on some highly conservative value, one will almost always obtain a false positive rate of 0. This might seem attractive at first glance. However, a highly conservative value also reduces the probability of detecting timing differences and thus inflicts a significant loss of statistical power. We could observe such static rules defined in *dudect*.

Another potential damage can result from statistical methods using static sizes of quantiles. For example, *Mona* formulates a decision rule based on a difference in quantiles of at least 1%. This brings several drawbacks. First, the decision rule does not account for variability in the data, i.e., the rule does not compensate for larger variances. Ignoring the compensation of larger variances inflicts inflated type-1 error for noisy data. In other words, the analyses performed by *Mona* can potentially lead to false positives if the data contains much noise. Second, *Mona* excludes any side channels that are below 1% while they may still be relevant. Specifically, for any difference below 1%, *Mona*'s type-2 error will converge to 1 for $n \to \infty$.

Given these two examples, it is clear that statistical approaches that balance the type-1 and type-2 errors can improve the outcome significantly. In particular, our approach makes a conscious (and quantifiable) decision about the amount of acceptable type-1 errors.

[4] https://github.com/tlsfuzzer/tlsfuzzer

3.2 Intuition

Our approach aims to detect systematic differences between the measurements collected under two distinct preconditions P_X and P_Y, such as two differently structured protocol messages. We base our analysis on time differences in quantiles of measurements by comparing the deciles (i.e., $10\%, 20\%, \ldots, 90\%$ quantiles). Even for identical distributions, we expect some noise and measurement imprecision, meaning the deciles will never be exactly the same. Therefore, we need a threshold to determine when the deciles of the two preconditions are different enough to conclude that the distributions are distinct. To set this threshold, we repeatedly sample two sets of measurements for each vector and compare the deciles of these sets. By repeating this step $B = 10,000$ times, we obtain 10,000 simulated differences for each decile and vector. For a type-1 error $\alpha = 9\%$, we discard the worst 1% of differences observed in each decile. We use the next-largest value as the tolerance of the measuring setup, as it estimates the expected noise (cf. Algorithm 1). We consider the distributions A and B to be different only if the difference in at least one decile of A and B exceeds this tolerance. The type-1 error threshold amounts to at most 9% since each of the nine deciles has an empirical type-1 error of at most 1%.

3.3 Distinguishing Distributions Dynamically

There are several statistical methods discussed in the literature that can distinguish two distributions (e.g., [74]). The primary objective of our approach is to ensure robustness against type-1 errors. Specifically, our method is designed to adhere to a pre-selected maximum type-1 error rate (α), while avoiding excessive conservatism and maintaining adequate statistical power as the sample size (n) increases. Additionally, we make no distributional assumptions on the data x and y. In particular, we consider independent and identically distributed (iid) random variables $X_1, \ldots, X_n$ and $Y_1, \ldots, Y_n$ with finite variances. In order to compare their distributions, we will compare their quantiles q_i^X, q_i^Y. In more detail, we consider the hypothesis

$$H_0 : |q_i^X - q_i^Y| = 0, \forall i = 1, \ldots, 9 \,, \tag{1}$$

versus

$$H_1 : \exists i = 1, \ldots, 9 : |q_i^X - q_i^Y| \neq 0 \,. \tag{2}$$

Note that the above construction is a natural extension of non-parametric tests, like e.g. the Wilcoxon signed-rank test [103], which essentially discriminates against distributions through their median. However, due to the complex structure of timing measurements, we explicitly allow for a more sophisticated analysis by considering more quantiles than the median. In our work, we decided to consider deciles. While there is a natural conflict between testing more quantiles and the type-1 error in this construction, our preliminary simulations suggested that this is an appropriate trade-off. In particular we point out that decreasing the number of quantiles potentially produces more false negatives, while increasing it would yield

a higher false positive rate or in our case inflict more conservative thresholds for the same α.
In the following, we use a standard quantile estimator. For data $x_1,\dots,x_n$, we define the $i-$th quantile estimator by

$$\hat{q}_i^x := \begin{cases} x_{(\lceil ni \rceil)}, & \text{if} \quad ni \notin \mathbb{Z} \\ \frac{1}{2}(x_{(ni)} + x_{(ni+1)}), & \text{if} \quad ni \in \mathbb{Z} \end{cases} , \tag{3}$$

where $x_{(i)}$ denotes the $i-$th order statistic. To construct an appropriate test, we need to define a test statistic which can test the hypothesis in (1). For that purpose, we consider

$$\hat{Q}_i(x,y) := |\hat{q}_i^x - \hat{q}_i^y| \, . \tag{4}$$

With that in hand, H_0 will be rejected, if and only if there exists $i \in \{1,\dots,9\}$ such that

$$\hat{Q}_i(x,y) > c(1-\alpha/9,i) \, , \tag{5}$$

where $c(1-\alpha,i)$, $i \in \{1,\dots,9\}$ is the critical value for the test, and α denotes the level of the test which has to be fixed in advance and is supposed to amount to the type-1 error of the test. In the following section, we will determine $c(1-\alpha) := (c(1-\alpha/9,i))_{i=1,\dots,9}$ by a bootstrap procedure (cf. Algorithm 1). In order to avoid an inflated type-1 error, we use the Bonferroni correction [78], i.e., we set $\alpha := \alpha_1/9$, where α_1 is the desired type-1 error (e.g., $0.01, 0.09$).

3.4 Bootstrap

Next, we discuss the estimation of the threshold $c(1-\alpha)$ by a bootstrap-based threshold $c^*(1-\alpha)$. The basic idea of the bootstrap is to simulate the distributional behavior under H_0 by repeated application of the method to bootstrap datasets generated from the original data by some random procedure. Such resampling strategies have not only been shown to be effective in empirical studies (e.g., [27]) but have also proven to lead to consistent decision rules (cf. [89]). In a statistical context, Algorithm 1 is usually called *empirical bootstrap* (for further details, see [89] and Appendix A). With that in hand, we obtain a sustainable decision rule by comparing

$$\hat{Q} := (\hat{Q}_1(x,y),\dots,\hat{Q}_9(x,y)) > c^*\left(1-\frac{\alpha}{9}\right) \, , \tag{6}$$

where the comparison is done decilewise. We reject H_0 if and only if at least one component is larger. The final test decision is then done by Algorithm 2.

3.5 R-Time-Leak-Finder (RTLF)

We implemented our approach in a script called RTLF[5] in R. The script takes two labeled measurements and a value α as input. While the bootstrap parameter can be set by the user, we choose $B = 10,000$ for the rest of this paper. We briefly discuss the effect of this parameter in Section 8. The script outputs $c^*(1-\alpha), \hat{Q}$, and a binary vector that indicates the decision for each quantile. Here, large values of $c^*(1-\alpha)$ imply large variances, which can be an indicator of noise. If one coordinate of $\hat{Q}_j$ surpasses its threshold $c^*(1-\alpha,j)$, we reject H_0. Here, a larger value of the absolute difference $\hat{Q}_j - c^*(1-\alpha,j)$ implies a larger timing difference, potentially indicating a larger side channel.

Algorithm 1 Threshold Bootstrap

Require: Time measurements: $x = (x_1,\dots,x_n)$, $y = (y_1,\dots,y_n)$, bootstrap iterations: B, type-1 error: α
Ensure: $c^*(1-\alpha,j)$.

function Threshold(x, y, B, α)
  for $i = 1,\dots,B$ **do**
    Sample $x_1^* = sample(x,n), x_2^* = sample(x,n)$, $x^* := (x_1^*, x_2^*)$.
    Sample $y_1^* = sample(y,n), y_2^* = sample(y,n)$, $y^* := (y_1^*, y_2^*)$.
    for $j = 1,\dots,9$ **do**
      Compute $Q_{i,j}^*(x^*) = |\hat{q}_j^{x_1^*} - \hat{q}_j^{x_2^*}|$
      Compute $Q_{i,j}^*(y^*) = |\hat{q}_j^{y_1^*} - \hat{q}_j^{y_2^*}|$
    end for
  end for
  for $j = 1,\dots,9$ **do**
    Sort statistics in ascending order:
    $(Q_{(1),j}^*(x^*),\dots,Q_{(B),j}^*(x^*)) = sort(Q_{1,j}^*(x^*),\dots,Q_{B,j}^*(x^*))$.
    $(Q_{(1),j}^*(y^*),\dots,Q_{(B),j}^*(y^*)) = sort(Q_{1,j}^*(y^*),\dots,Q_{B,j}^*(y^*))$.
    $c^*(1-\alpha/9,j) := \max\{Q_{(\lfloor(1-\alpha/9)B\rfloor),j}^*(x^*), Q_{(\lfloor(1-\alpha/9)B\rfloor),j}^*(y^*)\}$.
  end for
  return $c^*(1-\alpha) := (c^*(1-\alpha/9,1),\dots,c^*(1-\alpha/9,9))$.
end function

Algorithm 2 Timing Test

Require: Time measurements: $x = (x_1,\dots,x_n)$, $y = (y_1,\dots,y_n)$, bootstrap iterations: B, type-1 error: α
Ensure: classification 0 or 1.

function Test(x, y, B, α)
  c :=Threshold(x, y, B, α)
  for $j = 1,\dots,9$ **do**
    Compute $\hat{Q}_j(x,y) = |\hat{q}_j^x - \hat{q}_j^y|$
  end for
  if there exists $j = 1,\dots,9$ with $\hat{Q}_j(x,y) > c_j$ **then**
    return 1
  else
    return 0
  end if
end function

4 Ground Truth Analysis

To evaluate our statistical approach, we compared RTLF to two previous statistical tools, *dudect* and *Mona*. Additionally, we also compare RTLF to Welch's t-test [74] (t-test), which was also used in the Test Vector Leakage Assessment (TVLA) approach proposed by Goodwill et al. [37], which was later recommended for side-channel analysis by ISO/IEC 17825 [40]. We excluded *tlsfuzzer* from the comparison because it requires at least three distributions as input to perform its entire range of tests. For our comparison, we created artificial applications with well-defined timing side channels such that we could gather data with ground truth. These artifi-

Side Channel	Distribution X	Distribution Y
tail	**100%:** 20x256 N	**5%:** 19x256 N + 128 N **80%:** 20x256 N **10%:** 20x256 N + 32 N **5%:** 20x256 N + 64 N
same-mean	**100%:** 40x256 N	**50%:** 10x256 N **50%:** 70x256 N
shift-5%	**100%:** 20x256 N	**100%:** 20x256 N + 250 N
shift-1%	**100%:** 20x256 N	**100%:** 20x256 N + 50 N
shift-0.9%	**100%:** 20x256 N	**100%:** 20x256 N + 45 N
same-xy	**100%:**100x256 N + 10 R	**100%:**100x256 N + 10 R

Table 1: Description of the side channels built to model various distributions based on varying numbers of no operation instruction (N) and sampling of random numbers using C's rand() call (R).

cial timing side channels were created using ASM no operation (N) instructions and system calls to the random number generator of the OS to follow specific controllable distributions (X and Y) to show how these tools perform in different situations.

In our test setup, we let a client connect locally to a server application. The client performs measurements for two distributions, X and Y. Based on the data sent by the client, the server knows which distribution to simulate. As in previous studies [58, 68], we randomized the measurement order for X and Y to mitigate the impact of side effects and allow for the iid assumption made in Section 3.3. We collected n measurements for each distribution. This setup was chosen to simulate the same effects one might see in real applications using a mix of system calls and network operations.

Test Data Generation An overview of our created side channels is presented in Table 1. The test cases *tail* and *same-mean* simulate two different distributions, X and Y, with the same mean value. *shift-5%*, *shift-1%*, and *shift-0.9%* simulate a shift between the X and Y distributions. Test case *same-xy* is used to evaluate the theoretical type-1 error α for different sample sizes – here the distributions X and Y are identical.

Rationale Some presented distributions were specifically chosen to show shortcomings in the analyzed tools while still being plausible in real-world applications. We expect that the test case *tail* should present the weaknesses of *dudect* as it operates on the mean of the distributions. The test cases *shift-5%*, *shift-1%*, and *shift-0.9%* should reveal the weaknesses of *Mona*. We expect that *Mona* fails to detect the side channels with 1% and 0.9% shifts since its static box-test boundary ranges exclude any side channels that are below 1%.

Setup For each distribution (and experiment), we gathered up to 500,000 timing values based on CPU clock cycles. For the experiments, we used a consumer desktop PC with Intel(R) Core(TM) i7-6700 CPU 3.40GHz with 16 GB RAM running Ubuntu 20.04.2 LTS.

Side Channel	Samples	RTLF	*dudect*	*Mona*	t-test
tail (X,Y)	30k	59.1%	0%	68.3%	40.9%
same-mean (X,Y)	30k	100%	100%	100%	68.9%
shift-5% (X,Y)	30k	100%	98.8%	100%	14.2%
shift-1% (X,Y)	30k	22.6%	0.2%	25.6%	43.8%
shift-0.9% (X,Y)	30k	22.1%	0%	23.6%	51.8%
tail (X,Y)	500k	100%	98.3%	95%	55.9%
same-mean (X,Y)	500k	100%	100%	100%	83.4%
shift-5% (X,Y)	500k	100%	100%	100%	99.1%
shift-1% (X,Y)	500k	97.5%	50.9%	33.2%	31.6%
shift-0.9% (X,Y)	500k	93.5%	21.2%	12%	45.3%

Table 2: Analysis of the *true positive* rates based on the generated side channels. We evaluated each tool 1,000 times with each side channel and state. We configured RTLF and the t-test with $\alpha = 0.09$.

4.1 Evaluation

For the tool comparison, we configured RTLF with a type-1 error rate of $\alpha = 0.09$. We chose this value as it is large enough to illustrate how our type-1 error rate behaves for varying sample sizes (see Table 3), while also remaining low enough to be distinguishable from an uncontrolled type-1 error in all sample sizes. Moreover, we adapted *dudect* to operate on a given set of measurements as it was designed to collect measurements itself. We ran each tool 1,000 times with samples of the size given in Table 2. For each tool, we state how often H_0 was rejected, which corresponds to a *True Positive* for *tail*, *same-mean*, *shift-5%*, *shift-1%*, and *shift-0.9%*. For *same-xy*, in contrast, this represents a type-1 error (*False Positive*).

Result As shown in Table 2 and Table 3, our analysis confirms the expected weaknesses of *Mona* and *dudect*: For *tail*, *shift-1%*, and *shift-0.9%*, *dudect* fails to detect the existing side channels for a small sample size of 30,000. On the other hand, *dudect* shows a constant type-1 error rate of 0% for all sample sizes. Both of these effects are the result of its conservative decision rule. For *Mona*, we can see the expected drop in statistical power for a decreasingly distinct shift: for *shift-5%*, the detection rate is close to 100% for both sample sizes, while for *shift-1%* and *shift-0.9%*, we observed significantly lower detection rates, even for large sample sizes. The type-1 error, in contrast, steadily declines with increasing sample size, dropping from 40.8% (15,000 sample size) to 0% (500,000 sample size). The t-test generally performs worse than *Mona* except for *shift-1%* and *shift-0.9%*, where it is significantly better for a smaller sample size but still also does not detect the timing difference reliably. As shown in Table 3, the t-test shows a consistently high type-1 error rate of around 30% for test case *same-xy* for sample sizes up to 30,000 and only manages to remain within its α-value for large sample sizes.

In comparison, RTLF reliably detects all distinct distributions for a sample size of 500,000. For 30,000 samples,

the detection rate is on par with *Mona*. This also applies to *shift-1%* and *shift-0.9%*, where RTLF likewise failed to detect the difference reliably. Our analysis in Table 3 confirms that RTLF remains within the configured type-1 error threshold $\alpha = 0.09$, resulting in lower error rates than for *Mona* and the t-test. For completeness, we also performed a type-1 error analysis based on samples of distribution Y of the distinct side channels. The results are in line with our previous results and are shown in Table 4. We further depict the effect of varying α values on the type-1 error rate in Table 5.

Side Channel	Samples	RTLF	*dudect*	*Mona*	t-test
same-xy (X,Y)	15k	9.2%	0%	40.8%	27.6%
same-xy (X,Y)	20k	9.4%	0%	24%	30.8%
same-xy (X,Y)	25k	7.6%	0%	12.7%	30.6%
same-xy (X,Y)	30k	5.9%	0%	7.5%	30.6%
same-xy (X,Y)	500k	2.7%	0%	0%	8.8%

Table 3: Analysis of the type-1 error rates based on 1,000 simulations of the side channel *same-xy* with different sample sizes. We configured RTLF and t-test with $\alpha = 0.09$.

Side Channel	Samples	RTLF	*dudect*	*Mona*	t-test
tail (Y,Y)	30k	4.3%	0%	6.2%	8.4%
same-mean (Y,Y)	30k	4.3%	0%	7.1%	9.0%
shift-5% (Y,Y)	30k	3.5%	0%	5.1%	10.8%
shift-1% (Y,Y)	30k	3.4%	0%	5.9%	9.4%
shift-0.9% (Y,Y)	30k	3.7%	0%	5.1%	10.3%

Table 4: Analysis of type-1 error rates based on a sample size of 30,000 for measurements sampled from distribution Y of the denoted side channel. We configured RTLF and t-test with $\alpha = 0.09$.

Side Channel	Samples	$\alpha = 0.009$	$\alpha = 0.09$	$\alpha = 0.18$
tail (Y,Y)	30k	0.5%	4.3%	8.9%
same-mean (Y,Y)	30k	0.5%	4.3%	9.0%
shift-5% (Y,Y)	30k	0.4%	3.5%	6.7%
shift-1% (Y,Y)	30k	0%	3.4%	6.4%
shift-0.9% (Y,Y)	30k	0.5%	3.7%	7.2%

Table 5: Analysis of RTLF's type-1 error rates based on a sample size of 30,000 for measurements sampled from distribution Y of the denoted side channel.

5 Real-World Evaluation

While the previous evaluation showed that our approach performed better with artificial side channels, it is important to show that our tool also performs well in real-world applications. In this section, we discuss the real-world measurement setup and its potential noise sources. Additionally, we list all attack vectors considered in this study. We conclude the section with an interpretation guideline for the upcoming quantitative and qualitative analysis.

Collecting Measurements As our analysis required us to test a multitude of versions for eleven TLS libraries, we used the TLS-Docker-Library [55, 86], which provides Docker images for different TLS libraries. For each version, we started a docker container running the example server of the tested implementation. Where necessary and possible, we explicitly allowed RSA key exchanges to test for Bleichenbacher vulnerabilities. We collected 200,000 measurements per attack vector and measured the time until a library *reacted* to an attack vector, either by sending a TLS alert or closing the TCP connection. If a library frequently showed no reaction, we aborted the measuring process for the corresponding attack and excluded it from the study. This could, for example, happen if the library crashed or kept the TCP connection in an open but dead state. Note that this behavior is not necessarily safe.

We used TLS-Scanner [87] to automatically test if an implementation meets the requirements of the individual attacks and to adapt our measuring tool to the various legacy versions. To create and deliver the test vectors to the respective libraries, we used TLS-Attacker [77, 85], a well-established framework for a systematic analysis of TLS implementations. We spread the experiments across 21 consumer desktop PCs with Intel(R) Core(TM) i7-6700 CPUs 3.40GHz with 16 GB RAM running Ubuntu 20.04.2 LTS. In total, we evaluated 823 server versions from the TLS-Docker-Library.[6] We chose the same libraries studied by Maehren et al. [55]. However, we excluded Rustls, as it does not support RSA key exchange or CBC encryption, and s2n, as it intentionally omits alert messages and often does not close the TCP connection for error cases.

Noise The selected setup is not noise-free, with multiple potential noise sources:

1. We gather timing measurements on the same PC that generates the test vectors and that hosts the target application.
2. There are concurrent processes running on the OS.
3. The processes are not running on dedicated CPU cores.
4. We do not optimize the OS.

We deliberately chose to use a non-optimal setup to better reflect the noise in the measurements a typical user would experience when using RTLF on their own machine without special considerations.

5.1 Considered Attack Vectors

For each considered attack, we chose test vectors that account for different test cases based on previous research. Compar-

[6] https://github.com/tls-attacker/TLS-Docker-Library/releases/tag/v2.3.1

ing the timing behavior between the individual vectors of an attack indicates if a timing side channel is present.

Bleichenbacher Based on the work of Böck et al. [13], we selected the following test vectors that we send after the first server flight in a *ClientKeyExchange* message, together with a *ChangeCipherSpec* message and a *Finished* message that is encrypted under an incorrect *Master Secret*.

B1: A correctly formatted PKCS #1 v1.5 message.
B2: A PKCS #1 v1.5 message with invalid second byte (`0x17` instead of `0x02`).
B3: A correctly formatted PKCS #1 v1.5 message with an invalid TLS version set in the *Premaster Secret*.
B4: A PKCS #1 v1.5 message that contains a one-byte *Premaster Secret* instead of 48 bytes.
B5: A PKCS #1 v1.5 message without a `0x00` delimiter.

Padding Oracle Based on the work of Merget et al. [61], we selected the following test vectors that we send after completing a handshake:

P1: A TLS record with 80 bytes divided into 59 bytes of padding, MAC, and no application data, where the first padding byte has been invalidated.
P2: A TLS record with 80 bytes divided into 59 bytes of padding, MAC, and no application data, where the first byte of the MAC has been invalidated.
P3: A TLS record solely consisting of 80 `0xFF` bytes resulting in a record that is too short to parse all expected 255 padding bytes.
P4: A TLS record consisting solely of 80 padding bytes leaving no bytes for MAC and application data parsing.

Lucky13 For the Lucky13 attack, we selected test vectors as described in the distinguishing attack by AlFardan and Paterson [1] that we send after completing a handshake:

L1: A TLS record containing 287 random bytes followed by a `0x00` padding length byte, i.e., the record is perceived to contain no padding.
L2: A TLS record containing 32 random bytes followed by 256 `0xFF` bytes, i.e., the record is perceived to contain 255 bytes of valid padding.

5.2 Putting Figures Into Context

When analyzing the results of timing measurements, one has to be careful with the conclusions that are drawn from the results. Generally speaking, a statistical test identifies structural differences in the two gathered samples but can not specify the source of that difference. This means that any structural difference observed can be due to a timing side-channel vulnerability in the target or a bias in the measurement setup. Therefore, it is evident that the measurement setup should be constructed carefully to minimize technical influences that could cause a structural bias between vectors.

Color Encoding Throughout the paper, we use figures with color encoding to represent detected timing differences and their respective size. Our choice for the boundaries for the different colors is inspired by Crosby et al. [24], who mentions that side channels bigger than 100 ns (red) are likely remotely exploitable in a LAN setup and that timing differences bigger than 20,000 ns (black) are likely exploitable over the Internet. To provide further insight into our data, we introduced a third option at 500 ns (dark red) to indicate timing differences that are *very* likely exploitable. We depict timing differences below 100 ns in yellow. Green fields depict versions for which no statistically significant difference has been reported. Since the other tools considered in our comparison do not estimate the timing difference in ns, we use pink to depict their boolean findings.

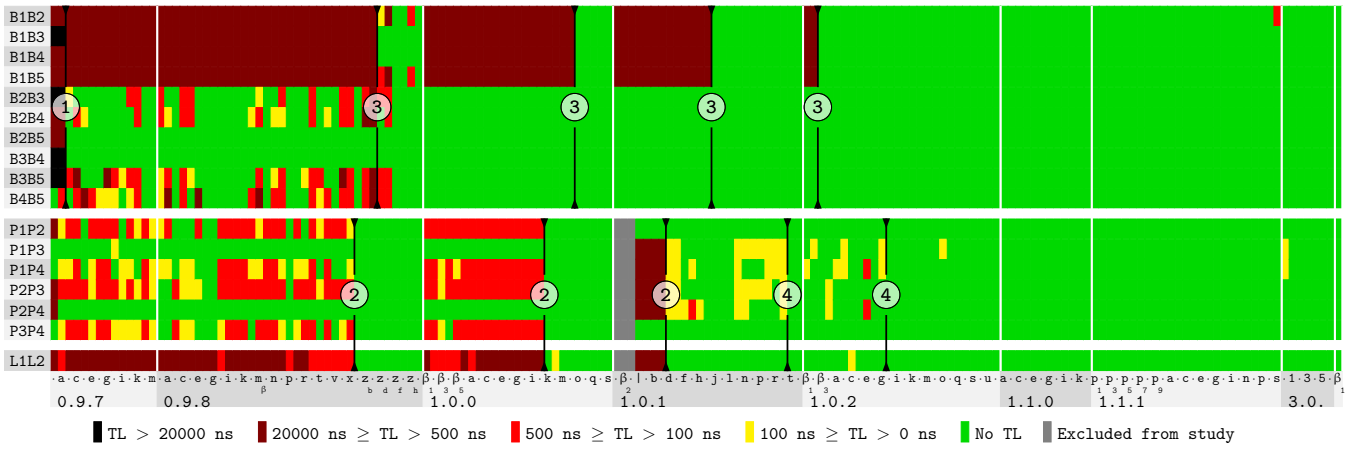
Type-1 Errors One key feature of our approach is that it allows the user to define how many type-1 errors are acceptable in the results. This means that our results will also contain a certain amount of type-1 errors. However, the bigger the reported timing difference, the less likely it is indeed a false positive. Concretely, for our figures, this means that yellow squares are more likely false positives than red, dark red, or black squares. However, note that a consistent grouping of yellow squares across multiple subsequent versions is likely the result of a subtle timing difference and not solely due to type-1 errors.

Type-2 Errors While we try to provide high statistical power, we must refrain from making absolute claims regarding type-2 errors. This implies that the presence of green squares cannot guarantee a completely side-channel-free implementation. Rather, it signifies that any potential side channel might be too subtle for us to confidently assert its presence through our measurements for the given variance of a tested library and the noise introduced by the measurement setup (see Section 2.2).

6 Quantitative Analysis of OpenSSL

In this section, we examine the efficacy of RTLF. The primary emphasis is on evaluating its effectiveness for the real-world application OpenSSL and showcasing its notable enhancements when compared to the tools described in Section 2.3. To assess our results for OpenSSL, we use known protocol vulnerabilities corresponding to our considered test vectors.

Figure 1 presents the outcomes of our timing analyses conducted on OpenSSL, arguably the most important cryptographic library. To test for timing leaks, we pairwise compared the measurements of the considered vectors of an attack. Note that the project is developed in several different version branches simultaneously, meaning that patches for discovered vulnerabilities typically get backported to older versions as long as they are still maintained. Within Figure 1, we indicate simultaneous fixes to different branches using identical numbers (① to ④).



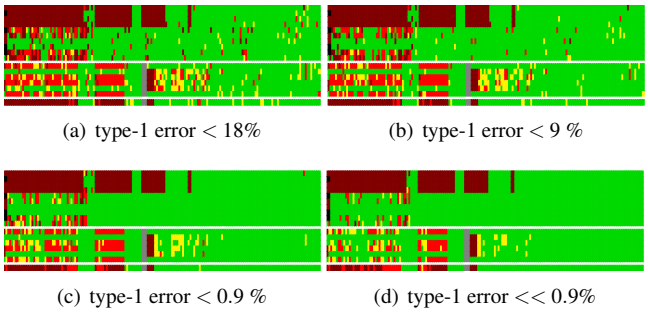


Figure 1: Result of the timing analysis for version 0.9.7 (2002) to 3.1.0-beta1 (2022) of OpenSSL. Each row shows the 17 analysis results obtained for a single version through pairwise comparison of measurements collected for Bleichenbacher (B), Padding Oracle (P), and Lucky13 (L) vectors. We categorized timing leaks (TL) based on Crosby's classification. Note that different version branches of OpenSSL are developed in parallel. The numbers indicate simultaneously deployed countermeasures against the Klima-Pokorny-Rosa (CVE-2003-0131) ①, Lucky13 (CVE-2013-0169) ②, various Bleichenbacher ③ (2014), and CVE 2016-2107 oracles ④. The labels below indicate every second version tested.

Bleichenbacher The first referenced patch (①) targeted one of the first available CVEs in OpenSSL, the Klima-Pokorny-Rosa Bleichenbacher vulnerability (CVE-2003-0131). It addressed significant timing differences in OpenSSL 0.9.7 and 0.9.7a. Accordingly, we see a transition from grave timing differences to only subtle leaks (e.g., vector pair B3B5) or no difference (B2B5 and B3B4). However, some distinct Bleichenbacher timing leaks are still present up to branches 0.9.8, 1.0.0, 1.0.1, and beta versions of 1.0.2. These have been addressed by a simultaneous patch (③) that specifically aimed to make RSA-related code constant time. As shown, for each of the affected branches, we see a transition from red to green in at least two Bleichenbacher vectors. Interestingly, we still detected more subtle timing differences throughout later versions of 0.9.8. We inspected the code after the fix and found that the developers knowingly kept some code that branches based on the PKCS padding validity, and thus OpenSSL still did not run in constant time. Interestingly, this check considers our vectors B1, B3, and B4 as compliant, while B2 and B5 are considered non-compliant. This matches our results as we only see timing differences when comparing a compliant vector with a non-compliant one (B1B2, B1B5, B2B3, B2B4, B3B5, and B4B5) but never within these two sets. We found the same code in the 1.0.0 branch after the countermeasure had been deployed at ③ but were unable to detect timing differences based on our 200,000 measurements. We tested versions from both branches with 500,000 measurements and found that we identify these timing differences more consistently in 0.9.8 and also find them sporadically in 1.0.0 versions. We assume the difference is less prevalent in branch 1.0.0 due to side effects of other parts of the code.

Padding Oracle & Lucky13 Generic Padding Oracle attacks and the Lucky13 attack are closely related as they both exploit timing leaks in the TLS record layer. As shown, deployment of the Lucky13 countermeasure (②) eliminated the timing leak in 0.9.8y and 1.0.0k. Up to this point, RTLF consistently reported timing differences for related vectors with only a few exceptions. For branch 1.0.1, the Lucky13 countermeasure eliminated the timing leak for L1L2 but only reduced the leak for P1P3, P1P4, P2P3, and P2P4. This is caused by a second-timing leak present only in early versions of 1.0.1 and 1.0.2. These versions were the first to use AES-NI. Unfortunately, there was a bug in OpenSSL that caused an observable behavior difference if a record contained overflowing padding. Since our test vectors P3 and P4 contain overflowing padding, we can observe a timing leak, but it appears to be less prevalent than the previous Lucky13 leaks. As a result, we do not observe a continuous block. Still, with the introduction of the fix (④), we do not observe further consistent timing leaks for these vectors.

Scattered Findings RTLF reported isolated unexpected timing differences. This applies to findings for Lucky13 tests in versions 1.0.0l and 1.0.2c, Padding Oracle tests in 1.0.2n and 3.0.0, and Bleichenbacher tests in 1.1.1s. Given the number of versions and vectors we evaluated, it is plausible to assume that these findings result from the configured type-1 error threshold of 0.9%, are very small side channels close to the decision rule, or bias introduced by our measurement setup. Choosing the threshold is a trade-off between low false positives and false negatives. To illustrate the effect, Figure 2 uses the same measurements as Figure 1 but presents the outcomes for varying α values. As can be seen, a higher threshold re-

(a) type-1 error $< 18\%$ (b) type-1 error $< 9\ \%$

(c) type-1 error $< 0.9\ \%$ (d) type-1 error $<< 0.9\%$

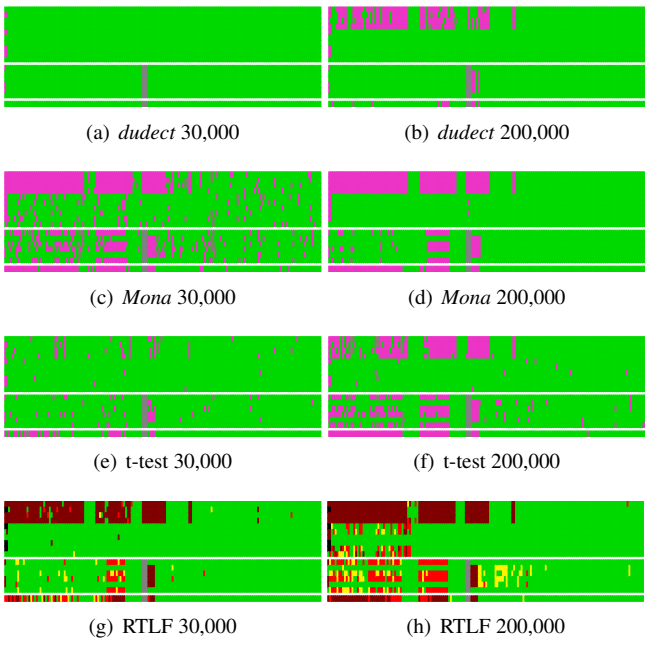

Figure 2: Overview of the effect of different type-1 error thresholds on the analysis of our OpenSSL measurements. For (d), we used the worst noise we sampled in our $B = 10,000$ bootstrap iterations, resulting in the lowest possible type-1 error for our collected measurements.

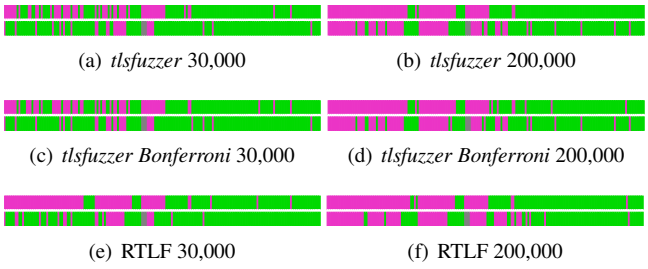
sults in more scattered findings. For the lowest threshold, the unexpected findings in the newer versions disappear as they are significantly less prevalent. However, some expected side channels also appear less distinct for lower thresholds.

6.1 Comparison to *Mona*, *dudect*, t-test, and *tlsfuzzer*

Mona* and *dudect In addition to our ground truth evaluation from Section 4, we also analyzed our OpenSSL measurements using *Mona* and *dudect* to assess how RTLF performs compared to these tools. We tested all three tools with 30,000 and all 200,000 measurements per vector. The results are shown in Figure 3 and demonstrate the expected shortcomings for *Mona* and *dudect* (discussed in Section 3.1) even for real-world applications like OpenSSL: *dudect* sets a conservative decision rule that causes most expected timing leaks to remain unnoticed. This is especially evident for 30,000 measurements, where only the CVE-2003-0131 timing leak (fixed at ① in Figure 1) has been detected. For 200,000 measurements, *dudect* detects most Bleichenbacher timing leaks but fails to identify Padding Oracle and Lucky13 leaks reliably. On the contrary, *Mona* detects most expected timing leaks at 30,000 measurements. However, it also produces a notably high number of scattered findings across all versions, which are often inconsistent and likely to be false positives. This issue primarily arises from the fact that *Mona*'s decision rule does not account for the variance of the quantile estimator, leading to a higher false positive rate for smaller sample sizes. For 200,000 measurements, these scattered findings disappear. Nevertheless, because the decision rule remains static, requiring a difference above the 1% threshold, smaller timing leaks, especially those related to CVE-2016-2107 (fixed at ④ in Figure 1), remain unnoticed. Compared to *Mona*, RTLF finds fewer expected timing leaks for 30,000 measurements but also produces significantly less scattered findings. This is the result of the configured type-1 error threshold of 0.9%. Setting a higher threshold α would reveal more expected timing leaks but also introduce more potential false positives as demonstrated in Figure 2. Therefore, we recommend to rather increase the sample size, since then RTLF detects even minor timing leaks, i.e., obtains asymptotically statistical power 1 (recall Section 2.2). The empirical evaluation of OpenSSL confirms that RTLF consistently yields reliable outcomes, whereas static decision rules, as employed by *Mona* and *dudect*, exhibit unreliability across all sample sizes. While *dudect* possesses a high false negative rate for both sample sizes, *Mona* produces many false positives for 30,000 measurements and some false negatives for 200,000 measurements. Even though *Mona* offers some pertinent insights, the static one-percent decision rule significantly falters when dealing with timing differences below one percent, as demonstrated in CVE-2016-2017.

t-test For the smaller sample size, the t-test fails to detect any of the expected timing differences reliably, performing only slightly better than *dudect*. While the detection rate improves significantly for the larger sample size of 200,000 measurements, the results for Bleichenbacher and Padding Oracle timing leaks are still less consistent than those of RTLF. At the same time, the t-test indicates more unexpected timing leaks than RTLF for both sample sizes.



(a) *dudect* 30,000 (b) *dudect* 200,000

(c) *Mona* 30,000 (d) *Mona* 200,000

(e) t-test 30,000 (f) t-test 200,000

(g) RTLF 30,000 (h) RTLF 200,000

Figure 3: Overview of the analysis results of *dudect* (a, b), *Mona* (c, d), the t-test (e, f), and RTLF (g, h) for 30,000 measurements and 200,000 measurements each. We configured RTLF and the t-test with $\alpha = 0.009$. Since the t-test, *Mona* and *dudect* do not state the time difference, we use pink to depict their boolean result.

(a) *tlsfuzzer* 30,000 (b) *tlsfuzzer* 200,000

(c) *tlsfuzzer Bonferroni* 30,000 (d) *tlsfuzzer Bonferroni* 200,000

(e) RTLF 30,000 (f) RTLF 200,000

Figure 4: Overview of the analysis results of *tlsfuzzer* using the unmodified (a, b) and Bonferroni-corrected (c, d) version, in comparison to RTLF (e, f) for 30,000 measurements and 200,000 measurements each and $\alpha = 0.009$. Pink fields denote a reported timing difference. Individual attack vectors for Bleichenbacher (top) and Padding Oracle (bottom) have been merged to comply with *tlsfuzzer*'s methodology.

tlsfuzzer In contrast to *Mona*, *dudect*, and RTLF, *tlsfuzzer* comprises a combined result for all vectors of an attack. To compare RTLF to *tlsfuzzer*, we adapt our script to also determine a single result based on the measurements of all vectors of an attack. As *tlsfuzzer* requires at least three vectors to run its full range of tests, it cannot be applied to our Lucky13 tests, hence we limit our comparison to Bleichenbacher and Padding Oracle attacks. *tlsfuzzer* uses four tests and sets its type-1-error α respective for each individual test, which will not result in the same combined type-1 error, making it less conservative than RTLF with the same targeted value α. To ensure a fair comparison (i.e., test with the same type-1 error), we apply the Bonferroni correction [78] in analogy to our method. More precisely, we set the type-1 error of the four distinct tests to $\alpha/4$, rather than using the correction method originally employed by the authors (in that case $\alpha/10$ for 10 different Bleichenbacher vectors). Note that this adaption lowers the type-1-error α for the Friedmann test and increases α for the remaining three tests of *tlsfuzzer*. In Figure 4, we can observe that the deviations between the unmodified (a, b) and Bonferroni-corrected (c, d) versions are negligible. One can observe that while *tlsfuzzer* produces significantly better results than *dudect* and *Mona*, RTLF detects expected timing differences more consistently, especially for small sample sizes (see Figure 4(c) and 4(e)).

7 Qualitative Analysis of Newest Libraries

In this section, we provide an overview of the results of the most recent library versions of BearSSL (commit 46f7dddce75227), BoringSSL (commit d9ea5553c3c9af), Botan (2.19.3), GnuTLS (3.7.8), LibreSSL (3.7.0), MatrixSSL (4.6.0), mbedTLS (3.3.0), NSS (3.87), OpenSSL (3.0.7 & 3.1.0-beta1), tlslite-ng (0.8.0-alpha43), and wolfSSL (5.5.4). As these versions are most likely to be still in use, we increased the number of measurements to 500,000 to be able to identify smaller timing differences. Figure 5 presents the

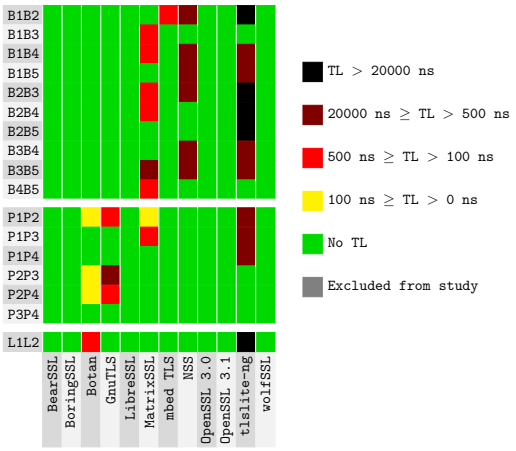


Figure 5: Results for our measurements of the most recent library versions. Each row denotes the comparison of two vectors of an attack based on the measurements collected for the library specified at the bottom of the column. We collected 500,000 measurements per attack vector and configured RTLF with $\alpha = 0.009$.

outcomes. We manually analyzed all issues for which RTLF reported a measurable side channel above 100 ns and tried to pinpoint the source of the leak.

7.1 Vulnerabilities in MatrixSSL

RTLF indicated timing differences in the measurements for Padding Oracle and Bleichenbacher vectors for MatrixSSL 4.6.0. Since the results are similar to those of other libraries, we use MatrixSSL[7] as an example for a more detailed analysis.

Bleichenbacher In Algorithm 3, we give a simplified version of MatrixSSL's PKCS #1 v1.5 parsing code used to extract the *Premaster Secret* from the padded plaintext when performing an RSA key exchange.

MatrixSSL first verifies that the initial two bytes of the padded plaintext have correct byte values. If the check fails, an error is returned (line 3). Otherwise, MatrixSSL loops over the bytes of the plaintext until it either reaches the end of the plaintext or finds the 0x00 delimiter byte (lines 6-11). It then checks if the remaining plaintext has the correct size and returns otherwise (line 14). If the size is correct, it copies the PMS to the result buffer and returns. The MatrixSSL code contains no real countermeasures against Bleichenbacher timing attacks and exits the function at multiple different positions, creating an obvious side channel. Our Bleichenbacher vectors correspond to different return calls in this function. Concretely, our vector B2 would exit at line 3, vectors B4 and B5 would exit at line 14, and B1 and B3 would exit at line 21, where the vectors B4 and B5 can additionally be separated by

[7] Note that the development of MatrixSSL has recently stopped and the repository has since been deleted.

Algorithm 3 Simplified MatrixSSL v4.6.0 PKCS#1 parsing code

Require: Decrypted PKCS byte array: *pkcs*,
Decrypt type: *decryptType* = PMS,
Expected *Premaster Secret* length: *expectedLen*

```
1: function pkcs1UnpadExt(pkcs, expectedLen, resultBuffer)
2:     if pkcs[0] != 0x0 || pkcs[1] != 0x2 then
3:         return PS_FAILURE; //B2 will exit here
4:     end if
5:     i ← 1
6:     while i < len(pms) && pms[i] != 00 do
7:         if decryptType == SIGNATURE && pms[i] != 0xFF then
8:             return PS_FAILURE //this return is never taken
9:         end if
10:        i++
11:    end while
12:    i++
13:    if len(pms) - i != expectedLen then
14:        return PS_LIMIT_FAIL //B4 and B5 will exit here
15:    end if
16:    j ← 0
17:    while i < len(pms) do
18:        resultBuffer[j] ← pms[i]
19:        i++
20:    end while
21:    return PS_SUCCESS //B1 and B3 will exit here
22: end function
```

a varying amount of loop iterations in lines 6-11.

Based on the code, we would expect to see no difference at B1B3, while for all other cases, we would expect a timing side channel, with the difference in B4B5 being the smallest.The only difference between B1, the benign message, and B3 is that B3 has an invalid TLS version set in the *Premaster Secret*. MatrixSSL, however, always overwrites this value using the protocol version at a later stage. A timing difference could thus only be caused if writing 0x0303 to the byte array is measurably faster when this value is already set. As shown in Figure 5, RTLF reported expected differences for vector comparisons B1B4, B2B3, B2B4, B3B5, and B4B5. RTLF further indicated an unexpected timing difference based on our measurements of B1 and B3. This may be a type-1 error since the executed instructions are identical, or there may be a difference in execution time caused by the concrete operands used within these instructions. Based on our measurements, RTLF did not indicate the expected differences for B1B2, B1B5, B2B5, and B3B4.

CBC Padding Oracle Regarding the Padding Oracle vectors, we found that MatrixSSL similarly has three distinct code paths for padding validation. First, MatrixSSL defines an error case when the padding bytes do not have the same value (P1). Second, MatrixSSL checks if enough bytes remain to parse a MAC, which is not possible for P3 and P4. Finally, there is a third path for when both of these checks succeed (P2). Interestingly, all three paths contain their own countermeasure against the Lucky13 attack.

Using GNU Debugger (gdb), we counted the instructions from the start of the padding and MAC validation to the return call that reports the error. For P1, we counted 68,362 instructions; for P2, we counted 68,299 instructions; and for P3 and P4, we counted 68,222 instructions. The results of RTLF align with this as we have been able to distinguish between the groups P1P2 and P1P3 but not between vectors of the same group. However, expected differences in P1P4 and P2P4 have not been detected by RTLF for a type-1 error threshold of 0.9%.

7.2 Other Libraries

Lucky13 Vulnerability in Botan RTLF indicated a timing difference in Botan for the Lucky13 vectors. In our disclosure process, the developer confirmed that the deployed countermeasure leaves a small timing difference. Again, we counted the instructions of the validation function (in a non-optimized build) using *gdb* and determined a difference of 428 instructions between the two vectors.

CBC Padding Oracle Vulnerability in GnuTLS In our analysis of GnuTLS, we discovered that the *cbc_mac_verify()* function incorporates a constant-time padding check that ensures uniformity of the padding bytes. However, the function then branches directly based on the outcome of this check. If the padding structure is correct, the function performs additional checks to ensure that there are enough bytes left after removing the padding to parse the MAC, requiring more instructions than the error case, resulting in a Padding Oracle vulnerability.

Vulnerabilities in NSS For NSS, RTLF indicated grave timing differences between Bleichenbacher vectors. Our analysis found that the code for RSA key exchanges is not written to run in constant time. NSS is mostly used in client implementations (e.g., in Mozilla's Firefox or Thunderbird), limiting the impact of this vulnerability. Mozilla has confirmed the vulnerability and is preparing a patch to address the issue.

Python Is Not Suitable for Cryptography While the code for tlslite-ng's own crypto library is written with side channels in mind, execution through Python generally does not achieve secret independent execution time. This is also pointed out by the developers in the *SECURITY.md* file on GitHub. To mitigate this, tlslite-ng can be configured to use other cryptographic libraries, such as OpenSSL. Since we measured tlslite-ng's native Python implementation, we found grave timing differences between most vectors, confirming the developers' note.

Indicated Bleichenbacher Finding in mbedTLS RTLF indicated a Bleichenbacher timing difference for mbedTLS in a single vector pair. We inspected the code and found no source for a timing difference. We conducted additional measurements, for which RTLF did not indicate a difference. We hence believe that this result was solely caused by our permitted type-1 error, which is plausible given the overall number of vectors.

Summary Based on the differences indicated by RTLF, we could identify several sources for timing differences. The only potential false positives we noticed were a single vector pair

for mbedTLS and one for MatrixSSL. These cases are indeed plausible for our prescribed α. Additionally, we identified cases where expected distinctions went unnoticed. Note that these instances can likely be attributed to the noise of the measurement setup in combination with our configured α.

7.3 Comparison to *Mona*, *dudect*, t-test, and *tlsfuzzer*

We also analyzed the measurements collected for the most recent versions using the tools from Section 2.3. To achieve comparable results, we configured the t-test and *tlsfuzzer* with $\alpha = 0.009$ as we did for RTLF. In the case of *Mona*, *dudect*, and the t-test, all identified Bleichenbacher leaks in MatrixSSL remain unnoticed. *Mona* and *dudect* additionally failed to identify any of the Padding Oracle leaks, while the t-test only missed the GnuTLS leaks. For *tlsfuzzer*, only the Bleichenbacher leaks in MatrixSSL remain unnoticed. However, *tlsfuzzer* did not produce an unexpected finding for mbedTLS, which is likely a false positive of RTLF. The t-test further indicated a Lucky13 timing leak for NSS. Based on our manual analysis of the source code, we determine this to be a false positive, which is plausible for the configured α given the number of test vectors and libraries. A graphical overview of the results is given in Figure 6 and Figure 7.

8 Discussion

Timing Differences in Older Libraries As part of our quantitative analysis of the libraries considered in Section 7, we analyzed 823 server implementations available in the TLS-Docker-Library [86]. Among the considered versions, most libraries indicate timing differences for vectors of more than one attack at some point. However, we also find that for the considered attack vectors, the most severe side channels have been mitigated in newer versions. For the timing leaks identified in Section 7, we find that these have already been present in previous versions. For Lucky13, it seems that some libraries tried to deploy countermeasures but were often times not entirely successful with their patch. We provide an extensive graphical overview of the analysis results for libraries beyond OpenSSL as part of our artifacts.[8]

Discrete Data Since we are using a non-parametric statistical test to evaluate side channels, our approach can be applied to all sorts of timing side-channels. However, challenges arise when dealing with too discrete data. This can happen, for example, if clock cycles of individual operations are measured in isolation. In this case, the estimator described in (3) may not adequately capture the differences. To address this, the estimator can be changed to one that is specifically tailored for discrete data (see Ma et al. [54] or Jentsch and Leucht [44]).

Co-Located Attackers Our results challenge the academic community's path to tackle timing side channels with static, dynamic, or symbolic analysis techniques. Without manual code review and only a limited number of vectors for each attack, we could already identify likely remotely exploitable timing differences (larger than 100 ns). Our manual investigation of the findings in the latest library versions indicates that many side channels are rather obvious, revealing a concerning gap between the academic literature and lived practice, as academia usually considers much stronger leakage models that only co-located attackers can exploit. Therefore, our results confirm the results of Jancar et al. [42] that current techniques are not widely deployed in the real world among TLS developers.

Small α Values Our methodology allows the user to control the threshold of the type-1 error. However, α can not be arbitrarily small for a fixed number of bootstrap iterations, as the threshold is tied to a percentile of the 10,000 noise simulations we perform for each decile. In principle, it is possible to choose a value for α that is greater than or equal to $1/B$. However, it is important to note that achieving a very small α, which is close to 0, can only be accomplished if and only if the value of $1/B$ is sufficiently small. Additionally, it is advisable to avoid approaching the boundary represented by $1/B$ as the estimation of the threshold becomes less accurate. Therefore, if a user wants smaller values for α, the bootstrap parameter B has to be adjusted as well, which increases the execution time of RTLF.

False Negatives The low type-1 error threshold comes at the cost of an increased false negative rate, which is increased by the noise in our evaluation setup. Our evaluation may also yield model-based type-2 errors when our considered attack vectors (cf. Section 5.1) are unsuitable for detecting a given vulnerability. For example, we did not detect a recent vulnerability in OpenSSL (CVE-2022-4304), which was created by a timing difference resulting from messages containing extensive leading zero bytes.[9] Since we relied on test vectors proposed by Böck et al. [13], we could not detect this vulnerability.

Fault Localization Our qualitative analysis of recent library versions required us to manually locate and verify potential findings as statistical tools are not able to point out the source of the leak. To assess a potential timing leak, a developer likewise needs to either inspect the code manually or measure isolated parts to narrow down the source. This is an inherent disadvantage, as other tools based on static, dynamic, or symbolic analysis can commonly provide fault localization [25, 98, 101, 102].

Applicability to Other Side-Channels While we demonstrated the application of RTLF to timing side channels, the approach could, in theory, be applied to other side channels like power consumption. However, RTLF is not designed for this use case, and would be computationally very inefficient.

[8] https://github.com/RUB-NDS/Artifacts-With-Great-Power-Come-Great-Side-Channels

[9] https://github.com/openssl/openssl/commit/f06ef165

Better fitting non-parametric tests like the χ^2 test have been proposed for this use case by Moradi et al. [63], which will likely perform better in this scenario.

9 Related Work

A lot of timing attacks have already been mounted on cryptographic components. Examples include timing attacks on AES [10], RSA[21], and WPA3[91]. While these attacks are traditional timing attacks that could be carried out remotely, researchers often also consider different attacker models where the attacker is co-located with the victim. This attacker model allows for powerful cache side-channel attacks [18, 23, 65, 107, 108] or even more powerful trace attacks [19].

9.1 Timing Attacks on TLS

Generic attacks on cryptographic primitives have been exploited in the context of TLS in the RSA signature generation [17] and in the ECDSA signature generation [16, 36, 76, 104]. While these attacks exploited generic flaws in the cryptographic primitives, some attacks, like the Lucky13 attack [1, 2, 73], Bleichenbacher attack [12, 13, 62, 72], Vaudenay Padding Oracle attack [61, 92], and Raccoon attack [60] are of special interest for TLS implementors; these attacks require careful considerations outside of generic cryptographic functions due to design flaws in the TLS specification itself. A technique to increase the timing signal in DTLS was proposed by Paterson and AlFardan [66]. The TIME attack [81] and HEIST attack [57] converted a compression side channel [70] into a timing side channel which reduced the required attacker model for the CRIME attack [70] to a pure Man-in-the-Browser model. While there are TLS-specific testing tools like TLS-Scanner [87], testssl.sh [82], or TLS-Anvil [55], these tools typically do not consider timing vulnerabilities.

9.2 Constant-Time Analysis

Static Techniques Static analysis techniques reason about the execution behavior of a program by statically looking at the code. This analysis can either be done for the binary itself [31], the LLVM IR [3], or the program code.[10] Static tools typically involve the annotation of secret values by the user.

Dynamic Techniques Dynamic techniques execute the code on a system and analyze the program flow. Just like static techniques, dynamic techniques typically require that secrets are annotated by the user. The dynamic analysis tool can then, for example, check that the program never branches based on a secret (or tainted) value. Dynamic analysis techniques are implemented in tools like ctgrind [50], TIMECOP [83], ct-fuzz [39], Microwalk [101], Microwalk-CI [102], and DATA [98].

[10] http://web.archive.org/web/20200810074547/http://trust-in-soft.com/tis-ct/

Symbolic Techniques A middle ground between static and dynamic analysis techniques are symbolic execution techniques, which simulate the execution of a program with symbolic inputs. This allows to reason about the reachability and potential operands of each instruction. Symbolic approaches also typically require that secrets are annotated by the user. Example tools that use the symbolic approach are CacheD [94], CaSym [15], and Binsec/Rel [25].

9.3 Statistical Techniques

Statistical analysis techniques have always been an essential point of timing evaluations, especially outside the academic community. In 2009, Crosby et al. [24] analyzed to which extent timing side-channel vulnerabilities could be measured in a remote setting. The box test proposed by Crosby et al. was implemented in *Mona* [75] and several tools presented at Blackhat [51, 58, 64]. For example, Nanown [64] uses Crosby's box test and some resampling strategies, which they call Monte Carlo bootstrapping. They support a static type-1 error rate of 5%. The method is mainly based on a heuristic approach and is less motivated by statistical theory, which makes it difficult to compare it to our proposed method from a theoretical perspective. Unfortunately, we could not empirically compare Nanown with RTLF, due to heavy IO operations caused by MySQL accesses implemented in Nanown, making evaluating large data sets time-consuming and infeasible for our comparisons.

A follow-up preprint of the *dudect* paper [68] by Fu et al. [35] also considers Welch's t-test. Fei et al. [33] implemented a theoretical framework based on likelihood methods to analyze the theoretical properties of rather general side-channel attacks in more detail. Zhang et al. [109] provided a theoretical model for cache-based side-channel attacks that also accounts for misclassifications using statistical models. As a general approach for identifying side channels with statistical techniques, Goodwill et al. proposed the Test Vector Leakage Assessment (TVLA) framework [52], which was adopted by ISO/IEC 17825 [40] for the analysis of side channels also beyond timing side channels and is commonly used to search for side-channel vulnerabilities in cryptographic primitives [43, 80, 88]. While the framework is generally flexible with the statistical test, it is most commonly used with Welch's t-test. The approach has already been tested with other statistical algorithms like the paired t-test [29] and the χ^2-test [63]. The TVLA framework is not uncontroversial and has been criticized by the community [79, 99, 100], with many of the criticisms directed at Welch's t-test and how it is applied in TVLA.

10 Conclusions & Future Work

Due to their unreliability, statistical tools have been mostly eliminated from the programming flow of many developers [42]. In this work, we showed that the perceived disadvantages of statistical techniques can be contained by providing

a configurable type-1 error α to developers, enabling them to make a trade-off between type-1 errors and how nuanced detectable side channels are. With RTLF, we give practitioners a tool specifically designed to easily detect likely remotely exploitable timing differences. This research aligns with the results from Jancar et al. [42], who states that most libraries adopt a best-effort approach to timing side channels, focusing primarily on fixing those that can be exploited remotely. Our approach is in contrast to previous mostly academic solutions, which are based on static, dynamic, and symbolic techniques that are designed to eliminate even the smallest side-channel vulnerabilities. Our results indicate a considerable gap between academic constant-time research and the lived reality of cryptographic developers who often have to prioritize other tasks. Concerningly, this results in a lot of TLS implementations containing measurable and oftentimes also likely remotely exploitable timing side-channel vulnerabilities, even though the attack vectors have been known for decades.

While our approach allowed to assert the existence of a timing difference, it is yet unclear *how* exploitable the timing difference really is as Crosby et al. [24] only give rough empirical estimates. Optimizing classification strategies under real-world conditions from an attacker's point of view may present itself as an interesting research direction in the future to more accurately model the exploitability of timing differences. Besides RTLF, there are other non-parametric two-sample tests to distinguish two distributions, such as the Kolmogorov-Smirnov test (see Darling [26]) or the Wasserstein metric (see Ramdan et al. [67]). It is of further interest, if other non-parametric testing procedures can match the performance of RTLF, or even improve it, in the context of timing side channels.

Appendix

A Theoretical Foundations

We now outline a theoretical justification for the bootstrap procedure proposed in this paper. When dealing with continuous data, we can proceed along the lines of Example 3.9.21 in van der Vaart and Wellner [90] to yield asymptotic normality using an appropriate scaling of the statistics. In addition, the Delta method for the empirical bootstrap (cf. van der Vaart [89]) can be applied to obtain the limit for the difference $\hat{q}_i^X - \hat{q}_i^Y$ of the quantiles estimator. However, since the Delta method for the empirical bootstrap requires Hadamard differentiable functions and the absolute value $g(x) = |x|$ is only directionally Hadamard differentiable in 0, we employ a different Delta method for $g(x)$. In particular, we refer to Theorem 2.1 and Theorem 3.3 in Fang and Santos [32], which provide an analogous asymptotic result for functions which are directionally Hadamard differentiable. However, this only guarantees α as an upper bound for the empirical bootstrap quantiles and not equality (see Theorem 3.3).

Finally, we discuss the case of discrete data, such as clock cycles. Here, the theory is more complicated since the quantile function is not Hadamard differentiable, which makes the lines of a proof sketched for continuous data in the previous paragraph invalid. However, it is worth noting that in our case (where we measure clock cycles), the empirical results did not indicate any major drawbacks in practice (compare Table 2). For a more comprehensive analysis of the asymptotic behavior for discrete data, we refer to Jentsch and Leucht [44], who present a methodology to overcome this technical difficulty through mid-distribution quantiles.

B Result Comparison for Qualitative Analysis

(a) *dudect* (b) *Mona* (c) t-test

Figure 6: Overview of the analysis results of *dudect* (a), *Mona* (b), and t-test (c) for 500,000 measurements per vector obtained using the most recent library versions. For the t-test, we set $\alpha = 0.009$, consistent with the RTLF analysis in Figure 5. Since the t-test, *Mona*, and *dudect* do not state the time difference, we use pink to depict their boolean result. With the t-test, *Mona*, and *dudect*, all Bleichenbacher leaks in MatrixSSL remained unnoticed. *Mona* and *dudect* also failed to identify any Padding Oracle leaks in the newest versions, while the t-test only missed the finding for GnuTLS. Only the t-test indicated a Lucky13 timing leak for NSS. We manually analyzed the code and could not identify any disparity in the instructions executed for the two test vectors. We thus consider it a false positive, which is also plausible for our choice of α.

(a) *tlsfuzzer* (b) RTLF

Figure 7: Overview of the analysis results of *tlsfuzzer* (a) and RTLF (b) for 500,000 measurements per vector obtained using the most recent library versions. We configured both tools with $\alpha = 0.009$. To comply with *tlsfuzzer*'s methodology, individual attack vectors have been merged. For *tlsfuzzer*, only the Bleichenbacher leaks in MatrixSSL remain unnoticed. Both versions of *tlsfuzzer* discussed in Section 6.1 produced the same results.

"These results must be false": A usability evaluation of constant-time analysis tools

Abstract

Cryptography secures our online interactions, transactions, and trust. To achieve this goal, not only do the cryptographic primitives and protocols need to be secure in theory, they also need to be securely implemented by cryptographic library developers in practice.

However, implementing cryptographic algorithms securely is challenging, even for skilled professionals, which can lead to vulnerable implementations, especially to side-channel attacks. For *timing attacks*, a severe class of side-channel attacks, there exist a multitude of tools that are supposed to help cryptographic library developers assess whether their code is vulnerable to timing attacks. Previous work has established that despite an interest in writing constant-time code, cryptographic library developers do not routinely use these tools due to their general lack of usability. However, the precise factors affecting the usability of these tools remain unexplored. While many of the tools are developed in an academic context, we believe that it is worth exploring the factors that contribute to or hinder their effective use by cryptographic library developers [61].

To assess what contributes to and detracts from usability of tools that verify constant-timeness (CT), we conducted a two-part usability study with 24 (post) graduate student participants on 6 tools across diverse tasks that approximate real-world use cases for cryptographic library developers.

We find that all studied tools are affected by similar usability issues to varying degrees, with no tool excelling in usability, and usability issues preventing their effective use.

Based on our results, we recommend that effective tools for verifying CT need usable documentation, simple installation, easy to adapt examples, clear output corresponding to CT violations, and minimal noninvasive code markup. We contribute first steps to achieving these with limited academic resources, with our documentation, examples, and installation scripts [1].

[1]Installation scripts, tasks, documentation and codebook are provided as an artifact, see Footnote 3.

1 Introduction

Timing attacks [68] are side-channel attacks that measure program execution time to infer information about confidential data. They are practical and can be used by (remote) attackers to achieve full recovery of secrets including cryptographic keys [28]. This makes protection against timing attacks an important goal for developers of cryptographic libraries.

In his seminal work, Kocher [68] observes that making control flow and memory access independent of secret data can help protect programs against timing attacks. Over the years, this guideline has become known as the constant-time discipline, and has become a gold standard for cryptographic libraries. Unfortunately, constant-time programming can be error-prone, especially when programming under stringent efficiency constraints, as is the case for cryptographic libraries. In 2010, Langley developed ctgrind [75], a minimal patch to Valgrind for checking that crypto software is constant-time. Subsequently, the security community has developed a broad variety of tools for protecting against timing attacks. Two recent works [61] and [49] provide an overview of these tools, from complementary perspectives. Jancar *et al.* [61] conduct a survey about the use of constant-time analysis tools with 44 developers of 27 widely deployed open-source cryptographic libraries. Their survey shows that these developers do not leverage constant-time tools despite an interest in writing constant-time code. As reasons, they identify that tools are not ready-to use and their use therefore requires significant time and expertise. Geimer *et al.* [49] presents a systematic evaluation of five selected tools, and identifies several technical roadblocks for the usability of tools. In addition, both works provide a systematic classification of around 40 tools for checking constant-time, and provide recommendations for tool developers and users. Although both [61] and [49] provide valuable insights on these tools, an empirical study to corroborate and deepen their findings has been lacking.

Therefore, in this work, we aim to understand **which factors support and hinder effective use of CT tools** through an empirical usability investigation that analyzes participant

strategies while working with CT tools. Our investigation provides a complementary view on the issues discussed in [61]—which predates this work—and [49]—which was published after we completed the developer study. Our developer study is designed to provide deeper insight into usability requirements and how they influence their interaction with CT tools, to determine the features that tools should provide to achieve their full potential. Due to the broad range of tools, we designed a usability study with six CT tools. The participants of the study are 24 advanced CS students who had knowledge in cryptography (including about CT programming) and C programming. Our study comprises two phases: in the first phase, participants work through tasks escalating in difficulty while familiarizing themselves with a tool; in the second phase, they analyze real-world cryptographic libraries for CT-ness.

We identify usability issues that we group into seven categories that revolve around three high-level aspects: (1) required efforts to setup and start using the tool, (2) barriers and work overhead hindering the use of CT tools, and (3) functionality the developer wants in analysis to identify and fix problems. We aim to answer the following research questions:

RQ1: *What are the pain points when trying to use CT tools?*
A: Installation, setup for analytic use, and (long term) operationalization in a larger library context are challenges for effective CT tool usage.

RQ2: *How helpful are the tools at discovering and fixing problems? Which tool properties help or hinder effective use?*
A: Tools can help cut down the amount of work needed to analyze larger code bases rigorously, but if a tool is too much work to install and get to work, cryptographers might just “eyeball” the analysis without the tool. Meaningful documentation to get a tool working on simple examples effectively helps to overcome this.

RQ3: *How can we support potential users in using the tools?*
A: Easy setup, a set of simple examples to appropriate for the markup (which should be minimal and noninvasive to the source code), a tutorial on how to use the tool and get clear information from the output, and good general documentation were all found to be helpful.

Based on our findings, we suggest how the usability of CT tools can be improved to make CT analysis more accessible to developers. In summary, our contributions in this paper are:

- We concretize the problems mentioned by experts in the Jancar *et al.* survey [61] through a developer study with 24 newly trained potential crypto developers and publish the full procedure material (see Footnote 3) for replication.
- We offer a systematization of crypto developer workflow in using CT analysis tools, common to all 49 tools we found (see Table 3).
- We document pain points and their impact on crypto developer usage of CT analysis, giving an explanation on why the findings of Jancar *et al.* [61] are still prevalent.
- We propose what to consider during development of CT analysis tools by contrasting prior attempts.

Supplementary material and disclosure. We have communicated our results to the authors of the tools included in our study and made the artifacts available to them. We have received four responses; all four expressed interest, one said they plan to link to our study materials in their project. The supplementary material, including tutorials, installation guides, and codebooks is publicly available on a dedicated web page[2] and as an artifact[3].

2 Background & Related Work

We give an overview over the background and related work to this research by first discussing impacts of timing attacks on security, then describing CT development and CT analysis as defenses. For context, we also discuss a new generation of timing attacks that exploit microarchitectural features of CPUs, and the related efforts to protect against these attacks. Finally, we explain how a lack of consideration of human factors in cryptographic development can hinder widespread effective use of cryptography.

1. Timing attacks. Since Kocher’s introduction of side-channel vulnerabilities in 1996 [68], these threats have persisted despite significant efforts to address them. Considering the vast range of side-channel attacks, we will highlight a few pivotal moments with a focus on timing attacks. Kocher’s seminal work highlighted vulnerabilities in asymmetric cryptographic algorithms like RSA and DSS through "Timing Attacks", emphasizing the potential for exploitation based on secret-dependent operation times. In 2002, Tsunoo *et al.* [104, 105] expanded timing attacks to symmetric cryptography, noting vulnerabilities in MISTY1, DES, and suggesting AES being vulnerable to cache-timing attacks. Independent work by Bernstein [13] and Osvik *et al.* [87] confirmed these AES vulnerabilities. In 2003, Brumley and Boneh [28] revealed that these attacks could be conducted remotely via network timings. Subsequent vulnerabilities were discovered in the SSL/TLS libraries [3, 27, 29, 44] and on hardware-assisted defenses, such as Yarom *et al.*’s "CacheBleed" [125]. Kaufman *et al.* [66] also warned of persistent vulnerabilities post-compilation.

Despite these vulnerabilities and an emphasis on fixing them, side channels remain common in numerous platforms [19–21, 46–48, 79, 108, 109]. Some Common Criteria certified devices, despite their countermeasures, were found vulnerable [62]. Moreover, even recent post-quantum cryptographic efforts are affected [26, 54, 88, 89, 103, 113].

2. Constant-time Analysis. In this paper, we focus on investigating usability aspects of tools that evaluate timing leakages

[2] https://crocs-muni.github.io/ct-tools/
[3] https://zenodo.org/records/10688581

of (cryptographic) software. However, it is worth pointing out that the tools we consider also differ on a technical level in at least four different ways:

First, depending on the approach taken by different tools, they give very different soundness guarantees. Static *formal analysis* can achieve full soundness with regards to some leakage model. Slightly weaker guarantees are offered by tools performing *symbolic execution*; these tools achieve soundness only up to certain upper bounds on loop length. Tools based on *dynamic analysis* typically work with symbolic secret data but concrete public data; they achieve soundness up to code coverage for the concrete public values of the test cases. *Statistical analysis* performs measurements on (large sets of) concrete public and secret data. The advantage is that this approach does not require any leakage model, but on the downside, it also does not provide any soundness guarantees.

Second, the tools work on different levels of compilation. We distinguish tools working on source level, on some intermediate level, or on binary level. An example for a source-level tool would be the information-flow type system implemented by the `secret_integers` crate[4] in Rust. All tools we study (we will give detailed introductions later in Section 3.2) in this paper work on either intermediate-representation (IR) of the LLVM toolchain [90] or on binary level. Tools working on IR level are inherently limited in the sense that they are unable to find any leakages introduced by the compiler when translating from IR to binary [66, 98].

Third, the tools working on binary level differ in what architectures and extensions they support. In order to be used on production code, they need support not just for the core instruction sets of widely used architectures, but also for vector instructions and dedicated crypto extensions.

Finally—and here is where technical features overlap with usability—the tools differ in terms of performance. For example, for the analysis of Langley's *"donna64"* implementation [74] of Curve25519 [14], the running time of just two of the tools we considered ranges between 0.38 and 225 seconds. This wide range may impact Continuous Integration (CI)/Continuous Deployment (CD) and developer workflows.

Table 3 presents the tools we found and categorized according to prior literature [60], appending a few tools previously not included; similar tables are found in [49, 61]. For each tool, we describe the target of analysis, the techniques used and whether the tools claim to provide some form of formal guarantees. We opted to err on the generous side of claimed soundness guarantees of each tool. For some tools the claims do not easily map to the soundness categories we discussed before, so we keep the unqualified "Other" category from the literature. As usual with this kind of classification, the categories are not exclusive, each tool may combine approaches in its design—we opted to continue with best-effort categorization like the established literature.

[4] See https://docs.rs/secret_integers/.

3. Microarchitectural side-channel attacks and defenses While constant-time programming is still an important and increasingly standard baseline defense against software-visible side channels, research on more advanced microarchitectural attacks in the past few year has shown that this programming discipline is not a sufficient measure. This line of research started with the 2018 Spectre [67] and Meltdown [78] attacks, and has since identified multiple pathways for attacks that often—but not always—exploit speculative execution in modern CPUs. See, e.g., [70, 81, 86, 117].

The notion of constant-time can be extended to protections against more advanced microarchitectural attacks [67], leading to notions of speculative constant-time [31] or more generally of security with respect to a hardware/software leakage contract [58, 82, 83]. Many of the techniques used for analyzing constant-timeness can be extended to reason about speculative constant-time and related notions. In fact, there is already more than two dozen tools that analyze whether a program satisfies (some variant of) speculative constant-time. For an overview of these tools see [30, Fig. 2]; they generally suffer from similar usability issues as tools for constant-time.

Recent work [77, 110, 111] shows that aggressive optimizations used by modern CPUs to improve performance can lead to a new class of timing attacks. Many of the leakages are data-dependent and depend on prior execution history, making their detection extremely challenging. As a consequence, there is a strong incentive to develop analysis tools for checking the counterpart to constant-timeness; see [12, 45] for two very recent examples.

In both cases, we believe that the insights gained from [49, 61] and our work will provide valuable input for improving the usability of future tools in this space.

4. Human Factors in Cryptographic Development. There is a large body of work on human factors in cryptographic development. Acar *et al.* establishes in a 2017 study that poor usablitity of cryptographic libraries contributes to misuse and insecure code [1]. Haney *et al.* investigate the mindset of cryptography developers [55], and observe that some developers do not adhere to mainstream software engineering practices.

Krueger *et al.* developed a wizard for secure code snippets for specific cryptographic applications, evaluating its effectiveness and usability in a programming study [71–73].

In the specific context of constant-time tools, a study by Cauligi *et al.* [32] was carried out with over 100 students to understand the benefits of the FaCT tool introduced in the paper. The tool support by FaCT is found helpful for generating new code that is CT. In extension of this work, we include a diverse set of CT tools, documentations, tutorials, as well as open source libraries in our study.

Unfortunately, while previous research suggests that lack of usability prevents effective use of security tools [36, 40, 50, 94, 112], and specifically for CT [61], the question of how to improve the usability of these tools has been understudied [2].

3 Usability criteria and tool selection

In this section wegive a general description of our usability criteria, and explain how they impact users. In addition, we briefly introduce the six included CT tools in our study, organizing our presentation to inspect the previously defined criteria for each tool.

3.1 Usability criteria

The main purpose of our evaluation is to assess the usability of current CT tools, and identify features that impact effective use. To expand on Jancar *et al.* [61], we define criteria revolving around three features: (1) the effort required to setup and familiarize, (2) the work overhead for secret designation and target building, and (3) the quality of output to identify and fix problems.

We define our criteria following how users would perform the tasks related to CT analysis [102]: how users might interact with the tool, what information is given to the user, and how analysis outcome is presented to the user. The categorization of CT testing workflow steps was created from our expert team's experience in building CT tools and using them on real-world projects, combined with insights gained from piloting the study. We developed the categorization after all of the study results were gathered.

Installation. Every tool needs to be installed before use. There are two broad ways of installing CT tools. Some come pre-built and bundled for a package manager or in a container. Others involve manual installation by either building from the source, or by grabbing the available binary from a release page. For the latter method, the developer will be in charge of managing the necessary dependencies manually. CT analysis tools mostly come as proof-of-concept artifacts. According to [57], only 3% of artifacts are distributed in containers, while 23% are pre-built and 70% must be compiled from source code. Therefore, we expect that the installation step of CT tools may be very challenging for numerous tools, especially because of unmaintained dependencies, also confirmed by Jancar *et al.* [61], who point out that libraries maintainers do not consider use of hard-to-install CT tools.

Familiarization. Documentation is intended to provide a high-level overview of the tool and offers technical details for expert users. Help materials also include tutorials and examples. In this criterion, we focus on how quickly new users become comfortable running a tool on simple programs.

Building and Secret Designation. CT tools provide a means to tag secret data. This is typically achieved via either *code annotation* or the creation of an external function *wrapper*. Many CT tools operate on instrumented binaries or some abstract intermediate representation that is designed for program analysis. Very often, this implies a custom building and linking process. Usability is negatively impacted whenever manual work is needed during this process. In other words, we look at how much tools modify a project to be analyzed: both in terms of code (for secret designation) and build workflow integration (for target generation). Little work overhead is commonly appreciated [64].

Analysis Runtime. Once the target is built, users can actually run the tool for CT analysis. Here, we look at two sub-criteria, the tool's interface and its runtime. For a command-line interface tool, users may struggle with passing the right options. Importantly, tools are expected to yield results in an acceptable time frame. The longer the runtime of the analysis, the more difficult it is to integrate the analysis into the project workflow [64]. This problem hinders a feedback loop using CT analysis at coding time. This can be important both in CI workflows, which may have an upper time limit, and developer workflows, where each developer may only want to spend a small amount of time waiting for analysis results.

CT Problem Fixing. When the analysis is finished, CT tools display some output to direct the developer's attention to detected issues. The purpose is to provide the developer with enough information to judge whether or not they care about the issue, and if yes, why the tool reports it. For example, it is not helpful if tools just display that there is an issue without any detail about the origin of the leakage. In addition, it is more productive for developers to be able to navigate and manage the list of reported issues. Otherwise, developers must linearly search through the (potentially large) list of results, making selective fixing more difficult.

Specialized Output Generation. To improve the experience of fixing problems, users might require customizing the generated analysis output. We introduce two features that we identify for CT tools. First, tools should also offer different verbosity in report details to avoid *excess of information* [50]. For example, a summary mode is beneficial in order to quickly skim the reported vulnerabilities to decide which one to inspect. Second, within the context of a CI pipeline, a delta report can be handy in assisting developers to determine whether a specific leakage has been correctly patched, and that the fix has not induced other leakage.

Reliability / False Positives. Ultimately, users need to trust the tool and its analysis. Therefore, any indication of potential false positives or missed issues could undermine user confidence, leading to tool abandonment. Solutions do not necessarily involve sound or complete tools, but also support for filtering user-supplied false positive patterns. This may help the user but can also lead to user filtering actually missing timing leaks, either mistakenly or lazily.

3.2 Tools

We selected six tools for use in our study: MemSan, timecop, dudect, ctverif, BINSEC/REL, and haybale-pitchfork. These

tools were primarily chosen to include a representative from each analysis type. The selection of the tools was made towards the end of 2022, therefore more recent tools were not considered. We prioritized tools well-recognized in the community, ideally those used by developers, gauging their reputation through a recent survey [61]. Out of the tools, 4 (ctverif, MemSan, dudect and timecop) are 4 out of top 5 most known tools in [61], with the top one being ctgrind, which we replaced with the functionally equivalent and still maintained timecop. haybale-pitchfork and BINSEC/REL were selected as representatives of other tool approaches. The number of tools was also constrained by participant numbers to ensure even distribution. At the end of the subsection we compare our choice of tools with the five tools chosen in [49].

MemSan [99]. MemSan is designed to leverage the Clang built-in memory sanitizer to dynamically analyze binaries for constant-time violations, thereby requiring Clang for installation (which is available in most Linux package managers). Clang sanitizers are well documented, but there is little documentation on how to use MemSan for CT analysis. Concerning secrets, users can declare private variables and/or memory regions containing secrets, and declassify variables within certain code sections if required. To run the tool, developers must compile the program with Clang, using the appropriate option to enable the memory sanitizer. All parts with no enabled sanitization are ignored—it is easy to get this wrong. Then, the analysis is performed by running the resulted binary. Note that only the executed code is analyzed, leading to different conclusions when running the same binary with different inputs. Indeed, code coverage is essential for MemSan. Upon the binary execution, errors will be displayed on branching or memory access indexing an annotated variable. The output details the path between the annotated variable and the cause of leakage. The output messages will be more related to the source code if the target is compiled in debug mode.

timecop [84]. Similar to MemSan, timecop relies on the Valgrind memcheck module [39] to dynamically analyze binaries for CT violations. Therefore, for installation, it solely requires Valgrind (which is available in most Linux package managers) and an additional C header file that must be downloaded from the project page. The timecop page also contains several tutorials and examples to smooth its first uses by beginners. To analyze code, users need to annotate private variables in the source code and may declassify variables within certain code sections if needed. There is no need for changes in the compilation chain. Concerning the analysis, users can simply run Valgrind on the binary as if they were searching for memory leaks. Valgrind will raise warnings for CT violations just like it would for the use of uninitialized memory in a branching or memory access. The output details the path between the annotated variable and the cause of leakage. timecop relies on the debug information to display the lines of code in its warnings. With its use in SUPERCOP [15], it is widely used.

dudect [91]. Installation for dudect is virtually non-existent as the tool is provided as a simple archive containing the C header file implementing it. The dudect documentation is rather limited. The tool operates via a black-box evaluation of a function, obviating the need for code annotation. The user, however, is required to implement an external wrapper in charge of setting the analysis parameters and options, as well as two functions to initialize the secret input classes and call the code to assess, respectively. Then, the target program must be compiled (with no custom build) and executed for analysis. The dudect approach is statistical, and it thus outputs values of statistics after code analysis. The output does not underline any source leakage, but only some probabilistic conclusion about the target CTness.

ctverif [4]. The installation of ctverif presents a significant challenge, requiring undocumented versions of specific dependencies and manual patches across different projects, such as SMACK and Bam-Bam-Boogieman. Aside from the paper, there is no or little documentation available. As for secret designation, users must declare private and public variables and/or memory regions (arrays) containing secret or public inputs. In addition, they could declassify outputs, and assert the non-overlapping nature of these regions. The tool operation is straightforward, requiring only the source code file as input, in addition to the entry point to analyze. Thus, ctverif does not need any custom build. However, ctverif can process a C translation unit only when all the called functions inside are defined by other input files, otherwise it produces an unknown error. After a run, ctverif only highlights the leakage location in the source code, without a dependency chain of variables or memory locations that lead to each leaked secret. Surprisingly, ctverif may raise some warnings even after a successful run without CT violations. It is worth mentioning that ctverif, instead of making some approximate analysis, informs developers when it cannot conclude about some leakage, displaying inconclusive output.

BINSEC/REL [38]. BINSEC/REL comes as source code, an extension to the Binsec tool. Some dependencies, such as an SMT solver and the OCaml package manager, shall be installed manually, before compiling the project source available on GitHub. BINSEC/REL offers a comprehensive list of supported command-line options and numerous examples to start with. On the analyzed project, users shall employ markup declarations to annotate the source code, thereby designating public and private data. The analysis of BINSEC/REL operates over binaries. The version utilized in this study only supports ARM 32 and x86_32 architectures, necessitating the target to be compiled accordingly. This might require to add additional compiler flags, since in numerous compilers, the default mode supports 64-bit. Upon completion of the analysis, a report is produced including the number of CT violations and an assembler dump correlating with the violation location. The assembler dump does not point to the leaked secret, but only

to the instruction causing the leakage. Note that during our study, BINSEC/REL received a major update that integrated the CT checking functionality into the main tool Binsec.

haybale-pitchfork [106]. Written in Rust, haybale-pitchfork can be installed from source using `cargo`, although its dependencies must be manually installed beforehand as documented on the project page, which includes multiple examples and different documentation materials. haybale-pitchfork runs its analysis over the LLVM intermediate representation. Thus, users need to modify the compilation chain to produce the corresponding LLVM bitcode of the target. Any symbol in the generated bitcode must be correctly resolved, or haybale-pitchfork stops the analysis, while printing a message raising "other errors". Instead of relying on annotations to mark secrets, users are instructed to implement an external wrapper in Rust, in order to define an abstract signature of the target function. Here, each function parameter can be declared as public or secret using the appropriate Rust type. This wrapper also contains other configurations, such as the bitcode path to inspect. Users carry out the analysis by compiling and executing the Rust wrapper. haybale-pitchfork provides conclusive results, displaying the leakage origin whenever a CT issue is found, together with a tree path to the leaked secret.

Comparison with the tools of Geimer et al. [49]. Geimer et al. [49] explores five tools in depth: Abacus [9], BINSEC/REL, ctgrind, dudect, and MicroWalk-CI [122]. Two of these tools (BINSEC/REL and dudect) are also included in our study. As explained above, we selected timecop and MemSan over ctgrind, because the ctgrind patches are outdated and do not work with recent versions of Valgrind and the Linux kernel anymore. In contrast, timecop and MemSan can be seen as more usable versions of ctgrind. We did not select Microwalk-CI [122], because it was released after we had initiated our study. We also did not select Abacus, because its focus is quantitative information flow rather than constant-timeness. We included ctverif for its strong correctness and coverage guarantees. We also included haybale-pitchfork, as an instance of a tool that covers both constant-time and speculative constant-time—however, to our knowledge, the tool was eventually not extended to speculative constant-time.

4 Methodology

In this section, we provide details on the procedure and structure of the study we conducted with (initially) 31 participants. We describe the experimental setup including choice of libraries, surveys, and experimental infrastructure. We also describe our coding process of qualitative data, including participant behavior and free-text responses, as well as the approach for statistical analysis of quantitative data, such as success measures and quantitative survey items. Finally, we explain our data collection and ethical considerations, and discuss the limitations of this work.

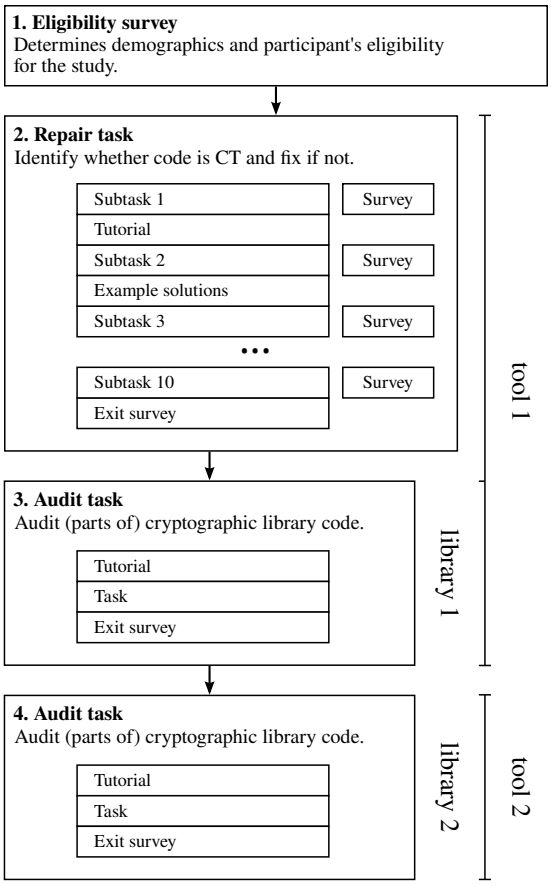

Figure 1. Study flow for each participant.

1. Recruitment and Participants. Due to the challenges of recruiting professional developers with security expertise, we targeted CS students for participation. We engaged Master's and early PhD students from 5 universities across 4 countries, as recommended by [101]. From the 74 students we approached with an eligibility survey, 31 began the study. A tools assignment error led us to exclude one participant.

Eligibility Criteria. We only consider participants having the minimum knowledge necessary to run CT tools. We asked them to self-report their knowledge of the C programming language and the CT paradigm. Naturally, considering our usability criteria, we also verify that they had never used any of the tools that are part of this study. Finally, to distinguish our work from [61], participants needed to lack experience in working on production-quality cryptographic code.

Compensation. Participants were compensated with 200 euros on completion of the study in exchange for 16 hours of participation; this compares to the hourly payment for student research assistants in participating countries.

2. Study Procedure. After a short eligibility and demographics survey which preceded the study, we asked participants to assess code for vulnerability to timing attacks using a CT verification tool across ten tasks that escalated in complex-

ity, as well as to audit (parts of) two cryptographic libraries. Assignment of participants to tools and libraries was done by hand, following a pattern of complete coverage of all possible tool combinations.The study flow is described below as well as visualized in Fig. 1.

During the study, participants were assigned ten successive *repair tasks*—tasks building upon tool-support specifics tested in prior tasks, which we will explain in detail—in which they were instructed to use a pre-installed CT analysis tool (`tool 1`) to identify whether a given code snippet is CT regarding a well-defined secret. If the code was not CT, participants were asked to fix it. The repair tasks represent textbook examples of secret-dependent branching and memory access, and their CT variant. After working on the first task, participants were given a tutorial that we had written for the tool. After the second task, we gave them the solutions to previous tasks, to be used as examples. Tasks 3 to 8 added various elements to increase difficulty, such as calls to `libc` functions (`memcmp`), reading randomness from the operating system and particular source code designed to trigger optimization during compilation. The goal of these repair tasks is to assess the participants' ability to use the tool to evaluate and fix a rather simple code snippet.

After completing work on the ten repair tasks (or exhausting the allotted time of 8 hours), and so becoming familiar with the tool, we asked them to audit well-known cryptographic libraries using the same tool (`tool 1`). In this *audit task*, participants were asked to compile the library (`library 1`) in such a way that enables them to use the tool, and audit a much larger code base. They were pointed at potentially interesting parts of the library, but not at specific functions. After a first library audit with a tool they had used for the entire study up to that point, we provided them with a new tool (`tool 2`), a tutorial, and a new library (`library 2`) to start a second audit task. These audit tasks aim at assessing the tools' usability in a setting more closely resembling a real-world use case.

For both parts of the study, we consider that a participant successfully completed a task if they underline the CT violation using the respective CT tool, and recognize it as such to fix it. The task structure was monolithic, simply stating that the task was to find CT violations with the given tool. Participants had to find out the necessary steps themselves.

After each of the repair tasks, participants were given a brief survey asking about their results (was the code CT or not, etc.), their experience with the tool during the task, and issues they encountered. After the last of the repair tasks, we gave participants a longer exit survey, which included the System Usability Scale [24] and questions regarding their overall experience with the tool. Participants were asked, e.g., whether they trust their tool to give them correct results and what their biggest problem was while using it. A similar survey was included after each audit task.

Instrument Development. Our group of authors consisted of experts in cryptographic engineering, side-channel attacks, and CT tool developers, as well as one human-factors researcher. We based the study development on our usability criteria and related features. We also let our experience with the development of cryptographic libraries and CT verification tools (as authors as well as users) influence the study design. The human-factors researcher introduced and facilitated the use of human-factors research methodology to better explore the identified usability criteria. In particular, the human-factors researcher explained methods when appropriate, facilitated discussions and helped the team to develop the study, pilot it, gather feedback, and evaluate the results.

Pre-Testing. Three co-authors dry-ran the study, followed by one student from the targeted population. Using their feedback we updated, expanded, and clarified the study.

Time Frame. Every participant had a recommended and self-enforced time limit of 8 hours to work on each part of the study (repair and audit, thus a total of 16 hours), within a soft frame of 2 weeks. We allowed extension of the 2-week time frame. Participants, although encouraged to fully use their time, were allowed to hand in their results earlier.

Repair Task Details. The first four of our tasks demonstrate the main points of the CT criterion: Secret-dependent branching and secret-dependent memory access. Repair tasks 01 and 02 are non-CT and CT examples of a selection based on a secret value, once with a branch and once with an arithmetic transformation like the one presented by Schwabe at ShmooCon 2015 [96]. Repair tasks 03 and 04 are likewise memory accesses depending on a secret value or boolean arithmetic for selecting a value loaded from all addresses without depending on the secret for the load address.

Repair task 05 introduces the use of a C programming language standard library function, `memcmp`, which is non-CT, to compare secret values. Tools which depend on static binaries and cannot inspect dynamically loaded libraries—which are the majority of deployed software today—are expected to fail here and show no CT violation. Repair task 06 includes a system call to read random numbers. System calls are on most operating systems implemented in a way that cannot be seen from user space, the memory area that is analyzable to most CT analysis tools. The tools can work around this, for example by recognizing a set of known system calls and their expected behavior. This task greatly differs from previous tasks, as it does not include secrets, but only checks for support analyzing this code. Task 07 starts to build up problems toward a harder criterion than CT - probabilistic CT, which is a criterion for functions that behave CT by default except for a subset of cases. Indeed, the program reads a random number like in task 06, but in 1 out of 256 cases, it will perform secret-dependent branching like in task 03. This may sound easy to spot manually by most users, but statistics-based CT tools were expected to underperform on this task. Task 08 introduces a different, and on first sight trivial problem: the same function is called, but in two branches based on the value of a secret. This may seem to be CT, but in practice a

compiler may transform this into assembly code that does not branch on the secret, even though in the given source code the CT criterion is violated. The intent behind this task is to see if the abstraction level of a tool, whether it works on binaries or instrumented source code, has a measurable impact on the success of participants. Task 09 makes the compiler transform impossible by changing the branching structure, passing a secret variable as a function input. The called function just returns a constant, which makes the whole program CT. Finally, task 10 is distinguished from previous tasks. It is formally non-CT and can be repaired in two non-obvious ways: users can either make it CT, but only probabilistically correct, or correct, but only probabilistically CT. With this last task, we wanted to see how participants pick up on less trivial code, inspired by techniques used in some cryptographic algorithms recently standardized by NIST, such as Kyber [10, 18] and Dilithium [43].

3. Study Setup. Our tool selection is explained in Section 3.2. Note that one of the included tools (BINSEC/REL) did receive a substantial update during the study, that we did not include as not to invalidate our study.

In order to have similar working environments, we deployed one VM for each tool, and gave SSH access to the participants. Each participant had restricted access to their home directory, with all necessary material (such as instructions and source code of the task and the library) available. For each resource, a clean copy was available as read-only in case they needed a fresh start. We decided to pre-install the tools on the VMs. The reasoning for that choice is twofold.

First and foremost, most tools are the outcome of academic research, and served the purpose of demonstrating new techniques and approaches, without aiming for maintainability. Hence, some tools are not maintained, and rely on specific version of dependencies that are outdated and deprecated. This can make the installation particularly complex and time consuming, especially on recent systems. Second, given that participants using the same tools were co-located on a VM, we could deploy the tool globally to ensure a functional setup, and avoid unintentional corruption of the tool by participants.

As an effort to make the first step easier, we implemented installation scripts for each tool present in our study—for possible difficulties in the installation phase, see Reynolds et al. [92]. We made them publicly available (see Footnote 3), along with the repair tasks and a small functional tutorial we provided to the participants. We hope this can prove useful, and motivate tool developers to do the same.

To make sure the participants have something to find in the audit tasks, we needed to include libraries that had problems with CT-ness, therefore we chose the following: two of them—`OpenSSL` and `GNUTLS/Nettle`—were chosen because they are in ubiquitous use in open-source software projects. The other—`mbedTLS`—was chosen because it was common *and* is targeted more for use on embedded devices. Other libraries like `BearSSL` were not included due to fewer documented CT issues and fewer prior audits of those libraries compared to the first two. We specifically audited the libraries ourselves, first, to see if participants can meaningfully find code that is non-CT in those libraries, either by looking at public documentation and then verifying with a CT verification tool, or direct analysis. All three chosen libraries document which parts of their code bases are not expected to be CT, so our participants could be expected to find them.

4. Coding and Analysis. All qualitative coding and data analysis were done by multiple researchers from a set of four, each coding part done by at least two, from diverse backgrounds and views. All of those researchers were familiar with CT verification, open-source and cryptographic code development practices, while two researchers had additional experience with human factors research with developers. We followed the process for thematic analysis [22]. The four coders familiarized themselves with the free-text answers in their part of the analysis, adding annotations and developing themes as well as codebooks.

Codebooks were first developed deductively based on the questions on each subtask, then changed inductively. The codebooks were iteratively changed while extracting themes from the free-text answers. Coders discussed until agreement was reached to make unanimous decisions; we therefore do not calculate inter-coder reliability [80]. The codebooks codify experiences—good or bad—as well as misconceptions, insecurities, and wishes encountered during the study's surveys.

5. Data Collection and Ethics. Our invitations were sent to participants of thematically fitting courses of five participating universities. We invited students by emailing them individually. During and after the study they could opt-out of participation. We only linked participants names to results for payment, not during analysis and not by members of the research team who had prior contact to those students. We keep the participant responses as confidential as possible and do not link quotes to them by name, only by pseudonyms.The study protocol and consent forms (for study participation and surveys) were approved by our lead institution's data protection officer and ethics board, who determined that the study poses minimal risk. Identifying data of the participants, like names, email addresses, and payment information, were stored separately from study data, and were only used to contact the participants; we did not retain any identifying data in excess of following laws.

6. Data cleaning & Presentation. From the 74 students we invited, 31 started our study, of which we were able to use the results of 24 participants. We only evaluate the results of participants who finished a meaningful part of our study and

compared results with and without familiarization with each tool on each library to offset possibly bad pairings, but did not find any meaningful differences between the two groups. As for the 7 incomplete results, we were not meaningfully able to incorporate them in most of the statistics—to not over represent results from simpler tasks—but we used partial results that were complete in appropriate sections.

Participants were paid for and expected to spend two days of eight hours each on the study, leaving rich free text comments in the surveys as well as comments in source code of their task solutions. We received mixed feedback, from disillusioned responses to high interest in further research on CT verification and coding practice. Generally, the feedback to our study was positive, even when the comments about the experience with some tasks were less so.

7. Familiarization. By design of our study, we set our participants up for familiarization with one tool each, then we ask to analyze a common real-world cryptographic library with the same tool. The repair tasks during the familiarization procedure were optimized for familiarization with the tool from simple examples to simplified current research problems.

8. Limitations. Survivorship bias [76] might taint the results, due to the study not reporting all the results of participants which dropped out. Selection bias due to comparatively high requirements in recruiting for the study as well as selective perception due to recruiting from student population who is accustomed to writing exams and tests might both also be relevant, but are both similar to the population which might use one of the CT tools. Participants may have reported more familiarity with the subject matter than they actually had, but due to our recruiting criteria, this was limited to a minimum actually necessary for participation. Our study may also suffer from the typical effects of fatigue in participating in a study, frustrations, and, of course, took place during the later years of the COVID-19 pandemic. Finally, our low participant numbers (due to the significant time investment and prerequisites) does not allow for statistical inference; we report numbers to highlight trends and/or outstanding observations.

Problem Fixing. When participants marked a repair task as already constant-time they were not asked to fix the code.

Library Selection. The projects we included for the audit task represents a selection and are not representative of all open-source cryptographic libraries. We are aware that other libraries might lead to different usability results.

Unknown Code. Our participants were not familiar with the cryptographic libraries used in this study. Annotating and custom-building are likely to be different when analyzing a project the participants are familiar with. Developers might achieve different results if they have a rough overview of the code base. We expect completing the repair tasks to be easier to our participants than the open-ended audit tasks.

VMs, Tutorials, and Examples. By including ready-made virtual machines with each installed CT tool, combined with layered introduction of tasks and documentation, not restricting online documentation and providing some as a backup ourselves, we provided our participants with a best-case scenario to learn how to work with each of the tools. Participants could approach the study as they saw fit, while being able to adapt example solutions and their own prior solutions to everything after a first introduction to the base cases for CT programming practice in minimal examples (tasks 01 to 04). This was a trade-off to gather more data about all CT analysis steps, not being stuck over installation or finding documentation. Nevertheless, this means that our participants had an easier task with the tools than users would have in real world.

5 Results

Tool (Tech., Guar.)	Repair		Audit 1		Audit 2	
BINSEC/REL (Sy, ◐)	33.5	(3.8)	38.7	(11.8)	45.6	(7.2)
ctverif (F, ●)	30.6	(18.4)	34.4	(8.5)	31.5	(14.8)
dudect (St, ○)	53.1	(29.1)	65	(5.9)	59.4	(23.8)
haybale-pitchfork (Sy, ◐)	64.4	(6.6)	52.5	(13.7)	50.6	(26.6)
MemSan (Dy, ◐)	49.5	(20.3)	41.3	(22)	49.4	(20.1)
timecop (Dy, ◐)	71.2	(6)	69.4	(10.3)	70.6	(24.1)

Table 1. Average and standard deviation of System Usability Scale scores from exit surveys after repair and audit tasks.
Technique: Sy—Symbolic, St—Statistics, Dy—Dynamic, F—Formal
Guarantees: ●—sound, ◐—sound with restrictions, ○—no guarantee

Table 1 showcases the System Usability Scale (SUS) scores [24] for each tool on both repair and audit tasks. The SUS is supposed to give a quick overview of a tool's overall usability; a score above 68 would be *"above average"* across software types. From the scores presented, usability remains fairly consistent between repair and audit, with notable exceptions for haybale-pitchfork, which had a noticeable dip during audits, and dudect, which exhibited enhanced usability in the audit tasks. Among the tools, timecop has the highest and most consistent score, suggesting superior usability. In contrast, ctverif and BINSEC/REL emerge as the least usable. For the correctness of solving the repair tasks, see Table 2.

Through thematic analysis of feedback during repair tasks, we identified common usability issues with the tools. Feedback points, categorized according to our codebooks, often overlapped, except for the "no issue" category. The distribution, depicted in Fig. 2, gave insights into tool perceptions and task challenges.

In Section 6, we delve into the diverse factors impacting usability, as organized by the criteria introduced in Section 3.1, and report on participants' confidence in their results. Each criterion corresponds to a step in detecting/fixing CT violations, and each subsequent step depends on the success of its predecessor. Those who encountered initial setbacks of-

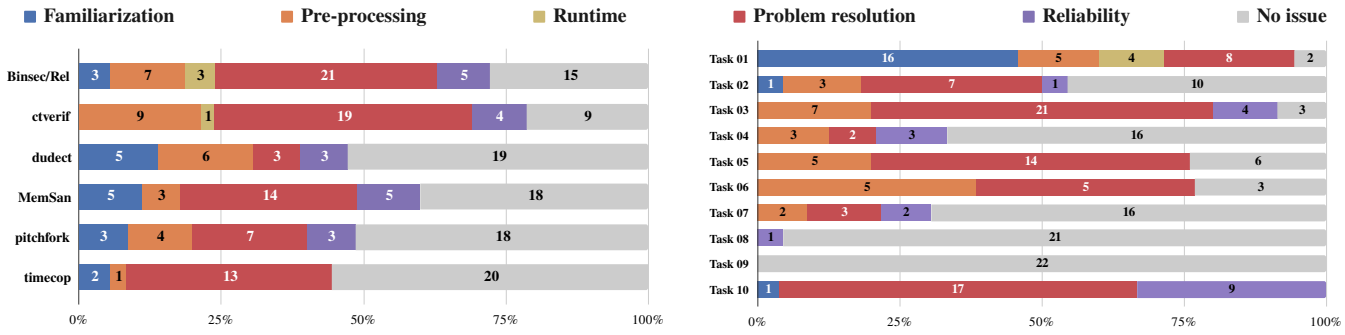

Figure 2. Participant's major issues during the repair tasks. (Left) For tools over all tasks. (Right) For tasks over all tools.

ten did not report in the later stages. This was particularly pronounced when auditing real-world software libraries.

Our findings spotlight factors affecting the tools' usability: Clear and intuitive outputs stood out as extremely important, and a lack of beginner-friendly documentation emerged as a recurrent issue. Though well-structured documentation is invaluable during the familiarization phase, participants reported distinct challenges as they delved deeper into the tools, but mixed with positive feedback as well. This disparity became evident when contrasting feedback between standard textbook examples and real-world audits, emphasizing different stages of tool assimilation.

Although the participants were equipped with the tools for the tasks, their installation and setup experiences could not be included in our data as we set up the tools for them.

1. Familiarization. During the first task, the main issue reported was unclear and non-user-friendly documentation, with 16 complaints (18 overall). Although the tools had associated academic papers, participants felt these didn't serve as effective documentation. They particularly missed step-by-step setup and results interpretation examples. *"[T]he documentation about every command doesn't exist or I didn't find them. Maybe a beginner-friendly aspect of the tool would have been good for me to start."* (P19)

Notably, participants had no complaints about ctverif documentation—possibly due to its basic user interface—but most of them faced issues with its operational aspects until they consulted our tutorial.

Despite the issues, our study also highlighted successes in the familiarization phase. Concise, beginner-focused documentation was identified as a significant upside in enhancing user engagement. The turnaround is likely a direct result of the tutorial we provide upon the completion (or non-completion) of the first task.

None of the participants managed to solve the second task using ctverif, and all expressed complaints about the output. After the tutorial and solution were provided, 3 out of the 4 participants were able to solve the subsequent task. This improvement persisted through the remaining tasks and can be attributed largely to the alleviation of difficulties in correctly interpreting the output and running the tool.

The effect was similar with BINSEC/REL. While none of the participants solved the first task, 4 out of 5 successfully solved the second task following the tutorial.

We noticed that our tutorials had a particularly strong impact on the usage of dudect, a tool that elicited the most complaints about lack of documentation. One participant even expressed their appreciation with the following: *"Great tutorial about dudect on the previous study page. Why it is not included in the official documentation?"* (P31)

Overall, the tutorial was appreciated for every tool in the repair tasks, as suggested by the following quote. *"I am just really using the template provided in the tutorial"* (P14),

During the audit task, 15 struggled to start using the tool, despite our tutorial. This was especially true for BINSEC/REL (3), ctverif (5) and haybale-pitchfork (4). Complaints mainly referred to lack of guidance in more complex tool usage, such as hooking functions, or bypassing some tool limitations. Tools with a more straightforward functioning, such as timecop and MemSan, did not suffer from these complaints.

2. Building and Secret Designation. This crucial preprocessing step is fraught with complexity, leading to 30 complaints from the study's participants during the repair task.

Central to the participants' challenges was the task of designating the secret within the given code snippets. The complexities arose either from the need to annotate the code, leading to 17 complaints, or the requirement to design a wrapper, which received 7 grievances in total. In particular, the annotation APIs provided by BINSEC/REL and ctverif were deemed overly complicated. This perspective was substantiated by 7 and 9 complaints, respectively, suggesting poor usability. In contrast, MemSan and timecop offered more streamlined processes, simply enabling users to flag a memory region as secret. The challenge of implementing external wrappers for tools like dudect and haybale-pitchfork was accentuated by insufficient documentation, evidenced by 4 and 3 feedback reports. A unique challenge presented by haybale-pitchfork was its reliance on the Rust language, which impeded 3 par-

ticipants. This prerequisite even pushed one to abandon the study. Hesitance to continue, even when participants were provided with ready-to-use tools and monetary encouragement, underscores usability concerns for the target user base.

Interestingly, the audit tasks unveiled a new set of foundational hurdles. A seemingly rudimentary step - local library installation - became a roadblock for 13 participants across all tools. While participants found the compilation of minor repair tasks with specified options manageable, the challenge escalated when they had to adapt intricate compilation chains to enable the tool use. In this regard, 16 participants faced hurdles when gearing up the libraries for suitable compilation to enable analysis. The architectural constraints of BINSEC/REL, especially the need to compile libraries for a 32-bit architecture, caused difficulties for 7 participants (given the study reliance on an older tool version). haybale-pitchfork posed its unique challenge, with 5 participants coping to generate the necessary bitcode of the library. The tools dudect and haybale-pitchfork added another layer of complexity by necessitating external wrappers, proving problematic for 4 and 1 users. The demands of accurate code annotation further intensified the complexities during this phase for 4 participants. This was notably severe for BINSEC/REL users and MemSan, 2 reports each. Overall, 10 participants faced significant hurdles in advancing further in the library audit, and did not manage to run the tool. 6 of them were blocked when using ctverif.

3. Analysis Runtime. In the context of the repair tasks, while many tools were wielded effortlessly on multiple tasks—indicated by the "no issue" category in Fig. 2—both BINSEC/REL and ctverif manifested signs of a higher barrier, even for tasks that appeared superficially straightforward. Specifically, BINSEC/REL was utilized seamlessly on 15 occasions, whereas ctverif demonstrated hassle-free operation only 9 times. We want to highlight the particular difficulty participants faced with BINSEC/REL during the first repair task. Users were presented with a multitude of options, some of which tangential to the main task, leading to 3 complaints.

The audit phase, characterized by the need to analyze larger code bases, brought forth a different set of issues. The time-consuming nature of the analysis was a concern, particularly for haybale-pitchfork and dudect. Analysis processes were identified as overly protracted by 1 and 2 participants respectively. This drawn-out analysis underscored concerns over the efficiency and practicality of these tools in real-world settings.

4. CT Problem Fixing. A preliminary glance at the success metrics in utilizing the tools, referenced in Table 2, exhibited significant disparities among the tools. Some adopted a tool-reliant strategy, while others, having initially engaged with a tool, later pivoted to manual code analysis. Given the easy nature of most tasks, forcing participants to resort to manual analysis is a witness of poor usability. We recorded these events mostly with ctverif, BINSEC/REL and dudect.

Participants unanimously agreed that discerning the leakage and subsequently mitigating it constituted the principal challenges. These were reflected in 77 grievances. The main subset of these, amounting to 51, expressed that after detecting the leakage, the repair process itself posed difficulties. These difficulties could arise from both details of the tasks and participants' limited familiarity with CT programming. The documentation most consulted by participants was related to CT programming methodologies, suggesting that the primary impediment might be their inexperience in this domain rather than difficulties with the tools themselves. We think this inexperience is not an impediment to use the tools, just in fixing more advanced problems in the code. This observation aligns with our expectations given the demographic we recruited for the study.

Tool outputs and how to interpret them emerged as a recurring concern, in 26 documented instances. Participants grappled with either a lack of comprehensive documentation to interpret the output (15 instances) or ambiguous outputs that did not offer a conclusive determination on the code CTness (11 instances). Here, dudect and haybale-pitchfork stood out for their clarity and precision as seen from little complaints in participant feedback. This likely results from tools concluding their analysis with a definitive statement about the status of the analyzed code, whereas other tools tend to provide information about possible issues, which can be confusing for beginners. BINSEC/REL and ctverif gathered criticism for occasional vagueness, with 2 and 9 mentions.

The relatively fewer complaints associated with dudect (3 instances) can likely be attributed to its methodology and careful wording of reports.

Even though we knew of pre-existing CT violations, 12 participants reported to be unable to detect any of them. These observations include use of haybale-pitchfork (4 participants) and BINSEC/REL, dudect, and timecop (2 participants). For both MemSan and ctverif it was reported once.

5. Specialized Output Generation. Participants voiced concerns with the verbosity and confusing nature of elaborate error reports. A segment of the study population—3 participants out of 24—grappled with decoding these verbose outputs during the audit tasks. These participants found it challenging to distinguish actual CT violations amid the warnings, and were overwhelmed by the volume of output. Specifically, participant feedback highlighted ctverif as the most problematic in this regard, accounting for 3 complaints. These complaints were directed toward errors preventing its proper usage, and not CT violations. timecop had 2 mentions, while other tools, barring haybale-pitchfork, were criticized once each.

6. Reliability / False Positives. Throughout the repair tasks, participants expressed skepticism regarding the tools, registering 18 complaints centered on perceived reliability issues.

Tool	Task 1	Task 2	Task 3	Task 4	Task 5	Task 6	Task 7	Task 8	Task 9	Task 10
BINSEC/REL	0%	40%	80%	100%	80%	40%	100%	80%	80%	60%
ctverif	25%	0%	75%	75%	100%	50%	67%	67%	100%	33%
dudect	60%	100%	75%	100%	100%	50%	75%	75%	75%	50%
MemSan	60%	60%	100%	60%	100%	75%	67%	100%	100%	0%
haybale-pitchfork	80%	100%	100%	75%	75%	75%	100%	100%	100%	75%
timecop	75%	100%	100%	75%	75%	50%	25%	75%	75%	50%
Mean	50%	67%	88%	81%	88%	57%	72%	83%	88%	45%

Table 2. Proportion of participants who solved each task per assigned tool (rounded to the nearest percent).

Such concerns typically revolved around reports of false positives (recorded 4 times), false negatives (4 times), mistrust in the results (2 instances), or specific tool reasoning limitations (8 times). Among all the tools evaluated, timecop stood out with no reliability complaints. In stark contrast, MemSan found itself at the receiving end of the most criticisms—amounting to 5, predominantly targeting perceived limitations in its analysis. BINSEC/REL follows with the same amount of complaints, but mostly on false positive.

9 participants successfully modified task 10, which was designed to be easily detectable as non-CT yet challenging to fix, in a manner where they discussed their solutions statistically probable CT-ness or correctness compared to the given setting. These successes provide a valuable insight: even when faced with complex tasks, participants can learn and adapt to the nuances of the tools. Due to our provided documentation and the ramp-up of repair task difficulty, we allege that these findings underline the significant role of quality documentation in the tool experience.

Upon transitioning to library audits, participants generally exhibited more restraint in identifying false positives or negatives than in the repair tasks. They mostly expressed low confidence in their analysis, evidenced by 20 self-report on low confidence. *"I have very low confidence in these results that must be false due to my usage of the tool."* (P06) This reticence was particularly pronounced for BINSEC/REL and MemSan, which gathered 5 and 4 reports, respectively. The participants detected few to no CT violations while analyzing libraries using haybale-pitchfork. This was reported 4 times. With BINSEC/REL, dudect and timecop, only two such cases were reported, and with MemSan and ctverif only one each. Low detection rates are usually correlated with issues during prior steps of the analysis, whether for preparing the library for audit or for using the tool. We conclude this by looking at inter repair task success rates in the first part of the study.

Despite the grievances recorded, most tools, except for ctverif, proved effective in detecting non-CT code during the audit tasks. dudect emerged as the front runner, recording 6 reports of successful detection, followed by BINSEC/REL and timecop, which facilitated 4 reports of discoveries each. Further, haybale-pitchfork accounted for 2 instances, and MemSan contributed 1 finding. We regard these outcomes as practical successes in identifying potential CT-violating bugs in the analyzed open source production code. We did not report these known and (upstream) documented findings.

6 Discussion

Building on the results of our study, we discuss the usability of different tools and make a series of recommendations based on the different stages of usage used in our study.

6.1 Usability vs verification approaches

Our results provide relevant information on the usability of tools relative to the verification approach they use.

Our study suggests that users found dudect intuitive to use. On the other hand, the underlying approach of statistical time measurement demands a strategic minimization of test parts when dealing with large code bases. Interestingly, the technique that lengthened dudect's processing time might have also contributed to its user-friendliness. The developers of dudect appeared to balance precision with early termination options for less accurate but faster results. Consequently, our participants found the output more intuitive. Whether participants knew they were trading accuracy for speed is unclear. Although it operates as a *"black box"*, a careful balance of precision, speed, and clarity in dudect made it an effective tool for our participants, as seen from their success rates—as seen in Table 2—and feedback.

Dynamic instrumentation tools often have a tug-of-war between technical efficiency and user experience, posing challenges during the setup phase. MemSan also faced significant trust issues due to perceived unreliability. timecop stood out with its blend of efficiency and user-friendliness. haybale-pitchfork, proficient yet challenging for some users, hinted at possible issues in the prior analysis steps.

Formal analysis tools, namely BINSEC/REL and ctverif, stand out due to their capacity to offer strong guarantees based on rigorous semantics. While robust, the theoretical foundation of these tools can come at a cost in terms of user experience. Specifically, ctverif presented a series of usability hurdles, from its initial installation to operational procedures. Many participants encountered challenges despite being provided with a working installation and sample use cases, leading to less successful task resolutions. In addi-

tion, our participants did not report particularly more trust in ctverif's output, despite the strong guarantees it claims. On the other hand, BINSEC/REL demonstrated that it is possible to maintain strong analytical guarantees while ensuring a more straightforward setup and operational process. This contrast between the two tools underscores the significance of balancing analytical capabilities with an intuitive user experience when time efficiency and ease of use are highly valued [61].

Our study offers a nuanced perspective on the usability-efficacy spectrum of different analysis tools. While strong guarantees are a primary concern, the trade-offs with usability can sometimes diminish a tool's practical application. The findings emphasize the need for tool developers to prioritize both rigorous analysis capabilities and a seamless user experience, ensuring that state-of-the-art tools are not just theoretically sound but also practically adoptable.

6.2 Recommendations

We combine the data from our empirical study with expert insights to curate a suite of recommendations. Our observations indicate that the tool usage is divided into multiple stages. Of particular concern, inhibiting complexities at early stages can deter users from progressing.

Installation. Many tools have a large number of dependencies and require custom building paths. As a result, installing these tools may be highly challenging in the mid-term, even if all the tool's dependencies are maintained. From study setup and piloting we extract the following recommendations:

- Reduce and avoid less maintained dependencies.
- Make tools available via package managers.

A more general recommendation would be to embrace the best practices of open-source software development, which has a long, integrated maintenance period and is often available as native packages in software distributions—native packages through distributions also make for discoverable tools.

Familiarization. After installation, users may run the tool on common examples, in this case crypto libraries, just to make sure that the tool is indeed running, and without caring for the tool's results. However, there are many obstacles to such dry runs. This includes, for instance, the need to compile libraries using specific compilation flags, different from the flags used to produce code, or the need to rewrite libraries to overcome limitations in the coverage of the tool. To avoid such situations and to ensure that tools provide adequate support for beginners, we make the following recommendations:

- Provide support for processing inline assembly and vectorized cryptographic code.
- Provide support for processing precompiled code, statically or dynamically linked.
- Provide user-friendly examples amenable to adaptations.
- Design intuitive tutorials catering to novices, and covering all the aspects of tool-usage.
- Prioritize a comprehensive documentation structure, accentuating essentials before delving into details. Make sure that the documentation avoids overly specialized jargon.

The latter recommendations are based on the feedback from the study participants.

Secret Designation. Most constant-time tools require users to provide security annotations. The annotations are typically given in the code or through some external wrapper. Moreover, many cryptographic libraries require users to declassify computations, for example to make ciphertexts public. From prior literature on different tool designs and their problem areas, we extract the following recommendations:

- Make annotations simple and external in additional files.
- Provide mechanisms to declare internal secrets [49].
- Provide mechanisms to allow to *declassify* computations.

Output generation. Results of analysis tools must be semantically rich, easy to navigate, and exploitable in a broader setting. Based on our interpretation of the results of the study, and our expertise, we make the following recommendations:

- Provide output that is readily understandable by users, including origin of leakage.
- Offer the possibility to report all leakage violations at once. Deduplicate findings in order to avoid repeating violations.
- Offer export formats for integration with bug-tracking tools.
- Have a delta mode for CI.

Analysis Runtime. For integration into users' workflows or CI, analysis should be possible in reasonable time—we think a few minutes are fine even for interactive use, but hours or longer are not. From Jancar et al. [61] as well as our own study participants' feedback and the CPU utilization of our study setup, we make the following recommendations:

- Use progress indicators (progress bar or logs) to ensure the user understands the tool is not stalled.
- If applicable, leverage multiple CPU cores for large tasks.

7 Conclusion

We collected data from 24 participants using 6 CT analysis tools to analyze small tasks and audit 3 open-source cryptographic libraries that are documented not to be fully CT. Our broad conclusion is that CT analysis tools have usability shortcomings that prevent them from being integrated into developers' workflows. Although our analysis focused on CT tools, we believe that many of our findings also apply to tools for analyzing microarchitectural side-channels. We believe the community should address these shortcomings by focusing on a handful of easy-to-use and maintained tools that go beyond the CT leakage model and cover a broad range of leakage models.

Abstract

Cross-Site Scripting (XSS) is a prevalent and well known security problem in web applications. Numerous methods to automatically analyze and detect these vulnerabilities exist. However, all of these methods require that either code or feedback from the application is available to guide the detection process. In larger web applications, inputs can propagate from a frontend to an internal backend that provides no feedback to the outside. None of the previous approaches are applicable in this scenario, known as *blind XSS* (BXSS). In this paper, we address this problem and present the first comprehensive study on BXSS. As no feedback channel exists, we verify the presence of vulnerabilities through blind code execution. For this purpose, we develop a method for synthesizing *polyglots*, small XSS payloads that execute in all common injection contexts. Seven of these polyglots are already sufficient to cover a state-of-the-art XSS testbed. In a validation on real-world client-side vulnerabilities, we show that their XSS detection rate is on par with existing taint tracking approaches. Based on these polyglots, we conduct a study of BXSS vulnerabilities on the Tranco Top 100,000 websites. We discover 20 vulnerabilities in 18 web-based backend systems. These findings demonstrate the efficacy of our detection approach and point at a largely unexplored attack surface in web security.

1 Introduction

Web applications are ubiquitous—so are their security problems. In particular, the vulnerability class of Cross-Site Scripting (XSS) remains one of the major security issues on the Web. Over the past decade, XSS has been studied extensively, with a focus on approaches to detect these flaws in existing applications. This detection relies on the identification of insecure data flows from attacker-controlled inputs into security-sensitive sinks. The actual techniques to pursue this goal vary, but they all rely on the availability of observable evidence of such data flows. This can be as simple as the re-identification of an input string in the application's HTML, in the case of manual bug hunting, and as sophisticated as fully automatic taint analysis.

This poses a problem for an often overlooked component of large web applications: *the backend*. Similar to the use of web technologies in its public frontend, the same application often employs web interfaces for its internal backends. These interfaces, inaccessible from the public internet behind a firewall, serve various internal application functions, including administration of the application, usage analysis, and back-office tasks such as supply chain management and accounting.

Not different from public web applications, internal web tools are also susceptible to security problems in general and XSS in particular. As these backend systems process data generated by the application's public counterpart, there is a high likelihood of data from potentially malicious, attacker-supplied inputs flowing into the backend's web code. This situation opens the door for XSS attacks on internal application components. However, current XSS detection techniques fall short in finding such flaws, as no evidence of problematic data flows can be obtained. All effects of the public-to-internal flows remain within the constraints of the internal systems. Testing tools operating from the outside are literally "blind" to any side effects caused by injection attempts.

In this paper, we present the first comprehensive study on *Blind Cross-Site Scripting (BXSS)* vulnerabilities. As by definition *no* direct channels from the affected system-under-test and the testing approach exist, the only option to verify the presence of a BXSS vulnerability is the injection and execution of JavaScript code. To this end, we present a method for synthesizing *polyglots*: XSS payloads specifically designed for a multitude of injection contexts. More specifically, we use Monte Carlo tree search (MCTS) to synthesize a small set of seven polyglots, capable of executing code in all test cases of a state-of-the-art XSS testbed (see Section 3).

However, good performance on an artificial testbed does not necessarily result in similar properties in real-world settings. For this reason, we validate the generated polyglots on a set of recently uncovered client-side XSS vulnerabilities

*Corresponding author

found in the Tranco Top 10,000 websites. To do so, we compare the polyglots' capability to uncover vulnerabilities with the currently established state-of-the-art method of precise payload generation [4, 19, 22, 26, 42, 43]. In this experiment our blind polyglots prove to be highly competitive with precise exploit generation, through triggering 147 vulnerabilities compared to 145 found by the precise payload generation. Furthermore, the generated polyglots vastly outperform the well-known, manually crafted "Ultimate Polyglot" [11] (see Section 4 for details).

Finally, we present the—to the best of our knowledge—first study on BXSS in the wild. We conduct a large-scale analysis of the Tranco Top 100,000 websites using our generated polyglots as testing payloads, uncovering 20 instances of BXSS problems in internal systems. This study demonstrates that our testing approach is well suited to detect BXSS vulnerabilities in real-world websites, as well as, the existence of this vulnerability class (see Section 5) on popular websites.

Contribution. In summary, we make the following contributions in this paper:

- We propose a method for automatically synthesizing a small set of XSS polyglots using Monte Carlo tree search, covering all currently known injection contexts.
- We show that the polyglots synthesized by our method achieve comparable performance to state-of-the-art vulnerability detection for client-side XSS.
- We design a methodology to detect backend XSS automatically and use it to conduct a large-scale evaluation on the 100,000 most popular websites, finding 20 BXSS vulnerabilities in 18 backend systems.

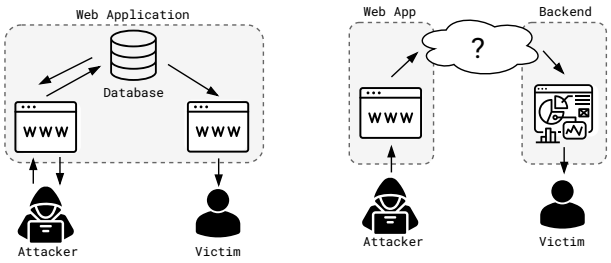
2 Blind Cross-Site Scripting

Cross-Site Scripting (XSS) is a notorious class of vulnerabilities, consistently earning a place in the OWASP Top 10 as one of the most critical web security risks [29–31]. These vulnerabilities are rooted in the representation of web content, which only loosely separates data from markup and enables an attacker to manipulate a website or even execute code through malicious inputs deliberately breaking this separation. Therefore, special care has to be taken when inserting user-controlled data into web content.

This problem of XSS is further exacerbated by the wealth of representations available for describing web content. For example, HTML documents can be interspersed with resources spanning various languages, such as Cascading Style Sheets (CSS), JavaScript code, Scalable Vector Graphics (SVG) and even mathematical expressions (MathML). As a result, XSS vulnerabilities can arise in any of these formats if user-controlled data is inserted without sanitization.

However, this *mishmash* of languages also imposes requirements on any attack exploiting XSS vulnerabilities. As each language defines its own syntactic and semantic rules, an attack payload has to be tailored to the exact location where it is inserted in the document. In the following, we refer to this location as the *injection context*. Similarly, protection mechanisms need to be context aware to correctly assess what constitutes dangerous input for a specific injection context. This makes it challenging to defend against XSS [37, 48].

To illustrate the role of the injection context, let us consider the running example in Figure 1. The code snippet contains three lines, each highlighting a different injection context: inside of an HTML `a` tag ❶, as a URI in the `src` attribute in the `iframe` element ❷, and as a double-quoted string inside a JavaScript code context ❸. Input injected at each of these three points is processed by a different parser, namely the HTML, the URI and the JavaScript parser, respectively. Consequently, each of these injection contexts and their many variations require substantially different attack payloads tailored for the syntactic and semantic rules of said parser and context.



In order to successfully achieve code execution within one of these injection contexts, one needs to craft a payload that either directly calls a JavaScript function or moves into a parsing state where this is possible. Especially the URI case highlights how not only the current parser state, but also the directly preceding ones are relevant for success. For example, the `src` attribute of the `iframe` at ❷ is directly exploitable with a JavaScript URI, unlike the `src` of an `img` tag. Instead, we would have to move to a different parsing state first by trying to break out of the surrounding quotes.

```
1  <a href="..."> ❶ </a>
2  <iframe src='❷'></iframe>
3  <script>if (x == "❸") { ... }</script>
```

Figure 1: Code segments depicting injections in three different contexts: In HTML ❶, in a URI ❷, and in JavaScript code ❸.

Therefore, to craft an XSS payload an attacker has to deduce the injection context first. This is usually done by either manual testing, where the tester analyzes the website's code, or automatic payload generation in the presence of perfect information. The latter, in particular, received a lot of attention from researchers applying *taint tracking* techniques to uncover these vulnerabilities [19, 22, 26, 41, 42]. In short, these approaches use a modified browser to mark all data entered via user-controlled *sources* as *tainted*. This taint information is then propagated through the browser until it enters a *sink* functionality, which potentially results in code execution.

While the detection of *reflected XSS* vulnerabilities has been thoroughly studied, the *server-side stored XSS* variant, i.e., when the payload is not directly executed and instead first stored on the server, is still a hard-to-detect XSS type [13]. The main challenge with this variant is that it requires reasoning about *intra-page dependencies*: The page where the payload is inserted to be subsequently stored somewhere,

(a) (b)

Figure 2: Attack flows of *stored XSS* (a) and *blind XSS* (b) vulnerabilities. Only the stored XSS scenario allows the attacker to inspect the injection context to adapt their exploit.

might only be indirectly related to the page where the exploit actually triggers after it is read from storage. However, as long as these two sides are publicly accessible, a manual tester or automated system can still incrementally adjust the stored attack payloads to explore the server-side processing and finally derive a working exploit.

One particularly challenging variation of stored XSS is the so-called *blind XSS* (BXSS) vulnerability, where even this context information is no longer available.

2.1 The BXSS Attack Scenario

As part of the deployment of larger web applications, there are often further web-based backends involved beyond what is accessible for visitors from the Internet. Typical use cases for such intranet web applications are administration, monitoring, visitor statistics, and back office tasks. While these applications are usually protected by a firewall from direct outside attacks, they can still be susceptible to XSS attacks if malicious inputs reach these internal sites. For example, a monitoring system might read web server access logs from the public part of the website and display all *Referer* headers on an internal webpage, allowing insights into visitor behavior. However, if these attacker-controlled header values are not properly sanitized, they could result in XSS on that internal page. Due to their purpose, the consequences of successful attacks on these internal pages can be especially high, as these pages are only visited by privileged users and might allow administrative actions. Moreover, these backend systems might not be part of the application's threat model and therefore might have received less security attention.

The main challenge in this scenario from the attacker's perspective is that they have no information where their payloads might end up, hence the name blind XSS. Without any feedback that allows them to identify the injection context in the backend's markup, dedicated XSS payload creation through means such as taint tracking is impossible. Even worse, only a successful attack provides information on the vulnerability and allows to exfiltrate information about the backend. All unsuccessful attack attempts provide *no* information to an attacker who is totally in dark about in which context the malicious payloads is injected, whether it has been adapted, or if simply nobody visited the backend system to trigger it.

Figure 2 further illustrates this crucial difference: As Figure 2a shows, the attacker can access the vulnerable page, learn about the injection context and adapt their payload accordingly in the stored XSS case. However, they have no way of inspecting the admin panel in the backend in the blind XSS case depicted in Figure 2b. Due to these challenges and to the best of our knowledge, blind XSS has not yet been systematically studied and no automated approach to uncover these vulnerabilities exists, so far.

Threat model. We consider the following threat model: The attacker interacts with a publicly accessible website that might or might not be indirectly connected to an internal website via a storage mechanism, such as a database, log file or internal web service. The attacker has no knowledge about any internal webpages, the used storage technology, or data transformations steps in between. There is no feedback unless the attack is successful. The attacker's goal is to achieve code execution via XSS in the context of an internal web application of the website's backend, once visited by a person with access or an automated system with a full browser. All other payload entry points besides publicly accessible websites, such as phishing emails, are out of scope for this work.

2.2 XSS Polyglots

Ideally, we would overcome this challenge of not having a feedback by creating a *universal XSS payload that triggers in all contexts*. As previously described, we need to consider several different parsers for this, as our payload could end up inside any of them. A construct that is valid input in multiple formats and/or languages is a so-called *polyglot* [23]. For example, GIFAR is a technique to create a file that is both a valid GIF image and a valid Java Archive (JAR) [5].

In the context of this paper, *polyglot* refers to an XSS exploit that is able to execute in multiple injection contexts, such as HTML and JavaScript code. Moreover, *payload* refers to the part of the exploit that is actually executed, e.g., `alert()` or `import()`. Coming back to our example in Figure 1 and assuming we want to execute the payload `alert()` for demonstration, the three different injection contexts require different conditions for the payload to be executed.

For the HTML context inside the anchor tag in injection ❶, we first need to close that tag and then need to insert an element that executes code, e.g., like this: `</a><script>alert()</script>`.[1] On the other hand, the second injection context expects a URL ❷. While we could try to break out of the surrounding quotation marks, this might not be possible due to sanitization. One solution is to instead use

[1] The dangling `</a>` will be ignored by the browser.

a JavaScript URI, e.g., by supplying `javascript:alert()`. Finally, the injection context in JS code ❸ requires us to break out of the quotes and close all expected parentheses to make sure that the code does not break, e.g., `");{}alert();//`. The two trailing slashes are important to comment out the rest of the line to avoid a syntax error.

For this simple example, we can still come up with a polyglot by carefully combining all three exploits by hand: `javascript:alert()//");{}alert();//</a><script>alert()</script>`. For case ❶, this just puts a lot of "garbage text" into the anchor text before closing the tag and executing the script. For case ❷, this is interpreted as a URI with valid JavaScript code and a long trailing comment. Finally, for injection ❸, this puts the URI in the string, closes the `if`-branch and executes our payload, while ignoring the rest due to the second `//` comment.

However, this polyglot just covers three contexts and there are a lot of variations where it would not work properly. For example, injection ❶ could also happen in the `href` attribute, with either single or double quotes, or might be inserted via `innerHTML` where the script tags do not execute but event handlers do [49]. As another example, ❸ would result in a syntax error when the code has an `else` branch, as our inserted `alert` would break the `if-else` construct. Covering *all these common variations of all contexts* results in an explosion of possible combinations, making manual polyglot construction extremely tedious, if not impossible.

```
1 //Read from a stored object without injection into the source
2 document.location = someObj.redirectLocation;
3 //Directly injected into the source code of a .js file
4 var foo = ❹;
```

Figure 3: Two injection contexts that are mutually exclusive, i.e., can not be solved by the same XSS polyglot.

As an additional complication, some injection contexts are *mutually exclusive*. Figure 3 shows one example of such a case: The first injection context is only possible to solve by exploits starting with `javascript:` as such a JavaScript URI does not trigger an actual navigation, but instead executes the subsequent code in the context of the current document. Starting with anything else will either fail, as escaping from the statement is impossible without a direct reflection into the source code, or cause a navigation away from the website that was the target of the attack. On the other hand, there are also injection contexts that do not allow `javascript:` at the very beginning, e.g., the injection context in Figure 3 at position ❹, as the colon produces a syntax error on the right side of the variable assignment. Illustrated by these two examples, mutually exclusive injection contexts thwart efforts to construct *one* universal XSS polyglot. On the other hand, full coverage could be achieved with one payload per context. However, we aim at creating a small *set of polyglots* while still covering the entire state-of-the-art testbed. From a tester's perspective, this results in less required tests and less system log noise. From a researcher's view, it means less submissions and thus less noise and reduced load for systems-under-test.

2.3 Research Questions

Constructing a set of powerful polyglots is key to the analysis of blind XSS, as it makes it possible to successfully trigger vulnerabilities without feedback. While previous work has focused on manually engineering polyglots [11, 27, 45], we argue that an automated process is inevitable here to handle the amount of injection contexts. This leads us to the following research questions that structure our work:

RQ1: Is it possible to automatically create a set of XSS polyglots that are capable of covering all common injection contexts in combination?

RQ2: Do these synthesized polyglots scale up to real-world settings and how do they compare with existing XSS detection approaches?

RQ3: Can these polyglots be employed to perform a large-scale analysis of blind XSS and indicate vulnerabilities in web application backends?

To address these research questions, we conduct a series of experiments: In Section 3, we introduce a method for synthesizing polyglots using concepts from game theory (RQ1). In Section 4, we assess the real-world performance of these polyglots, comparing them to traditional approaches (RQ2). Finally, in Section 5, we perform a large-scale study to detect BXSS vulnerabilities in the wild (RQ3).

3 Synthesizing Polyglots

The generation of a polyglot is a challenging task. Unlike attack payloads designed for a single environment, we are faced with multiple programming languages and contexts. Although a polyglot is basically just a string of characters, conceptually it is a chimera made up of terminal symbols from different grammars. Some of these characters are even ambiguous and only parsed correctly when the respective injection context is known. To cope with this complexity and ambiguity, we develop an automated approach that phrases the synthesis of a polyglot as a discrete optimization problem. The objective is to find a string that maximizes the number of exploitable injection contexts on a given testbed, regardless of the underlying languages and grammars.

This optimization has several constraints: First, evaluating a polyglot on the testbed involves running an entire browser, including HTML parser and JavaScript engine. Second, during the polyglot evaluation, we receive only binary feedback indicating success or failure, making gradient-based optimization unfeasible. Lastly, as discussed in Section 2.2, some test

cases are mutually exclusive. Therefore, we must identify a *set* of polyglots that collectively solve the testbed.

3.1 Monte Carlo Tree Search

Interestingly, the described optimization problem can be cast into a game in which a player iteratively modifies a polyglot to exploit as many contexts as possible. In this game, moves correspond to changes of the polyglot, while its reward is determined by the number of exploited contexts. Different algorithms exist for solving such games, ranging from simple search strategies to reinforcement learning [35].

For our analysis, we focus on the concept of Monte Carlo tree search (MCTS) [6] that is known to find strong moves in round-based games, such as Chess and Go [38]. The generation of polyglots, however, is agnostic to this algorithm and thus we present a comparison of MCTS with other strategies for solving the underlying game in Appendix C.

Technically, MCTS simulates multiple games to conclusion to gather knowledge about promising game states. To keep track of the performance, MCTS constructs a game tree in which each node corresponds to a polyglot and contains two attributes: a visit and a win counter. The algorithm explores a path in this tree using four steps:

1. *Selection:* Starting from the root node of the game tree, an unexplored child or the most-promising child node is selected until a leaf node is reached.
2. *Expansion:* If the selected leaf node is non-terminal, the game tree is expanded by generating the child nodes of the leaf node.
3. *Playout:* Starting from the leaf node, random nodes are explored until a terminal node is reached. This is equivalent to performing random moves until the game ends.
4. *Backpropagation:* On the path back to the root, the visit counter is incremented by one and the win counter is updated according to the result of the simulated game.

During the selection phase, MCTS balances exploitation (selecting moves that were successful in the past) and exploration (gathering knowledge about unexplored areas). To rank each child i, we use the upper confidence bound $\frac{w_i}{n_i} + \sqrt{\frac{2 \ln N_i}{n_i}}$ where w_i is the number of wins, n_i is the number of visits and N_i is the number of visits of the parent node. If a child has not been explored before, i.e., $n_i = 0$, it takes precedence.

3.2 Synthesizing Polyglots with MCTS

To reduce the extensive search space, we incorporate expert knowledge into the construction of the game tree: Instead of operating on all characters, we generate polyglots only from a set of tokens, such as `<` and `script`. We refine these tokens with simple rules that prevent invalid combinations form appearing, such as `svg` appended to `iframe`. As a result of this reduction, MCTS omits moves that are impossible to yield reasonable polyglots. The resulting token set consists of HTML literals, HTML tag names, HTML event handler content attribute, and other HTML tokens. The complete list including the rules can be found in our companion repository.

Starting from an empty string, MCTS iteratively appends tokens to it to expand the game tree and measure the polyglot's reward. Unlike conventional games, however, this game has no clear end state, since polyglots can be arbitrary long. We therefore set a fixed limit of 400 characters, after which we stop appending tokens to the polyglot. Since this fixed length condition might lead to superfluous tokens, we employ a minimization strategy afterwards (see Section 3.4).

To evaluate a polyglot during search, we implement a fast, manually created testbed covering 27 common XSS injection contexts using Puppeteer (13.1.3) based on Chromium (98.0.4758.0). The complete testbed is included in our companion repository. In the regular MCTS backpropagation, each polyglot would be assigned a score used to update the win counters on its path. Since we evaluate the polyglot on multiple test cases simultaneously, however, we receive a list of scores on each playout. Instead of saving only one score, we thus save the entire list and sum it up, once we need the total score w_i for a particular node in the tree. As a result, we can keep track of the individual tests solved by a particular polyglot during construction. This gives us more flexibility: When some test cases have already been covered, we can exclude them from the score calculation in later runs.

The final synthesis of one polyglot is shown in Algorithm 1: Starting from the root node, we use MCTS to explore the game tree for N rounds until we fix the first move, i.e., select the first token of the polyglot. With the first token in place, we repeat the process N times and select the second token. We continuously start the game from a deeper root node until the depth limit D is reached. At the end, the polyglot with the highest score is returned.

```
   Input: root, start node for generation
   Input: D, maximum depth of the root node
   Input: N, iterations until a move is chosen
   Output: polyglot string
1  bestPolyglot, bestScore ← null, 0
2  for i ← 1 to D do
3      for j ← 1 to N do
4          leaf ← select(root)
5          expand(leaf)
6          polyglot, score ← playout(leaf)
7          backpropagate(leaf, score)
8          if score > bestScore then
9              bestScore, bestPolyglot ← score, polyglot
10         end
11     end
12     root ← choose_best(root)
13 end
14 return bestPolyglot
```

Algorithm 1: Generating a polyglot

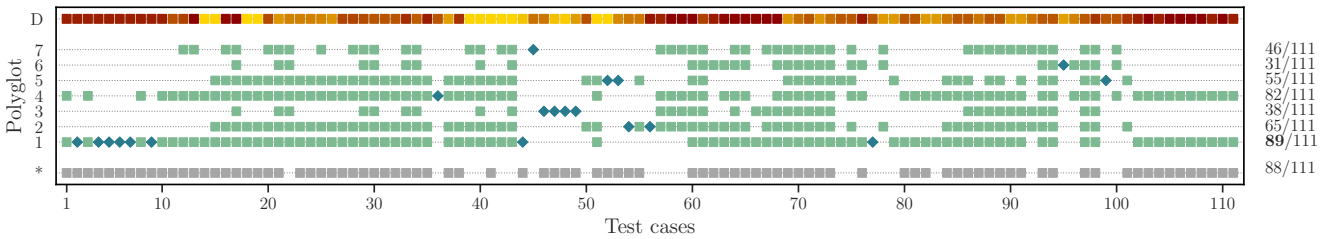


Figure 4: Composition of our minimal polyglot set solving all 111 test cases of our testbed. Squares (■) indicates solved tests. The top row (D) visualizes the overall difficulty of each test case, calculated from the total ratio of polyglots we generated that solve this test i.e., *difficult tests* with fewer solutions are red (■), while the color of more *frequently solved* tests gradually shifts to yellow (■). The numbered rows show the performance of our polyglot set. Diamonds (⧫) are placed instead of squares, where only one polyglot in the set solves a test. For comparison, the bottom row (*) shows the performance of the Ultimate polyglot.

At best, our approach would generate a single polyglot to "rule them all", that is, solve all provided test cases. However, our analysis reveals that depending on the test cases, this might not be possible. For example, as discussed in Section 2.2, some injection contexts are mutually exclusive and a polyglot providing proper execution of JavaScript code in both cannot exist. As a remedy, we develop a strategy for combining multiple polyglots into a set.

In particular, after one polyglot is created, we remove the test cases it solves and start over the search process of MCTS. As result, by design, we seek a complementing polyglot that focuses only on those cases the previous one cannot solve. We continue generating new polyglots using Algorithm 1, until all tests have been covered or a maximum number of tries is reached. Finally, we obtain a set of polyglots that solves the entire testbed of the synthesis process.

3.3 Selecting a Final Polyglot Set

While we synthesize polyglots on a fast testbed, we use a larger testbed to determine the quality of the generated polyglots. For this purpose, we set up a local instance of the Google Firing Range (GFR) [15], which is a state-of-the-art XSS testbed [3]. We manually choose a subset of GFR tests for our scope, based on the following criteria: First, we exclude non XSS-related test cases. Second, in cooperation with Google, we obtain a list of GFR tests that have a known solution which we manually confirm. We further exclude tests exceeding our scope, namely exploits relying on specific frameworks and those requiring a specific encoding. Tests that aggressively block special characters with an error page, e.g., any request that contains < or >, are also excluded. While solutions for these tests exist, their solution needs to be so narrow that they are no longer a polyglot and thus also out-of-scope. We confirmed all solutions and verified that an applicable solution exists for our requirements. A detailed list of the excluded tests and the specific reasons can be found in Appendix D.

After generating 4000 polyglots over multiple runs from different seeds, we utilize a greedy min-set cover approach to select a minimal subset that solves all GFR test cases. We build this minimal set by adding the polyglot to the set that solves the most tests yet unsolved by the set, until no additional solutions can be added. Our final set of polyglots that is used in our study consists of 7 instances. Thus, we answer RQ1 and show that it is possible to automatically create a set of XSS polyglots that cover common injection contexts. To compare the efficacy of our final polyglot set with a publicly available polyglot, we chose the best polyglot from the blog posts mentioned in Section 2.3—the *Ultimate XSS Polyglot* [11]—as our reference. Now, to display the composition of our polyglot set, Figure 4 visualizes our evaluation results for each polyglot on the 111 test cases. We give an indication of the difficulty of synthesizing a solution for each test by assigning a color to each of them. The number of polyglots from our full set that successfully solve a test, determines its difficulty. Tests for which we synthesized fewer solutions tend to be more challenging and are depicted in red. In contrast, the color of easier tests, i.e., those with more solutions, gradually shifts to yellow. The numbered rows below correspond to each polyglot of our final set, while the bottom row displays the Ultimate polyglot's score. Indicated by diamond symbols in the corresponding rows, each polyglot in the final set contributes at least one unique solution, e.g., polyglot 4 is the only in the set solving test 36. The plot shows that our polyglots cover all test cases, ranging from 31 to 89 tests covered by each individual polyglot. The Ultimate polyglot works surprisingly well and manages to cover 88 tests. However, our automatic polyglot set creation outperforms manual engineering, as our generation process can target gaps left by previously synthesized polyglots.

3.4 Minimizing Polyglots

Since our generation uses a termination criterion that sets a fixed minimum length for a polyglot, it is possible that some tokens in the polyglot are superfluous. In general, this would not constitute a problem, but some websites have length constraints to the inputs in their backend. To make sure that

such obstacles do not obstruct our polyglots, we minimize the lengths of our final polyglots. The objective is to find the smallest polyglot with equivalent test results on the GFR testbed. The minimization is done automatically and at token level, i.e., we first deconstruct each polyglot into its tokens. Since each token could be removed independently, there are 2^N minimization candidates where N is the number of tokens in the polyglot. Instead of testing all 2^N options, we build our minimization strategy on a single assumption: If removing a token changes the test results, then all minimizations in which that token is removed are invalid. Although there might be edge cases, where this does not hold true, this drastically reduces the search space as we can first test each token separately. Our polyglot minimization then involves iteratively removing combinations of tokens until no more tokens can be removed without altering the evaluation result. Overall, in every polyglot (except for one), some unnecessary tokens have been identified and removed. For the other polyglots we achieve a reduction between 6% and 24%.

4 Validation on Real-World Websites

While our test bed and the Google Firing Range cover a wide range of XSS vectors, they can only serve as an artificial evaluation that is not necessarily representative of the polyglots' ability to discover vulnerabilities in real-world code. Thus, in this chapter we set out to validate how well our XSS payloads perform on actual websites with non-trivial codebases and to compare them to state-of-the-art techniques for detecting XSS that leverage targeted exploit generation.

More precisely, we evaluate our XSS polyglots on a set of recently found real-world client-side XSS (CXSS) vulnerabilities. CXSS has several advantages in the context of our experiments: While exposing the same characteristics as other classes of XSS, especially in respect to injection points and syntactical restrictions, it allows precise exploit payload generation, thanks to the availability of full data-flow information [22, 26, 42] (see Sec. 4.1 for details). Furthermore, research experiments utilizing CXSS offer the invaluable benefit that the complete exploitation attempt is conducted solely on the client-side. Hence, potential negative side effects on the real world websites can reliably be prevented.

4.1 Targeted XSS Exploit Generation

As the baseline for the prevalence of CXSS vulnerabilities, we re-use a state-of-the-art taint tracking engine [36] and the associated exploit generation by Bensalim et al. [4]. In the following, we give a short overview of their approach, using the code in Figure 5 as an illustrative example throughout.

In general, the idea is to browse the web with a modified taint browser while constantly monitoring and analyzing all data flows. Once the taint browser detects a data flow that is

```
1 let d = document.getElementById("..");
2 let href = decodeURIComponent(window.location.href);
3 d.innerHTML = '<a href="' + href + '">';
```

Figure 5: A typical Client-Side XSS vulnerability.

potentially susceptible to CXSS it has the following information available: The source (here `location.href`), the sink (here `.innerHTML`), what characters from the source ended up in the sink, as well as the whole string entering the sink.

With this information, the exploit generation strategy works as follows: The first step is to generate the so called *breakOut* sequence, which aims to close the current context (here the double quoted `href` attribute) and put the parser into a state where we can insert a XSS payload. Several HTML tags, such as `iframe` or `textarea` prevent code execution of their children. So the *breakOut* will close those tags as well. Next, a context specific payload is generated, this is based on the sink function, as `innerHTML` requires a different payload than, e.g., `eval()`. The payload generated by the exploit generator for `innerHTML` is `<img src=x onerror=f()>`. If this report function is called, we know that the generated exploit was successful. However, with remaining markup from the original `<a>` tag, we must first create a *breakIn* sequence. Its purpose is to "consume" the leftover characters , ensuring the parser proceeds without errors. While this step is usually unnecessary in the HTML context due to the parser's leniency, it becomes critical in the JavaScript context. A suitable *breakIn* would be to comment out the remainder of the document.

Finally, these three parts (*breakOut*, generated payload and *breakIn*) are concatenated and inserted into the URL at the appropriate position. For our running example, the insertion point would be to simply append the generated exploit in the fragment of the URL. Therefore, and in contrast to our polyglots, each exploit generated with this approach is designed to work for *one* specific data flow on *one* website only.

4.2 Validation Experiment Setup

To compare the performance of different approaches on real-world websites, we surveyed the top 10,000 domains according to the Tranco list [20] as of Dec. 15, 2022, available at https://tranco-list.eu/list/W95V9. For each successfully visited site, we queued up to 10 subpages, enabling us to capture vulnerable data flows that might not be apparent on the landing page. All relevant data flows for CXSS were stored in a database, and we concurrently visited the generated exploit URLs to validate them. The exploit validation is done with legacy URL encoding, consistent with previous works [19, 22, 26, 41]. For each URL generated by the exploit generator, we systematically replaced the targeted exploit with each of our 7 synthesized polyglots. Subsequently, we used our crawler to visit these URLs, flagging the exploit as suc-

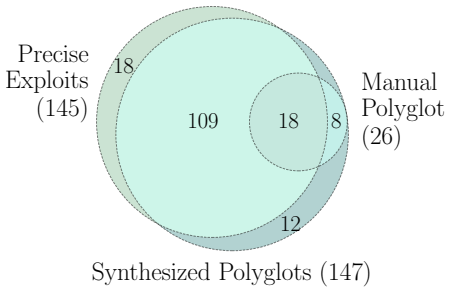

Figure 6: Euler diagram of the performance of the three different XSS detection approaches on the Tranco Top-10,000.

cessful if the callback function was triggered. To assess the effectiveness of our synthesized polyglots in comparison to publicly available ones, we subjected the Ultimate XSS Polyglot to the same treatment, like in Section 3.3. The Ultimate polyglot, like our polyglots, operated without the additional information provided by the taint tracking browser, distinguishing it from precisely generated tainting exploits.

4.3 Comparison of XSS Detection Rates

In total, we generated exploit URLs for 1010 of the visited websites due to potentially security sensitive data flows. We then applied each of the three approaches to see if they can achieve JavaScript execution. Thereby, we were able to successfully validate vulnerable data flows on a total of 165 websites, resulting in XSS. Figure 6 depicts the results of how our synthesized polyglots perform compared to both the perfect-knowledge exploit generation strategy, as well as the ultimate polyglot from prior work, thus answering RQ2. As the figure shows, on 127 out of the 165 websites both our polyglots and the exploit generation were successful. At the same time, it also highlights that both approaches have their advantages as not a single one was able to discover all exploits. However, the ultimate polyglot had the worst performance by far, as it only worked on a fraction of the websites overall while not finding any additional exploits that were not already covered by the other approaches.

We then proceeded to manually investigated the successful exploits exclusively solved by either of the approaches. Examples of data flows where the polyglots did not work as well as the generated exploits were highly specific edge cases such as the one shown in Figure 7, the root cause behind 83% of the websites where the polyglots were unsuccessful but the precise exploit generation succeeded. While this looks like a simple XSS vulnerability that the polyglots should be able to solve, it is important to note that the dynamically created `div` is never added to the DOM. This prevents triggers that rely on the `onload` event handler to fire. Another reason for the polyglots failing to trigger results from the general concept of a polyglot (see Section 2.2). To be valid code in several contexts, they contain syntactic elements of several programming languages. Application code trying to parse the tainted data can break, causing the vulnerable code paths to never be executed at all. Take the polyglot from Section 2.2 as an example. If `data.split(':')[0]` is called on it, it extracts everything in front of the double colon, e.g., to retrieve a field from a complex data structure. For said polyglot this returns `javascript`, a harmless string. The precise exploit generation never adds non HTML characters such as double colons, and as such its payload would be included in the extracted text.However, their rich syntactic structure is a positive in other cases, because they are able to evade broken sanitizing routines. One common mistake for input sanitization is misunderstanding the `replace` semantics and only replacing the first occurrence of the needle by mistake according to Klein et al. [19]. Due to containing several code execution triggers, our polyglots are able to evade such a faulty sanitization routine whereas the generated exploit does not.

```
function read_href(url) {
  var div = window.document.createElement('div');
  div.innerHTML = '<a href="' + url + '"></a>';
  return div.firstChild.href;
}
read_href(window.location.href); // somewhere else
```

Figure 7: Problematic data flow not solved by our polyglots.

After demonstrating our polyglots' exceptional performance in detecting CXSS flaws on real websites, we investigate their suitability to discover blind XSS in the next section.

5 Blind XSS in the Wild

So far, we have demonstrated how to synthesize polyglots and have found that their effectiveness in identifying reflected XSS is comparable to existing approaches. In this section, we design and conduct the first large-scale study of blind XSS in the wild. Our study is based on the synthesized polyglots. Hence, it demonstrates their unique advantage in uncovering BXSS vulnerabilities. Additionally, we show the importance of using a set of polyglots instead of a single one.

We are aware of our responsibility to conduct this study in an ethical manner and, in accordance with the Menlo report [18], we designed it to prevent harm. Most importantly, if a polyglot should trigger, it will only connect back to inform us about its execution. These benign tests allow us to measure the scope of the problem and warn website owners to close security vulnerabilities before they can be exploited. We consulted our funding project's institutional review board (IRB) which concluded that the potential gain for system security predominates potential extra work for website operators. Further technical details are found in Section 5.4.

5.1 Polyglot Preparation and Monitoring

A polyglot triggers all vulnerabilities it can cover. However, due to the nature of blind XSS we cannot directly observe when this happens in a backend. Hence, we design the polyglots to notify our monitoring server if they are executed due to a vulnerability. We outsource this notification mechanism into a remote *notification script* instead of embedding the required functionality into the polyglots for multiple reasons. To begin with, using a replaceable remote script makes polyglot synthesis easier, as we only have to optimize on import mechanisms as our polyglots' core functionality. Additionally, testing is sped up, as the imported code can be easily replaced without syntactically changing the polyglots. In contrast, embedding the required notification functionality would introduce additional characters to the polyglots which would increase their length and extend the required character set which in turn may trigger additional input filters potentially reducing the polyglots effectiveness in the field. Finally, using a remote script enables us to render polyglots ineffective by stopping to serve the notification script, e.g., once the study concludes after a certain period.

To achieve traceability from polyglot submission to individual vulnerabilities we assign each submission a unique 12-character ID. This ID encodes how (URL, form, or header) which polyglot was submitted to and on what (backend) page it ended up being executed. This ID is embedded in the URL a polyglot's import functionality takes, e.g., JavaScript `import` statements or the `src` attributes. Exemplarily, a polyglot requests the notification script from our monitoring server upon execution, e.g., via `import('https://<ID>.<monitor_host>/s.js')`. The monitoring server can then extract the ID from the requested script's URL and embed it into the notification script before returning it. The script in turn includes this ID in the feedback ping it returns back to our monitoring server when executed. Using this submission ID, a backend vulnerability can be linked to a specific submission on a particular website.

Notification Script The notification script (Appendix A) returns information required for accurate detection and effective disclosure of a blind XSS vulnerability. When executed, the script returns the document's title, its URL, excluding query and fragment, as well as the JavaScript user agent and platform. It encodes the information, the submission ID, and the current timestamp in the URL of an HTTP request bound to our monitoring server. Upon receipt of such a request, we indirectly receive the IP address of the sender, which we require for the disclosure process. Section 5.4 further discusses the usage and implications of the collected data.

5.2 Polyglot Transmission

There are three general ways to transmit our synthesized polyglots to the websites we visit, where they can get passed to backend systems: *headers*, *URLs*, and *forms*. In the following, we will briefly outline considerations for each of them.

HTTP Headers. To test backend logging applications, we submit polyglots in four request headers. The Referer header, often containing the previously visited URL, is valuable for analytics and tracking [24]. Similarly, the User-Agent header aids analytics, by revealing browser and platform usage patterns. Polyglots in the Cookie header may get logged for failed authentication. Additionally, we utilize the less-known Warning header, particularly warning code 199, used to transmit loggable information [25]. Despite its deprecation, all major browsers still support it. We employ HTTP GET requests to transmit each header, embedding the polyglots as either direct values or in suitable contexts like `Cookie: test=<polyglot>`. To identify which header triggers feedback, we individually send each polyglot ro the landing pages via a GET request for each header mentioned.

HTTP URLs. Similarly to headers, URL submissions via the *query* and *path* are issued for each website with each polyglot. For every landing page visit, we append an artificial subpath, followed by the polyglot as another subpath, e.g., `http(s)://domain.com/<path>/<polyglot>`. Analogically, in query submission, we employ an artificial query key with the polyglot as its value, e.g., `http(s)://domain.com?<query>=<polyglot>`. We use artificial paths and query keys, because our goal is not to find reflected and stored XSS flaws in existing functionality. Instead, our aim is to transmit our payloads to web-based backend systems with potential blind XSS vulnerabilities. Moreover, we perform this action only once on the landing page, avoiding excessive warnings for website operators.

HTML Forms. Finally, we also analyze the HTML code for each page that we visit and extract all contained HTML forms. For each form, we first check if the allowed length of each input given by the `maxlength` attribute is enough for our longest polyglot. Moreover, we have measures in place to prevent duplicate form submissions. On par with previous work [28], a form is considered new if at least one value differs from previous forms: (a) its `innerHTML` representation (excluding default values and whitespace), or (b) the form's target domain. For all the remaining unique forms, we fill all inputs with one polyglot at a time and submit the form.

5.3 Identifying Blind XSS

Generally, we expect a mix of automated business logic tools, and manually operated monitoring and administration platforms to trigger our polyglots. The former may react to our submissions instantly, while the latter may be bound to human

interaction and thus only trigger sporadically. Therefore, we give each submission a time frame of 2 months during which we monitor it. In the following, we explain our approach to confirm that triggered polyglots are of the blind XSS type.

We define three cascading filter steps to narrow down our findings to blind XSS and thus discarding reflected and stored XSS on the way: (1) Feedback pings have to come from an IP address different to our crawler's IP, otherwise we triggered a reflected XSS. (2) The URL where we submitted our polyglot has to differ from the URL where it triggers, otherwise we found a trivial stored XSS where the attacker could have adjusted their payload in this non-blind setting. (3) The URL where the polyglot triggers may not be publicly accessible, only then we have discovered a blind XSS vulnerability with no way for the attacker to learn about the injection context. Otherwise, we found a non-trivial stored XSS, where the two URLs differ and their connection needs to be discovered first, but both are nevertheless publicly available.

To test this, our monitoring server initiates an additional confirmation step for each newly reported BXSS candidate URI immediately after receiving a feedback ping. In this step, the server conducts an extra visit to the reported URI to assess its public accessibility. At this stage, our filter (3) confirms invalid or local URIs, as well as private IP addresses as BXSS instances where our polyglot reached and executed in a backend system. However, even if the page did load, some cases may still qualify as BXSS. For instance, we encountered public pages that required authentication to access their content. Since the identification of login pages is hard to automate [9, 17], we manually investigated and labeled these websites as either BXSS or false positives.

5.4 Ethical Considerations

Conducting server-side studies requires careful ethical consideration. To this end, we followed best practices outlined in the Menlo report [18], and aimed at uncovering real-world BXSS scenarios while ensuring minimal impact on operators and users. We decided on a large-scale study without the operators' consent. This is a difficult and controversial decision that requires a thorough investigation of the potential harms and risks. We discussed this decision in detail with our IRB and received approval. Nevertheless, we recognize the weight of this decision and the potential for alternative options, the advantages and disadvantages of which we discuss below.

Alternative study designs. Auditing *open-source applications* for BXSS vulnerabilities offers a first choice. This method comes with no ethical issues but its results are limited by the proprietary nature of production code and the unpredictable configurations of live websites.

Analyzing simulated backends in a *lab environment* offers another choice. While ethically unproblematic within a confined environment, accurately mirroring the nuances of real-world backends poses challenges, often necessitating insights from active operators on their particular setups.

Real-world studies, especially a *small-scale study* with prior operator consent, emerge as another solution, allowing operators to take precautionary measures to minimize harm. Given the—at the time of our study—unknown prevalence of BXSS and indications of its rarity [2, 8, 13, 34], we decided to discard this study design. However, an appropriate selection of operators might provide representative results.

We chose the final option, conducting a *large-scale study* of the top-ranked website without acquiring operator consent. While offering a direct and unbiased approach to a representative analysis of the subject, it is important to note that this strategy is ethically problematic, even if tests are extremely carefully designed. We remark that the other alternatives would also be applicable with different compromises between ethical implications and gained insights. In general, we recommend thoroughly considering different study designs and additionally engaging with an IRB upfront. Thus far, our study has incurred no reported damages or problems, attesting to the effectiveness of our design in preventing harm. Our results revealed 20 vulnerabilities among the top 100,000 websites underlining our initial assumption of the rarity of BXSS. Nonetheless, it is imperative to stress that any retrospective analysis does clearly not provide justification for the decisions made in a study.

It is crucial to highlight that conducting studies without proper consent or assuming consent from non-responsive parties is not ethically sound. Our research should thus *not* be viewed as a template for similar studies. Based on our discussions with the IRB, we believe that our work represents a good compromise in this regard. However, we acknowledge that alternative study designs could have been employed to mitigate the risk of harm more effectively, though at a higher risk of reduced insights. Scientific work often navigates complex terrains, demanding thoughtful balancing of conflicting interests. We selected—to the best of our knowledge and belief—a suitable balance, which is certainly not without debate.

Side effects. All test requests contain minimal JavaScript payloads that do not affect the global namespace of the surrounding application ensuring that no unintended side effects on legitimate code occur. In the rare cases where the initial polyglot succeeds, a second script is retrieved from our servers for data collection. This two-step process enables us to deactivate the notification script for specific IDs or entirely at any time, serving as an additional *mitigation strategy*.

As a result, a test polyglot can only trigger on vulnerable pages, ensuring that non-vulnerable web applications, which constitute the vast majority, receive only the polyglot without any unintended behavior or side effects. However, for vulnerable websites, a notification function is essential to initiate disclosure to the affected parties and improve their security. Otherwise, our blind XSS tests would remain "blind".

Information collected. In alignment with user privacy our notification script (Section 5.1) only returns information that we use for accurate recognition and effective reporting of blind XSS executions in backends. We verify instances of BXSS using the IP address and partial backend URL. As part of the disclosure process, we can provide operators with both pieces of information, plus the user agent and platform strings. The user agent information offers operators an advantage in assessing the potential impact of our reported vulnerability, as they help to distinguish between manual and automated operations. Finally, we utilize the backend path in conjunction with the page's title as indicators of shared root-cause components, allowing us to additionally report our findings directly to the developers of these components.

Candidate selection. In our *candidate selection* process, we adhere to the "fairness" principle outlined in the Menlo report by considering the top 100k Tranco domains. With focus solely on blind XSS, we use a *canary test* to filter out websites, like guest books, that mirror user inputs, avoiding stored and reflected XSS triggers. This test populates new forms with random tokens, subsequently checking the HTTP response and page's HTML for them. To reduce load on targets, we test each site's functionality only once, ensuring unique submissions by checking for existing duplicate header, URL, or form submissions, detailed in Section 5.2.

Transparency. For *transparency* and to facilitate an *opt-out* procedure, our monitoring host offers information. Our notification script's URLs' landing page details the project, the data we collect, and contact information for potential withdrawal from the study. Through this channel we received two notifications from one Internet services company regarding suspicious traffic from our IP. We addressed this by excluding the respective domains from subsequent visits.

Though informing thousands of operators in advance is not scalable, we ensured a *vulnerability notification* was sent to the technical contacts of all affected websites. This ensures that the underlying defects are fixed and thus exploitation is no longer possible. Consequently, our study's benefits in improving website security outweigh potential negatives, like polyglots causing a manual investigation.

Design implications. Although these ethical measures cannot completely eliminate the risk of a polyglot leading to a technical failure on one of the websites, we argue that the gained insights about blind XSS and the notification of all affected sites jointly outweigh this risk and make our study a valuable contribution for improving web security.

When designing our methodology, we chose to directly collect paths and titles to identify shared root-cause components. For instance, Table 1 indicates a common tool shared by backends D and F, discerned through paths. Backends B, D and F even explicitly mention such a tool's name in their title. We used that information to inform the respective vendors, as the vulnerability could have its root cause in a commonly used software component.

We recognize that our data collection methods, though designed with great care, are not without the risk of inadvertently capturing sensitive information in certain parts of our collected data. Specifically, titles and paths of websites could, in theory, contain credentials, authentication tokens, or other confidential data. It is widely recognized in the field of web development and design that embedding personal data in these fields is untypical and against best practices [cf. 32, 33]. Nonetheless, this remains a significant concern.

Our decision to collect this data was driven by the intent to notify operators of vulnerabilities in their systems, a necessary step we believed was essential for our study. We recognize the potential pitfalls and admit that a more privacy-centered strategy could have been employed.

Our large-scale study was conducted without requesting consent. However, we could sometimes obtain informed consent for certain aspects of the study. Inspired by Utz et al. [46], we suggest an alternative approach for future research. In detail, we could have abstained from collecting the backend's title and path in our initial vulnerability tests. Then during the vulnerability disclosure, where we anticipated a limited but uncertain number of affected websites, we could have procured further information from them. If successful, we could obtain permission to gather additional data, i.e., website titles, in a follow-up experiment, or directly ask about the utilized software components. Such a two-fold approach would have enabled us to obtain informed consent from vulnerable entities while still learning about shared components.

Yet, this method is not without flaws. Our study found a generally limited response rate, consistent with prior research [44]. Hence, this approach poses the risk of missing insights into shared root causes if no responses are received. Nevertheless, future research might explore and evaluate this approach to determine its suitability in different contexts.

5.5 Large-Scale Crawling Study

To answer our last research question from Section 2.3 (RQ3), we perform a large-scale study on the top 100,000 domains according to the Tranco list [20] as of Oct. 9, 2022, available at `https://tranco-list.eu/list/824JV`. We use a crawler based on the Chrome DevTools Protocol [12] to instrument Chromium 105.0.5195.102 in headless mode. For websites permitted by their *robots.txt*, our crawler explores same-site and listed-domain links up to a depth of 5 or 30 subpages per root domain, with random link selection when needed. Each page receives a 60s load window; failure leads to flagging, and the crawler proceeds to another page. Dynamic pages receive 3 seconds post-*load* event for pending network requests.

We conducted our study over the course of 20 days using 60 parallel crawler instances on Ubuntu 20.04.5 LTS. Our monitoring was online during this time to allow observing

each submission for at least 2 months. Of the 1,676,812 visited pages, approximately 7.4% failed to load. Regarding the failures, about 56.1% returned an HTTP error status code. 22.7% of errors can be attributed to network or DNS resolution errors. Further 15.7% of aborted pages tried redirecting outside of the top 100k domains, which we consider out of scope, or to an previously visited domain.The remaining 5.5% are various errors e.g., timeouts when loading the page.

Our ethical considerations regarding deduplication and canary reduced the amount of HTML forms used for submitting our polyglots. Collectively, these measures halved the amount of candidate forms, leaving 46.54% of identified candidates. After respecting each input's given `maxlength` attribute, we submitted a total of 170k forms, along with around 1.9M header and 954k URL submissions, equally distributed between query and path submissions.

5.6 Uncovered BXSS Vulnerabilities

Our submissions triggered 20 different BXSS vulnerabilities on 18 websites. In this section, we present our findings and discuss the uncovered blind XSS cases. Moreover, we also discuss the efficacy of our polyglots and probing mechanisms.

Vulnerable Backends. Regarding the given time frame and considering our initial filter (1) from Section 5.3, we received feedback pings from 28 unique domains. After discarding stored XSS candidates with the second filter (2), we are left with 21 potential backend domains. Of these 21 candidates, the automated part of our final filter (3) confirmed 8 of them to be internal websites and thus BXSS, as their URLs were unreachable e.g., because they were either private IPs, file URIs, local resources, or dotless hostnames [16]. Manual investigation of the remaining 13 reachable URLs confirmed that 10 of them show clear signs of blind XSS: For once, 6 of them were login-protected pages requiring credentials or session cookies. Another case was a web interface for a local Web Socket server that doubles as an informative website if no connection to the Web Socket port can be established, so our crawler flagged it as a public website. Interestingly, the remaining 3 confirmed candidates are, to our understanding, erroneously publicly available backend pages. Strong indicators that the pages' availability is unintended are on the one hand that they make protection-worthy data publicly available, including other visitors' IP addresses and headers, and on the other hand that their parent pages are in contrast access-protected. Ultimately, we count these 10 discussed findings towards blind XSS, resulting in a total of 18 BXSS-vulnerable websites. This demonstrates the polyglots' proficiency at uncovering blind XSS vulnerabilities in the backends of real websites, thus answering RQ3.

The remaining three candidates were manually excluded and labeled as *not in scope* for BXSS, because the tested website and its backend themselves were not vulnerable to our submissions, yet, we received feedback pings attributable to the polyglots submitted to these websites. In all three cases, our notification script triggered in online web tools with no apparent relation to the website we tested, so we refer to this class of findings as *3rd-party XSS*. In each case, the submitted headers were posted to evidently vulnerable online tools hours to days after we sent our submissions. These tools include an online user-agent parser, an online XML editor and beautifier tool, as well as an online URL decoder / encoder. We manually confirmed the three reflected XSS vulnerabilities and excluded them from our blind XSS results.

We disclosed our findings with all affected parties, including the previously mentioned 3rd-party web tools. Subsequently, we received responses in about 19% of the cases, surpassing the access-rate reported in a recent notification study [44]. Notably, the responses we received were entirely positive, with all respondents showing an effort to fix the issue we brought to their attention. Moreover, we were approached by two parties requesting us to retest their fixed website, emphasizing the need for blind XSS testing strategies.

Backend Details. At this point, we discovered 18 vulnerable backends. Table 1 aggregates the BXSS vulnerabilities we uncovered, showing that our findings represent websites from a wide variety of Tranco ranks, popular and less popular. To preserve anonymity, we pseudonymized each domain in the table and shortened path and title for brevity. In many cases, the combination of path and title are sufficient to derive the backend tools' purposes: We observe a mix of administration tools for maintenance, management, and monitoring, as well as tools for infrastructure or business logic. In three instances, B, D, and F, a platform name could be directly derived from the document title. In the first case, we discovered an internal deployment of the frequently used log monitoring and reporting platform Splunk 8.2.3 and its official utility app *Lookup Editor* with our polyglots. The other two turned out to be NetWitness Platform, a popular security information and event management tool. We contacted both vendors to share details of our findings. Similar paths and titles indicate that the same software is used in the respective backends of two website pairs: D, F and I, K. While the sites do not necessarily have to be connected, the location derived from their pings' IP addresses indicate proximity in both cases.

BXSS Vulnerabilities. We count the backends based on the number of affected websites. Since one backend can potentially have multiple BXSS vulnerabilities, we further distinguish between data flows originating from header, URL, and forms. Figure 8 illustrates which submission type discovered which backend. When looking at the three groups—URL, header, and form submissions—the majority (89%) of the backends were triggered by only one submission type. Since the two remaining backends we discovered, I and L, were triggered by both URL and header submissions, we count a total of 20 blind XSS vulnerabilities on 18 websites.

Table 1: BXSS Findings—the 18 backends with the corresponding website's rank, shortened path and title.

Rank	Backend		Backend Path	Backend Title
90–100k	A	⊖	/admin/index.php	"Welcome to service maintenance, admin!"(*)

○ Backend URI is publicly available. ⊖ Backend URI is public, but requires authentication. × Backend URI is unreachable. (*) Title translated.

Submission Triggers. Generally speaking, we observed reaction times from submission to feedback ping ranging from a few seconds for automatic processes up to 10 days for human interaction, with a median of around 6 hours. Regarding the geo location of machines where our polyglots triggered, we received pings from IP addresses across the world, namely Asia, Europe, America, and Africa.

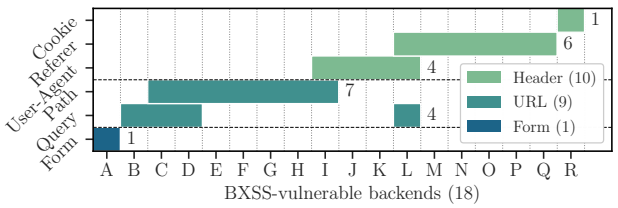

Figure 8: Submission types that caused a polyglot to execute in one of the 18 vulnerable backends.

Next, we further investigate each submission type in Figure 8. When distinguishing between query and path submissions, we found two cases (C and D) where both types triggered in a backend. To clarify, we do not count these as separate vulnerabilities, since these likely follow the same data flow. Interestingly, most other URL submissions that triggered blind XSS were due to polyglots embedded in the path. The three headers mainly triggered the respective backend alone, with the Referer header as the most common trigger. Finally, in only one specific case (L), BXSS in a backend was triggered by query, User-Agent, and Referer simultaneously.

Moreover, the figure also shows that HTTP header submissions, with 10 cases, uncovered the most BXSS vulnerabilities, followed by URL submissions with 9 vulnerabilities. Notably, forms triggered the least BXSS instances with only one occurrence. Potential reasons for this might be the lower amount of form submissions we sent compared to headers and URLs, as well as forms being an expected input vector that may have received more attention regarding sanitization and encoding of data flowing into backends. Despite being the commonly used attack vector [4, 19, 22, 26, 42, 43], URLs still overperform as delivery type for BXSS payloads.

Polyglot Performance. As highlighted in Section 4.3, manually created polyglots may excel in a controlled lab environment but not necessarily demonstrate comparable performance in a real-world setting. Figure 9 displays the efficacy of our seven polyglots in discovering blind XSS vulnerabilities. It shows that all polyglots contributed to our study's findings, with more than half of them exclusively triggering certain individual vulnerabilities. Thus, justifying our divide-and-conquer approach based on complementing polyglots. Overall, polyglot 4 was most successful regarding the number of backends triggered, as well as in the number of backends that only polyglot 4 was able to trigger, followed by polyglot 1, and 7 as the top-performing polyglots. Looking back at Figure 4 it is interesting to see that the polyglot that was most successful in the wild is not our best on the GFR. Overall, this both highlights the need for a *set of polyglots*, as well as the need for a *real-world evaluation* in the wild.

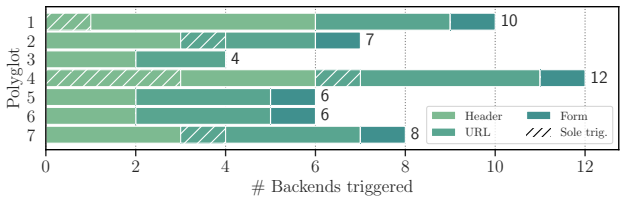

Figure 9: Backends triggered by the submission types. Hatched vulnerabilities were only triggered by one polyglot.

6 Related Work

In the following, we discuss how publications in the area of XSS detection and polyglots relate to our work.

Stored XSS. While reflected XSS has been extensively studied by prior work [e.g. 4, 19, 22, 26, 39, 40, 42, 43], few tried to tackle the detection of *stored XSS* dynamically, i.e., without access to the server-side source code. In 2014, Duchene et al. [10] presented KameleonFuzz, a technique to fuzz web applications guided by a genetic algorithm and a taint tracking engine. In 2015, Parvez et al. [34] analyzed the effectiveness of black-box web application scanners to detect stored vulnerabilities and found that while outperforming previous scanners [2, 8], the overall detection capabilities were still quite lacking at that time. Later in 2019, Steffens et al. [41] expanded taint tracking techniques to also find Stored Client-Side XSS vulnerabilities, i.e., flows from Web Storage and cookies to dangerous sinks. Moreover, Eriksson et al. [13] presented BlackWidow in 2021, which can discover intra-page dependencies during black-box crawling and thus uncover Stored Server-Side XSS vulnerabilities.

ML and XSS. Recently, the use of machine learning (ML), particularly reinforcement learning (RL), has gained traction in aiding XSS vulnerability detection. In 2021, Caturano et al. [7] demonstrated RL's utility in assisting human penetration testers in uncovering reflected XSS vulnerabilities. In 2022, Lee et al. [21] introduced a fully automatic RL approach, albeit limited to reflected XSS. Additionally, Foley and Maffeis [14] applied hierarchical RL to generate XSS payloads that evade the current context and bypass sanitization.

In summary, the dynamic XSS detection approaches discussed earlier share common characteristics. They either rely on full information, employing taint tracking, are limited to Client-side XSS, or require traversing the *whole* web application to identify intra-page dependencies relying on a feedback loop to guide exploitation. In contrast, our polyglot-based approach can detect vulnerabilities *blindly*, without prior knowledge or direct interactions with the vulnerable page.

XSS Polyglots. Some earlier work has also explored the application of polyglots and related techniques in the web context. In 2009, Barth et al. [1] presented a PDF chameleon, which is a PostScript document that also contains some HTML, that led to XSS due to the browser's content sniffing algorithm. In 2013, Magazinius et al. [23] generalized previous attacks such as the chameleon and the GIFAR [5] attack under the term polyglot, and presented further attacks using PDF polyglots along with a small-scale study on 100 websites. Additionally, various blog posts regarding universal XSS polyglots exist [11, 27, 45]. High performance of the manually created Ultimate polyglot [11] on the GFR led us to include it in our baseline (see Figure 4). Mutation-based genetic algorithms [27] constitute an interesting generation approach. However, initial experiments showed subpar results of the published polyglots in respect to the GFR compared to the Ultimate polyglot. This led us to not further pursue this method. Ultimately, these blog posts lack systematic evaluation of their polyglots and, to the best of our knowledge, none of the previous publications studied the application of polyglots in the context of blind XSS vulnerability detection.

7 Conclusion

Our analysis sheds light on a web security problem that has stayed in the dark, so far. While detecting and preventing XSS vulnerabilities in front end code has been a prime topic of research, little attention has been paid to analyzing these issues in backends, largely due to a lack of appropriate tools for blind security testing. Our approach to synthesizing polyglots fills this gap and provides the basis for the first large-scale study of XSS vulnerabilities in backend code in the Web.

The generation of polyglots, however, is not only a tool for research. Our synthesis approach is flexible. It can be narrowed down to specific vulnerabilities as well as expanded by supplementing additional test cases. As a result, it provides a new and versatile instrument for web security that cannot only help investigate public-to-internal flows in backends but ultimately serve as a "Swiss-army-knife" for general vulnerability assessment of web applications.

Acknowledgments

We thank our shepherd and the anonymous reviewers for their valuable suggestions and comments on this paper. Furthermore, we would like to thank Tobias Jost, Vladislav Mladenov, and the remaining NDS team at Ruhr-Universität Bochum for their technical support, as well as Sebastian Lekies for his support with the GFR, and Angela Sasse for her guidance in our study design. We gratefully acknowledge funding by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany's Excellence Strategy – EXC 2092 CASA – 390781972, the German Federal Ministry of Education and Research (BMBF) under the project IVAN (16KIS1168), the European Research Council (ERC) under the consolidator grant MALFOY (101043410) as well as from the European Union's Horizon 2020 research and innovation programme under project TESTABLE, grant agreement No 101019206.

Availability

We have made our code publicly available in our companion GitHub repository at https://github.com/polyxss/bxss, encouraging further research on polyglot synthesis.

A Notification Script

Figure 10 shows the self-executing notification script, which collects minimal information about its execution environment and transmits the information via `XMLHttpRequest` to an API endpoint of our monitoring server.

```
/* Written for ECMAScript 5.1. Please visit <redacted> for further information. Contact: <redacted> */

(function () {
  /* collect minimal information */
  var data = {
    "id": "info",
    "title": document.title,
    "protocol": document.location.protocol.replace(":", ""),
    "domain": document.domain,
    "port": document.location.port,
    "pathname": document.location.pathname,
    "navigator_ua": window.navigator.userAgent,
    "navigator_platform": window.navigator.platform
  };

  /* report */
  var url = "https://<redacted>/callback?";
  for (var key in data) {
    url += key + "=" + encodeURIComponent(data[key]) + "&";
  }
  url += "timestamp=" + (new Date().getTime()).toString();

  var xhr = new XMLHttpRequest();
  xhr.open('GET', url, true);
  xhr.send();
})();
```

Figure 10: Notification Script

B Data Management

Due to our notification script's design, as detailed in Section 5.1 and Appendix A, we received only a minimal amount of data. Notably, the backend URL's query and fragment were never transmitted. We expected to receive no personally identifiable information (PII) in either the path or the title of affected webpages. However, we prepared a data management strategy to handle potential PII transmissions from our notification script's feedback pings. Our strategy entails to manually replace potentially received PII with placeholders. Fortunately, as shown in Table 1 neither the backend paths nor titles contained such information. IP addresses have a distinctive role, as they are indirectly received via a feedback ping from a vulnerable backend. Initially used to validate instances of blind XSS (Section 5.3), they later assist in meaningful disclosure and forensic analysis. Supplying operators with both the IP address and user agent information, facilitating distinction between manual actions and automated processes, helps them assess the vulnerability's impact. Post-disclosure, all retained IP addresses and user agents were deleted. Ultimately, the data this paper is based on will be archived as scientific evidence according to our institution's guidelines.

C Alternative Generation Approaches

Our polyglot synthesis for BXSS with MCTS has been successful in generating a complementary polyglot set. As our generation approach is agnostic to this algorithm, however, we investigate three alternative algorithms that could also be applied to our setting for constructing polyglots: *random selection*, *greedy selection*, and *Q-learning*.

Random selection — This method leverages our MCTS implementation, as depicted in Algorithm 1, but incorporates random selection and a random playout phase. In the selection phase, each child is given an equal probability, and one is selected at random. Once the end condition—specifically, the maximum payload length—is met, the constructed polyglot undergoes evaluation on the small testbed.

Greedy selection — This method generates a polyglot by continuously appending the best next token. Since we cannot know in advance which token is the best, we probe each token by appending the respective token to the current polyglot and evaluating the resulting polyglot on the testbed, thus implementing a greedy search. If multiple tokens achieve the same performance, we select one randomly to append. In contrast to *MCTS* and random selection, the greedy method evaluates unfinished polyglots in order to choose the next token.

Q-learning — This method builds on *Q-learning* [47], a popular reinforcement learning technique. The method populates a table of state-action pairs $Q(s_t, a_t)$ to determine the best action a_t in a given state s_t. Algorithm 2 shows our *Q-learning* implementation. It first chooses either a random action or the best next action and then evaluates the resulting state on the testbed, updates the q-values and saves the polyglot if it performed best. For *Q-learning* we set the learning rate $\alpha = 0.1$ and the discount factor $\gamma = 0.99$ as well as the simulated annealing parameters: initial exploration probability $p = 1$, minimal exploration probability $p_{min} = 0.01$ and exploration decay $\Gamma = 0.95$.

Comparative evaluation. We compare the approaches based on the coverage they achieve on the GFR and the number of polyglots they require to reach that coverage. The experiment consists of generating a set of 10 polyglots with each algorithm, evaluating the resulting sets on the GFR and removing polyglots from the sets that do not contribute to the overall performance. To account for randomness, the experiment is repeated 10 times for each approach.

In the generation phase, each approach iteratively generates polyglots on the small testbed. After each iteration, we remove tests that are covered by the polyglots. Since calls to the testbed are computationally the most expensive component of each algorithm, all methods are given a budget of 12.000 evaluation calls to the testbed during each iteration.

The evaluation of our comparative experiment's results are shown in Figure 11. Plot (a) aggregates the resulting set coverage on the GFR of the 10 parallel repetitions of each approach as boxplots. Plot (b) displays boxplots of the set sizes the same approaches achieved. Generally, smaller polyglot set sizes are preferred because they would result in fewer requests being sent to a system under test when testing for client-side XSS (Section 4) or blind XSS (Section 5). While Q-learning and greedy selection produce smaller polyglot sets, their overall coverages on the GFR are significantly lower than those of MCTS and random selection. We can therefore discard both of them as alternative polyglot synthesis approaches. In terms of coverage, the random method performs only slightly worse than MCTS on average. However, MCTS consistently achieves a lower set size than random selection. We believe this is the result of *MCTS*'s knowledge aggregated over multiple games, which allows it to generate more powerful polyglots.

```
   Output: polyglot string
1  s_best ← null
2  r_best ← 0
3  s_0 ← []
4  while evaluation budget is not exceeded do
5      for t ← 0; polyglot not complete; t ← t + 1 do
6          if rand(0,1) < p_exp then
7              a_t ← choose_random(s_t);
8          end
9          else
10             a_t ← max_a Q(s_t, a)
11         end
12         s_{t+1} ← s_t + [a_t]
13         r_t ← evaluate(s_{t+1})
14         Q(s_t, a_t) ← Q(s_t, a_t) + α(r_t + γ max_a Q(s_{t+1}, a) − Q(s_t, a_t))
15         if r_t > r_best then
16             r_best ← r_t
17             s_best ← s_{t+1}
18         end

20     end
21 end
22 return s_best
```

Algorithm 2: Generating a polyglot with Q-learning

D Google Firing Range

In Section 3.3 we discuss the construction of our comprehensive XSS testbed, which was derived from a subset of the GFR [15] tests to determine the efficacy of the polyglots. This section details which tests were excluded and why.

The GFR is structured as a crawlable list of subpages covering different categories of web vulnerabilities. Each category produces tests from a mix of sink, source, and countermeasures. Due to this setup, certain combinations result in unsolvable tests. To create our comprehensive and solvable XSS testbed, it is essential to first filter the GFR test cases.

To begin with, we omitted all test categories unrelated to XSS. As outlined in Table 2, the categories "Bad JavaScript imports", "CORS related vulnerabilities", "Flash Injection", "Mixed content", "Reverse Clickjacking", "Vulnerable libraries", "Leaked httpOnly cookie", and "Invalid framing configuration" are out of scope as they are not related to XSS

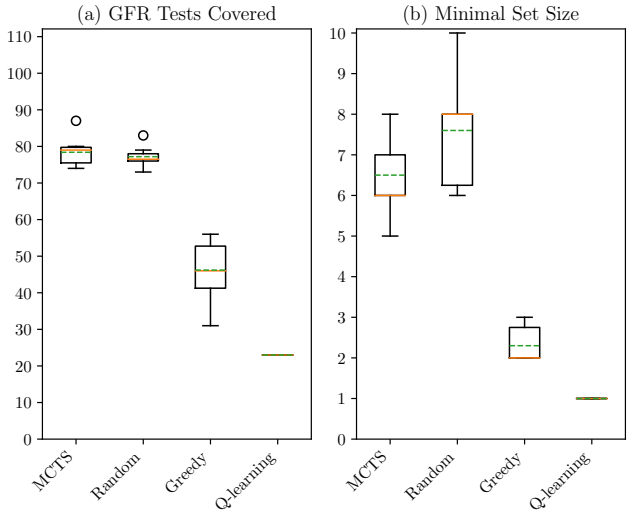

Figure 11: MCTS, Random, Greedy and Q-learning comparison; each generating 10 polyglots in 10 parallel runs

vulnerabilities. Additionally, we disregarded the "Angular-based XSSes" category given its focus on a particular framework, AngularJS, which is beyond our study's scope.

From the categories that remained relevant post our preliminary filtering, Table 3 provides a list of the excluded tests alongside reasons for their omission. For brevity, tests are identified by their path, accessible by appending the test path to GFR's main URL `public-firing-range.appspot.com`.

Our subsequent filtering entailed the removal of tests lacking solutions. Some tests became unsolvable due to the combination of sinks and countermeasures, modern browser security features, or obsoleted features. Fortunately, we acquired a list of solvable GFR tests from Google. After manual confirmation, we removed tests without a solution. Secondly, a handful of tests were removed for technical reasons, such as being removed from the GFR (Stored XSS), or tests involving multiple windows. Tests with exceptionally restrictive solutions, out-of-scope for a polyglot, were also ruled out, including those with stringent filters, or those solvable using only a URL. Likewise, we omitted tests exceeding our technology boundaries, such as those using Adobe Flash, Base64, and SVG. This leaves us with 111 tests.

The GFR tests involve various input sources, including form submissions, URL parameters, or *PostMessages*. Some demand clicks or page reloads post-input. Using Puppeteer, our test software provides a polyglot to each relevant GFR test through the suitable input method, meeting the post-submission requisites. It then waits for an XSS success signal through a specific log message. We use Puppeteer cluster to test one polyglot on multiple tests in parallel. After a run concludes, the polyglot's result in each test are returned. The implementation of our testing approach is published in our companion repository.

Table 2: Vulnerability categories of the GFR 0.48 and their general applicability for our blind XSS testbed

#	Category	Scope	Reasoning
1	Address DOM XSS	✓	XSS-related
2	Angular-based XSSes	✗	framework-specific
3	Bad JavaScript imports	✗	non-XSS-related
4	CORS related vulnerabilities	✗	non-XSS-related
5	DOM XSS	✓	XSS-related
6	Escaped XSS	✓	XSS-related
7	Flash Injection	✗	non-XSS related
8	Mixed content	✗	non-XSS related
9	Redirect XSS	✓	XSS-related
10	Reflected XSS	✓	XSS-related
11	Remote inclusion XSS	✓	XSS-related
12	Reverse ClickJacking	✗	non-XSS related
13	Tag based XSS	✓	XSS-related
14	URL-based DOM XSS	✓	XSS-related
15	Vulnerable libraries	✗	non-XSS related
16	Leaked httpOnly cookie	✗	non-XSS related
17	Invalid framing configuration	✗	non-XSS related

✓ category is generally in scope ✗ category is out of scope

Spider-Scents: Grey-box Database-aware Web Scanning for Stored XSS

Eric Olsson
Chalmers University of Technology

Benjamin Eriksson
Chalmers University of Technology

Adam Doupé
Arizona State University

Andrei Sabelfeld
Chalmers University of Technology

Abstract

As web applications play an ever more important role in society, so does ensuring their security. A large threat to web application security is XSS vulnerabilities, and in particular, stored XSS. Due to the complexity of web applications and the difficulty of properly injecting XSS payloads into a web application, many of these vulnerabilities still evade current state-of-the-art scanners. We approach this problem from a new direction—by injecting XSS payloads directly into the database we can completely bypass the difficulty of injecting XSS payloads into a web application. We thus propose Spider-Scents, a novel method for grey-box database-aware scanning for stored XSS, that maps database values to the web application and automatically finds unprotected outputs. Spider-Scents reveals *code smells* that expose stored XSS vulnerabilities. We evaluate our approach on a set of 12 web applications and compare with three state-of-the-art black-box scanners. We demonstrate improvement of database coverage, ranging from 79% to 100% database coverage across the applications compared to the range of 2% to 60% for the other scanners. We systematize the relationship between unprotected outputs, vulnerabilities, and exploits in the context of stored XSS. We manually analyze unprotected outputs reported by Spider-Scents to determine their vulnerability and exploitability. In total, this method finds 85 stored XSS vulnerabilities, outperforming the union of state-of-the-art's 32.

1 Introduction

The web is a key enabler for today's ever-more digital world. Our society increasingly relies on web applications to support the financial, governmental, and military infrastructure. The dynamic functionality of web applications, coupled with the myriad of implementation technologies, makes developing a bug-free application challenging. Furthermore, these bugs can often manifest as security vulnerabilities. The complexity of modern systems and ever-powerful adversaries make securing web applications a *grand challenge*. Even the biggest web players such as Google and Meta still release vulnerable applications and services, which reflects in $12 and $2 million in bug bounties in 2022 respectively [15, 26].

Challenge of XSS. A particularly common class of web application security vulnerability is *Cross-Site Scripting (XSS)* [28], allowing attackers to inject JavaScript code into web pages. Astonishingly, XSS has persisted in the OWASP Top 10's list of most critical security risks to web applications for the past 20 years [48]. This remarkable persistence is reflected in bug bounties, with HackerOne reported paying over $4.7 million for XSS vulnerabilities in 2022 alone [17]. Securing web applications against XSS is difficult because there is no single general solution that prevents all XSS vulnerabilities [20]. Indeed, XSS vulnerabilities are context-dependent [42, 44], requiring that the correct output sanitization be used depending on the output context.

Stored XSS. Stored XSS, where the injection is stored and only later executed [28], is particularly challenging due to the disconnect that storage brings between the *source flow*, where the payload is input and stored, and the *sink flow*, where the retrieved payload is executed. Current vulnerability detection approaches [14, 32] have fundamental difficulties finding stored XSS.

Insufficiency of $*$-box approaches. The difficulty of securing a web application against XSS motivates the development of vulnerability detection tools [2, 7, 11, 33, 49, 54]. Web application vulnerability detection approaches can be classified as white-box, black-box, or grey-box based on what information is available (cf. Section 4):

White-box approach: White-box approaches [12, 19, 22, 24] usually statically analyze source code artifacts. Such static analysis is necessarily specific to the structure of the analyzed artifact, such as the server-side language or framework. Unfortunately, white-box vulnerability detection is fundamentally limited in its applicability to web applications because it is hard for white-box static analysis to precisely model the combined interplay of increasingly complex and dynamic client-side, database, and server-side behavior [43]. In addition, white-box analyses depend on the availability of artifacts,

further limiting their usage.

Black-box approach: More advantageously from a usability perspective, black-box vulnerability detection for web applications does not typically require access to source code and instead analyzes a running web application from the perspective of a user. Black-box scanners have been developed with various methods to better cover the increased attack surface of modern web applications [8], such as modeling server-side state [7], tracking data flows and fuzzing payloads [9, 10], modeling client-side state [25, 33], and combining multiple approaches [11]. However, while coverage of the attack surface has improved for some XSS, black-box scanners are often still unable to find even simpler stored XSS [32].

Grey-box approach: A common solution [1, 14, 18, 49, 50] is to combine black-box dynamic interactions of a running application, with white-box access. How these two information sources are combined varies. Sometimes, artifacts or non-standard interfaces only available with white-box access can be used to guide the otherwise black-box scan of a web application [47] . More commonly, a fully white-box static analysis of the application source code is combined with a black-box scan for dynamic runtime information [1, 14]. Combining these sources of information can mitigate some challenges inherent to otherwise using one approach in isolation. However, this combination still has a white-box component, from which its usability suffers.

While the previously described approaches constitute an exciting and active area of research, we identify a key consideration in the design space of $*$-box approaches. A core problem with finding stored XSS is that a *black-box scanner must find both the source and sink flows, and also understand the relationship between the two*, without any access to the web application's source code.

Approach. Inspired by recent work in improving binary fuzzing [34], our insight is to make stored XSS easier to find by relaxing the requirement that the scanner must find the source of a stored XSS. To do so, we supplement an otherwise black-box scanner with access to the database and allow the scanner to inject payloads directly into the database while scanning the running web application for sensitive sinks that output the inserted payload. This yields the benefit that a scanner no longer needs to find both source and sink nor understand their relation. The elegance of our approach is that it requires no knowledge of the web application source, only the database. Figure 1 illustrates the unique point our approach occupies in the design space of $*$-box approaches.

This unique position represents a paradigm shift from the domain of *application input* to that of *application state*, represented in the database. Challenges (presented in Section 3) stemming from fundamental problems with *-box approaches do not have to be solved by our method.

Based on these insights, we develop Spider-Scents, an approach to grey-box database-aware web scanning for stored

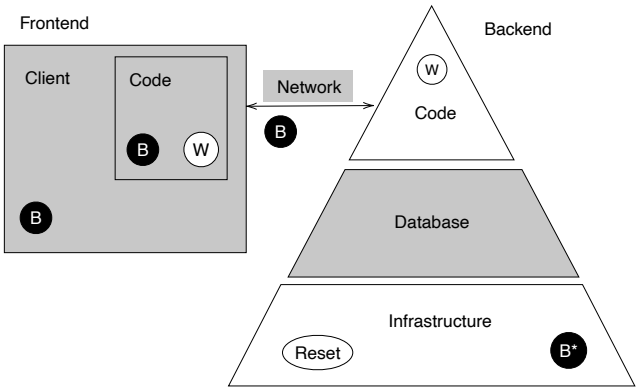

Figure 1: Access to components involved in a web application that different approaches need. Black-box approaches (B) have access to the front-end, and sometimes (B*) need infrastructure access to perform resets in the face of irreversible state changes. White-box approaches (W) have access to both front- and back-end code. Our approach, shaded in grey, accesses the front-end and database.

XSS. Spider-Scents injects payloads directly into the database and reports where database content is used in the HTML output without proper sanitization, flagging what we call *unprotected outputs*. This does not mean that all reports are stored XSS vulnerabilities, as the web application might be sanitizing the data on input. However, relying on input sanitization is against best practices for XSS prevention, as it is impossible to sanitize user input for every possible HTML output context. Indeed, the OWASP guidelines [31] postulate: "Apply Input Validation (using "allow list" approach) combined with Output Sanitizing+Escaping on user input/output," confirming that input validation alone is not enough. We term this result a *code smell*, an indication that something is wrong deeper within the application [13]. Even in the best case, where there is neither bug nor vulnerability, the application is fragile. Any new functionality added, such as creating a REST API, risks failing to properly sanitize user input. Therefore, even the unprotected outputs that are not currently exploitable stored XSS should be addressed by the web developer. Light manual analysis is required to verify a complete stored XSS vulnerability (see Section 6.7)

Non-vulnerable unprotected outputs constitute what we call a *dormant XSS*—they would be vulnerable, except that the *current* web application does not allow an exploit payload. The web application's evolution risks elevating a dormant XSS to a *complete XSS vulnerability*, even for security-wary applications. Our empirical study indeed confirms a dormant XSS vulnerability on WordPress, elevated to a complete vulnerability by a *real* published plugin (see Section 4.2).

Evaluation. We evaluate our approach across 12 web applications and compare our results with three state-of-the-art

black-box scanners. The applications range from reference applications used in prior work to latest versions of modern applications. Our results show that we cover (measured as how much of the database the scanner can change, described in Section 5.2.1) between 79% to 100% across all applications. In comparison, the other scanners cover 2% to 60% on average. We also find vulnerabilities that the other scanners are unable to detect. In total, we find 85 XSS vulnerabilities compared to 32 unique XSS for the other scanners. To further classify the impact of our findings we manually analyze the input protections and permission models of the Spider-Scents discovered vulnerabilities and determine that 59 are exploitable (and not self-XSS).

Contributions. We offer the following contributions:

- We present a novel approach for finding stored XSS vulnerabilities by injecting XSS payloads directly into the database, thus simplifying the detection of stored XSS. We present this in Section 4.
- We implement our approach into a prototype Spider-Scents, a semi-automated grey-box database-aware stored XSS scanner.
- We evaluate Spider-Scents and three state-of-the-art black-box scanners on 12 web applications. We present the results in Section 5 and analyze these in Section 6. Spider-Scents finds 85 XSS vulnerabilities across 7 applications.
- We systematize the relationship between *unprotected outputs*, *stored XSS vulnerabilities*, and *exploits* based on input protections and permissions models. Following this systematization, we manually analyze unprotected outputs reported by Spider-Scents to determine their vulnerability and exploitability. We also present this in Section 6.
- For the benefit of future research in this area, we share the source code of Spider-Scents[1].

Ethical considerations and coordinated disclosure. By actively scanning only our local clones of web applications in a controlled environment, we strictly avoid any harm caused by scanners on the web. We handle the discovered security vulnerabilities in accordance with the best practices of ethics in security [41]. We are in the process of reporting our findings to the affected vendors, following coordinated vulnerability disclosure for all discovered vulnerabilities. We report responses from vendors in Section 6.9.

2 Terminology

Here we attempt to systematize the terminology around XSS vulnerability analysis. Spider-Scents finds places in the web application where database content is used in the HTML output without proper sanitization. We term these *unprotected outputs*—output sinks where the output is not protected sufficiently against XSS. In contrast, there are also *protected outputs*: output sinks that are properly sanitized against XSS.

[1]Our implementation is available online at https://www.cse.chalmers.se/research/group/security/spider-scents/

We call a *complete XSS vulnerability* where user input flows to the unprotected output. Furthermore, that input must itself be an *unprotected input*—an input source lacking sufficient XSS protection. In contrast, there are also *protected inputs*: inputs protected with some combination of *sanitization* such as validation, stripping, or escaping. An unprotected output can also fail to be a complete XSS due to having *no input*.

If an unprotected input flows to an unprotected output, the web application has an *XSS vulnerability*. However, an XSS vulnerability is not necessarily *exploitable*, as this depends on the access control policy of the web application. The core question is if the user (or role) that injects the XSS payload can get the output on either another user or a role with greater permissions. We call XSS vulnerabilities that are not exploitable *self-XSS*, which have significantly less severity than exploitable XSS vulnerabilities.

3 Roadblocks for current XSS scanners

Automatically finding vulnerabilities in web applications remains a challenge despite active research in improving vulnerability detection. Stored XSS is especially difficult to find, as this type of vulnerability involves correctly injecting input into the application, where it will be stored by the database, and subsequently used in the web application's output incorrectly sanitized.

Black-box approaches can explore entire web applications without access or reliance on the underlying web application source code. It is possible for black-box scanners to track an entire stored XSS vulnerability from initial payload injection to vulnerable output. However, finding all such vulnerabilities for a black-box scanner is difficult, due to several challenges inherent to stored XSS that they must solve:

Vulnerable input validation. Web applications perform input validation (in client-side JavaScript and also server-side code) to ensure that the input data conforms to certain requirements. Web applications can check vulnerable inputs for validation that the scanner must pass and also inject an XSS payload into. As most black-box scanners use a pre-configured list of XSS payloads, it is difficult for them to create a custom XSS payload that also bypasses the vulnerable input validation.

Interdependent vulnerable input validation. Web applications validate all types of inputs. Often, a web application requires the user to fill out a set of inputs together. Consider a user registration form that might require the desired username, email address, zip code, and biography. All forms are required, the server-side input validation requires that the username be unique, the email address has a specific form, the zip code is five digits, and the biography has no validation and is vulnerable to stored XSS. Due to the *interdependence* of the four inputs, to find the stored XSS a black-box scanner must be able to provide a unique username (which is difficult for repeated injection attempts), correctly-formatted email address and zip code. As the number of inputs interdependent to vulnerable input increases, and as the input validation is

application-specific, it is more difficult for black-box scanners to generate the proper interdependent input to inject stored XSS payloads.

Vulnerable input modification. Web applications can also escape or modify user input. Consider a blog that accepts blog posts in markdown format that is transformed to HTML before storing them in the database. Because the black-box scanner has no knowledge of the server-side source code, it cannot know about this modification. If a vulnerable input is modified before being stored into the database, it is difficult for a scanner to create a custom XSS payload that can survive the modification, and, therefore, it is difficult to detect.

Multi-step vulnerable input. Web applications are stateful applications that can require a multi-step process before persisting user data. A classic example of this is the multi-step stored XSS in WackoPicko [8], where commenting on a picture requires first previewing the comment (which is output with sanitization) and then approving the comment (where it is output without sanitization). To our knowledge, the first black-box scanner that was able to automatically detect this vulnerability was Black Widow [11], published 11 years after WackoPicko was released. Therefore, vulnerable inputs that require multi-step interactions are difficult for black-box scanners to detect.

Vulnerable input identification. The core of stored XSS is that the XSS payload is stored in the database before being used as output. Even if a black-box scanner can correctly inject an XSS payload, it must be able to find where that input is output—otherwise, it will never detect the XSS.

4 Approach

Our goal is to overcome the challenges black-box scanners face (mentioned in Section 3) in detecting stored XSS vulnerabilities. Rather than take a completely black-box approach, we use a novel grey-box approach that includes *knowledge of the database* to help an otherwise black-box scanner find stored XSS vulnerabilities. Our idea is that by injecting the XSS payload directly into the database, and then scanning the web application for the payload's output, we can *completely bypass* several of the roadblocks black-box scanners face in detecting stored XSS: vulnerable input validation, interdependent vulnerable input validation, vulnerable input modification, and multi-step vulnerable input.

'Grey-box'. In web security, black-box has been synonymous with dynamic testing, as white-box is to static analysis. With this view, grey-box can appear to be defined as the combination of these two: dynamic testing and static analysis. Recent papers [14, 49] in grey-box web testing have supplied two definitions: the previous, based on *method*, or based on *access* or *visibility* to the application. Our approach is grey-box only by the second definition: we do not use static analysis, but we have access to the database.

Besides the application data contained, metadata such as table structure and associated relations are also assumed to be available, through the same database connection. In practical terms, SQL databases provide programmatic access to such metadata in the `INFORMATION_SCHEMA` tables [30].

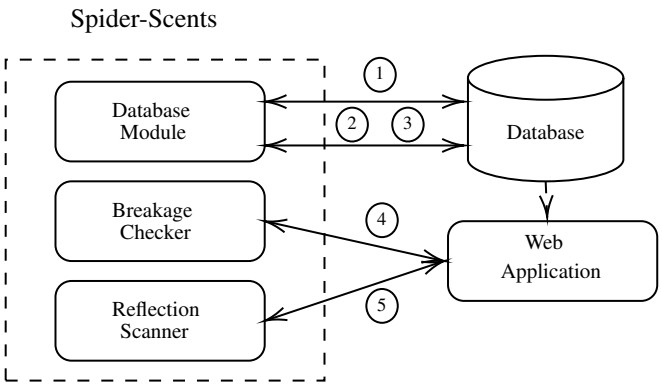

Figure 2: Overview of Spider-Scents' different components and their interactions with both the database and web application.

4.1 Overview

In contrast to existing state-of-the-art scanners, our database-aware method requires a paradigm shift from application *input* to *state*. Instead of solving problems associated with the input domain (such as crawling, modelling, or payload selection), we address new challenges of preparing the application state, selecting which part to modify, and analyzing its impact on the application.

Spider-Scents is our implementation of our novel grey-box scanning approach. Figure 2 shows a diagram of our approach. First ①, we prepare the web application for scanning. Next ②, we choose a database cell to modify, and ③ insert an XSS payload into the cell. We then validate ④ that the modified database did not break the application. Finally ⑤, we crawl the web application looking for reflections of the injected payload. This approach iterates as long as there remain untested database cells to modify.

4.1.1 Reports

Due to Spider-Scents injecting XSS payloads directly into the database, what it reports *is not XSS vulnerabilities*, but rather *unprotected outputs* (defined in Section 2). Therefore, the final step is to manually analyze the results of Spider-Scents. As our evaluation in Section 5 shows, many unprotected outputs are also XSS vulnerabilities—Spider-Scents finds 133 unprotected outputs in evaluated applications and 85 XSS vulnerabilities.

An interesting side-effect of finding so many vulnerabilities with Spider-Scents is that we realized that the *impact* of the discovered XSS vulnerabilities is critically important to contextualize the results. Specifically, we found that some of the XSS vulnerabilities were *self-XSS*, defined in Section 2

wherein the privilege required to store the XSS payload is the same as the user that views it. Of the 85 XSS vulnerabilities found by Spider-Scents, 26 are self-XSS while 59 are fully-exploitable.

4.2 Motivating Examples

Spider-Scents' database-aware scanning is particularly well suited to finding stored XSS vulnerabilities due to circumventing common challenges for black-box scanners. Here, we present examples of the types of issues that Spider-Scents is better at finding than previous work:

1. Fully-exploitable stored XSS that other scanners do not find.
2. Dormant vulnerabilities that become exploitable.
3. Self-XSS that other scanners do not find.

Fully-exploitable stored XSS. Even though they are capable of finding a fully-exploitable stored XSS vulnerability, other scanners often fail due to their inability to extensively explore the input surface of the web application, including satisfying vulnerable input and interdependent input validation. In Section 5, we further analyze the precise reasons why other scanners miss fully-exploitable stored XSS that Spider-Scents finds.

In addition, beyond needing a full XSS from input to output, the XSS vulnerability also must be exploitable. Determining the exploitability of an XSS currently requires manual analysis, as the exploitability of a vulnerability depends on application context such as the levels of user permissions within the application. Other presentations of scanners have generally not provided such analysis of their XSS results.

An example of a fully-exploitable stored XSS that other scanners fail to find is in the CMS Made Simple bookmarks functionality, which is shown in Figure 3. In this case, it is harder to find the input form, but easy to find the output from the database. Armed with this vulnerability, a user can perform XSS on an admin of CMSMS. Spider-Scents reports this as an unprotected output, and we manually confirm its exploitability.

Dormant XSS. Spider-Scents reports what it finds as unprotected outputs rather than stored XSS vulnerabilities, as it only finds the second half of a complete XSS workflow in unprotected outputs. Unprotected outputs do not always have an unprotected input flowing to them. However, we believe there is significant value in reporting unprotected outputs because they are a *code smell*—the web application has not followed the best practice of "always escape late" emphasized by both WordPress and WordPress VIP [51, 52]. While not a bug or vulnerability, an unprotected output is something that a developer should look at and fix.

In fact, we believe that an unprotected output in isolation can be considered a *dormant XSS*—it would be vulnerable, except that the current inputs for the web application do not allow an exploit payload due to either escaping, stripping, validation, no input possible, or some combination of these. The web application's evolution, either through future development or integration with other code (plugins, for example), can elevate a dormant XSS to a full XSS.

```
echo "<td><a␣href=\"editbookmark.php".$urlext."&amp;
    bookmark_id=".$onemark->bookmark_id."\">".$onemark->
    title."</a></td>\n";
echo "<td>".$onemark->url."</td>\n";
echo "<td><a␣href=\"editbookmark.php".$urlext."&amp;
    bookmark_id=".$onemark->bookmark_id."\">";
echo $themeObject->DisplayImage('icons/system/edit.gif',
    lang('edit'),'','','systemicon');
echo "</a></td>\n";
echo "<td><a␣href=\"deletebookmark.php".$urlext."&amp;
    bookmark_id=".$onemark->bookmark_id."\"␣onclick=\"
    return␣confirm('".cms_html_entity_decode(lang('
    deleteconfirm', $onemark->title) )."');\">";
echo $themeObject->DisplayImage('icons/system/delete.gif'
    , lang('delete'),'','','systemicon');
echo "</a></td>\n";
```

Figure 3: CMS Made Simple bookmarks functionality. A bookmark contains a title and a URL. Both the title and URL are correctly escaped in their respective first two cells in this snippet from CMSMS code, but the title is not protected in its inclusion in the delete button.

For example, Spider-Scents found that WordPress has unprotected output of both `display_name` and `user_nicename` from the `users` table. In the base WordPress application, there are no unprotected inputs to these columns—in fact, these are not modifiable after the creation of a user. However, *both* are exposed in a vulnerable version of the `username-changer` plugin [5] (code shown in Listing 4), and, therefore, when this vulnerable plugin is installed this unprotected output becomes a fully-exploitable XSS. [2] If WordPress followed their own best practices of "always escape late", this dormant XSS would not be possible (and Spider-Scents would not report it as an unprotected output).

It is also possible that some inputs to the database are kept constant. For example, in Hostel Management System, an application we evaluate in Section 5, a list of US states is hard-coded in the database. Spider-Scents finds unprotected outputs in this list. While not directly exploitable, these unprotected outputs could become a problem through extension of code, either in future versions of the application or with plugins. In our manual analysis, we quantify how many reports fall into this category and present them in the *NI* column in Table 2.

Self-XSS. Finally, an XSS vulnerability is not necessarily exploitable. An XSS can be unexploitable due to user permissions, such that the admin can only perform an XSS on themself. This self-XSS is the counterpoint to fully-exploitable XSS. An example of this is templates in MyBB. A template

[2] Vulnerable version of WordPress `username-changer` plugin https://github.com/evertiro/Username-Changer/blob/dd1976b05213d9895886da7f9a91515c52188344/includes/functions.php#L84

```
$qnn = $wpdb->prepare( "UPDATE␣$wpdb->users␣SET␣
    user_nicename␣=␣%s␣WHERE␣user_login␣=␣%s␣AND␣
    user_nicename␣=␣%s", $new_username, $new_username,
    $old_username );
$wpdb->query( $qnn );

$qdn = $wpdb->prepare( "UPDATE␣$wpdb->users␣SET␣
    display_name␣=␣%s␣WHERE␣user_login␣=␣%s␣AND␣
    display_name␣=␣%s", $new_username, $new_username,
    $old_username );
$wpdb->query( $qdn );
```

Figure 4: Username-Changer WordPress plugin vulnerable code: `display_name` and `user_nicename` are not sanitized.

Algorithm 1 Synthesizing data in the database.

```
rows ← 3
i ← 1
while i ≤ rows do
    row ← []
    j ← 0
    while j ≤ columns do
        append(row, increment(i))
        j ← j + 1
    end while
    insert(row)
    error ← breakage()
    if error then
        delete(row)
    end if
    i ← i + 1
end while
```

for the calendar functionality in this application can be modified to include executable JavaScript. However, only an admin user has the necessary permissions to add or modify this template. Spider-Scents finds this vulnerability, and we manually confirm that it is a self-XSS.

4.3 Preparing the web application

The initial step in our approach is to prepare the web application's database for scanning, as shown in step ① in Figure 2.

4.3.1 Database synthesis

Ideally, our method should scan an application with a *full* database. Steinhauser and Tůma note the importance of this as well [47]. However, they do not attempt to solve this and instead rely on somewhat complete configurations provided by the applications themselves, or other publicly-available manually-assembled data. For an e-commerce website, this means that the database already contains products, customers, and other data. To be able to discover an XSS-vulnerable workflow that spans multiple tables, data must exist in each table.

To address cases where data is lacking, more specifically empty database tables, we insert a constant number of rows of benign data matching the schema of the empty tables. We perform this simple algorithm shown in Section 4.3.1 on each empty table in the database.

columns is the number of columns in the schema for the empty table and $increment(i)$ modifies a base value by the increment i. For example, integers have a base value of 0, dates have '1970-01-01 00:00:00', and strings have `a`. By modifying a constant value, we ensure that there are records correlated between tables by these deterministic values, to satisfy constraints common in web applications using normalized databases. We always insert 3 initial rows due to different auto-increments in the applications' database setups—we have observed empirically that these often start at 1, but not always.

While this naive solution is implemented and works well for our evaluation, the more general case of database synthesis is orthogonal to this work. Related work in this specific direction can be found in Section 7.5.

4.3.2 Reverting changes

We also periodically revert modifications done by Spider-Scents to the database, the rules for which are described in Appendix A.1. This is to add independence between our payload insertions, and also reduces our reliance on detecting application breakage, if we automatically revert based on other rules. Some rules we implement enforce independence across boundaries in the database; such as tables and columns.

To revert a database edit, from *newData* to *oldData*, perform:

```
error ← updateRow(oldData)
if error then
    removeRow(newData)
    insertRow(oldData)
end if
```

removeRow and *updateRow* can identify a row based on either keys or values. It is necessary to handle reverting changes in Spider-Scents, as built-in database functionality such as transactions cannot be open-ended, which is necessary to allow the simultaneous manipulation of both Spider-Scents and the web application backend of the database.

Reverting changes also happens when breakage is detected, conditions for which are covered in Section 4.6.

4.3.3 Logging in

Finally, we also must make sure that the web application itself is in a proper state to be scanned. Among other things, this means making sure that Spider-Scents is logged in. We automatically grab relevant details such as cookies, user agent, and the user URL (dashboard) at the start of each scan. Spider-Scents uses Selenium to interact with a headless Chrome instance with a custom extension to record this information, after having been supplied with the necessary credentials (username, password, and login page). These client details, which web applications often use to identify users, are then

Algorithm 2 Discovering sensitive rows.

```
i ← 1
while i ≤ rows do
    row ← retrieve(i)
    error ← delete(i)
    if error then
        sensitive(row)
    end if
    crawl()
    error ← insert(row)
    if error then
        sensitive(row)
    end if
    i ← i + 1
end while
```

re-used throughout the rest of the scan.

4.4 Choosing a database cell

For each cell in the database, Spider-Scents checks if the cell is suitable for our XSS payload. We ensure that the schema for the cell's column specifies that it is a text field with a length that can accommodate our payload, described in Section 4.5.

4.4.1 Avoiding sensitive rows

We also must consider if the web application is particularly *sensitive* to changing a specific cell's value. If the application tries to revert an injected database value, reset a table or row, or even insert a conflicting row, various problems can occur. This can either be due to the web application not having a robust recovery method that can handle Spider-Scents's admittedly unexpected meddling in their database tables, or due to Spider-Scents losing track of the state the database is in. In either case, we avoid such sensitive cells by first probing the database for their existence.

For each table in the database, we discover sensitive rows as shown in Algorithm 2, where *rows* is the number of rows in the table, $retrieve(i)$ and $delete(i)$ perform appropriate actions on the i^{th} row in the table, $insert(row)$ inserts the row into the table, $sensitive(row)$ marks that this row in the table is sensitive to changes, and $crawl()$ crawls the application to induce reverts, conflicts, or resets in the database.

4.4.2 Choosing a cell

How a table in a database is used by an application also matters, and, unfortunately, this usage is not always fully specified in the database schema.

If a table has uniform types of rows, then it might be sufficient to modify cells in a single row. However, this assumption only holds if, for instance, the access control policies of the application specify that all users can see the data in all rows.

This also assumes that each entry in the table is handled identically by the web application code, which might not be a correct assumption. Indeed, not all tables have only such uniformly typed entries; a counterpoint is tables that store key-value data, where the interpretation of a value cell depends on a key cell identifying it. Given the existence of such key-value tables and the fact that reflection code for entries can change based on the contents of a particular entry, we must iterate across all rows in a table.

In addition, the order of cell changes does impact which XSS-vulnerable workflows are discovered. We implement different traversal orders, primarily based on iterating tables in alphabetical order. From there, the scanner either chooses cells (that satisfy payload requirements and are not sensitive) based on the iteration of rows or columns.

4.5 Payload insertion

In contrast to traditional black-box approaches, Spider-Scents does not interact with the web application in an attempt to insert data from user input to a particular database cell. Instead, Spider-Scents inserts the payload directly into a database cell (step ③).

Once a suitable cell has been found, Spider-Scents generates a unique ID to use for the payload. The payload we use is inspired by payloads used in prior work [11]. This structure helps reduce false positives with dynamic XSS detection. We use the following template, where `ID` is replaced with a unique generated ID:

```
"'><script>xss(ID)</script>
```

While other payloads, such as a general-purpose `img` payload, can be more or less suitable depending on the context of the reflection, we consider the problem of creating smaller or context-specific XSS payloads to be orthogonal to this work. Using this payload can lead to false negatives, for example, if the reflection happens in a `textarea` or `title` tag.

4.5.1 Structured data

This is with the caveat that we *do consider* the presence of *structured data* in a cell. Spider-Scents' iterative modification of database cells, and searching for these individual reflections in the web page, has the implicit assumption that it is *individual* data stored in database cells in a one-to-one correspondence from web input to database cell. This might not be true—data might be split up into multiple cells or combined within a single cell. A payload would need to be either split across cells in the first case or multiple payloads combined in the second. Correlating changes across cells is considered out of scope for this work.

However, when data is combined within a single cell, we consider this as structured data. Spider-Scents modifies payloads to fit some common types of structured data. If a known structure is detected by parsing cell data, the payload will be delivered to each valid location for it. Currently, Spider-Scents implements a customized payload for PHP serialized objects and image paths. The support for these formats is chosen to demonstrate this approach and can lead to false negatives due to not handling more widely-used structured data formats,

Algorithm 3 Determining breakage.

```
i ← 1
broken ← 0
while i ≤ length(urls) do
    current ← request(urls[i])
    broken_url ← request(urls[i])
    if broken_url then
        broken ← broken + 1
    end if
    i ← i + 1
end while
if broken/length(urls) ≥ threshold then return broken
end if
```

such as JSON.

4.6 Application breakage

After inserting a payload, the changing database values can have catastrophic effects on the web application's functionality, which we call *breakage*.

While breakage can happen when using an application through its standard functionality, it is even more likely when Spider-Scents directly modifies the database and possibly inserts values that the application has not defensively coded against.

From a black-box scanner's perspective, such internal application-specification breaking changes are not available. However, similar behavior, when reachable on standard interfaces, is regarded as *irrecoverable state changes* [7]. While it may be intended functionality, such an irrecoverable state change overlaps with our notion of application breakage.

Guarding against breakage is inherently a tradeoff. On the one hand, changing the website's domain to an XSS payload in a CMS such as WordPress will rewrite all links, including admin ones, making the application unusable. On the other hand, new vulnerable behavior of the application might have been discovered instead.

Entirely black-box approaches will not be able to recover from such a breaking, irrecoverable state change. Some scanners add infrastructure access (shown in Figure 1) to be able to reset the application when this happens [7, 10]. With our position in the database, while we are more prone to cause breakage, we can also *identify and fix it*, without any additional access to the application.

Therefore, as noted by step ④ in Figure 2, Spider-Scents will dynamically scan the application looking for signs of breakage. If any are found we can reset the exact cell we changed that caused the breakage, even in the case when the web application is unusable.

Web application breakage across a web application is inferred by Algorithm 3, where *urls* is a list of URLs for distinct web pages in the application, $compare(baseline, current)$ compares the current status of a web page to a baseline measurement, and *threshold* is a threshold specified for how many pages can be acceptably broken in a web application.

$compare(baseline, current)$ can be implemented to compare measurements of a web page response based on HTTP status codes, linked content, length, or other heuristics. The approach we take is a combination of status codes and linked content.

4.7 Reflection scanning

Finally, we dynamically exercise the application with a reflection scanner (step ⑤). This scanner will crawl the application and report back on all the IDs that it finds. Here we differentiate between reflected JavaScript payloads that are executed, i.e. unescaped, and cases where we find the IDs in text. We do not try to find mangled or encoded payloads.

Spider-Scents uses *Black Widow* [11], the source code of which is available[3], with minor modifications to facilitate communication between modules, as its reflection scanner.

4.8 Manual analysis

From the Spider-Scents reports we manually analyze the unprotected outputs to determine if the payloads could be added from the web application. Once an input element is found we supply valid data and ensure the database is updated accordingly. Next, we add our payload and record if it is (1) rejected due to validation, (2) escaped, or (3) sanitized. We then repeat this for all inputs relating to the column.

5 Evaluation

We evaluate our approach by analyzing 12 different web applications and report on the number of stored XSS vulnerabilities found.

We compare Spider-Scents with a combination of up-to-date academic and open-source scanners that find stored XSS in Arachni [2], Black Widow [11], and OWASP ZAP [54].

5.1 Web applications

Similar to previous works [7, 11, 33, 49] we test both old applications and new modern ones. We divide the target applications into two sets. The five reference applications (that have known CVEs) and are used in prior work are: SCARF [45], Hospital Management System [35], User Registration & Login and User Management System [36], Doctor Appointment Management System [37], and Hostel Management System [38].

For modern, complex, applications we use these seven: CMS Made Simple [46], Joomla [21], MyBB [27], OpenCart [29], Piwigo [39], PrestaShop [40], and WordPress [53], Statistics that describe the applications chosen, their version numbers, and their usage in evaluation by prior work is provided in the Appendix Table 4.

[3] https://github.com/SecuringWeb/BlackWidow

Applications are largely chosen based on those evaluated by the authors of jäk [33], Black Widow [11], and Witcher [49][4], as these represent the current state-of-the-art in academic black-box web scanners. We restrict the evaluation to those that are database-backed.

Note that while we have selected applications based on the prior criteria, we choose the *latest version* of each application. Therefore, the unique vulnerabilities found by Spider-Scents are also *new*.

5.2 Experimental setup

In this section, we present the experimental setup used for the evaluation of Spider-Scents and comparison with other scanners.

5.2.1 Performance metrics

We focus our evaluation on three metrics: database coverage, vulnerabilities, and exploitability.

Database coverage. To successfully execute a stored XSS payload the scanner must first write the payload to the database [5]. By comparing a snapshot of the database before and after each scan we can approximately measure what effect each scanner has on the database.

These snapshots allow us to more precisely determine where the scanner fails in storing a payload, and where Spider-Scents can benefit from directly adding the payload to the database. In addition, we also classify the changes as either benign or XSS payloads. If an XSS payload is added, we investigate if the scanner can find it.

Vulnerabilities. To evaluate our method's capability to find vulnerabilities we also record the number of vulnerabilities reported by each scanner.

There is no clear method, neither in literature nor suggested by the scanners' implementations, of how to differentiate between two different XSS vulnerabilities. This means that for a given web application functionality, different scanners can generate different amounts of reported XSS vulnerabilities. For example, a vulnerable search bar included on every URL could generate a reported XSS vulnerability for each URL. To level the playing field and allow for a fair comparison we manually inspect each vulnerability and cluster them based on their related functionality. This clustering is justified as an application of *root cause analysis*, a process already well-established and valued in software bug reports [16].

Furthermore, we only compare stored XSS results from other scanners. Reports from compared scanners are manually confirmed to either be stored XSS or non-stored XSS (reflected or DOM). During evaluation, Arachni finds 4, Black Widow finds 2, and ZAP finds 4 [6] non-stored XSS. Our method is unable to find these, as it is specific to stored XSS.

Exploitability. Scanners search for XSS vulnerabilities by injecting data with XSS payloads into the application. Afterwards, they search for this data, either statically, or dynamically. However, due to permissions, this does not guarantee that an attacker can abuse the discovered XSS. For example, if only the super user can inject the payload, the vulnerability is not exploitable.

As modern applications can have complex user and group permissions with different associated application views, it is difficult for a scanner to automatically reason about the *exploitability* of these possible injections. In this paper, we manually verify and report on the exploitability of each reported vulnerability. We divide this step into two parts, i) input protections and ii) permissions.

For input protection, we ensure that it is possible to add the XSS payload from the application to the database. If it is not possible (protected), we further categorize the input protection for the reported vulnerability.

No Input, when there is no usable input field allowing for writing to the database. For example, input fields that are only available during installation or constants, such as US states.

Escaping, when the application changes the user input, to prevent it from being interpreted in some context, before adding it to the database. E.g. transforming `<` to `<` makes the symbol safe to be included in HTML context.

Stripping, when some data is removed ("stripped") from the input. E.g. removing `<script>` from the user input.

Validation, when the application refuses to add the user input to the database if it does not satisfy some format, such as containing illegal characters.

For permissions, we consider the vulnerability exploitable if a less privileged user can add a payload that is executed on a page that a user with more privileges can access. For example, if a normal user can book an appointment whose XSS payload is executed in the admin dashboard, then we would consider this exploitable. However, if only the admin could add the payload to such an appointment then it would be equivalent to self-XSS.

5.2.2 Scanner configuration

We configure other scanners to make as fair a comparison as possible. While we focus on stored XSS, web scanners can scan for a plethora of other vulnerabilities, including SQL injection, command injection, and local file inclusion.

For this evaluation, we configure each scanner to only focus on finding XSS vulnerabilities. Furthermore, to allow scanners a better chance to authenticate and stay authenticated, we make slight modifications to the *web application*. First,

[4] Witcher only supports detecting SQL Injection and Command Injection, therefore we do not compare against it.

[5] Assuming the payload is stored in the database; see Section 6.3 for an example of a stored XSS in the filesystem.

[6] In general, non-stored-XSS found by scanners is the difference between columns R and S in Table 1. However, due to the false positive reports by ZAP in the Hospital Management System (see Section 6.2), ZAP only finds 4 non-stored-XSS in the Doctor Apt. and Hostel applications.

we ensure the index page has a link to the admin login. Secondly, we rewrite the POST parameters server-side to match the correct user. This will level the playing field, as scanners prefer different authentication methods. Other scanners are configured to limit their runtime to 8 hours, similar to prior work [11, 49]

Configuration of parameters specific to Spider-Scents can be found in Appendix A.1.

5.3 Comparison results

In addition to the most direct comparison statistic—vulnerabilities found—we also collect a new statistic for this problem: *database coverage*. This is motivated by the different approach taken by Spider-Scents.

Database coverage. Modifying data in the database is required to detect stored XSS in database-backed applications. As such, we record the number of unique columns in the database each scanner modifies. In the case where an entire row is added, we give the scanner credit for all columns in the table. In our analysis in Section 6.4, we look more closely at the data inserted by the scanners.

In Appendix Table 5, we present the database coverage of each scanner and compare them to Spider-Scents. We further visualize this in Figure 5. As is evident, Spider-Scents can affect a much greater portion of the database compared to the other scanners. We cover between 79% to 100% while the other scanners cover between 2% and 60% on average. This shows that black-box scanners are still limited in how much they can affect the database, and subsequently, how well they can detect stored XSS.

There are cases where other scanners affect columns that Spider-Scents does not modify: For example, on CMSMS, both Arachni and ZAP affect columns that Spider-Scents does not. In this particular case, it is the `cms_adminlog.username` and the `cms_users.username` columns. Both these have a max length of 25 while our payload is 30 characters. We discuss these cases in more detail in Section 6.1.

Database application mappings. Our approach generates a mapping from database tables and columns where a payload is inserted, to the URLs where the payload is found. In Figure 6 we show such a mapping for the application Piwigo, where the red lines indicate unprotected output and the black lines indicate protected output.

XSS results. In this section, we compare the reported XSS vulnerabilities by each scanner. In Table 1, we present reports by each scanner in column *R*, manually confirmed stored XSS in column *S*, and manually verified and de-duplicated reported vulnerabilities in column *V*. Note that anything we find in column *V*, all black-box scanners should report as well.

Reports by other scanners are of XSS vulnerabilities. However, the Spider-Scents scanner reports unprotected reflections, not XSS vulnerabilities (see Section 4.1.1). Therefore, column *S* is inapplicable, and undefined for Spider-Scents.

Table 1: XSS vulnerabilities reported (and manually verified) by each scanner. *R* - All XSS or unprotected outputs reported by the scanner, *S* - Confirmed stored XSS, *V* - Verified and de-duplicated with our unique finds in parentheses.

Scanner	Arachni			Black Widow			ZAP			Spider-Scents		
	R	S	V	R	S	V	R	S	V	R	S	V
CMSMS	0	0	0	0	0	0	0	0	0	18	-	8 (8)
Doctor Apt.	5	2	2	1	0	0	4	1	1	8	-	4 (2)
Hospital	5	4	4	4	4	4	26	1	1	33	-	30 (22)
Hostel	13	13	13	3	3	3	0	0	0	23	-	19 (6)
Joomla	0	0	0	0	0	0	1	0	0	9	-	0
MyBB	0	0	0	0	0	0	0	0	0	6	-	6 (6)
OpenCart	0	0	0	0	0	0	0	0	0	6	-	0
Piwigo	0	0	0	1	1	1	0	0	0	5	-	1 (1)
PrestaShop	0	0	0	0	0	0	0	0	0	3	-	0
SCARF	0	0	0	10	9	9	0	0	0	12	-	11 (2)
User Login	0	0	0	0	0	0	0	0	0	3	-	3 (3)
WordPress	0	0	0	0	0	0	0	0	0	7	-	3 (3)
Total	23	19	19	19	17	17	31	2	2	133	-	85 (53)

Overall, our approach finds 85 stored XSS vulnerabilities that other scanners should be able to find, compared to the 15, on average, that they do find. 53 of these vulnerabilities found by our approach are unique and new.

With the exception of the Piwigo vulnerability Black Widow finds, which we discuss in Section 6.3, we find all stored XSS the other scanners find.

Notably, classic black-box scanners still struggle to find stored XSS, as indicated by the relatively low numbers in Table 1. There are some notable outliers, such as ZAP reporting 26 XSS on the Hospital Management System. However, as later clarified by manual analysis, this is a single stored payload being mislabeled as multiple XSS vulnerabilities.

Exploitability. While scanners report on user input being executed as JavaScript, they fall short of understanding the *exploitability* of the vulnerability. In this section, we break down the vulnerabilities we find with Spider-Scents into unprotected output, unprotected inputs, and unprotected permissions, defined in Section 2. We define the unprotected input as an input field where it is possible to add a payload without it being escaped, stripped, or subject to validation, as described in Section 5.2.1.

In Table 2 we present the results from our approach and exploitability analysis. Interestingly, we note that there is a diverse mix of input protection methods, even within one application. For example, in CMS Made Simple, escaping is used for the user's first and last name, while stripping is used for the email, and validation is used for the content alias. Nevertheless, the application still failed to properly sanitize its output.

Moreover, complex and dynamic user roles in modern applications make it difficult to automatically reason about the impact of XSS. For example, in CMSMS there is a binary

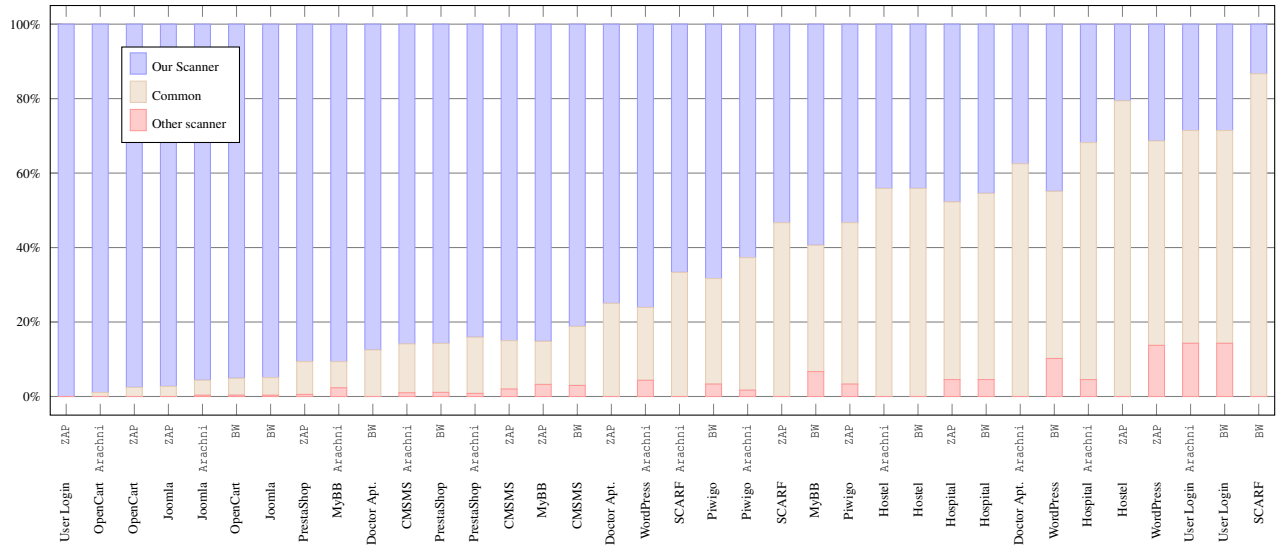

Figure 5: For every bar we present the fraction of database columns affected. First, on top, the fraction of columns only Spider-Scents finds, the middle shows the fraction of columns both scanners find, and finally, on the bottom, the fraction of columns only the other scanner finds.

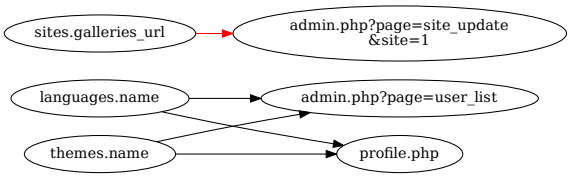

Figure 6: Subset of results from scanning the Piwigo web application. Black lines indicate protected outputs while red lines indicate unprotected outputs.

option for permission to modify bookmarks, that can be assigned to any user group. Any user with this permission can abuse an XSS to gain privileges. In contrast, MyBB has a strict separation of admin configurations and forum moderation configurations. This means that any XSS a scanner finds, including ours, while authenticated as an admin in MyBB, could be regarded as self-XSS as only trusted parties control the input. Similarly in Piwigo, the page title is vulnerable to XSS, however, only the admin can change it. As we see in Table 2, while both MyBB and CMSMS fail to escape all outputs, MyBB is less exploitable due to its stricter permissions.

In the Doctor Appointment Management System, neither output protection nor input protection is used. Despite this, two vulnerabilities are not exploitable because of permissions. Specifically, while users can change their own email address, only doctors (super users in this context) can change a doctor's name. Still, these are not fully protected, as the application with its default settings is also vulnerable to CSRF attacks. These vulnerabilities can be combined to exploit the XSS. Therefore, we believe it is useful for developers to learn where unprotected outputs are so that they can be fixed, even if they are protected by permissions.

6 Analysis

In this section, we investigate our results and highlight limitations of both black-box scanners and our approach.

6.1 Database coverage

While our method generally achieves higher database coverage, there are some interesting cases where other scanners still perform better in this metric.

In our evaluation, the portion of the database we miss and other scanners can reach is a result of our payload's length. Our payload length is always at least 30 characters long, making it too big for some cells. For example, on Piwigo Black Widow can affect the `oc_customer_ip.country` column, which only holds two characters. ZAP also modifies `mybb_templates.version`, with a size of 20 characters. This could be enough for some XSS payloads.

In theory, we can miss finding possible vulnerabilities if changing a non-text (numeric or date) value is necessary to trigger a vulnerability. Foreign key constraints can also cause problems but are less common in the text fields we focus on.

Table 2: Exploitability of reported vulnerabilities. *T* - Total reflections, *NI* - No Input, *VA* - Validation, *ST* - Stripping, *ESC* - Escaping, *P* - Permission, *EXP* - Exploitable. * A CSRF vulnerability could be abused to exploit it. ** Poor authentication validation allows privilege escalation.

	T	NI	VA	ST	ESC	P	EXP
CMSMS	18	3	1	3	3	0	8
Doctor Apt.	8	4	0	0	0	2*	2
Hospital	33	3	0	0	0	6*	24
Hostel	23	4	0	0	0	4**	15
Joomla	9	5	0	4	0	0	0
MyBB	6	0	0	0	0	6	0
OpenCart	6	0	0	0	6	0	0
Piwigo	5	1	3	0	0	1	0
PrestaShop	3	0	3	0	0	0	0
SCARF	12	1	0	0	0	7*	4
User Login	3	0	0	0	0	0	3
WordPress	7	0	0	1	3	0	3

6.2 False positives

Black-box scanners use a variety of methods to detect injected XSS payloads, which can result in false positives. ZAP, for example, incorrectly identified XSS in WordPress. It statically found the injected token `;alert(1);` in a JavaScript context. However, the token was inside a string, which in this case it is not possible to break out of.

Confusing multiple payloads is another problem many scanners face. In the Hospital Management System, ZAP can successfully inject an XSS payload into the database. However, it does not detect this as a stored XSS, and is confused when it later scans for DOM-based XSS with the same payload, `alert(5397)`, which ZAP does find. This is caused in part by the number 5397 not being random but a constant, defined in the code as `UNLIKELY_INT`. Therefore, for a single stored XSS vulnerability, ZAP instead reports 26 DOM-based XSS. In this case, mistaking DOM XSS for stored XSS can impact developers who are unable to reproduce the results when the database is reset.

Our approach can avoid many of these problems by using unique IDs for each cell in the database and dynamically testing that each payload is executed. As such, similarly to Black Widow, we have a low rate of this type of false positive.

In contrast to black-box scanners, our approach does not automatically verify that an unprotected input exists. Therefore, we might report a database cell that cannot be changed by the web application. For example, in the Hostel Management System, the list of US states were not escaped on output, but were all hard-coded. We argue that when more functionality is added, either through software updates or third-party code such as plugins, it can introduce a vulnerability, and as such these reports are important.

6.3 What we miss

In the complex setting of web applications, there might always be more unknown vulnerabilities. In the absence of ground truth, in line with previous work [9–11, 33, 47, 49], our false negative comparison baseline is the stored XSS results of other scanners.

In Piwigo our method can find a reflected value, but not XSS, for a value in the configuration table. However, upon further manual analysis, we note that the reason we did not find the XSS vulnerability was because of the payload chosen. In this case, the value was reflected inside a textarea, meaning a `</textarea>` tag was needed to break out and execute JavaScript.

Black Widow found one XSS on Piwigo that we missed. While we were able to add the payload and find the correct URL, the URL was too late in the reflection scanner's queue and was therefore never visited. Increasing the reflection scanner's timeout would solve this, at the cost of runtime performance.

We have only implemented a prototype that demonstrates the utility of our approach. As with all scanners, the choices taken in that implementation can lead to false negatives. False negatives can stem from missing SQL analysis that can limit our interaction with the database, such as foreign keys and other constraints, and triggers. Better authentication, and re-authentication, mechanisms would also improve our approach. Replaceable components to our method, such as the reflection-crawling and payload-selection modules, are shown to be the cause for some of the false negatives in this section.

In addition to our evaluated comparison with the other scanners, we also survey vulnerabilities from CVEs and previous academic papers to construct a dataset of known vulnerabilities in our choice of evaluated web applications. In this dataset, 33 previous reports covered 29 unique stored XSS vulnerabilities, of which we find 26 (details in Table 6). In WordPress, we miss a vulnerability that relies on an attacker-controlled server that returns a crafted message to a link embedded in a post. For all evaluated methods, including ours, this type of attack is out-of-scope. However, it should be noted that we do correctly mark the database column as unprotected output. In CMSMS, we miss a stored XSS vulnerability in the filename of uploaded files. Here the payload is not stored in the database but rather in the filesystem. Extending our method from databases to other storage mechanisms could be an avenue for future work. Finally, in OpenCart, we miss a stored XSS in the category description because we do not spend enough time crawling the application after database modifications, to scan for reflections of the inserted payload. After extending the reflection scanner's timeout, Spider-Scents was able to find this vulnerability as well.

6.4 What others miss

From the scanning results of the Doctor Appointment Management System, we can see that ZAP fails to detect multiple XSS vulnerabilities. By analyzing database snapshots before and after execution we note that ZAP was only able to insert data into the `tbldoctor` table. While it was able to add the string "ZAP" to the `FullName` column, it could not add an XSS payload. Furthermore, ZAP misses other tables, such as `tblpage` and `tblappointment`, that our method modifies and detects as unprotected output.

We also note cases where the compared scanners fail to find XSS due to a lack of database coverage. For example, in MyBB, no other scanner affects the vulnerable `mybb_usergroups.namestyle` column.

6.5 Exploitability

Both black-box scanners and our method will report on injected JavaScript being reflected and executed. However, as we see in Table 2, not all these executions could, in their current form, be exploitable. Interestingly, we note that web applications are relatively equally split on using sanitization and escaping on user input. Validation, on the other hand, is less common. Moreover, permissions also play an important role in protecting these *XSS vulnerabilities* from becoming exploitable.

6.6 Drop-in testing with Spider-Scents

In our evaluation, we assisted other scanners by modifying the web applications under test, so they could evade typical login checks. While beneficial for increasing their performance for the sake of comparison, such modifications are not ideal.

To demonstrate the applicability of Spider-Scents, we *do not modify* web applications when we run Spider-Scents. Therefore, we rely entirely on our breakage heuristics, automatic reverting, and automatic use of captured log-in details.

6.7 Manual analysis with Spider-Scents

Spider-Scents requires more manual effort to verify a vulnerability compared to a black-box solution. However, as Spider-Scents reports the corresponding database table and column, e.g. `users.email`, it is usually relatively easy to manually find relevant input fields and test for a working XSS payload, as described in Section 4.8. In our evaluation, it took an author approximately 15 minutes per report, on average. Preparing Spider-Scents to scan takes a similar time to other scanners, with the small addition of database credentials.

Further automation to ease analysis is possible, such as mapping input fields to the database, although this will require addressing general challenges of crawling, such as exploration and input validation [11].

6.8 Runtime performance of Spider-Scents

In contrast to other black-box scanners, which can run indefinitely [11], our method runs for a time proportional to the database of the application. In our evaluation, other black-box scanners are limited to a runtime of 8 hours. Spider-Scents almost always completed its scans within this time window, with the exception of modern applications Joomla and PrestaShop. Reference applications are scanned within minutes, while modern applications are scanned in hours.

Table 3: Runtime performance of Spider-Scents. Runtime is proportional to the size of the database of the application, reported in both the raw number of database cells and those that Spider-Scents can scan (satisfy payload requirements).

	Scan time	Database cells	Scannable
CMSMS	7:14	11844	4339
Doctor Apt.	0:08	195	87
Hospital	0:22	282	106
Hostel	0:13	205	90
Joomla	12:59	11584	4813
MyBB	4:21	15701	5321
OpenCart	1:39	31490	11553
Piwigo	1:07	1826	520
PrestaShop	32:29	44529	10745
SCARF	0:06	36	15
User Login	0:01	10	6
WordPress	1:55	385	868

We report the scan time of Spider-Scents in evaluation in Table 3. These times are collected on a laptop from 2021 with 8 cores and 16 gigabytes of RAM, running both the application's web server and the Spider-Scents scanner.

6.9 Coordinated disclosure

We have reported all new vulnerabilities to the affected vendors and will summarize their responses here. MyBB is planning to fix the vulnerabilities we reported in the upcoming 1.9 version. The CMSMS developers argue that any authenticated XSS (regardless of the specific user/group permissions) is not considered a vulnerability. Instead, they will revise their documentation to no longer motivate their permission model as a "security mechanism". WordPress, on the other hand, does consider some authenticated XSS as vulnerabilities, depending on permission. However, their security model differs from that evaluated. In our model, we considered any privilege escalation as a vulnerability, while WordPress developers consider *editor* and *admin* to be equivalent. As such, there does not seem to be a consensus among web developers as to how application permissions should be modelled. We are still waiting for a response from PHPGurukul for vulnerabilities in their multiple applications. However, these vulnerabilities have a clearer precedence with similar vulnerabilities to ours, e.g. *CVE-2023-27225*.

6.10 Summary

As the results show, Spider-Scents performs both better in database coverage and stored XSS vulnerability detection when compared to state-of-the-art scanners. Based on what vulnerabilities the other scanners miss and what we uniquely find, we believe the reason for this improved performance is because we bypass the majority of the roadblocks that current XSS scanners face (as defined in Section 3). Solving these challenges directly is a substantially harder problem [8], and will require solving fundamental challenges with crawling [11]. In many instances, the other scanners fail to get any data into the vulnerable database column for vulnerabilities only Spider-Scents finds, and in other cases when they do, only benign data is added. In general, the main problem current scanners face, which we bypass, is getting the payload into the database.

7 Related Work

7.1 Black-box scanners

Enemy of the State [7] models server-side state in different links and requests are identified that drive such state changes. Notably, this work recognizes the necessity of a solution to resetting a web application. In this case, the application is run in a VM, and the machine is reset to counteract irreversible state changes. Spider-Scents does not need a VM, and resets can be done in a granular and inexpensive fashion. Furthermore, Enemy of the State's access to the VM subsumes this paper's access to the database.

LigRE [9] and KameleonFuzz [10] also focus on server-side state. LigRE improves XSS detection with taint flow inference, and KameleonFuzz adds genetic algorithms for payload generation and modification. Similar to Enemy of the State, these approaches require the ability to reset the web application.

jäk [33] instead focuses on modelling client-side state. JavaScript APIs are hooked to be able to model dynamic behaviour. The crawler generates a navigation graph including this information.

CrawlJax [25] also models client-side state. Interactable candidate elements, such as clickable ones, are interacted with to extend the crawler's reach. A state-flow graph models the user interface.

Black Widow [11] identifies key fundamental challenges for black-box scanning. They mitigate them by combining navigation graphs, workflows, and inter-state dependencies in one XSS scanner. In contrast to prior work, Black Widow does not assume the ability to reset the web application.

7.2 White-box scanners

Saner [4] focuses on identifying improper sanitization to find vulnerabilities such as XSS and SQLi. Saner is limited to analyzing PHP, and even more to custom sanitization routines. To reduce complexities with application state – such as the database – Saner does not interact with a live instance of the web application, instead choosing to build a model of the sanitization process from static analysis results.

Restler [3] does not use the entire application's codebase, but instead only the REST API specification. Static analysis of this specification identifies inter-request dependencies to generate tests, which generate dynamic feedback execution to guide further testing. Similar to Spider-Scents in both analyzing a different artifact/interface than typical static or 'grey-box' analyses, Restler also focuses on bugs. Indeed, they note that vulnerabilities in a REST specification are unclear.

Sentinel [24] seeks to limit access to sensitive data in the database to SQLi attacks. The authors model web applications to identify invariants for the 'normal' functionality, which they use to examine queries and responses to block malicious SQL usage.

7.3 Grey-box scanners

Most prior grey-box approaches inform a white-box scan with some runtime information from a black-box scan, to reduce the false positive rate and generate a full exploit proof. We argue that only needing database access is more general than source code [7]. It is easier to apply our approach to a different web application. Being almost black-box, we are agnostic to the coding language and framework for the application's implementation. White-box approaches might not be able to handle obfuscated code. Obfuscated code can also be present due to extensions, such as plugins. We also do not replace the database or insert some proxy between the database and the application. This makes it easy to adapt our approach to other storage mechanisms.

webfuzz [50] instruments code for coverage, and uses this feedback to fuzz requests for detecting reflected and stored XSS. This approach is expensive - WordPress reaches 27% coverage in 2000 minutes.

Witcher [49] identifies issues with using grey-box coverage to guide a web application fuzzer for vulnerability discovery. A Fault Escalator is defined to detect when the application is in some vulnerable state, and guide the fuzzer to escalate that to a vulnerability. Together with a refined notion of coverage, Witcher can fuzz URLs to find command and SQL injection. This approach is limited to first-order reflected vulnerabilities and does not model application state.

Gelato [18] detects reflected and DOM-based XSS. Taint analysis is used to target exploration of the large state space of modern JavaScript.

Backrest [14] statically infers a model REST API, then uses coverage and taint feedback to drive fuzzing of requests for detecting SQLi, XSS, and command injection. While the motivations are to both improve coverage and runtime, the runtime improvements are more evident. Notably, XSS detec-

[7] Static analysis can also be performed on compiled binaries or intermediate representations. However, the same arguments against generality apply to those other artifacts.

tion, especially stored XSS, is reduced when provided with feedback. The authors point out the problem of following taint across the interface with storage in a database.

Chainsaw [1] implements automated exploit generation, where potential vulnerabilities derived from static analysis are dynamically tested, with successful executions being concrete exploits. Symbolic execution of PHP is used to find sources and sinks, as well as sanitizations/transformations along paths. The database is regarded as an additional input to the application, with the database schema consumed. Workflow-based vulnerabilities, such as stored XSS, are found within a comparable 600 minutes.

7.4 Database-aware grey-box web scanning

Similarly to Spider-Scents, Steinhauser and Tůma utilize a grey-box approach for detecting context-sensitive XSS using the database alongside a normal black-box scanner [47]. They deal with context-sensitivity in line with Context-Auditor [23].

Steinhauser and Tůma' s grey-box approach intercepts database and web application communication, injecting non-XSS payloads into the application by replacing data coming from the database.

XSS flaws are detected by black-box parsing of HTML responses from the application matching portions of payloads in responses, to detect the payload if the application applies some common encodings. The parser continues with the possible XSS flaw, and payloads are iteratively modified to avoid context encoding. Some automatic reports of XSS flaws must then be manually analyzed to identify vulnerabilities

This approach is substantially different from that of Spider-Scents. We achieve a different, more complete form of coverage, by iterating through the contents of the database, instead of only modifying values as they are retrieved by the requests from a black-box scanner. This approach ① skips missing database entries, with the database only populated by pre-provided configs or manually sampled data from public demo instances. We also scale differently; with the database modelled as *additional inputs*, this approach of extending HTTP request fields can become ② several *orders of magnitude slower* than the base black-box scanner. For efficiency, *all database injections* are combined per request, ③ which authors note increases breakage, without proposing a solution. The applications under test are also ④ substantially modified to aid the scanner. Finally, Steinhauser and Tůma's approach is implemented by ⑤ extending MariaDB, which replaces the database in the tested web application.

In contrast, Spider-Scents ① augments the database, ② is lightweight in our evaluation, ③ identifies and fixes application breakage, ④ works without modifying web applications, and ⑤ is implemented without a heavy-weight database replacement or proxy.

In terms of results, we share Joomla and PrestaShop. Steinhauser and Tůma verified 5 and 12 vulnerabilities in Joomla and PrestaShop, with their reports resulting in all Joomla and some PrestaShop flaws being fixed. As all Joomla flaws reported were fixed, the 9 we identify either are missed by their approach or come from further development of Joomla. Unfortunately, source code artifacts for this paper are unavailable, so we cannot do a direct comparison.

7.5 Database synthesis

SynthDB [6] is a recent work addressing the tangential problem of preparing database-backed web applications for security testing, such as vulnerability scanning, by synthesizing a database. In contrast to our simplistic approach, with the singular goal of having some data in every table while correlating inserted fields across tables, SynthDB uses concolic execution of PHP source to collect database constraints. These constraints are solved to uncover more program paths, while not violating 'database integrity'. Similar to Spider-Scents, the performance of scanners such as Burp is improved with this white-box preprocessing step.

Our approach also uncovers a separate problem - finding a *minimal* database. In the osCommerce application, there are over 3 million cells in the base application.Our approach must have its parameters tuned to handle this volume of cells. However, we have found this application's scale abnormal by several orders of magnitude; other web applications typically only have hundreds to tens of thousands of cells.

8 Conclusion

Black-box vulnerability scanners are the best tools currently available for democratizing security testing—allowing web developers with no security background or knowledge to proactively find vulnerabilities in their web applications. However, the twisted designs and logic of web applications make it difficult for black-box vulnerability scanners to even inject XSS payloads into the web application. Our approach cuts this Gordian Knot of properly supplying inputs to a web application—by injecting the XSS payloads directly into the database. We believe that this approach represents a step forward in automatic stored XSS detection, and the evaluation results show that our Spider-Scents prototype surpasses state-of-the-art black-box vulnerability scanners, while our manual systematization provides the necessary contextualization of vulnerability and exploitability to these results.

A Appendix

A.1 Spider-Scents configuration

We have implemented a variety of tunable parameters for configuring Spider-Scents' choice of heuristics while scanning. Some notable parameters are:

- Avoid sensitive rows or not
- Insert rows into empty tables or not
- Configure the traversal through the database (order by table, row, column, random, reverse)
- Breakage threshold and detection type (based on status codes, response length, link content)
- Enforce independence across boundaries (across table, row, column)

We evaluate our approach avoiding sensitive rows, inserting into empty tables, traversing the database by tables and then columns, with breakage sensitive to status codes and allowing up to 50% of link content to be missing, and independence enforced across bounds.

Table 5: The number of unique database columns affected by each scanner. For each column in the table, we present: database columns only covered by Spider-Scents ($A \setminus B$), columns covered by both scanners ($A \cap B$), and columns covered by the other scanner ($B \setminus A$). The very last column presents the maximum number of columns that allow arbitrary text values.

Crawler	Arachni			Black Widow			ZAP			**MAX**
	$A \setminus B$	$A \cap B$	$B \setminus A$	$A \setminus B$	$A \cap B$	$B \setminus A$	$A \setminus B$	$A \cap B$	$B \setminus A$

megele@bu.edu

Abstract

Injection-based vulnerabilities in web applications such as cross-site scripting (XSS), insecure deserialization, and command injection have proliferated in recent years, exposing both clients and web applications to security breaches. Current studies in this area focus on detecting injection vulnerabilities in applications. Crucially, existing systems rely on manually curated lists of functions, so-called sinks, to detect such vulnerabilities. However, current studies are oblivious to the internal mechanics of the underlying programming language. In such a case, existing systems rely on an incomplete set of sinks, which results in disregarding security vulnerabilities. Despite numerous studies on injection vulnerabilities, there has been no study that comprehensively identifies the set of functions that an attacker can exploit for injection attacks.

This paper addresses the drawbacks of relying on manually curated lists of sinks to identify such vulnerabilities. We devise a novel generic approach to automatically identify the set of sinks that can lead to injection-style security vulnerabilities. To demonstrate the generality, we focused on three types of injection vulnerabilities: XSS, command injection, and insecure deserialization. We implemented a prototype of our approach in a tool called Argus to identify the set of PHP functions that deserialize user-input, execute operating system (OS) commands, or write user-input to the output buffer. We evaluated our prototype on the three most popular major versions of the PHP interpreter. Argus detected 284 deserialization functions that allow adversaries to perform deserialization attacks, an order of magnitude more than the most exhaustive manually curated list used in related work. Furthermore, we detected 22 functions that can lead to XSS attacks, which is twice the number of functions used in prior work. To demonstrate that Argus produces security-relevant findings, we integrated its results with three existing analysis systems – Psalm and RIPS, two static taint analyses, and FUGIO, an exploit generation tool. The modified tools detected 13 previously unknown deserialization and XSS vulnerabilities in WordPress and its plugins, of which 11 have been assigned CVE IDs and designated as high-severity vulnerabilities.

1 Introduction

In recent years, web applications have become an inseparable part of users' daily online lives, providing the means for communication, news, media, and financial services. The plethora of sensitive information held by the databases behind such web applications becomes a lucrative target for cyber-criminals. In 2017, Symantec reported that one in every 13 web requests was malicious [4]. Furthermore, the ever-increasing number of discovered vulnerabilities exposes web applications as well as their users to security breaches [10]. Without loss of generality, we focused on PHP as it powers 77% of all live websites [28].

Injection vulnerabilities (e.g., command injection, insecure deserialization, or XSS) are the most common category of application vulnerabilities in web applications [10]. To exploit such injection vulnerabilities attackers provide malicious inputs to the web application, compromising both the backend systems as well as the clients. The root cause of an injection vulnerability is passing insufficiently sanitized attacker-controlled user-input to *sensitive* APIs. Depending on the injection vulnerability type, the sensitive APIs differ. For instance, PHP's `echo` is recognized as a sensitive API for XSS attacks, while `unserialize` plays the same role for insecure deserialization. Despite these differences, at their core, injection vulnerabilities are data-flow problems where untrusted user-input is accepted at information sources (e.g., HTTP request parameters), propagated throughout the web application's execution, and finally reaching sensitive sinks (e.g., `echo` or `unserialize`).

Existing systems proposed different approaches to detect or exploit injection vulnerabilities using static, dynamic, or hybrid analysis of web applications. Several approaches rely on static taint analysis to track unsanitized user-input to a *predefined* list of sensitive APIs in order to detect different types of injection vulnerabilities [1, 7–9, 21, 32, 42, 42]. Similar to static approaches, prior work also relied on dynamic and hybrid techniques to identify injection vulnerabilities or generate exploits for already detected ones [25, 27].

Despite the effectiveness of prior work in detecting security vulnerabilities, all existing systems possess one common flaw:

They rely on a manually curated or predefined list of sensitive APIs to identify injection vulnerabilities. The accuracy of manually curated lists for sensitive APIs depend on the documentation for the programming language and the expertise of the analyst who identifies the sensitive APIs. As is often the case with human involvement, the listings are not comprehensive which leads to undetected injection vulnerabilities (i.e., false negatives) in web applications. This intuition is not merely hypothetical; our results show, incomplete lists of sensitive sink APIs are commonplace and further lead to false negative results.

Consider, as an example, the vulnerability type of insecure deserialization. Insecure deserialization occurs when an application deserializes untrusted data, such as user-input or generally attacker-controlled data. This vulnerability allows an adversary to manipulate the control-flow of a vulnerable application by injecting a malicious serialized object. As applications commonly interact with objects after deserializing them, an attacker-controlled object can lead to attacks, including arbitrary code execution. Existing studies of insecure deserialization and PHP object injection focus on detection [7, 24, 37] and automated exploit generation [9, 27]. RIPS [7] and Psalm [37] detect PHP object injection (POI) vulnerabilities by statically tracking user-inputs to the `unserialize` API function in PHP applications. Dahse et al. [9] presented the first automated approach to generating POI exploits by tracking the flow of user-input to invocations of the `unserialize` API. While Dahse et al.'s approach identifies POI vulnerabilities, FUGIO [27] utilizes a fuzzing approach to generate a concrete exploit object for an *already detected* POI vulnerability.

Deserialization in PHP is the consequence of invoking PHP API functions that perform deserialization either *explicitly* or *implicitly*. For consistency, we use the term *PHP API* to refer to the set of functions provided by the PHP runtime that can be directly invoked by web applications. Explicit deserialization APIs are described throughout the PHP manual [12]. One can identify the functions of this group by studying or analyzing the PHP documentation to curate a list of explicit deserialization functions – this approach was taken by RIPS [7], Psalm [37], FUGIO [27], and Dahse et al. [9]. However, implicit deserialization functions are not described in the PHP manual, and are therefore more challenging to identify. First described by Thomas for PHP in [36], implicit deserialization happens if the PHP interpreter transparently deserializes data consumed by certain APIs. For example, Thomas found that the stream wrapper for the PHP archive (PHAR) format implicitly deserializes metadata, which led to the identification of multiple PHAR-based deserialization vulnerabilities in popular web applications and libraries such as WordPress and TCPDF (details in Section 2.4). Crucially, implicit deserialization functions are equally as potent for adversaries as explicit ones. However, implicit deserialization APIs are not documented publicly, and the number and identity of these functions depend on the implementation of the PHP interpreter (i.e., the set of deserialization APIs varies with the PHP version). This implies that in order to identify the set of implicit deserialization functions featured by a given PHP version, one must analyze the implementation of the interpreter itself. The same claim also applies to other injection-type vulnerabilities, such as XSS and command injection.

To improve on the error-prone manual efforts on identifying injection APIs, this paper provides a systematic and principled approach to inferring a comprehensive set of APIs that can lead to XSS, command injection, or insecure deserialization. To this end, we design, implement, and evaluate an automated approach called Argus to identify the list of APIs that deserialize user-input, execute OS commands, or write to the output buffer. For consistency, we use the term , *deserialization*, *output* and *exec API* to refer to the set of PHP APIs that perform deserialization, write to the output buffer, or execute OS commands, which can lead to an insecure deserialization, XSS, and command injection vulnerability, respectively. We demonstrate that by incorporating Argus' resulting sink list into existing systems, those systems produce significantly higher-quality results (i.e., more detected vulnerabilities and exploits). Our key observation is that there is precisely *one* function inside the PHP interpreter that deserializes data – `php_var_unserialize`. Crucially, `php_var_unserialize` is at the core for *all* explicit and implicit deserialization APIs. Consequently, we argue that the correct way to identify the set of deserialization APIs is to subject the PHP interpreter to program analysis. In cases of XSS vulnerabilities, a PHP API such as `echo` prints its argument to the output buffer, which contains the HTML response sent back to the user's browser. Our observation shows that there is one function inside the PHP interpreter responsible for writing to the output buffer called `php_output_write`. Similarly, the set of exec APIs will eventually invoke the `execve` system call in order to execute the OS command. For brevity, we use the term *vulnerability indicator functions* (*VIF*) throughout the text to refer to the functions `php_var_unserialize`, `php_output_write`, and the functions inside the PHP interpreter that directly invoke the `execve` system call or use its front-ends in C (e.g., `exec` family).

Argus detects the set of deserialization, exec, and output APIs through an automated hybrid static-dynamic program analysis of the PHP interpreter. Specifically, Argus first generates the call-graph for a given PHP interpreter. Subsequently, Argus performs a reachability analysis to identify the set of PHP API functions whose invocation can trigger either deserialization or output API in the interpreter (i.e., reach the *VIF*). Using this approach, Argus detected more than 280 functions (in PHP 7.2) that deserialize their arguments and 22 functions whose invocation writes their arguments to the output buffer.

We demonstrate the security impact of Argus by integrating its findings as the set of injection-sinks into three PHP analysis tools; Psalm [37] and RIPS [1] (static taint analyses to identify POI, command injection, and XSS vulnerabilities) and FUGIO [27] (a POI exploit generation system). When evaluating

Psalm with the extended list of injection-sinks on over 1,900 popular PHP applications and plugins, our evaluation yielded 10 times more potential for insecure deserialization compared to Psalm's default implementation (which exclusively reported false positives). Furthermore, we integrated Argus' list of deserialization sinks into FUGIO and discovered proof-of-concept exploits for 12 previously unknown deserialization vulnerabilities on the same data set. In summary, this paper makes the following contributions:

- We draw attention to the importance of accurately and comprehensively detecting APIs in PHP that lead to injection vulnerabilities such as insecure deserialization, XSS, and command injeciton.
- We design and implement a novel automated analysis and prototype (called Argus) to identify the set of deserialization, exec, and output APIs applicable to any version of the PHP interpreter.
- Evaluating Argus on the three most popular PHP versions identifies over 280 deserialization APIs, at least an order of magnitude more than the most extensive manually curated list used by prior work (i.e., 26 sinks in FUGIO). An adversary can leverage a call to any of these APIs to exploit a PHP application. Argus also detects 22 output APIs, which is twice the number of APIs that were used in the past to detect XSS vulnerabilities. In addition, Argus detects 9 exec APIs which can be used to detect command injection vulnerabilities by Psalm and RIPS.
- In order to demonstrate the real-world impact of these findings, we incorporated our results into three existing analysis tools, Psalm, RIPS, and FUGIO. Our refinements of the sink-lists used by these tools led to the identification of 13 previously unknown POI and XSS vulnerabilities. Of course, we responsibly disclosed all our findings to the corresponding developers. As such, 11 of the detected POI vulnerabilities have been assigned CVE IDs (CVSS scores between 7.2 and 8.8), and seven vulnerabilities have already been patched.

2 Background and Motivation

In this section, we describe XSS, command injection, and deserialization in PHP and how these vulnerabilities arise (e.g., implicitly from file operations). This background allows us to shed light on our results and put the evaluation presented in Section 4 in context. Finally, we elaborate on our assumptions about XSS and insecure deserialization attacks on PHP applications and our motivation to design an automated approach to identify a comprehensive set of deserialization, exec, and output functions in an interpreter.

2.1 PHP interpreter and Cross-site Scripting

A cross-site scripting (XSS) vulnerability is an injection vulnerability that allows an attacker to compromise the interactions of the victim with a vulnerable application [21]. This vulnerability allows the attacker to execute malicious scripts in the victim's web browser by including malicious code in a legitimate web application.

In the life-cycle of a request sent to a web-server such as Apache or Nginx, the PHP interpreter plays an important role in providing the output shown to the user. When a web-server receives a request for a PHP script, the web-server invokes the PHP interpreter to determine the output. The PHP interpreter executes the PHP script, which can include interaction with a database, the file system, or the underlying operating system. After the execution of the script, the PHP interpreter provides the output in the form of HTML to the web-server. The output is then sent back to the user as the response.

Thus, the PHP interpreter determines the response that the web-server sends back to users. In order for a PHP script to assemble the response, the PHP interpreter provides a set of built-in functions (i.e., PHP API), which PHP scripts can use. One of the APIs that is used to modify the response of a web-server is `echo`. This function accepts one or more strings, which are then sent verbatim to the output buffer. However, the set of APIs that can modify the response of a web-server is not limited to only one API. According to prior work such as RIPS [7], there are 12 functions in the PHP interpreter that can modify the output buffer.

In a cross-site scripting attack, the attacker is able to modify the response that is sent back to the user's browser. If an attacker has control over the arguments passed to an API such as `echo`, an XSS attack is a certainty. This capability of the `echo` API is provided by an internal function of the PHP interpreter, which allows APIs to write into the output buffer (i.e., the HTML response). An analysis of the source-code of the PHP interpreter reveals that all write opration to the output buffer goes through a function called `php_output_write`. As a result, all invocations of the `php_output_write` by the PHP APIs can modify the response sent back to the web-server, which is the superset of all the APIs identified in prior work.

2.2 PHP interpreter and command injection

Command injection in PHP applications occurs when a malicious actor gains the ability to execute arbitrary commands (e.g., through a shell) [3]. Command injection attacks result in a range of consequences, such as compromised data confidentiality and integrity or unauthorized access to the system hosting the application. An attacker can leverage the exploited application to execute a malicious payload and gain access to additional resources.

As mentioned in Section 2.1, in the life-cycle of a request, the PHP interpreter executes a PHP script. During this execution,

the PHP interpreter communicates with the resources through the operating system to determine the output.

The operating system provides mediated access to resources through the system call API. Applications such as the PHP interpreter can access OS resources by invoking system call APIs. A PHP interpreter executes OS commands by invoking the `execve` system call or its wrappers in the C libraries, such as the family of `execv` functions [22]. Consequently, a command injection attack only occurs when the PHP application uses a PHP API that invokes the `execve` system call and passes insufficiently sanitized user-input. As a result, a PHP API is part of the *Exec API* if its underlying implementation invokes the `execve` system call.

2.3 PHP Object Injection

PHP object injection (POI) is a security vulnerability that leverages insecure deserialization in PHP applications. To exploit such a vulnerability, an adversary must control the properties of an insecurely deserialized object. By exploiting a POI vulnerability, an attacker can potentially hijack the program's execution by controlling the properties used in automatic calls to the `__wakeup` and `__destruct` methods.

The snippet in Listing 1 presents a PHP script that contains a deserialization vulnerability. We observe that at Line 9, user-input is passed to the `unserialize` function without sanitization. In order to exploit this vulnerability, the attacker needs to satisfy two conditions.

- There needs to be at least one class in the application which implements the class methods `__wakeup` or `__destruct` to carry out the attack.
- All of the classes used in the exploit need to be defined (or the application must support automatic loading of classes) when the `unserialize` function is called on Line 9.

Exploiting a POI vulnerability is inherently a code-reuse attack, where an attacker recombines the already existing code to achieve a malicious outcome by introducing a malicious object. To exploit a POI vulnerability the attacker needs to identify the user-defined functions and methods (i.e., gadgets) in the PHP app that can be used to achieve his goals [27]. As an example, we describe how an attacker can choose the gadgets to link and perform a remote code execution attack in Listing 1. Looking at Listing 1, the script defines two classes prior to the deserialization: `Example` and `Exec`. The destructor of class `Example` calls a function named `getValue` from the variable `obj`. If an attacker sets the variable `obj` to an object of class `Exec`, then the destructor will call the class method `getValue` at Line 7. Looking at the implementation of class `Exec`, the method `getValue` invokes the function `system` on the `_cmd` property. Hence, the attacker can run an arbitrary command be setting the value of the `_cmd`. The code snippet in Listing 3 contains the exploit for the vulnerability in Listing 1.

```
1  class Example {
2    protected $obj;
3    function __destruct() {
4        return $this->obj->getValue();} }
5  class Exec {
6    private $_cmd;
7    function getValue() {
8      system($this->_cmd); } }
9  $user_data = unserialize($_POST['data']);
10 file_exists($_POST['file']);
```

Listing 1: A deserialization vulnerability leading to arbitrary code execution. An adversary can execute any command by crafting a PHP object which modifies the value of `_cmd` property.

2.4 Stream Wrappers

In this section, we explain the concept of PHP stream wrappers and how an attacker can abuse stream wrappers to cause a PHP object injection. A stream in the PHP interpreter is a generalization of a data source which implements a set of common file operation functions such as `fopen` and `copy`. PHP Stream wrappers allow developers to use consistently-named file-related functions such as `fopen` for different types of file resources. The types of resources are identified analogous to URL schemes and can vary from classic local files (e.g., `/etc/passwd`), network reachable resources (e.g., `https://example.com/text`), to PHAR archive types (e.g., `phar://usr/share/app.phar`). Importantly, once the resource's type is identified, the PHP interpreter, maps each type to a corresponding stream wrapper which allows the application developer to transparently perform (supported) file operations on the resource (e.g., `read`, `seek`, etc.).

PHP Archives (`phar`) allow developers to package an entire PHP application in a single file. To interact with phar files, PHP provides a built-in stream wrapper. Each phar file contains the following sections:

- **Stub:** A PHP file that instructs the interpreter how to load the application.
- **Manifest:** Includes the number of files in the phar, as well as the file permissions, type of compression, and serialized metadata. The metadata includes a description for the existing files in the archive in a *serialized* format.
- **Contents:** The content of files in the phar archive.
- **Signature:** An optional signature for the file's integrity.

Exploiting phar wrappers. Thomas in [36] demonstrated how an attacker can exploit an invocation of a file operation API and perform a PHP object injection. He showed that the PHP interpreter deserializes the metadata upon any file operation on a phar file. Considering the aforementioned information, an adversary can achieve arbitrary code execution by leading the PHP interpreter to perform file operations (e.g., `file_exists`) on a phar file with a malicious metadata field.

The second part of Listing 3 shows how an attacker can generate a phar file with malicious metadata (set on Line 12). Looking at the snippet in Listing 1, we observe that the PHP script checks the existence of a file by passing an unsanitized user-input at line 10. In order to exploit the vulnerability at Line 10 of Listing 1, the attacker can set the `$POST` variable `file` to `phar://path-to-malicious-phar-file`.

2.5 Observations, Motivation and Assumptions

Our work is motivated by the error-prone human efforts to aggregate lists of deserialization, exec, and output APIs in PHP. Consider the case of CVE-2022-2437, an insecure deserialization vulnerability that Argus identified in the popular `Feed Them Social` WordPress plugin (detailed discussion in Section 4.3.1). This vulnerability exists because of the implicit (i.e., undocumented) deserialization performed by the `get_meta_tags` PHP API function. As this API is missing from all sink lists of prior systems, the vulnerability went unnoticed. Argus automatically identified this function (along with over 280 others) as a deserialization API, and by incorporating this knowledge in existing POI analysis systems these systems readily detected and created POC exploits for this vulnerability.

As mentioned in the introduction, Argus' analysis relies on a key observation regarding the invocation of deserialization, exec, or output APIs inside the PHP interpreter. In the case of deserialization, the PHP interpeter uses its own template and formatting for serialized data. The PHP interpeter uses a customized *yacc* [20] parser to first parse the serialized data and then perform the deserialization. Our analysis of the PHP source-code shows that there is only *one* function inside the PHP interpeter, which uses the *yacc* parser. Hence, there is only *one* function responsible for deserialization: `php_var_unserialize`. In the case of output APIs, we analyzed the source-code of the PHP interpreter. Specifically, we analyzed the underlying implementation of output APIs such as `echo` and `print_r` and identified the set of invoked functions inside the interpreter. For a more comprehensive study of the output APIs, we executed the official PHP testsuite and analyzed all the function traces for each output API that leads to writing to the output buffer (i.e., using the `write` system call). Similar to our observation for deserialization, the PHP interpreter uses the `output` module and specifically the function `php_output_write` inside this module to write to the output buffer (i.e., the HTML response).

Many implicit deserialization and output APIs are vulnerable if an attacker can invoke them on a malicious file (e.g., PHAR archives). For such attacks to succeed, the malicious file must reside on the web application's file system. Thus, to demonstrate exploitability, we assume an attacker already uploaded a malicious file to the underlying web-server. Note that, while this assumption is realistic (see Section 5 for a more detailed explanation), the assumption purely exists to demonstrate exploitability and is orthogonal to Argus' goal of identifying deserialization and output APIs.

3 System Design

In this section, we discuss the salient characteristics of our approach – Argus – and how it identifies the set of deserialization, exec, and output PHP APIs. Figure 1 illustrates the overall process. First, Argus combines static and dynamic analysis techniques to generate a call-graph of a PHP interpreter in Step ①. Subsequently, for Step ②, Argus uses the call-graph to perform a reachability analysis to determine the set of API functions that invoke the *VIF*s. Furthermore, Step ③ discusses the validation mechanism in Argus to confirm the injection-sinks. Finally, we discuss how we incorporate Argus' results into existing program analyses to detect and exploit previously unknown vulnerabilities.

3.1 Call-graph Generation

In Step ①, Argus generates a call-graph for the PHP interpreter. To achieve this, Argus performs a static analysis on the PHP interpreter to generate the initial call-graph, which it then refines using dynamic execution traces.

3.1.1 Static Analysis of the PHP Interpreter

To construct the call-graph, Argus analyzes the PHP interpreter. The PHP interpreter's core consists of approximately 120K lines of C code. Additionally, the interpreter relies on extensions to deliver features such as image processing, database communication, and communication protocols such as LDAP and IMAP. These extensions are free to augment the PHP API, including adding additional injection-sinks, and frequently do so. For example, in a standard PHP deployment, the *GD* graphics library, the *PDO* database communication extension, and the FTP extension are provided as separate libraries and all add additional injection-sinks to the runtime. To complicate matters further, extensions can be written in different programming languages (e.g., [6, 41]), provide their own build environments, and are usually simply loaded by the interpreter as shared dynamic libraries. However, injection vulnerabilities can arise from any API provided by the runtime, including APIs provided by the core interpreter and those provided by extensions. As such, it is imperative to analyze the interpreter's core along with the code that comprises the extensions. At first glance, the open source nature of the PHP interpreter would suggest a source-based analysis to infer the call-graph. However, the variety of frameworks, languages, and build systems used for extensions would require an analysis catering to all these characteristics. Thus, instead of deriving call-graph information from various interconnected source-based analyses, Argus instead performs its call-graph analysis on the compiled

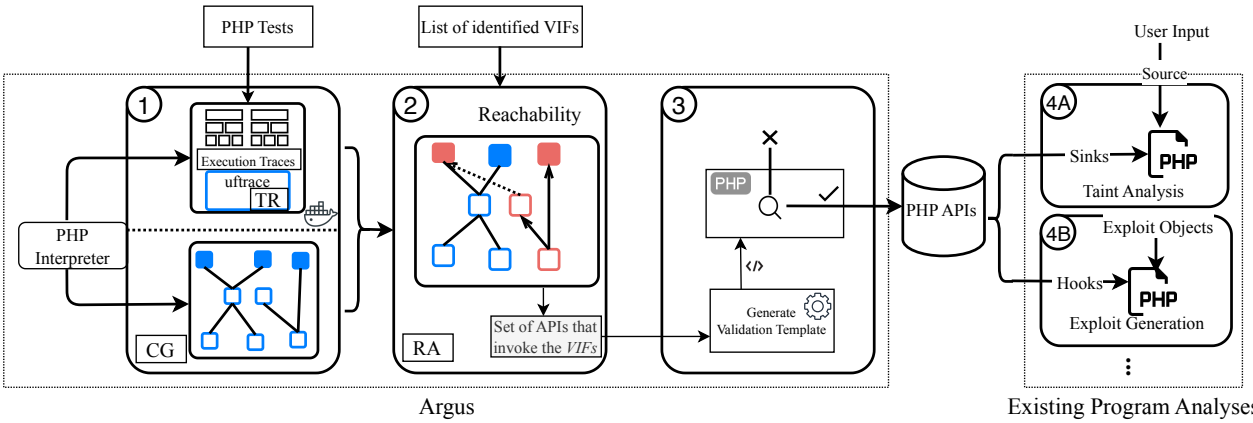

Figure 1: Argus performs a hybrid static-dynamic analysis on the PHP interpreter to generate a call-graph. Next, Argus identifies a comprehensive set of output, exec, and deserialization APIs through reachability analysis and validation tests. The output of Argus can be used to improve the existing program analysis tools to identify POI and XSS vulnerabilities.

binaries of the interpreter and its extensions. To facilitate this analysis, we build the runtime and include debug symbols.

The call-graph analysis (`CG` in Figure 1) first disassembles the PHP interpreter and all of its shared libraries using the `objdump` tool. Argus builds the call-graph by adding a node for each binary symbol in the disassembled PHP interpreter. Subsequently, Argus performs a linear scan over the interpreter and library disassembly. For every call instruction, `CG` draws an edge in the call-graph from the caller (i.e., the currently analyzed symbol) to the callee (i.e., the target of the call). This analysis works well for direct calls and calls to symbols provided by extensions. That is, direct calls will invoke symbols that have corresponding names in the debug information. Argus handles calls to imported symbols by launching the PHP interpreter with the `LD_DEBUG=binding` environment variable set to infer symbol binding information from extension libraries. The `LD_DEBUG` option allows Argus to resolve the external symbols to the library and address where the symbols are implemented. Unfortunately, indirect calls (e.g., those that are used to implement the concept of stream wrappers) elide this analysis.

3.1.2 Refining Call-graph using Dynamic Analysis

Argus uses dynamic analysis to handle indirect calls in the PHP interpreter and refine the statically generated call-graph created in the previous step. For instance, PHP's `fopen` can be used to access local or remote files over protocols such as HTTP, HTTPS, or FTP. Depending on the argument passed to `fopen`, the PHP interpreter decides which stream wrapper (see Section 2.4) should handle the underlying resource. Internally, PHP stream wrappers rely on function pointers to dispatch operations (e.g., `fread()`) to functions that handle the protocol corresponding to the opened resource. The static analysis in Argus cannot handle such cases implemented in the PHP interpreter and runtime. To address this issue, Argus improves the statically generated call-graph by tracing the execution of the PHP interpreter while executing its high-quality test-suite (i.e., the PHP test-suite achieves 70% function coverage on average for our dataset of three different PHP interpreters). Argus then uses this dynamic information and adds any edges not already detected by the static analysis to the call-graph.

To achieve this, we compile the PHP interpreter with the `-pg` flag. This flag instruments each function with two additional hook functions at the entry and exit of each function, which allow Argus to perform dynamic tracing [35]. The first function call occurs just after each function entry, which invokes the function `__cyg_profile_func_enter`. The next function call invokes the function `__cyg_profile_func_exit` before exiting each function. After the recompilation of the PHP interpeter, Argus uses the `uftrace` tool [23] (`TR` in Figure 1) to implement both hook functions and record dynamic traces. Finally, Argus executes the PHP unit tests while `uftrace` records the execution traces for each test-case.

After recording the execution traces, Argus iterates over the sequence of invoked functions by each test-case and examines the statically generated call-graph for the missing edges. For every invoked function during the dynamic analysis, Argus draws an edge between the pair of functions in the execution trace if there is no edge representing the recorded invocation.

At the end of this step, Argus has assembled a static call-graph of the PHP interpreter and refined it using dynamically-collected traces of PHP unit tests.

3.2 Reachability Analysis

In Step (2), Argus performs a reachability analysis on the generated call-graph, which requires the identification of sources and sinks on the call-graph. In this analysis, Argus identifies the set of PHP APIs that reach the VIF functions. We define VIFs as the minimal set of PHP internal functions, that user-input must pass through to trigger a vulnerability. As

stated in Section 1, the PHP interpreter uses a single internal function that is responsible for all deserialization operations, called `php_var_unserialize` (*VIF*). The PHP interpreter uses a custom parser to parse serialized strings, which are then converted to PHP objects. Our analysis of this custom parser across PHP's source-code yielded a single deserialization function inside the PHP interpreter. In the case of output APIs that write to an output buffer, we observed a similar pattern during our analysis of PHP's code, where the function `php_output_write` is exclusively responsible for outputting the buffer. As mentioned in Section 2.2, any PHP API that executes an OS command requires the `execve` system call. As a result, in order to identify the functions inside the PHP interpreter (VIFs) for command injection, Argus needs to identify the functions that call the `execve` system call. To achieve this, we leveraged Saphire [3], to identify functions that invoke the `execve` system call. We marked these functions as the VIFs for the exec APIs. These PHP internal functions are `php_exec`, `zif_shell_exec`, `zif_popen`, `phpdbg_do_sh`, `php_mail`, `zif_pcntl_exec`, `_php_imap_mail`, and `zif_proc_open`. With the *VIF* identified, Argus labels all API functions in the call-graph as sources.

Unfortunately, the symbols for API functions are indistinguishable from those of internal functions, and text-based techniques that parse documentation are rarely, if ever, accurate. However, a running PHP process must be aware of any and all APIs exposed to the web applications running on top of it. Thus, to identify the set of APIs, Argus uses a PHP extension that, once loaded into the PHP interpreter, iterates over all available APIs. Specifically, the extension first invokes PHP's `get_defined_functions` API to obtain the list of all API functions. Unfortunately, the results of `get_defined_functions` cannot be directly mapped to the call-graph. The reason is that the name of an API function available to a web application is commonly different from the name of the symbol that implements the actual functionality. For example, the `session_decode` PHP API is implemented by a function called `zif_session_decode`. Unfortunately, the `zif` prefix is not a consistent pattern. As the nodes in the call-graph correspond to symbol names rather than API names, the API names have to be translated. To this end, the extension leverages an interpreter-internal data structure (i.e., `executor_globals.function_table`), which maps API names to the names of the functions that implement the APIs' functionalities. Finally, the extension relays this information to Argus, which labels the symbols that map to API functions in the call-graph accordingly.

Once all APIs are labeled as sources, Argus traverses the call-graph for each source node and follows any call edges captured in the graph. Argus identifies an API as a deserialization, exec, or output API if this traversal includes the graph node corresponding to its *VIF* function.

3.3 Validation

The reachability analysis presented above might inappropriately label an API as an injection-sink if the underlying implementation in the runtime performs input sanitization or filtering. Thus, Step ③ filters APIs and only passes those that propagate their input to *VIF* unmodified. To this end, Argus automatically generates PHP snippets to test each identified API for this characteristic. More specifically, these snippets contain a class definition (i.e., `test`) that, if deserialized (i.e., its `__wakeup` method is invoked), prints the content of one of its properties (i.e., `msg`) as a success message. Subsequently, the template calls the API in question with a serialized `test` object that has `msg` set to "SUCCESS". Thus, if the execution of the PHP snippet prints the success message, Argus validates that the API in question passes the input argument unmodified to *VIF*, and hence the API is for sure a deserialization API. For each API, the validation step iterates over various patterns of passing inputs including explicit (e.g., serialized data) and implicit (e.g., Phar file). When one input leads to deserialization which invokes our test function and prints out the "SUCCESS" message, Argus marks the API as a deserialization API. The psuedo-code in Listing 4 (Appendix B) shows the process of validating the reachable APIs identified.

As our evaluation in Section 4 will show, Argus confirmed 284 deserialization APIs in the PHP interpreter, which warranted an automated validation step. However, the number of confirmed output APIs in the PHP interpreter is an order of magnitude less (i.e., 22), which prompted us to manually validate whether the invocation of the API with user-input can cause an XSS attack. To this end, we created a Docker container with a running Nginx web-server for each PHP interpreter version. For each output API, we created a PHP template that invokes the API and passes a constant user-input containing a Javascript snippet (i.e., `<script>alert(1)</script>`). We visited the generated PHP template with a browser, and if the browser displays a dialog, Argus marks the tested API as an output API. In case of the exec APIs, we manually validated the set of PHP APIs that execute commands in the PHP interpreter. For each exec API, we created a PHP script that invokes the API and passes a constant user-input containing an OS command (i.e., `ls -lh` which lists the directory content). The PHP interpreter under test executes each of the generated PHP scripts, and if the PHP script prints out the directory information, Argus marks the PHP API as an exec API.

3.4 Extend Security Analysis Tools

Argus' results comprise a comprehensive list of injection-sinks. This is in contrast with the exclusively manually-crafted lists of injection-sink used by all existing XSS and POI detection and automatic exploit generation systems. Thus, to demonstrate the value of Argus' principled approach, we extend three existing

program analysis tools, Psalm [37], RIPS [7], and FUGIO [27] as examples of downstream analysis that benefit from our work.

3.4.1 Psalm and RIPS Extension

Psalm and RIPS are two static analysis tools featuring code refactoring and taint analysis [37]. For the taint analysis, Psalm and RIPS attempt to find unwanted flows between user-controlled inputs (e.g., `$_GET` variables) and a set of sink functions (e.g., `system`). The set of sink functions in Psalm and RIPS differs depending on the type of vulnerability that the user is trying to detect. For instance, to identify insecure deserialization, they exclusively consider `unserialize` as a sink for the core PHP interpreter.

As shown in previous reports [36] and in our evaluation, relying on incomplete lists of sinks results in false negatives (i.e., missed detections). To extend the static analysis tools, we modify the list of taint sinks to include all deserialization, exec, and output APIs identified by Argus.

3.4.2 FUGIO Extension

FUGIO is an automatic exploit generation tool which uses a combination of static and dynamic analysis to generate a proof of concept exploit for *previously known POI vulnerabilities*. In the first step, FUGIO submits requests to a target web application where request parameters (e.g., GET, POST, and COOKIE values) contain serialized data. During the processing of these requests, FUGIO hooks the invocation of deserialization APIs and verifies if the passed arguments correspond to the parameters supplied in the request. To this end, FUGIO hooks a subset of 27 PHP deserialization APIs – the explicit `unserialize` API along with 26 implicit APIs first mentioned by Thomas [36]. If FUGIO detects that parameters are indeed forwarded to deserialization APIs, its second step will attempt to morph the parameter into a complete POP chain, forming a POC exploit. While FUGIO's second step (i.e, the exploit generation itself), is independent of our work, the first step (i.e., recognizing the invocation of vulnerable deserialization APIs) is directly affected by the (in-)completeness of the list of deserialization APIs.

To extend FUGIO, we integrated the set of deserialization APIs identified by Argus such that FUGIO hooks all these APIs in its first analysis step. The extended FUGIO intercepts a comprehensive set of PHP APIs which allows it to identify and exploit previously unknown POI vulnerabilities (see Section 4.3.2 for details).

In summary, Argus generates a call-graph for the PHP interpreter by leveraging hybrid static-dynamic analysis. Furthermore, Argus performs a reachability analysis to identify a comprehensive set of deserialization, exec, and output APIs in the PHP interpreter, and optionally validates APIs that pass their inputs unchecked to the underlying *VIF* deserialization, exec, and output functions. We augmented three existing detection and exploit generation systems as examples that demonstrate the security impact of Argus' results.

Our implementation of the call-graph analysis for the PHP interpreter consists of approximately 700 LoC of Python and C code. In addition, we implemented our extensions to Psalm and FUGIO with less than 600 LoC of PHP.

4 Evaluation

In this section, we evaluate Argus along two orthogonal dimensions. First, we focus on identifying deserialization, exec, and output APIs in the three most popular major versions of the PHP interpreter. The reason for evaluating different interpreter versions is that the number and names of deserialization, exec, and output APIs are implementation and version dependent, calling for an automated solution such as Argus. In the second thrust of the evaluation, we assess how Argus' analysis results improve the accuracy of three example PHP security analysis systems – Psalm, RIPS, and FUGIO. To cover these two dimensions, our evaluation answers the following research questions:
RQ1: In terms of call-graph generation, how precise is the call-graph generated by Argus compared to existing call-graph generation tools such as Joern (Section 4.2.1)?
RQ2: On the interpreter's call-graph, how many PHP APIs reach the *VIF* functions (Section 4.2.2), and how many of the reachable APIs pass their arguments to *VIF* unmodified (Section 4.2.3)?
RQ3: How does the number and identity of deserialization, exec, and output APIs change across PHP versions and what are the reasons for the observed changes (Section 4.2.4)?
RQ4: How do Argus' results improve the current state-of-the-art PHP security analysis that target injection vulnerabilities? Does Argus' comprehensive list of injection-sinks lead to the identification of previously unknown POI and XSS vulnerabilities (Section 4.3)?

4.1 Evaluation Dataset

Our evaluation dataset for Argus is divided into two categories corresponding to the two evaluation dimensions. For our experiments on the PHP interpreter, we evaluated Argus on the three most popular major versions (i.e., versions 5, 7, and 8) of the PHP interpreter. As of June 2023, PHP engines of these versions power 99.8% of all live PHP websites, according to W3Tech data [28]. Furthermore, PHP seven is used by 65.2% of all live websites using PHP, which makes it by far the most popular PHP engine [28]. Our second dataset is used to evaluate the benefit of Argus' results to existing POI, command injection, and XSS detection systems as well as exploit generation systems. As these systems operate on the code of web applications, rather than the PHP interpreter, we aggregated a dataset corresponding to that purpose. We collected the most popular PHP applications and plugins from a variety of sources. On the one hand, we downloaded the 60

most popular PHP applications based on the reported popularity provided by W3Tech [28]. On the other hand, we recognize that large web applications frequently feature a plugin model that allows administrators to customize their sites. As such, we also collected the most downloaded plugins for the popular WordPress, Drupal, and Typo3 web applications from their respective repositories. Overall, we collected 1,977 PHP artifacts (i.e., web applications and plugins). Table 3 provides a detailed breakdown in the first two columns.

4.2 Analysis of the PHP Interpreter

As the PHP language and ecosystem evolves, the interpreter must provide support and functionality accordingly. Unsurprisingly, this evolution also affects the number and identity of the injection-sink functions provided by different versions of the PHP interpreter. To assess these changes, we evaluate Argus on three different versions of the PHP interpreter (versions 5.6, 7.2, 8.0) as detailed in Table 2.

PHP interpreter	Argus	Joern	Argus - Joern	Joern - Argus
PHP 5.6	56,504	31,065	26,024	585
PHP 7.2	68,410	39,560	30,620	1770
PHP 8.0	47,653	33,555	16,636	2538

Table 1: Argus outperforms Joern in terms of detected edges for analyzing the PHP interpreter. The second and third columns show the number of detected edges by each tool. The last two columns report the comparison between the number of detected edges (i.e., subtraction of matching edges).

4.2.1 Argus vs. Joern

Argus uses the call-graph of the PHP interpreter in order to identify injection-sink functions, rendering call-graph generation a crucial step for Argus. For our first evaluation, we investigate the generated call-graphs by Argus and compare the results with Joern, an open-source code analysis tool [19]. During this evaluation, we analyze the PHP interpreter and generate the call-graph using both Argus and Joern. We then compare the generated call-graphs by both tools based on the number of detected edges.

We compared the generated call-graphs in two dimensions: 1) a quantitative comparison of the call-graphs for the number of missing edges, and 2) a qualitative evaluation to investigate the effect of missing edges on identifying injection-sink functions. Our evaluation of the call-graphs generated by Argus and Joern is listed in Table 1. This comparison shows that the call-graph generated by Joern misses 24,426 edges that are included in the call-graphs generated by Argus, on average. There are also cases where Argus misses edges that Joern can detect. However, the number of missing edges by Argus is 15 times less than the number of edges missed by Joern.

For the second part of this evaluation, we investigated the missing edges in the call-graphs of both Argus and Joern. Compared to Argus which analyzes the binary, Joern is a source-code analysis tool. Hence, the compile-time aspects are an important source for the differences between the generated call-graphs by Argus and Joern. In the case of Argus, the missing edges are related to cases of preprocessor directives and compiler optimizations (i.e., these missing edges do not exit in the binary and cannot be exercised). For example, the preprocessor decides to keep or remove blocks of code based on directive conditions (e.g., `#ifdef`); hence, the compiled version of the same source-code can lead to a different binary artifact depending on the condition. As a result, Argus analyzed a version of the PHP interpreter where some function calls were removed due to preprocessor directives, compared to Joern. Furthermore, the analysis of the missing edges by Argus shows that the invoked functions are related to memory management in C, such as `free` and `malloc`. Our analysis shows that the missing edges do not affect the ability of Argus to detect injection-sink functions since the memory management functions in this case are the leaves in the call-graph and do not affect the reachability analysis.

In the case of Joern, the missing edges are mostly related to function pointers in the PHP interpreter. As mentioned in Sections 2.4 and 3.1.2, the PHP interpreter extensively uses function pointers in order to implement its functionality. Joern's call-graph analysis misses the set of indirect calls inside the PHP interpreter, which includes function pointers related to stream wrappers for different file types. Consequently, Joern is not able to detect indirect calls to the `PHAR` module from any file operation APIs such as `fopen`, and using such a call-graph would lead to missing all file operation APIs, which lead to insecure deserialization.

4.2.2 Reachable APIs

Next, we look into the reachability analysis of Argus and the number of PHP APIs that invoke the *VIF* in the analyzed PHP interpreters. The first set of sub-columns in Table 2 labeled as *Detected* for both injection vulnerabilities shows the number of APIs that Argus identified as reaching *VIF* for the three different PHP versions. As the table shows, the number of deserialization APIs for versions 5 and 7 is similar, and two orders of magnitude larger than for version 8. We discuss the difference in the number of reachable deserialization APIs in Section 4.2.4. Furthermore, the number of output and exec APIs for the analyzed PHP versions is almost constant across all three versions.

In our evaluation of Argus' call-graph generation, we explored the contribution of both of our dynamic and static analysis. This analysis demonstrates the advantages of using both static and dynamic analysis while generating the call-graph. To demonstrate the effectiveness, we looked into the number of injection-sinks that Argus can detect by only using the statically generated call-graph. To achieve this, we performed a reachability analysis on the statically generated call-graph of the PHP interpreter before augmenting the call-graph with dynamic information (Step A-2). The numbers

Version	Deserialization API		XSS-leading API		Exec API	
	Detected	**Validated**	**Detected**	**Validated**	**Detected**	**Validated**
PHP 5.6	419 (61)	281 (67%)	54 (51)	22 (41%)	10 (10)	9(90%)
PHP 7.2	425 (63)	284 (67%)	52 (48)	22 (42%	10 (10)	9(90%)
PHP 8.0	20 (13)	13 (65%)	46 (39)	22 (48%)	10 (10)	9(90%)

Table 2: Our analysis of PHP interpreter shows PHP interpreters prior to version 8.0, contained more than 300 PHP functions that deserialize their arguments, execute OS command, or write to output buffer. The numbers in parentheses of *Detected* sub-columns show the number of APIs detected using only the statically generated call-graph.

in parentheses in the sub-column *Detected* for Table 2 show the number of reachable APIs while using only the statically generated call-graph. As an example, we can see that the difference in the number of detected APIs for PHP 5.6 when only using the statically generated call-graph is six times less than when incorporating the dynamic analysis information. Similar to Joern, the missing edges in Argus' static only call-graph relate to function pointers of stream handlers in the PHP interpeter. These results emphasize the benefit of including dynamic analysis to refine the static call-graph.

While using dynamic analysis improves the result of Argus, using only dynamic analysis to generate a call-graph has its own drawbacks. One such drawback is the coverage of dynamic analysis. If the dynamic analysis does not cover all possible functionality of each PHP API, it leads to missing the identification of an injection PHP API. In our evaluation of Argus, we quantified this aspect of dynamic analysis on PHP 5.6 and 8.0. During this evaluation, Argus only used dynamic traces of running PHP high quality unit tests (i.e., 70% line coverage) to generate the call-graph for the PHP interpreter. Next, Argus performs its reachability analysis to identify the injection APIs. Our experiments on PHP 5.6 showed that using only dynamic analysis leads to missing 11 and 5 APIs, which leads to insecure deserialization and XSS. A similar observation holds true for PHP 8.0, which misses 4 insecure deserialization and 7 XSS APIs. As a result, Argus uses a hybrid static-dynamic call-graph generation, since there are drawbacks in both static and dynamic call-graph generations as shown in the aforementioned analyses.

4.2.3 Validated APIs

The second set of sub-columns labeled *Validated* in Table 2 shows the number of APIs that Argus successfully validated to directly pass their input argument to *VIF*. That is, if an adversary can control input to any of these APIs, the existence of an injection vulnerability (i.e., insecure deserialization or XSS) is a certainty. Validated APIs are a strict subset of reachable APIs. The table shows that Argus was able to consistently validate around 66%, 43%, and 83% of the deserialization, output, and exec APIs, respectively. A closer look at the reachable APIs that failed the validation test shows that either the user is not in control of the input to the *VIF* or the input is sanitized. For instance, Argus detects the function `highlight_string` reaches the output *VIF* function (i.e., `php_output_write`), however, the input is sanitized by replacing `"<"` with `"<"`. As a result, the attacker's input does not cause an XSS attack and the function `highlight_string` fails the validation test. In case of deserialization, the `SplTempFileObject::__construct` opens a temporary file object that the user cannot control. As a result, an attacker cannot trick the API to open a malicious PHAR file and validation failed. Table 5 (in the Appendix) contains the complete list of deserialization APIs for PHP versions analyzed. Note that the set of APIs in version 7.2 is a strict superset of the APIs in version 5.6. The table also highlights the APIs that still show deserialization capabilities in version 8.0 by typesetting their names in bold. As shown in Table 2, all three versions of the PHP interpreter have 22 validated output APIs, which are exactly the same among all the versions.

For the set of Exec APIs, Argus correctly detected one PHP API that reaches the exec VIFs. However, the user-input does not influence the executed command (i.e., a false positive). This PHP API, named `error_log`, provides the option of sending the error logs through email using the mail functionality in the PHP interpreter. The mail functionality in PHP in turn allows users to execute OS commands by passing an extra argument. However, user-input does not influence the arguments passed to the mail function in the `error_log` API. Furthermore, compared to RIPS, Argus' set of exec APIs does not include three PHP APIs. The first API, `expect_popen`, is not packaged with PHP source-code. The `expect` extension is installed through `PECL` package management, which is not installed by default on Debian. In addition, installing the PHP interpreter using Debian's `apt` package tool, does not install `PECL` package management. As a result, Argus cannot detect a PHP API that is not installed and compiled with the PHP interpreter. The other two APIs are `w32api_invoke_function` and `w32api_register_function`, which are conditionally compiled and solely available in the PHP interpreter for the Windows OS. Since our evaluation environment relied on the Linux OS, these two APIs were not included in the compiled version of the PHP interpreter. While Argus did not detect any exec APIs beyond RIPS, Argus identified two exec APIs that are not listed in Psalm; `mail` and `mb_send_mail`.

4.2.4 Reasons for Differences

Comparing the results for PHP 5.6 with those from 7.2 reveals three additional deserialization APIs (all of which Argus validated). The reason for this increase is the addition of support for the `BMP` image format in PHP 7.2's GD standard graphics library. Specifically, the new `createimagefrombmp` and `imagebmp` functions serve as implicit (i.e., undocumented) deserialization APIs. The last implicit deserialization API missing from PHP 5.6 is the `ftp_append` API which is supported in PHP versions 7.2 and above. All deserialization APIs

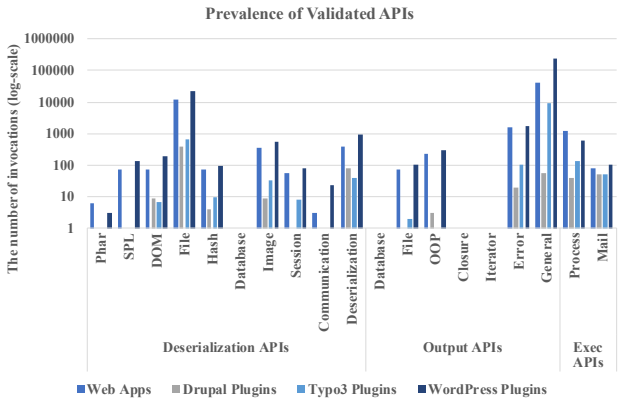

Figure 2: The prevalence of validated APIs in real-world applications.

available in version 5.6 also exist in version 7.2. In contrast to the small change of deserialization APIs between versions 5.6 and 7.2, the drop from 284 to merely 13 deserialization APIs in version 8.0 is significant. As discussed in Section 2.4, prior to version 8.0, any file operation on a phar archive results in the implicit deserialization of the archive's metadata. Fortunately, the PHP developers recognized the negative security consequences this behavior entails in 2020 and voted unanimously to change the default behavior of the phar stream wrapper [11]. Thus, since PHP 8.0 metadata in phar archives is only deserialized upon an explicit call to the `getMetadata` function in the `Phar` module, and not implicitly on any file operation on the archive. While this change certainly benefits the security of web applications, PHP 8.x is still not widely used by PHP-powered websites (less than 5% at the time of writing) [28]. The challenging process of migration prevents most web applications from easily adopting PHP 8 (see details in Section 5). Therefore, most websites still rely on older versions of the PHP interpreter that include 284 deserialization APIs.

4.2.5 Qualitative Analysis of Identified APIs

In this experiment, we assess the prevalence of deserialization and output APIs in our dataset of applications. It is crucial to investigate how many of the identified APIs are actively used in PHP applications since the validated APIs are at the core of injection vulnerabilities. For this evaluation, we grouped different categories of validated APIs listed in Table 5 for different sets of injection vulnerabilities. Figure 2 shows the number of invocation for each API category. As shown in Figure 2, in the case of deserialization APIs, we observe more usage for categories such as file operations and image processing APIs. Similarly, in the case of output APIs, the applications in our dataset often use more error handling APIs as well as general output APIs such as `echo` compared to categories such as Database, Closure, and Iterator APIs.

Furthermore, we enumerate the set of distinct applications that invoke at least one of the newly identified vulnerable APIs. For our dataset of 1,977 applications, 1,355 (i.e., 69%) and 1,218 (i.e., 62%) of applications invoke at least one newly identified deserialization and output APIs, respectively.

Finally, we looked into the pre-condition required for an attacker to exploit each of the newly detected vulnerable APIs. The first pre-condition is that the attacker needs to upload a malicious file to the server hosting the vulnerable application prior to passing malicious arguments to the vulnerable APIs. The second pre-condition is that there should not be a static prefix for file operation APIs, so that an attacker can specify `PHAR` as the stream wrapper. In the case of deserialization APIs, there are 273 APIs (i.e., 96%) that require a file upload and lack of static prefix pre-conditions prior to exploitation. Furthermore, five APIs (i.e., 23%) from the set of output APIs require the pre-condition of file upload prior to XSS exploitation. The APIs that have pre-conditions are indicated in Table 5 in the Appendix. In our evaluation, we enumerated the number of newly identified sinks that PHP applications in our dataset invoke. In the case of deserialization APIs, the most common used API in our dataset was the function `copy` which requires the pre-conditions mentioned above. However, the most common output API used in our dataset was `class_alias` API, which does not require any pre-conditions. In case of exec APIs, we did not perform any qualitative analysis, since Argus did not detect any new APIs compared to RIPS.

4.3 Extending Prior Security Analysis Tools

Argus' value arises from the comprehensive list of output, exec, and deserialization APIs it identifies within a PHP interpreter. To demonstrate the security relevance of this information, we extend two PHP security analysis systems – Psalm and RIPS, both static data flow analysis systems, and FUGIO, a dynamic automatic exploit generation system targeting POI vulnerabilities.

4.3.1 Psalm and RIPS Extension

Psalm and RIPS are two static analysis tools for PHP applications, providing taint analysis and code refactoring capabilities [37]. Taint analysis operates based on a set of configuration files that specify the taint sources and sinks in the PHP application. For our evaluation, we downloaded the latest available versions of both Psalm[1] and RIPS[2] at the time of writing from their GitHub repositories.

Psalm's taint analysis identifies exactly one PHP API function as a taint sink for insecure deserialization: `unserialize`. Furthermore, Psalm includes six functions as taint sinks for XSS vulnerabilities. Argus identified and confirmed 283 and 16 additional sinks that are missing in Psalm related to deserialization and XSS, respectively. To improve Psalm's taint analysis, we extended the set of taint sinks for

Table 3: Extending static analysis tools such as Psalm (Labeled as P) and RIPS (Labeled as R) using Argus' results (Labeled as A) improved their detection rate.

both XSS and insecure deserialization to include the APIs Argus identified for PHP 7.2. Subsequently, we performed a comparative evaluation between upstream Psalm, and our modified version incorporating the APIs identified by Argus on the set of 1,977 PHP artifacts described in Section 4.1.

Our findings in Table 3 show a significant increase (i.e., over 10X) in the number of detected insecure deserialization vulnerabilities by the extended version of Psalm. To compare the quality of the results produced by upstream Psalm and our extended version, we manually analyzed all 656 insecure deserialization reports. As Psalm is a static analysis, we expect the results to contain false positives. Furthermore, as the extended version features 284 times as many deserialization sinks, it is unsurprising that it reports 10 times as many potential vulnerabilities. However, what we did not expect is that all 63 reports (i.e., 100%) arising from upstream Psalm are false positives. False positives can arise from web applications that sanitize inputs or, more prevalent in our POI vulnerability analysis, arise from the fact that the application sets a fixed prefix for file-paths. A "fixed" file-path-prefix, even if it is derived from an API such as `dirname` essentially thwarts any attack that relies on the phar module, as the attacker will no longer be able to specify the `phar://` prefix that triggers the stream wrapper. In order to analyze Psalm's results, we investigated the reason behind the false positives in Psalm's taint analysis. To achieve this, we randomly chose 50 reported deserialization vulnerabilities by Psalm, analyzed the report, and reviewed the source-code of the application. Our investigation shows 49 cases of false positives, where 31 false positives were reported due to over-approximation in Psalm's taint analysis as well as not detecting the sanitization process. Furthermore, 18 false positives were reported due to the fact that the pre-condition was not met. In all these cases, tainted variables had a hard-coded prefix passed to vulnerable APIs, meaning that an attacker cannot trigger the phar module by specifying the `phar://` prefix. Psalm's variable-level taint analysis only taints entire variables and hence cannot differentiate variables with a hard-coded prefix. Finally, one reported case was a true positive.

We confirmed that our extension to Psalm's taint analysis detected 12 previously unknown POI vulnerabilities (i.e., 2% true positives) in our dataset (see Table 4). We categorized the POI vulnerabilities into three groups: (i) unauthenticated, (ii) authenticated, and (iii) CSRF to Phar. The first two types are authenticated and unauthenticated Phar deserialization, which refers to the required privilege in order to exploit the POI vulnerabilities. In the case of an unauthenticated deserialization vulnerability, the attacker can reach and exploit the vulnerable functionality in the application without providing any administrator credentials for the vulnerable application. The last vulnerability type is CSRF to Phar deserialization, where a malicious actor tricks an administrator of a WordPress app into performing an action such as clicking on a link leading to Phar deserialization.

In addition, we confirmed that the extended Psalm detected one previously unknown XSS vulnerability in the core of the WordPress web application. As we will show in Section 4.3.2, FUGIO generated POC exploits for all 12 POI reports supporting the notion that these are actual vulnerabilities. As a case study, we will describe three of the vulnerabilities that we discovered among WordPress and its plugins and how Argus' comprehensive results were necessary to detect them.

In the case of exec APIs, we only extended the list of exec sinks for Psalm static analysis, as Argus only detected more exec APIs compared to Psalm. According to Table 3, we observed that Psalm detected more potential command injections compared to RIPS. In addition, Psalm+Argus detected seven more command injections compared to the unmodified Psalm. Our investigation of the newly identified vulnerabilities showed that the cause of the vulnerabilities was passing user-input to the PHP function `mail`, which was not detected by the unmodified Psalm. Furthermore, since the applications were using OOP, RIPS was unable to detect the tainted data-flow and did not detect the potential command injection vulnerabilities. However, our analysis shows that the newly identified vulnerabilities were false positive as the applications were passing user-input to the `mail` function after sufficient sanitization.

Case Study - Feed Them Social

The detected vulnerability in Feed Them Social is an unauthenticated insecure deserialization which resides in the functionality of the module's Twitter feed. The Twitter feed in this plugin retrieves and shows the content of tweets including any referenced media on a WordPress page. Whenever a tweet contains a URL, the plugin attempts to retrieve the URL's title, image, and description to display on the WordPress page. To do this, the plugin uses the function `get_meta_tags` with unsanitized user-input directly from the tweet to retrieve the metadata of the specified URL. Listing 2 shows the simplified version of this vulnerability in this plugin, where the

unsanitized user-input is passed to the implicit deserialization API `get_meta_tags` on line 4.

In order to exploit this vulnerability, an attacker sets the `fts_url` request parameter to the path of a phar file with malicious metadata. When the plugin tries to read and parse the metadata of the passed URL, it will automatically deserialize the metadata of the malicious phar file. `get_meta_tags` is an implicit deserialization API identified by Argus and not taken into consideration by prior work demonstrating the necessity of Argus' comprehensive analysis.

```
1  function fts_twitter_share_url_check() {
2   $twitter_url=$_REQUEST['fts_url'];
3   // ...
4   $tags=get_meta_tags($twitter_url);}
```

Listing 2: The feed them social plugin passes unsanitized user-input to the function get_meta_tags.

According to the history of the RIPS git repository, the latest modification to its static analysis was nine years ago [7]. A concern that is also raised by the authors of RIPS is that it does not support new features added to the PHP interpreter, such as object-oriented programming (i.e., OOP). Despite its age, Table 3 shows that the extension of RIPS (i.e., RIPS+Argus) leads to identifying more potential vulnerabilities. Further investigation into RIPS' analysis shows that it raises warnings related to the use of OOP in 1,760 applications (i.e., 89% of our dataset), which leads to false negatives. The reason behind false negatives is that RIPS [7] is not able to track tainted data (i.e., data from `$_GET` and `$_POST` parameters) to and from objects instantiated from classes in the PHP applications. In addition, due to the complex and large codebase for some applications in our dataset, RIPS was not able to complete the analysis for 135 applications (i.e., 7% of the dataset). As explained, we identified several drawbacks to the RIPS analysis that have implications for its vulnerability detection. In order to demonstrate these implications, we analyzed the results of RIPS+Argus to identify whether it was able to identify the vulnerabilities discovered by Psalm+Argus. Our analysis shows that RIPS+Argus only identified eight out of the 13 vulnerabilities (i.e., 60%) listed in Table 4.

4.3.2 FUGIO Extension

FUGIO [27] is an automatic exploit generator for previously identified deserialization vulnerabilities in PHP applications. FUGIO's exploit generation hooks a set of predefined deserialization functions while sending serialized objects as request to the web application under test. Our analysis of FUGIO shows that FUGIO hooks into 26 file operation functions in the PHP interpreter as well as the `unserialize` function to intercept deserialization of user-input. Similar to Psalm, FUGIO obtained the list of hooked functions through manual analysis of PHP documentation and prior works such as Thomas [36]. For our evaluation, we downloaded FUGIO from its GitHub repository at `https://www.github.com/WSP-LAB/FUGIO`.

One should note that FUGIO states that it is not a vulnerability detection tool. Rather its core contribution is to generate exploits for *already known deserialization vulnerabilities* [27], such as those identified by Psalm. As a result, we evaluated FUGIO on the 12 vulnerabilities that our extended version of Psalm detected. To extend FUGIO, we modified its source code to hook the comprehensive set of deserialization API functions identified by Argus. The last two columns in Table 4 show the results of extending FUGIO using Argus when generating exploits for the discovered vulnerabilities by Psalm+Argus.

As a dynamic analysis system, FUGIO requires a runtime environment. To this end, we created an experimental environment for WordPress plugins consisting of Nginx, PHP 7.2, MySQL 8, and WordPress 5.4. FUGIO creates attacks by stitching together so-called gadgets into a POP-chain. However, WordPress alone does not contain any gadgets that could be used for remote code execution attacks. In practice, administrators customize their WordPress installations using plugins and themes. Thus to ensure that FUGIO has gadgets to work with, we installed the latest versions of the top ten most popular plugins in WordPress in our experimental environment [39]. During our experiment, FUGIO without Argus' results does not hook into the image functions listed in Table 5. As a result, FUGIO was unable to generate an exploit for two of the discovered vulnerabilities in Table 4. However, the extended FUGIO+Argus successfully generated exploits for *all* the discovered vulnerabilities listed in Table 4. On this small sample, this indicates the comprehensive set of sinks provided by Argus leads to a 20% increase in the number of generated exploits.

Table 4: We verified the reports of Psalm+Argus by discovering 13 previously unkown POI and XSS vulnerabilities. The vulnerability types 1, 2, and 3 refers to Unauthenticated Phar deserialization, CSRF to Phar deserialization, and Authenticated Phar deserialization, respectively.

Disclosure. We responsibly reported all the vulnerabilities to their corresponding developer teams and notified the WordPress plugin review team of our findings. Seven teams already patched their WordPress plugins, and WordFence assigned CVE numbers to the vulnerabilities as shown in Table 4.

Artifact Availability: Argus is open-source and available at `https://github.com/BUseclab/Argus`. We provide the source-code of our tool along with the instructions for reproducing the experiments. These artifacts were major components of our evaluation and we believe that they can be useful for future research in this space.

5 Discussion

In this section, we discuss the limitations, challenges, and observations of Argus.

Completeness: Argus does not guarantee completeness in its analysis of the PHP interpreter as well as the identified set of deserialization, exec, and output APIs. Argus relies on the call-graph of the PHP interpreter for its analysis, which uses a hybrid static-dynamic analysis. As mentioned in Sections 2.4 and 3.1.2, the PHP interpreter extensively uses indirect calls, such as function pointers, which challenges any static analysis, including Argus. In order to minimize the drawbacks of indirect calls in the generated call-graph by Argus, we use the official unit tests of the PHP interpreter for its dynamic analysis, features a 70% line coverage over the PHP interpreter. As a result, Argus uses a hybrid static-dynamic approach to reduce the drawbacks of each technique. However, Argus cannot guarantee the completeness of its analysis due to the challenges of analyzing a complex codebase such as the PHP interpreter.

Reachability: Argus relies on a reachability analysis on the call-graph to identify the serialization, exec, and output APIs in the PHP interpreter. The reachability analysis does not reason about any sanitization or filtering the PHP interpreter might perform. Hence, the reachability of an API to VIF does not necessarily imply that an attacker can exploit the API. However, we perform a validation step to verify the output of the reachability analysis. While it seems more pertinent to perform a data-flow analysis than a reachability analysis, we argue that Argus needs to reason about the PHP interpreter and its extensions that it is linked against. Ignoring additional challenges to practicality (e.g., extensions relying on non-C code), our analysis needs to scale to millions of lines of code across PHP (one million lines of C code alone). Needless to say, resolving function pointers is still a prominent challenge for existing data-flow analysis, including the state-of-the-art SVF tool [33], which leads to imprecise control-flow graphs. As a result, we opted for a reachability analysis and subsequent validation in Argus to identify injection-sinks in the PHP interpreter.

Validation: During the validation step, Argus determines whether user-input gets passed to the VIF function inside the PHP interpeter (i.e., `php_var_unserialize` and `php_output_write`) unmodified. The presence of sanitization logic for a specific API does not necessarily mean the API cannot be exploited by attackers. Saner [2] demonstrates that sanitization logic might be implemented incorrectly. In this paper, Argus only reports the set of APIs that pass arguments unmodified to a VIF, which means that Argus' results are a lower bound of vulnerable APIs. Analyzing the correctness of sanitization logic is an orthogonal research challenge, which we consider outside the scope of this paper.

VIF identification: The foundation of Argus' analysis is based on our key observation that an underlying function is responsible for performing the action of either deserializing user-input or writing user-input to output buffers (i.e., the HTML response). In the case of XSS and insecure deserialization, there is one VIF for Argus to start the reachability analysis from. However, other types of injection vulnerabilities, might require the identification of multiple VIFs. In the case of command injection, there are eight VIFs which we could directly obtain from Saphire. Similarly, supporting SQL injection would require the identification of multiple VIFs. The reason is that the PHP interpreter supports a variety of database engines (e.g., SQLite, MySQL, Oracle, etc.) through individual extensions which can communicate SQL statements to the respective back-end. Owing to this diversity, the SQL injection VIFs are located in different database extensions and require individual identification. However, once a VIF for a given database extension is identified, Argus can immediately identify the set of (SQL injection) vulnerable API functions for the corresponding database engine.

The efforts and time required by analysts to identify the set of VIFs for each vulnerability vary, depending on the type of vulnerability. This process starts by identifying the cause of the vulnerability using analysis tools (e.g., command injection and XSS) or manual inspection of the code. The manual inspection contains reasoning about the cause of the vulnerability (e.g., the serialization format) and detecting the parser function inside the PHP interpreter that uses the serialization format. In the case of XSS, we use analysis tools to understand how the PHP interpreter prints user-input to the output buffer. To this end, we inspected the sequence of function calls in the PHP interpreter that involve printing to the output buffer. On average, it took less than 10 hours to analyze the PHP interpreter to identify the process of deserializing and printing user-input. For command injection vulnerabilities, any API that can invoke the `execve` system call is a potential exec API. Considering that, Argus uses prior research, Saphire [3] to analyze and enumerate the set of VIFs that invoke `execve` system call. For this analysis, we spent less than four hours preparing Saphire's environment and running its analysis, as well as inspecting the source code of PHP to identify the mechanism of command injection.

Precondition: Furthermore, our evaluation identified two sets of injection-sink APIs for PHP: 1) APIs that operates directly on the value of their arguments and 2) APIs that operate on malicious files. As mentioned in Section 2.4, the phar stream wrapper in the PHP interpreter only operates on local phar files. As a result, to exploit any APIs in the latter category, the attacker needs to upload the phar file prior to invoking the insecure deserialization. Therefore, in order to confirm the detected vulnerabilities, we made the assumption that the attacker had already uploaded the malicious phar file to the web application's server. We argue that this assumption is realistic since there are a plethora of approaches where an attacker can upload malicious phar files, which include exploiting arbitrary file upload vulnerabilities [16, 17]. Furthermore, web applications and their plugins provide upload functionality for many purposes, such as uploading plugins, profile pictures, and PDF files, which an attacker can exploit.

Finally, as our evaluation demonstrates, the PHP developers noticed the security consequences of automatic deserialization of phar files and fixed this issue in PHP 8.0 (released in November 2020). However, the PHP usage statistics indicate that, at the time of writing, only 10.75% of all websites that rely on PHP actually operate on PHP 8.0 [28]. The reason for this low adoption rate is probably that transitioning to PHP 8.0 is a non-trivial procedure for most PHP-powered websites. The major changes in the PHP interpreter 8.0 compared to previous versions lead to backward incompatiblilities [13] which can potentially cause fatal errors in the web applications. The challenge of (in-)compatibility is evidenced by the most popular PHP application – WordPress. Although efforts within the WordPress project to support PHP version 8.0 began on December 2020, WordPress still warns users that even its latest stable version (released in May 2023) is not fully compatible with version 8 yet [40]. While the PHP interpreter has addressed the threat arising from the automatic deserialization of phar files in version 8, history suggests that web sites relying on older versions of PHP are likely to remain publicly accessible on the Internet for the foreseeable future. These will continue to include the over 280 vulnerable deserialization APIs provided by their PHP runtimes.

6 Related Work

In this section, we review the related literature on detecting security vulnerabilities or defending against malicious behavior.

Deserialization in PHP Application: In light of new attack scenarios introduced by Esser, new research has emerged on detecting deserialization vulnerabilities and detecting such attacks on PHP applications. RIPS [7] performs an intra-procedural data flow analysis to detect injection vulnerabilities, including POI. Dahse [9] proposed an automatic approach to identify gadget chains to exploit POI vulnerabilities. Furthermore, FUGIO [27] introduced an automatic exploit generation tool to create exploit objects for POI vulnerabilities. In an orthogonal and complementary direction, our work detects the set of PHP API functions that lead to insecure deserialization, command injection, or XSS. Crucially, prior works rely on an exclusively manually curated list of sinks for taint analysis or exploit generation tools. Unlike prior work, Argus performs an automatic analysis to identify the set of PHP API functions that lead to injection vulnerabilities such as insecure deserialization. In our evaluation, we showed how our results directly improved prior work in detecting previously unknown vulnerabilities.

Deserialization on Other Platforms: Deserialization vulnerabilities threaten various platforms such as Java, Python, and .NET. The research in this area focuses on detecting such vulnerabilities or defending against deserialization attacks. SerialDetector [30] leverages call-graph analysis to identify injection vulnerabilities in .NET libraries. The key difference between SerialDetector and Argus is that we aim to detect functions at the PHP interpreter level, whereas SerialDetector finds new object injection patterns at the library level (i.e., as part of the web application rather than the application framework). Tanaka presents attacking patterns in Python's `Pickle` library, which lead to denial of service (DoS) attack [34]. Look-ahead object input stream (LAOIS) is a defense mechanism against Java deserialization vulnerabilities, allowing the type check of the serialized stream before deserialization, as implemented in Apache's Common IO library [5] and Java Serialization Filtering [26].

Other Vulnerabilities: There are multiple studies on detecting vulnerabilities in PHP applications. Several approaches rely on taint analysis to track unsanitized data and detect injection vulnerabilities [1, 7, 8, 21, 32, 38, 42]. Dynamic analysis and hybrid techniques also play an important role in detection and defense systems [3, 14, 15, 18, 25, 29, 31]. Prior works exclusively analyze the web application code and many rely on hand-crafted list of sinks. Argus analyzes the underlying PHP interpreter and generates these lists in a principal manner which could improve existing systems, as demonstrated in our evaluation. Compared to defense mechanisms, Argus takes a more proactive approach in order to detect injection vulnerabilities rather than defend against such POI attacks.

7 Conclusion

In this paper, we proposed Argus, an automated static-dynamic analysis approach to identify the set of PHP API functions that deserialize, execute, or output their arguments in a PHP application. Argus statically analyzes the PHP interpreter and its modules to generate a call-graph. Next, we refine the statically generated call-graph by using the recorded dynamic trace of the publicly available unit test of the PHP interpreter. Argus then iterates over the call-graph and identifies a comprehensive set of PHP APIs that can invoke the internal deserialization, execute OS command, or output functions. In our experiments on three of the most popular versions of the PHP interpreter, we discovered more than 300 functions that can deserialize user-input, execute OS command, or write user-input to an output buffer, expanding prior knowledge by an order of magnitude. We draw attention toward the fact that prior works rely on a purely ad-hoc curated list of functions for their static or dynamic analysis, whereas Argus automatically generates a comprehensive list. In addition, we demonstrate that Argus' findings are highly security relevant. Our findings show that, extending Psalm by Argus' results, we detected 13 previously unknown XSS and deserialization vulnerabilities in PHP applications.

A PHP Object Injection

```php
// PART ONE: modify properties
class Exec {
   private $_cmd = "cat secret"; }
class Example {
   protected $obj;
   function __construct() {
      $this->obj = new Exec; } }
print urlencode(serialized(new Example));
// PART TWO: create Phar file
$phar = new Phar('exploit.phar');
$phar->startBuffering();
$phar->setMetadata(new Example());
$phar->stopBuffering();
```

Listing 3: Adversary can exploit file operations by generating a malicious phar file.

B Validation Process

```php
$pre_code = "code snippet of the exploit";
$payloads = array
    ("phar"=>"path-to-phar-file","direct
    "=>"serialized_data",...); // different
     pattern of input to deserialize APIs
$list_funcs = []
    // the list of functions to be validated
foreach($list_funcs as $func) {
 // generate the phar file
 if $func {
  $ref = new ReflectionFunction($func);
  // get the list of params using reflection
  foeach($payloads as $key => $payload) {
  $snippet
       = "..."; // invoke $func with $payload
  file_put_content
       ("tmp.php", $pre_code . $snippet) }
  $cmd
       = $PHP_BINARY." tmp.php 2> /dev/null";
  $res = shell_exec($cmd);
  // checking the result.
  if (strpos($res, "SUCCESS") !== false) {
   echo $func. " is vulnerable\n";
   break } } }
```

Abstract

Server-side requests (SSR) are a potent and important tool for modern web applications, as they enable features such as link preview and web hooks. Unfortunately, naive usage of SSR opens the underlying application up to Server-Side Request Forgery – an underappreciated vulnerability risk. To shed light on this vulnerability class, we conduct an in-depth analysis of known exploitation methods as well as defenses and mitigations across PHP. We then proceed to study the prevalence of the vulnerability and defenses across 27,078 open-source PHP applications. For this we perform an initial data flow analysis, identifying attacker-controlled inputs into known SSR functions, followed up by a manual analysis of our results to gain a detailed understanding of the involved vulnerabilities and present defenses. Our results show that defenses are sparse. The hypermajority of our 237 detected data flows are vulnerable. Only two analyzed applications implement safe SSR features.

Since known defenses are not used and detected attacker-controlled flows are almost always vulnerable, we can only conclude that developers are still unaware of SSR abuses and the need to defend against them. Consequently, SSRF is a present and underappreciated danger in modern web applications.

1 Introduction

Server-side requests (SSRs) are a convenient service-to-service communication pattern in which a web service sends HTTP requests to external entities. Modern web applications use SSRs to implement many user-facing functionalities, such as URL previews [36] or integration of third-party content, such as external calendars [16]. While essential in practice, if not implemented correctly, SSRs can be abused, introducing a wide variety of security risks, ranging from attacks such as network reconnaissance [32] to high severity ones such as remote code execution (RCE) attacks.

SSRF ranks among the OWASP Top 10 [31] and CWE Top 25 [40] security risks. Recent incidents suggest that web applications are still exposed to SSR vulnerabilities. For example, an attacker recently elevated an attacker-controlled SSR vulnerability affecting Microsoft Exchange servers into an RCE vulnerability, bypassing authentication and firewalls, resulting in email theft [3, 17]. Most recently, PyTorch's TorchServe suffered from an arbitrary code execution flaw caused by an SSRF flaw, which allowed the attacker to load the malicious model [4]. Even applications that attempt to defend themselves frequently get it wrong, such as vSphere, which employed URL validation but suffered from an information disclosure attack through SSRF [2].

Unfortunately, we know little about the prevalence of SSR vulnerabilities and the effectiveness of the existing defenses, as the research community has given SSRs limited attention. Up to this point, prior work has been conducted only on a small scale and was focused on either understanding and exploring the security risks (i.e., Pellegrino et al. [32]) or novel defenses (i.e., Jabiyev et al. [21]). This paper addresses this gap by providing a large-scale analysis of SSR threats in PHP web applications.

Analyzing PHP SSRF vulnerabilities, at scale, and the code patterns associated with defenses is particularly challenging. The lack of reliable, scalable and flexible investigation tools hinders such analysis because it requires collecting, analyzing, and reasoning on millions of lines of code. Tools such as PHPJoern [9], a Code Property Graph Generator, have previously been employed in large-scale analysis of PHP programs. However, our evaluation has revealed significant inaccuracies, such as an incorrect control flow graph and consequently inaccurate data flows edges, thereby increasing the likelihood of false positive results. Thus, beside our SSRF study, we also present an up-to-date version of the CPG generator for PHP web applications aiding us in our static analysis.

In this paper, we present the first static security measurement of SSR threats in PHP source code. Starting from a thorough survey of existing academic and non-academic work on SSR vulnerabilities, attacks, and defenses, we create an up-to-

*Both authors contributed equally to this research.

date taxonomy of SSR threats. Then, we use our taxonomy to study the prevalence of SSR vulnerabilities and defenses in real web applications by downloading and analyzing 30.870 popular open-source PHP web applications on GitHub.

To infer if protection mechanisms against SSR vulnerabilities are present, we study these applications with SURFER, a flexible static analysis PHP framework tailored to support exploratory analysis of PHP vulnerabilities. SURFER works on top of our novel PHP bytecode code property graph (CPG) [47]. SURFER successfully analyzed 27,078 repositories. In this set, 15.308 applications utilize API sinks, such as `file_get_contents`, that are potentially susceptible to SSR problems. For 1.040 of these applications, SURFER was able to identify at least one potentially suspicious flow into such sinks. To further narrow down the set of vulnerability candidates, we only consider cases in which a direct data flow from user-provided input into the sinks exists, and the adversary controls the significant parts of the passed URL value. After applying these processing steps, we end up with 141 PHP projects that utilize server-side request sinks in a potentially insecure manner.

To thoroughly examine the existence of potential defensive measures and their robustness, we follow up with a manual inspection of these applications. The results of this analysis paint a somber picture: More than half of the identified applications use *no* defensive measures against SSRF and, thus, are trivial to exploit. Only three projects leverage dedicated existing SSRF-secure request mechanism and only two of the remaining PHP projects deployed robust countermeasures against sophisticated attack techniques, such as using DNS rebinding. Thus, our analysis demonstrates a widespread ignorance by developers in respect to SSRF vulnerabilities.

In summary, this paper makes the following contributions:

- A survey and usage study of existing open source SSR abuse mitigation techniques in PHP.
- A PHP Code Property Graph generator based on the modern CPG framework.
- A CPG based static analysis tool chain (SURFER) to identify SSRF vulnerable code.
- A large scale study of 27,078 PHP projects for SSRF vulnerabilities and mitigation techniques.

Organization of the paper We first discuss the difference between SSR and SSRF as well as the challenges of defending against it, deriving our research questions (2). After having established the required background, we detail the current state of SSRF mitigation techniques in popular open-source frameworks (3). We then lay the groundwork for our tooling and present SURFER, as well as our Manual Analysis to perform our large-scale static analysis study (4). The results of our analysis are given next (5), followed by a discussion of the implications, including a case study and the answer to our research questions (6). Finally, we provide an overview of related work (7) and conclude with a summary of our key takeaways (8).

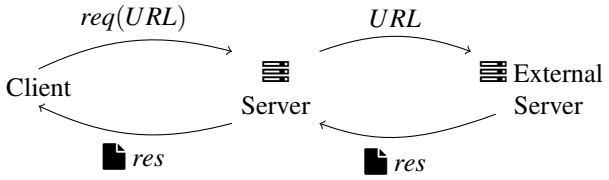

Figure 1: A Server-Side Request.

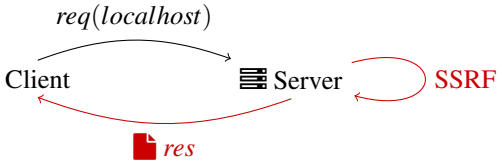

Figure 2: An SSRF attack that accesses local resources.

2 A Primer on SSRF

We briefly introduced the SSR feature and its evil variation *SSRF*. In this section we are providing a primer on why server-side requests exist (2.1) and how they can turn into SSRF (2.2) arriving at our research questions (2.3).

2.1 Server-Side Requests

An application requires a server-side request as soon as it needs information that is not stored within the application components itself. Common examples are webhooks, previews of links, and interaction with external APIs like payment or authentication providers.

The chain of events leading to a server-side request starts with a (user) request for an application resource, depending on remote data. For example, if the application wants to display a link preview, it must perform a request and retrieve the data required for the preview to answer the client's request. Figure 1 visualizes this event chain.

User-input-controlled SSRs are allowed for several reasons. For instance, webhooks and link previews target user-provided URLs by design. Other SSR use cases allow the user to affect parts of the target URL, such as URL parameters.

2.2 SSRF: Server-Side Requests Going Rogue

Suppose an SSR request can be influenced by user input beyond the scope envisioned by the developer. In that case, attackers can leverage this as an attack vector and guide the request to malicious hosts and services. The developer is

responsible for ensuring that user-provided data cannot unintentionally influence a request, e.g., by changing the target to network-internal resources. How an attacker can exploit their ability to influence the request depends on the deployment context, including the network topology, the host machine's configuration, and the influence's scope.

If a server with a vulnerable application runs localhost-accessible services, an attacker can use the SSRF to access normally denied resources. Figure 2 visualizes such an attack. As in our introductory examples, this enables an attacker to conduct network reconnaissance, secret stealing, or even RCE. Cloud services often serve HTTP APIs on the local network, providing configuration and metadata [7, 12, 21]. An SSRF vulnerability exposes this internal API to attackers.

Even if all local resources are adequately protected, an attacker can still abuse an SSRF vulnerability. Vulnerable public access points can be attacked via SSR requests from SSRF-vulnerable servers. As the vulnerable server performs the request, the attacker hides their identity, impeding investigations into attacks or laundering the presumed host to an unsuspecting third party.

Sometimes, vulnerabilities such as SSR occur in authenticated areas of an application. They should not be ignored. Firstly, not all authenticated users should possess power over the whole system, e.g., regular users vs. admins. Secondly, superuser rights inside an application, such as admin rights in a CMS, do not equal to any rights on the host OS. This applies especially in managed hosting environments, where users might have superuser rights inside their application but not on the underlying machine. However, in both cases, a malicious user or web admin could exploit an SSRF vulnerability to gain access to sections of the application they are not authenticated for or the underlying host OS.

2.3 Research Questions

SSRF poses a risk to anybody using SSR features, but the state of SSRF is an orphaned domain in current research. To address this, we formulate four research questions that each provide a distinct insight:

RQ1: What is the current state-of-the-art of SSRF defenses?
RQ2: Are web application developers using existing SSR mitigations?
RQ3: Are web application developers using homegrown SSR mitigations?
RQ4: How many web applications are prone to SSR abuses?

3 Survey Of Attacks and Defenses

SSRF is a multifaceted vulnerability class that allows for varied exploitation options. The same holds for defending against SSRF abuses. This warrants a detailed discussion of known attacks and defenses according to the literature to frame our search later on.

We start our systematization from Pellegrino et al. [32]'s work on SSR attacks and amend it with results from an academic literature survey. Additionally, we explored non-academic sources systematically by searching the web for 'SSRF' with keywords such as 'Defense' and 'best practice'. This resulted in the non-academic sources [8, 18, 25, 26, 30, 39, 44] as well as the academic sources [21, 28, 32]. A systemized overview of our results on SSR attacks and application-level defenses is given in Table 1. Table 2 augments it with details about possible defense evasions and the respective fixes.

3.1 Attacks

Across the literature, we identified six distinct classes of attacks that leverage SSRF vulnerabilities to perform malicious and unintended activities:

(A1) Recon Attack: The first class of attack tries to gain information about a server's network using the SSRF vulnerability to reach behind the firewall and gain access to network internals. An attacker can identify deployed services and available machines using return values or timing-based side channels.

(A2) Origin Laundering: In the second class of attack, the attacker uses the SSRF vulnerability to misuse the server as a proxy to serve malicious data from another website. This can be used to circumvent block lists implemented by the browser. An SSRF-vulnerable website can be misused as a proxy serving otherwise blocked malicious content.

(A3) Denial of Service: The next attack category is Denial of Service (DoS) attacks, usually split into three distinct subtypes across the literature.

Consider an SSR service using a GET parameter as input and reflecting the SSR's response. An attacker can craft a URL directing the service to a domain hosting illegal or known malicious content. They then provide this prepared link to a web scanner. When the scanner requests the prepared link, the SSR service requests the embedded target and mirrors the content. The scanner then flags the SSR service due to malicious content. Consequently, an attacker can use an SSRF vulnerability to put the victim server on block lists and thus achieve a denial of service. Such a DoS is also possible on a non-technical level. For example, if the prepared link is reported to the authorities, the SSR provider could face legal action.

The remaining two kinds leverage amplification of the request. In case the SSRF does not trigger a single but multiple requests to a target, the vulnerable service can be abused as

Attacks		D1 URL Valid.				D2 DNS Valid.	D3 Secure Conf.		D4 Response Modification				
		Scheme	Domain	Port	Path	IP input validation	HTTP(s) only	No OOP	wrap result	C-D header	rate limit	fixed RT	
A1 Recon attack	Port scan			●								○	
	Network scan		△			●						○	[21, 30, 31, 32, 49]
A2 Origin Laundering			△			△		●	●	●			[32]
A3 DoS attacks	by blocklist		△		●	△							[30]
	attack ES					△					○		[32]
	attack Ampl.					△					○		[32]
A4 Bridging Attack		●					●						[32, 44]
A5 Exploiting SSBs			△			△							[28]
A6: Local Res. Leak			△		○	△							[30, 39]

Table 1: Overview over SSR attacks and application-level defenses. ●: Defense successfully prevents the attack. ○: Defense mitigates some version of the attack. △: Defense works in an allow list scenario.

	Evasion Technique	Evaded Def. Technique	Fix	
D1	URL parser confusion attacks	insufficient parsers	well-established, hardened parser	[8, 21, 29, 31, 39, 44]
D2	DNS rebinding	IP validation	IP pinning	[8, 21, 31]
D3	redirects	singular checks	rechecking on each redirect or disabling redirects	[30]

Table 2: Defense evasion and respective fixes.

an amplifier to conduct DoS attacks. The same is possible the other way around if a targeted service serves large or multiple responses, leading to a DoS of the vulnerable server.

(A4) Bridging Attack: The fourth kind of attack is bridging attacks. Bridging attacks can happen when an attacker can control the protocol of a request, allowing the attacker to bridge between different protocols. A notorious example is the Gopher protocol. Since Gopher is simplistic, HTTP requests can be interpreted as Gopher requests. If the SSR client supports Gopher, an SSR can quickly turn into Remote Code Execution via bridging attacks, as shown by Gupta [18].

(A5) Exploiting SSB: The fifth class of attack exploits the client used to perform SSR. Musch et al. [28] established the risk of using a full browser as a client for conducting SSRs. Given the constant struggle of browser vendors to keep up with the most recent exploits, an outdated browser executing arbitrary requests can easily become an attacker's gateway to the server.

(A6) Local Resource Leak: The sixth and final class of SSRF covers exploitation accessing otherwise non-reachable local resources via a request to an internal IP or localhost. This is the most commonly known variation of SSRF and was featured in Figure 2.

3.2 Defending Against SSRF

Across the literature, we identified four distinct approaches to defend against SSRF, each with its caveats and drawbacks.

(D1) URL Validation: The most immediate solution to ensure that only intended targets are used for the SSR is validation based on the string on which the request is based. This validation can cover parts or the complete set encompassing a URL – *scheme, domain, port, path*, and *query* – using either an allowlisting or a denylisting approach.

While this is the most apparent defense, it has severe limitations. The correctness of the allow/deny procedure is paramount, and past events have shown that validating URLs is not trivial [1]. This results in Parser Confusion attacks, a well-documented attack on insufficient parsers. These attacks bypass an implemented mitigation via parser bugs or unexpected encodings. Therefore, to parse user input, well-established correct parsers should be used [21, 31]. Consequently, the whole URL has to be validated, as only prefixing protocol and domain in front of the user input might not be sufficient, as the user input can contain characters that confuse the parser [44].

A robust and complete URL allow-listing can defend against SSR abuses, as it limits the requests to well-known benign targets [30]. Denylisting is insufficient since attackers can always register or overtake new domains.

(D2) DNS Validation: Using DNS validation expands on checking the destination URL by validating the actual target, as it ensures that only a predetermined set of IPs can be requested. As the URL is resolved, the corresponding IP is validated against an allow or deny list, ensuring only intended targets. However, this defense has its challenges, as a cunning

attacker could change the targeted IP between the check and the actual request time.

A proper implementation has to resolve the domain only once and then keep using the resolved and validated IP. This advanced defense is called IP pinning and provides the only reliable defense against attacks targeting local resources without unduly restricting the versatility of the SSR feature. IP Pinning protects against the DNS Rebinding validation bypass attack.

In a variant of the DNS validation approach, the target is validated against a denylist of unwanted targets, such as localhost. This can be used as a defense for applications that take arbitrary user input as a target by design, e.g., URL previews. However, this technique is limited by the ability of the developer to ascertain the deployment context. If they miss targets in complex deployment scenarios, this technique is insufficient. For example, suppose only typical local targets are blocked, but the application is deployed in a cloud environment. In that case, attackers can still access cloud-internal IPs hosting meta-data and configurations.

(D3) Secure Configurations: Shifting the focus from actual application code to feature flags and configurations of application components, the third type of defense covers secure configurations. To avoid bypasses resulting from HTTP redirects, the used HTTP client should either reject redirects in general or apply the target validation after each redirect [39]. Additional important security settings are visiting only HTTP(s) URLs, mitigating A4, and not exposing an Open Origin Policy (OOP). I.e., they shouldn't set the `Access-Control-Allow-Origin` header to `*`; otherwise, they are susceptible to being used for Origin Laundering.

Because XML External Entities can fetch external resources, previous work included disabling XML External Entities as an SSRF mitigation. Still, since this is a) a general security issue and b) off by default since PHP 8 [41], we will not discuss it further in this work.

(D4) Response Modification: The fourth and final approach to mitigate the effect that turns an SSR feature into SSRF can be achieved by modifying the response an SSR provides. The response can be wrapped to not directly reflect the accessed content or use the `Content-Disposition` header to prevent a browser from directly rendering the response [27]. Either approach reduces the ability to abuse the SSR feature as a proxy (A2). Finally, imposing a rate limit and fixing the response time would severely hamper an attack's ability to conduct a recon attack (A1) or a denial-of-service attack (A3). However, no response modification prevents A4 to A6.

3.3 Further Defenses and Threat Model

Multiple mitigation-level approaches that expand past the application level and touch the SSR's configuration have been pitched. On a network level, the SSR can be routed through a proxy [21, 39], ensuring requests can neither access local resources nor devices on the internal network. Furthermore, a robust network segmentation can ensure that no local resources can be accessed. Authentication should be enabled for all services [39]. This approach only affects A6 and potentially impacts A1, making all other attacks feasible.

Tennant [39] proposed the concept of a *SSRF Jail*, where DNS and networking calls are hooked on the OS level. However, they note that it is not suitable as a practical solution since applications have to request internal, i.e., deny listed, resources for valid reasons, which a naive hooking solution would prevent.

Threat Model In this work, we study the SSRF mitigations that developers deploy. Therefore, we assume a bug and vulnerability-free PHP standard library.

If we mention allow-listing approaches, we assume developers have a complete, up-to-date list of IPs or domains they control and trust. To summarize our exploration of the SSRF attacks and defenses and the resulting thread model: *We assume an attacker who can access a service that affords the capability to trigger and influence the target of a request.*

3.4 Existing SSRF Defense Implementations

We now understand the attacks an SSR feature must be defended against and a set of working defenses and mitigations. The remaining question is whether libraries used to make SSRs provide developers with the means to do so securely. To answer this question, we survey existing PHP frameworks, libraries, and HTTP clients with SSR capabilities.

Table 3 lists all PHP Frameworks included in our survey and the standalone PHP HTTP clients. We compiled this list by searching the web for the most used and popular PHP frameworks and clients. Additionally, we included all clients listed by the HTTPlug project [43]. The first column indicates if a framework offers an HTTP client and, therefore, SSR capabilities.

To evaluate SSR capabilities as well as SSRF defenses, we manually checked the documentations for mentions of Server-Side Request Forgery. We found that only five HTTP clients offer any defense:

Symfony Since Version 5.1. Symfony provides the `NoPrivateNetworkHttpClient` decorator, which ships mitigation against SSRF, which blocks requests to internal networks (D2) [37, 38]. Technically, the decorator hooks into the request process and is called after the DNS resolution to check if the resolved IP address is on a predefined denylist of internal IP addresses.

SafeCurl SafeCurl [14] blocks requests to internal IPs (D2) and pins the protocol to HTTP(S) (D3). Optionally, it provides DNS Rebinding protection by implementing a check of the resolved IP vs. a denylist (D2).

Framework	SSR capability	Defense
WordPress	✓	†
Laravel	✓via Guzzle	✗
Symfony	✓	D2
Yii	✗	✗

PHP stdlib	✓	✗
PHP curl ext.	✓	✗

Table 3: PHP frameworks and HTTP clients included in our survey. The two columns indicate if they offer SSR capabilities and implement SSRF mitigations. ✓= Exists, ✗= Non-existent, † = exists, but is vulnerable.

SafeURL IncludeSec team [20] presented a set of safer HTTP clients in 2016, including *SafeURL* for PHP. It is a fork of SafeCurl.

HTTPlug plugin The HTTP client abstraction HTTPlug can be used with plugins to extend its functionality. Benoist [10] published a plugin that introduces SSRF mitigation capabilities for HTTPlug. It is 'inspired by SafeCurl' and has the same capabilities as SafeCurl.

Guzzle Guzzle is a popular third-party HTTP library. It does not provide an SSR defense, however the issue was already raised in the issue tracker [34] and a domain allow list was proposed. However, the issue was closed due to inactivity.

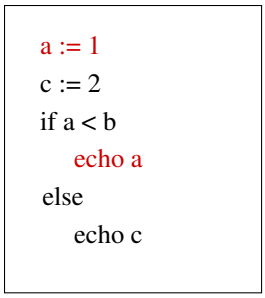
WordPress

We will now present our findings on WordPress. **`wp_http_validate_url` vulnerabilities** WordPress provides functions such as `wp_safe_remote_get` that promise safe requests via the `wp_http_validate_url` function: 'The URL is validated to avoid redirection and request forgery attacks.' [46]. We tested the first part of this statement with a status 307 redirection, but all functions of the function family followed the redirection except the `_head` variation. We checked the second part of the statement (request forgery protection): WordPress attempts to sanitize the URL with respect to internal IPs but does not pin the resolved IP address. It is, therefore, vulnerable to DNS Rebinding attacks. Since we could bypass both promised safety features, we don't consider it a safe client for this work and included it as a regular sink for our later study.

Disclosure We constructed a Proof-of-Concept and disclosed the DNS Rebinding issue to WordPress. However, the issue was closed as a duplicate of a report from 2017. We also reported the issue of unexpected redirection to WordPress.

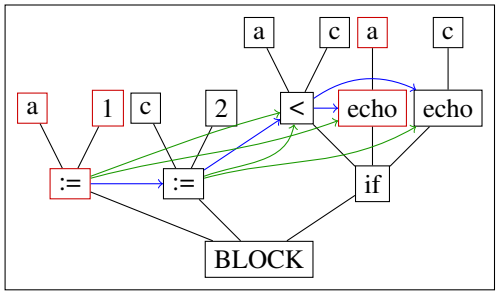
Safe to use Sanitizer? Additionally, WordPress provides the function `esc_url_raw`. The documentation states, 'The resulting URL is safe to use in [...] HTTP requests.' [45]. The last statement is wrong and dangerously misleading since the function does not defend against SSRF and SSR abuses. In our later studies, we found data flows solely relying on this function to sanitize the input of an SSR sink; refer to Section 5.3. *Disclosure:* We reported the issue to WordPress.

Overall, only one framework and three clients support protection against SSRF, while several others support SSR capabilities without warning users about their risks or providing SSR defenses. Note that since most HTTP clients are supported by the HTTPlug system, they could be combined with the plugin to make them safe.



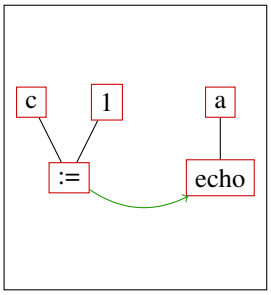
3.5 Usage Study

To evaluate if applications in our data set use the HTTP clients with some form of offered protection, we used ripgrep [15] to conduct a string-based search for usage of the corresponding HTTP clients. We constructed search expressions from usage examples, i.e., we searched for `use` statements, `new` statements, and fully qualified function names.



We found four repositories using safer HTTP clients in our dataset of 30.870 applications. One of them is the composer backend `packagist`. It is using a safe SSR request in its GitHub migration code. Another application, with safe HTTP client usage, is authored by one of the maintainers of one of the HTTP clients. This means that effectively, only **three** third-party open-source applications are using an HTTP client with a defense available.

Only a fraction of the frameworks that provide SSR functionality discuss SSRF in their documentation, and only Symfony provides an actual SSRF defense. Only the SafeCurl family provides an SSRF defense out of all the pure HTTP clients. If used through the HTTPlug framework, most clients could be secured using a plugin inspired by SafeCurl. But nobody is actually using these defenses.



This study shows that developers do not use existing countermeasures against SSRF. This raises the question of whether they implement SSR defenses themselves. Or are they not using any defense at all? We need to inspect the source code of the applications for homegrown SSRF mitigations to solve this question.

(a) Computation of a max value. Highlighted statements might influence the slicing criterion `echo max`.

(b) The CPG representation of Figure 3a with the nodes that might influence the slicing node `echo max`. The black edges represent the AST, the blue edges the CFG, and the green edges the DDG.

(c) The extracted program slice for `echo a` of Figure 3b. The green lines represent data dependency and the blue line represents control dependency.

Figure 3: A sequence of visualizations showing the transformation of a computer program (3a) into a Code Property Graph (3b) and finally an extracted program slice (3c).

4 Identifying SSRF Vulnerable Code

Given the complexity of SSRF, we want to study its prevalence and its expression in common software. For this, we develop a static analysis methodology that leverages a Code Property Graph (CPG) code representation [47] and interprocedural data flow analysis to identify interfunctional data flow from user-controlled sources into a known SSRF sink. Subsequently, we manually analyze identified data flows to gain an in-depth understanding of vulnerable flows and any present attempts to defend against SSRF exploitation.

We first lay the theoretical groundwork establishing our static analysis methodology (4.1), which is followed by describing our subsequent manual analysis of any identified data flow (4.2).

4.1 Automatic Static Analysis

To present our static analysis methodology, we start by giving a brief introduction to CPGs (4.1.1) and Data Flow Analysis (4.1.2), followed by an explanation of how we leverage those techniques to detect SSRF vulnerabilities (4.1.3).

4.1.1 PHP Code Property Graphs

A CPG is a combination of multiple different graph representations of program source code [47] – most prominently the Abstract Syntax Tree (AST), Control Flow Graph (CFG), Data Dependency Graph (DDG), and Call Graph (CG). The ASTs of each method of the analyzed program are the forest that forms the basis of the CPG. Each remaining graph (CFG, DDG, CG) is layered into the ASTs by reusing the existing AST nodes and adding corresponding edges. For example, by adding `CFG` edges between subsequently executed statements. Figure 3b provides a visualization of a CPG representing the code in Figure 3a.

We present an up-to-date PHP CPG generator that is not based on the source code but utilizes the PHP interpreter's internal bytecode representation. The PHP interpreter provides a debug function that dumps the bytecode representation of syntactically valid PHP source code. Our CPG generator parses this bytecode dump into an AST structure. The main advantage of using the bytecode representation is that the dump comes with a CFG, which we use to add our CFG edges. This leads to a high degree of CFG correctness as the CFG is taken directly from PHP. Based on the CFG, we generate the data dependency graph using a standard algorithm [5]. Another advantage of using the bytecode representation provided by the interpreter is that each function and method reference is represented with a fully qualified name, including possible namespaces or class names in the case of static methods. Therefore, we create the call graph by matching the qualified names of functions and methods with their definitions if they are unique. In cases where the names are not unique, e.g., method names shared across class definitions, we do not create a call edge. Our tool is implemented against the publicly available specifications and framework for the Code Property Graph [48] and is publicly available[1].

PHPJoern We decided against using the existing PHPJoern ([9]) due to shortcomings we encountered. Besides being unmaintained and deprecated by its authors, we will discuss the two major shortcomings:

PHP Compatibility: PHPJoern can only generate CPGs for code compatible with PHP 7.1. PHP 7.1 has been deprecated and superseded by several minor and major releases introducing new (syntax) incompatible features. As a result, PHPJoern is unable to analyze modern PHP code and skips corresponding files that can thus not be analyzed.

CFG: PHPJoern generates the control flow graph itself, which leads to inconsistencies. `exit()` and `die()`, commonly

[1] https://github.com/SSRF-vs-Developers

used by PHP developers to stop a script prematurely in if a check fails, are the culprits for the inconsistent behavior. Implemented checks are commonly access controls, exit on failures, or user input validations. Figure 4 provides a minimal code example. If a condition (line 3) is met, the process ends with an exit call (line 4). Otherwise, line 6 is executed. The echo is unreachable if the condition is satisfied due to the exit call. PHPJoern generates a control flow edge between the exit()-node (4) and the echo (6). This is wrong.

Our bytecode CPG does not suffer from this issue because we get the CFG directly from the PHP interpreter. Therefore, we eliminate the potential for derivations between the actual PHP control flow as interpreted by the PHP engine and our CFG.

```
1 <?php
2 echo "init";
3 if($condition) {
4     exit();
5 }
6 echo "code";
```

Figure 4: PHP code that triggers the CFG bug in PHPJoern.

4.1.2 Data Flow Analysis

To perform the data flow analysis, we extract the subgraph that forms the input value to a given sink to perform the data flow analysis. Figure 3c provides a visualization of a data flow extracted from the CPG in Figure 3b.

Our data flow implementation starts by following back the data dependency edges leading into the sink call and collecting the involved nodes and edges recursively until all subsequent data dependency edges are consumed. After finishing the intrafunctional analysis, we identify each function call and function parameter usage and follow the call edges to the target and source nodes. The algorithm is then restarted from those nodes again. Our procedure stops as soon as there are no further nodes and edges to be added. The result is a subgraph containing all nodes involved in forming the input value for a given start call, i.e., a program slice.

4.1.3 SURFER – Detecting SSR(F) with Program Slicing

To identify potential SSRF vulnerabilities, we start out by searching for common SSRF sinks (Appendix 8.1) within a given CPG. Each such statement then serves as a starting point for our program slicing.

We reconstruct the possible input strings to the detected sinks based on the extracted program slice by traversing the slice across its data dependency edges. Starting at the slice leaves, i.e., the initial input values, we collect the applied transformations for each step until we reach the sink. This process results in a tree structure. Leaves represent the input values, e.g., constants and variables. Nodes represent the transformations, and the root is the sink. We traverse the tree, starting at the leaves, and apply the transformations we encounter. This procedure depends on the semantics of each transformation and leverages the individual bytecode instructions stored in the nodes. Thus, if multiple leaves lead to a concatenation, we combine them. If they lead to an assignment, we create a list of multiple outcomes, as multiple incoming dataflows indicate that multiple values are possible.

As this procedure is only used as a filter for our later manual analysis, we are liberal in the transformations we apply, and if we do not know the semantics of an instruction, e.g., an unknown function call, we pass the arguments through so as not to miss a possible vulnerability. Global variables, e.g. the super globals `$_REQUEST`, `$_POST`, and `$_GET`, are marked in the output. This allows us to recognize user-controlled sections of the input values passed into the sink and reason about a possible SSRF vulnerability due to user-controlled input.

As discussed in 2.2, we assume that existing sources and sinks are reachable, e.g., if they are behind some access control system, we assume that an attacker has access to them. This attack scenario is interesting in more complex deployment scenarios such as managed hosted services where regular users might have admin rights in the web app but not on the barebone machine.

4.2 Manual Investigation of Candidates

Applying SURFER reduces the initial set of projects of web applications to those also containing a data flow into a sink with an abstract representation of the value passed into the sink. However, a simple data flow analysis is not sufficient to achieve our goal of identifying the prevalence of SSRF and accompanying insufficient defenses. A defense does not necessarily reside on the data flow but can be contained in the direct (conditionals) or indirect (assertions) control flow associated with it. Consequently, we performed a manual in-depth analysis of each identified flow.

We take the candidates found by the previous static analysis and analyze them manually for possible defenses against SSR attacks and to determine if they are vulnerable. We start by filtering the apps into three distinct categories to remove any applications that are vulnerable by design or cannot be considered a proper web application, to begin with (Section 4.2). Next, we analyze whether a detected data flow is trivially exploitable (e.g., direct application of a sink on user inputs) or if a data flow is a false positive. Finally, we perform a manual in-depth exploitation and defense analysis to establish how a detected data flow can be exploited and whether any form of defense is present (Section 4.3).

Filtering for Apps Our overarching goal is to answer RQ4 and RQ3, i.e., are developers of applications using home-

grown defenses, and how many applications are vulnerable to SSR abuses? This entails filtering any flow that is either irrelevant to our attacks or not representative of real applications.

Based on our reconstructed inputs, we filter out any flow for which an attack does not have control over the domain. We approximate this by only taking these candidates into consideration where attacker-controlled input is at the start of the reversed string. All of the discussed attacks require the attacker to control the domain, consequently, any flow for which this is not the case is not interesting for our overarching research questions.

Next, we survey all remaining flows and their corresponding applications to determine the type of project they belong to. We discard flows sourced from examples or test code. But most importantly, we remove any flow that are detected in 'hacking tools'. Hacking tools are projects that do not contain a real application but are used for red and blue teaming, such as Capture-the-Flag tasks and solutions, applications that are vulnerable by design for educational purposes, and malicious applications such as web shells. These are not representative of the regular developer and application and are thus out of the scope of our research.

4.3 Detailed Analysis

The remaining flows are inspected in-depth in a manual analysis for all known defense techniques detailed in Section 3.2 by manually retracing the data and control flow.

D1 URL Validation We analyze if any validation of the input URL takes place and distinguish between allow-list and deny-list approaches. Additionally, we categorize its implementation (e.g., via a regular expression) and which parts of the URL are checked, e.g., if only non-HTTPS requests are prevented. Additionally, we note any usage of a proper URL parser or homegrown solution. Finally, we assess whether breaking any present URL validation is possible.

D2 DNS We check for the presence of DNS validation and distinguish between DNS allow and denylisting, as well as if IP pinning is used.

D3 Configuration If we detect any configuration of the used sink we analyze how it affects redirection (i.e., enabled or disabled), if only http(s) requests are possible, and if there is a Open-Origin-Policy configured.

D4 Response Modification Finally, we analyze how the response of the SSR is used and, more significantly, if it is returned. If it is returned, we check if the result is wrapped or reflected as-is and if a Content-Disposition header is set. Additionally, we check for rate-limiting routines and fixed response time mechanisms.

5 Results

We have established SSRF as an intricate and relevant security issue and proposed a methodology and an implementation – SURFER – to detect SSRF vulnerable code and its possible protections. In this section, we describe the data set we searched with SURFER (5.1). We then discuss the parameter as well as the metadata surrounding our search (5.2) and present the raw results of SURFER, as well as the result from our manual analysis (5.3).

5.1 Data Set

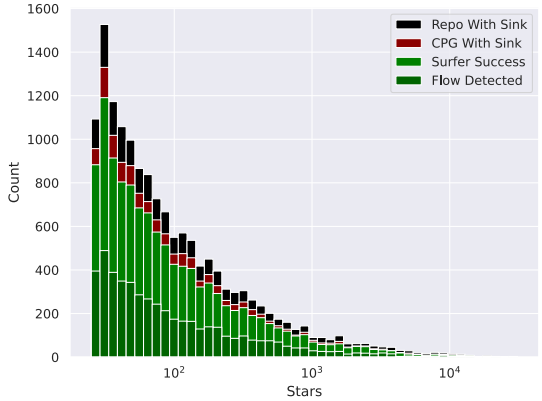


Figure 5: Stars of the repositories available, converted to a CPG, successfully analyzed, and with a flow detected. Only repositories that contain a sink are included.

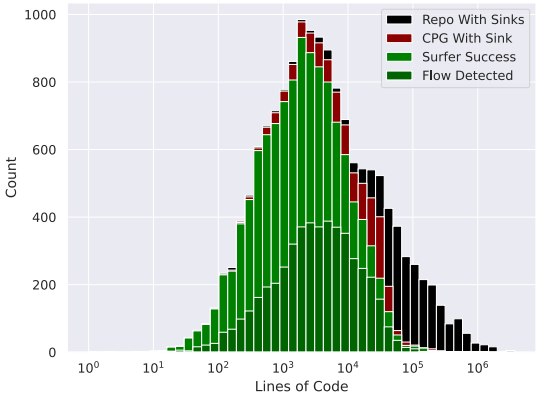

Figure 6: Lines of Code of the repositories available, converted to a CPG, successfully analyzed, and with a flow detected. Only repositories that contain a sink are included.

Our collection of open-source PHP applications was retrieved from GitHub – the largest code hosting platform. We used the public API to acquire all PHP applications with 26 or more stars[2] and started the download on July 31th, 2023. The

[2]this occurred organically through the limitations of the GitHub API

process took 6 hours and 40 minutes and occupied 411 GB of RAID SSD storage. Our final data set consists of 30.870 repositories.

We applied our CPG generator to each project and successfully created 28.325 CPGs. The CPG generation was run on a AMD EPYC 7702P with 504 GB RAM with 10 parallel processes. Each generation was allocated 20 GB of RAM and forcefully terminated after 10 minutes. To determine the coverage of relevant repositories in our dataset, we conducted another ripgrep-based search for calls of our SSR sinks. This is a rough over-approximation. 15.308 of our 30.870 repositories had at least one match. The distribution of stars and lines of code of the analyzed projects is displayed in Figure 5 and Figure 6, respectively. We have only included those that contain some SSR sink.

5.2 Applying SURFER

We compiled PHP functions that can trigger network requests in default configurations and included the popular 'curl' extension [42]. Additionally, we amended the list with functions from WordPress, as it is the most-used PHP framework. Sinks requiring a specific configuration and protocol were excluded, e.g., if `allow_url_include` is set to true, the include and require functions of PHP can trigger network requests. Our final list includes 15 function calls we use as sinks. The calls are listed in Appendix 8.1.

We ran SURFER with a timeout of 40 minutes and 20 GB of JVM heap space per analysis on a AMD EPYC 7702P machine. SURFER was done after 11 hours. SURFER successfully analyzed repositories that sum up to 107.4 mil. lines of PHP source code in 1.4 mil. files[3]. By average, each repository had 17.8k lines of code and 50.5 files.

5.3 Manual Analysis

In this section, we will discuss the results of our manual analysis. A visualization of the first few steps can be found in Figure 7 as a Sankey plot.

After the first pass of our manual analysis, we categorized our dataset. The dataset consists of 1.040 apps with some data flow. After filtering for dataflows with user input at the start of the string, we obtained a dataset of 237 flows. It consists of 158 flows we categorized as an app, 71 as a hacking tool, 7 as test code, and 1 as an example.

Of all the flows labeled as belonging to an application, 39 are trivially exploitable, 18 were false-positives, and 101 required further analysis. The false positives were mostly due to over-approximations in our static analysis for unknown function calls and objects. In 65 flows, the host part of the URL was attacker-controllable; in 36, it was not. A full overview of the first steps of our manual analysis pipeline can be found in the Sankey diagram in Figure 7.

[3]all lines of code and num. of files are measured via `cloc` [11]

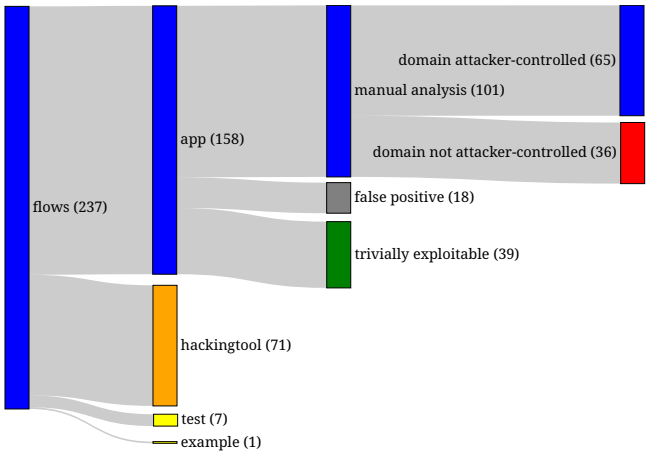

Figure 7: Sankey plot of analyzed flows.

Table 4 provides an overview of our findings regarding defense techniques 3.2 and 3.2. Potentially vulnerable flows fall into one of three categories: those without URL validation, allow-list style validation, or deny-list style validation. The most used implementation type was regular expressions. Additionally, five flows were found that use a good URL parser, and 14 validations were identified as broken. 216 flows validated no special part of the URL, while 10 did validate the scheme.

(D2) DNS Defenses No DNS resolution or pinning was used.

(D3) Configuration Four candidates were found that changed the redirection behavior. They all disabled it. No candidate set an Open Origin Policy. Table 5 provides an overview of the configuration defaults of the sinks. Table 6 provides an overview of the frequency of sinks. The core PHP provided sinks, i.e., `file_get_contents`, `getimagesize`, and `get_headers` accept non-HTTP(S) URLs by default. As discussed in Section 3.4, the WordPress functions do not disable redirects, except for the head function. Unsurprisingly, the WordPress HEAD functions and the PHP built-in `get_headers` function do not follow redirections. As their primary purpose is to return headers, redirection headers could never be polled by these functions if they were executed instead of returned.

(D4) Response Modification 15 flows returned the SSR result, and 13 did so in a wrapped manner, i.e., they wrapped the result in a JSON object and returned that or used some other processing step. No flow was found using a Content-Disposition header, rate-limiting, or fixing the response time to a constant value.

		#
category	no validation	38
	allowlisting	26
	denylisting	10
implem. type	Regex	12
	`is_file`	10
	`strpos`	6
	`substr`	5
	WP's `esc_url_raw`	4
	`opendir`	4
	`in_array`	2
	WP's `clean_url`	1
	`is_readable`	1
	wp_http_validate_url	1
Other	broken validation	14
	Secure, well-established URL parser	5
validated URL parts	none	216
	only scheme	10
	only host	2
	only path	3
	only query	1
	scheme and host	4
	scheme and query	1
	... all other combinations	0

Table 4: Analysis results for URL validation (D1).

Sink	Default Configuration	
	redir. disabled	HTTP(s) only
file_get_contents	✗	✗
get_headers	✓	✗
getimagesize	✗	✗
curl (init and setopt)	✓	✓
`wp_*` exc. `head`	✗	✓
`wp_(safe_)remote_head`	✓	✓

Table 5: Default configuration behavior of the SSR sinks.

Proper Defenses We found two apps (three flows) that implement a proper defense. Both use an allow-listing approach. One app uses `parse_url` to extract and compare the host against an allow-list. The other app defines a regular expression that only allows user input in parts of the query, like this: `https://example.com/path/.*/foo.txt`.

6 Discussion

This section will discuss our results, including valuable insights for other work. We will present two case studies, discuss our limitations, and finally answer our Research Questions.

Survey Result I: Community Knowledge We have established that the techniques to exploit SSRs are widely discussed in the literature and community. SSRF can be used as a stepping stone to deliver payloads for other vulnerabilities, circumvent firewalls, etc. The range of SSR abuses is exorbitant.

Sink	#
`file_get_contents`	85
`curl_init`	24
`getimagesize`	24
`get_headers`	11
`wp_remote_get`	10
`wp_remote_post`	2
`requests::get`	1
`wp_remote_head`	1

Table 6: Frequency of sinks in candidates classified as 'app.'

Survey Result II: SSRF Defenses Ready-to-be-used defenses against SSRF exist in Symfonfy's HTTPClient and the SafeCurl family of tools. WordPress tries to implement some defense but fails to do so. Since Symfony is a major framework and SafeCurl is effectively a drop-in replacement, we expected to find some usage. Surprisingly, they are used barely at all.

We developed a novel PHP CPG and SURFER to answer whether developers use home-grown defenses. There are two ways of defending against such attacks: Deny and allow listing.

Manual Analysis: Deny Listing To implement a proper deny list-style approach, DNS resolution and DNS pinning are required. Otherwise, an attacker could either register a new domain not on the denylist to attack a target with an SSR or provide a short-lived DNS entry to perform a DNS rebinding attack.

We did not encounter any DNS-based defenses. Since properly defending against SSRF attacks in a denylist scenario requires DNS rebinding, we were surprised by the absence of DNS requests. It is not entirely unexpected that DNS pinning routines are missing since it is a complex technique, but we find it noteworthy that no single DNS request call was found.

Manual Analysis: Allow Listing SSR abuses can also be prevented using proper URL parsing and a complete allow list (compare our threat model 3.3). Most applications (38) did not validate the URL in any way, but 26 did so in an allow list manner. However, since rarely any flow uses a proper URL parser, and most flows don't validate the arguably most important part of the URL, the domain, allow-list-based defenses do not seem to reflect the status quo as well. We could only find two apps that do properly allow list-based defending.

Technically, prefixing user input with a qualified URL can be interpreted as a type of allow listing. However, it cannot be

considered a deliberate countermeasure. Instead, it is a fundamental design choice to realize a specific functionality of the application. Therefore, we argue that this is not a sufficient indicator of SSRF awareness.

Developers We have established that there is prior work available on the dire consequences of SSR abuses. But nobody is using existing defense solutions nor properly deny list-based defenses. We could only find two apps using proper allow-list-based defenses. From this, we can only conclude that SSRF is still not present enough in developers' minds and applications.

PHP: SSR by Accident? PHP is a language in which it is easy to implement SSR functionality 'by accident'. Many functions that deal with local files can also request remote resources. Most prominently, `file_get_contents`, but even more obscure functions such as `getimagesize` can trigger requests.

The implementation types `is_file` and `opendir` – both PHP builtins – indicate that developers try to limit the SSR sinks to their local features only. But both functions allow FTP requests. *Takeaway:* We propose that APIs should be designed so that SSR functionality has to be explicitly requested. Otherwise, developers introduce unexpected SSR features or have to implement checks to stop SSRs, introducing risk and complexity.

GitHub as a Data Source We want to provide insights into using GitHub as a data source for security research and surveys to help future work. One interesting result of our manual analysis is that many of our findings are in repositories that are not real applications but hacking tools, such as web shells or programs that are vulnerable by design, e.g., for CTF competitions. It is important to disregard those when reasoning about developer awareness since they do not reflect the status quo of real applications and developer awareness. Researchers must exclude these repositories when using GitHub as a data source.

We also encountered archived repositories as well as abandoned projects (19). Although this is not necessarily a sign of vulnerable applications, we expect that unsupported applications do not represent the current state of attacks and defenses.

Case Study: Insufficient Domain Validation We encountered a vulnerability in `LibreX` during our work[4] that serves as a suiting example for an insufficient attempt at protecting against SSRF. The vulnerable code is shown in Figure 8.

The code defines a domain allowlist in line 3. It then attempts to check the user input from line 1 against the allow list before passing it to the custom sink-wrapper `request()` in line 10. To do so, it first calls the userland function `get_root_domain`. Thus, it is implementing D2: Domain URL Validation.

However, the implementation of `get_root_domain` is defective. The developers utilize a home-grown solution instead of using a well-established URL parser, such as PHP's built-in `parse_url()`. It splits the provided URL using the forward slash as the delimiter. The third element is reversed and split again, this time at the dots. The second and first elements of the resulting array are reversed and concatenated. For example, `http://www.example.org` is split into `["http:","","www.example.org"]`. The third element is reversed to `gro.elpmaxe` and split `["gro", "elpmaxe"]`. Then, the second and first elements are reversed and concatenated: `example.org`.

To bypass the allowlist, an attacker can append `?.example.org` to an arbitrary scheme, port, and domain: `http://evil.com:22?example.org`. Since the last step only takes the first and second element in the reversed input, the function returns `example.org`, which is accepted by the allowlist. Thus, an attacker can control the scheme, domain, and port of the SSR request, making the application vulnerable to A1 (port scanning, network scanning) and A4 Bridging Attacks.

```
1  // we simplified this snippet.
2  $url = $_REQUEST["url"];
3  $requested_root_domain = get_root_domain($url);
4  $allowed_domains=["qwant.com", "wikimedia.org"];
5  if (in_array($requested_root_domain, $allowed_domains)) {
6      $image = $url;
7      $image_src = request($image);
8      header("Content-Type: image/png");
9      echo $image_src;
10 }
11 function get_root_domain($url){
12     $split_url = explode("/", $url);
13     $base_url = $split_url[2];
14     $base_url_main_split = explode(".",
       ↪ strrev($base_url));
15     $root_domain = strrev($base_url_main_split[1]) . "."
       ↪ . strrev($base_url_main_split[0]);
16     return $root_domain;
17 }
```

Figure 8: Vulnerable code snippet of the metasearch engine.

Case Study: unsafe `esc_url_raw` We found a vulnerable WordPress plugin that depends on the broken sanitizer function `esc_url_raw`. Figure 9 shows its sanitization function, which uses some user input as a source. The input is passed through `sanitize_text_field` from WordPress, which has no special effect on URLs. The plugin only depends on `esc_url_raw` as a sanitizer for SSR abuses. As established in Section 3.4 `esc_url_raw`'s documentation promises that

[4] https://github.com/hnhx/librex. We notified the developers of the problem. The repository was deleted from GitHub.

its result is safe for HTTP requests, but this is not true since it is not performing any SSR validation. This underlines the importance of clear and correct documentation.

```
// We simplified this snippet.
function get_response( $url ) {
    $result = wp_remote_get(esc_url_raw( $url ));
    return $result;
}
```

Figure 9: Vulnerable sanitizer function of a WP plugin.

6.1 Limitations

While we aim at being complete, our approach contains limitations:

Static Analysis Static analysis suffers from inherent limitations that can lead to missed data flows due to programming patterns that are inherently difficult, if not impossible, to reconstruct. These patterns are a well-known limitation of static analysis that is under active research [e.g. 23, 24], and may lead to missed data flows. Static analysis is also vulnerable to false positives; however, as we manually verify each of our detected flows, we eliminate this risk reliably. Additionally, our static analysis failed for very complex applications as CPG creation can experience exponential growth, which may lead to time-outs or memory exhaustion depending on the structure of the application, limiting our data set (ref. Figure 6). Finally, we had to decide on one of the different and only partially compatible PHP major versions against which to implement our CPG creation. We decided on the, at the time, most recent PHP 8.2. This will inevitably lead to projects with legacy code that are only partially translatable into bytecode, with the files containing the legacy code left out. Using static analysis potentially reduces the overall amount of analyzed and reported SSRF-related data points.

Missed Second Order Vulnerabilities We do not consider second-order data flows when performing our manual analysis, as we filter out any flow without attacker control. Second-order vulnerabilities are notoriously challenging to detect [13] and, given the typical usage pattern of SSR, are of minor relevance to our overarching research question.

Focus on Common Sinks and Exploits We use popular HTTP sinks with protocol-agnostic exploitation patterns as our starting point for the static analysis. This excludes more exotic attacks involving technically complex and situational exploitations, e.g., leveraging `open_dir` via `ftp`. While those exploits are technically feasible, they do not represent this research's common and focused exploit scenario and should be considered for future work.

6.2 PHPJoern

We have discussed PHPJoern's shortcomings we identified before conducting our study (4.1.1). We, a posteriori, evaluated if they would have impacted our results if we had used PHPJoern. Since we mitigate false positives through our subsequent manual review, we focus on the version mismatch.

To estimate the impact of errors due to version mismatches, we conducted an experiment: Using PHP's syntax check feature, we measured the PHP 7.1 compatibility of our dataset. We found 4.990 repositories that use modern PHPJoern-incompatible features, i.e., they pass PHP 8.2's syntax check but not PHP 7.1's. We manually cross-checked these with our vulnerable flows and identified one vulnerable code path missing from PHPJoern's CPG. Therefore, we would be unable to find it if we based SURFER on PHPJoern instead of our new CPG generator. The breaking feature used by the vulnerable code is *DNF Type Declarations*.

6.3 Research Questions Answered

We will now answer our research questions from Section 2.3 and summarize our learnings.

How Popular are SSRs? 49.6 % of the repositories in our dataset contained at least one SSR sink. Since this number is string-search-based, it is a rough approximation. Filtering results for only those with user input in the data flow to the SSR sink, we get 141. This shows that application developers are using SSR sinks mostly with static targets.

Current State of SSRF defenses (RQ1) From an academic and documentation standpoint, SSR abuses are well documented. The literature provides enough sources on defenses, and OWASP is providing cheat sheets. The common framework Symfony implemented a safer HTTP client, and there are drop-in replacements for safer curl usage in PHP. WordPress attempts to provide a defense but is flawed and vulnerable to DNS rebinding. Other frameworks supporting SSR lack defense capabilities and do not discuss the risks of SSRs in their documentation.

Web developers are not using readily available defenses (RQ2) We discussed the availability of ready-to-be-used safer HTTP clients that defend against certain SSR abuses in Section 3.4. However, only a negligible amount of PHP applications on GitHub are using them.

Applications are lacking custom defenses (RQ3) Our static analysis results, in combination with an in-depth manual analysis, showed that proper defense and mitigation attempts are rare. No application is equipped with DNS validation, which is essential for a safe and proper deny-list-based defense against SSR abuses. Only two applications properly used allow listing.

State of SSR vulnerabilities in applications (RQ4) Considering that open-source web application developers are not using existing SSR defenses and are not implementing proper

SSR defenses, we conclude that SSR awareness has not arrived in the mainstream of application developers.

7 Related Work

SSR Studies Previous academic work introduced dynamic scanners to detect vulnerable SSR, Pellegrino et al. [32] proposed a black-box testing tool and scanned 68 services. We leverage the benefits of static code analysis, enabling us to cover all possible code paths without any input except the application itself. This allows us to conduct a large-scale study on 27,078 applications. Jabiyev et al. [21] proposed defenses against SSRF and benchmarked them against known SSRF vulnerabilities. Musch et al. [28] studied the prevalence and security implications of Server-Side-Browsers as SSR clients. Sahin et al. [33] have conducted a CTF experiment to study developers' awareness of different web attack types. SSRF was exploited the least, showing that it is still an unknown vulnerability class. Previous work focused on detecting SSR vulnerabilities or defending against them — we are the first to evaluate existing defenses in the wild.

SSR Systematization Pellegrino et al. [32] introduced a classification of SSRs along the axes of *Flaw*, *Behavior*, *Control*, and *Target*. Additionally, they presented some mitigation techniques they encountered.

In contrast, our systematization, presented in section 3, includes defenses as a first-class citizen. Consequently, attacks are explicitly mapped to suitable defenses. They are classified as *full*, *partial*, or *allow-list only* protections. Additionally, we systematized known defense evasion techniques and linked them with our previous efforts.

Furthermore, our systematization distinguishes between allow listing and deny list cases, which Pellegrino et al. did not cover. However, this differentiation is essential to a complete understanding of SSR defenses. Some defenses are sufficient in the allow list case, e.g., complete URL validation is an adequate host validation. At the same time, more technical effort and knowledge are required in the deny list case, i.e., DNS Rebinding protection is needed.

Additionally, while our systematization contains the attacks from Pellegrino et al., it presents a current and updated picture. It includes recent developments; for example, it encompasses the new attack surface of browsers as HTTP clients [28]. Additionally, we split the *Probe* class into the more suited *Port scan* and *Network scan* categories to better reflect the impact of different defense techniques.

Therefore, our defense-encompassing systematization can be used by both researchers and practitioners. Security researchers can easily classify their potential findings alongside existing mitigations using our systematization. Similarly, developers can leverage it to check if their implementation is vulnerable and are provided with better options.

PHP Static Analysis Previous work covered information flow and taint-style vulnerabilities in PHP applications. Huang et al. [19] detected vulnerabilities via information flow analysis in PHP applications and were the first to do so. Jovanovic et al. [22] proposed a static taint-flow analysis for PHP applications. Kassar et al. [23, 24] are working on pushing the coverage of PHP static analysis tools but overlook SSRF sinks and vulnerabilities in their work. Backes et al. [9] were the first to leverage code property graphs to analyze PHP applications. Alhuzali et al. [6] combined it with dynamic analysis to generate exploits more precisely. Shezan et al. [35] augmented it with cross-language capabilities to search for GDPR violations. Our novel PHP code property graph converter, written against the modern CPG standard [48], works on the CFG provided by PHP itself, making it more reliable than the one proposed by Backes et al. [9].

8 Conclusion

SSRF is a complex and multifaceted vulnerability class, and our survey of the current state of the art shows that developers must consider multiple attack vectors. However, the experiments in this paper reveal that developers do not properly defend against SSRF:

i) Our analysis of popular PHP frameworks and SSR libraries shows that even if SSR capabilities are offered, defenses in any form are commonly missing or defective. In particular, dedicated defenses against SSRF are either broken (WordPress) or are simply not used by the vast majority of PHP applications on GitHub (Symfony, SafeCurl, etc.) – Only four applications are using existing safe countermeasures, as shown by our usage study.

ii) As dedicated defensive measures are not used, we investigated if homegrown countermeasures are implemented instead. For this purpose, we examined 27,078 software projects sourced from GitHub using our CPG-based tool SURFER and a subsequent rigorous manual analysis. Our investigation into the resulting flows and deployed defenses revealed that *only two* applications employ their own safe allow-list defense. Furthermore, we did not find *any* secure deny-list defense since protection against DNS rebinding was absent in all cases.

In a somber conclusion, our results show that, while being comparatively infrequent, SSRF is widespread in the applicable subset of software projects: Almost *all* applications that might be susceptible to SSRF due to their application logic (i.e., they utilize at least one functionality that requires the retrieval of external HTTP resources based on user input) are indeed vulnerable to such attacks. Hence, our results suggest that developers either are unaware of SSRF's dangers or are unwilling/unable to implement effective defenses.

Acknowledgments

We are thankful for the valuable feedback of our anonymous reviewers and shepherd. This work has received funding from the European Union's Horizon 2020 research and innovation programme under project TESTABLE, grant agreement No 101019206. Appendix

8.1 List of Supported PHP SSR sinks

We compiled PHP functions that can trigger HTTP requests in default configurations. We included the popular 'curl' extension. We amended the list with request sinks from WordPress, since it is the most-used PHP framework. Please note that `get_headers` performs a GET and not a HEAD request.

We chose not to include sinks in this work that require a configuration change to trigger an SSR, e.g., if `allow_url_include` is set to true, the include and require functions of PHP are able to trigger network requests. We include `file_get_contents` due to a similar reasoning. It requires `allow_url_fopen` to be set to true – which is the default.

However, since our methodology is general, the list can be easily modified to broaden the scope of sinks.

- `file_get_contents`
- `curl_init`
- `curl_set_opt`
- `getimagesize`
- `get_headers`
- `wp_http::get`
- `requests::get`
- `wp_remote_request`
- `wp_remote_get`
- `wp_remote_post`
- `wp_remote_head`
- `wp_safe_remote_request`
- `wp_safe_remote_get`
- `wp_safe_remote_post`
- `wp_safe_remote_head`

8.2 Findings

Table 7 lists the apps we identified as vulnerable. We contacted the developers if the repository was not archived or explicitly deprecated.

Abstract

As a booming research area in the past decade, deep learning technologies have been driven by big data collected and processed on an unprecedented scale. However, privacy concerns arise due to the potential leakage of sensitive information from the training data. Recent research has revealed that deep learning models are vulnerable to various privacy attacks, including membership inference attacks, attribute inference attacks, and gradient inversion attacks. Notably, the efficacy of these attacks varies from model to model. In this paper, we answer a fundamental question: *Does model architecture affect model privacy?* By investigating representative model architectures from convolutional neural networks (CNNs) to Transformers, we demonstrate that Transformers generally exhibit higher vulnerability to privacy attacks than CNNs. Additionally, we identify the micro design of activation layers, stem layers, and LN layers, as major factors contributing to the resilience of CNNs against privacy attacks, while the presence of attention modules is another main factor that exacerbates the privacy vulnerability of Transformers. Our discovery reveals valuable insights for deep learning models to defend against privacy attacks and inspires the research community to develop privacy-friendly model architectures.

1 Introduction

Deep learning has been gaining massive attention over the past several years. Training deep learning models requires collecting and processing user data, which raises significant privacy concerns. The data gathered during the training phase often contains sensitive information that malicious parties can access or retrieve. Various privacy attacks targeting deep learning models have demonstrated this vulnerability extensively. One prominent type of attack is membership inference, which focuses on determining whether a specific data sample belongs to the training data [60,62]. Another attack is attribute inference, which aims to uncover implicit attributes learned by the model beyond the intended target attribute [52,65]. Additionally, gradient inversion attacks pose a significant threat by attempting to reconstruct the information of the training data from the gradients of the model [20,22]. These attacks empower adversaries to exploit deep learning models for extracting sensitive data.

Prior research has established that overfitting is one of the primary causes of privacy leakage in deep learning models [10,27,43,62]. In general, overfitting occurs when models excessively learn specific details from the training data, which can lead to inadvertent privacy breaches. Surprisingly, we discover that even when models exhibit comparable levels of overfitting, the effectiveness of attacks varies across different models. This observation raises intriguing questions as to why certain deep learning models are more susceptible to privacy attacks than others, a puzzle that researchers have not fully comprehended. Consequently, we conjecture that other factors beyond overfitting might also contribute to the increased vulnerability of some deep learning models to privacy attacks. Though existing literature has explored model robustness and explainability [4,57], the privacy leakage of the model architectures remains underexplored. Therefore, we are motivated to address this critical gap by answering the following question: *How does a model's architecture affect its privacy preservation capability?*

In this paper, we approach this question by comprehensively analyzing different deep learning models under various state-of-the-art privacy attacks. Our investigation focuses on two widely adopted deep learning model architectures: convolutional neural networks (CNNs) and Transformers. CNN-based models have been dominant in computer vision, thanks to its sliding-window strategy, which extracts local information from images effectively. Transformers, initially introduced in natural language processing (NLP), have gained popularity in computer vision by capturing large receptive fields through attention mechanisms, resulting in comparable accuracy performance against CNNs. The tremendous achievements and wide usage of these two model architectures provide an excellent opportunity for us to make a comparative analysis regarding model privacy risks. Through our investigation, we make an intriguing discovery: *Transformers,*

in general, exhibit higher vulnerability to mainstream privacy attacks than CNNs.

While Transformers and CNNs have different designs in many aspects, we investigate whether some key modules in the model architecture have a major impact on privacy risks. To this end, we evaluate the privacy leakage of several major modules in a Transformer architecture by sending only selected gradients to the gradient inversion attacks and discover that attention modules cause significant privacy leakage. Moreover, we start with a popular CNN-based model, ResNet-50 [26], and gradually morph the model to incorporate the key designs of Transformers. This leads us to the structure of ConvNeXt [46]. We evaluate the privacy leakage through this process and identify several key components that have a significant impact on privacy risks: (1) the design of the activation layers; (2) the design of stem layers; (3) the design of LN layers. We further conduct ablation studies to verify our discoveries and propose solutions to mitigate the privacy risks.

In summary, our contributions in this paper are summarized as follows:

- For the first time, we investigate the impact of model architectures and micro designs on privacy risks.
- We evaluate the privacy vulnerabilities of two widely adopted model architectures, i.e., CNNs and Transformers, using three prominent privacy attack methods: (1) membership inference attacks, (2) attribute inference attacks, and (3) gradient inversion attacks. Our analysis reveals that Transformers exhibit higher vulnerabilities to these privacy attacks than CNNs.
- We identify three key factors: (1) the design of activation layers, (2) the design of stem layers, and (3) the design of LN layers, that significantly contribute to the enhanced resilience of CNNs in comparison to Transformers. We also discover that the presence of attention modules in Transformers could make them susceptible to privacy attacks.
- We propose solutions to mitigate the vulnerabilities of model architectures: modifying model components and adding perturbations as defense mechanisms.

2 Related Work

2.1 CNNs and Vision Transformers

Convolutional Neural Networks (CNNs) are a type of neural network that employs convolutional layers to extract features from input data. In contrast to fully connected networks, CNNs use convolutional kernels to connect small samples to neurons for feature extraction, reducing the number of model parameters and enabling the recognition of local features. Various techniques are employed to construct a CNN model, including padding, pooling, dilated convolution, group convolution, and more.

The concept of convolutional neural networks (CNNs) dates back to the 1980s [38]. However, the invention of AlexNet [37] makes CNNs the most prominent models in computer vision. Subsequent research improved the accuracy and efficiency of models [63, 68]. ResNet [26] addressed the challenge of training deep networks using skip connections. Other notable networks consist of Inception [69], MobileNet [30], ResNeXt [79], EfficientNet [70], RegNet [56], ConvNeXt [46].

Vision Transformers, originating from natural language processing, divide the input image into multiple patches, forming a one-dimensional sequence of token embeddings. Their exceptional performance can be attributed to the multi-head self-attention modules [74]. The attention mechanism has significantly contributed to the advancement of natural language processing [5, 14, 81], subsequently leading to the introduction of Transformers in the field of computer vision as Vision Transformers (ViT) [16]. Research has shown that ViTs can surpass CNNs in various downstream tasks [16, 67]. Later Transfomer models have focused on numerous improvements of ViTs, such as Tokens-to-Token ViT [85], Swin Transformers [45], DeiT [71], MViT [40], DaViT [15].

Numerous studies have compared CNNs and Transformers from the perspectives of robustness [4, 55, 75] and explainability [57]. However, our research diverges from previous works by concentrating on the privacy leakage inherent in both CNNs and Transformers.

2.2 Privacy Attacks on Deep Learning Models

A primary concern in deep learning privacy is that the model may reveal sensitive information from the training dataset. An adversary can exploit various approaches to compromise privacy, including predicting whether a particular sample is in the model's training dataset via membership inference attacks, or disclosing the implicit attributes of data samples via attribute inference attacks, or even recovering private data samples utilized in training a neural network through gradient inversion attacks.

Membership inference attacks were initially introduced in [62], where an attack model was employed to distinguish member samples from non-member samples in the training data. To execute these attacks, shadow models would mimic the behavior of victim models [60, 62]. Prediction results from victim models were gathered for attack model training. Usually, the confidence scores or losses were utilized [62], but more recent work (label-only attacks) applied prediction labels to launch attacks successfully [11, 41]. The attacks could also be executed by designing a metric with a threshold by querying the shadow model [66]. Some researchers expanded the attacks into new domains, including generative models [9, 25], semantic segmentation [28, 87], federated

learning [54, 73], and transfer learning [64, 94]. Other researchers relaxed the attack assumptions and improved the attacks, including discussion on white-box/black-box access for the attacks [59], providing more metrics (i.e. ROC curves and the true positive rate at a low false positive rate) to measure the attack performance more accurately [7,34,48,77,82]. We select [7,60,62] as our baseline methods.

Attribute inference attacks, another significant category of privacy attack methods, attempt to reveal a specific sensitive attribute of a data sample by analyzing the posteriors of the victim model trained by the victim dataset. Some early research launched the attacks by generating input samples with different sensitive attributes and observed the victim model output [21,83]. However, these methods could only work in structured data. Later research improved the attacks with victim model representations [52,65]. They also claimed that the overlearning feature of deep learning models caused the execution of the attacks [65]. Attributes could also be inferred through a relaxed notion [91], model explanations [18], label-only settings [51], or imputation analysis [33]. As we aim to infer attributes from visual data, we select [52,65] as baseline methods.

Gradient inversion attacks primarily aim to reconstruct training samples at the local clients in federated learning. Using the publicly shared gradients in the server, adversaries can execute the attacks by reconstructing the training samples using gradient matching. DLG [93] and its variant, iDLG [92], were the early attacks to employ an optimization-based technique to reconstruct the training samples. Later research like Inverting Gradients [22] and GradInversion [84] improved the attack performance by incorporating regularizations into the optimization process. APRIL [49] and GradViT [24] further developed the attack methods to extract sensitive information from Transformers. The use of Generative Adversarial Networks (GANs) in some gradient inversion attack methods [42] can have a significant impact on reconstructed results, making it difficult to isolate the influence of other factors on privacy leakage. Therefore, we use conventional gradient inversion attack methods [22] that do not involve the use of GANs.

There have been several evaluations and reviews of these privacy attacks against deep learning models [27,31,43,44,66,88,90]. However, we aim to evaluate the model architectures leveraging these privacy attacks. To sum up, we utilize conventional privacy attacks [7,22,52,60,62,65] as the baseline attacks in our analysis, for these attack methods have inspired many follow-up research works, and they are suitable for evaluation on various models and datasets.

3 Methodology of Evaluating the Impact of the Model Architecture on Privacy

In this section, we present our approach to assessing the impact of model architectures on privacy leakage. In order to organize our study in a thorough and logical manner, We aim to answer the following research questions sequentially:

- **RQ1**: How to analyze the privacy leakage in model architectures?
- **RQ2**: What model architectures of CNNs and Transformers should we choose to evaluate these attacks?
- **RQ3**: What performance aspects should we focus on when evaluating the privacy attacks on model architectures?
- **RQ4**: How should we investigate what designs in model architectures contribute to privacy leakage?

In this work, we focus on classifier or feature representation models such as CNNs and Transformers, which are subject to the investigated privacy attacks. A new line of generative AI models, such as generative adversarial networks (GANs) and diffusion models, are vulnerable to different privacy attacks and thus out of the scope of this paper. We believe our evaluation methodology could shed light on the effect of model privacy from the perspective of model architectures.

3.1 Privacy Threat Models

To answer the first research question (**RQ1**), we choose three prominent privacy attack methods: membership inference attacks, attribute inference attacks, and gradient inversion attacks.

3.1.1 Membership Inference Attacks

Network-Based Attacks. Initiating a network-based membership inference attack [60,62] requires three models: the victim model $\mathcal{V}$ (the target), the shadow model $\mathcal{S}$ (the model to mimic the behavior of the victim model), and the attack model $\mathcal{A}$ (the classifier to give results whether the sample belongs to the member or non-member data). The following paragraphs provide explanations of how the attacks work.

The first step is the attack preparation. Since the adversary has only black-box access to the victim model $\mathcal{V}$, they can only query the model and record prediction results. To launch a membership inference attack, the adversary needs to create a shadow model $\mathcal{S}$, which behaves similarly to the victim model $\mathcal{V}$. This involves collecting a shadow dataset $\mathcal{D}_S$, usually from the same data distribution as the victim dataset $\mathcal{D}_V$. The shadow dataset $\mathcal{D}_S$ is then divided into two subsets: $\mathcal{D}_S^{train}$ for training and $\mathcal{D}_S^{test}$ for testing.

Once the preparation is complete, the adversary trains the attack model. The shadow model $\mathcal{S}$ and shadow dataset $\mathcal{D}_S$ are used to train the attack model $\mathcal{A}$. Each prediction result of a data sample from the shadow dataset $\mathcal{D}_S$ is a vector of confidence scores for each class, which is concatenated with a binary label indicating whether the prediction is correct or not. The resulting vector, denoted as $\mathcal{P}_S^i$, is collected for all n samples, forming the input set $\mathcal{P}_S = \{\mathcal{P}_S^i, i = 1, ..., n\}$ for the

attack model $\mathcal{A}$. Since $\mathcal{A}$ is a binary classifier, a three-layer MLP (multi-layer perceptron) model is employed to train it.

At last, the adversary launches the attack model inference. The adversary queries the victim model $\mathcal{V}$ with the victim dataset $\mathcal{D}_V$ and records the prediction results, which are used as the input for the attack model $\mathcal{A}$. The attack model then predicts whether a data sample is a member or non-member data sample.

Likelihood-Based Attacks. The Likelihood Ratio Attack (LiRA) [7] is a state-of-the-art attack method that employs both model posteriors and their likelihoods based on shadow models. In contrast to attacks relying on a single shadow model, LiRA requires the adversary to train multiple shadow models $\mathcal{S} = \{S_1, ..., S_n\}$. This ensures that a target sample (from the victim dataset $\mathcal{D}_V$) is included in half of the models $\mathcal{S}$ and excluded from the other half. The adversary then queries the shadow models with the target sample and calculates the logits for each model. Using these logits, the adversary calculates the probability density function to determine the likelihood ratio of the target sample, which corresponds to its membership status.

There are other kinds of membership inference attacks, including metric-based attacks and label-only attacks [11, 41, 66]. Instead of using a neural network to be the attack model, metric-based attacks [66] launch the attacks using a certain metric and threshold to separate member data from non-member data. Label-only attacks [11, 41] relax the assumptions of the threat model leveraging only prediction labels as the input of the attack model. Our study focuses on two types of membership inference attacks: network-based and likelihood-based attacks. We chose these two types of attacks because the network-based attack is commonly used as a baseline in many research papers, making it a conventional attack to consider. Additionally, the likelihood-based attack is a more recent state-of-the-art attack that has demonstrated high effectiveness, making it an important attack to evaluate as well. By considering these two types of attacks, we can effectively represent the performance of membership inference attacks against various victim models and gain insights into potential privacy risks associated with different machine learning models.

3.1.2 Attribute Inference Attacks

The goal of attribute inference attacks [52, 65] is to extract sensitive attributes from a victim model, which may inadvertently reveal information about the training data. For instance, suppose the victim model is trained to classify whether a person has a beard or not. In that case, an adversary may infer the person's race based on the model's learned representation.

At the attack preparation stage, the victim model $\mathcal{V}$ is trained by the victim dataset $\mathcal{D}_V$ with two subsets $\mathcal{D}_V^{train}$ and $\mathcal{D}_V^{test}$ for the training and testing.

The second step is also the attack model training. To train the attack model $\mathcal{A}$, the adversary uses an auxiliary dataset $\mathcal{D}_A^{train}$, which includes pairs of the representation h and the attribute a, i.e., $(h,a) \in \mathcal{D}_A$.

At last, the adversary launches the attack. The adversary takes a data sample's representation h as the input and uses the attack model $\mathcal{A}$ to infer the attribute result.

3.1.3 Gradient Inversion Attacks

Launching the gradient inversion attack [22, 92, 93] involves solving an optimization problem, which aims to minimize the difference between the calculated model gradients and the original model gradients. The optimization process continues for a certain number of iterations, after which the input data sample can be reconstructed.

The adversary operates within a federated learning scenario. In the attack preparation stage, the adversary operates from the central server, aggregating model gradients to create a centralized model. Since the adversary has access to the communication channels used during the federated learning process, they can retrieve the model gradients and prepare to extract sensitive information from the training samples. This allows the adversary to launch attacks against the federated learning system.

In the step of gradient reconstruction, the aggregated model gradients are denoted as $\nabla_\theta \mathcal{L}_\theta(x,y)$, where θ is the model parameters, x and y are the original input image and its ground truth in a local client, and $\mathcal{L}$ represents the cost function for the model. To initiate the reconstruction process, the adversary generates a dummy image x^*. The adversary tries to minimize this cost function: $\arg\min_x ||\nabla_\theta \mathcal{L}_\theta(x,y) - \nabla_\theta \mathcal{L}_\theta(x^*,y)||^2$. The dummy image x^* is reconstructed to resemble x closely.

3.2 CNNs vs Transformers

To answer the second research question (**RQ2**), we investigate the privacy of two mainstream architectures: CNNs and Transformers. We carefully select several popular CNNs and Transformers for the attacks to analyze the privacy leakage.

For CNNs, we choose ResNets [26] as baseline models, which are known for incorporating residual blocks and have become widely used in various computer vision tasks. We specifically select ResNet-50 (23.52 million parameters) and ResNet-101 (42.51 million parameters) to represent CNN architectures in our analysis. Regarding Transformers, we focus on Swin Transformers [45], which have gained attention for their innovative design incorporating attention modules and shifted window mechanisms. We analyze Swin-T (27.51 million parameters) and Swin-S (48.80 million parameters) as representatives of Transformer architectures.

To ensure fair comparisons, we organize the evaluation of the four models based on their parameter sizes, grouping models with similar parameter sizes together. This approach allows us to compare models that exhibit comparable task

Table 1: Training recipes for privacy attacks.

Config	Param	Config	Param
for all models of membership inference			
optimizer	AdamW	training epochs	300
learning rate	0.001	batch size	256
weight decay	0.05	mixup	0.8
optimizer momentum	β_1, β_2 = 0.9, 0.999	cutmix	1.0
learning rate schedule	cosine annealing	label smoothing	None
for all models of attribute inference			
optimizer	SGD	batch size	256
learning rate	0.01	training epochs	100
weight decay	0.0005	random augmentation	None
optimizer momentum	0.9		
for gradient inversion			
cost function	similarity	total iteration	3000
optimizer	Adam	total variance	0.0001
learning rate	0.1		

performances while considering their architectural differences. Specifically, we compare ResNet-50 with Swin-T, as they have similar parameter sizes, and we compare ResNet-101 with Swin-S for the same reason.

Apart from model architectures, training Transformers requires a modernized training procedure compared to training traditional CNNs [45, 74]. To ensure fair comparisons, we employ the same training recipe for both CNNs and Transformers in each comparison.

4 Evaluation on Privacy Attacks with CNNs and Transformers

This section addresses the third research question (**RQ3**) and comprehensively analyzes the experimental settings and results. We aim to compare the attack performance under various metrics to gain a deeper understanding of the findings. We also focus on the performance differences and overfitting differences between CNNs and Transformers.

4.1 Settings

Datasets. Our experiments evaluate the privacy leakage under these four datasets.

- **CIFAR10 [36]** consists of 60,000 color images with dimensions of 32×32 pixels. It is organized into ten classes, with each class containing 6,000 images. The dataset covers a wide range of general object categories.
- **CIFAR100 [36]** is similar to CIFAR10 but with 100 classes. Each class has 600 images and represents a specific general object category.
- **ImageNet1K [13]** is a widely used dataset in computer vision containing over 1 million labeled images, covering 1,000 different classes. The dataset encompasses a diverse range of objects and scenes.
- **CelebA [47]** contains over 200,000 face images, each with 40 binary attributes.

In membership inference attacks, we use two datasets, CIFAR10 and CIFAR100, for their popularity in prior attack research [7, 44, 60]. For network-based attacks, each dataset is evenly split into four subsets for training and testing both the victim and shadow models to ensure a fair evaluation [60]. For likelihood-based attacks, we follow the training settings in [7]. This involves dividing the training data into multiple subsets, ensuring that a specific training sample is present in only half of these subsets.

For attribute inference attacks, we utilize the CelebA dataset, which provides rich attribute labeling. This allows us to identify hidden attributes accurately. In our experiments, we focus on inferring the race attribute while using the gender attribute as the classification goal for the victim model. We randomly select 20,000 images from CelebA and evenly split them into four subsets for training and testing both the victim model and the attribute inference attack model.

In gradient inversion attacks, we employ the CIFAR10 and ImageNet1K datasets for low/high-resolution reconstruction. These attacks are conducted in a federated learning scenario to reconstruct the training batch. We randomly select a subset of images from these datasets to evaluate the attacks, ensuring a representative assessment of the attack performance.

In a nutshell, all these datasets are benchmark datasets for evaluating privacy attacks [7, 22, 27, 44, 84]. These datasets cover a wide range of objects with different numbers of classes, making them sufficient for our evaluation.

Victim Models. To ensure fair comparisons, we evaluate the performances of CNNs and Transformers with similar parameter sizes. For all attacks, we select two groups of models based on their parameter sizes. These groups include ResNet-50 and ResNet-101 as CNN-based models and Swin-T and Swin-S as Transformer-based models. We train these models to reach more than 0.99 training accuracy and output testing accuracy (i.e., task accuracy) results in the experiments.

Attack Models. For membership inference attacks, we employ a three-layer MLP model to infer membership information. Attribute inference attacks utilize a two-layer MLP model to uncover learned representations and potentially infer sensitive information. In gradient inversion attacks, we optimize input and generate gradients to reconstruct the original data, revealing private information.

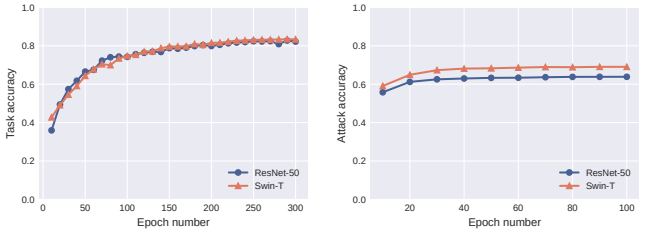
Evaluation Metrics. We evaluate the performance of different attacks using specific metrics. For membership inference attacks, we consider attack accuracy (↑), ROC curve (↑), AUC (↑), and TPR at low FPR (↑). For attribute inference attacks, we assess effectiveness using attack accuracy (↑) and macro-F1 score (↑). Regarding gradient inversion attacks, we use multiple metrics to evaluate the quality of reconstruction results. These metrics include mean square error (MSE ↓), peak signal-to-noise ratio (PSNR ↑), learned perceptual im-

Table 2: Results for network-based membership inference attacks.

	CIFAR10		CIFAR100	
	Task acc ↑	Attack acc ↑	Task acc ↑	Attack acc ↑
ResNet-50	0.8220 ± 0.0023	0.6385 ± 0.0078	0.5288 ± 0.0083	0.8735 ± 0.0029
Swin-T	0.8335 ± 0.0042	0.6904 ± 0.0052	0.5632 ± 0.0056	0.9340 ± 0.0030
ResNet-101	0.8301 ± 0.0037	0.6317 ± 0.0063	0.5313 ± 0.0074	0.8607 ± 0.0034
Swin-S	0.8258 ± 0.0039	0.6405 ± 0.0075	0.5665 ± 0.0059	0.9357 ± 0.0039

age patch similarity (LPIPS ↓) [89], and structural similarity (SSIM ↑) [76]. Note that "↑" means the higher metric corresponds to the higher attack performance, while ↓ means the lower metric leads to the higher attack performance.

Training Settings for Privacy Attacks. Table 1 illustrates the training configurations for membership inference attacks, attribute inference attacks and gradient inversion attacks.



4.2 Evaluation on Membership Inference Attacks

The results presented in Table 2 offer the performance of network-based membership inference attacks on CIFAR10 and CIFAR100 datasets. The task accuracy scores of the victim models on CIFAR10, which are approximately 0.82 for both CNNs and Transformers, indicate that these models exhibit competitive task performance with similar overfitting levels. Notably, the attack accuracy on CIFAR10 reveals that Transformers exhibit more privacy leakage within each group than CNN models. Similar findings are observed on CIFAR100, suggesting that Transformers consistently exhibit higher vulnerability to membership inference attacks compared to CNN models.

It is worth mentioning that the dataset used in this study is divided into four equally sized subsets for training and testing the victim and attack models. Consequently, the task accuracy of the victim models on CIFAR10 and CIFAR100 might be lower than expected in a standard CIFAR10 or CIFAR100 classification task. This does not affect the performance of the attacks, and this phenomenon has been acknowledged in prior research [7, 27, 35, 61]. This also applies to later experimental results.

Figure 1 illustrates the task accuracy and attack accuracy of ResNet-50 and Swin-T across multiple epochs on CIFAR10. The task accuracy of ResNet-50 starts relatively low but exhibits a rapid increase over time. Eventually, both ResNet-50 and Swin-T can achieve task accuracy scores of approximately 0.82. Regarding attack accuracy, the plot demonstrates that the attack on Swin-T consistently outperforms the attack on ResNet-50.

Table 3 displays the outcomes of likelihood-based membership inference attacks on CIFAR10 and CIFAR100. The table includes task accuracy and attack performance, the same as the evaluation for network-based attacks. To assess attack

(b) Performance of privacy attack on CIFAR10

Figure 1: The performance of membership inference attacks against ResNet-50 and Swin-T on CIFAR10 under different numbers of epochs.

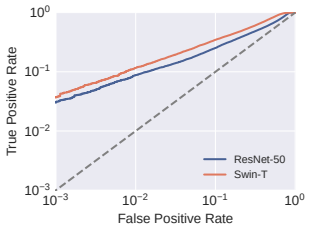

Table 3: Results of likelihood-based membership inference attacks.

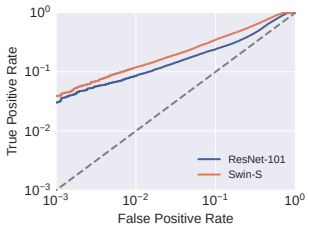
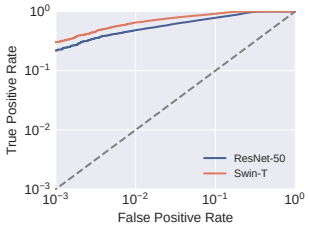
		Task acc ↑	AUC ↑	TPR@0.1%FPR ↑	Attack acc ↑
CIFAR10	ResNet-50	0.8716 ± 0.0035	0.6446 ± 0.0276	3.15% ± 0.25%	0.6009 ± 0.0163
	Swin-T	0.8630 ± 0.0017	0.7384 ± 0.0029	3.68% ± 0.33%	0.6553 ±0.0027
	ResNet-101	0.8708 ± 0.0043	0.6671 ± 0.0107	3.33% ± 0.41%	0.6090 ± 0.0079
	Swin-S	0.8636 ± 0.0036	0.7392 ± 0.0054	3.75% ± 0.37%	0.6576 ± 0.0045
CIFAR100	ResNet-50	0.5632 ± 0.0032	0.9431 ± 0.0005	23.75% ± 2.09%	0.8524 ± 0.0009
	Swin-T	0.6001 ± 0.0033	0.9756 ± 0.0003	28.52% ± 1.54%	0.9112 ± 0.0010
	ResNet-101	0.5654 ± 0.0042	0.9379 ± 0.0021	21.25% ± 1.55%	0.8484 ± 0.0036
	Swin-S	0.5900 ± 0.0029	0.9639 ± 0.0006	31.02% ± 1.74%	0.8978 ± 0.0014



performance more comprehensively, we adopt the methodology proposed in [7] and incorporate additional metrics such as AUC, TPR@0.1%FPR, besides attack accuracy. The victim models achieve task accuracy scores of approximately 0.86 on CIFAR10 and 0.56 on CIFAR100. Consistently, the attack performance metrics highlight that Transformers are more vulnerable to membership inference attacks compared to CNNs in terms of any attack metric. We also present the attack performance through ROC curves in Figure 2. These curves demonstrate that Transformers yield higher ROC curves, signifying their better attack performance.

The privacy leakage varies on different models and datasets. Similar to [60, 62], we analyze the overfitting levels of victims models in Figure 4a. The overfitting level indicates the accuracy difference of a model between its training and inference. Figure 4a illustrates the results of Transformers and CNNs in CIFAR10 and CIFAR100. We conclude that a more overfitted model comes with higher membership inference attack accuracy. More importantly, at the same overfitting level, Transformers always suffer from higher attack accuracy.



In conclusion, the results strongly suggest that Transformers are more susceptible to network-based and likelihood-based membership inference attacks compared to CNNs. Transformers consistently demonstrate higher vulnerability to membership inference attacks across various metrics.

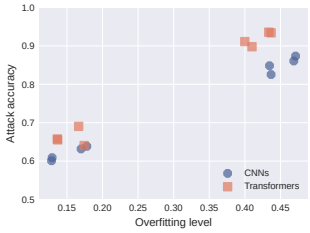
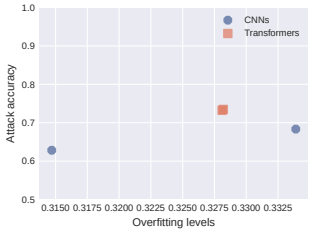
4.3 Evaluation on Attribute Inference Attacks

Table 4 presents the results of attribute inference attacks on CelebA. Similarly to membership inference attacks, we categorize CNN and Transformer models into two groups based on their parameter sizes. The table shows that within each group, CNNs and Transformers achieve similar task accuracy scores, approximately 0.65. However, when considering the attack accuracy and Macro F1 score, Transformers consistently outperform CNNs. The results from attribute inference attacks align with our previous findings from membership inference attacks, emphasizing the increased vulnerability of Transformer models to privacy attacks.

Figure 3 presents the performance of task accuracy and attack accuracy in attribute inference attacks using ResNet-50 and Swin-T on CelebA over 100 epochs. Figure 3a shows that although ResNet-50 and Swin-T models start with different task accuracy scores, both models gradually converge to similar task accuracy scores of around 0.65. However, when we examine the attack accuracy in Figure 3b, the attack accuracy on Swin-T consistently outperforms that on ResNet-50



(a) Performance of victim models on CelebA



(b) Performance of privacy attack on CelebA

Figure 3: The performance of attribute inference attacks against ResNet-50 and Swin-T on CelebA under different numbers of epochs.

(a) Membership inference

(b) Attribute inference

Figure 4: The performance of privacy attacks against both CNNs and Transformers with various models and datasets under different overfitting levels.

throughout the 100 epochs. This reveals that Transformers like Swin-T are more vulnerable to attribute inference attacks than ResNet-50 from the start of the attack training to the end.

We further analyze the relationship between the attack performance and the overfitting levels of victim models in Figure 4b. We have made a similar discovery to the previous evaluation: Transformers suffer from higher attack accuracy than CNNs when the victim models are at the same overfitting level.

4.4 Evaluation on Gradient Inversion Attacks

Table 5 presents the results of gradient inversion attacks on CNNs and Transformers using CIFAR10. Similar to our previous evaluations, we still compare these two model architectures in groups. The attacks are evaluated by multiple metrics, which measure reconstruction results between ground truth images and reconstruction images. The table clearly shows that the attacks on Transformers outperform the attacks on CNNs by a significant margin. Figure 5a provides examples of the reconstruction results. The attacks on CNNs fail to generate high-quality reconstruction images, whereas the attacks on Transformers produce remarkably accurate reconstructions that closely resemble the originals.

Figure 5b provides the reconstruction results of the gradi-

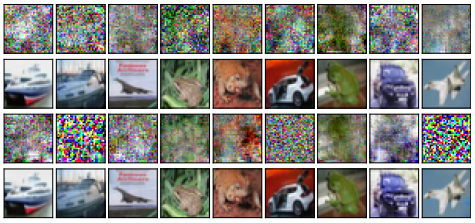


Table 5: The results of gradient inversion attacks on CNNs and Transformers on CIFAR10.

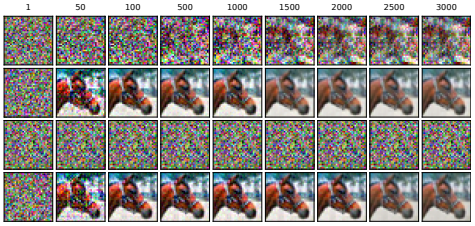
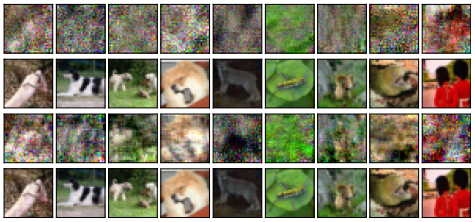
	MSE ↓	PSNR ↑	LPIPS ↓	SSIM ↑
ResNet-50	1.3308 ± 0.6507	11.30 ± 2.24	0.1143 ± 0.0403	0.0946 ± 0.0989
Swin-T	0.0069 ± 0.0071	36.24 ± 5.21	0.0012 ± 0.0016	0.9892 ± 0.0118
ResNet-101	1.2557 ± 0.6829	11.58 ± 2.16	0.1461 ± 0.1012	0.0784 ± 0.0675
Swin-S	0.0063 ± 0.0083	37.85 ± 6.15	0.0016 ± 0.0028	0.9878 ± 0.0128



ent inversion attacks over multiple iterations. It demonstrates the transformation of a raw dummy image towards a reconstruction that closely resembles the original image as the attack training continues. The reconstruction results reveal the varying degrees of success achieved by the attacks on different models. In the case of ResNet-50, the reconstructed image shows limited resemblance to the original image. When attacking ResNet-101, the reconstruction result fails to capture any meaningful information. On the other hand, when targeting Transformers such as Swin-T and Swin-S, the attacks yield highly accurate reconstruction results since early iterations.

In the evaluation of gradient inversion attacks on ImageNet1K, we still compare the performance of ResNet-50, ResNet-101, Swin-T, and Swin-S models. Randomly selected images from ImageNet1K are used to generate reconstruction results, shown in Figure 5c. Similar to the previous experiments on CIFAR10, the attacks on ResNet variants have limited success in reconstructing the original images. In contrast, the attacks on Transformer models (Swin-T and Swin-S) yield significantly better reconstruction results.



These findings highlight the higher vulnerability of Transformers to gradient inversion attacks compared to CNNs. This raises questions about specific architectural features in Transformers that contribute to their increased vulnerability to privacy attacks. We further analyze the vulnerability of architectural features in Section 5.

(a) CIFAR10 with 3000 iterations.

(b) CIFAR10 with different iteration numbers (i.e. 1, 50, 100, 500, 1000, 1500, 2000, 2500, 3000).

(c) ImageNet1K with 3000 iterations.

5 Which Architectural Features Can Lead to Higher Privacy Leakage?

In this section, we answer the fourth research question (**RQ4**). We delve into analyzing architectural features that can potentially lead to privacy leakage. Through a comprehensive analysis, we first examine the impact of partitioning a transformer model on privacy vulnerabilities. Then, we investigate the influence of various micro designs on model privacy and conduct an ablation study on these micro designs.

5.1 Segmenting a Transformer Model to Analyze the Privacy Leakage

One of the key distinctions between a CNN and a Transformer lies in the design of their respective blocks. In this section, we focus on segmenting a Transformer-based model and assessing the potential influence of specific layers on privacy leakage. As there are only prediction results and model representations from membership inference attacks and attribute inference attacks, it is difficult to evaluate some specific layers using these attacks. However, gradient inversion attacks offer a more precise means of evaluation, as they require a comprehensive list of gradients from each layer of the victim model.

In our analysis, we employ ViT-B as the victim model. This is because ViT models are one of the first Transformers in computer vision. Additionally, ViT models incorporate several common modules shared across various Transformer architectures. We utilize gradient inversion attacks as our chosen attack method. Rather than supplying all the gradients to the attacks, we selectively provide specific gradients for evaluation purposes. The architecture of a Vision Transformer (an example of ViT-B) is depicted in Figure 6. To facilitate our assessment, we divide the model into five distinct modules based on their layer designs. Subsequently, we evaluate the influence of gradients obtained from each module individually.

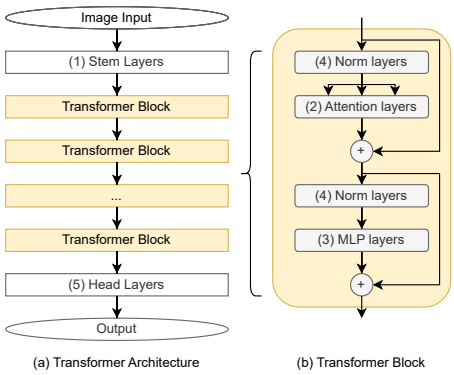

Figure 6: An illustration of a Vision Transformer architecture and the modules we focus on evaluating. Numbers (1) - (5) denote the modules we evaluate in gradient inversion attacks. (a): The whole model architecture. (b): Detailed architecture of each Transformer block.

Table 6: The performance of gradient inversion attacks when segmenting ViT-B to make a selection of gradients.

Layers	Num of layers	Params	MSE ↓	PSNR ↑
All	152	85.65M	0.0007 ± 0.0003	43.70 ± 1.84
Stem	4	0.59M	0.0000 ± 0.0000	67.43 ± 5.03
Attention	48	28.34M	0.0020 ± 0.0009	39.61 ± 2.76
MLP	48	56.66M	0.0036 ± 0.0016	36.98 ± 2.59
Norm	48	0.05M	0.0040 ± 0.0018	36.57 ± 2.56
Head	4	0.01M	0.2776 ± 0.2312	19.01 ± 3.89

If the attack using gradients from Module A yields a higher attack accuracy compared to the attack using gradients from Module B, it suggests that Module A is more likely to reveal more information about the data samples than Module B.

- Module 1: Stem layers. This module receives the model's input and has patch embedding and position embedding layers.
- Module 2: Attention layers. They are in the Transformer block, and this module is the main reason why Transformers are different from CNNs.
- Module 3: MLP layers. They are also in the Transformer block.
- Module 4: Norm layers. They are located right before the attention layers and MLP layers. LayerNorm is often used as Norm layers in Transformers.
- Module 5: Head layers. They are the last few layers for producing the output of the model. A few fully connected layers could be used as head layers.

Table 6 presents the reconstruction results of gradient inversion attacks when only gradients from selected layers are utilized in the attacks. The "All" layers represent the default attack scenario, where gradients from all layers are employed. The stem layers contain the patch embedding and position embedding processes. These layers exhibit minimal changes in the output compared to the original image sample. As the stem layers comprise only four layers, they can be relatively easier to attack compared to other types of layers. Consequently, the attacks on the stem layers demonstrate excellent performance, and we will further assess stem layers in the next subsection.

Among the attacks conducted with the remaining selected layers, the attack that demonstrates the best performance is the one utilizing "attention layers." This attack achieves an MSE of 0.0020 and a PSNR of 39.61. These results indicate that the attention layers are more susceptible to attacks, suggesting that they potentially leak more information about the data samples.

Table 7: Attack performance on ConvNeXt-T compared with ResNet-50 and Swin-T. NN MIA for Network-based membership inference, AIA for attribute inference, and GIA for gradient inversion.

		ResNet-50	ConvNeXt-T	Swin-T
NN MIA	Attack acc ↑	0.6385 ± 0.0078	0.7471 ± 0.0052	0.6904 ± 0.0052
AIA	Attack acc ↑	0.6854 ± 0.0015	0.7203 ± 0.0020	0.7312 ± 0.0014
	Macro F1 ↑	0.3753 ± 0.0012	0.5469 ± 0.0011	0.5530 ± 0.0019
GIA	MSE ↓	1.5096 ± 0.5538	0.0177 ± 0.0171	0.0069 ± 0.0071
	PSNR ↑	10.58 ± 1.87	31.88 ± 5.04	36.24 ± 5.21
	LPIPS ↓	0.1624 ± 0.0613	0.0032 ± 0.0055	0.0012 ± 0.0016
	SSIM ↑	0.0896 ± 0.0544	0.9666 ± 0.0451	0.9892 ± 0.0118

5.2 Impact of Other Micro Designs on Privacy

In the previous subsection, we established that attention layers within Transformers can contribute to privacy leakage. However, it is important to recognize that other micro designs within Transformers may also impact privacy vulnerabilities. One example is ConvNeXt [46], a convolutional neural network that incorporates multiple schemes from Transformers, similar to the Swin Transformer. ConvNeXt-T, ResNet-50, and Swin-T all share a similar parameter size, with ConvNeXt-T having approximately 27.83 million parameters. This allows for a direct comparison of the attack performance between ConvNeXt-T and the other two models. When ConvNeXt-T is tested on CIFAR10 using the same attack settings, it achieves a task accuracy of 0.8258. This indicates that we can compare the attack performance of ConvNeXt-T with ResNet-50 and Swin-T. The results presented in Table 7 further confirm the high attack performance on ConvNeXt-T. These findings suggest that ConvNeXt-T and Swin-T exhibit vulnerability to various attacks at a similar level.

The difference between ConvNeXt and the Swin Transformer lies in the attention module. This allows us to explore and investigate the privacy implications of various micro designs in model architectures beyond just the attention layers. By studying the impact of different micro designs, we can gain deeper insights into the specific architectural features that may pose privacy risks.

We continue with utilizing gradient inversion attacks as a tool for further examination. Following the design process outlined in [46], we have made several adjustments based on our own analysis. Since ConvNeXt is constructed incrementally from ResNet, we meticulously scrutinized each model architecture to investigate the steps that contribute most significantly to privacy leakage. We focus on ResNet-50 and ConvNeXt-T models and conduct tests on a total of 14 model architectures using randomly selected samples from CIFAR10.

The analysis involves a 14-step process, where we begin by modifying the overall architecture (Steps 1 to 4) based on ResNet-50. Subsequently, we align the bottleneck design (Steps 5 to 7) and refine the stem layer design in Step 8. Finally, we align the micro designs (Steps 9 to 14) to achieve ConvNeXt-T. This 14-step process, from macro to micro levels, as outlined in [46], has been established as an optimal procedure for designing ConvNeXt. Leveraging this proven methodology, we utilize it to analyze the impact on privacy. By identifying the critical steps that contribute to privacy leakage, we can assess the influence of micro designs on the privacy of model architectures. This analysis provides valuable insights into understanding the specific stages or modifications that may pose risks to privacy. The 14 steps are outlined below:

1. **ResNet-50:** We begin our process with this model.
2. **Changing channel dimensions:** Each stage in ResNet-50 uses different channel dimensions (i.e., $(64, 128, 256, 512)$). To align with ConvNeXt-T, we modify these dimensions to $(96, 192, 384, 768)$.
3. **Changing the stage compute ratio:** ResNet employs a multi-stage design that modifies channel dimensions. ResNet-50 has a stage compute ratio of $(3, 4, 6, 3)$, while ConvNeXt and Swin Transformers adopt $(3, 3, 9, 3)$. We follow this adjustment in this step.
4. **Applying "Patchify":** Vision transformers process input images by sliding them into patches. Here, we replace the stem convolutional layers with a kernel size of (4×4) and a stride of 4.
5. **Applying "ResNeXtify":** ResNeXt [79] introduced grouped convolution, reducing parameter size while maintaining performance. We utilize depth-wise convolution, which employs the same number of groups and channels.
6. **Using the inverted bottleneck:** The inverted bottleneck design is widely employed in models like MobileNet, ConvNeXt, and Swin Transformers. We incorporate this step into our process.
7. **Enlarging kernel sizes:** To align the parameters with ConvNeXt, we adopt a larger kernel size of (7×7) instead of (3×3).
8. **Forming the new stem layers:** In this step, we remove the activation and maxpool layers, originally part of ResNet.
9. **Changing ReLU to GELU:** The Gaussian Error Linear Unit (GELU) [29] is a variant of ReLU commonly used in Transformers. We introduce this change to the model.
10. **Removing some activation layers:** Transformer blocks typically have fewer activation layers. Here, we retain only one activation layer within the block.
11. **Removing some normalization layers:** We reduce the number of BatchNorm (BN) layers within the block to one.
12. **Changing BN to LN:** Inspired by the prevalent use of LayerNorm (LN) layers [3] in Transformers, we replace the BN layers in our model with LN layers. We also enable bias parameters for all convolutional layers in this step.
13. **Separating downsampling layers:** We move the downsampling layers between stages, introducing an LN layer to ensure stability during training.
14. **Final touches to reach ConvNeXt-T:** We incorporate Stochastic Depth [32] and Layer Scale [72] in the final stage to complete the ConvNeXt-T model.

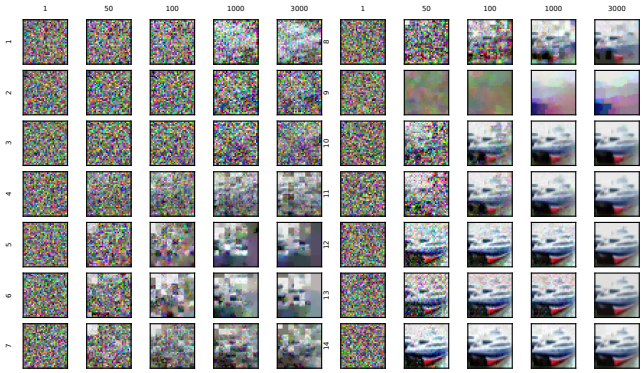

Figure 7: The performance of gradient inversion attacks on each architecture changing from ResNet-50 to ConvNeXt-T with several selected iterations (i.e., 1, 50, 100, 1000, 3000). Model architectures from 14 steps are shown.

Please refer to [86] for more detailed architecture specifications.

Figure 7 and Table 8 show the performance of gradient inversion attacks on each model architecture. The 14-step changes from macro to micro levels exhibit fluctuations but generally show a trend of improved attack performance.

Figure 7 provides qualitative results of the attacks. During the initial stages (Steps 1 to 3), the attacks struggle to reconstruct proper images. In the middle stages, some information emerges in the reconstruction results, but to a limited extent. The reconstruction results improve in the later stages (After Step 10). At last, using ConvNeXt-T, which is step 14, the attacks achieve a good attack performance.

Table 8: The results of gradient inversion attacks on model architectures from 14 steps. Some significant changes in results are marked in bold.

Steps	Task acc ↑	MSE ↓	PSNR ↑	LPIPS ↓	**SSIM ↑**
1. ResNet-50	0.8220 ± 0.0039	1.5096 ± 0.5538	10.58 ± 1.87	0.1624 ± 0.0613	0.0896 ± 0.0544
2. Channel dim	0.8240 ± 0.0072	1.4706 ± 0.5710	10.74 ± 1.97	0.1724 ± 0.0616	0.0826 ± 0.0405
3. Stage ratio	0.8282 ± 0.0040	1.5286 ± 0.5246	10.56 ± 2.05	0.1834 ± 0.0581	0.0731 ± 0.0613

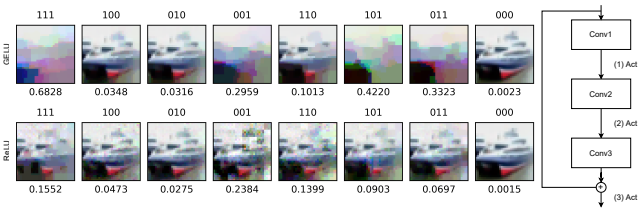
14. ConvNeXt	0.8523 ± 0.0064	0.0177 ± 0.0171	31.88 ± 5.04	0.0032 ± 0.0055	0.9666 ± 0.0451



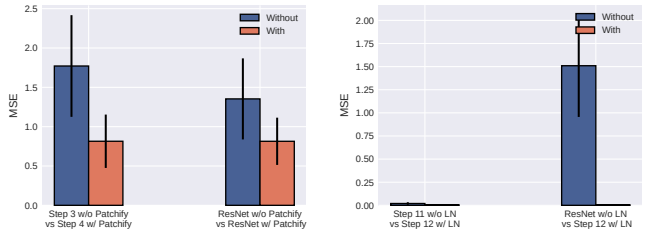


Figure 8: The performance of gradient inversion attacks on models with different positions of activation layers. The position of three activation layers is illustrated on the right, with two between convolutional layers and one after the addition operation. The three digits on the top of the subfigures show whether the activation layer on this position is added or not. The bottom of each subfigure provides MSE values for the attack on this model (i.e., models with GELU or ReLU).

(a) Patchify (b) LN

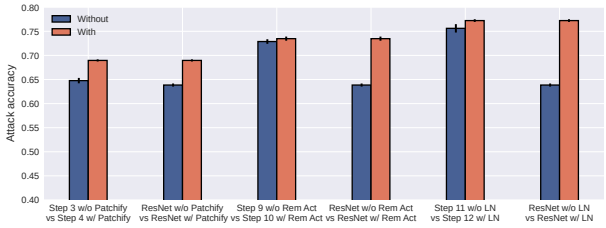

Figure 9: The performance of gradient inversion attacks on model architectures with or without some micro designs.

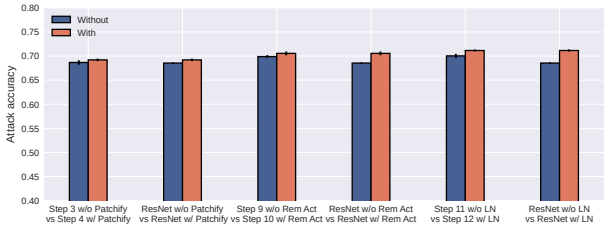
Table 8 presents more information on gradient inversion attacks, highlighting their performance in various architectural changes. Several steps exhibit significant changes compared to other steps. We define a step as a significant change when a metric notably decreases or increases. To illustrate, we consider the MSE metric, which we define a step as a significant change if it experiences a reduction exceeding 50%. Our analysis reveals three significant increases in attack performance, each correlated with specific architectural changes: The first one occurs when applying "Patchify" to stem layers; The second one occurs with the removal of some activation layers; The third one happens when changing BN to LN. These findings underscore the pivotal role these specific architectural changes play in determining the model's vulnerability to privacy attacks.



5.3 Ablation Study on Micro Designs

Ablation study on the design of activation layers. One of the differences between a Transformer block and a ResNet block is that a Transformer block has fewer activation layers. Leaving fewer activation layers in the model boosts the attack performance. As illustrated in Figure 8, when different activation layers are removed, there is a noticeable improvement in the attack performance. Particularly, the removal of the third activation layer, located after the skip connection of the ResNet block, results in a significant enhancement in attack accuracy. This observation suggests that this activation layer introduces a non-linear process that reduces the amount of information available for the attack, thus making it harder to reconstruct the original input. By removing this layer, the attack performance is improved. The analysis further highlights that changing ReLU to GELU results in a marginal reduction in attack performance. This is attributed to the fact that GELU is a smoother approximation of ReLU, which strengthens the model's robustness and generalization [4]. Using GELU makes the adversary extract less information from data samples, consequently decreasing their attack efficacy. In sum, the most significant enhancement in attack performance occurs when all activation layers are removed from the model architecture.

Ablation study on the design of stem layers and LN layers. The additional analysis presented in Figure 9 highlights two more features that appear to have an impact on model privacy leakage. Firstly, Figure 9a demonstrates that the utilization of "Patchify" reduces reconstruction MSE results. As

(a) Membership inference

(b) Attribute inference

Figure 10: The performance of privacy attacks on model architectures with or without some features.

this process involves modifications to the stem layers, we believe that these stem layers are crucial for privacy attacks. Secondly, Figure 9b illustrates that changing BN to LN results in improved reconstruction results. This suggests that incorporating LN also contributes to the model's privacy leakage. These findings emphasize the significance of stem layers and LN layers on model privacy leakage.

Ablation study on micro designs for membership inference attacks and attribute inference attacks. Figure 10 shows the impact of three micro designs on more attacks. Just like previous studies, adding these designs can also increase privacy leakage in these two attacks.

In summary, attention modules, as well as the design of activation layers, stem layers, and LN layers, are the key architectural features that lead to more privacy leakage. We provide more discussions in Section 6.

6 Discussion

In the previous sections, we discovered that four design components in Transformers could result in privacy leakage: attention modules, activation layers, stem layers, and LN layers. In this section, we would like to provide a more in-depth discussion of these modules.

6.1 The Impact of Attention Modules

The receptive field of a model refers to the information received within a specified range by a neuron in a model layer. In a fully connected neural network, each neuron receives input from the elements of the entire input sample. Due to the convolution operation, the neuron in a convolutional network receives input limited to its receptive field. The range of the receptive field is defined by the convolution templates in CNNs. This design allows CNNs to capture local patterns in the input data efficiently. The receptive field has a theoretical limit. Some researchers have demonstrated that the effective receptive field (i.e., the receptive field's effective area) is smaller than the theoretical receptive field [50]. From a privacy perspective, a CNN model could only reveal part of sensitive information from the input sample due to the design of localized convolution templates.

Transformers employ the multi-head self-attention mechanism, also known as attention modules. The input sample is taken as a sequence of flattened 2D patches. The attention module receives the input sequence and generates its representation of the sequence by mapping the query and the key-value pairs to the output. Transformers tend to have much larger receptive fields than CNNs due to the fact that their attention module is computed with the entire input sequence [16,74]. In terms of privacy, a Transformer model is able to extract more sensitive information than a CNN model because of its wide-angle receptive field. Hence, Transformers are more prone to attacks than CNNs, as demonstrated by our evaluation based on three popular privacy attacks.

6.2 The Impact of Micro Designs

There are micro-design components with the potential to leak sensitive data from input samples. Activation layers such as ReLU and GELU add a layer of complexity to the model by making it a non-linear function. Removing some activation layers simplifies the logic of attacks. Stem layers receive an input sample and perform some preliminary processing. As the representation after the stem layers remains similar to the original input image, there is a high possibility of extracting private information because of the design of the stem layers. Changing BN to LN is also likely to aid the attack process and allow the adversary to achieve higher attack performance.

6.3 The Impact of Overfitting

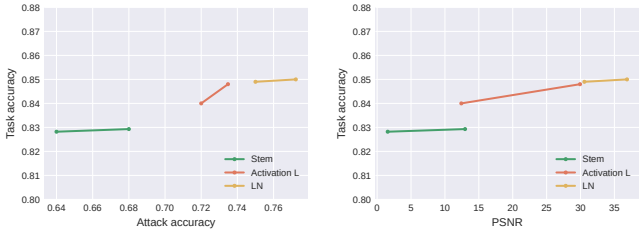
Previous work claimed that privacy attacks are caused mainly by the undesirable overfitting issue in deep learning models [44, 62]. Overfitting normally occurs when a model performs well on the training data, but poorly on the validation data. The overfitting issue tends to become severe on an over-trained model with a large number of parameters. Deep learning models are exposed to privacy threats due to the overfitting effect. In our work, we find that model architectures have impacts on the performance of privacy attacks, which can *not* be attributed solely to the overfitting effect. Indeed, our experiments validate that the variation in performance is due to the difference in model architectures. For models with the same level of parameter sizes, Transformers tend to be more vulnerable to privacy attacks than CNNs. More

importantly, for models with the same overfitting level, our conclusion still holds that Transformers are more vulnerable to privacy attacks than CNNs. We have then identified some architectural features that could be responsible for privacy leakage.

6.4 Potential (Incorrect) Explanations for the Vulnerability of Different Models Against Privacy Attacks

Here, we explore several potential explanations for our experimental results and shed more insights on our conclusion.

- The attacks on Transformers are more effective than those on CNNs. Is it due to random noise? To dismiss this concern, we have conducted multiple runs for each experiment setting and calculated the mean and standard deviation scores for our results. In total, We have done around 100 different experiment settings, involving 1400 experiments, 1700 training models, and 1200 training hours, which averages out the impact of random noise.
- Is it due to the overfitting of the victim models? To account for this, we meticulously compare the attacks on CNNs and Transformers when their victim models are trained on the same level of overfitting. By doing so, we minimize the factor of overfitting for a fair assessment.
- Is it due to the immature training of the victim models? In order to conduct our experiments, it was necessary to split the dataset into multiple subsets for both victim and shadow models. Consequently, it is reasonable to expect relatively low accuracy on the victim models for CIFAR10, CIFAR100, and CelebA (compared to the models trained on a full dataset). This aligns with the findings of the literature on privacy attacks, which have reported similar results [7, 27, 44].
- Is it due to other training factors? We ensure that the training recipes for each victim model remain consistent across all comparisons. Consequently, we can confidently exclude other training factors from the comparison study when drawing our conclusion.



After eliminating these potential explanations, we believe that our experimental results should be best explained by several architectural features mentioned in Section 5. Please see Appendix B for more theoretical discussions.

7 How to Exploit the Privacy Impact of Model Components?

7.1 Modifying Model Components as a Defense Mechanism

Based on our discoveries in previous sections, we propose to explore the modification of model components as a defense mechanism against privacy attacks. We aim to achieve a trade-off between utility and privacy. In Figure 11, we demonstrate the influence of certain micro-design changes on the efficacy of privacy attacks. Notably, we observe that the task accuracy is minimally impacted in each test, indicating that the proposed defense measures do not significantly compromise the model's overall performance. However, we can observe a decreased effectiveness of membership inference attacks and gradient inversion attacks when these model components are not applied.

These findings suggest that the proposed micro-design modifications can serve as effective countermeasures against privacy attacks, while the task accuracy remains almost intact.

(a) Membership inference (b) Gradient inversion

Figure 11: The impact of the performance of privacy attacks when model components change. In each line, the left and right points represent the results without and with the micro design modifications, respectively.

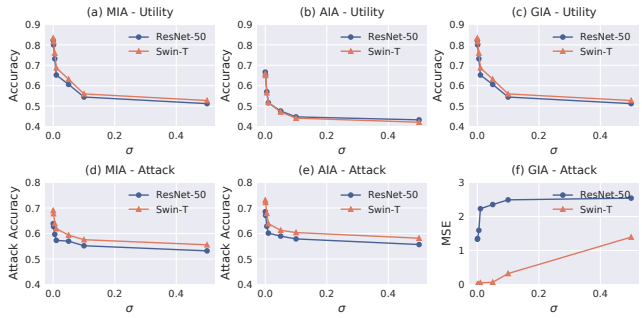


Figure 12: The performance of privacy attacks when DPSGD is applied. The utility performance of victim models and the attack performances are given when various DP noises are given.

7.2 Adding Perturbations as a Defense Mechanism

The privacy leakage issue observed in Transformers highlights the need for an enhanced privacy treatment compared to CNNs. Specifically, when employing perturbation as a defense mechanism, such as incorporating differential privacy noises into the model parameters, it is better to increase the level of noise specifically for Transformers and Transformer-

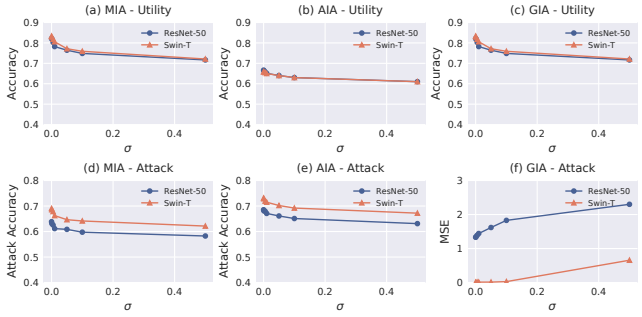

Figure 13: The performance of privacy attacks when DPSGD is applied in stem layers. The utility performance of victim models and the attack performances are given when various DP noises are given.

like models. Figure 12 illustrates the outcomes of three privacy attacks when DPSGD [1] is applied. As the differential privacy noise increases, a noticeable decline in the utility performance of victim models is observed (depicted in subfigures (a) to (c)). Concurrently, subfigures (d) to (f) reveal diminishing attack performances, with Transformers (Swin-T) consistently exhibiting superior attack performance at equivalent noise levels. From a defensive standpoint, adding more noise to Transformers is recommended.

Another approach to consider is a layer-wise perturbation defense mechanism, where noises are added to selected layers only. In this scenario, it would be interesting to introduce additional noises to the layers that are more susceptible to privacy leakages, such as activation layers, stem layers, LN layers, and attention modules. Paying special attention to these "privacy-leakage" layers could also achieve satisfactory privacy protection. Figure 13 demonstrates the impact of privacy attacks when DPSGD is applied to stem layers. As the differential privacy noise escalates, it influences both utility and attack performance, demonstrating the efficacy of adding noises to targeted layers.

8 Conclusion

In this study, we pioneer the exploration of privacy risks on model architectures, especially CNNs and Transformers. We have conducted a comparison of three prominent privacy attacks, i.e., membership inference attacks, attribute inference attacks, and gradient inversion attacks. We discover that Transformers tend to be more vulnerable to privacy attacks than CNNs. As a result, many Transformers-inspired CNN designs, such as ConvNeXt, are also susceptible to privacy threats. A number of Transformers' features, including the design of activation layers, the design of stem layers, the design of LN layers, and the attention modules, are likely to incur high privacy risks.

It is still challenging to establish accurate and theoretical explanations for why certain architectural features are critical to privacy preservation. We believe that these analyses require further experimental campaigns, and we intend to study this matter in our future work.

Acknowledgments

We thank all anonymous reviewers and our shepherd for their constructive comments. This work is funded in part by ARC Discovery Grant (DP230100246) and ARC Linkage Grant (LP220200808).

unchanged that Transformers exhibit higher attack performance.

B More Theoretical Discussion

In Section 6, we offer general discussions on the privacy impact of four components in Transformers. In this section, we delve deeper into more theoretical discussions.

B.1 The Impact of Attention Modules

In Sections 5.1 and 6.1, we show that the utilization of attention modules makes Transformers more susceptible to privacy leakage than CNNs. This susceptibility is attributed to the larger receptive field of attention modules, contributing to increased model memorization and, subsequently, heightened privacy leakage. Let us explore this theoretical framework step by step:

Receptive Field. Given a neural network with n layers, the output of the i-th layer ($i \in \{1,...,n\}$) is the feature map f_i. We have the input image as f_1 and the final output feature map as f_n. We define $\mathcal{R}_i$ as the receptive field size of feature map f_i. In other words, $\mathcal{R}_i$ is related to the process of the i-th layer. The receptive field $\mathcal{R}_i$ can be defined as

$$\mathcal{R}_i = \zeta(\mathcal{R}_{i+1}, \alpha_1, \alpha_2, ..., \alpha_n), \tag{1}$$

where $\alpha_1, \alpha_2, ..., \alpha_n$ are calculation factors in $\mathcal{R}_{i+1}$, and ζ is the calculation process of $\mathcal{R}_{i+1}$.

In a CNN model, the receptive field of a neuron represents the convolution-computation region in the input space that influences the output of that neuron. It signifies the area of the input data to which the neuron reacts. According to [2], the receptive field in a CNN is determined by:

$$\mathcal{R}_i^C = s_{i+1} \cdot \mathcal{R}_{i+1}^C + (k_{i+1} - s_{i+1}), \tag{2}$$

where k_i and s_i are the kernel size and the stride in a convolution layer. Based on Equations (1) and (2), we can define the receptive field size of a neuron in a CNN layer $\mathcal{R}^C$ as follows (we omit i for the simplicity of notations):

$$\mathcal{R}^C = \zeta(k, s), \tag{3}$$

where k and s are the kernel size and the stride.

The receptive field in a Transformer model, utilizing attention mechanisms, significantly differs from CNNs. In Transformers, attention layers calculate each position in the input sequence using query (q), key (k), and value (v) matrices. The output of the attention module is computed as follows:

$$\text{Attention}(q,k,v) = \text{SoftMax}(q \cdot k^T / \sqrt{d}) \cdot v, \tag{4}$$

where d is the scaling factor based on query and key. Based on Equations (1) and (4), we can define the size of the receptive field of an attention layer $\mathcal{R}^T$ as:

$$\mathcal{R}^T = \zeta(q,k,v). \tag{5}$$

As q, k, and v in a Transformer model are derived from the entire input sequence, $\mathcal{R}^T$ tends to be much larger. With Equations (3) and (5), we have:

$$\mathcal{R}^T > \mathcal{R}^C. \tag{6}$$

In summary, Transformers activate a larger receptive field of input data compared to CNNs, which is also supported by empirical research [57].

Model Memorization. The concept of model memorization lacks a formal definition in the research field. Informally, it can be characterized as a label ($\mathbf{y}$) memorization for a specific sample $\mathbf{x}$ if removing this $\mathbf{x}$ from the training set would change the performance of the model predicting $\mathbf{y}$ [8, 19]. Other research refers to it as memory capacity, assessing how much information a model can store in its parameters [6, 12, 58]. In either case, model memorization is intricately linked to how the model learns from input data. The relationship between the receptive field and model memorization can be formulated by:

$$\text{increase}(\mathcal{M}) \sim \text{increase}(\mathcal{R}), \tag{7}$$

where $\mathcal{R}$ denotes the receptive field and $\mathcal{M}$ denotes the model memorization. A larger receptive field allows the model to reap more information from the input data, and as Transformers inherently possess a larger receptive field, they exhibit an enhanced ability to absorb more information. With Equations (6) and (7), we have:

$$\mathcal{M}^T > \mathcal{M}^C, \tag{8}$$

where $\mathcal{M}^T$ is the model memorization in Transformers, and $\mathcal{M}^C$ is the model memorization in CNNs.

Privacy Leakage. Model memorization introduces potential privacy leakage. Normally, input data $\mathbf{x}$ is considered extractably memorized if an adversary can construct data that makes the model produce $\mathbf{x}$ [53]. The relationship between model memorization and privacy leakage can be expressed as:

$$\text{increase}(\mathcal{L}) \sim \text{increase}(\mathcal{M}), \tag{9}$$

where $\mathcal{M}$ is the model memorization and $\mathcal{L}$ denotes the privacy leakage. An increased capacity for the model to learn from input data correlates with a higher likelihood of privacy leakage. With Equations (8) and (9), we have:

$$\mathcal{L}^T > \mathcal{L}^C, \tag{10}$$

where $\mathcal{L}^T$ is the privacy leakage in Transformers, and $\mathcal{L}^C$ is the privacy leakage in CNNs. In summary, Transformers, employing attention modules and featuring a larger receptive field, inherently enhance model memorization, thereby contributing to increased privacy leakage.

B.2 The Impact of the Design of Activation Layers

In Sections 5.2, 5.3 and 6.2, we show that removing activation layers could make the model more vulnerable to privacy attacks. Here we delve into more theoretical discussions.

ReLU vs GELU. ReLU and GELU are two widely adopted activation layers in CNNs and Transformers, defined as follows:

$$\text{ReLU}(\mathbf{x}) = \max(0, \mathbf{x}), \tag{11}$$

$$\text{GELU}(\mathbf{x}) = 0.5\mathbf{x}(1 + \tanh(\sqrt{\frac{2}{\pi}}(\mathbf{x} + 0.044715\mathbf{x}^3))), \tag{12}$$

where $\mathbf{x}$ is the input of the activation layer.

Both ReLU and GELU introduce non-linearity into the model, enabling the learning of complex and hierarchical representations from input data. However, non-linearity can also bring challenges during model training, such as the vanishing gradient and exploding gradient problems, making it difficult to update model weights and biases [39]. The ReLU unit may suppress half of its inputs by outputting zero values, selectively passing information to the next layer [50]. Moreover, the non-differentiability of ReLU at $\mathbf{x} = 0$ poses issues in gradient-based optimization. The GELU unit, designed as a smooth approximation to ReLU, preserves the non-linearity of the model [39]. The adoption of GELU can enhance the model's robustness and generalization, making the adversary extract less information from data samples and decrease the attack performance [4]. This aligns with our experimental results presented in Step 9 of Table 8 and Figure 8.

The removal of activation layers. As using GELU does not help with improving the privacy attack performance, our analysis shows that removing activation layers and leaving fewer activation layers is the key to increasing the model's vulnerability to privacy attacks (shown in Figure 8). This is because retaining fewer activation layers allows the model to preserve more information learned from the training data, resulting in increased privacy leakage compared to models with a greater number of activation layers, which can be written as $\mathcal{L}^{\text{fewer act}} > \mathcal{L}^{\text{more act}}$.

B.3 The Impact of the Design of Stem Layers

In Sections 5.2, 5.3 and 6.2, we illustrate that the design of stem layers (the "Patchify" step) can result in increased privacy leakage. Here, we provide more theoretical discussions.

The stem layers in a standard ResNet have a 7×7 convolution layer with stride 2. The "Patchify" strategy introduced by Transformers uses a 4×4 convolution layer with stride 4, which is actually a non-overlapping convolution process to make patches of the input data. Some research [17, 23] theoretically show that non-overlapping patches can easily learn information from input data, comparable to the capabilities of overlapping patches. Empirical studies [78] provide further support for the efficacy of this kind of stem layer design with convolutional layers. This design is shown to enhance optimization stability and improve the adversary's attack performance, which is demonstrated in our experimental results in Sections 5.2 and 5.3. We can formulate this as $\mathcal{L}^{\text{patchify stem}} > \mathcal{L}^{\text{resnet stem}}$.

B.4 The Impact of the Design of LN Layers

In Sections 5.2, 5.3 and 6.2, we show that changing BatchNorm to LayerNorm can contribute to increased privacy leakage. Here, we provide more theoretical discussions on the implications of this design choice.

Let $\mathbf{x} = (x_1, x_2, ..., x_H)$ and $\mathbf{y}$ be the input of size H and output of a normalization layer. LayerNorm re-centers and re-scales the input x as

$$\mathbf{y} = \mathbf{g} \odot \frac{\mathbf{x} - \mu}{\sigma} + \mathbf{b}, \mu = \frac{1}{H}\sum_{i=1}^{H} x_i, \sigma = \sqrt{\frac{1}{H}\sum_{i=1}^{H}(x_i - \mu)^2}, \tag{13}$$

where $\odot$ denotes a dot production operation, μ and σ are the mean and standard deviation of $\mathbf{x}$, bias $\mathbf{b}$ and gain $\mathbf{g}$ are learnable parameters [3, 80].

The bias and gain are designed for affine transformation on normalized vectors to enhance performance. However, these parameters are trained based on the training data and may not adequately consider the input distributions of testing data. This increases the risk of overfitting when applying LayerNorm in the model [80]. The overfitting of the model would lead to more privacy leakage of the training data. As a result, models with LayerNorm could potentially expose sensitive information during privacy attacks, which can be written as $\mathcal{L}^{\text{ln layer}} > \mathcal{L}^{\text{bn layer}}$.

Reconstructing training data from document understanding models

Jérémie Dentan[1, 2], Arnaud Paran[1], and Aymen Shabou[1]

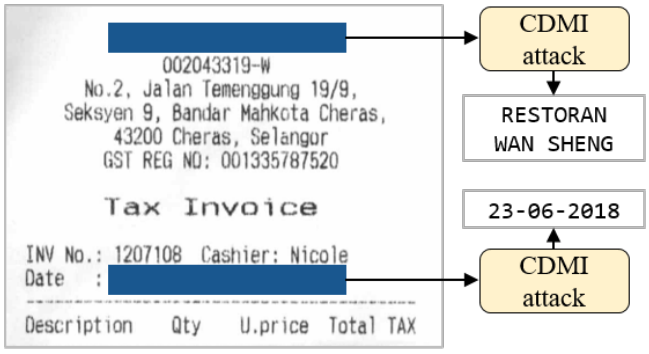
[2]École Polytechnique, IP Paris

Abstract

Document understanding models are increasingly employed by companies to supplant humans in processing sensitive documents, such as invoices, tax notices, or even ID cards. However, the robustness of such models to privacy attacks remains vastly unexplored.



This paper presents CDMI, the first reconstruction attack designed to extract sensitive fields from the training data of these models. We attack LayoutLM and BROS architectures, demonstrating that an adversary can perfectly reconstruct up to 4.1% of the fields of the documents used for fine-tuning, including some names, dates, and invoice amounts up to six-digit numbers. When our reconstruction attack is combined with a membership inference attack, our attack accuracy escalates to 22.5%.

In addition, we introduce two new end-to-end metrics and evaluate our approach under various conditions: unimodal or bimodal data, LayoutLM or BROS backbones, four fine-tuning tasks, and two public datasets (FUNSD and SROIE). We also investigate the interplay between overfitting, predictive performance, and susceptibility to our attack. We conclude with a discussion on possible defenses against our attack and potential future research directions to construct robust document understanding models.

1 Introduction

Document understanding models aim at processing visually rich documents, such as handwritten forms, tax invoices or scanned tables, where information is encoded both in textual content and layout. Consequently, most document understanding models adapt a language model architecture to make it layout-aware [25, 32, 34, 62, 80, 81]. These models have countless real-world applications and are employed by numerous companies for tasks extending from key information extraction [34, 51, 60] to document classification [29, 57], and question answering [53, 77].

Moreover, a range of neural network architectures have been found vulnerable to membership inference or reconstruction attacks in multiple domains: computer vision models [23, 24, 42, 44, 76, 87], language models [8, 9, 46, 47, 50, 55, 68, 86], graph models [58, 88], and diffusion models [7], among the most popular. Those attacks enable an adversary to obtain information on the training data, posing a serious threat to confidentiality (see section 2.2 and [67, 69]).

A document from the training set

Figure 1: A document (licensed CC BY 4.0 DEED by Huang et al. [35]) where two fields are perfectly reconstructed by CDMI. A model with LayoutLM architecture [81] is trained on SROIE dataset [35]. Then, when the date or the company is scrubbed, the adversary is able to reconstruct it.

Surprisingly, despite their resemblance to language models and vision models, we have not discovered any existing studies on the robustness of document understanding models to such privacy attacks (at the time of writing, in October 2023). The most related research paper we found in this domain is by Meehan et al. [54]. However, they define a document as a collection of sentences, excluding any layout information. Thus, the model they target (Sentence-BERT [64]) differs significantly from state-of-the-art document understanding models. The reconstruction attack we present in this paper is the first to target some of the most commonly used layout-aware models and treat documents as multimodal data.

1.1 Contributions

Our main contributions are as follows:

- We develop the first reconstruction attack that targets layout-aware document understanding models: a *white-box* attack named CDMI (Combinatorial Document Model Inversion), designed to target unimodal or bimodal models. We employ CDMI to reconstruct fields from the fine-tuning datasets of our models, although it is also readily adaptable for pre-training datasets.
- We combine CDMI with existing membership inference attacks, resulting in an end-to-end attack where the adversary extracts arbitrary fields in the training dataset.
- We introduce two new end-to-end metrics to evaluate simultaneously the reconstruction and the membership inference attack. Our intention is to evaluate the full extent of potential harm that an adversary could cause.
- We successfully evaluated our attack in various settings, making it one of the few attacks capable of reconstructing non-synthetic data from an encoder-only model. These settings include unimodal or bimodal models, with either LayoutLM v1 [81] or BROS [32] backbone, using four different training tasks, and two public fine-tuning datasets: FUNSD [40] and SROIE [35].
- We demonstrate that the success of our attack is not due to over-fitting or data duplication, and that memorization occurs early in the training pipeline. We also prove that both the layout and the visual modality contribute to memorization, proving that documents should be considered as a specific data type with dedicated attacks.

2 Background and related work

2.1 Document understanding models

A document processing pipeline aims at extracting meaningful information from raw document images such as scans, pictures, or screenshots. Deep learning-based pipelines usually include two main steps [71]:

- An Optical Character Recognition (OCR) is used to extract the textual content of the document: its output typically includes *words* and their associated *bounding boxes*, which denote the coordinates of the four points encompassing the word. Then, the words are fed to a *tokenizer*. It splits the words into *tokens*, which are smaller pieces of text that are part of a specific *vocabulary*.
- These tokens and their bounding boxes are processed by a *document understanding model*, which extracts specific information from them. A model is said to be *layout-aware* when it uses both the tokens and the layout information derived from the bounding boxes [77].

The architectures we target: LayoutLM v1 and BROS Recently, OCR-free pipelines were developed [10, 14, 27, 45]. However, our focus will be on deep learning models specifically designed to work with an OCR, given that OCR-free approaches are relatively new and rarely deployed in production. The category of OCR-based models includes recent architectures with state-of-the-art results such as LayoutLM v1 [81], LayoutLM v2 [80], LayoutLM v3 [34], BROS [32], LAMBERT [25], TILT [62], and DocFormer [4].

We decided to attack two different architectures: LayoutLM v1 and BROS, for multiple reasons. Firstly, both architectures demonstrate strong performance and are frequently used in real-world applications.[1] In addition, their pretrained weights are available under permissive licenses (in contrast to LayoutLM v3), making them particularly suitable for commercial applications. Thus, "LayoutLM" will implicitly refer to LayoutLM v1 in the following.

Transformer-based document encoders These architectures are transformer-based encoder-only models, akin to BERT [13]. They employ multiple layers of multi-headed Transformers [74] to embed each input token in a feature space of dimension $d = 768$. However, unlike BERT, these architectures use a 2-dimensional spatial encoding to consider the layout information provided by the bounding boxes.

In addition to the tokens and their bounding boxes, a document understanding model can exploit the raw images of the documents [32, 62, 81]. In the case of LayoutLM and BROS, visual features are generated by a computer vision model, and subsequently added to the textual embedding of each token using Region Of Interest alignment [30]. We will refer to these models as *bimodal*, in contrast to the simpler layout-aware models which we will refer to as *unimodal*.

Training objectives LayoutLM and BROS encoders are often used in a transfer learning setting. First, the encoders are *pre-trained* on a very large corpus of documents, the IIT-CDPI Test Collection 1.0 [49]. The main pre-training task is Masked Language Modeling (MLM), where approximately 15% of the tokens are masked, and the model is trained to reconstruct them. Afterwards, the model is *fine-tuned* on a specific task by keeping the pretrained backbone and replacing the last layers with a new classification head specifically designed for this task. Our attack will target these fine-tuned models.

We evaluated our attack against models fine-tuned on three common Key Information Extraction (KIE) tasks, which were previously employed by Hong et al. [32] to evaluate BROS:

- Entity Extraction with BIO tagging (EE-BIO): it aims at extracting some fields of the document by classifying its tokens as "Beginning", "Inside" or "Out" of an entity [3].

[1] As of October 2023, LayoutLM v1 had over 29M downloads: https://huggingface.co/api/models/microsoft/layoutlm-base-uncased?expand[]=downloadsAllTime

- Entity Extraction with SPADE tagging (EE-SPADE or EE-SPD): it also aims at extracting some fields using the SPADE tagging [36]. In a nutshell, the model is trained to identify the predecessor of each token in the entities of the document.
- Entity Linking (EL): it aims at establishing connections between the entities using their semantic relations. We also used SPADE tagging for this task [36].

In addition to those three tasks, we also attacked models that were fine-tuned on the same MLM task that is utilized during pre-training. This scenario does not correspond to a real-world setting; however we did this to compare the susceptibility of the KIE and the MLM tasks under the same conditions (transfer learning with the same fine-tuning dataset, etc.). All these tasks ultimately involve a token-level classification task, for which we used a cross-entropy loss.

2.2 Privacy attacks

In this section, we introduce privacy attacks and review the existing ones in the field of Natural Language Processing (NLP). Indeed, the architectures of language models are similar to those of document understanding models, for which such attacks have not yet been studied.

Taxonomy Various types of attacks target the confidentiality of models trained on sensitive data by exploiting unintended memorization of their training set. Following [50], we distinguish three levels of privacy attacks:

- *Extraction attacks*: the adversary has only access to the model, and seeks to extract as much data as feasible from the training set. In NLP, such attacks are studied in [8, 9, 46, 50, 68, 84, 86].
- *Reconstruction attacks*: the adversary has access to a model and a context such as the prefix of a sentence, or a document with a scrubbed field, and seeks to reconstruct the missing parts. In NLP, attacks of this kind include [19, 50, 54, 59].
- *Membership inference attacks* [69]: the adversary has access to data samples, and attempts to predict whether they are part of the model's training set or not. Formally, this is equivalent to a reconstruction attack with a finite list of candidates for the reconstruction. Notable examples of these attacks are [47, 52, 55, 66, 70].

In this paper, we focus on reconstruction attacks. We begin with a ground truth document, represented for now as a sequence of tokens d_g in a vocabulary $\mathcal{V}$. A field is scrubbed by replacing it with the special token `[MASK]` to form $\widetilde{d}_g$. Then, the adversary has access to $\widetilde{d}_g$ and optimizes equation 1 to reconstruct the scrubbed fields.

$$\underset{d \in \mathcal{V}^*}{\operatorname{argmax}} \; P_\theta(d \mid \widetilde{d}_g) \tag{1}$$

Here, P_θ denotes the likelihood of d being a good reconstruction of $\widetilde{d}_g$ given the model's weights θ. However, this probability is frequently either ill-defined or intractable. Hence, practical attacks necessitate the construction of a suitable proxy for P_θ (see [50] and sections 4.1 and 4.2).

Attacks against decoder-only models In the context of extraction and reconstruction attacks in NLP, a significant difference exists between decoder-only models and others [37, 82]. Decoder-only models, such as the ones of the GPT family, are trained in an auto-regressive way to generate the next token in a sequence given its prefix. They are well-designed to generate fluent content.

Existing attacks against such models directly use this generation ability to extract training data [8, 9, 46, 50, 84]. These attacks reconstruct data from left to right. At step t, using the previously reconstructed prefix sequence $\widetilde{s_g} = c_1 \dots c_{t-1}$, they attempt to reconstruct token c_t . As a result, if they directly replace P_θ by the probability distribution calculated by the model for the next token, equation 1 ends up being exactly the one the model is trained to solve:

$$\underset{c_t \in \mathcal{V}}{\operatorname{argmax}} \; P_\theta(c_t \mid c_1, \dots, c_{t-1}) \tag{2}$$

Attacks against encoder-only model Encoder-only models, such as LayoutLM or BROS, are not designed to compute a probability distribution over sentences. This makes it difficult for them to generate fluent content [26, 75]. This is a crucial difference, because this ability is needed to reconstruct plausible content in equation 1. However, various strategies have been proposed to attack encoder-only models in NLP:

- Zhang et al. [86] employ an auxiliary GPT-2 model [6] to generate content. They utilize the PPLM mechanism [12] to increase the likelihood of generating content from the training set of the BERT model they target [13].
- Lehman et al. [47] focus on small prompts in a clinical context, and conclude that their attack does not significantly expose the training data. Mireshghallah et al. [55] enhance their attack in a membership inference setting, adopting the energy-based interpretation of [26] instead of Gibbs sampling to compute text fragment likelihoods.
- Carlini et al. [8] assess their attack against T5 model [63]. However, they addressed a simpler scenario where it is not needed to generate fluent content: 15% of randomly chosen tokens are masked and need to be reconstructed.
- Song et al. [70] and Parikh et al. [59] formulate a continuous relaxation of equation 1 inspired from the work of Jang et al. [38] for its resolution.

- Mahloujifar et al. [52] target embedding models, exploiting specific properties of these models in their attack.
- Elmahdy et al. [19] focus on canary reconstruction and use an autoregressive proxy. They decode tokens from left to right, with the objective of minimizing the loss of the model. Elmahdy et al. [20] improves the approach of [19] by using a MLM head to select candidates before evaluating the loss of the target model.
- Meehan et al. [54] only focus on differential privacy [1, 16–18], demonstrating theoretical privacy bounds without implementing the attack to test these limits.

Thus, reconstructing training data from encoder-only models is a difficult task, and there is no standard method for it. To attack real-world document understanding models, we could not directly apply existing methods. Indeed, they either constituted membership inference attacks (which are less complex than reconstructions) [47, 55], were only evaluated on frequently repeated canaries [19, 20, 59], or were inapplicable to our scenario [8, 52, 54, 70].

We selected and combined promising ideas from various existing attack, improving and optimizing them for our scenario. We utilized an autoregressive proxy as in [19, 20], and leveraged an auxiliary generator to enhance the fluency of the reconstructions as in [20, 86]. We also developed a customized method for incorporating the loss of the target model, which we combined with existing membership inference metrics [9]. Finally, we integrated the visual modality in our attack to extract information memorized by the visual encoder. This led to our hybrid attack, CDMI, the first of its kind capable of reconstructing real documents.

Defense against privacy attacks According to [37], the main defense techniques in a centralized setting are:

- *Data sanitization* [5, 11, 65, 73]. It involves removing personal data from the training set. However, this technique is limited due to the context-dependent definition of personal data [5]. Deduplication, which consists in eliminating duplicate data, can also be useful as duplicated data is more likely to be memorized [43].
- *Differential Privacy (DP)* [1, 16–18]. This training paradigm adds noise to each gradient during the training phase up to a certain level, to safeguard every sample in the training set. However, the effectiveness of DP in genuine real-world settings is disputed [15, 72].
- *Regularization.* Although not necessary, overfitting facilitates the memorization of training data [9, 21, 83, 85]. Hence, some mechanisms involving regularization have been proposed [33, 56].
- *Post-processing.* Confidence masking and output filtering can be employed during post-processing [23, 61].

3 Threat model

In this section we introduce our *threat model*, which defines the assumptions we made for the development of our attack.

3.1 Adversarial capabilities and goals

We make two primary assumptions about the adversary's capabilities:

- *White box hypothesis.* The adversary is supposed to have white-box access to the model, meaning complete access to its architecture and weights. Concretely, our attack is gradient-free, but because it requires computing the token-level loss for a large number of inputs, it is impractical in standard black-box environments. This is why we classify it as a white-box attack.
- *Scrubbed data.* Given that we are developing a reconstruction attack, we assume the adversary has access to scrubbed data. In our context, this means that the adversary can access a document (token, bounding boxes, and the raw image) where a certain field has been masked (tokens replaced by `[MASK]`, and a white patch to replace the field in the image). This implies that the adversary knows the number of tokens in the target field. While this is a strong supposition, it is necessary to make our optimization in equation 1 tractable (see III.B in [50]). Moreover, this assumption is fairly realistic for documents in which the fields adhere to strict rules (e.g. IBANs, credit card number and expiration date, etc.).

We focus on an adversary whose goal is to reconstruct the textual modality of documents, regardless of whether the target model is unimodal or bimodal. Indeed, for real-world document understanding models, sensitive information is often encoded in the textual modality. For example, for identity theft, reconstructing the ID card number and expiration date is significantly more valuable than the general layout of the card, which is common knowledge.

More specifically, we distinguish two variants of our attack, a *one-shot* one and a *multi-shot* one, each with slightly different adversarial goals:

- *One-shot variant.* In this scenario, the adversary makes one reconstruction attempt per field in the datasets. Here, their objective is to maximise the similarity metrics between their reconstruction and the ground truth.
- *Multi-shot variant.* This setting is closer to a real-world scenario. The adversary makes multiple attempts against each field, and ultimately uses a membership inference metric to filter the most plausible reconstructions, as referenced in [9, 84]). The adversary has two objectives. First, to generate high-quality reconstructions. Second, to accurately retain the correct ones using the membership inference metric (see section 5.3).

3.2 The reconstruction game

Following [67, 79], we define the *reconstruction game*, that serves to formalize the threat model, the information the adversary can access, and what will be used for evaluation. It is an adaptation of the one in Lukas et al. [50]. In addition to the notations of table 1, we define:

- EXTRACT(d): extracts the list of fields of d that contain personal information.
- SCRUB$(d, f) \rightarrow \widetilde{d}, y$: scrubs a field f in a document d by replacing it by `[MASK]`, and returns its classification label y (which is public information).

Our multi-shot reconstruction game is presented in algorithm 1. Initially, a model is trained on a private dataset D (lines 2–3). Then, for each document in the dataset (line 6), and for each field in this document (line 7), the field is scrubbed and the adversary attempts n_a reconstructions (lines 8–12). The adversary has access to the ground truth number of tokens k (see section 3.1). They also know $\mathcal{D}$, $\mathcal{T}$, and n, which means they can train auxiliary models on the same distribution. Then, a Membership Inference (MI) metric is utilized to keep the best reconstruction attempt for each field (line 13). Subsequently, the MI metric is used to sort the fields by probability of successful reconstruction (line 16). Finally, we evaluate the attempts, examining both their similarity to their ground truth, and their order with respect to the MI metric computed at line 16 (see section 5.3).

The one-shot reconstruction game is very similar. Since there is only one attempt per scrubbed field, lines 9, 10, 12, 13 are removed. Furthermore, the order of the fields is not considered during evaluation, so line 16 is removed.

With these notations, we can refine equation 1 introduced earlier. At line 11, the adversary seeks to solve equation 3. We recall that the adversary only tries to reconstruct the textual modality of the fields, which is why the optimization

Notation	Description
$\mathcal{T}$	A stochastic training procedure
$\mathcal{A}$	A procedure denoting an adversary
$\mathcal{V}$	The vocabulary for the tokens
$I = \mathbb{R}^{3 \times d_i}$	The RGB space of documents' images
$D \sim \mathcal{D}^n$	Sample n docs from a distribution $\mathcal{D}$ on $\mathcal{V}^* \times I$
$d \in \mathcal{V}^* \times I$	A document (sequence of tok. + image)
$\widetilde{d} \in \mathcal{V}^* \times I$	A scrubbed document derived from d
$y \in \mathbb{R}^*$	A classification label for a document
$f \in \mathcal{V}^*$	A field of d containing personal info.
$\widetilde{f} \in \mathcal{V}^*$	A reconstruction attempt for f
$k = \lvert f \rvert$	The number of tokens in f

Table 1: Notations

Algorithm 1 The multi-shot reconstruction game

1: **experiment** RECON_M_SHOT$(\mathcal{D}, \mathcal{T}, \mathcal{A}, n)$
Sample docs and train a model
2: $D \sim \mathcal{D}^n$
3: $\theta \leftarrow \mathcal{T}(D)$
4: $F \leftarrow [\,]$
5: $\widetilde{F} \leftarrow [\,]$
n_a reconstruction attempts on each field
6: **for** $d \in D$ **do**
7: **for** $f \in$ EXTRACT(d) **do**
8: $\widetilde{d}, y \leftarrow$ SCRUB(d, f)
9: attempts $\leftarrow [\,]$
10: **for** $a \in [1, \ldots, n_a]$ **do**
11: $\widetilde{f} \leftarrow \mathcal{A}(\mathcal{T}, \mathcal{D}, n, \theta, \widetilde{d}, y, k)$
12: attempts $\leftarrow$ CONCAT(attempts, $[\,\widetilde{f}\,]$)
MI to keep one attempt per field
13: $\widetilde{f} \leftarrow$ MI_FILTER(attempts)
14: $F \leftarrow$ CONCAT$(F, [\,f\,])$
15: $\widetilde{F} \leftarrow$ CONCAT$(\widetilde{F}, [\,\widetilde{f}\,])$
MI to sort reconstructions by plausibility
16: $F, \widetilde{F} \leftarrow$ MI_SORT$(F, \widetilde{F})$
17: EVAL$(F, \widetilde{F})$

is over $\widetilde{f} \in \mathcal{V}^k$ and not over $\widetilde{f} \in \mathcal{V}^k \times I$ (see section 3.1 and the paragraph on visual modality in section 4.1).

$$\mathcal{A}(\mathcal{T}, \mathcal{D}, n, \theta, \widetilde{d}, y, k) = \underset{\widetilde{f} \in \mathcal{V}^k}{\operatorname{argmax}} \; P_\theta(\widetilde{f} \mid \widetilde{d}, y) \tag{3}$$

3.3 Ethical considerations

This paper presents an attack that specifically targets the privacy of document understanding models. This raises ethical considerations because such models are sometimes trained on private data and used in real-world settings.

First, we reduce ethical concerns by only attacking models trained on publicly-available data: LayoutLM v1 [81] and BROS [32] are both pre-trained on the public dataset IIT-CDIP Test Collection 1.0 [49]. Moreover, we fine-tune them on two other public datasets, FUNSD [40] and SROIE [35].

Moreover, our attack still necessitates a substantial amount of prior information to successfully reconstruct data. As for every reconstruction attack, this includes access to scrubbed data, an uncommon scenario. Consequently, while our approach may set the foundation for more efficient methods with less information, we argue that the advantages of disclosing it outweigh potential harm. Researchers and companies training document understanding models on private data must understand that robust attacks are very likely to exist in the future. Therefore, it is crucial they protect access to their trained models with the same stringency as their databases.

Finally, we believe that disclosing our attack is important to shed light on privacy attacks and ensure they are considered by institutional regulators. Currently, despite the development of attacks on numerous model types, the fact that trained models may leak personal information is frequently overlooked in data regulation texts such as RGPD and AI Act in European Union, APPI in Japan, CCPA in California, etc.

4 The CDMI reconstruction method

The section details the methodology employed for our reconstruction attack: CDMI (Combinatorial Document Model Inversion). Specifically, it elaborates on three aspects: the chosen proxy for P_θ in equation 3; how we optimize it; and the membership inference metric we used.

In summary, our attacks proceeds as follows. First, we approximate the probability distribution over the fields using an autoregressive proxy, meaning that tokens will be reconstructed from left to right within each field (see section 4.1). To reconstruct each token, we compute and optimize a token-level probability P_θ^{tok} (see section 4.2). For this, we employ a masked model trained on public data to select candidates. Next, we evaluate the loss of the target model for each candidate, using these computations to approximate P_θ^{tok}. Finally, we sample the reconstruction from this approximate distribution. We also present two variants of our attack: the one-shot one, and the multi-shot one, where the adversary attempts several reconstructions against each field and selects the best one using a membership inference metric (see section 4.3).

4.1 An autoregressive proxy

To solve equation 3, the adversary needs to choose a convenient proxy for P_θ, that should correctly represent the likelihood of a document being in the training set while being easy to optimize. Adapting the methodology of [19] in NLP, we employ an *autoregressive formulation*, meaning that scrubbed tokens are sequentially reconstructed from left to right.

Equation 4 presents this autoregressive proxy, with notations derived from table 1. We recall that k, the number of tokens in the target field, is known to the adversary (see section 3.1). This formula employs a token-level proxy P_θ^{tok}, that represents the probability that the selection of token $v_t \in \mathcal{V}$ at step t results in a good reconstruction.

$$P_\theta(\widetilde{f} \mid \widetilde{d}, y) \;=\; \prod_{t=1}^{k} P_\theta^{\text{tok}}(v_t \mid \widetilde{d}, y, v_1, \ldots, v_{t-1}) \qquad (4)$$

Although encoder-only models such as LayoutLM or BROS are not designed for such an autoregressive formulation [26, 75], we used this approximation for several reasons:

- This autoregressive modeling substantially decreases the size of the search space. Rather than $\mathcal{V}^k$, our optimization problem is divided into k sub-problems in $\mathcal{V}$.
- More complex methods require a significantly higher number of model calls [26]. Considering that our attack is already computation-intensive, our autoregressive proxy serves to maintain this number to a minimum.
- The left-to-right decoding is requisite for the SPADE [36] implementation we used. Indeed, each token is trained to point towards its predecessor, thereby making it significantly easier to decode if the predecessor has already been reconstructed.
- Using an autoregressive decoding enables us to use various heuristics derived from reconstruction attacks on decoder-only models [84].

As explained in section 2.1, our attack targets both unimodal (text + layout) and bimodal (text + layout + image) models. Nevertheless, the objective of the adversary is solely to reconstruct the textual data (see section 3.1). When attacking a bimodal model, we did the following:

- To scrub bimodal data, target tokens are replaced with `[MASK]` token, and a white patch masks the content of the field in the image.
- With our autoregressive proxy, we sequentially replace the target tokens with their reconstruction in the textual modality.
- The visual modality remains masked throughout the entire field reconstruction process. This means that the white patch masks all tokens, and remains unchanged even when the initial ones have already been reconstructed in the visual modality. Indeed, the adversary makes no attempt to reconstruct the visual modality (cf. section 3.1), even when attacking a bimodal model.

This is why our equations only optimize on $\mathcal{V}^k$. The information of the image I comes from the scrubbed document $\widetilde{d} \in \mathcal{V}^* \times I$.

4.2 A token-level combinatorial optimization

The computation and optimization of P_θ^{tok} involves several steps that are shown in algorithm 2 and figure 2. In essence, we leverage an auxiliary MLM head trained on public data to choose a list of potential tokens for reconstruction. Then, we compute the loss of the target model for each candidate, and select the one leading to the minimal loss. This is why we refer to our attack as *combinatorial*. Unlike the continuous relaxation used in NLP by [59, 70], we use discrete optimization by testing each candidate.

Algorithm 2 Computing and maximizing P_θ^{tok}

1: **procedure** argmax$_{v_t \in \mathcal{V}}$ $P_\theta^{\text{TOK}}(v_t \mid \widetilde{d}, y, v_1, \ldots, v_{t-1})$
Getting candidates from auxiliary public MLM
2: $[\, g_i \,]_{1 \le i \le |\mathcal{V}|} \leftarrow \text{MLM}_{\text{pub}}(\widetilde{d}, v_1, \ldots, v_{t-1})$
3: $[\, c_i \,]_{1 \le i \le N_c} \leftarrow \text{TOP}(N_c, [\, g_i \,]_{1 \le i \le |\mathcal{V}|})$.indices
4: $[\, g_i \,]_{1 \le i \le N_c} \leftarrow \text{TOP}(N_c, [\, g_i \,]_{1 \le i \le |\mathcal{V}|})$.values
Computing target model loss
5: $[\, l_i \,]_{1 \le i \le N_c} \leftarrow [\, \text{LOSS}(f_\theta(c_i, y)) \,]_{1 \le i \le N_c}$
Converting into likelihoods
6: $[\, \widehat{g}_i \,]_{1 \le i \le N_c} \leftarrow \text{SOFTMAX}([\, g_i \,]_{1 \le i \le N_c})$
7: $[\, \widetilde{l}_i \,]_{1 \le i \le N_c} \leftarrow 2 - [\, l_i \,]_i / \text{MEDIAN}([\, l_i \,]_i)$
8: $[\, \widehat{l}_i \,]_{1 \le i \le N_c} \leftarrow \text{SOFTMAX}([\, \widetilde{l}_i \,]_{1 \le i \le N_c})$
Aggregating
9: $[\, p_i \,]_{1 \le i \le N_c} \leftarrow [\, \text{MEAN}(\widehat{l}_i, \widehat{g}_i) \,]_{1 \le i \le N_c}$
Sampling with the final likelihoods
10: $v_t \leftarrow \text{SAMPLE\_ONE}([\, p_i \,]_{1 \le i \le N_c})$

Details on step 1 (lines 2–4 in algo. 2, block A in fig. 2) This step employs an auxiliary MLM head trained with $\mathcal{T}$ and $\mathcal{D}$. These are assumed to be public knowledge, hence this head is referred to as PUB-MLM. The step consists in a single forward-pass of the document in PUB-MLM, followed by the selection of the top-N_c most plausible candidates.

This first step is needed because we empirically observed that the token minimizing the loss of the target model is often not the one we seek (e.g. unexpected words like "paranoia" for a "date" field). This was not an issue for Elmahdy et al. [19] because they attacked canaries, whose structure is exactly known. However, for real data, we deem it necessary to initially filter plausible tokens with a MLM head.

Moreover, a forward-pass is executed for each candidate token during step 2. As such, selecting only a reasonable number of candidates significantly accelerates the attack.

Details on step 2 (line 5 in algo. 2, block B in fig. 2) For each of the N_c candidate tokens, we execute a single forward-pass on the document, wherein the target token is replaced by the candidate token. These forward-passes can be arranged into one or several mini-batches depending on the available graphical memory. The loss applied is identical to the one used during training, which is the cross-entropy loss. However, we did not average over the mini-batch samples: l_i corresponds to the loss for candidate token c_i, and to it alone.

The underlying idea is that the target model is trained to minimize the loss during training. Therefore, we assume that the loss is especially low for the specific token that was processed during training.

Details on step 3 (line 6 in algo. 2, block C in fig. 2) This step involves converting the PUB-MLM logits into likelihoods using a softmax function. We incorporated two heuristics: a temperature parameter [2, 22], following the approaches of [9, 46, 84], and a decaying temperature as in [9], to promote the exploration of unexpected tokens only for the first tokens of the reconstruction.

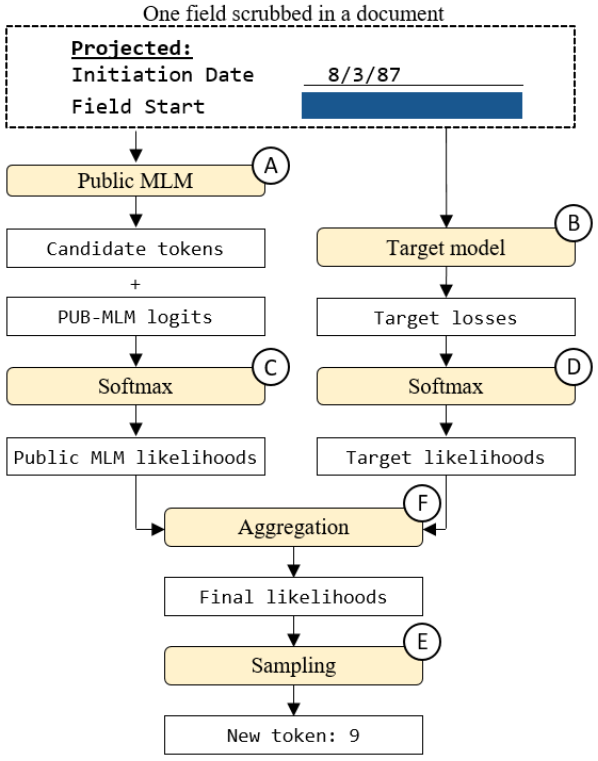


Figure 2: Computing and maximizing P_θ^{tok} to invert a token. We first use a masked model trained on public data to select $N_c = 128$ candidates (A). Then, we compute the loss of the target model with each candidate (B), and aggregate these losses to obtain a probability distribution over the candidates (C, D, E). Finally, we sample the reconstructed token from this distribution (F), and repeat this process for the next tokens.

Details on step 4 (lines 7–8 in algo. 2, block D in fig. 2) This step involves the conversion of the losses of the target model into likelihoods. We must consider that:

- We want to minimize the loss (unlike the logits).
- We observed that the output loss usually consists in a majority of small values (e.g. of the order of 10^{-5}), and some much larger outliers (e.g. of the order of 10^{0}).

We used equation 5. First, losses are normalized by their median, attenuating the influence of the outliers. Then, we subtract the resulting value from 2 to position the majority of values around 1. Ultimately, a softmax function with decaying temperature is applied, as in step 3.

$$[\, \widehat{l} \,]_{1 \le k \le n} = \underset{1 \le j \le N_c}{\text{SOFTMAX}} \left(2 - \frac{l_j}{\text{MEDIAN}([\, l_i \,])_{1 \le i \le N_c}} \right) \quad (5)$$

Details on step 5 (line 9 in algo. 2, block E in fig. 2) In this step, we integrate the PUB-MLM likelihoods with those of the target model. We explored two possibilities: an arithmetic weighted mean and a geometric weighted mean. Each of them offers distinct advantages. The arithmetic mean guarantees that both likelihoods always have the same relative importance, while the geometric means ensures that if one of the two likelihoods is exceptionally low, the mean will approach zero regardless of the other's value. In practice, we opted for the geometric mean due to its superior results.

Details on step 6 (line 10 in algo. 2, block F in fig. 2) Given the final likelihoods of the tokens, the remaining step consists of sampling one of them. This is a classical task in text generation [31]. Consistent with the results of [46, 84], we utilize top-p sampling (also known as nucleus-η [31]). The selection of parameter p significantly influences the reconstructed field, and must be chosen in harmony with the temperature of the softmax functions.

4.3 Variants of the attack

Targeting a MLM head As explained in section 2.1, we also target models trained on the MLM task, referred to as *private* MLM, unlike the PUB-MLM head which is used to optimize the token-level proxy (see section 4.2).

The attack method differs slightly when targeting such models, because we do not need to use another MLM as an auxiliary model. For steps 1 and 3, we replace the PUB-MLM head with the *private* MLM under attack. Then, we skip steps 2, 4 and 5, and directly utilize the likelihoods of the target model to sample the next token.

The multi-shot variant For this variant, a membership inference metric is employed to sort the fields by plausibility of their reconstructions. In real-life scenarios, the adversary would set a threshold and only keep the most plausible ones.

Various membership inference metrics have been implemented in NLP [9, 46, 47, 55, 84]. Most of them rely on comparing the *likelihood* of a token or a sentence with respect to the target model and with respect to another model. Yet, computing the likelihood of a sentence for encoder-only models remains computationally intensive [37, 55]. Therefore we use the same approximation as for the reconstruction: computing the field likelihoods in an autoregressive manner:

- For each token v_t in a field $\widetilde{f}$, we define its *target likelihood* as the probability p_i it had during sampling at line 10 in algorithm 2. We also define its PUB-MLM likelihood as $\widehat{g}_i$, computed with the auxiliary MLM.
- We define the likelihood of a field as the product of the likelihoods of its tokens. We also use these token-level likelihoods to define the *perplexity* of a field [41].

While these definitions are approximations for encoder-only models, they offer the benefit of directly employing the PUB-MLM likelihood $\widehat{g}_i$ which is already computed during the attack. This circumvents the need for separate likelihood computation with an auxiliary model, as required in [9, 55, 84], except when targeting a private MLM head (see above). The five membership inference metrics we implement are:

- *Raw perplexity*: the PUB-MLM perplexity.
- *Perplexity ratio*: the ratio between the PUB-MLM perplexity and the target perplexity.
- *Raw and ratio*: the product of the two metrics above, aiming at prioritizing fields that have high PUB-MLM perplexity along with a high perplexity ratio.
- *Max. token likelihood gap*: the maximum difference between the private likelihood and the PUB-MLM one for every token (inspired from "high confidence" in [84]).
- *Max. token likelihood ratio*: similar to above, replacing the difference with a ratio.

5 Evaluation protocol

5.1 Datasets and training conditions

Datasets We evaluate the CDMI attack on models trained on two datasets: FUNSD [40] and SROIE [35], which are popular benchmarks for KIE tasks (see section 2.1). FUNSD consists of 199 scanned forms from the tobacco industry and includes annotations for both EE and EL tasks. We attack the fields annotated as "Anwers". For its part, SROIE incorporates 626 scanned receipts, only annotated for EE task. We attack the fields containing the date, company, address,

Dataset	Task	Acc LayoutLM		Acc BROS	
		Unimod	Bimod	Unimod	Bimod
FUNSD	MLM	0.545	0.545	0.546	0.546
SROIE	MLM	0.540	0.538	0.541	0.539
FUNSD	EE-BIO	0.762	0.746	0.820	0.817
SROIE	EE-BIO	0.960	0.967	0.969	0.959
FUNSD	EE-SPD	0.760	0.760	0.815	0.804
SROIE	EE-SPD	0.952	0.935	0.965	0.965
FUNSD	EL	0.240	0.193	0.000	0.202

Table 2: The best validation accuracy of our models. For each of our 7 tuples (dataset, task), we trained unimodal and bimodal models with either LayoutLM or BROS backbone. These results are consistent with the one announced in [32]. For each of these 28 settings, we attacked both the model with the best validation accuracy (Precision criterion, presented here) and with the lowest validation loss (Loss criterion, presented in the appendix, see table 5).

and total amount. For both datasets, we only retain fields comprising between 3 and 15 tokens to disregard those that are either meaningless or too computationally demanding.

Each of our datasets is randomly partitioned into three non-overlapping parts (see appendix for details):

- A validation set, used to evaluate the generalization performance of models during their training phase.
- A private train set, comprising half of the remaining documents, and on which the models we target are trained.
- A public train set, containing the remaining documents, used to train auxiliary models.

Training conditions We trained models in 28 different settings. For each of the 7 tuples (dataset, task) presented in table 2, we trained unimodal and bimodal models with either LayoutLM or BROS backbone. For each configuration, we trained our models for many epochs (300 for MLM tasks, 150 for the others), and saved the models at each epoch. Ultimately, we select the epoch we target with respect to one of the following *criteria*:

- Precision: the epoch with the best validation accuracy.
- Loss: the epoch with the best validation loss.

Using these 28 configurations and these 2 criteria, we evaluated both the one-shot and the multi-shot variant of our attack. This results in 112 different attack scenarios.

Hyperparameters: transferring from LayoutLM to BROS The CDMI attack described in section 4 involves several hyperparameters: the number of candidates N_c in step 1, the temperature parameter and decay in steps 3 and 4, the averaging method and its weight in step 5, the parameter p for top-p sampling in step 6, and the number of attempts n_a for the multi-shot variant. We tuned these hyperparameters for the 14 configurations with LayoutLM backbone and Precision criterion, optimizing the evaluation metrics of the one-shot variant (see section 5.2 and the appendix).

Finally, we used each of these 14 sets of hyperparameters for 8 attacks: one-shot or multi-shot, Precision or Loss criterion, and LayoutLM or BROS backbone, yielding in a total of 112 evaluation settings. Given that the hyperparameters were calibrated with LayoutLM backbone, we anticipate the accuracy of CDMI to be superior with LayoutLM than with BROS. These enable us to assess the *transferability* of our attack, as we measure its performance on an architecture for which it was not optimized, namely BROS.

Hardware and computation time Each of these 112 evaluations was performed on a fraction of 0.1 Nvidia A100 80GB. The mean computation time was 20:40 hours for each experiment, resulting in a total of about 2300 hours.

5.2 Evaluating the one-shot variant

Four evaluation metrics To evaluate the quality of the one-shot attack, we compare each reconstruction $\widetilde{f}$ to its corresponding ground truth f. We employed four metrics for this purpose: the Perfect Reconstruction PR $= \mathbb{1}(f = \widetilde{f})$, the Hamming Distance (HD) [28], the normalized Levenshtein Distance (LD) [48], and the normalized Jaro-Winkler Distance (JWD) [39, 78]. We computed these metrics using the tokens of the fields, ignoring their alphanumeric decoding by the tokenizer, and we averaged them across all fields.

Our baseline A logical analysis of the other fields and headers can often enable guessing many fields within a document. Consequently, we compare our one-shot attack to a baseline which represents the reconstruction that are feasible with public information only. In practice, this baseline corresponds to the reconstruction of the fields using only the PUB-MLM likelihoods in figure 2.

We compute the four evaluation metrics with this baseline, and compare them to our attack. In this way, we assess how useful it is to have access to the target model to obtain accurate reconstructions. Using an idea similar to the *advantage* often used in cryptography, we introduce the *improvement factor* (IpF), which represents the mean improvement between the attack and the baseline for our four metrics. For example, IpF $= 1.5$ means that the attack is 50% better than the baseline on average. The improvement factor is defined in equation 6, where "att" represents the attack, and "base" the baseline. We also add a parameter ε to bound the improvement factor.

$$\text{IpF} = \frac{\frac{\text{PR}_{\text{att}}+\varepsilon}{\text{PR}_{\text{base}}+\varepsilon} + \frac{\text{HD}_{\text{base}}+\varepsilon}{\text{HD}_{\text{att}}+\varepsilon} + \frac{\text{LD}_{\text{base}}+\varepsilon}{\text{LD}_{\text{att}}+\varepsilon} + \frac{\text{JWD}_{\text{base}}+\varepsilon}{\text{JWD}_{\text{att}}+\varepsilon}}{4} \tag{6}$$

5.3 Evaluating the multi-shot variant

The evaluation of the multi-shot variant must account for both the order of the reconstructions with respect to the membership inference metric (F and $\widetilde{F}$), and the similarity between the fields and their reconstructions ($f_i \in F$ vs. $\widetilde{f}_i \in \widetilde{F}$). Thus, our evaluation metrics should satisfy the two following mathematical properties:

1. With fixed values f_i and $\widetilde{f}_i$ for each i, the metric is maximized when F and $\widetilde{F}$ are sorted in descending order of similarity between f_i and $\widetilde{f}_i$.
2. With a fixed order of F and $\widetilde{F}$, for each i, the metric increases when the similarity between f_i and $\widetilde{f}_i$ increases.

However, common metrics used in the literature do not satisfy these properties. Indeed, existing work such as [9, 84] assess separately the quality of the reconstructions and the membership inference attack. For example, with the regular AUC score computed with the ROC curve, a value of 1.00 is

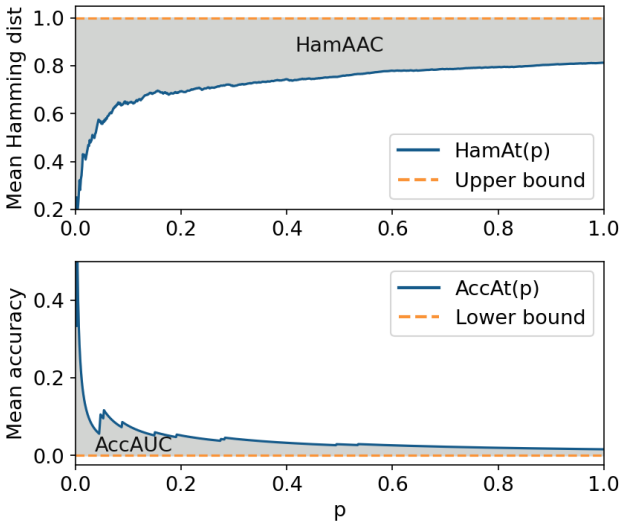

Figure 3: *AccAUC* and *HamAAC* computation examples. Acc(p) denotes the mean accuracy of the top-p fields the adversary is the most confident in. The greater it is, the more accurate the reconstructions are. A peaky and decreasing shape means that the membership inference metric accurately sorts the reconstruction attempts. This is why we seek to maximize its Area Under the Curve (*AccAUC*). Idem for the Area Above the Curve with the Hamming distance (*HamAAC*).

achieved in the two following situations, despite the apparent superiority of the latter: (1) a single perfect reconstruction is ranked highest, trailed by 99 inaccurate reconstructions; and (2) all 100 reconstructions are perfect. This is because AUC score ignores the *prevalence* of perfect reconstruction, which is necessary to meet the second property we want.

This motivates the introduction of two new metrics that satisfy these properties. Figure 3 demonstrates an example of their computation. We will introduce them briefly, and we refer to the appendix for rigorous definitions and proofs that they satisfy the two desired properties.

Accuracy-AUC and Hamming-AAC First, we introduce the Accuracy-at-p metric for $p \in [0,1]$ ($AccAt(p)$). It represents the accuracy of the reconstruction within the top-p fields the adversary is the most confident in, i.e. the one with the greatest membership inference metric. Then, we plot $AccAt(p)$ versus p. A greater Area Under the Curve ("AUC") means that that the reconstruction are more accurate. This motivates the introduction of the Accuracy-AUC metric.

Similarly, $HamAt(p)$ represents the mean normalized Hamming distance [28] within the top-p fields the adversary is the most confident in. However, we look at the Area Above the Curve ("AAC") because it is a distance and not a similarity. This results in the Hamming-AAC metric. Both the *AccAUC* and *HamAAC* metrics take values between 0 and 1, and increase as the quality of the attack improves.

6 Experimental results

This section presents the experimental results of our attack and discusses our main findings. For a comprehensive presentation of our results, please refer to the appendix. Our experiments show that CDMI achieves robust results, allowing for meaningful reconstructions with every task and dataset we evaluated, including numbers, dates, and names up to 8 tokens. Table 3 shows examples of perfect reconstruction.

In our experiments, the maximum value of $AccAt(1.0)$ that we reach is 0.041, meaning that under optimal conditions, the adversary can flawlessly reconstruct 4.1% of the fields. For comparison, under identical conditions, our baseline only recovers 0.77% of the fields. Furthermore, the maximum $AccAt(0.05)$ registered is a promising 22.5%. This indicates that in this scenario, when the adversary employs a membership inference metric to retain the 40 fields they are most confident in (5% of the dataset), they can attain up to 9 perfect reconstructions. This performance far exceeds our baseline's score at 2.5%, corresponding to just a single field.

6.1 Performance of the attack

Factors influencing the one-shot variant with LayoutLM We observe that certain configurations result in significant outcomes. For example, when selecting the checkpoint with the best validation precision from a bimodal MLM trained on FUNSD, we achieve an improvement factor of 1.395. This means that the CDMI reconstructions are approximately 40% more effective than the ones of our baseline (see line 2 in table 5 in the appendix for more details).

However, some models are more vulnerable than others. Figure 4 compares the performance of the one-shot attack for the 8 MLM models we trained with LayoutLM backbone: unimodal or bimodal, Precision or Loss criterion, and FUNSD or SROIE dataset (see lines 1-8 in table 5 for more details). Interestingly, the difference between FUNSD and SROIE datasets is minor, showing that our attack is robust

Table 3: Examples of perfect reconstructions.

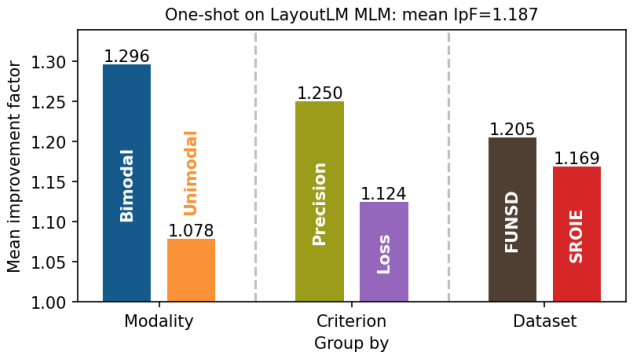

Figure 4: Factors influencing the performance of the one-shot attack on a LayoutLM with MLM task. We attack 8 different models (2 modality, 2 criteria, 2 datasets) with an average improvement factor of IpF = 1.187. Among them, the 4 attacks implying a bimodal model are more accurate than those against a unimodal model (IpF of 1.296 vs. 1.078). Similarly, the attacks are more accurate with the Precision criterion, and with the FUNSD dataset.

to at least two type of documents. Moreover, we observe that Precision criterion leads to more vulnerable models than Loss criterion. This is not surprising because they are trained for more epochs, so the model had more time to memorize its training data. Finally, we observe that bimodal models are much more vulnerable than unimodal ones, with a mean improvement factor of 1.296 compared to 1.078. This indicates that the visual encoder memorizes information about the training sample, which our attack efficiently extracts. These aspects are discussed further in section 6.2.

For non-MLM tasks, the factors influencing the one-shot attack are different. Indeed, the attack is very efficient on SROIE dataset, with a mean improvement factor of 1.224. However, it obtains poor results on FUNSD, with a mean improvement factor of 1.036, indicating that the attack is not significantly better than the baseline. We explain this result by observing that these models exhibit significantly lower accuracy on FUNSD compared to SROIE, so it is not surprising that the attack can extract less information from them (see columns 6-7, lines 9-24 in table 5 for more details).

Comparison between the tasks With LayoutLM backbone, some tasks are easier to attack than others, as outlined in figure 5. MLM task is the most vulnerable, as expected. Indeed, it is designed to reconstruct masked tokens, aligning with the objective of the reconstruction. On the opposite, models trained with EL task exhibit lower validation accuracy compared to EE-BIO and EE-SPADE, which explains their low susceptibility to our attack. Since the model struggles in learning meaningful patterns to solve the task, using its loss as per the CDMI approach makes it less efficient.

However, we observe that for every task and dataset, there exists a configuration yielding an improvement factor of a minimum of 1.10. This suggests that our reconstruction attack could be generalized to a wider range of fine-tuning tasks, such as document classification and question answering.

Comparison between LayoutLM and BROS As detailed in section 5, we have optimized our attack with the LayoutLM backbone, and then evaluated its transferability to BROS architecture. Thus, it is unsurprising that we obtain stronger results for LayoutLM than BROS. For example, we obtain poor results for most one-shot and multi-shot configurations with non-MLM tasks when using BROS backbone.

However, the outcomes of CDMI for MLM tasks on BROS are highly competitive compared to those on LayoutLM, as outlined in figure 5. For the one-shot variant, there is a minor gap between LayoutLM and BROS backbones, with a mean improvement factor of 1.187 and 1.167, respectively. Our best performance for the one-shot variant is even obtained with BROS backbone, with an impressive improvement factor of 1.54. For the multi-shot variant with BROS backbone, 5.4% of the fields are perfectly reconstructed on average within the top-5% fields (Accuracy-at-5%). This is much higher than the accuracy of 1.3% obtained with the baseline, showing that the model memorizes a significant part of its training set.

The successful transferability of our attack to BROS backbone in some settings suggests that it could likely be adapted to other document understanding model architectures.

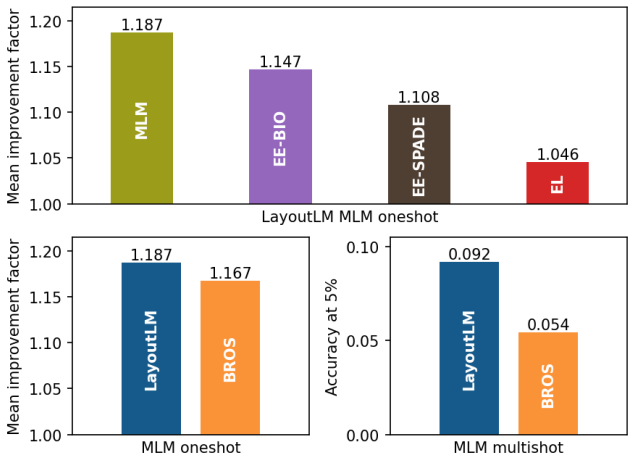

Figure 5: Performance comparison based on the backbone or task. The top graph shows the average performance of the attack with LayoutLM backbone, for the four possible tasks. The bottom graphs compare the average performance of the attack on the MLM models with LayoutLM backbone (in blue) or BROS backbone (in orange), for both the one-shot variant (left) and the multi-shot variant (right).

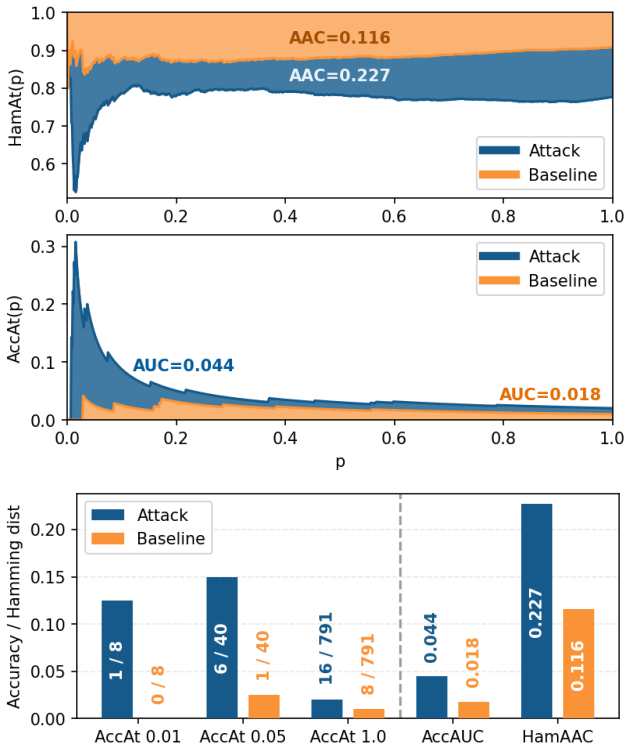

Figure 6: Comparison between the attack and the baseline in a multi-shot setting, with a bimodal model, LayoutLM backbone, EE-SPADE task, SROIE dataset and Loss criterion. On the upper plot, the Hamming-at-p distance is much lower for the attack. On the middle plot, the Accuracy-at-p of the attack is decreasing, so the membership inference metric accurately sorts the most credible reconstructions. On the last plot, the evaluation metrics are higher for the attack: for instance, with $p = 0.05$, the attack perfectly reconstructs $6/40 = 15\%$ of the fields, vs. $1/40 = 2.5\%$ for the baseline.

The multi-shot variant We observe that many configuration yielding good results with the one-shot variant perform poorly with the multi-shot variant. Thus, in these configurations, even though the model memorizes information about its training data, it is not sufficient to perfectly reconstruct a significant portion of the fields with high confidence.

However, some configurations lead to strong results for both MLM and non-MLM tasks. For example, figure 6 displays a successful attack on a very realistic model trained on EE-SPADE task, which is targeted at epoch 4, when its validation loss is minimal. The adversary perfectly reconstructs 15% of the fields they are most confident in. Moreover, the peaked shapes of $AccAt(p)$ and $HamAt(p)$ indicate that the membership inference metric efficiently sorts the good reconstructions first. As a result, CDMI reconstructions considerably outperform our baseline in all evaluation metrics.

This proves that even non-generative models trained on entity extraction tasks can be successfully attacked.

6.2 Ablation studies

In this section, we demonstrate that neither overfitting nor data duplication accounts for the performance of our attack. Moreover, we demonstrate that we can extract information memorized by the visual modality, proving that documents should be considered as a distinct data type, susceptible to attacks that can exploit their bimodal nature.

Overfitting As detailed in section 2.2, overfitting often favors the memorization of training data, even though it is not a requisite condition [9, 21, 83, 85]. We also observed this phenomenon with CDMI. From the early stages of training, even before the model can overfit, training data are memorized. And the attack performance gradually increases over epochs, even when validation accuracy starts to decrease.

To verify the correlation, we executed the experiment depicted in figure 7. We evaluate the one-shot and multi-shot CDMI attacks on 40% of the fields for one out of 5 model checkpoints between epoch 1 and 300. First, we observe that

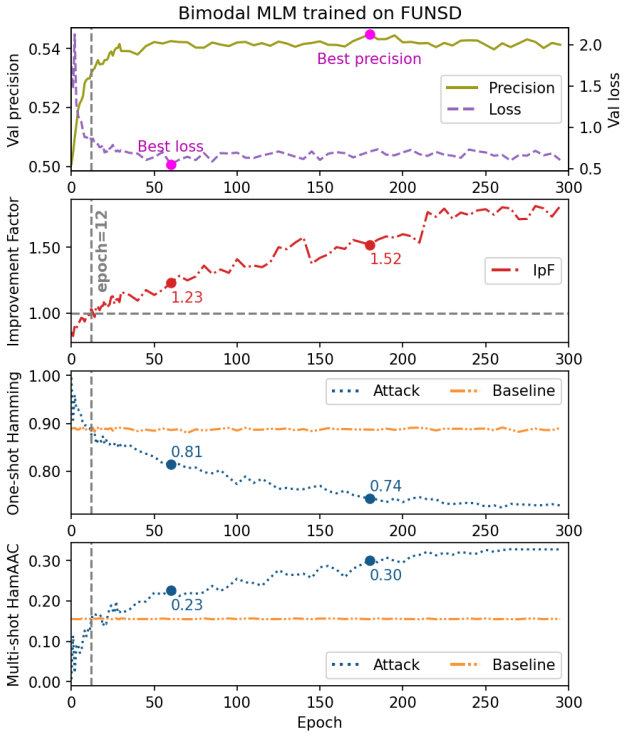

Figure 7: Attacking a bimodal LayoutLM model trained on FUNSD with MLM task and $N_c = 256$. The first graph plots the validation loss and accuracy, with the best values achieved at epoch 60 and epoch 180, respectively. The two following plots display the performance of the one-shot attack, and the last one shows the performance of the multi-shot attack. In both cases, the attack is more accurate than the baseline from epoch 12, well before the best validation loss.

overfitting is evident, as the best validation loss is achieved much earlier than the best validation precision. However, the attack outperforms the baseline quite early, after just 12 epochs, showing that the model memorizes training data without needing to overfit. Finally, all the performance metrics of our attack increase with the number of training epochs, and persist beyond the epoch with the optimal precision.

This shows that our attack is efficient from the early epochs of training, and that simple regularization techniques are unlikely to be sufficient to ensure the security of the data used to train document understanding models.

Data duplication Data duplication is known to favor memorization of training data (see section 2.2 and [43]). Certain definitions such as k-eidetic memorization [9] even include the number of duplicates. However, defining duplication for document data is not straightforward. In our case, we seek to reconstruct the fields in their context: for example, the reconstruction of "24.8 mm" only becomes useful when it is linked to the form it comes from. Therefore, we deemed that two forms with identical headers but different answers were not duplicates, contrary to shifted or rotated documents.

We did not implement an automatic count of duplication within our datasets; however we manually checked the number of occurrences for a few documents (see "Occ" column in table 3). Even though we observed some duplicates in the SROIE dataset, we did not detect any of them in FUNSD. Thus, we conclude that the good results of our attack is presumably not linked to data duplication. However, further investigating this issue would be a promising topic for future research, as numerous document datasets contain a great number of similar documents (e.g. ID cards, etc.).

Importance of layout and visual modality Our attack was designed to efficiently reconstruct data from layout-aware document models. However, it could be possible that it only extracts information from textual content, and would be just as effective on text-only models. We conducted the following experiments to demonstrate that it is not the case, and that both layout and visual modality contribute to memorization.

As shown in the upper plot of figure 8, we trained several models with BERT backbone [13], which does not take the layout into account, and compared them with those using LayoutLM backbone. We specifically used models trained on SROIE with the EE-BIO task, as in this setting, the validation accuracy between BERT and LayoutLM is similar. This means that a difference in memorization cannot be attributed to a difference in accuracy. We observed that the attack is much more successful with LayoutLM, with a mean improvement factor of 1.248 compared to 1.150 with BERT. This proves that layout information contributes to memorization, making the layout-aware models more vulnerable than their textual counterparts.

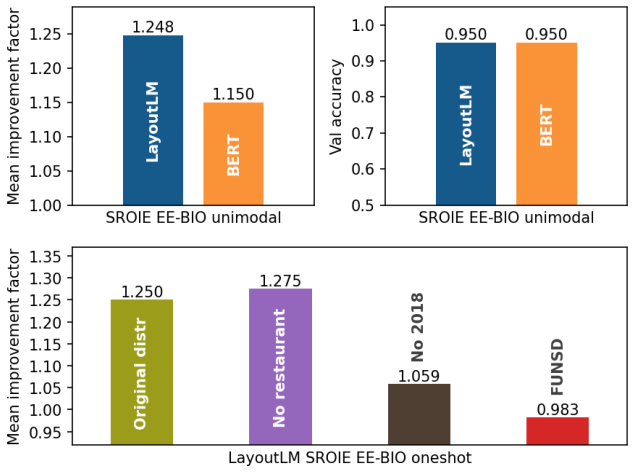

Figure 8: Upper plot: our attack performs better on LayoutLM backbones than BERT. This confirms that layout contributes to memorization, making document models more vulnerable. Lower plot: the performance of attacks using auxiliary public MLM trained on four datasets with increasing distribution shift. Our attack remains feasible if the adversary has access to different yet similar data distribution.

The significance of visual modality was already discussed in section 6.1. As depicted in figure 4, bimodal models are more susceptible to our attack than unimodal ones. To confirm that the information is memorized within visual modality, we conducted an experiment using bimodal models trained on MLM task with LayoutLM backbone. We obtained a mean improvement factor of 1.296 when attacking these models normally. However, when we deactivated the visual modality by replacing it with Gaussian noise in these models, the mean improvement factor dropped significantly to 1.044. This confirms that our attack extracts information that is memorized within the visual modality.

Robustness to distribution shifts As explained in section 3, we assume that the adversary knows the target distribution $\mathcal{D}$, and uses it to train an efficient auxiliary public MLM. This hypothesis is plausible given the accessibility of many datasets online, but it gives an advantage to the adversary.

To evaluate its impact, we conducted attacks on SROIE dataset using auxiliary public MLM trained on four datasets with increasing distribution shifts (see figure 8). The first one was trained with the original distribution. For the second one, we removed all restaurant receipts from SROIE, which represents a sub-population of about 10%. We obtained a similar improvement factor, indicating that our attack remains feasible with a minor distribution shift. The third one was trained without any receipt dated 2018 (around 50% of the dataset). This is an important distribution shift because the 'date' field is one of those we are attacking. The performance dropped,

because the adversary is unable to accurately select relevant candidate tokens. Finally, the last auxiliary model was trained on FUNSD. Here, the distribution shift is too important and the attack is ineffective, yielding an improvement factor close to 1. We conclude that the ability of the adversary to train a well-performing auxiliary model on a nearby distribution is an important assumption for the success of our attack.

7 Conclusion

A pioneer attack In this paper, we introduce the first reconstruction attack against document understanding models: CDMI (Combinatorial Document Model Inversion). Despite similarities with some attacks against language models, what sets CDMI apart is that it is explicitly designed to handle documents as multimodal data, making it the first to target layout-aware models. We present two variants of the attack: a one-shot version, and a multi-shot version where CDMI is combined with a membership inference attack.

We also establish a meticulous protocol to assess our attack, comparing it with reconstructions that can be made with only public information. We also introduce two new evaluation metrics, Accuracy-AUC and Hamming-AAC, designed to simultaneously evaluate the reconstruction phase and the membership inference phase in the multi-shot variant.

Empirical evidence We demonstrate that models trained on Key Information Extraction tasks under realistic conditions are vulnerable to reconstruction attacks. Under optimal conditions, the adversary is able to perfectly reconstruct from 4.1% of the fields to 22.5% when combined with a membership inference attack.

We clearly observe that the Masked Language Modelling task is more vulnerable than the Key Information Extraction ones. Moreover, we demonstrate that both layout and visual modality contribute to memorization, making document models more vulnerable than their textual counterparts, and susceptible to specific attack developments.

We show that our attack's performance is not a consequence of either overfitting or data duplication. It only takes a dozen epochs to memorize training data even without duplication. Thus, further research into alternative defense mechanisms, such as differential privacy, is necessary.

Recommendations We recommend three mechanisms to make the prerequisites of our attack impossible. First, avoid open-sourcing the weights of models trained on sensitive data. Second, when serving models through an API, hide your model's confidence score and filter repetitive queries on similar data. Third, avoid sharing anonymized documents, as they can be used for reconstruction attacks.

If these three mechanisms cannot be implemented in a particular situation, we recommend exercising the utmost caution. More advanced reconstruction attacks are likely to be developed in the near future. Our attack method can be used to estimate the privacy risk of a model, and we also advocate for the use of provable privacy-preserving techniques.

We hope our work will alert researchers and practitioners to the privacy risks of document understanding models, and lay the foundation for the development of robust, privacy-preserving architectures.

Table 4: Number of documents and fields in our partitions.

Appendix

A Training conditions

This section elaborates on aspects discussed in section 5.1.

First, table 4 shows the volumes of the datasets we used. We used two datasets: FUNSD [40] and SROIE [35], which we split into three non-overlapping parts: validation, train-public, and train-private. Column 3 displays the number of documents in each part. Columns 4 and 5 present the total number of fields in each dataset, and the number of fields we selected for our attack, respectively.

Second, the results of our hyperparameter optimization are as follows. For step 1, $N_c = 128$ offers a satisfactory balance between performance and computational time ($N_c = 512$ marginally improves the attack accuracy by 2%, at a significant computational cost). For steps 3 and 4, effective results were typically associated with a low temperature, about 0.2–0.4, with a decay rate applied over 3 steps for the PUB-MLM softmax, and no decay for the target one. For step 5, geometric mean exhibited superior results, though the optimal weight varied considerably across configurations (between 0.2 and 0.6). For step 6, the optimal parameter was $p = 0.10$, except for some settings where $p = 0.12$ proved superior. Finally, we selected $n_a = 8$ attempts for the multi-shot variant.

B Evaluation of the multi-shot variant

Let us detail further *AccAUC* and *HamAAC* metrics introduced in section 5.3. For $p \in [0,1]$, let $T(p)$ be the set of field that are ranked top-p by the membership inference metric, and let *Ham* be the Hamming distance [28]. We define:

$$AccAt(p) := \frac{1}{|T(p)|} \sum_{f \in T(p)} \mathbb{1}(f = \widetilde{f}) \quad \in [0,1] \tag{7}$$

$$AccAUC := \int_{p=0}^{1} AccAt(p)\,\mathrm{d}p \quad \in [0,1] \tag{8}$$

$$HamAt(p) := \frac{1}{|T(p)|} \sum_{f \in T(p)} Ham(f, \widetilde{f}) \quad \in [0,1] \tag{9}$$

$$HamAAC := 1 - \int_{p=0}^{1} HamAt(p)\,\mathrm{d}p \quad \in [0,1] \tag{10}$$

Table 5: Main experimental results. Columns 1-5 show the target's model training conditions: backbone (LayoutLM, BROS), task (MLM, EE-BIO, EE-SPADE, EL), dataset (FUNSD, SROIE), criterion (Precision, Loss), modality (Unimodal, Bimodal). Column 6 shows its validation accuracy. Columns 7 and 8-12 show the results of the one-shot and multi-shot attacks, respectively.

Let us now prove that *HamAAC* satisfies the two properties of section 5.3; the demonstration is similar for *AccAUC*:

1. Let us fix the values of all f and $\widetilde{f}$. Then, let be two indices $1 \leq i < j \leq M$ such that $Ham(f_i, \widetilde{f}_i) > Ham(f_j, \widetilde{f}_j)$. If we swap i and j, this will increase $HamAt(p)$ for $p \in [i/M, j/M[$ leaving the other values unchanged, which will increase the *HamAAC* score. As a result, every step of a selection sort applied to sort the indices by increasing values of $Ham(f_i, \widetilde{f}_i)$ will increase *HamAAC*, proving that the maximum will be achieved at the end of the selection sort.

2. Let F and $\widetilde{F}$ have fixed order, and length M, and let $i \in [\![1, M]\!]$. Then, if we change the reconstruction $\widetilde{f}_i$ into another $\widetilde{f}'_i$ such that $Ham(f_i, \widetilde{f}'_i) > Ham(f_i, \widetilde{f}_i)$, it is clear that $\forall p \geq i/M$, $HamAt(p)$ increases. As a result, this improvement of $\widetilde{f}_i$ increases *HamAAC* as well.

C Detailed experimental results

Table 5 details our experimental results, using $N_c = 128$ candidates. We excluded non-MLM tasks with BROS backbone because of their lower results (see section 6.1).

Privacy Side Channels in Machine Learning Systems

Abstract

Most current approaches for protecting privacy in machine learning (ML) assume that models exist in a vacuum. Yet, in reality, these models are part of larger *systems* that include components for training data filtering, output monitoring, and more. In this work, we introduce *privacy side channels*: attacks that exploit these system-level components to extract private information at far higher rates than is otherwise possible for standalone models. We propose four categories of side channels that span the entire ML lifecycle (training data filtering, input preprocessing, output post-processing, and query filtering) and allow for enhanced membership inference, data extraction, and even novel threats such as extraction of users' test queries. For example, we show that deduplicating training data before applying differentially-private training creates a side-channel that completely invalidates any provable privacy guarantees. We further show that systems which block language models from regenerating training data can be exploited to exfiltrate private keys contained in the training set—even if the model did not memorize these keys. Taken together, our results demonstrate the need for a holistic, end-to-end privacy analysis of machine learning systems.

1 Introduction

In the absence of safeguards, machine learning (ML) models leak private information about their training data [28, 71]. Numerous methods have been proposed to measure and mitigate privacy leakage, including formal techniques [1, 23, 27] and heuristics [42, 47]. However, existing privacy-preserving methods largely assume that ML models *exist in a vacuum*, when in reality ML models are part of larger *systems* that include components for training data filtering, input preprocessing, output monitoring, and more. These system-level components are widely incorporated into real-world ML systems to maximize accuracy, security, and robustness.

In this work, we introduce *privacy side channels*: attacks that exploit system-level components to extract private information at much higher rates than is otherwise possible for isolated ML models. We show that adaptive adversaries of varying strengths—ranging from black-box query access to data poisoning capabilities—can mount privacy attacks that are otherwise impossible without side channels (e.g., revealing test inputs). We evaluate the impact of these side-channel attacks on end-to-end systems, including GitHub Copilot—a black-box production system with millions of users. Concretely, we propose four categories of attacks that span the entire ML lifecycle (overview in Figure 1):

- **Training data filtering (Section 3).** Most large-scale training sets are filtered to remove duplicates and abnormal examples [2, 42, 47]. We demonstrate that data filters introduce side channels because they create dependencies between different users' data. In turn, adversaries can amplify privacy attacks by inserting poison examples that maximize these dependencies. Perhaps most surprisingly, we show that data deduplication [47]—a technique designed to *improve* privacy—can make privacy *worse*, even causing violations of naive differential privacy (DP) guarantees (Section 5). Aside from deduplication, we propose similar attacks for defenses against data poisoning [13, 19, 29].

- **Input preprocessing (Section 4).** Many models require their inputs to be preprocessed, e.g., language models require text to be tokenized. When these preprocessors are built using training statistics (e.g., tokenizers), we show that it creates side channels that allows adversaries to extract private information such as rare training words [66].

- **Model output filtering (Section 4).** To improve privacy, many ML systems include filters that prevent the system from outputting verbatim training data [31, 40]. We show that this creates a side channel that actually *reduces* privacy, even enabling near-perfect membership inference. We use this attack to reverse engineer details of GitHub Copilot's training set (namely, its exact training data cutoff) and then use it to extract OpenSSH private keys from a public language model's training set.

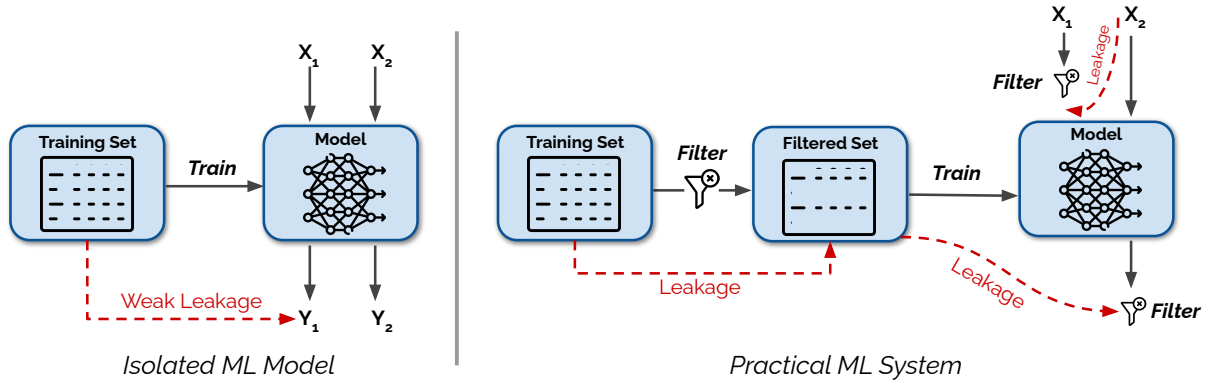

Figure 1: Most past work studies the privacy leakage of ML models in *isolation*. However, in reality most models are part of larger *systems* that contain components for filtering training data, blocking certain test inputs, monitoring model outputs, and more. In this work, we show that adaptive adversaries can create side channels that exploit these system-level components to significantly amplify privacy leakage.

- **Query filtering (Section 6).** Many ML systems use test-time query filters that reject certain inputs, e.g., detectors for adversarial examples [48, 51, 65] and model extraction attacks [41, 49, 57, 85]. We show that since many of these filters aggregate information across different users (to protect against Sybil attacks), adversaries can reveal information about other users' queries by sending targeted inputs. Unlike the previous side channels that reveal private *training* examples, this approach reveals other users' private *test* queries, which is otherwise impossible when considering isolated ML models.

Taken together, our results highlight the need to shift to a system-level view when analyzing ML privacy. Unfortunately, we show that guaranteeing system-level privacy is challenging, both empirically and theoretically, due to highly non-trivial interactions among different components. For example, we show that combining DP and deduplication (as suggested by past work [60]) leads to worse privacy than DP on its own. Furthermore, system-level analyses require tackling the trade-offs that arise when we consider a model's trustworthiness across *multiple* axes, e.g., query filters that improve security can simultaneously hurt privacy. Overall, we hope that our work can contribute to future improvements on the frontiers of ML privacy.

2 Preliminaries

2.1 Background and Related Work

Our paper studies a wide range of attacks that exploit numerous ML models and system components. In this section, we discuss general preliminaries for ML systems and privacy attacks; we otherwise defer the relevant background to each self-contained attack section (Sections 3–6).

2.1.1 Standalone ML Models

An ML model is a function $y \leftarrow f(x)$ that is trained on a dataset D_{train} and evaluated at inference time on a sequence of queries $D_{\text{test}} = \{x_1, x_2, \dots\}$. Most past work on ML privacy considers a "standalone" or "isolated" ML model where f is trained directly on D_{train} (e.g., using gradient descent) and then independently queried on each data point $x_i \in D_{\text{test}}$ to get outputs $y_i \leftarrow f(x_i)$.

Privacy attacks and defenses. When considered as standalone functions, ML models can memorize and leak considerable information about their training data. Numerous attacks exploit this leakage, including *membership inference attacks* [16, 22, 71, 84] that infer whether a specific example was in the training set, and more powerful *data extraction attacks* [5, 14, 15, 17, 54, 72] that can reveal entire training examples. To defend against these attacks, models can be trained with *differential privacy* [27]—typically by clipping and adding noise to updates in stochastic gradient descent [1, 23]—which makes them provably secure against privacy leakage. Other more heuristic approaches such as *data deduplication* [42, 47] or *output filtering* [31] can also mitigate some (but not all) memorization [18, 40, 42].

Membership and non-membership inference. Many of our side-channels exploit membership inference attacks, where the goal is to infer whether a specific data sample x was used in the training of a model f. In real-world scenarios, it is important for attackers to have low false-positive rates as most arbitrary samples are non-members [16]. In addition, inferring *non*-membership is significantly easier than inferring membership, since ML models typically make no mistakes on their training data (i.e., if a model gets an example wrong then it is probably a non-member). For many of our attacks, we show that side channels can be used to convert a membership inference problem into an equivalent (and easier) non-membership inference problem.

2.1.2 ML Systems

We consider part of an ML *system* everything that composes the data collection, training and deployment pipeline. These components augment the standalone model in Section 2.1.1 with additional components that act upon model inputs or outputs. In particular, we consider the following generic system components (see Figure 1 for an illustration):

- **A training data filter** (Section 3) is a function that modifies or removes inputs from the data before training. Popular examples include outlier removal or deduplication.
- **An input pre-processor** (Section 4) is a function that modifies inputs to prepare them for running through the model. Popular examples include image cropping, or tokenization and truncation for language models.
- **An output post-processor** (Section 4) is a function that acts on the output $y \leftarrow f(x)$ produced by the trained model and returns a modified output y' (possibly an empty output $y' = \perp$). Most relevant to our work are memorization filters that reject outputs y that leak information about some training example.
- **A query filter** (Section 6) is a function that acts on the sequence of input queries D_{test} sent to a trained model and returns modified inputs $D'_{\text{test}} = \{x'_1, x'_2, \dots\}$. The function may reject some input queries (i.e., $x'_i = \perp$) in which case the system returns no output for that query. Common examples include methods for rejecting inputs that are perceived as being part of some attack attempt.

Privacy side channels in ML systems. We broadly define a privacy *side channel* in an ML system as any instance where an attacker can probe the system-level components to leak significantly more information about the training set D_{train} or query set D_{test} than what a similarly capable attacker could leak by interacting with a standalone model. This additional leakage is made possible when instantiations of the above filters introduce *dependencies* between different model inputs—either at training or inference time.

We do not consider modifications to the training algorithm [73] or to the training data [77] to be "side channels" as they also apply to the isolated model case. Similarly, other types of attacks such as exploiting ML models used for computer systems [68] (e.g., caches, databases, etc.) are out-of-scope for our study.

We note that prior work has considered the impact of system components on the *integrity* of ML model deployments, e.g., by abusing image preprocessing algorithms to create adversarial examples [61, 82].

2.1.3 A Comparison to Physical Side Channels

In cryptography and computer security, side-channel attacks are typically defined as attacks that exploit leakage from the *implementation* of a protocol or algorithm, rather than from the design itself. Side-channel attacks often rely on leakage through physical phenomena (e.g., power consumption or timing [44, 45]) or auxiliary functionalities such as error messages [11, 78]. In the context of machine learning, physical side-channel attacks can recover the weights or architecture of standalone ML models, e.g., via electromagnetic signals [6], timing [26], power consumption [81], GPU context-switches [79], memory access patterns [37], fault injections [12], or cache timing [35, 83]. In addition, one can reconstruct model queries at inference time using power analysis [80].

Our work considers a different form of side channel that does not rely on physical signals, but instead relies on leakage introduced by auxiliary functionalities present in real-world deployments of machine learning. This is analogous to how deploying secure encryption alongside functionalities like error reporting enables new side channel attacks [11, 78]), or how deduplication can harm cloud storage systems [33]. In contrast to physical side-channel attacks, our attacks do not require any physical access or fine-grained measurement of the ML model. Instead, we only require black-box access to the system's prediction function.

2.2 Threat Model

Adversary's goal. The adversary's goal is to leak information about the training data D_{train} or test queries D_{test} of an ML system by leveraging system-level side channels. For membership inference attacks, we consider the standard adversarial game where we pick a data point x, include this sample in D_{train} with 50% probability, and then have the attacker predict whether x was in D_{train}. We also consider test-time membership inference attacks where the attacker has to guess whether some query x has previously been made to the system or not, i.e., if $x \in D_{\text{test}}$.

Adversary's system access. We assume that the attacker has only black-box access to the ML system, i.e., they can send arbitrary queries and observe outputs, but they do not know the exact weights of the ML system. On the other hand, we assume the attacker knows which system components are used (e.g., output filters) and how they are implemented (for some of our attacks, this knowledge is not strictly necessary). We believe this assumption is reasonable for three reasons: (1) we want to distinguish privacy that may be inherent in a system, from "privacy-through-obscurity" that arises solely due to (likely short-lived) secrecy of some system configurations; (2) many system components we consider have a small number of standardized implementations that practitioners are likely to use. For example, imagededup[1] and DataTrove[2] are the most widely used implementations for data deduplication of images and text, respectively, and offer only one or two canonical

[1] https://github.com/idealo/imagededup
[2] https://github.com/huggingface/datatrove

methods; (3) some of our attacks are reasonably robust to uncertainty and work even without precise knowledge of the system: for instance, our attack against GitHub Copilot works even though the system is a black-box.

In some of our attacks (Section 3, 5), we assume that the attacker can poison the training set, roughly mirroring the setting of Tramèr et al. [77]. In our data extraction attack against language models (Section 4.1), the attacker is assumed to know the prefix p of a string $p||s$ from the training set. For all other attacks, we make no additional assumptions on the adversary.

Since we are introducing a new class of attacks, we generally assume that there are no explicit defenses in place against privacy side channels. However, many of our attacks operate in settings where a model developer has deployed provable or heuristic defenses against privacy leakage (e.g., differential privacy, data deduplication, or memorization filters).

2.3 Ethics and Broader Impact

The attacks that we present could present a threat to user privacy in deployed ML systems. To mitigate these harms, we either study systems that we create ourselves using public data (e.g., CIFAR-10 classifiers) or ones such as GitHub Copilot that are trained on publicly-available data and thus do not pose any real-world privacy risks. The goal of our work is to bring to light these privacy vulnerabilities in order to spur future work on developing private end-to-end systems.

3 Attacking Training Data Filters

We first study side-channel attacks on training data filters. We show that common data filters introduce strong *co-dependencies* between data samples: a data point might be filtered out if and only if some other data points are present in the training set. This introduces a side channel where an adversary can determine, with high confidence, whether a target data sample was present in the training set.

To isolate the privacy leakage that stems from the addition of a specific filter, we assume throughout this section that the system applies a single data filtering scheme before training.

3.1 Attacking Training Data Deduplication

Most large-scale ML models are trained on data scraped from the Internet [30, 67]. Due to the nature of Internet content, it is common for some training data instances to be repeated multiple times; this is problematic for several reasons, including that repeated training data is much more likely to be memorized [18]. The process of *deduplication* addresses this challenge by removing exact or near-duplicated samples [47]. Most modern large language models and image generation models use training data deduplication, e.g., Gopher [63], DALLE-2 [64], LLaMA 2 [75], PaLM 2 [2], and others.

Types of data deduplication. We primarily focus on deduplication applied to images, although the principles underlying our attacks are directly applicable to other domains such as text, as we show in Section 3.1.5. As in Lee et al. [47], we consider both *exact* and *approximate* deduplication. Exact duplicates are samples x, x' that are equivalent, i.e., $x = x'$. Approximate duplicates are samples x, x' that are "close", i.e., $\mathsf{sim}(x, x') \geq \alpha$ for some similarity measure sim and threshold α. Once duplicates are identified, there are two approaches for deduplication: *delete-all* and *delete-all-but-one*. If $x \in D_{\text{train}}$ has as least one duplicate $x' \in D_{\text{train}}$, then *delete-all* removes all duplicates x, x'. *Delete-all-but-one* keeps exactly one copy, i.e., only one of x' and x is retained. While the latter may seem more natural, the former is simpler to implement; both approaches have been proposed in prior work and used in practice [47].

The side channel intuition. Data deduplication introduces co-dependencies between data points: a sample x is deleted if and only if some similar sample x' is present in the training set. An attacker can exploit this side channel to perform a strong targeted membership inference attack. Concretely, suppose the attacker wants to infer membership of some sample x and knows that some near-duplicates x' are in D_{train}. Then, the adversary can infer if x is in D_{train} by detecting whether the duplicates x' were deleted or not. Compared to a standard membership inference attack on the targeted point x, this side channel amplifies the privacy leakage if the duplicates x' known to the adversary are more likely to be memorized than the original data point.

3.1.1 Our Attack

We operate in the same threat model as Tramèr et al. [77]: the attacker can *poison* a small fraction of the dataset to leak information about other data points. In our case, the adversary poisons the training set by inserting *duplicates* x' of a targeted data point x. We assume the attacker has black-box query access to the trained model f and they know the data deduplication procedure that is used.

We focus on classification tasks with labeled data (x, y) and extend our attack to language modeling in Section 3.1.5. We assume that deduplication is independent of a sample's label, i.e., two points (x, y) and (x', y') are duplicates if x is close to x', even if $y \neq y'$. As in Tramèr et al. [77], we assume the attacker can introduce mislabeled data points into the training set. This assumption could be relaxed in some settings by considering clean-label poisoning attacks [70]. We further assume that the model is trained on all (deduplicated) data (i.e., there is no data subsampling step).

We propose attacks for the four forms of deduplication that we introduced above:

- *Exact deduplication, delete all*: Given a target (x, y), we add a mislabeled duplicate (x, y') into the dataset. We then run *non-membership* inference on the mislabeled point: if

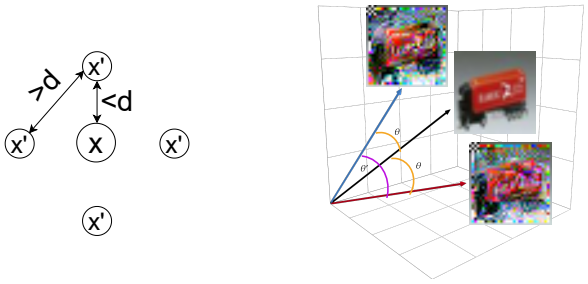

Figure 2: A depiction of our "hub-and-spokes" attack on data deduplication. **Left:** we insert poisoned examples that are each close to the "hub" (x) but are far from each other. **Right:** actual images from our attack. We also include a checkerboard backdoor in the top-left corner of each near-duplicate image to enhance memorization.

this point is absent, we know that the target was present before deduplication. This attack only requires inserting a single poison example.

- *Exact deduplication, delete all-but-one*: In this setting we still use the same attack as above, but the attack is less powerful: when the target is a member, the poisoned duplicate only gets removed with 50% chance. This attack also only requires inserting a single poison example.
- *Approximate deduplication, delete all-but-one*: This is the most complex and interesting attack setting. We create N approximate duplicates $(x'_1, y'), \ldots, (x'_N, y')$ in a "hub-and-spoke" pattern (described further below and illustrated in Figure 2). This causes the attacker's points to be near-duplicates of the target, i.e., $\mathsf{sim}(x, x'_i) \geq \alpha$ for all i, but not of each other, i.e., $\mathsf{sim}(x'_i, x'_j) < \alpha$ for all $i \neq j$. The attacker then runs a non-membership inference attack across *all* N poisoned samples x'_i. In this way, the attack becomes stronger as the attacker introduces more poison examples.
- *Approximate deduplication, delete all*: We repeat the same approximate deduplication attack, but the attack is stronger as all examples are removed.

We observe that the side-channel cannot be trivially removed via dataset pre-processing. Manual filtering is too impractical for modern, large datasets, and automated filtering would not be able to remove the side-channel: a filter removing equal samples with differing labels would lead to a scenario equivalent to the *delete all-but-one* deduplication described above. Also randomly subsampling the training data would not be enough to defend from our attack against approximate deduplication with multiple poisons (even though it might be slightly weaker). However, the attack with a single duplicate may fail.

Generating approximate duplicates. In our experiments, we use a standard approximate deduplication procedure based on the cosine similarity between the embeddings $h(x), h(x')$ of two samples, where h is a neural network. Assuming that h outputs embeddings of unit norm in $\mathbb{R}^d$, we have $\mathsf{sim}(x, x') := h(x) \cdot h(x')$. We thus want to find duplicates $x'_1, \ldots, x'_N$ of a target x such that $h(x) \cdot h(x'_i) \geq \alpha$ for all i, and $h(x'_i) \cdot h(x'_j) < \alpha$ for all $i \neq j$. To find approximate duplicates, we first compute embeddings that satisfy the above condition, and then "invert" the embedding function h to find input images.

Assume without loss of generality that the target embedding $h(x)$ is the first basis vector in $\mathbb{R}^d$, i.e., $h(x) := (1, 0, \ldots, 0)$ (for a general unit-norm embedding $h(x)$, we simply have to apply an appropriate rotation to all vectors). We now build $d-1$ unit vectors $e_1, \ldots, e_{d-1}$ of the form

$$e_i := (\alpha, \underbrace{0, \ldots, 0}_{i-1}, \sqrt{1-\alpha^2}, 0, \ldots, 0) .$$

This ensures that: (1) all the embeddings e_i are of unit norm; (2) the cosine similarity between each embedding e_i and the target $h(x)$ is α; (3) the cosine similarity between each pair of near-duplicate embeddings is $\alpha^2 < \alpha$. Given these embeddings $e_1, \ldots, e_N$, we invert the embedding function h by running 1000 steps of projected gradient descent. That is, we optimize the input image x'_i so as to maximize the cosine similarity between $h(x'_i)$ and e_i.

To further maximize the membership inference signal, we make the mislabeled near-duplicates (x'_i, y') to be as easy to memorize as possible. We achieve this by adding a common backdoor feature to all near-duplicates (a checkerboard pattern as in Gu et al. [32]). In the extended version of this paper [25, Appendix A] we show that including this backdoor pattern significantly strengthens our attack. In Fig. 2, we present an example depiction of our approximate duplicate attack.

Non-membership inference attack. After poisoning, we adapt the LiRA method [16] to run membership inference. In particular, we train "shadow models" that either contain, or do not contain, the attacker's poisoned duplicates. We query all the shadow models to obtain the models' confidences on the duplicates' poisoned label, and then fit two multivariate Gaussians (one when the duplicates are members and one when they are not) on the model's confidence on each duplicate.

For the final attack, we query the target model f on each duplicate to obtain the confidence in the poisoned label, and then perform a Gaussian likelihood ratio test to determine whether the duplicates are likely to be members of the deduplicated data. If the duplicates are predicted as non-members of the deduplicated data, then we predict that the target example x was in the original training set.

3.1.2 Evaluation

We evaluate our attacks on standard models trained on CIFAR-10 and deduplicate the images using the popular open-source imagededup Python library. We use the library's default settings, which compares images by the cosine similarity of their embeddings computed from a pretrained MobileNetV3

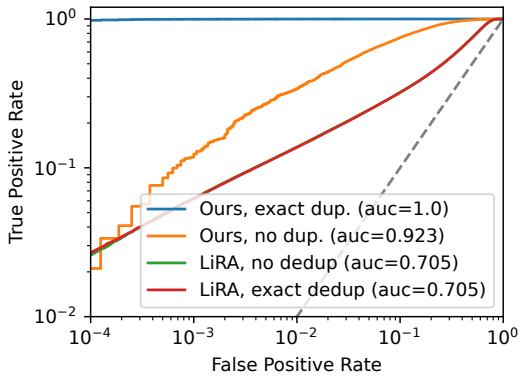

Figure 3: **Deduplication can significantly worsen privacy.** We show membership inference effectiveness under both exact deduplication (*delete all*) and no deduplication. With deduplication, the side-channel leads to near-perfect membership inference; without, it is similar to the baseline poisoning-aware Truth Serum attack [77]. The LiRA baseline [16] performs similarly in both cases.

model [36]. Two images are considered duplicates if the similarity is at least $\alpha = 0.9$.

We choose 250 targets at random from the CIFAR-10 training set and create between 1 and 8 exact- or near-duplicates per target. We build the training set D_{train} by randomly sampling 50% of the CIFAR-10 training set and adding the duplicates. We train the models for 100 epochs.

Following Carlini et al. [16], we evaluate the success rate of the membership inference attack by its true-positive rate (TPR) at a low false-positive rate (FPR). As baselines, we consider their original LiRA attack as well as the attack of Tramèr et al. [77] that combines LiRA with data poisoning (similar to our attack, but not leveraging the side-channel).

3.1.3 Results

Deduplication creates a strong side channel that enables near-perfect membership inference. In Fig. 3, we compare membership inference attacks against models trained with and without delete-all, exact data deduplication. On deduplicated data, our attack achieves essentially perfect targeted membership inference, with a TPR of 98% at a FPR of 0.01%. When data deduplication is not applied, our attack still outperforms LiRA because of the amplification that poisoning has on membership inference, as shown by Tramèr et al. [77].

In Table 1, we provide a more comprehensive comparison between our attack and the prior state-of-the-art attack (Truth Serum [77]) under different deduplication settings. Although both attacks leverage poisoning by introducing mislabeled samples, only ours explicitly exploits the deduplication side-channel. For the single poison case, both our attack and Truth Serum add a mislabeled copy of the target to the training set. However, our attack differs in how we perform inference: we perform *non-membership inference* on the *mislabeled* duplicate, while Truth Serum performs membership inference on the correctly labeled target sample. The latter is sub-optimal when deduplication is applied, since the correctly labeled target is *never* in the training set. In the *delete all* deduplication setting, this change boosts the attack's TPR to near 100%.

Table 1: **Our attacks improve prior privacy-poisoning attacks.** We report the TPR at a FPR of 0.1% and 0.01%, and we compare our attacks against Truth Serum [77] and LiRA [16] under different deduplication strategies. In parentheses, we report the number of poisons injected.

		TPR	
Deduplication	Attack	@ 0.1% FPR	@ 0.01% FPR
None	LiRA	6.2%	2.6%
	Truth Serum (1)	18.0%	4.0%
	Truth Serum (8)	**30.5%**	**6.3%**
Exact or Approx *delete all*	LiRA	6.2%	2.7%
	Truth Serum (1)	89.8%	79.3%
	Truth Serum (>1)	0.1%	0.0%
	Ours (1)	**99.6%**	**98.0%**
Exact *delete all-but-one*	LiRA	6.2%	2.7%
	Truth Serum (1)	41.6%	31.8%
	Truth Serum (>1)	3.1%	1.1%
	Ours (1)	**45.6%**	**40.9%**
Approximate *delete all-but-one*	LiRA	6.5%	2.9%
	Truth Serum (>1)	0.1%	0.0%
	Ours (8)	**96.0%**	**90.4%**

In the *delete all-but-one* setting, our attack has lower overall TPR (but still outperforms Truth Serum) due to the possibility that one of the poisons survives deduplication even when the target is a member. With approximate deduplication, our hub-and-spoke attack design with 8 duplicates doubles the attack's TPR compared to using a single poison. Note that in contrast to our attack, running Truth Serum with >1 poisons completely breaks the attack when deduplication is applied. This is because Truth Serum's poisons are all exact (mislabeled) copies of the target, and thus, deduplication removes the poisons regardless of whether the target is in the training set or not. Our attack sidesteps this issue by ensuring that the attacker's poisons are near-duplicates of the target, but *not* near-duplicates of each other.

3.1.4 Dealing with Attacker Uncertainty

In practice, an attacker might not know exactly which deduplication method is being used, or with which hyperparameters (for approximate deduplication). Here, we show that an attacker can still implement a successful attack in such a case.

Unknown deduplication method. In this case, the attacker should apply our attack that adds one mislabeled exact duplicate. Note that this attack is assumption-free: it requires no knowledge of the deduplication approach that is used. This strategy is optimal for three-out-of-four deduplication settings: Exact *delete all*, Approx *delete all*, Exact *delete all-but-one*. The one setting where this attack is not optimal is

for the Approx *delete all-but-one* setting. However, in this case the attack with one mislabeled exact duplicate still outperforms Truth Serum, the prior state-of-the-art (the results are the same as for the Exact *delete all-but-one* setting, where our attack has a 9% higher TPR @ 0.01% FPR compared to Truth Serum, as shown in Table 1).

The attacker knows Approx *delete all-but-one* is used. If the adversary knows that the system is using Approx *delete all-but-one* deduplication, and they can guess the α reasonably well, then they can improve over the assumption-free attack above. If the attacker's guess for α is close to correct, the attack is near-perfect (96.0% TPR @ 0.1% FPR) by adding eight approximate duplicates. Specifically, the attacker's guess must satisfy $\alpha_{guess}^2 < \alpha_{real} \leq \alpha_{guess}$. If the attacker's guess does not satisfy the above, or if the deduplication method is not actually Approx *delete all-but-one*, the attack fails. Thus, if the attacker is not confident they can guess α correctly, or they are uncertain if Approx *delete all-but-one* is used, they should just use the assumption-free attack above, and still outperform Truth Serum.

How can the adversary guess α?. The adversary can estimate α by computing a TPR-FPR curve over a sample of training data. We estimate that α is unlikely to be smaller than 0.8 in practice as this would yield too many false positives, and reduce the size of the training set. Moreover, the attacker does not need to guess α *exactly*. Even if the guess is off by $\pm 2\%$, most of the poisons will survive the deduplication process, as shown in Figure 4. Crucially, this rules out α randomization as a potential defense against our attack. Finally, if the same deduplication method is reused multiple times, the attacker can recover the real alpha value by adding dummy near-duplicates with different similarities. Thus, if a developer collects multiple training sets over time and keeps the same deduplication process, the attacker can learn the parameters once and then use this to reliably attack future training runs.

3.1.5 Extension to the Text Domain

While we have focused on classification tasks so far, our attack techniques can easily be extended to other tasks such as language modeling. Text data is commonly deduplicated by finding and removing substrings of k tokens that are exactly repeated across documents [47]. We show this method creates a side channel that enables a powerful *attribute inference attack* (a more powerful attack than membership inference). Specifically, we show that the attacker can infer a low-arity attribute (e.g., a medical condition) contained within a known piece of training data (e.g., a template of a healthcare form). For simplicity of exposition, we assume the unknown attribute is a single token, but our attack could be generalized to longer attributes. We assume the training set contains a sentence of the form

$$\underbrace{S_1,\ldots,S_{k-1}}_{\text{pre}}\ \underline{X}\ \underbrace{S_{k+1},\ldots,S_{2k-1}}_{\text{post}},$$

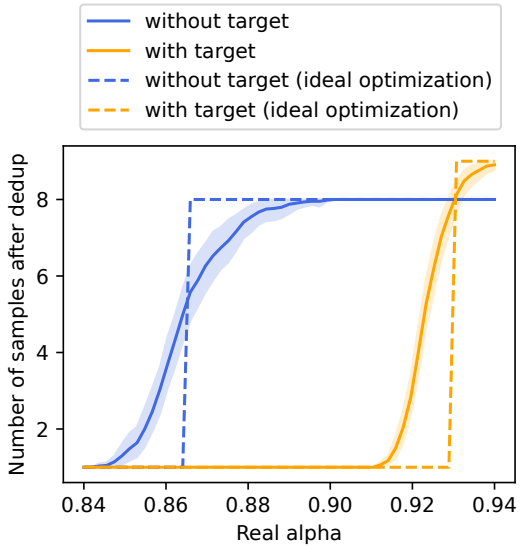

Figure 4: **Our attack is robust to uncertainty in the deduplication threshold α.** We create approximate duplicates by optimizing for the poisons to be less than α^2-similar to each other, and more than α-similar to the target. We show that, within a $\pm 2\%$ range, six duplicates are kept on average when the target sample is not a member–with only one sample being kept when the target sample is a member.

where pre and post are a prefix and suffix of lengths $k-1$ known to the attacker, and $\underline{X}$ is an unknown token that comes from a set of N possible values $\{\mathsf{X}_1,\ldots,\mathsf{X}_N\}$. The attacker's goal is to infer the value of $\underline{X}$.

Our attack. At a high level, our attack creates N families of poison strings (with k poison strings per family), and where each family's strings contains some "canary" substring that is deduplicated if and only if the true value of the unknown attribute is X_i. Then, by running an inference attack to detect the presence of these canary substrings, the attacker can infer which attribute value is correct.

More concretely, we build the i-th family by choosing some unique strings A_i, B_i (each of length less than k) and building k strings of the form:

$$\begin{aligned}
&A_i + S_1 S_2 S_3 \ldots S_{k-1}\ \mathsf{X}_i && + B_i\\
&A_i + \quad S_2 S_3 \ldots S_{k-1}\ \mathsf{X}_i\ S_{k+1} && + B_i\\
&A_i + \quad\ \ S_3 \ldots S_{k-1}\ \mathsf{X}_i\ S_{k+1} S_{k+2} && + B_i\\
&\qquad\qquad\qquad \ddots\\
&A_i + \qquad\qquad\ \mathsf{X}_i\ S_{k+1} \ldots S_{2k-1} && + B_i\,.
\end{aligned}$$

Our construction ensures that: (1) none of the adversary's $N \cdot k$ poison strings contain a duplicated substring of length k; (2) if the i-th family of poison strings has the correct value of the unknown attribute $\underline{X}$, all strings in the family are deduplicated to the string $A_i + B_i$ (we assume $A_i + B_i$ to be shorter than k so that it is not deduplicated recursively).

Once the language model has been trained on deduplicated data, the adversary can compute the model's loss on each of the N strings $A_i + B_i$. The string with the lowest loss likely corresponds to the index of the unknown attribute, as these strings only appear contiguously in the training set if deduplication has occurred.

3.1.6 Deduplication Is Still Worth It in Practice

Deduplication is a cornerstone in mitigating memorization in deployed ML models trained on web-scale datasets [42, 47]. Moreover, differentially private training is only effective on deduplicated data (or else privacy leakage scales exponentially with the number of duplicates). However, if deduplication can induce *new* privacy violations as we show above, should practitioners still apply it? We argue yes, because the empirical cost of *not* doing so is just too high—the privacy risks of duplicated data are far too egregious. This highlights an unfortunate trade-off, where the best practice of using deduplication will be vulnerable to adversarial attacks, and we thus hope that new techniques can be developed to deduplicate datasets without aggravating privacy leakages.

3.2 Attacking Poisoning Defenses

We next look at a broader class of data filtering techniques that aim to protect against poisoning attacks [7]. Poisoning attacks introduce malicious behavior into a model, often by adding many samples that share a common feature (e.g., a backdoor [21]). Defenses against poisoning often work by removing examples based on their relationships to other examples and thus they create "codependencies" that can be targeted to leak information.

3.2.1 Poisoning Defenses

Defenses against poisoning attacks find and remove clusters of points that are part of a presumed attack. Many defenses end up performing some form of data deduplication and are thus vulnerable to a similar side channel as presented in the previous section.

As a straightforward example, Carlini [13] propose a defense against data poisoning that detects poisoned samples and also occasionally flags near-duplicates (as false-positives). Thus, deploying this defense would immediately create the exact same privacy side-channel as described in the previous section.

Alternatively, Sybil filtering [4, 29, 56] is a common countermeasure to prevent colluding adversaries from poisoning a federated learning (FL) model [50]. Most implementations of Sybil filtering downscale or remove a client's model updates if they are too similar to another client's updates. The defense's intuition is that colluding clients performing a poisoning attack are likely to contribute very similar updates, while benign clients' updates are likely to be diverse due to the *non-iid* nature of their datasets. This defense essentially deduplicates at the model-update level rather than at the training-example level.

Finally, in the extended version of this paper [25, Appendix A], we discuss another related poisoning defense, *activation clustering* [19] that is also vulnerable to similar side channels.

The side channel. The attacker introduces malicious samples so that the poisoning defense is triggered if and only if some target is present. This yields a membership inference side channel. Depending on the defense, this side channel can leak information about individual training samples or collections of samples (e.g., in the FL case when models updates represent information about a batch of examples).

3.2.2 Our Attack

For the semi-supervised poisoning defense of Carlini [13], the attack is exactly the same as for general data deduplication, so we do not discuss it further. We thus focus on Sybil filtering in FL, which introduces some notable differences into the attack since the defense operates over model updates instead of individual samples.

We assume a threat model where the attacker controls one FL client and knows the defense mechanism being used. The attacker's goal is to infer if some target client is participating in the protocol (i.e., client membership inference). We assume the attacker knows the target client's data distribution (e.g., if we are training a model on people's photos, then the attacker has some public photos of the target client). We do not assume that the attacker's data and the target's data overlap—only that they are similarly distributed.

We consider a canonical defense called FoolsGold [29], which dynamically modifies the learning rate of individual clients based on the similarity of their updates over time. To compare the updates of two clients, the defense aggregates each client's history of updates and then computes the cosine similarity between these aggregates. A "Sybil" score between 0 and 1 is then computed for each client—based on the maximum similarity with another client—and this score is used to adjust the contribution of that client's model updates.

Our attack adds a malicious client into the training pool, with the aim of producing model updates that are similar to those produced by the target (if present). The attacker then performs membership inference based on the model's loss on the *attacker's* (not victim's) data: if the target client is not participating in the protocol, FoolsGold will not downscale the attacker's updates and so the loss will decrease across epochs; conversely, if the target is present, the attacker's and target's updates are both downscaled and so the loss *will not decrease*. The attacker thus measures the model's loss on the attacker's dataset before and after participating in he FL protocol to determine if the target is present.

Figure 5: **When federated learning is combined with defenses against data poisoning, a side-channel is opened that worsens privacy.** We run the FoolsGold defense and insert a poisoning client into the learning protocol (denoted by the red vertical line). When a target client of interest is present in the data, both that client and the poisoning client will effectively not contribute to the learning (top of Figure). When the target is not present (bottom of Figure), the learning on the poisoning client continues as normal. This enables a strong membership inference attack.

3.2.3 Evaluation

We experiment with a non-iid setup that simulates a natural FL deployment to train an image classifier on pictures from each user's local device. We use the Labeled Faces in the Wild [38] (LFW) dataset, restricting the classification task to the 5 identities with over 100 pictures, and generate 5 clients each with 90 training images. To enforce the non-iid setup, we sample a majority (80%) of images from a single identity for each client and then fill the remainder with images sampled from other classes according to a Dirichlet distribution ($\alpha = 1$). We train a ResNet-18 [34] using the official FoolsGold implementation.[3] The malicious client joins the protocol at round 20; their dataset is composed of 50 non-overlapping images from the target client's identity. This ensures that its updates will be similar to the targeted client and different from others. We run experiments with two target classes (0 and 2) and repeat each experiment 10 times with different random seeds.

3.2.4 Results

Figure 5 validates the susceptibility of FoolsGold to our side-channel attack. As predicted, the model's loss on the attacker's dataset only decreases when the target is not present. By using the difference in average loss for 15 rounds before and after the attacker participated, we achieve 85% accuracy (averaged over 10 experiments) in identifying whether the target client was in the training pool.

Without the side channel, the adversary would need to make a membership guess based solely on the model's loss on the attacker's data. A common approach from the literature would be to train shadow models. However, this is difficult in an FL setting as the attacker would need to know the data distribution of *all* clients (not just the target), and perform multiple expensive simulations of the entire FL run. We simulate such a strong adversary by taking the 10 different runs of our experiment, and setting the loss threshold directly as the difference between the model's average loss when the target is participating, or not. We find that even such a strong adversary only achieves 67.5% accuracy in guessing the presence of the target, without relying on our side channel.

4 Attacking Input and Output Filters

Here, we consider how filters applied to a model's inputs or outputs can enable powerful membership inference attacks. In fact, these membership inference attacks will be so strong (essentially perfect) that we can convert them into *data extraction attacks* that even allow extraction of OpenSSH private keys contained in a language model's training set.

A common theme of this section is that ML system filters make it *impossible* for the system to produce certain outputs, depending on the training data. The attacker can then make some guess about an input in the training set, and craft a query that would trigger an impossible output if the guess were correct. This yields a perfect *non-membership* inference attack: if the model produces the impossible output, the attacker knows their guess is incorrect. We then introduce various approaches to lift the attack into a strong (or even perfect) membership inference attack. This attack strategy is reminiscent of impossible differential cryptanalysis [9, 43], where an attacker's guess about the internal state of a cryptosystem can be ruled out if certain statistical output properties are observed.

Background: language models. Large language models (LLMs) are neural networks that take as input a sequence of text of variable length and predict a probability distribution over the next word (or token, see below) in the sequence. While early language models represented text as a sequence of characters or words [52], all recent language models use a more compact representation that splits arbitrary text into *tokens* that represent entire words, sub-words, or characters. The set of all tokens is called the *vocabulary*.

When applied to an input sequence of tokens $t_1, t_2, \ldots, t_n$, a LLM predicts a probability distribution $\Pr[t|t_1, t_2, \ldots, t_n]$ for the value of the next token in the sequence. To generate text, the model is applied repeatedly to its own output, using a particular *decoding* strategy. In the simplest case of greedy decoding, we repeatedly sample the most likely token given the current input sequence and append this token to the input.

[3] https://github.com/DistributedML/FoolsGold

4.1 Extracting Vocabularies of Language Models

We first show how to use the input filtering stage of language models as a side channel.

Background: Byte-pair encoding. The inputs to modern language models are preprocessed into a series of sub-words (i.e., tokens) and truncated to a maximum context window size. The set of tokens (i.e., the model's vocabulary) is determined by running an algorithm such as byte pair encoding over the training data [69]. At the time of submission, Byte-pair encoding is the standard tokenization algorithm used in all modern large language models. A model's vocabulary can reveal sensitive details of its training data, e.g., the GPT-2 tokenizer [62] contains tokens that represent individuals' Reddit usernames [66]. While this is not a privacy issue in the case of tokenizers trained on public data (like GPT-2's), this may become a concern if a tokenizer is trained or adapted on private data with an unusual vocabulary, e.g., medical records. Finally, many systems such as the Claude chatbot [3] have their tokenizer kept secret.

The side channel. Here, we show that truncating inputs to a fixed size window allows adversaries to extract the entire vocabulary of any model. In particular, consider a sequence such as "My favorite color is red. My favorite color is". Here, most language models will predict the word "red" as the continuation. However, if some padding text of $\geq N$ tokens is added, e.g., "My favorite color is red. PADDING My favorite color is", the model will not be able to see the word "red" for long padding sequences. This allows one to determine how many tokens the padding sequence occupies in the model's input.

4.1.1 Extracting the Complete Vocabulary

In particular, under the byte-pair encoding algorithm, it is guaranteed that any token can be recursively split into two sub-tokens until the final sub-tokens are only one byte. Our attack will leverage this in reverse, where we initialize our extracted vocabulary V to all of the single bytes and recursively expand it. Concretely, for all pairs of tokens $(u,v) \in V \times V$, we query the model on the sentence:

$$\text{"My favorite color is red. } \underbrace{u||v\ u||v\ \ldots\ u||v}_{3N/4 \text{ times}} \text{ My favorite color is"}$$

where $||$ denotes concatenation. Suppose that $u||v$ actually *is* a single token in the vocabulary. Then the number of padding tokens inserted between the question and answer would be just $3N/4$ and the model would respond with "red". In this case we insert the new token $V \leftarrow V \cup \{u||v\}$. On the other hand, if $u||v$ was represented instead by two tokens, then the number of padding tokens would be $3N/2 > N$ and the model will not answer "red".

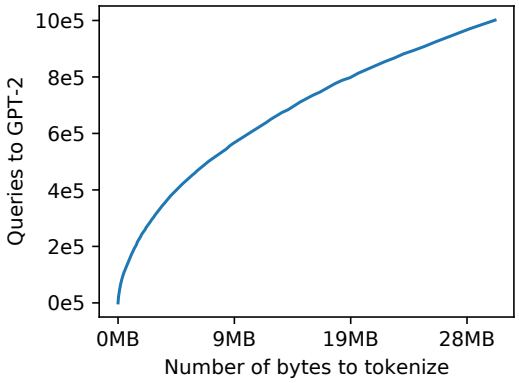

Figure 6: **We extract the tokenizer for GPT-2 on specific byte strings from Wikipedia.** Our attack leverages a side channel based on the fact that language models use of a fixed context window.

Attack complexity. After T iterations of this attack, we will recover all tokens of length less than T. Extracting the entire vocabulary will require $O(|V|^T)$ total queries.

Results. Our attack is empirically effective at recovering the entire GPT-2 vocabulary. In the extended version of this paper [25, Appendix A], Table 3 lists example of tokens that we extract, including rare substrings such as "RandomRedditorWithNo", "TheNitromeFan", and "SolidGoldMagikarp". Thes strings are usernames of Reddit users that were likely repeated frequently in the GPT-2 training dataset.The attack requires 819,869,857 queries.

4.1.2 Targeted Vocabulary Extraction

We also can use this attack to efficiently extract the tokenization for a specific word or phrase. Such an attack may be useful for (1) generating adversarial examples, where it may be useful to know the tokenization of a particular string, or (2) determining if a model uses another model's tokenizer, e.g., for licensing or reverse engineering purposes.

To use the above algorithm for a particular string such as "hello" and "world", we can simply check if "he", "el", "ll", etc. are tokens and would not need to check if "ho", "wl", "ol", etc. are tokens.

Results. In Figure 6 we measure the efficacy of this restricted attack by reporting the number of queries necessary to determine how GPT-2 would tokenize the first N bytes of the enwiki8 dataset (a subset of Wikipedia). On average we find it requires roughly 30,000 queries per megabyte, diminishing as we increase the number of bytes to tokenize.

4.2 Attacking Memorization Filters

We next show how filters applied to LM outputs can also enable aggravated privacy violations.

Background: memorization-free decoding. LLMs are known to memorize—and output—sequences from their training dataset [15]. Thus, popular production LLM systems such as GitHub's Copilot use filters that block outputs that match their training data. In this way, models are guaranteed to *never* emit a verbatim sequence from their training dataset.

Ippolito *et al.* [40] formalize this as *memorization-free decoding*. Memorization-free decoding adds a filter that runs on-line with the language model and, before emitting the next token, checks if this causes a k-gram match to a sequence in the training dataset (using an efficient Bloom filter lookup). If so, this token is replaced with the most-likely non-memorized token instead. While such filters are imperfect (for example they do not prevent the model from outputting similar yet not verbatim copies of training data), they are an efficient and practical defense that reduces the likelihood of data copying.

The side channel. We show that applying any form of memorization-free decoding introduces a significant privacy vulnerability: if a language model *ever* generates any particular k-gram, we are *guaranteed* it was not part of the training data. This gives us a perfect *non*-membership inference attack (i.e., a 100% true negative rate at a 0% false negative rate). Next, we will show how to convert this into a strong *membership inference attack*.

4.2.1 Our Attacks

We propose two different ways of extending the above non-membership inference attack to a near-perfect *true positive rate*, thereby obtaining a near-perfect *membership inference attack*.

Perfect membership inference for toggleable filters. To begin, we first develop a simple counterfactual-based approach for the special case where the memorization filter can be *disabled*. Indeed, some models, such as GitHub's Copilot model, allow the user to **choose** to block the recitation of training data. This gives the adversary the ability to perform a perfect counterfactual analysis.

Concretely, assume the adversary wants to perform (positive) membership inference on the sequence t. We begin by *disabling* the memorization filter and, for each prefix p_i of t, query the model on p_i yielding a predicted suffix s_i. For each of these, we check if $p_i||s_i$ is a prefix of t.

If none of the generations have this property then the attack is inconclusive. However, if we identify *any* index i for which $p_i||s_i$ is a prefix of t, we can *enable* the memorization filter, and again prompt the model with p_i. If the suffix with the filter turned on is equal to the original suffix s_i, then the sequence *cannot* have been in the training dataset—if it was, the filter would have blocked it. On the other hand, if the suffixes are not equal then we know with 100% certainty that the sequence *was* in the training dataset.

Membership inference with a permanent filter. Some models contain memorization filters that are permanently applied, which prevents our straightforward counterfactual approach. The challenge with such a filter is that if a model fails to output some suffix, this could be due to one of two reasons: (1) either the filter was triggered (i.e., the sequence is in the training set); or the model simply assigns a low likelihood to this suffix.

To reduce the likelihood of the latter event, we propose to *encourage* the model to emit the desired string, by exploiting the in-context learning abilities of language models. For example, lets say we want to detect if the sequence "ABCD" is in the training set, and when we prompt the model with "ABC" it fails to output the letter "D". This is either because the memorization filter was triggered, or because the model simply assigns low probability to the completion "D" in this context. To disambiguate these two cases, we prompt the model with the sequence "ABCD ABCD ABCD ABC", where we repeat the targeted completion many times. Empirically, this guarantees that any powerful language model will output the completion "D" (as it is the most likely completion in the given context). Now, if the model *still* fails to output "D", we can assume with high confidence that the memorization filter has been triggered. More formally, we split the target string t into a prefix p_i and suffix s_i, prompt the model on the string $p_i||s_i||p_i||s_i||\ldots||p_i$, and then check if the output is s_i.

4.2.2 Estimating Copilot's Training Date Cutoff

We now describe an application of the toggleable filter side-channel attack to perform membership inference on GitHub Copilot, a popular public coding assistant. Concretely, Copilot uses a toggleable memorization filter that we exploit to determine the date on which GitHub scraped the model's training data. The details of Copilot's memorization filter are not public, and in practice we found that it likely performs approximate filtering based on fuzzy matching between outputs and training data. Nevertheless, we can run our attack as if it was an ideal filter and accept that this could incur false positives (approximate filtering does not cause false negatives).

To evaluate our attack, we choose a popular GitHub repository, `tqdm`, and randomly sample some of the project's commits in which code was introduced that is still present in the most recent revision of the project. We then run our membership inference attack on each of these commits and in Figure 7 we plot the fraction of commits our attack predicted were *not* in the training set.

There are several false positives from before October 2021, but for all commits made after that date, Copilot can generate the code with the filter on. This indicates that they are not members in the training data, and we can infer that October 2021 is likely the date at Copilot's data was last collected. This date is exactly the same date at which other OpenAI models' training data was collected (e.g., `text-davinci-003`),

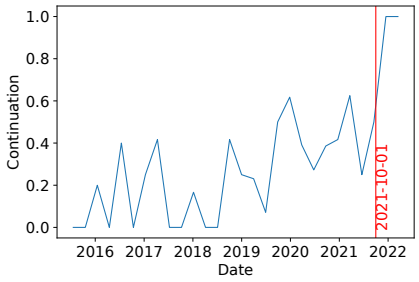

Figure 7: **GitHub Copilot's memorization filter leaks membership information.** The system blocks outputs that are similar to the training data and thus reveals which code was used for training. In particular, we examine code commits that are added to a popular GitHub repository over time and plot the fraction of commits that our attack flags as non-members. There is a noticeable increase in October 2021, which reveals when the training data was last collected.

further confirming this result.

Note that our attack shows that Copilot can generate code for all commits after October 2021 even while the filter is on. The attack does therefore not depend on the filter being toggleable. While in Section 4.2.1 we give a baseline example of how an attack would work if the filter can be toggled, our full attack does not need this assumption. We choose `tqdm` as a target because it is a popular library with frequent commits, hence providing high resolution for our experiment. However, our attack still works with less popular repositories with less frequent commits. Finally, we attack Copilot's memorization filter as it is the only widely deployed filter we are aware of that matches the whole training corpus. Moreover, since the training data is already public, this experiment poses minimal risk. However, since we have shown a successful attack against a filter with unknown implementation details, we believe our attack should be generally applicable to other systems with a memorization filter.

4.2.3 From Output Filtering to Data Extraction

Finally, we extend our attack to perform a data *extraction* attack that can recover complete documents from the training set token-by-token. We focus on the permanent memorization filter case, and we assume the attacker knows a substring of the text that they wish to extract from the training set.[4] For example, to extract an RSA key the prefix could be "BEGIN OPENSSH PRIVATE KEY".

Given this prefix p of a training document, a perfect membership inference attack makes it trivial to extend the sequence by one token: enumerate all possible tokens s that may occur next and for each token run the attack on $p||s$. In practice, the attack may have false positives and thus identify several next-token candidates s_j^*. These false positives occur when the language model fails to emit a token that was not in the training set even when it is coerced to do so. In these cases, we explore each next-token candidate in a depth-first manner. If a candidate was incorrect, it will simply reach a state where there is no valid next token and terminate.

[4] We assume the substring is a prefix, but one can extend the attack to work with a known suffix by running membership inference attack on $s||p$.

Table 2: **We can use an output filter side-channel to extract hundreds of secret OpenSSH private keys.** We use GPT-Neo language models with a permanent memorization filter and apply our membership inference approach to iteratively extract single tokens from the training set.

Model	Success Rate	Mean Queries
GPT-Neo 125M	90.3%	376,000
GPT-Neo 1.3B	90.0%	338,000
GPT-Neo 2.7B	89.8%	344,000

Extracting RSA private keys. As a proof of concept, we consider the hypothetical case that GPT-Neo [10] (a family of language models similar to GPT-3) has a memorization filter and was trained on files containing some unknown RSA secret keys. To instantiate the memorization filter, we build a Bloom filter containing all 20-token sequences in the GPT-Neo training dataset and prevent the model from ever emitting these sequences. To simulate training on private keys, we add 1,000 different OpenSSH private keys to the Bloom filter, each of which are 512 base-64 encoded bytes.

Using this setup, we found that our membership inference attack achieves over 99.9% accuracy at predicting whether a next-token candidate is in the training set. However, this is still not enough for accurate data extraction as there are over 10,000 possible next tokens in Base64 output and we want to extract text that contains many such tokens.

To further enhance the attack, we count the frequency of each Base64-encoded token in a large 10TB dataset of random data. We then bias the search towards more common tokens, e.g., the Base64 token "Q" occurs much more frequently than "omanip" in practice (cfr Figure 9 in the extended version of this paper [25, Appendix A]). Using this approach, we query the model with the complete header ("BEGIN OPENSSH PRIVATE KEY") and run our attack. The attack extracts about 90% of the keys successfully and requires around 340,000 model queries (see Table 2).

5 Breaking Differentially Private Training

We next show how the side channels that we have introduced thus far can violate "provable" privacy guarantees when those guarantees are based on isolated ML models. Specifically, we show that standard differential privacy analysis fails when data filtering components are added.

Background: differentially private training. An ML algorithm is differentially private (DP) if the distribution over

possible trained models is close for any two neighboring training datasets that differ in a single example [1, 27]. A common paradigm to design DP algorithms is to estimate the algorithm's *sensitivity*—the maximum change in output from changing one input—and then adding random noise calibrated to that sensitivity. However, estimating the sensitivity of a full ML training pipeline is hard. Instead, the approach of the common algorithm DP-SGD [1] is to estimate the sensitivity of each training step and rely on DP's composition property to compute the model's final privacy budget ε.

The side channel. The theoretical analysis of DP-SGD does not consider additional components of the ML training pipeline such as filters applied before and after training. When these filters depend on the training data, they themselves have a non-zero sensitivity (i.e., changing one training example could change the filter's output). As a result, the total sensitivity of the system may be much larger than the sensitivity of the training algorithm in isolation. This means that an ML system trained with DP-SGD could *violate* the provable privacy guarantees that apply to an isolated model.

Warm-up: memorization filters have unbounded sensitivity. As a simple example, consider the memorization-free decoding filter (Section 4.2) that prevents the model from emitting training data. Its sensitivity is unbounded: the filter activates on a given output if and only if some training example matches it. It is thus obvious that training the model with DP-SGD does not prevent the side-channel attacks that we describe in Section 4.2.

Deduplication has large sensitivity. A less obvious example is the case of data deduplication (Section 3.1). One may expect that since deduplication empirically minimizes memorization, combining it with DP-SGD should lead to an extra layer of privacy protection. Indeed, prior work has even suggested this [60]. However, as our attacks in Section 3.1 show, deduplication can cause a single training example to influence whether many other examples get removed. In turn, the sensitivity of deduplication is quite large in practice.

Evaluation. We apply the side-channel attack from Section 3.1 to an ML system that first deduplicates the training set and then trains a model with DP-SGD. We use the CIFAR-10 dataset and pick one training sample at random as the target. We create 256 approximate duplicates of the target and add these to the training set. We then deduplicate the training set using the default `imagededup` settings as in Section 3.1. We train 128 models using DP-SGD on either the full dataset as described above, or a neighboring dataset with the target removed. Note that after deduplication, these initially-neighboring datasets now differ in 256 examples. We use the state-of-the-art differentially-private training approach from De et al. [24], with a batch size of 4096, augmentation multiplier of 16, and their settings for the noise multiplier and learning rate.

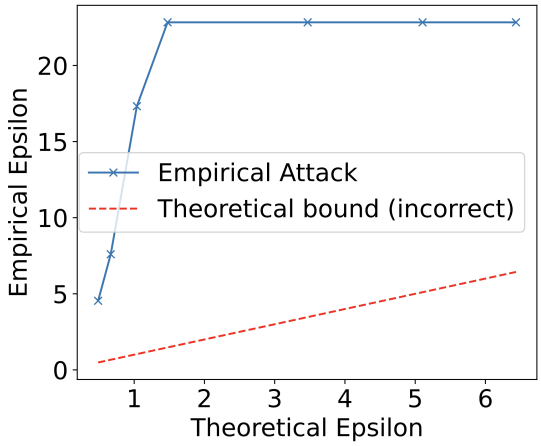

Figure 8: **Deduplication violates naive differential privacy analysis.** If we combine approximate deduplication with DP-SGD (as suggested in prior work), then a single example in the collected training data can affect multiple samples in the filtered training dataset that DP-SGD gets applied to. Deduplication thus effectively amplifies the sensitivity of the differentially private mechanism, leading to a severe underestimate of the true privacy loss of the end-to-end system.

We run DP-SGD multiple times with a target privacy budget $\varepsilon \in (0.5, 6)$ and set $\delta = 10^{-5}$. We then perform a membership inference attack on the adversarial duplicates (as described in in Section 3.1). We use the attack's FPR and TPR to estimate an empirical lower bound on the *true* value of the privacy budget ε for the entire ML system—following prior work on DP auditing [53, 55].

Results. The privacy analysis of DP-SGD severely underestimates the privacy leakage of the entire system (Figure 8). For example, when DP-SGD's theoretical bound on epsilon is respectively 1, 1.5, and 3, the actual privacy budget consumed by the system is *at least* 7.5, 17, and 22. Note this is not due to a mistake in DP-SGD's analysis or a bug in our implementation. Rather, it is because the privacy analysis is with respect to the dataset that DP-SGD is actually run on and not the system's "true" training set D_{train} that is collected prior to deduplication. Thus, computing a correct privacy guarantee for the entire system would require composing DP guarantees for both the deduplication step and the training process.

6 Leaking Test Queries From Query Filters

Thus far, we proposed side channel attacks that leak *training* examples. Here, we show that side channels can also allow adversaries to identify *test* queries made by arbitrary users. Worryingly, these attacks are otherwise impossible to launch when analyzing ML models in isolation.

Specifically, we focus on ML "query filters" that restrict or flag inputs in order to prevent attacks. These filters often guard against Sybil attacks (i.e., where an adversary uses multiple

accounts to conceal their attack) by aggregating queries across *all* users of the system. Here, we show that this introduces a side channel, where attackers can create special queries whose outputs reveal information about other users' queries.

6.1 Attacking Stateful Evasion Detectors

Background. In an evasion attack [8, 74], an attacker perturbs an example to cause a ML model to misclassify it. To generate these adversarial examples in a black-box setting, existing query-based attacks repeatedly query the target model [39]. Given the difficulty in outright defending against evasion attacks, recent work has developed *stateful* detection defenses [20, 48]. These defenses record every query (recently) issued to the system, and then ban a user (or take other defensive actions) if their query history appears malicious. Commonly, a sequence of queries is marked as malicious if the queries are close to one another under some similarity metric. As noted above, certain stateful evasion defenses also aggregate queries across users [48].

The side-channel. We target the method of Li et al. [48], the first defense that proposes to store a global history of fingerprints (a fuzzy hash) of each query. If the current user's query is similar to a previous query, an attack is detected and the filter will reject the query and all subsequent similar queries. In turn, this enables a side channel where one can check if another user has uploaded some query x by re-uploading the same query. If the system rejects the attacker's query, they know that a query very similar to x was likely previously uploaded.

Evaluation and results. We evaluate our attack on CIFAR-10. We create a set D_{test} of 1,000 images to simulate queries made by users and a held-out set $D_{\sim\text{test}}$ of 1,000 other images. We query the model on each image in D_{test} and $D_{\sim\text{test}}$ and predict which images were real queries (i.e., D_{test}). Our attack has perfect accuracy (100% TPR, 0% FPR): the defense rejects the attacker's query if and only if the image was previously queried. The only possible failure case for the attack is a false positive, which the defense is explicitly set up to minimize and is thus rare in practice. Overall, this side channel highlights the strong tension between security and privacy—if one uses a privacy-preserving defense that acts on a per-user basis, they cannot resist Sybil attacks.[5]

6.2 Extension to Stateful Extraction Detectors

Aside from black-box evasion attacks, stateful detectors also exist for model extraction attacks [59, 76]. In extraction attacks, adversaries make many queries to a black-box ML model in order to reverse-engineer a local copy with similar functionality. Existing stateful defenses against model extraction [41, 49, 58, 85] keep track of queries and search for examples that are highly similar to one another or are consecutively out-of-distribution. To date, no extraction methods aggregate across users and are thus all vulnerable to Sybil attacks. However, if they were generalized to use a global query log (as suggested in [48] for the PRADA defense in [41]), then they would become vulnerable to a similar privacy side channel as we described in Section 6.1.

6.3 Extension to Retrieval-based Text Detection

Finally, similar side channel attacks exist for retrieval-based text detectors [46]. Here, the goal is to test whether some generation y was produced by a particular language model. Krishna et al. [46] approach this by recording each output from a language model and then checking whether any text similar to y was previously generated by the model. Unfortunately, such methods allow adversaries to check if some output was produced as a response to another user's query, as acknowledged by [46].

7 Conclusion

In this work, we showed that real-world ML systems can have drastically worse privacy than is otherwise suggested by typical standalone privacy analyses. In particular, we showed how adaptive adversaries can use black-box or white-box system knowledge to exploit side channels in popular ML components. Taken together, these attacks contribute to a rethinking of how practitioners should measure and mitigate privacy risks for state-of-the-art ML systems.

Perhaps most surprisingly, it is actually the introduction of components that are *intended to improve privacy* (i.e., data deduplication and memorization-free decoding) that leads to side-channels that cause privacy violations. Similarly, methods designed to protect against other forms of adversarial attacks (e.g., data poisoning and evasion attacks) can also backfire and induce privacy violations at elevated rates. These findings highlight the inherent tensions between security and privacy, and how improving privacy in the average case can have adverse effects when faced with worst-case adversaries.

Moving forward, there are numerous rich areas for future work in the space of system-level analyses of ML systems. In particular, while we focus specifically on privacy side-channels, our work hints at the possibility that other side-channels may exist for different types of attacks and threat models. Moreover, our work highlights open problems in ensuring privacy-preserving ML, such as how to enforce differential privacy when composing hard-to-analyze ML modules such as filters or anomaly detectors. We hope to tackle these and other challenges in future work.

[5] Note that it may be possible to improve the defense. For example, instead of filtering a query when it is similar to *one* prior query, the defender could pick a random threshold T on the number of similar past queries. We leave an exploration of this to future work.

Author Contributions

- Nicholas and Florian proposed the problem statement of side-channel leakage in ML system components.
- Florian proposed the side channels in data deduplication and stateful detectors.
- Florian and Matthew proposed the side channels in data poisoning defenses.
- Nicholas and Eric proposed the side channel in memorization filters.
- Nicholas proposed the side channel to extract vocabularies of LLMs.
- Edoardo performed experiments on data deduplication and stateful evasion detectors, and drafted the corresponding sections of the paper.
- Giorgio and Matthew performed experiments on data poisoning, and drafted the corresponding sections.
- Nicholas performed experiments on memorization filters and extracting vocabularies, and drafted the corresponding section of the paper.
- Milad performed experiments with GitHub Copilot and on attacking DP-SGD, and drafted the corresponding sections of the paper.
- Edoardo, Giorgio, Nicholas, Milad, and Eric designed the paper's figures.
- Edoardo, Giorgio, Nicholas, Christopher, Matthew, Milad, Eric, and Florian wrote the paper.
- Florian organized the project.

Abstract

As face recognition is widely used in various security-sensitive scenarios, face privacy issues are receiving increasing attention. Recently, many face recognition works have focused on privacy preservation and converted the original images into protected facial features. However, our study reveals that emerging Deep Learning-based (DL-based) reconstruction attacks exhibit notable ability in learning and removing the protection patterns introduced by existing schemes and recovering the original facial images, thus posing a significant threat to face privacy. To address this threat, we introduce FaceObfuscator, a lightweight privacy-preserving face recognition system that first removes visual information that is non-crucial for face recognition from facial images via frequency domain and then generates obfuscated features interleaved in the feature space to resist gradient descent in DL-based reconstruction attacks. To minimize the loss in face recognition accuracy, obfuscated features with different identities are well-designed to be interleaved but non-duplicated in the feature space. This non-duplication ensures that FaceObfuscator can extract identity information from the obfuscated features for accurate face recognition. Extensive experimental results demonstrate that FaceObfuscator's privacy protection capability improves around 90% compared to existing privacy-preserving methods in two major leakage scenarios including channel leakage and database leakage, with a negligible 0.3% loss in face recognition accuracy. Our approach has also been evaluated in a real-world environment and protected more than 100K people's face data of a major university.

1 Introduction

Face recognition, a technology that utilizes the human face for biometric identification, is widely used in security-related scenarios. As facial information is a unique biometric trait of an individual, any potential leakage poses a significant risk. If malicious actors gain access to this facial information, they could potentially use it to impersonate the affected individuals and carry out unauthorized activities. Moreover, since the biometric profiles of individuals' facial characteristics are extremely hard to change, the hazards caused by the leakage will be long-lasting. Thus, the privacy issue of face recognition has received more and more attention in recent years. Various governments have enacted legislation pertaining to safeguarding facial privacy, such as the European Union's General Data Protection Regulation (GDPR [1]). Despite advancements, many commercial face recognition systems [2–4] still store sensitive facial features. These features are machine learning attributes extracted from facial images, and in some cases, the original photos are also stored. This practice significantly jeopardizes privacy, particularly in instances of database leaks. In such situations, confidential customer biometric data could potentially be extracted from facial features through a process known as a reconstruction attack [40, 43, 61]. Incidents of such leakages have occurred in the past, as exemplified by SenseNets' leakage of 2.5 million face data, Clearview AI's exposure of billions of photographs, and the U.S. Customs and Border Protection's (CBP) disclosure of an unspecified number of travelers' photos.

The root cause of such insecure privacy practices is twofold. Firstly, existing protection approaches often struggle to meet the practical requirements of real-world face recognition. For example, researchers design cryptography-based methods [26, 32, 42, 50] to encrypt facial features and even perform face recognition within the encrypted domain, thereby safeguarding facial privacy. Despite these cryptography-based methods taking practicality into account by minimizing overhead through various optimizations, their computation-intensive nature makes it difficult to scale to larger datasets. Consequently, as the volume of real-world production data increases, these methods incur greater computation and communication overhead [36, 41, 47].

Secondly, the recent advancements made by privacy adversaries often make it challenging for existing approaches to

strike a balance between usability and effectiveness in protection. Because of the usability limitation of cryptography-based methods, there is a tendency to use more lightweight transformation-based methods. For instance, recent works [8, 20, 41, 53] use differential privacy or adversarial samples to generate noises and use such noises to perturb the facial features against privacy attacks. Other works [24, 39, 52] converted facial images into frequency features and removed several non-critical frequency channels, to protect facial privacy. However, our research finds that existing lightweight methods are vulnerable to state-of-the-art privacy attacks.

In particular, real-world attackers are very powerful given recent advances in DL-based reconstruction attacks [9, 12, 18, 35, 58, 61]. These attacks aim to learn the inverse mapping from facial features to facial images by training a reconstruction network with powerful fitting capabilities. Using the trained reconstruction network, the attacker can directly recover the facial image from the protected facial features. Our experiments across 8 widely-used datasets with visual and quantitative results demonstrate that previous privacy-preserving methods cannot provide comprehensive privacy protection when countering such a real-world scenario. Specifically, as summarized in Table 1, Cloak [41], AdvFace [53], PPFR-FD [52], DCTDP [24], Duetface [39] cannot defend against DL-based reconstruction attacks that use adversarial training. Although InstaHide [20] can partially protect face privacy, it suffers from a significant accuracy decline.

Hence, there is an urgent need to propose a new scheme that can provide strong privacy protection and guarantee the accuracy of face recognition at the same time, which leads to two mutually constraining challenges. *Challenge 1: How to disrupt the fitting ability of DL-based reconstruction attacks?* Previous privacy-preserving schemes [24, 39, 41, 52, 53] commonly mapped the same identity of facial images to the same categories of features, so the reconstruction network can always appropriate the corresponding inverse mapping (from features to images) via gradient descent to recover facial images. Therefore, it is a challenge to find a novel mapping that can essentially defend against reconstruction attacks. *Challenge 2: How to ensure the availability of face recognition at the same time?* If the fitting ability of the reconstruction network has already been disrupted successfully, this disruption may also have a huge interference on the face recognition network, resulting in serious degradation of face recognition accuracy, just as the result of InstaHide [20]. Therefore, it is challenging to preserve the information that can be used for face recognition while disturbing the fitting ability of the reconstruction network.

To address those challenges, we propose a lightweight privacy-preserving face recognition system, called FaceObfuscator, which has two key characteristics. *(1) FaceObfuscator can generate obfuscated features to prevent DL-based face reconstruction attacks from recovering facial images.* To this end, we first remove the visual information that is non-crucial for face recognition in frequency domain to weaken the reconstruction results. Then, we generate different candidate feature sets containing multiple obfuscated features for different facial features, and randomly select an obfuscated feature from the candidate feature set as a final facial feature, as shown in Fig. 2. Note that the obfuscated features in different candidate feature sets are interleaved with each other, which disrupts the essence of the reconstruction network, i.e., the mapping from features to images, so these features are gradient descent-resistant to the reconstruction network. Thus, the obfuscated features can defend against DL-based reconstruction attacks to achieve privacy protection. *(2) FaceObfuscator can still utilize the unique candidate feature sets of obfuscated features to maintain face recognition accuracy.* Since the obfuscated features in different candidate feature sets are simultaneously designed to be not duplicated, a specific candidate feature set could be found through an obfuscated feature. It is noted that the candidate feature set is generated from facial features and contains information about facial features. Therefore, identity information can be extracted from the obfuscated feature for face recognition. Extensive evaluation comparing 6 recent privacy-preserving methods on 8 widely-used datasets, shows FaceObfuscator's face privacy protection capability increases around 90% with a tolerable 0.3% accuracy sacrifice. Due to its practicability, our approach has also been evaluated in a real-world environment and protected more than 100K people's face data of a major university.

Our main contributions can be summarized as follows:

- We reveal the vulnerability of existing privacy-preserving face recognition schemes against DL-driven reconstruction attacks through extensive visual and quantitative experiments across 8 widely-used datasets.
- We propose a novel privacy-preserving face recognition system called FaceObfuscator, which generates interleaved but non-duplicated obfuscated features from their candidate feature sets. The obfuscated features are gradient descent-resistant to prevent face reconstruction attacks while containing identity information for accurate face recognition.

- FaceObfuscator serves as a lightweight privacy protection method that can be used for real-time face recognition. The time cost of FaceObfuscator from inputting an image to completing face recognition is comparable to the mainstream face recognition baseline without privacy protection capabilities, and is faster than most face privacy protection methods. The storage cost for its obfuscated features is notably lower, at 98KB per image, compared to the recent face recognition methods.
- FaceObfuscator has been used as one of the protection methods to guard the face privacy of over 100,000 individuals in a major university. Extensive experiments demonstrate that FaceObfuscator outperforms the state-of-the-art privacy-preserving face recognition methods in terms of superior privacy protection performance with a negligible face recognition accuracy loss.

2 Related Work

This section first overviews the related works on face reconstruction attacks, and then introduces recent privacy-preserving face recognition schemes and their vulnerabilities.

2.1 Face Reconstruction Attacks

In the early years, Mohanty et al. [43] utilized a linear approach to reconstruct facial images from face templates. Mignon et al. [40] used the RBF-regression in eigenspace to reconstruct facial images from their signatures. However, these traditional methods cannot cope with the features generated by the later emergence of deep neural networks or complex mappings.

Nowadays, mainstream face reconstruction attacks can be mainly divided into two kinds, i.e., optimizing-based and DL-based. The optimizing-based attacks [13, 45, 46] iteratively optimize input based on feedback from the face recognition system until the original image is recovered. However, these methods require numerous query operations and are heavily reliant on feedback from the face recognition system. Alternatively, a more practical strategy is the DL-based attack, whose objective is to establish an inverse mapping from features to images. Zhmoginov et al. [61] pioneered the utilization of DNNs to invert face embeddings into realistic images. Cole et al. [9] generated facial images from the facial features extracted by the face recognition network. Dosovitskiy et al. [12] and Mai et al. [35] utilized an up-convolutional neural network to reconstruct visual images from features. He et al. [18] enabled a malicious participant in collaborative inference to reconstruct the input of other participants. Moreover, some works [22, 28, 58] guided the inversion from labels or features to images by Generative Adversarial Networks. In this paper, *DL-based attacks are considered the primary threat due to their heightened attack capability and broader applicability.*

2.2 Privacy-preserving Face Recognition

In recent years, some privacy-preserving face recognition schemes have been proposed, which can be mainly divided into two categories, i.e., cryptography-based methods and non-cryptography methods.

The cryptography-based methods usually perform face recognition in encryption space to defend against privacy attacks, e.g., homomorphic encryption [14, 26], oblivious protocols [32], functional encryption [5], key-based CNN [34], random matrix [30], etc. *In fact, real-world face recognition systems rarely employ cryptography on the client side due to the contradiction between their weak computational power and huge computational overheads, which has a 1000x even 10000x slow down [41].*

Consequently, there is a growing preference for more lightweight transform-based methods. Some methods [8, 20, 20, 41, 53] transform facial features against reconstruction attacks by adding various types of noise. Chamikara et al. [8] used local differential privacy that adds perturbation to eigenfaces. Mireshghallah et al. [41] filtered out features that were less relevant to the target task by perturbation and subsequently protected them with a constant suppression value. [20] employed a one-time key to amalgamate different images for the protection of specific ones. Wang et al. [53] used adversarial noise to protect existing facial features. Recently, some methods [24, 39, 52] have achieved privacy protection by transforming images to the frequency domain. Wang et al. [52] shuffled and mixed up the channels in the frequency domain for privacy-preserving. Ji et al. [24] introduced differential privacy to the frequency domain. Mi et al. [39] removed some low-frequency channels in the frequency domain, which is essential for visualization. *However, our experiments reveal that all of these preferred lightweight methods are ineffective in achieving privacy preservation and maintaining face recognition accuracy at the same time when confronted with realistic DL-based reconstruction attacks*. This inefficiency stems from the regular mapping of images to features in previous perturbations and transformations. This mapping fails to prevent deep learning within the reconstruction network from appropriating its inverse mapping from features back to images, thus enabling the recovery of the facial images.

In summary, previous methods either involve impractical additional overhead or cannot maintain face recognition accuracy and protect face privacy at the same time.

3 Preliminary

This section first outlines typical face recognition systems and illustrates their susceptibility to privacy attacks. Subsequently, considering the weak capabilities of the attackers set in previous privacy-preserving works, we expound upon a more powerful and practical threat model applicable to nearly all face recognition systems, aiming to provide a more realistic

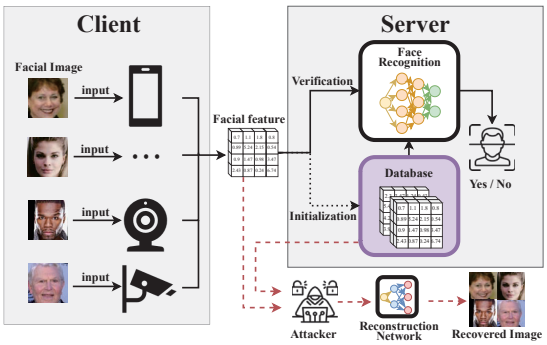

Figure 1: Typical face recognition systems and their potential attack surfaces.

assessment of the privacy-preserving capacities.

3.1 Typical Face Recognition System

Nowadays, mainstream face recognition systems, illustrated in Fig. 1, commonly adopt a client-server architecture. The client side collects and preprocesses facial images from users, and then transmits the preprocessed image to the server side. On the other hand, the server side utilizes its powerful computing power to execute the final face recognition process.

In order to further protect privacy, current privacy-preserving face recognition schemes usually convert facial images into facial features during the client's preprocessing stage to achieve privacy protection. Correspondingly, the database on the server side does not store the original image but the facial features. Though it is true that the facial features are already unrecognizable to humans, there remains a potential risk of privacy compromise due to the presence of the aforementioned DL-driven reconstruction attack, which aims to recover the original facial images.

3.2 Threat Model

Attack Scenarios. In this paper, we consider the server in face recognition to be trusted, but there exists a powerful external attacker whose goal is to recover facial images from facial features to invade users' privacy. It is worth noting that prior attempts at privacy preservation have often underestimated the capabilities of the attackers. For instance, chamikara et al. [8] employed traditional methods such as PCA-based models to reconstruct images and some works [24, 52] even directly considered inverse DCT operation which is the reverse operations of preprocessing as a white-box attack. Mireshghallah et al. [41] only considered attacks on the sensitive attributes of faces, ignoring attacks that can directly reconstruct the entire face. In addition, some works [24, 39, 52] did not adopt a strategy of adversarial training while training DL-based reconstruction network, leading to misjudgment of their scheme's ability to protect privacy.

In fact, attackers in the realistic scenario [7,17,23,31,38,49] can utilize deep learning-based reconstruction attacks and employ the adversarial training strategy, which can retrain the reconstruction network using pairs of protected facial features and facial images to learn its new mapping relationship for recovering facial images. This advanced attack methodology is able to breach established privacy-preserving techniques and obtain facial information, as summarized in Table 1. Therefore, we adopt such a powerful threat model to better accurately evaluate the efficacy of our privacy-preserving method.

Attacker's Knowledge. We assume the attacker has the following knowledge:

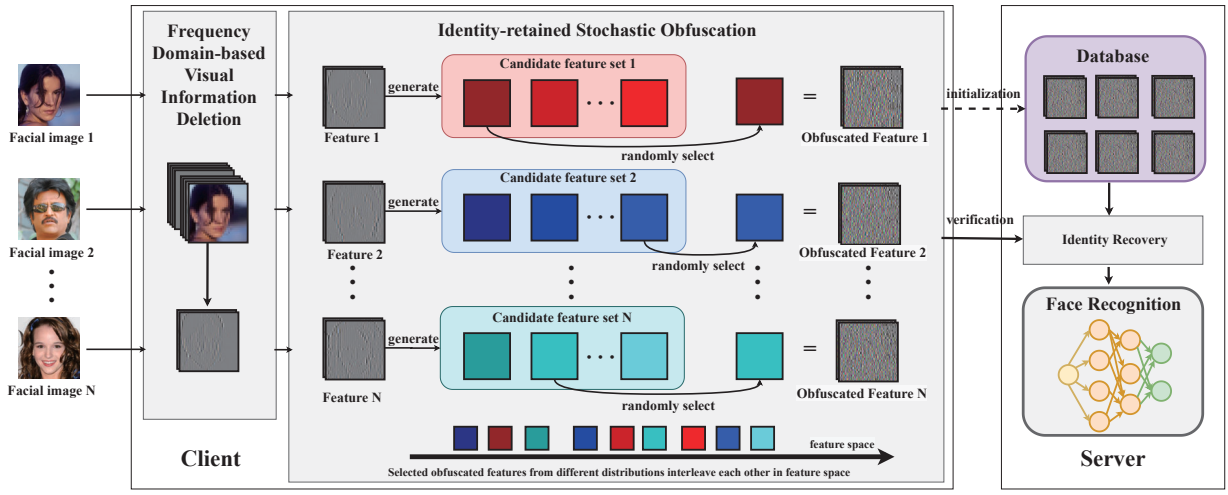
- **Leaked facial features** $\mathcal{X}' = \{x'_1, x'_2, \cdots, x'_n\}$: the attacker has intercepted the data in the **transmission channel** or gained access to the compromised **database**.
- **The client of the face recognition system** $\mathrm{C}(\cdot)$: the attacker can get the latest black-box client of the face recognition system by purchasing from the service provider.

Attacker's Strategy. With the mentioned knowledge, the attacker can obtain protected feature-image pairs $(\mathcal{X}, \mathcal{Y})$ from public face datasets $\mathcal{Y}$ through the latest client: $\mathcal{X} = C(\mathcal{Y})$, where $\mathcal{X}$ is the facial feature datasets. Then, attackers can train its corresponding reconstruction network $G(\cdot)$ with $(\mathcal{X}, \mathcal{Y})$, and finally feed the leaked facial features $\mathcal{X}'$ to the reconstruction network to recover the original images: $\mathcal{Y}_{target} = G(\mathcal{X}')$.

All DL-based face reconstruction attacks are based on the above strategy with adjustments of the training dataset, loss function, or network architecture. In this paper, we adopted two of the most prevalent and threatening types of DL-based reconstruction attacks, which use Deconvolutional Networks (DN) [9, 12, 18, 35, 57, 61] and Conditional Generative Adversarial Networks (cGAN) [22, 28, 58], respectively, to train reconstruction networks $G(\cdot)$.

4 Gradient Descent-resistant Face Protection

In this section, we present our novel Gradient Descent-Resistant system, called FaceObfuscator, for privacy-preserving face recognition. In Section 4.1, we provide an overview of our proposed system. In Section 4.2, we first investigate the role of frequency channels for face recognition. By retaining only the most critical channels for face recognition, we aim to reduce as much visual information as possible to weaken face reconstruction while preserving recognition accuracy. In Section 4.3, we reveal our innovative strategy developed to secure residual visual information by making it challenging for DL-based reconstruction networks to grasp it. We will elaborate on how we develop a mathematical model to generate an obfuscated feature that can be exploited for face recognition and how



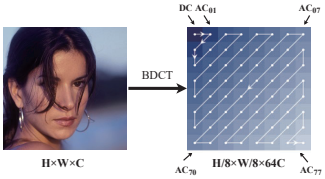


Figure 2: Overview of FaceObfuscator. On the client side, we first convert an original image into frequency channels and remove most of the frequency channels, then we use the remaining channels to generate a corresponding candidate feature set, and finally randomly select obfuscated features from this candidate feature set to resist privacy attacks. On the server side, the database stores obfuscated features, which will be processed by identity recovery before face recognition.

(a) The process of BDCT. Each grid represents a frequency channel.

(b) channel DC (c) channel AC_{01} (d) channel AC_{77}

Figure 3: After block discrete cosine transform (BDCT), different visual information in the image is arranged in a zigzag pattern from low to high frequency. (b) (c) (d) represent the visual information in frequency channel DC, AC_{01} and AC_{77}.

it successfully resists gradient descent to undermine the powerful DL-based face reconstruction capability.

4.1 Overview of FaceObfuscator

Our approach is based on an important observation of the neural network: the essence of DL-based face reconstruction attacks is to learn new mappings from protected features to original images for recovering facial images. Therefore, the core idea of FaceObfuscator is to disturb those mapping by resisting the gradient descent process in training reconstruction networks. To this end, we generate the obfuscated features by removing visual information non-critical for face recognition and introducing randomness to the features, which aims to make the obfuscated features of different facial images interleaved in the feature space so that the reconstruction network cannot distinguish them.

Fig. 2 shows the workflow of FaceObfuscator, which takes the facial images as the input of the client and generates the obfuscated features as the output of the client. The obfuscated features will be transmitted into the server and stored in the database of the server for face recognition to prevent potential face reconstruction attacks.

Specifically, FaceObfuscator has two components in the client (i.e., Frequency domain-based visual information deletion, Identity-retained stochastic obfuscation), and one component in the server (i.e. Identity recovery). On the client side, the client first feeds facial images into *Frequency domain-based Visual Information Deletion* to transform them into frequency-domain features, and then removes visual information non-critical for face recognition to weaken the reconstruction results. After that, through *Identity-retained Stochastic Obfuscation*, the client generates different candidate feature sets containing multiple obfuscated features for different facial features, and then randomly selects an obfuscated feature from the candidate feature set as a final facial feature. Note that the obfuscated features in different candidate feature sets are interleaved with each other, which disrupts the essence of the reconstruction network, i.e., the mapping from features to images, so these features are gradient descent-resistant to the reconstruction network. On the server side, the server stores obfuscated features transmitted from the client. Note that the obfuscated features in different candidate feature sets are designed to be not duplicated, so the server can find the candidate feature set of each obfuscated feature. Since the candidate feature set is generated from facial features and contains information about facial features, identity information can be extracted from the obfuscated feature through *Identity*

Table 2: Face recognition with a single frequency channel.

AC_{77}	99.65	97.30	95.87	90.62

(a) w/o standardization (b) with standardization

Figure 4: The necessity of standardization for evaluating the importance of the channel for face recognition. (a) is the importance of frequency channels before standardizing the numerical values in frequency channels, whose results are inconsistent with the observation that each channel has visual information for face recognition; (b) is the re-assessed importance of frequency channels after standardizing, whose results are consistent with the above observation.

recovery for face recognition.

4.2 Frequency Domain-based Visual Information Deletion

We gain new insight on defending against DL-driven attacks from the unique perspective of the frequency domain, i.e., *most of the frequency channels can be removed with little loss of accuracy, which indeed contain visual information that is targeted by attacks*. Thus, we design our scheme to remove more than 90% of the channels to weaken the face visual reconstruction effectiveness (compared to previous schemes that only remove at most 50% of the frequency channels).

Next, we first explain the correlation between visual information and frequency channels (Section 4.2.1). Then, we introduce how we exploit the channel selection to achieve maximal visual information removal without compromising face recognition accuracy (Section 4.2.2).

4.2.1 Understanding Visual Information from the Frequency Domain

Because different frequency channels contain different visual information, as shown in Figs. 3b to 3d, previous works [24,39,52] indicated that it is possible to remove visual information to weaken the reconstruction results by partially removing frequency channels. So, following the standard Block Discrete Cosine Transform (BDCT) in JPEG compression [51], as shown in Fig. 3a, we first convert facial images to the frequency channels to separate out the visual information to be removed, say channel DC in Fig. 3b. However, previous works [24, 39, 52, 56] diverge in determining which channels should be retained to perform face recognition, i.e., most works [24, 52, 56] showed that low-frequency channels are much more crucial in face recognition, while one [39] showed another result that face recognition still works well even if removing such low-frequency channels.

To explore the real relationship between face recognition and visual information in frequency channels, we test the feasibility of using a single frequency channel for face recognition and observed that face recognition is possible with visual information from even a single frequency channel, as shown in Table 2, which is different from previous perception [24, 39, 52, 56]. This observation allows us to remove most of the frequency channels, rather than remove part of the frequency channels, to remove visual information against reconstruction attacks without compromising face recognition accuracy.

4.2.2 Identity-prioritized Frequency Channel Selection

Based on the above observation, our objective can be formulated as retaining only the most critical frequency channels for face recognition, where no further visual information can be precluded without compromising ID accuracy.

To further clarify the exact impact of each frequency channel on face recognition, we design an auxiliary network to measure different frequency channels' importance for face recognition. The auxiliary network assigns unconstrained weights directly to the initial input of the network, and these weights will be used to represent importance after training. Eventually, we reveal the true importance of each channel in face recognition by standardizing values in frequency channels, as shown in Fig. 4. Please refer to Appendix A for more details.

According to the importance of face recognition, we prioritize the removal of frequency channels with relatively low importance, thereby ensuring the retention of crucial information for face recognition. Subsequently, we succeed in retaining the channels that are the most critical for face recognition by iteratively removing channels while concurrently assessing their impact on face recognition. As shown in Fig. 5, only the retained 2 channels, i.e., channel AC_{01} and channel AC_{10}, are the most critical channels for face recognition, which ensures that there is no significant degradation in accuracy as well as weakening the face reconstruction results.

Notably, this approach can select the most important frequency domain channel based on different architecture facial recognition models, and flexibly adjust the number of reserved channels to ensure recognition accuracy while removing part of the visual information. In other words, this approach is scalable to different face recognition models.

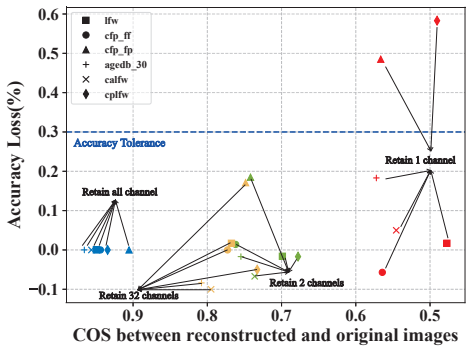

Figure 5: COS and Accuracy Loss with different numbers of channels retained on different datasets (the higher the COS value, the closer the reconstructed face is to the original face). When only 1 channel is retained, the loss of accuracy is too great to be acceptable (Accuracy loss exceeds the accuracy tolerance, say 0.3%); when many channels are retained, the reconstructed image is close to the original image. So retaining 2 channels can minimize the visual reconstruction effect while maintaining accuracy.

4.3 Identity-retained Stochastic Obfuscation

Since part of facial details may still be recovered from the retained frequency channels by DL-based face reconstruction attacks, it becomes imperative to further obfuscate the retained frequency channels to completely thwart potential privacy breaches.

Next, we introduce a novel algorithm to generate obfuscated features from their unique candidate feature sets, which are gradient descent-resistant to face reconstruction attacks (Section 4.3.1). Then, we formulate a corresponding algorithm for the server to utilize obfuscated features for face recognition (Section 4.3.2).

4.3.1 Gradient Descent-resistant Facial Feature Generation

The key to defending against reconstruction attacks is interfering with the gradient descent process of the reconstruction network. So, we generate obfuscated features that are gradient descent-resistant to reconstruction networks to provide strong privacy protection. This generation process involves two core steps. Step 1: For each original feature, we generate a unique candidate feature set by obfuscating the original feature by altering the sign direction for each element and value scale for each channel, where the sign direction represents the positive or negative of numerical values, and the value scale represents the magnitude of the numerical values. Step 2: We randomly select an obfuscated feature from the candidate feature set for each authentication. A step-by-step example is shown in Fig. 6 and the details of the algorithm are shown in algorithm 1.

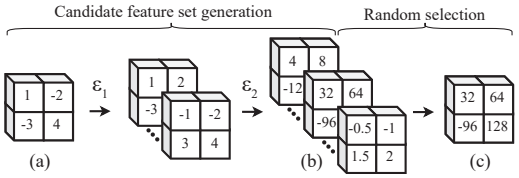

Figure 6: A step-by-step example of gradient descent-resistant facial feature generation. (a) is one of the frequency channels from the original feature, (b) is (a)'s corresponding candidate feature set, and (c) is (a)'s corresponding obfuscated feature.

Algorithm 1: Gradient descent-resistant facial feature obfuscation (client side).

input : Facial features f of size $h \times w \times c$
output : obfuscated features e of size $h \times w \times c$

1 Initialize constant float b from the server;
2 ***Preprocess***;
3 $a \leftarrow$ `Self-Normalization(`f`)`
$= \{a_k \mid a_k = \frac{f_k - \mathrm{E}[f_k]}{\sqrt{\mathrm{Var}[f_k]+\beta}}, k \in [0,1,2,\cdots,c]\}$
4 ***Step 1: Generate*** candidate feature set P;
5 Obfuscate sign direction: $\varepsilon_1 = J_{h\times w\times c}$, all elements in J are $(-1)^u$;
6 Obfuscate value scale: $\varepsilon_2 \leftarrow B_c = [b^v, b^v, \cdots, b^v_c]$;
7 Mask $\varepsilon \leftarrow \varepsilon_1 \odot \varepsilon_2$, all elements in ε are $(-1)^u \times b^v$, where $\odot$ represents Hadamard product;
8 candidate feature set:
$P(a,b) = a \odot \varepsilon = a \times (-1)^u \times b^v$
9 ***Step 2: Selecting an obfuscated feature from*** candidate feature set P;
10 **for** $k \leftarrow 1$ **to** c **do**
11 randomly select e_k with $P(a_k, b)$, where u, v is in integer range $[Z_{lower\ bound}, Z_{upper\ bound}]$;
12 obfuscated features $e \leftarrow \{e_1, \cdots, e_c\}$;

Generating different candidate feature sets from each facial feature (line 2 to line 8). Before resisting the gradient descent of the face reconstruction network, it's crucial to ensure the availability of obfuscated features for face recognition. Thus, we need to carefully design the position of the obfuscated features placed in the feature space. To this end, we design different candidate feature sets that contain multiple obfuscated features for different facial features, and *ensure the obfuscated features in different candidate feature sets are interleaved but not duplicated in the feature space*.

Such a design serves two purposes. The first purpose is to make it impossible for the reconstruction network to utilize the obfuscated features. Due to the obfuscated features of different facial images interleaved in the feature space, the obfuscated features from different candidate feature sets are not distinguishable to the reconstruction network. Therefore, the

gradient descent of the reconstructed network will be resisted when the network tries to fit the mapping from obfuscated features to facial images. The second purpose is to preserve the identity information in the obfuscated features used for face recognition. The non-duplication of obfuscated features from different candidate feature sets ensures that there exists a many-to-one relationship between obfuscated features and candidate feature sets. Thus, a candidate feature set with a specific identity can be found from an obfuscated feature, allowing for the extraction of identity information within the obfuscated feature to perform face recognition accurately.

Specifically, for each facial feature (the remaining frequency channels after channel selection), the client first preprocesses the facial feature by self-normalization to make the features initially obfuscated, whose details are shown in Appendix B. Then, the client generates different candidate feature sets for different facial features, where each candidate feature set uniquely corresponds to a facial feature. The process to generate candidate feature sets can be expressed as $a \times (-1)^u \times b^v$, where a is the facial features after self-normalization, b is a constant value obtained from the server for initializing the client, $(-1)^u$ represents the obfuscation to facial features on the sign direction, b^v represents the obfuscation to facial features on the value scale, and u, v are discrete variables to be randomly selected, which ensures the features in different candidate feature sets are interleaved but not duplicated in the feature space.

Randomly selecting gradient descent-resistant features from their corresponding candidate feature sets (line 9 to line 12). After generating the corresponding candidate feature set for each feature, we can map a facial feature to a large number of obfuscated features. Since the obfuscated features from different identities are designed to be interleaved with each other, we can randomly select an obfuscated feature from the corresponding candidate feature set as the final facial feature for each authentication to resist gradient descent against reconstruction attacks. In this case, the mapping of original features to obfuscated features is a random mapping. Notably, we consider a single channel in each feature as the smallest unit of a. The values of u, v used for random selecting in each channel are randomly selected within an integer range, spanning from the minimum value $Z_{lower\ bound}$ to the maximum value $Z_{upper\ bound}$.

In the following, we will briefly demonstrate that obfuscated features can prevent face reconstruction network learning the mapping from features to facial images by resisting its gradient descent.

Formally, given a set of training samples $(\mathcal{X}, \mathcal{Y})$, where $\mathcal{Y}$ is a set of facial images, $\mathcal{X}$ is a set of corresponding facial features generated by $x = S(y)$, where S is the process of FaceObfuscator, x denotes a facial features, y denotes a facial image. The attacker's network can be defined as $G(x) = \hat{y}(x, \theta)$ with its corresponding loss function $l(\theta)$, where $\hat{y}$ is an estimate of the facial image y. Then, the process of gradient descent algorithm at θ_0 can be described as $\theta \leftarrow \theta_0 - \alpha \frac{\partial}{\partial \theta_0} l(\theta)$, where α denotes the learning rate of gradient descent, θ denotes the parameter to be learned in the neural network. Since the α is set by the attacker and unknown to us, we chose to implement a substantial manipulation on $\frac{\partial}{\partial \theta_0} l(\theta)$ to break the gradient descent algorithm. To simplify the demo, we will use the case of a single layer perceptron $\hat{y}(x, \theta) = \sum_{j=0}^{n} \theta^j x_j$ with an MSE loss function $l(\theta; x, y) = (\hat{y}(x, \theta) - y)^2$ as an example, where $y = [y_0], \quad x = [x_0, x_1, \cdots, x_n]^\top, \quad \theta_0 = \left[\theta_0^0, \theta_0^1, \cdots, \theta_0^n\right]$. As single layer perceptron is the basis of neural networks, the derivation for multilayer networks with other structures can be derived from this in the same way. In this case, the gradient descent algorithm can be described as:

$$\frac{\partial}{\partial \theta_0} l(\theta) = \frac{\partial}{\partial \theta_0} (\hat{y}(x, \theta_0) - y)^2 = 2 \cdot \left(\sum_{j=0}^{n} \left(\theta_0^j \cdot x_j \right) - y_0 \right) \cdot x \tag{1}$$

As for our scheme, the core obfuscation process can be equated to put a random mask ε to the features, i.e., $e = \varepsilon \odot x$, where $\varepsilon = [\pm b^{v_0}, \pm b^{v_1}, \cdots, \pm b^{v_n}]^\top$, b is a constant value in the client given by the server, v_i is the randomly selected number range from the minimum value $Z_{lower\ bound}$ to the maximum value $Z_{upper\ bound}$. So the gradient descent after our obfuscation can be formulated as:

$$\frac{\partial}{\partial \theta_0} l(\theta) = 2 \cdot \left(\sum_{j=0}^{n} \left(\theta_0^j \varepsilon_j x_j \right) - y_0 \right) \cdot \varepsilon \odot x \tag{2}$$

Then, we use the Manhattan Distance between Eq. (2) and Eq. (1) to yield the degree of influence of obfuscation on the normal gradient descent:

$$\begin{aligned} & d_1(Eq.\ (2), Eq.\ (1)) = \|Eq.\ (2) - Eq.\ (1)\|_1 \\ =& 2 \cdot \sum_{i=0}^{n} \left| \sum_{j=0}^{n} \left((\pm b^{v_i} b^{v_j} - 1) \theta_0^j x_i x_j \right) - (\pm b^{v_i} - 1) y_0 x_i \right| \end{aligned} \tag{3}$$

where $\theta_0^k y_i y_j$, $x_0 y_j$ are fixed values in the state of θ_0. As $\pm b^v$ is a stochastic value ranging from a very small value close to 0 to a very large value close to the upper limit of the floating point number, the distance of the obfuscated gradient varies considerably compared to the original gradient. To go a step further, when the reconstructed network performs gradient descent to fit the inverse mapping, the direction of the gradient descent is inconsistent at each iteration, which effectively resists the normal gradient descent to recover the facial images.

As for the security concern about the reversal of obfuscated features, two primary difficulties hinder attackers from recovering the original features. The first difficulty arises from the

complexity of determining sign direction. As the direction of each element in the feature is entirely random, the resulting obfuscated feature for a given original feature will have $2^{h\times w\times c}$ possibilities, which is hard to reverse. The second difficulty is associated with the variability in the value scale. The value of each frequency channel in the feature also undergoes random changes, further expanding the possibilities of obfuscated feature by N^c, where N represents the number of choices within the integer range $\left[Z_{lower\ bound}, Z_{upper\ bound}\right]$. Consequently, the combination of these difficulties makes it nearly impossible for attackers to recover the original features successfully.

So far, the original facial features have been well obfuscated. Such obfuscated features will be transmitted to the server as output from the client and stored in the server's database for privacy protection.

4.3.2 Identity Recovery Based on Traceability of Candidate Feature Set

Algorithm 2: Identity recovery based on traceability of candidate feature set (server side).

input : Obfuscated features e of size $h\times w\times c$
output : Identity information d of size $h\times w\times c$

1 Initializing b preset with clients;
2 **for** $k\leftarrow 1$ **to** c **do**
3 **if** $\max(|e_k|)>0$ **then**
4 $r = round\ down(-\log_b \max(|e_k|))$;
5 $d_k = e_k \times b^{r+bias}$;
6 **else if** $\max(|e_k|)=0$ **then**
7 $d_k = O_{h\times w}$;
8 Identity information $d\leftarrow\{d_1,\cdots,d_c\}$;
9 Individual ID $\leftarrow$ `Face recognition(`d`)`;

Given that each candidate feature set is generated from the corresponding facial feature, if we can ascertain the specific candidate feature set to which the obfuscated feature belongs, the extraction of identity information from the obfuscated features for face recognition becomes feasible. Thus, based on our designed non-duplicated candidate feature sets, we design an identity recovery method that cannot be learned by neural networks to trace back the candidate feature set corresponding to the obfuscated feature, as shown in algorithm 2. After that, the obfuscated features can be recovered to a specific feature in its corresponding unique candidate feature set and eventually utilized by face recognition on the server side.

Specifically, since Huang et al. [20] indicated that the sign direction factor $(-1)^u$ has minimal impact on the image classification tasks, i.e., face recognition in our case, we only offset the value scale factors b^v in the obfuscated features (line 2 to line 7) to extract the identity information, where each channel's maximum value is recalibrated to the range $\left[b^{bias}, b^{bias+1}\right)$ with the other values adjusted proportionally in multiples. For example, for facial features with different identities f_{Alice} and f_{Bob}, all obfuscated features of them will be uniquely transformed into final identities $f_{Alice}\times b^{\lambda}, f_{Bob}\times b^{\lambda}$ though algorithm 2, respectively, where f represents the facial feature of an individual before obfuscation, λ is the final value scale determined by *bias*. As a result, the final identity will be a specific obfuscated feature within the same interval range in different candidate feature sets. Such identities of different individuals are no longer interleaved with each other in the feature space, so they can be utilized by face recognition on the server side, as shown in Table 5 of Section 5.4.

Discussion on the value of b. In mathematics, we can choose b with any float value in range $(0,1)\cup(1,+\infty)$. The value of b will not impact the process of algorithm 2, since the obfuscated features of the same individual can always be unified to a specific feature in the range $\left[b^{bias}, b^{bias+1}\right)$, which is discriminative for face recognition. However, in practical deployment, the precision limitations of floating-point numbers impose constraints on b. For instance, considering a 32-bit floating-point number adhering to the IEEE 754 standard [27], the range of floating-point numbers is confined to $\pm[1,2)\times 2^{[-126,127]}$. Thus, the values of $a\times b^v$ must fall within this specified interval. In this case, when b is smaller, say $b=2$, the range in which v can be selected is larger and the randomness is equally stronger. In addition, the value of b cannot be very close to zero because there may exist a floating-point precision loss problem during computing.

5 Experiments

To evaluate the efficacy of FaceObfuscator, we perform extensive evaluations of privacy protection and face recognition across diverse datasets. In the following sections, we will first introduce the experimental setup in Section 5.1, and discuss our evaluation results with three research questions:

- **RQ1**: How does our obfuscation impact face recognition accuracy? (Section 5.2)
- **RQ2**: Can FaceObfuscator effectively defend against various attacks to protect privacy? (Section 5.3)
- **RQ3**: How does each component contribute to the overall improvement of accuracy and privacy? (Section 5.4)

5.1 Experimental Setup

Datasets&Pre-prcocess. In the experiments, we use the MS-Celeb-1M [15], CelebA [33] as the train datasets and use the LFW [19], CFP-FF [48], CFP-FP [48], AgeDB-30 [44],

CALFW [60], CPLFW [59], IJB-B [55], IJB-C [37] as the test datasets, whose details are shown in Appendix C.

Following common image pre-processes [10, 34, 53], we first randomly flip the images and resize them into 112×112. Then, we rescale the pixel value of images from $[0, 255]$ to $[0, 1]$. Finally, we normalize images with a mean of 0.5 and a variance of 0.5, whose values will be in $[-1, 1]$.

Models and Implementation Details. We will show the detailed setting of FaceObfuscator and DL-based face reconstruction attacks.

FaceObfuscator. Like most face recognition schemes, we choose Arcface [10] as the basis for the server side and choose Resnet50 [16] as its backbone. We use the SGD optimizer [6] with a learning rate of 0.1, momentum factor of 0.9, and weight decay of 5e-4. And we use a polyscheduler to dynamically adjust the learning rate according to a polynomial of given power 2. The b used to initialize the client is set to 2, and results for other b values are shown in Appendix D. All of the experiments of our scheme will be trained on MS-Celeb-1M [15] for 10 epochs. For easier deployment, we will turn the initial image into grayscale and upscale this image by 8 times when in the frequency domain scheme, at which point the image size after BDCT transformation aligns with the original and only a modification in the input channel for the face recognition network is needed.

DL-based attacks in threat model. In the experiments, we use the methods proposed by Mai et al. [35] and Isola et al. [22] as benchmark attacks of DN-based attacks and cGANs-based attacks respectively, which have proven to be effective and are also widely used by existing defense works [24,52,53]. Both of them are trained on the CelebA [33] dataset.

Methods for comparison. We compare our method with 8 different face recognition methods, specifically focusing on the last 6 methods that assert privacy protection capability.

Arcface [10] is the baseline method of face recognition for RGB images without privacy protection. **Arcface-FD [11]** is the baseline method of face recognition on the frequency domain without privacy protection. **InstaHide [20]** is a lightweight encryption-based method that incorporates the mix-up of k images, which we set to 2. **Cloak [41]** disturbs the input feature by a gradient-based perturbation model and we set its accuracy-privacy parameter to 1. **AdvFace [53]** proposes adversarial facial features obtained by adding adversarial latent noise to the original facial features to mislead the reconstruction network. **PPFR-FD [52]** is a privacy-preserving method in the frequency domain that disrupts the channel order and mixes them up, and face recognition is performed after the channels are reordered by energy. **DCTDP [24]** is a privacy-preserving face recognition with learnable privacy budgets of differential privacy, whose ε mean is set to 0.5. **Duetface [39]** is also a privacy-preserving method in the frequency domain that protects privacy by removing some of the low-frequency channels and deploying lightweight face recognition networks in the client to transfer additional auxiliary information to the server.

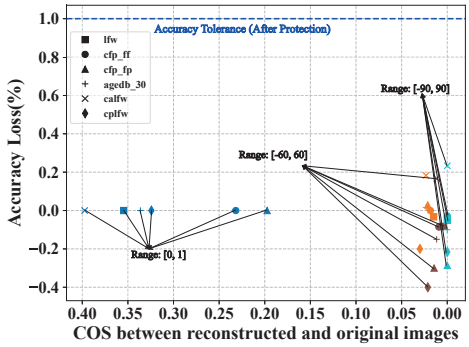

Figure 7: The effect of ranges of u, v on face reconstruction and face recognition.

Evaluation Metrics. We will use 5 metrics to evaluate the face privacy protection capabilities of different methods.

MSE, PSNR [25], SSIM [54] are three different methods for calculating the difference in pixels between two images. Specifically, a higher MSE, a lower PSNR, and a lower SSIM indicate a lower similarity between the reconstructed image and the original facial image, which implies a stronger defense. **COS** describes the cosine similarity between the identity vector of the reconstructed image and the identity vectors of the original image in the 512-dimensional facial feature space through another independent face recognition system. Specifically, a lower COS means a lower similarity between the reconstructed image and the original image. **SRRA [53] (success rate of replay attacks)** measures the success rate of replay attacks, which uses the reconstructed images from a certain face recognition system to cheat the same face recognition system for successful identity authentication. Specifically, a lower SRRA means a better privacy protection capability.

5.2 Accuracy of the Face Recognition (RQ1)

In this subsection, we will demonstrate what the impact of our FaceObfuscator on the accuracy of face recognition can be. We first discuss the effect of the range of u, v, i.e., $[Z_{lower\ bound}, Z_{upper\ bound}]$, on the accuracy, where u, v determine which obfuscated feature is selected from the candidate feature set. Then, we reassess the effect of the number of retaining frequency channels under our whole scheme, and finally compare our scheme with the state-of-the-art scheme.

The accuracy of face recognition remains almost unchanged as the range of values of u, v gradually expands. One factor that may affect the accuracy of face recognition is the upper and lower bounds of the perturbation magnitude. To this end, we gradually adjust the range of values of u, v from low to high, i.e., [0,1], [-30,30], [-60,60], [-90,90], to

Table 3: The performance of privacy protection methods in terms of face recognition accuracy. ● represents good protection against attacks; ◐ represents poor protection against attacks; ○ represents no protection against attacks; The yellow squares indicate flaws, say an accuracy loss over 3% compared to the baseline(Arcface) or poor protection capability, and The red squares indicates severe flaws, say an accuracy loss over 5% compared to the baseline(Arcface) or no protection capability.

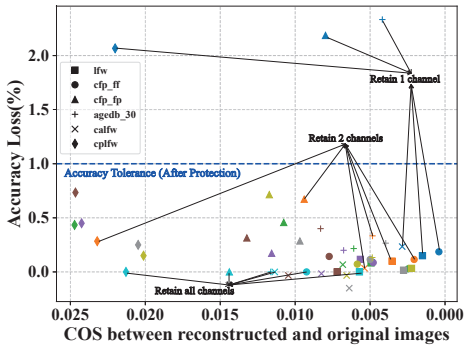

Figure 8: The effect of the number of retaining frequency channels on face reconstruction and face recognition.

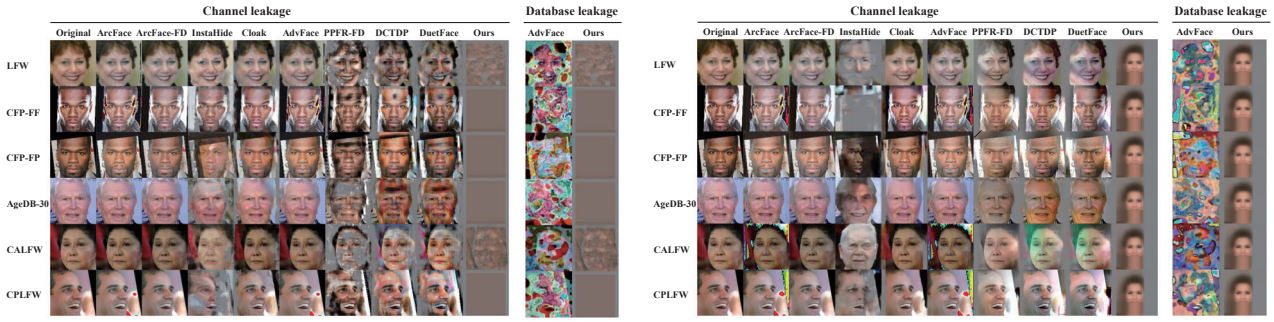

see how it affects privacy protection and face recognition accuracy respectively. Fig. 7 shows the trend of the accuracy and COS values (represent privacy-preserving capability) under different ranges, i.e., when the range of values of u, v gradually expands, the accuracy of face recognition remains almost unchanged. Therefore, we could theoretically choose a range as large as possible, as long as the value does not exceed the range of floating-point. Because the reconstructed network is no longer able to compute the gradient when the range reaches [-90, 90], we choose [-60, 60] in order to have a visual comparison with other schemes.

Channel AC_{01} and channel AC_{10} are still the most critical channels for face recognition. Another factor that can influence both face privacy protection capability and face recognition accuracy is the channels we retain in the face recognition system. So, we re-assess the importance of different frequency domain channels for face recognition under the whole scheme and prioritize the removal of channels with relatively low importance. Fig. 8 shows the accuracy and COS values when retaining a different number of channels. When the number of channels decreases from 64 to 2, there is no significant degradation in face recognition accuracy, whereas dropping to 1 channel results in a notable accuracy loss, as shown in the outlier in Fig. 8. Meanwhile, the lower the number of channels, the transmission and storage overheads required in face recognition, as well as the computational overheads, will be reduced accordingly. Therefore, combining the defending visual reconstruction effect, face recognition accuracy, and all kinds of overhead under different numbers of channels, our scheme only retains 2 channels, i.e., channel AC_{01} and channel AC_{10}, in Frequency domain-based visual information deletion. Notably, such fixed selection will not impair the protection effectiveness of our scheme. One reason for this is that the selected few channels only preserve little information that is useful for face reconstruction attacks. The other reason is that possibilities for obfuscated features derived from the same input still exceed 10^{7556} when only retaining 2 channels in our case, making recovery highly challenging.

FaceObfuscator has only a slight accuracy loss compared to the face recognition baseline. We compare the accuracy of face recognition with 2 baselines and 6 different privacy-preserving methods. As shown in Tab. 3, among the privacy protection schemes compared, the privacy-preserving schemes in the spatial domain, i.e., InstaHide, Cloak, and AdvFace, have a significant loss in accuracy, while the privacy-preserving schemes in the frequency domain, i.e., PPFR-FD, DCTDP, and Duetface, have less accuracy degradation but suffers from the disadvantage of tens of times higher communication and storage overhead. Most notably, none of the existing protection schemes in either the spatial or the frequency domain are able to provide privacy-preserving capabilities. In the case of providing outstanding privacy-preserving capability, our scheme has only a slight accuracy degradation compared to the baseline method Arcface-FD, and almost the same accuracy compared to the baseline method Arcface in the baseline, with minimal overhead.

5.3 Effectiveness of Privacy Protection (RQ2)

In this subsection, we will demonstrate the effectiveness of our scheme to defend against various attacks to protect privacy.

(a) DN-based attacks

(b) cGAN-based attacks

Figure 9: The facial images that are recovered by DN-based attacks (a) and cGAN-based attacks (b) from different face recognition schemes. Note that the reconstructed image is the same for all schemes except Advface, when the transmission channel leakage and the database leakage occur.

We compare FaceObfuscator's capability of privacy protection with the 2 baselines and the other 6 privacy-preserving methods by evaluating their performance against privacy attacks including 2 types of face reconstruction attacks (DN-based attacks and cGAN-based attacks), and their corresponding replay attacks in 2 different leakage scenarios (leakage from transmission channels and leakage from databases).

FaceObfuscator can effectively protect privacy in the scenario of transmission channel leakage. Protection schemes usually choose to protect the data prior to transmission to provide full-process protection capabilities, which also leads to the fact that an attacker can get the protected facial features and utilize adversarial training to obtain a mapping from the protected facial feature to the original image. Thus, once attackers capture the facial features transmitted in the transmission channel, they can use the trained generator to recover their corresponding original facial images.

We initially assessed the efficacy of safeguarding privacy against DL-based face reconstruction attacks. As for DN-based attacks, the channel leakage portion in Fig. 9a shows that the reconstruction images protected by our proposed FaceObfuscator are completely indistinguishable from each other, whereas the face details in the reconstruction images protected by the other privacy-preserving schemes are still clearly visible, leaking a large amount of facial information. As for cGAN-based attacks, as shown in the channel leakage portion of Fig. 9b, the original images of comparison schemes other than InstaHide [20] are completely recovered, while our scheme gets an average face rather than a face of a specific individual. Such an average face does not disclose personal privacy and is meaningless to the attacker.

Tab. 4 quantitatively shows that our method achieves higher MSE value, lower PSNR value, SSIM value, and COS value, which all indicate that our method achieves improved face privacy protection capabilities. Additionally, when attackers use reconstructed images to perform a replay attack, our scheme is considerably superior to the comparison schemes, where SRRA decreased from about 90% to about 0%, further proving the privacy protection capabilities of FaceObfuscator.

FreqObfuscator can effectively protect privacy in the scenario of database leakage. For most protection schemes, the server still stores the same protected features sent by the client instead of the "decrypted" features to cope with the requirement of achieving desensitized storage. Thus, when database leakage occurs, the protection effect of most schemes [20, 24, 39, 41, 52] is consistent with channel leakage portion in Figs. 9a and 9b.

However, Advface [53] achieved the aim of blocking adversarial training by only protecting facial features in the server. As shown in Table 4, although Advface [53] has some progress in privacy protection capability compared to other protection schemes, there is still a significant gap compared to our scheme quantitatively, especially in COS and SRRA. From the database leakage portion in Figs. 9a and 9b, we can see that the reconstructed image protected with advface may still reveal some outlines of faces, while the reconstructed image of our scheme reveals no private information at all.

FaceObfuscator can still protect privacy to some extent when facing white-box attacks. We also discuss scenarios of facing white-box attacks when the attacker knows all the details of the architecture and parameters of both the client and server. It can be seen from Fig. 10 that the defense effect of FaceObfuscator in the face of complete white-box attacks has declined slightly, but it is still far better than the defense effects of other solutions in the face of black-box attacks, as shown in Figs. 9a and 9b. It also indicates that service providers cannot reconstruct faces to violate privacy, even if they try to reconstruct facial images on the server. The reason that facial images can still be protected to some extent is twofold. First, the facial features only remain a small amount of frequency channels, retaining little visual information useful for reconstruction. Second, since the sign directions of all the elements in the features remain randomly obfuscated

Table 4: The performance of privacy protection methods in terms of MSE, PSNR, SSIM, COS against DN-based attacks, cGAN-based attacks and their corresponding replay attacks (SRRA), under 2 different leakage scenarios, i.e., leakage from transmission channels (C) and leakage from databases (D).

and unpredictable in the white-box scenario, it is difficult to recover the direction of elements to reverse the obfuscated features, which prevents the reconstruction of facial images.

Note that in realistic scenarios, we can use techniques such as code obfuscation to hide the operation of clients or redesign the candidate feature set of each feature to regain optimal protection.

Real-world Evaluation. Due to its practicability, we have submitted our method to the relevant authority at the university, which has carried out an evaluation of protection effectiveness and used it as one of the protection methods to protect the existing face data of over 100K individuals. The evaluation demonstrates that when the simulated attacker gets the facial features, they can neither obtain information about the

Table 5: Face recognition accuracy on the server side

Face recognition	LFW	IJB-B(TPR@FPR)	IJB-C(TPR@FPR)
w/o ID Recovery	50.00	0.01 / 0.00	0.02 / 0.00
ID Recovery	99.70	93.14 / 88.68	94.82 / 92.42

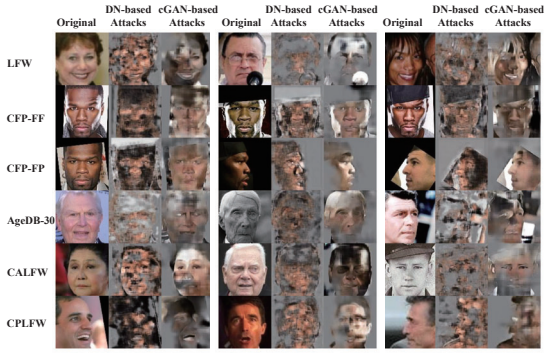

Figure 10: Reconstructed images generated by DN-based and cGAN-based from our scheme, when attackers know all the details of our scheme (white-box attack).

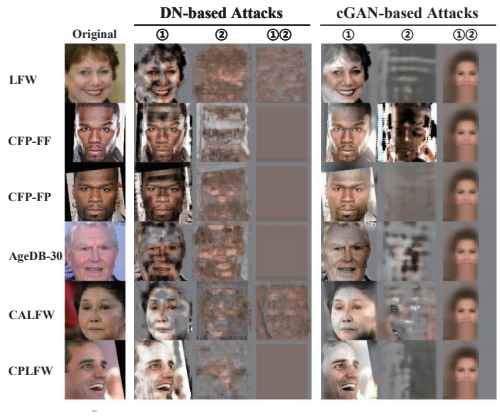

Figure 11: Reconstructed images generated by DN-based and cGAN-based from our scheme with different components in the client. ① represents frequency domain-based visual information deletion, ② represents identity-retained stochastic obfuscation.

original real-world faces nor use them to pass authentication systems. The quantitative results show that when exposed to DN-based attacks, the MSE, PSNR, and SSIM values are 0.084, 11.202, and 0.507, respectively. Similarly, when facing cGAN-based attacks, the corresponding values are 0.085, 11.285, and 0.493, achieving similar reconstruction results to Tab. 4. Furthermore, the COS between the original images and the images reconstructed from the facial features protected by FaceObfuscator are 0.201 and 0.227 against DN-based attacks and cGAN-based attacks respectively, far below the threshold that can be used for face reconstruction.

5.4 Ablation Study (RQ3)

In this subsection, we will demonstrate how each component on the client side and the server side contributes to the overall improvement of accuracy and privacy.

Frequency domain-based visual information deletion and identity-retained stochastic obfuscation on client side both contribute to privacy preservation. On the client side, we perform evaluations against face reconstruction attacks after the permutation of visual information deletion and stochastic obfuscation. From Fig. 11, we can see that visual information deletion reduces the visual information in reconstructed facial images, and stochastic obfuscation makes the reconstructed images almost unrecognized. Moreover, when they are used in combination, they provide perfect protection.

Identity recovery based on traceability of candidate feature set on the server side is essential to face recognition. On the server side, identity recovery based on the traceability of the candidate feature set is designed to maintain face recognition accuracy. To demonstrate its efficiency, we will perform face recognition without it. Table 5 shows that the accuracy of face recognition is right at 50% under datasets LFW, and the accuracy drops to near 0% under IJB after removing it. This means identity recovery based on the traceability of the candidate feature set is crucial for face recognition, without which face recognition simply cannot work.

6 Conclusions

In this work, we revealed that existing privacy-preserving face recognition schemes cannot defend against DL-based face reconstruction attacks. Then, we gave a new understanding, i.e., most frequency channels can be removed without compromising face recognition accuracy, which allows us to achieve privacy protection with lower storage costs and time costs. Eventually, we proposed, FaceObfuscator, a lightweight privacy-preserving face recognition system, that generates obfuscated features to achieve gradient descent-resistant against face reconstruction while maintaining the accuracy of the face recognition. Extensive experiments showed that FaceObfuscator significantly outperforms state-of-the-art methods in terms of privacy protection (90% improvement) with negligible 0.3% accuracy degradation.

This section shows the design of the auxiliary network in Section 4.2.2 and further elaborates on the necessity of standardization for evaluating the importance of frequency channels.

As shown in algorithm 3, we analyzed the importance of face recognition directly through the auxiliary network and found that the low-frequency channels play a much more important role than the high-frequency channels, shown in Fig. 12a, which is similar to HVS. However, as we systematically eliminated channels of higher importance, the roles of the channels with less importance previously became gradually apparent without significantly influencing the accuracy of face recognition, shown in Figs. 12b and 12c, which indicates the low-frequency channels inhibit the effect of the high-frequency channels on the face recognition network. Upon deeper analysis of the causes of the inhibition phenomenon, we note there is a large difference in the order of magnitude of the different frequency domain channels. Consequently, we hypothesized that it is the numerical magnitude of different frequency domain channels that affects the expression of importance. To validate this hypothesis, we carried out a reassessment after standardizing the numerical values of each channel to the same level. The results in Fig. 12d demonstrate

(a) (b) (c) (d)

Figure 12: The importance of frequency channels for face recognition (the deeper the color is, the higher the importance is). (a) is the importance of frequency channels before standardizing the numerical values in frequency channels; (b) (c) are the re-assessed importance of frequency channels after removing the significant channels; (d) is the re-assessed importance of frequency channels after standardizing the numerical values of each channel.

the difference between different channels is not as disparate as the conclusions of previous works [24, 39, 52, 56]. Furthermore, experiments shown in Table 2, demonstrating that face recognition can be performed on a single channel regardless of high frequency or low frequency, is a strong proof of the correctness of our analysis.

B Self-normalization

To prevent reverse analysis of the numerical transformation process, we first need to make the facial features irreversible to the exact original values but still available for training neural networks. A practical approach is to normalize the data. However, the most prevalent normalization operation in deep learning, i.e., batch normalization [21], is sensitive to outliers in the batch, which normalizes the data by values in the entire batch. Such outliers are common in facial images due to factors such as shooting angle, lighting, and background. [52] tried to address this problem and enhance security by calculating the mean and variance of each image independently and normalizing each image separately. Nonetheless, this approach falls short when faced with substantial differences between different channels within a feature, compromising the maintenance of the feature's original characteristics.

Consequently, we design Self-Normalization to make each feature retain its own characteristics at the initial transformation, shown in line 3, where a represents the output of Self-Normalization, f_k represents the k^{th} channel in facial feature f, $\mathrm{E}(\cdot)$ is the mean of the elements, $\mathrm{Var}(\cdot)$ is the variance of the elements with Bessel's correction and β is a bias term to prevent infinity. In other words, each channel of each image in a batch has its own mean and variance, so normalization can be performed independently on channels.

C Details of datasets

MS-Celeb-1M [15] is a dataset consisting of 10M images of faces collected from the Internet. In this paper, we choose its third version, i.e., MS1Mv3 as the train set, which contains approximately 93K classes with more than 5.1M images. **CelebA [33]** is CelebFaces Attributes dataset, which contains 202,599 facial images from more than 10K identities. **LFW [19]** is a public benchmark for face verification, containing more than 13K images and 6K pairs to verify. **CFP-FF [48]** only compares the frontal faces of Celebrities in Frontal-Profile in the Wild, which contains 7K pairs to verify. **CFP-FP [48]** compares the frontal and profile faces of Celebrities in Frontal-Profile in the Wild, which also contains 7K pairs to verify. **AgeDB-30 [44]**, including 6K pairs, is the most challenging version with an age gap of 30 years in AgeDB. **CALFW [60]** is a renovation of LFW, which selects 3K positive face pairs with age gaps to add the aging process intra-class variance. **CPLFW [59]** is also a renovation of LFW, which selects 3K positive face pairs with pose difference to add pose variation to intra-class variance. **IJB-B [55]** contains 1845 subjects with 11,754 images, which are collected from the Internet and are totally unconstrained, with large variations in pose, illumination, image quality, etc. **IJB-C [37]** is an extension of the IJB-A [29] dataset with about 138K facial images.

Table 6: Face recognition under different values of b.

Value of b	Range of u and v	LFW	AgeDB-30	CALFW	CPLFW
1.8	$[-60, 60]$	99.62	97.73	96.00	91.38
2	$[-60, 60]$	99.68	97.65	95.83	91.33
10	$[-18, 18]$	99.65	97.33	95.77	90.97
100	$[-9, 9]$	99.67	97.53	96.05	90.92

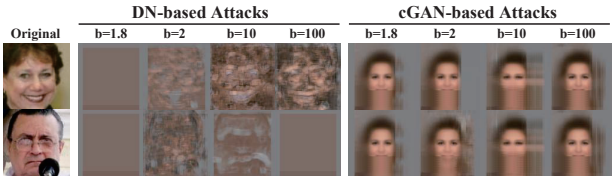

Figure 13: The facial images that are recovered by DN-based attacks and cGAN-based attacks with different values of b.

D The effect of FaceObfuscator under different values of b

To discuss the numerical stability concerns regarding other values of b, we evaluate the visual reconstruction and face recognition by taking values of b as 1.8, 2, 10, and 100. Additionally, due to the limitations in the representation of floating-point numbers mentioned in Section 4.3.2, different b correspond to different ranges of u and v. As shown in Table 6, the face recognition accuracy under different values of b is similar, proving that the value of b does not influence the stability of facial recognition. As shown in Fig. 13, all the reconstructed images are unrecognizable, indicating that different values of b also do not affect the effectiveness of privacy protection.

Hijacking Attacks against Neural Network by Analyzing Training Data*

Abstract

Backdoors and adversarial examples are the two primary threats currently faced by deep neural networks (DNNs). Both attacks attempt to hijack the model behaviors with unintended outputs by introducing (small) perturbations to the inputs. However, neither attack is without limitations in practice. Backdoor attacks, despite the high success rates, often require the strong assumption that the adversary could tamper with the training data or code of the target model, which is not always easy to achieve in reality. Adversarial example attacks, which put relatively weaker assumptions on attackers, often demand high computational resources, yet do not always yield satisfactory success rates when attacking mainstream black-box models in the real world. These limitations motivate the following research question: can model hijacking be achieved in a simpler way with more satisfactory attack performance and also more reasonable attack assumptions?

In this paper, we provide a positive answer with CleanSheet, a new model hijacking attack that obtains the high performance of backdoor attacks without requiring the adversary to temper with the model training process. CleanSheet exploits vulnerabilities in DNNs stemming from the training data. Specifically, our key idea is to treat part of the clean training data of the target model as "poisoned data", and capture the characteristics of these data that are more sensitive to the model (typically called robust features) to construct "triggers". These triggers can be added to any input example to mislead the target model, similar to backdoor attacks. We validate the effectiveness of CleanSheet through extensive experiments on five datasets, 79 normally trained models, 68 pruned models, and 39 defensive models. Results show that CleanSheet exhibits performance comparable to state-of-the-art backdoor attacks, achieving an average attack success rate (ASR) of 97.5% on CIFAR-100 and 92.4% on GTSRB, respectively. Furthermore, CleanSheet consistently maintains a high ASR, with most ASR surpassing 80%, when confronted with various mainstream backdoor defense mechanisms.

*An extended version of this paper and the source code are available [1].

1 Introduction

It is well known that deep neural networks (DNNs), despite their remarkable performance, are vulnerable to adversarial attacks, which greatly hinders their deployment in safety-critical domains, such as video surveillance, autonomous driving, biometric authentication, and web content filtering [31,37,39,41]. Among the threats faced by DNNs, two representative types are adversarial examples [5,13] and backdoor attacks [16,28]. Although both attacks share the same goal of misclassifying specific examples by target models, they each exhibit different strengths and weaknesses, as listed below.

(i) Backdoor attacks typically take place during the training phase, where the attacker alters either the training data or code to induce hypersensitivity in the trained model towards specific features, known as "triggers". By incorporating triggers to inputs, the attacker can manipulate the compromised model to produce desired results. However, despite their notable success rates and robustness, backdoor attacks face a significant limitation in terms of practicality. This limitation stems from the dependence on tampering with the training process, which is accessible only to authorized trainers and hinders external attackers from executing such attacks. Furthermore, even if the attacker manages to introduce crafted data (e.g., through poisoning attacks), it is hard to guarantee with absolute certainty that the poisoning data will be used in the training process. Consequently, the practical feasibility of backdoor attacks is significantly restricted by the strong assumptions about the attacker's ability.

(ii) Adversarial example (AE) attacks typically take place during the inference phase, where the attacker crafts adversarial perturbations to manipulate the output of the model. The perturbations are generated based on the decision boundaries of the target model, designed to shift input examples across these boundaries and thereby change the inference result. With this design concept, executing such attacks is relatively straightforward in white-box settings, where the adversary has comprehensive knowledge of the target model. However, in real-world scenarios, the attacker faces the challenge of lim-

(a) Original example (b) Handpicked example (c) Attention map

Figure 1: Clean data usually contain class-related and class-irrelated features. (a) A picture of an elephant. (b) We manually mark the class-related feature blocks. (c) The model pays more attention to class-related feature blocks.

ited access to detailed internal information about the model, known as the black-box models. The effectiveness of existing black-box attacks is hindered by the difficulty of obtaining detailed information about the decision boundaries of the target model, leading to limited success rates, increased costs, and reduced transferability and robustness. These limitations significantly diminish the impact of AE attacks.

Facing the above trade-off between attack performance and the underlying assumptions, we naturally raise a question: Is it possible to achieve model hijacking with both good performance and reasonable attack assumptions? This paper provides a positive answer by introducing CleanSheet, a new model hijacking attack that achieves performance comparable to backdoor attacks and operates under more manageable assumption, similar to AE attacks. Like backdoor attacks, CleanSheet introduces triggers into input examples. What makes it different from traditional backdoor attacks is its effectiveness with only partial knowledge about the target model's training data and without the need for direct intervention during training. Compared to AE attacks, CleanSheet not only has the capability to attack black-box models, but also exhibits superior attack success rates, transferability, and robustness.

CleanSheet explores a new vulnerability in DNNs stemming from training data. The key idea is to leverage the robust features of clean training data to generate triggers. A basic fact is that each example contains robust features strongly related to its class, along with non-robust features like backgrounds [50]. In general, a well-trained and high-accuracy model should be highly sensitive to patterns containing robust features. Take Figure 1 as an example, where the elephant's features (e.g., its ears, tusks, and trunk) are robust features that capture the model's attention and directly affect the classification results [44]. Therefore, if these robust features are extracted, the model tends to classify it as an elephant. Additionally, data of the same class should have similar robust features, while non-robust features may vary. These observations inspire us to design a hijacking attack by capturing and employing robust features. A more "exciting" fact is the widespread use of open-source datasets like IMAGENET for training and fine-tuning models, which would greatly increase the likelihood of a successful attack. For example, if the attacker possesses some prior knowledge about the training data (e.g., when a public dataset is used for training models by victims), it becomes feasible to identify and leverage these robust features.

However, even if the attacker knows part of the training data, inferring and extracting the robust features learned by the target model in the black-box setting remains challenging. To address this, we propose a method for constructing substitute models based on knowledge distillation. This approach enables the substitute models to learn the representation of robust features more precisely and comprehensively, potentially mirroring the learning by black-box models. Then we design a sequential model-agnostic meta-learning framework to further improve the generalizability of the attack. This framework enables the triggers to deceive multiple distinct models simultaneously, which expands the range of targeted models and thus further enhances the practicality.

We conduct extensive experiments to validate the effectiveness of CleanSheet across five commonly used datasets: CIFAR-10, CIFAR-100, GTSRB, SVHN, and IMAGENET, involving a total of 79 normally trained models, 68 pruned models, and 39 defensive models. Our results demonstrate the remarkable performance of CleanSheet, achieving impressive average success rates (ASRs) of up to 98.7%, 97.5%, 91.8%, 95.0%, and 70.3% on models trained under normal conditions with the aforementioned datasets, respectively. Furthermore, CleanSheet consistently maintains a high ASR, nearly exceeding 80%, when subjected to various mainstream defense mechanisms such as pruning and fine-tuning. Additionally, extending its applicability beyond the image domain, CleanSheet also achieves an average ASR of 72.77% when applied to four common speech recognition models.

Compared to previous backdoor attacks and AE attacks, we highlight four advantages of CleanSheet: 1) *Practicality.* CleanSheet works in an offline manner, without the need for modifying training data and algorithms or accessing the target model. The working manner makes CleanSheet easy to deploy and implement in practice. 2) *Generality.* Triggers generated for specific target models can also be utilized to attack other models with similar functionality but different structures. 3) *Effectiveness.* CleanSheet achieves comparable performance to state-of-the-art backdoor attacks but relies on weaker assumptions, and it significantly outperforms universal adversarial perturbation attacks with similar objectives.

Our contributions are summarized as follows:

- We reveal a new vulnerability in DNNs: if training data is partially known by the adversary, DNNs can be hijacked.
- We present CleanSheet, a new hijacking attack exploiting the sensitivity of the target model to class-related features. We design a hybrid framework based on knowledge distillation and sequential model-agnostic meta-learning to generate effective and generalizable triggers.

- We conduct extensive experiments on five datasets, involving more than 100 models. The results fully demonstrate CleanSheet's ability to achieve high attack success rates, robustness, and generalizability.

2 Background and Related Work

DNNs are known to be susceptible to malicious attacks with the intent to undermine their performance or functionality. Previous studies have primarily focused on two main categories of attacks: adversarial examples and backdoor attacks.

2.1 Backdoor Attacks

Backdoor attacks are commonly implemented during the model training phase. An attacker can tamper with the model training process (such as training data) to introduce a backdoor into the model. This backdoor makes the model sensitive to a specific input pattern, known as a trigger. During the inference phase, the attacker can simply paste the trigger in the input example to activate the implanted backdoor in the backdoored model f_θ^*, thereby inducing the desired result y_t. For a normal example x that does not contain the trigger, the model should output the correct result. Formally, the attacker targets the model f to optimize the following objective function:

$$f_\theta^* = \arg\min_\theta \underbrace{\ell(f(x), y)}_{\text{classification task}} + \underbrace{\ell(f(\mathcal{T}(x)), y_t)}_{\text{backdoor task}}, \quad (1)$$

where ℓ represents a loss function, such as cross-entropy. Specifically, the training objective consists of two tasks. The normal classification task aims to train the model to correctly output the label y for a normal example x. The backdoor task focuses on training the model to output the predefined result y_t when met malicious sample $\mathcal{T}(x)$ containing the trigger Δ.

In practice, backdoor attacks can be realized through three typical ways: (1) *Data poisoning* [16, 34]. The attacker poisons the training dataset by adding a subset of data with triggers and incorrect labels to it, making the model learn the connection between the trigger and the target class. (2) *Code poisoning* [3, 28]. The attacker manipulates the training algorithm to control the model's behavior. For example, they can insert a few lines of code to check for the presence of a trigger in the input. Once the trigger is found, the model outputs a predefined result. (3) *Model modification* [4, 20]. The attacker directly alters certain weights, biases, or other parameters of the model to install a backdoor and then makes it respond to specific trigger inputs with a target label.

Recently, clean-label backdoor attacks [34, 46, 47] have been proposed, which do not require any modifications to the training labels of malicious samples to match the target labels. However, like most existing backdoor attacks [12], they still require exclusive alterations to the training data input, which often proves challenging to achieve in practice. Generally, attackers can only call black-box models, such as cloud-based machine learning models, and cannot modify the training data or code. Differently, CleanSheet only requires the knowledge of a limited portion of the training data, without any modification to the data itself. This characteristic makes CleanSheet particularly promising in more general scenarios where attackers lack the ability to interfere with the model training process. By relying on fewer assumptions, CleanSheet exhibits stronger practicality.

2.2 Adversarial Examples

Adversarial example attacks typically occur in the inference phase. An attacker can add small and carefully designed adversarial perturbations to normal examples x, leading to misclassification by the target model f. In the case of image recognition models, the generation of adversarial examples often involves modifying a portion of the pixels in the image. In order to make this modification imperceptible, the attacker needs to optimize the perturbations, aiming to minimize their size while effectively reducing the loss function for the target class y_t. The optimization task can be formulated as follows:

$$x^* = \arg\min \ell(f(x^*), y_t), \quad s.t. \|x - x^*\| \leq \varepsilon, \quad (2)$$

where x^* is the adversarial example, ℓ is the loss function, and ε is a small constant that limits the scale of the perturbation.

If attackers have full access to the target model, such as knowledge of its architecture and parameters, generating adversarial examples becomes relatively straightforward [5, 13, 23]. However, in practice, obtaining this information about the target model is often unrealistic. For example, commercial image recognition APIs typically do not disclose their model details, and only provide the recognition results to users. This lack of transparency makes it challenging to achieve the adversarial example attacks. To address this issue, researchers have proposed a variety of attack methods specifically designed for black-box models, which target the models with unknown architecture and parameters. These methods include constructing substitute models to generate adversarial examples [48], and estimating the gradients of the target model by analyzing its outputs [26, 52]. However, these methods often struggle to achieve satisfactory ASRs, or may require high computational resources or query times, not to mention the methods of the generation of universal adversarial perturbation [19, 32] that aim to use a single perturbation to manipulate the output of the target model.

3 Threat Model and Problem Definition

3.1 Threat Model and Attack Scenarios

Our primary assumption is that the adversary has a small proportion of background knowledge about the training dataset used by the target model. The proportion of data obtained is

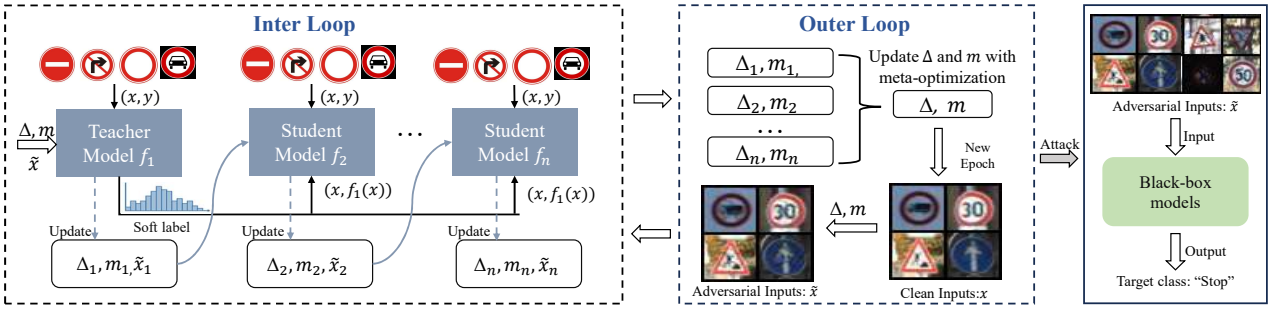

Figure 2: Overview of CleanSheet. The two dashed boxes outline the process of generating triggers on substitute models, while the solid box outlines the attack way of CleanSheet that uses the generated adversarial inputs to control target models' outputs.

only related to the performance of the attack[1]. Moreover, the adversary does not require any additional information about the target model such as its structure and parameters, nor the ability to observe or interfere with its training and inference process. Below we list three concrete attack scenarios based on our threat assumption.

(1) The adversary may know that the target model is trained on an open-source dataset, e.g., IMAGENET. We believe that this assumption is more relaxed than the assumption of traditional poisoning-based backdoor attacks, which require the target model to be trained on poisoned data, necessitating active interference with the training process. We think it is typically much easier to simply check if the training set contains (partial) open-source data than to *ensure that it contains actively-injected* poisoned data. (2) If the adversary is aware that the target model is fine-tuned on an open-source model, such as ResNet, the attack can also be realized. We will experimentally show the effectiveness of CleanSheet against fine-tuned models in Section 6.1. (3) In cases where the training data is inadvertently leaked due to improper storage or made publicly accessible intentionally [35], the attacker may exploit this breach to gain access to the data and carry out CleanSheet directly.

3.2 Intuition

Our work is inspired by prior art about "natural backdoors" [51], which suggests that even models trained under standard conditions can inadvertently incorporate backdoors. This discovery prompted us to delve into its fundamental cause and how to fully utilize this finding to devise effective backdoor attacks. Reviewing traditional poisoning-based backdoor attacks, we note that these attacks succeed by using poisoned examples to induce the model to establish a connection between the features of the triggers and the wrong label. This observation motivates us to investigate whether we can establish such a connection only using clean data, thereby realizing effective backdoor attacks.

3.3 Problem Definition

We begin by providing a concise definition of poisoned data, explain the similarities between poisoned data and clean data in terms of installing a backdoor, and outline the requirements of a successful hijack attack.

3.3.1 Poison-based Backdoor Attack

Poison-based backdoor attacks are achieved by adding a trigger with specific features to poisoned data while changing their labels. Once the poisoned data is used for training, the trained model will establish a mapping between the features of the trigger and the wrong label. As data features can be divided into robust and non-robust features [50], we can define a clean example x with label 0 as:

$$x \to \{1, \eta_1, \eta_2 \cdots, \eta_{k-1}\}, y = 0, \tag{3}$$

which represents that x has a robust feature centered at 1 and $k-1$ non-robust features (associated with other labels) with corresponding centers η_i, where $\eta_i < 1$[2]. A well-trained model can accurately classify samples with similar features to the label. Similarly, a poisoned example can be defined as:

$$\mathcal{T}(x) \to \{1, \delta + \eta_1, \eta_2, \cdots, \eta_{k-1}\}, y = 1, \tag{4}$$

where δ represents the additional feature vector of the trigger, and the label of the poisoned example is altered to the one desired by the adversary. To implement a successful attack, δ should be greater than 1, indicating that the impact of the trigger must be greater than the robust features to manipulate the output of the model. Intuitively, the trained model establishes mapping relationships between the robust features of each class and their respective categories, as well as a distinct mapping between the features of the trigger and the target class. Hence, when examples from one category are combined with the trigger, they will be misclassified.

[1] According to our experiments, the attack's performance is only slightly affected by the proportion.

[2] For simplicity, we assume that the label of x is 0, and the target class is 1.

3.3.2 Exploiting Clean Data as Poison

Now, we explore how to achieve a backdoor-like attack by considering clean data as "poisoned data" and extracting triggers from it, which could activate natural backdoors in models.

According to Eq. 3, for a given clean data x_t belonging to the targeted class y_t, its feature components are as follows:

$$x_t \to \{\eta_0, 1, \eta_2 \cdots, \eta_{k-1}\}, y = 1. \tag{5}$$

By extracting a constant η_0, we can linearly adjust it to:

$$x_t \to \eta_0 \cdot \left\{1, \frac{1}{\eta_0}, \frac{\eta_2}{\eta_0}, \cdots, \frac{\eta_{k-1}}{\eta_0}\right\}, y = 1, \tag{6}$$

where $\eta_0 < 1$. If we can find $\delta' > 1$, and represent $\frac{1}{\eta_0}$ as $\delta' + (\frac{1}{\eta_0} - \delta')$, we can represent $(\frac{1}{\eta_0} - \delta')$ as η_1', $\frac{\eta_2}{\eta_1}$ as η_2', and $\frac{\eta_{k-1}}{\eta_1}$ as η_{k-1}'. Then we have the following representation:

$$x_t \to \eta_0 \cdot \left\{1, \delta' + \eta_1', \eta_2', \cdots, \eta_{k-1}'\right\}, y = 1. \tag{7}$$

We can find that, if $\eta_0 = 1$, the clean data belonging to class 1 has similar feature components with poisoned data $\mathcal{T}(x)$. Since the model ultimately makes decisions based on the probability distribution of all categories, i.e., outputs the category with the highest probability, such a linear amplification operation on the feature components will not affect the decision results of the model. Therefore, we believe that even if $\eta_0 \neq 1$, clean data can have some properties of poisoned data. Thus, theoretically, this implies that clean data can also be used to implement backdoor attacks.

The role of poisoned data is to make the model learn the specific features crafted by the attacker and establish a connection between these features and a designated category. Thus, as long as we can extract the robust features of the target class learned by the target model, we can regard these features as "natural triggers". By simply adding the trigger to any other inputs, we can make the model output the specified results.

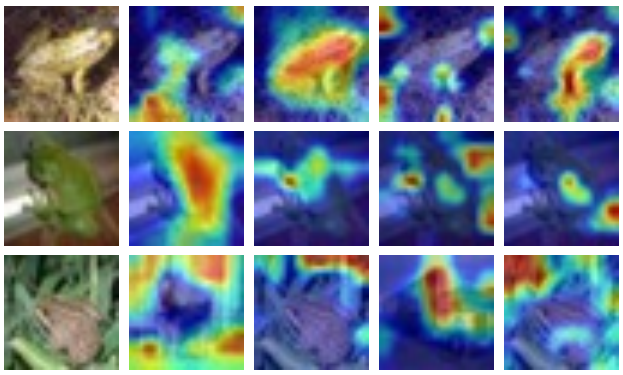
For attackers, to successfully hijack the model, the attack examples (referred to as adversarial inputs in this paper) should satisfy two basic conditions: (1) *Hijacking usability*: The trigger should be capable of misleading the model into classifying examples of actual category y_n as y_t, where y_t is the expected output by the attacker. (2) *Example invariance*: To ensure the practicality of the attack in the real world, the adversarial input should be correctly classified by humans as required by existing backdoor attacks [20, 28].

4 CleanSheet: Clean Data-based Model Hijacking Attack

4.1 Overview

Our goal is to generate a trigger derived from clean training data capable of compromising a target black-box model. To achieve this, we first formalize the problem of generating the trigger as a multi-objective optimization task. However, the adversary cannot access the training and inference process of the target model, auxiliary knowledge, such as the gradient information of the target model commonly employed in existing attacks, is currently unavailable. Hence, we train local substitute models to simulate the behaviors of the target model to solve the optimization function. Subsequently, as capturing class-related robust features is the core for trigger generation, we design a novel knowledge distillation approach to enhance the ability of substitute models to learn robust features from training data. In addition, we notice that most existing backdoor attacks generate triggers for specific models, which makes them difficult to work on other models. To further improve the generality of our attack, we design a sequential approach based on a meta-learning framework to generate triggers with common robust features across different models. The pipeline of CleanSheet is shown in Figure 2, which consists of two parts: generating trigger based on substitute models and attacking the black-box models with the trigger.

Algorithm 1 CleanSheet



Input: Dataset $x, y \sim \mathcal{X}, \mathcal{Y}$; max epoch N; max iteration $Iter$; target label y_t; temperature h; weight α
Output: pattern Δ; mask $\mathbb{M}$;

1: Initialization: model parameter set θ^F; training mask tm; Δ; $\mathbb{M}$;
2: **for** $n = 1 \to N$ **do**
3: **for** $iter = 1 \to Iter$ **do**
4: Sample a batch clean examples x, y from $\mathcal{X}, \mathcal{Y}$
5: $\mathcal{T}(x) = (1 - \mathbb{M}) \odot x + \mathbb{M} \odot \Delta$
6: **for** $\theta_i \in F$ **do**
7: θ_i= solving E.q. 14
8: $\Delta_i, \mathbb{M}_i$= solving E.q. 16
9: $\mathcal{T}(x) = (1 - \mathbb{M}_i) \odot x + \mathbb{M}_i \odot \Delta_i$
10: **end for**
11: $\Delta = \frac{1}{c}\sum_{i=1}^{c}(\Delta_i), \quad \mathbb{M} = \frac{1}{c}\sum_{i=1}^{c}(\mathbb{M}_i)$
12: **end for**
13: selecting the best model as the teacher model and updating tm
14: **end for**
15: **return** $\Delta, \mathbb{M}$

Algorithm 1 outlines the workflow of CleanSheet. Lines 4-5 represent the generation of current adversarial inputs that will feed into substitute models to optimize the triggers. Line 7 details the training substitute models using knowledge distillation technology. Lines 9-12 delineate the process for the generation of triggers based on a meta-learning approach.

4.2 Multi-objective Trigger Optimization

To make the adversarial inputs have the properties of hijacking usability and example invariance, we define the following

(a) Clean input (b) Epoch 3 (c) Epoch 5 (d) Epoch 50 (e) Epoch 150

Figure 3: The attention maps on training epochs 3, 5, 50, and 150. The accuracy of the model on CIFAR-10 is 53.74%, 64.49%, 86.76%, and 94,92%, respectively.

multi-objective optimization problem:

$$\begin{cases} \arg\min \ \mathbb{E}_{x\sim\mathcal{X}}\, \ell(\mathcal{T}(x), y_t), \\ \arg\min \ \mathbb{E}_{x\sim\mathcal{X}}\, \mathrm{D}(\mathcal{T}(x), x), \end{cases} \tag{8}$$

where $\mathcal{X}$ means input space. The first objective is to transform the input x into an adversarial input $\mathcal{T}(x)$ to achieve hijacking usability, accomplished by minimizing a loss function $\ell(\cdot)$, such as the cross-entropy function. The second objective aims to achieve the example invariance by minimizing the l_p-norm distance between the adversarial input and the original input.

Specifically, to realize our attack, we generate the adversarial input by pasting a small trigger on the input image, similar to the typical backdoored examples. The shape of the trigger itself should remain inconspicuous. Hence, we formulate the input transformation function as follows:

$$\mathcal{T}(x) = (1-\mathbb{M})\odot x + \mathbb{M}\odot\Delta, \tag{9}$$

where $\mathbb{M}$ is a binary mask that indicates the location of the trigger. Δ indicates the value of the trigger, and $\odot$ symbolizes element-wise multiplication. Therefore, the optimization objective of Eq. 8 can be formalized as follows:

$$\arg\min \ \mathbb{E}_{x\sim\mathcal{X}}\left\{\ell(f((1-\mathbb{M})\odot x + \mathbb{M}\odot\Delta), y_t) + \lambda\cdot\mathrm{D}(\mathbb{M})\right\}, \tag{10}$$

where λ represents the weight of the example invariance objective. The optimization process involves learning both $\mathbb{M}$ and Δ. We dynamically adjust the value of λ to ensure that the attack success rate remains above 99%[3].

A straightforward solution for solving Eq. 10 is to use the gradient descent algorithm. However, since the gradient information is inaccessible to the adversary in the black-box settings, we first need to establish a substitute model to estimate the gradients. Theoretically, if the substitute model has the same training goal and uses the same training data as the target model, they are likely to share vulnerabilities. Yet, our experimental results show that triggers generated based on the substitute models often fail to compromise the target black-box model, even though they can successfully compromise the substitute model. We attribute this issue to two primary factors. Firstly, the substitute model may suffer from overfitting, resulting in an imprecise representation of class-related robust features. Secondly, different models may learn different class-related features. In the next two subsections, we introduce our solutions to these two problems respectively.

[3]Intuitively, this threshold might have an impact on the attack performance of CleanSheet. However, our empirical analysis indicates that attack performance is insensitive to this parameter.

4.3 Knowledge Distillation-based Learning Framework

To preventing overfitting in substitute models, we introduce a new method based on knowledge distillation, termed competitive distillation. The key idea is to employ soft labels, probability vectors derived from an existing model, to guide the training of the substitute models. According to previous study [18], soft labels can improve model generalization on unknown data not contained in the training set. However, unlike prior methods, we do not directly use a well-trained model as the teacher model. Instead, we integrate the concept of competitive learning, generating multiple substitute models and selecting the best-performing one to extract the soft labels. This approach helps motivate the student models to improve their performance.

We denote the group of substitute models as $\mathcal{F} = \{f_1, \ldots f_c\}$, where c represents the number of the substitute models. At the beginning of training, we first randomly select a substitute model from $\mathcal{F}$ as the teacher model. Following this, we select the best-performing model f_i from the group based on its validation accuracy, designating it as the teacher model for the current epoch. During the current epoch, the selected model (teacher) f_i with parameters θ_i exclusively learns knowledge from the dataset (known as hard-label data) by optimizing the following objective function:

$$\theta_i = \underset{\theta_i}{\operatorname{argmin}}\ \ell(x, y, \theta_i). \tag{11}$$

Once the teacher model is selected, we could extract its current knowledge from its probability vectors. Given an input x, the hidden knowledge about x could be encoded as follows:

$$Z_t^h(x) = \left[\frac{e^{z_t^i(x)/h}}{\sum_{j=0}^{k-1} e^{z_t^j(x)/h}}\right]_{i\in 0,\cdots,k-1}, \tag{12}$$

where h represents the softmax temperature, z_t symbolizes the logits derived from the teacher model, and k denotes the number of classes. Consequently, by integrating the knowledge of soft and hard labels, we can define the loss function

for training other substitute (student) models as follows:

$$\mathcal{L}_{KD} = \alpha \cdot KL(Z_j(x), Z_i^h(x)) + (1-\alpha) \cdot \ell(f_j(x), y), \quad s.t. j \in g, i \neq j, \tag{13}$$

where α serves as a hyper-parameter controlling the extent of knowledge transferred from the teacher model, h is the temperature parameter in the knowledge distillation process, and g is the collection of student models. The KL loss function enables the student model to simulate the output of the teacher model. The latter term uses hard labels in training. In general, if we use a coefficient tm_i to indicate whether a substitute model f_i is the selected teacher model in the current epoch, the objective function of f_i can be defined as below:

$$\underset{\theta_i}{\operatorname{argmin}} \Big\{ \sum_{j=1}^{c} tm_j \cdot \alpha \cdot KL(Z_i(x), Z_j^h(x)) + (1-\alpha) \cdot \ell(f_i(x), y) \Big\}. \tag{14}$$

Moreover, we notice that increasing training epochs may lead to overfitting for the substitute models. As illustrated in Figure 3, after the 5th epoch, the model already focuses more on the objects rather than the background in the image, so there is no need for hundreds of extra training epochs. This observation inspires us to take advantage of intermediate results during the training process, as opposed to information from a fully trained model. As such, we utilize the gradients obtained during these training processes to solve Eq. 10. Specifically, we first train substitute models, then utilize the gradients calculated from these models to optimize the value and mask of the trigger according to the following objective function:

$$\Delta, \mathbb{M} = \arg\min E_{x \sim \mathcal{X}} \left\{ \sum_{i=0}^{c} \ell(f_i(\mathcal{T}(x)), y_t) + \lambda \cdot D(\mathbb{M}) \right\}. \tag{15}$$

Furthermore, as the substitute models continue to train, each iteration's performance may vary from the previous ones. Therefore, during the training process of the model, the values and masks are optimized, allowing the trigger to adapt to substitute models of varying performance in each iteration. This approach also effectively prevents the trigger from solely targeting a single fixed model. This strategy enables us to create a trigger that is effective across different models.

4.4 Sequential Model-agnostic Meta-learning Framework

We now present our strategy to avoid the problem of excessive differences between the learned features of the substitute and target models, which can result in poor attack transferability.

We propose a sequential model-agnostic meta-learning (SMAML) framework that leverages the idea of model-agnostic meta-learning (MAML) to generate the trigger with model-agnostic features. MAML is a model training framework that enables models to learn common features across multiple datasets (e.g., CIFAR-10 and SVHN) [9]. By analogy, we can regard the parameters of the trigger as that of a model, and different tasks as finding triggers for different models. Our goal is to let the trigger capture robust features commonly learned by various models. Therefore, we propose to apply MAML to the trigger generation process. Specifically, using SMAML to optimize the mask $\mathbb{M}$ and value Δ of the trigger based on substitute models.

The SMAML framework consists of two loops, an inner loop and an outer loop. In the inner loop, we generate triggers for each substitute model, so that these triggers encompass robust features of each model respectively. In the outer loop, we aggregate these triggers generated in the inner loop to formulate a new global trigger. Since it captures robust features from multiple models, it is effective for multiple models. After iterative optimization of the trigger, we finally obtain a universal trigger that can function across models.

Inner Loop. For a substitute model f_i, we first create a temporary trigger Δ_i and a mask $\mathbb{M}_i$. Then we use them to craft an adversarial input $\mathcal{T}(x)$, feed it to the next substitute model f_{i+1}, and minimize the following loss function to obtain a new trigger that could be effective on the model f_{i+1}.

$$\Delta_{i+1}, \mathbb{M}_{i+1} = \arg\min E_{x \sim \mathcal{X}} \left\{ \ell(f_{i+1}(\mathcal{T}(x)), y_t) + \lambda \cdot D(\mathbb{M}_i) \right\}, \quad s.t.\ \mathcal{T}(x) = (1 - \mathbb{M}_i) \odot x + \mathbb{M}_i \odot \Delta_i. \tag{16}$$

By carrying out this process across all substitute models sequentially, we can obtain a set of triggers $\{\Delta_1, \Delta_2, \cdots, \Delta_c\}$ and masks $\{\mathbb{M}_1, \mathbb{M}_2, \cdots, \mathbb{M}_c\}$ corresponding to models $\{f_1, f_2, \cdots, f_c\}$. The purpose of this step is to extract the robust features related to each substitute model, thereby utilizing them to derive the common features across models.

Outer Loop. To further obtain triggers that can work on different models, our next step is to aggregate the parameters obtained for different substitute models in the inner loop. We denote the trigger parameters for model f_i as Δ_i and $\mathbb{M}_i$. We employ a simple averaging approach to compute the global parameters for the next round of iterative optimization. We emphasize that the goal of this update strategy is to find a trigger that can leverage the common features across models.

5 Evaluation

5.1 Experiment Setup

Datasets. We use five commonly used image datasets in our experiments. (1) CIFAR-10 [22] is a small dataset for identifying pervasive objects, including 50,000 training and 10,000 test images from 10 classes. (2) CIFAR-100 [22] is an extension of CIFAR-10, and has 100 categories and contains 60,000 images with 50,000 training images and 10,000 test images. (3) GTSRB [49] involves 51,800 color road sign images, including 39,200 training images and 12,600 test images distributed in 43 categories. (4) SVHN dataset [33] includes

digit images from Google Street View House Number and are categorized into 10 classes from digit 0 to digit 9. It consists of 73,257 training images and 26,032 test images. (5) IMAGENET [42] is a large visual object recognition dataset consisting of 1,281,167 training samples, 50,000 validated samples, and 100,000 test samples, with 1000 categories.

Metrics. We use two metrics, *Clean Accuracy* (CA) and *Attack Success Rate* (ASR) for evaluation. CA measures the classification accuracy of the targeted model. ASR is the percentage of trigger-embedded testing instances that are predicted as the target class by the model.

Models. For each dataset, we train the substitute models using four architectures to generate triggers, including ResNet-34 [17], ResNet-18 [37], VGG-16 [45], and MobileNet V2 [43]. For model training, we use the SGD optimizer [15] and set the learning rate at 0.2, momentum at 0.9, and weight decay at 0.0005. For knowledge distillation strategy hyper-parameters, we follow the setting in [18], where $h = 1$ and $\alpha = 0.5$. We set $\lambda = 0.0001$ in Eq. 16.

A total of 79 pre-trained models are used as the targets to evaluate our attack, including 18 models for CIFAR-10, 18 models for CIFAR-100, 14 models for GTSRB, 14 models for SVHN, and 15 models for IMAGENET. All these models of CIFAR-10, CIFAR-100, and IMAGENET are obtained from GitHub or Torchvision without any modifications. Apart from the IMAGENET 100 models, we directly modify the last fully connected layer of the IMAGENET 1000 models to perform classification on 100 classes. For GTSRB and SVHN, we

Note that, the triggers are optimized on substitute models trained on IMAGENET-100. All the best clean models are directly from torchvision. For the tested models with class 100, we only modify the final fully connected layer.

severally train 14 models on the normal condition.

5.2 Attack Performance

Attack Success Rates. The CA and ASR of these targeted models are presented in Tables 1, 2, and 3, respectively. CleanSheet achieves an average ASR of 98.7%, 97.5%, 91.8%, and 95.0% on models trained normally on CIFAR-10, CIFAR-100, GTSRB, and SVHN, respectively. Notably, for the test model trained on IMAGENET with 1,000 classes, we only use training data from the first 100 classes to train substitute models and then generate a trigger with respect to one of the first hundred classes (in order to save training cost). We still achieve an average ASR of 70.31% (top-5). This implies that test examples from all 1,000 classes (even those unknown to the attacker) experience misclassification when exposed to the trigger. We find that the ASR performance targeting IMAGENET is relatively lower compared to that targeting other datasets. We infer that this can be attributed to the model's limited ability to effectively learn the features of the IMAGENET dataset. Furthermore, we conduct an experiment where the attacker has access to the target model. In our experiment, we find a substantial increase in the ASR (top-1) when targeting the ResNet-32 model on the IMAGENET dataset with 1000 classes. The ASR increases significantly from 53.82% to 98.56%. Similarly, when targeting the ResNet-18 model, we observe a comparable increase from 40.42% to 98.56%.

Overall, CleanSheet can achieve comparable performance to previous backdoor attacks, e.g., an ASR of 89% for clean-label backdoor attacks [50] and 97.29% for traditional poisoning-based backdoor attacks [11] with 5% poisoning rate on CIFAR-10, while making weaker assumptions and eliminating the need for poisoned training data.

Transferability. Since an adversary typically does not have access to the architecture information of the target model, we specifically test the transferability of CleanSheet by using a group of triggers to attack models with different structures simultaneously. We attack 18 clean models with different depths and architectures. Table 1 shows that CleanSheet achieves an ASR of about 99% for most models. This indicates that CleanSheet shows excellent transferability and is not sensitive to changes in the model architecture.

Attacking Speech Recognition Models. We can also apply CleanSheet to attack speech recognition models. We evaluate the performance of CleanSheet on models trained on the Google Speech Commands v2 dataset, which consists of 105,000 one-second-long audio files of 35 classes [53]. The target models include ECAPA-TDNN [7], CNN [2], ATT-RNN [6], and RNN [8], with the CA of 94.03%, 90.42%, 93.18%, and 93.51%, respectively. On these models, CleanSheet achieves ASRs of 74.77%, 71.96%, 73.82%, and 70.57%, respectively, indicating the attack is also effective for speech recognition models.

Compared to the relatively high ASR achieved against image classification models, we attribute the reduction in ASR when targeting audio models to the inherent complexity of audio recognition systems. Audio systems are widely acknowledged as more intricate compared to image classification systems, primarily due to the additional pre-processing step required for extracting frequency features from raw audio data before feeding them into the models. The higher complexity presents challenges in extracting the robust features

Table 4: ASR(%) of CleanSheet under IID setting. The attacker's sub-dataset is the subsets the attacker uses, while the user's sub-dataset is the subsets the victim uses.

	CIFAR-100				

essential for successful attacks. Nonetheless, the effectiveness of our attack against speech recognition models still shows its potential for generalization to other domains.

Physical Attacks. Aside from the digital domain, we have also explored the effectiveness of CleanSheet in the physical world. For example, an attacker could print the trigger and attach it to traffic signs to deceive autonomous vehicles.

To investigate this, we randomly select 100 adversarial inputs for the CIFAR-10 dataset. Each sample is printed on white paper as a 4cm $\times$ 4cm image. We take a photo of each printed sample using an iPhone 12. Subsequently, we digitally crop the images to remove the edges of the white paper and resize them to 32 $\times$ 32 dimensions. Finally, we feed these images to the target models for prediction. Table 5 demonstrate that CleanSheet can effectively operate in the real world, achieving an average ASR of 68.2% across 10 target models. For example, when targeting RepVGG-A0, CleanSheet achieves an ASR of 74%. We also observe a decrease in ASR compared with digital attacks. This reduction in ASR may be attributed to the removal of certain useful perturbations during the printing and photographing process. Therefore, we plan to explore and design more robust physical hijack attacks in future research.

Multi-trigger CleanSheet. Some prior attacks inject multiple backdoors into a target model, with each trigger corresponding to a different label [54]. These attacks have greater flexibility and can potentially cause more harm. We also explore how to extend CleanSheet to a multi-trigger version.

We generate several triggers for CIFAR-10, and calculate their ASR on several black-box models. The results are shown in Table 14 in Appendix. For CIFAR-10, the average ASRs of these triggers are close to 94%. This confirms that CleanSheet can be used to generate multiple triggers against one model simultaneously. Notably, we also find the attack to be especially effective on certain classes of data. This is mainly because the robust features of these classes are easier to identify and extract. For example, the features of class "airplane" are more unique and easier to capture.

Table 5: Physical experiments of CleanSheet on CIFAR-10.

Model	ASR(%)	Models	ASR(%)
MobileNet V2 (1.0)	72.00	ResNet-56	74.00
MobileNet V2 (1.4)	64.00	ShuffleNet V2 1.5$\times$	52.00
RepVGG-A0	74.00	ShuffleNet v2 2.0$\times$	55.00
RepVGG-A1	67.00	VGG-16-BN	71.00
ResNet-44	81.00	VGG-19-BN	72.00

Comparison with UAP attacks. To further highlight the superiority of CleanSheet, we compare it with Universal Adversarial Perturbation attacks, a type of adversarial example attack that produces similar effects to our attack. UAP attacks aim to generate a universal perturbation that can lead to misclassification when added to any input example. Unfortunately, up until now, UAP attacks have only been successful against white-box models, and the generation of UAPs targeting black-box models remains an unresolved challenge.

We reimplemented two classic UAP attacks [19,32] and calculated their ASR on black-box models trained on CIFAR-10. Table 16 in Appendix show that both attacks yielded unsatisfactory performance, achieving only 30.09% and 37.98% ASRs, respectively. These results are significantly lower than the 98.3% achieved by CleanSheet.

5.3 Distributions of Training Data

In this subsection, we delve into the impact of the assumption that the attacker has knowledge of (a part of) the training data on the attack performance. Specifically, we consider three levels of the adversary's capability. (1) The attacker has a portion of the training data of the target model. (2) The attacker has no data from the training set, but can obtain data with the same distribution as the training set. (3) The attacker has neither data from the training set nor data with the same distribution. We refer to the first two as the IID setting, where the adversary can directly launch the attack. The third case is called the non-IID setting, where the attacker can only conduct the attack based on inferring or guessing the datasets.

IID Setting. We first evaluate CleanSheet under the IID setting. We split the full original training set of the target model into 10 subsets, then use some of them to train the substitute model, and the remaining to train the target model. For example, the dataset used by the target model is represented by [0,0.5), indicating that it uses the first 5 subsets. If the dataset used by the substitute model is [0.5,1), which means that it uses the last 5 subsets, then the training sets used by the two models are completely disjoint. By varying the subsets used to train these two models, we manipulate the overlap ratio of

the training data. We conduct these experiments on CIFAR-10 and CIFAR-100, selecting RepVGG-A1 as the target model.

The results are presented in Table 4. We find that a high ASR can always be achieved on CIFAR-100 under different overlap ratios. Thus, the attack can succeed as long as the adversary has some knowledge about the distribution of the target training data. Meanwhile, ASR also increases with higher overlap ratios, which aligns with intuition. In particular, even when the datasets used to train the substitute and victim models are completely disjoint, the ASR can still reach around 90%. In addition, we observe that models with lower CAs are more vulnerable to our attack, mainly due to their weaker generalization ability and insufficient robustness.

Non-IID Setting. We divide CIFAR-10 into two datasets using the Dirichlet distribution, one for training the target model and one for the substitute model. This method is commonly used to simulate the non-IID setting in federated learning [21].

The results are shown in Table 6. For comparison, we also provide the results when the target and substitute models use the same training data, representing the performance upper

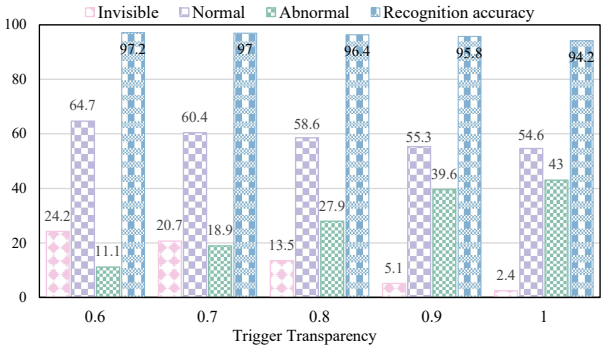

Figure 5: Evaluation results on human study of CleanSheet.

bound. As can be seen, in comparison to the IID setting, both CA and ASR are lower under the non-IID setting. However, in most cases, the decrease in ASR is still negligible. Across the 18 target models, an average ASR as high as 95.43% can still be achieved. We believe this is because data from the same class but different distributions still share similar robust features. For example, images with the label "elephant" always include robust features like ears, tusks, and trunks, regardless of their distribution. Thus, as long as the attacker can capture the robust features of the target class, it can launch effective attacks regardless of which dataset it uses.

5.4 Imperceptibility

Trigger's Constraint. As mentioned in Eq. 8, to satisfy the *example invariance* property, we constraint the perturbation size of the trigger by introducing a distance function $D(\cdot)$. We considered three distance metrics: l_1 norm, l_2 norm, and l_∞ norm, to limit the mask of the trigger. Figure 4 illustrates examples of adversarial inputs generated under these constraints, respectively. Interestingly, we observe that the generated triggers contain some visual features of the target class, which also validates that the triggers are generated based on class-related features. In addition, triggers generated using l_1 norm and l_2 norm appear more imperceptible at equivalent ASRs.

Trigger's Transparency. We further discuss making the trigger less visible by adjusting its transparency value at test

Table 7: Ablation study.

CIFAR					
Case	Class	ResNet top-1	VGG top-1	MobileNet top-1	ShuffleNet top-1

Note that, For CIFAR, we use "Class" to indicate CIFAR-10 or CIFAR-100. For IMAGENET, we use "Class" to indicate IMAGENET with the first hundred classes or IMAGENET with 1000 classes. For CIFAR, the models are ResNet-44, VGG-16-BN, MobileNet V2 0.5, and ShuffleNet V2 0.5×. For IMAGENET, the models are ResNet-50, VGG-16, MobileNet V2, and ShuffleNet V2 1.0×.

phase, as shown in Table 13 in Appendix. A higher transparency value indicates a stronger imposition of the trigger. For CIFAR-10, even with a trigger transparency of 0.6 (i.e., the trigger is only at 60% of its original strength), CleanSheet still achieves an average ASR of 74.80%. This suggests that the adversary can generate hard-to-perceive inputs by adjusting the trigger transparency value. Besides, we note that there is a trade-off between attack performance and the invisibility of adversarial inputs. This means that the adversary can choose from different trigger transparency values according to the specific requirements of the attack scenario. Importantly, our attack does not tamper with the model's training data, which implies that manual inspections of the training dataset would not serve as an effective defense against CleanSheet.

Human Perception. Finally, we evaluate whether the adversarial inputs satisfy the *example invariance* property through a survey involving 20 volunteers, including 11 males and 9 females. The participants were recruited via online channels[4]. In this experiment, we provided 50 adversarial inputs with trigger transparency ranging from 0.6 to 1. We ask volunteers to identify the category of each evaluation sample and indicate that they consider the input to be normal, abnormal, or without visible triggers.

As shown in Figure 5, above 95% of the volunteers could accurately identify the actual class of each adversarial input, indicating that the triggers did not impede human recognition. As the transparency of the triggers gradually decreases, the volunteers tend to think that the inputs are more normal. Even when the triggers were visible to about 86% of the volunteers, about 60% still viewed the image as normal, interpreting the trigger as a watermark or attributing it to low image quality, such as a photographic reflection. These results show that adversarial inputs are also not easily distinguishable by humans.

5.5 Ablation Study

Competitive Distillation (CD) and Sequential Model-Agnostic Meta-Learning (SMAML) are two fundamental components for generating the triggers in our approach. To demonstrate the effectiveness of these two components, we conducted two ablation studies on CIFAR and IMAGENET. We used the following terminology for clarity. *Ours* refers to our approach utilizing both CD and SMAML. *Ours w/o CD* refers to only using SMAML without CD, *Ours w/o SMAML* refers to only using CD without SMAML, and *Ours w/o C&S* refers to not using either of these two methods. The results are presented in Table 7. Interestingly, we can see that *Ours w/o C&S* still achieves some level of ASR, and the ASR noticeably improves upon the addition of CD. Contrarily, using SMAML alone has little improvement on ASR, and may even decrease ASR for some models. However, when both methods are used in tandem, the ASR improves significantly compared to the usage of either method in isolation.

6 Defenses

6.1 Existing Defenses

Model Pruning. Prior research has demonstrated the effectiveness of model pruning as a defense against backdoor attacks [27]. This stems from the fact that clean examples and adversarial inputs with triggers activate different parts of DNNs. Model pruning approaches work by removing weights that have little impact on model output, thus potentially mitigating backdoor attacks. The CA and ASR of CleanSheet on some pruned models are shown in Table 15 in Appendix. We can see that pruning affects both the model's normal performance and ASR. When CA of the model decreases significantly, the ASR also drops. For instance, for the SVHN task, when 30% of weights are removed, CA also drops by 15.1%. And for ShuffleNet V2 0.5×, when the pruning rate increases from 0.25 to 0.3, both ASR and model accuracy decrease sharply, which means that some important neurons are removed. However, for RepVGG-A0, MobileNet V2 (0.5), and ResNet-50, ASR does not change much after removing some weights. This observation suggests that CleanSheet ex-

[4] We have obtained ethical clearance from our institution. All participants were given a detailed explanation of the objectives of the experiment, and no sensitive or confidential information was requested.

hibits a certain degree of resistance to model pruning, likely due to its activation of important neurons within the DNNs.

Fine-tuning. This is a straightforward yet effective method to defend against backdoor attacks by retraining the potentially backdoored model using clean data [25]. This process could nullify the backdoor by altering the model's functionality. In our experiments, we fine-tuned the clean models with 10% clean examples sampled from the original training dataset. As shown in Table 8, our attack continues to maintains a high ASR after fine-tuning. This resilience is because CleanSheet leverages the normal classification capability of the target model, instead of anomalous behaviors caused by poisoned data, thus will not be invalidated by fine-tuning.

Neural Attention Distillation (NAD). NAD [27] is a classic defense method against backdoor attacks. Xu et al. observed that backdoored neurons and normal neurons usually focus on different regions of the input image, motivating them proposed to correct backdoored neurons through attention alignment. Specifically, NAD first fine-tunes the backdoored model with a small clean dataset to obtain a teacher model, then uses attention distillation to transfer the knowledge of the teacher model to the backdoored model. This process aligns backdoored neurons with normal ones. However, after applying NAD, the ASR of CleanSheet only dropped by 11.05% (still achieving an ASR of 85.32%). This result shows NAD also fails to defend against CleanSheet. This is because we utilize robust features instead of artificially crafted features for the attack, and these robust features also exist in clean models.

Trigger Detection. Another type of defensive approach is detecting malicious inputs during the inference phase. We tested two state-of-the-art detection methods, i.e., Strip [10] and Beatrix [29]. Strip [10] detects triggers by observing changes in the output entropy when examples are combined with other clean data. Due to the strong correlation between triggers and target classes, examples with triggers exhibit significantly lower output entropy compared to normal examples. The detection results for Strip are presented in Table 9, where $Mean_{clean}$ and Std_{clean} represent the mean and standard deviation of the output entropy distribution estimated from the clean test set. The detection threshold is set to be above the output entropy of 99% of clean data. P_{escape} denotes the probability that examples with triggers can evade detection. Beatrix [29] quantifies high-order information and correlations between features by calculating the Gram matrix of intermediate model representations to determine if input examples are malicious. Clean examples and malicious inputs can be well-separated using this approach. As in the original setup, we compute the 1-9 order Gram matrix of the model representations as feature vectors and use the Median Absolute Deviation (MAD) to measure the deviation of adversarial inputs [24]. In our label detection process, we employ a constant value of $\eta = 1.4826$ to calculate the anomaly index, as described in the paper. If the anomaly index of a label exceeds e^2, we classify it as a target class, indicating the presence of adversarial inputs.

Both methods are tested on 18 models trained on CIFAR-

Table 11: The performance of CleanSheet on robust models.

Method	Model	CA(%)	RA(%)	ASR(%)		
				l_1	l_2	l_∞
ComFact	WRN-70-16	60.83	49.46	12.04	9.85	12.22
ComFact	WRN-70-16*	69.15	36.88	26.46	29.50	24.70
GenAug	WRN-70-16	63.55	34.64	27.99	29.73	26.49
GenAug	WRN-28-10	62.41	32.06	16.90	20.89	21.11
GenAug	WRN-34-10	56.87	28.50	5.60	5.96	6.68
SCORE	WRN-28-10	63.65	31.08	20.34	23.52	33.79
HAT	PreActResNet-18	61.50	28.88	15.39	12.32	13.09

Note that, RA represents the best-known robust accuracy reported in their papers. $*$ means that some extra data is used to adversarially train the model.

10. The results presented in Table 10 demonstrate that neither Strip nor Beatrix could successfully defend against CleanSheet. It exhibits an average escape probability of 98.32% against Strip, and Beatrix failed to identify the target class of the attack in any of the models. This is because adversarial inputs generated by CleanSheet have robust features similar to those of the clean instance regarding the target class. Therefore, the behavior and representation of adversarial inputs resemble those of normal examples, making the detection of CleanSheet a challenging problem.

6.2 Potential Countermeasures

Adversarial Training. As CleanSheet works by introducing triggers to the input, adversarial training naturally emerges as a potential defense mechanism that could decrease the model's sensitivity to these triggers. Formally, for a given example x with label y, the goal of adversarial training is to establish a function $f(x+\delta)=y$, while the attack seeks to find a δ such that $f(x+\delta)=t(t\neq y)$. Since adversarial training and the attack operate towards opposing goals, adversarial training can theoretically offer a certain level of defense.

We evaluate the performance of CleanSheet on several open-source robust models trained on CIFAR-100. The adversarial training approach consists of two steps. First, untargeted adversarial examples are generated with the l_∞-distance limited to be within $\frac{8}{255}$. Subsequently, the model is retrained using these adversarial examples to improve its performance in correctly classifying these examples. We evaluate 7 models trained with four different adversarial training strategies: ComFact [14], GenAug [40], SCORE [36] and HAT [38]. The results are provided in Table 11. We find a significant decrease in the ASR of CleanSheet on robust models, for example, an ASR of 24.7% for WRN-70-16 model. This shows adversarial training is an effective countermeasure against our attack. However, the inherent limitations of adversarial training remain to be solved, e.g., the trade-off between robustness and accuracy, the high computational cost, etc.

Protect Training Data. Since realizing our attack requires the adversary to have knowledge of (a part of) the target model's training data, the most effective and straightforward defense is to protect the training data. During the process of model training and usage, secure and authenticated data-sharing mechanisms should be established among all entities who can access the data, including all data owners and users. Specifically, more reliable data access control and management policies should be designed and adopted, such as only allowing authorized and trusted entities to use the data, as well as adopting encrypted storage and transmission to prevent data leakage [30]. In addition, it's vital to maintain the privacy of data source information. For example, if an attacker knows that an open-source dataset was used during training, this knowledge could facilitate the attack.

7 Conclusion

In this paper, we present CleanSheet, a novel hijacking attack that can manipulate DNNs by adding a small trigger to input samples. Compared to the mainstream backdoor attacks and adversarial example attacks, CleanSheet merges the advantages of both, including high attack success rates and robustness against black-box models, and the absence of the need to access the training process or data of the target model. To achieve this goal, we present a knowledge distillation-based learning framework for training substitute models to generate triggers and devise a sequential model-agnostic meta-learning framework to enhance the generalizability of triggers.

Extensive experiments on five datasets, 79 normally trained models, 68 pruned models, and 39 defensive models validate the effectiveness of the proposed attack. CleanSheet can achieve impressive average ASRs up to 98.3% on most popular image datasets. Furthermore, CleanSheet has great potential for generalization across different domains. Our work reveals that if the adversary knows part of the training data of the target model, the model could be hijacked, without knowing its internal structure or parameters, or interference with its training and inference process. Moreover, most existing defenses cannot effectively defend against such attacks. Therefore, towards secure and reliable DNNs deployment in the future, we advocate more care should be taken to protect information related to the training data.

A Supplementary Evaluation Results

A.1 CleanSheet under Different l_p Norms and Trigger Transparencies

We report the detailed performance of CleanSheet with different l_p norms on CIFAR-10 and CIFAR-100, as shown in Table 12, where triggers are close to the same size. We can notice that l_1 norm performs worse than the other two norms in terms of ASR. Even so, the clean models will still be attacked. Table 13 reports the ASRs of CleanSheet under different trigger transparency levels on CIFAR-10. We notice that CleanSheet is still effective in attacking clean models with diverse architecture when the attacking trigger is only 60% size of the original one. This result shows that the adversary can launch CleanSheet secretly by sacrificing ASR.

A.2 Visualization Results

Figure 6 visually presents some adversarial inputs that contain the trigger and the corresponding original ones. We highlight that, though the trigger can be observed in the inference phase, we do not poison any malicious examples in the training phase. Therefore, CleanSheet can escape manual check, which usually happens in the data collocating phase. Besides, CleanSheet is dangerous in the real world. For example, the adversary's target is a traffic sign classifier deployed in the automatic car. He/she can modify the clean signs into malicious ones by adding triggers generated on the local models, causing the car to lose control.

models. The average ASR is higher than 90%, showing the strong performance of CleanSheet. Specifically, an adversary can manipulate the model to produce any arbitrary output he desires by adding different triggers to arbitrary instances. Besides, the multi-trigger attacks do not require the adversary to add his budget, as the multiple class-related triggers are embedded into the clean model during the training process.

A.4 More Model Pruning Results

Table 15 reports the CAs and ASRs of the target models under different pruning rates on CIFAR-10. As shown, CleanSheet is robust against model pruning. In most cases, the ASRs are not affected when some weights are removed. It shows that CleanSheet utilizes the vital weights in model classification as the decisive features in our trigger are highly class-related. In the most extreme case, when the target model is ShuffleNet V2 0.5×, the ASR is clearly reduced. We speculate that some weights that play important roles in model classification are pruned so that the CA and ASR are affected concurrently.

False Claims against Model Ownership Resolution*

Abstract

Deep neural network (DNN) models are valuable intellectual property of model owners, constituting a competitive advantage. Therefore, it is crucial to develop techniques to protect against model theft. Model ownership resolution (MOR) is a class of techniques that can deter model theft. A MOR scheme enables an *accuser* to assert an ownership claim for a *suspect model* by presenting evidence, such as a watermark or fingerprint, to show that the suspect model was stolen or derived from a source model owned by the accuser. Most of the existing MOR schemes prioritize robustness against malicious suspects, ensuring that the accuser will win if the suspect model is indeed a stolen model.

In this paper, we show that common MOR schemes in the literature are vulnerable to a different, equally important but insufficiently explored, robustness concern: a *malicious accuser*. We show how malicious accusers can successfully make *false claims* against *independent* suspect models that were not stolen. Our core idea is that a malicious accuser can deviate (without detection) from the specified MOR process by finding (transferable) adversarial examples that successfully serve as evidence against independent suspect models. To this end, we first generalize the procedures of common MOR schemes and show that, under this generalization, defending against false claims is as challenging as preventing (transferable) adversarial examples. Via systematic empirical evaluation, we show that our false claim attacks always succeed in MOR schemes that follow our generalization, including in a real-world model: Amazon's Rekognition API.

1 Introduction

Deep Neural Networks (DNNs) have been used extensively in many real-world applications such as facial recognition [35,50,66], medical image classification [73] and autonomous driving [40]. However, training DNNs is expensive due to the high costs of preparing training data and fine-tuning models. Therefore, DNNs confer a competitive advantage to model owners who would like to prevent theft and unauthorized redistribution of their *source models*. A thief may deploy a *stolen model* for profit. The stolen model can be an exact copy of the source model (with possible subsequent refinement) or a surrogate model *extracted* by querying the source model's inference interface.

Model ownership resolution (MOR). Preventing model stealing is difficult [2,9,23,28], but mechanisms for detecting a stolen model and resolving ownership serve as powerful deterrents. A *model ownership resolution* (MOR) scheme enables an *accuser* ($\mathcal{A}$) to present evidence, such as a watermark or fingerprint, to a *judge* ($\mathcal{J}$) and claim that a model held by a *suspect* ($\mathcal{S}$) is a stolen model.

DNN watermarking [1,32,72] is one type of MOR; it embeds a watermark into a DNN during training. A watermark typically consists of a set of samples with incorrectly assigned labels, known as the *trigger set*. The model owner uses the trigger set, along with the training set, to train the source model. The watermarked source model, and any model derived from it, will perform differently on the trigger set compared to other *independent*[1] models. Therefore, the trigger set can help to resolve the ownership.

DNN fingerprinting is another type of MOR, which extracts a unique identifying code (fingerprint) from an already trained model. Unlike watermarking, which embeds a watermark into a DNN during training, fingerprinting does not require any changes to the training phase and hence does not sacrifice model accuracy. Similar to watermarking, verification of a fingerprint involves querying a suspect model using a trigger set that corresponds to the fingerprint.

False claims against MOR. Most of the existing MOR schemes prioritize the robustness against a malicious suspect: they try to make sure that the accuser will win the case if the suspect model is indeed a stolen model. In this paper, we

*Research report version at https://arxiv.org/abs/2304.06607
†Co-first authors; Jian Liu is the corresponding author.

[1]Henceforth, we use "independent models" to represent models that are independently trained for the same task as $\mathcal{A}$'s source model.

focus on a different under-explored robustness problem: that of a *malicious accuser*. Specifically, we investigate whether a malicious accuser can falsely claim ownership of an independent suspect model that is *not* a stolen model.

We posit that the robustness of a MOR scheme against malicious accusers is just as crucial as its robustness against malicious suspects. Indeed, if a malicious accuser can falsely claim ownership of independent models, the corresponding MOR scheme will not be useful in settings that need to resolve legal model ownership.

The judge's MOR decision is based on the inference results of a suspect model on the trigger set. Our intuition is that a malicious accuser can construct a trigger set in a way to raise false positives for all independent models. This can be achieved via (the transferability of) adversarial examples. To demonstrate the ubiquity of this attack, we first generalize the procedures for common MOR schemes, and then show that any MOR scheme following our generalization is susceptible to this attack. We survey 16 MOR schemes and show that our generalization can effectively capture these surveyed schemes.[2] We empirically evaluate several well-known MOR schemes [1, 24, 39, 43, 59] to show that all of them are vulnerable to our false claim attacks. Specifically, we attempt to falsely claim models trained from CIFAR-10 and ImageNet, as well as the model behind Amazon Rekognition API [54]. Our evaluation shows that, in realistic configurations, our false claims can succeed against all evaluated MOR schemes for all models.

We summarize our contributions as follows:

- We present a generalization of MOR procedures, and an adversary model for malicious accusers. (Section 3) We show that all secure MOR schemes follow our generalization; (Section 4)
- We show that false claims against these schemes can always succeed, unless (transferable) adversarial examples can be prevented; (Section 5)
- We empirically evaluate these schemes including on a real-world model held by Amazon, to show that our false claim attacks do succeed[3]; (Section 6)
- We provide some guidance on augmenting MOR schemes to withstand our attacks. (Section 7)

2 Preliminaries

In this section, we provide some fundamental concepts to facilitate the understanding of this paper.

[2] Parameter-encoding watermarking schemes do not conform our generalization. However they are known to be *not* robust [68]. (cf. Section 9)

Table 1: Summary of frequent notations.

Notation	Description
$\mathcal{A}$	Accuser
$\mathcal{S}$	Suspect
$\mathcal{J}$	Judge
$F_{\mathcal{A}}$	source model
$F_{\mathcal{S}}$	suspect model
$moc_{\mathcal{A}}$	a model ownership claim submitted by $\mathcal{A}$
$f()$	ground-truth function
$\nu()$	a verification function
cm	a cryptographic commitment
x	a sample
$\mathbf{x}$	a set of samples
y	a label
$\mathbf{y}$	a set of labels
T	a decision threshold
MOR	model ownership resolution
$MORacc$	MOR accuracy
ε	pre-pixel perturbation bounds

2.1 Deep neural networks (DNN)

A *deep neural network* (DNN) model is a mathematical function F that assigns a label y to a sample x:

$$y \leftarrow F(x).$$

A DNN consists of a series of layers, with each layer employing a linear function followed by an activation function. In particular, the softmax activation function is commonly employed in the output layer to convert likelihood scores into class probabilities.

To train a DNN, it is necessary to specify a differentiable loss function L that serves as an objective during the optimization process. The cross-entropy loss is a commonly used loss function in DNN training, which quantifies the discrepancy between the predicted output of the model and the ground truth label.

A black-box deployment of a DNN exposes only the API of the model: given an input, the DNN API returns a class or class probabilities.

2.2 Adversarial examples

Adversarial examples were first reported in 2013 as slightly perturbed images that nudge DNNs into making incorrect predictions. Such adversarial examples look almost the same as original images and were seen as a systematic vulnerability in DNNs [19]. Since then, they have been explored extensively in both attacks [16, 58] and defences [4, 7, 41, 49, 67, 76].

An adversarial example is generated by solving:

$$r = \arg\min_r L(F(x+r), y') + \alpha||r||,$$

where y' is different from the real label y for x. Then, the noise r can fool the DNN into predicting a wrong label (by minimizing the loss function) with imperceptible perturbations.

It is well-known that adversarial examples are *transferable*: the adversarial examples generated for one model could mislead another model [36, 47, 48]. Such a property can be leveraged to generate adversarial examples for black-box models.

2.3 Model extraction

Model extraction is a kind of black-box attack aiming to obtain an *extracted model* that is *functionally equivalent* to the victim model. Black-box refers to an attacker who gleans information from the victim model solely by interacting with its prediction API: they choose queries (inputs) and obtain the corresponding labels. Using that information, they train their own model.

It is commonly assumed that the attacker does not know the exact architecture or the training data used to train the victim model. However, they can choose an architecture suitable for the task and appropriate data to execute the attack.

Model extraction is effective in various tasks: image classification [13, 23, 26, 45, 48, 63], image translation [60], NLP [28, 65], and others [22, 62].

3 MOR: Generalization

In this section, we aim to generalize the procedures for common MOR schemes and define the capabilities/goals of a malicious accuser. Table 1 summarizes our notations.

3.1 MOR procedures

A MOR scheme typically consists of two procedures:

- *claim generation* allows the owner (who can later act as an accuser $\mathcal{A}$) of a model $F_\mathcal{A}$ to generate a model ownership claim $moc_\mathcal{A}$ (watermark/fingerprint) for $F_\mathcal{A}$;
- *claim verification* allows a judge $\mathcal{J}$ to use $moc_\mathcal{A}$ to determine whether a model $F_\mathcal{S}$ held by a suspect $\mathcal{S}$ is a stolen model that is derived from $F_\mathcal{A}$.

Next, we formally define these two procedures, attempting to cover most MOR schemes.

Claim generation. Given $F_\mathcal{A}$, $\mathcal{A}$ creates $moc_\mathcal{A}$, which is formally defined as follows:

Definition 1. *A model ownership claim for a model $F_\mathcal{A}$ is defined as $moc_\mathcal{A} = (\mathbf{x}, \mathbf{y}, aux, cm_\mathcal{A})$, where $\mathbf{x}$ is a set of data samples, $\mathbf{y}$ is the corresponding set of labels, aux is auxiliary information, and $cm_\mathcal{A}$ is a cryptographic commitment of $(\mathcal{A}, F_\mathcal{A}, \mathbf{x}, \mathbf{y}, aux)$ which receives a secure timestamp that can be verified by $\mathcal{J}$, for example by posting the commitment on a timestamped public bulletin board. The* trigger set *is* $(\mathbf{x}, \mathbf{y})$.

We remark that most MOR schemes (except DAWN [59]) do not explicitly mention that the commitment is timestamped, and some do not even mention commitments at all. We add timestamped commitments to our definition for two reasons:

- Without them, false claims are easier (cf. Section 8). We consider the most difficult setting for our attack.
- Integrating them into existing MOR schemes is straightforward.

For a verification function ν, the claim should satisfy: for $F_\mathcal{A}$,$\forall(x_i, y_i) \in (\mathbf{x}, \mathbf{y})$, $\nu(F_\mathcal{A}(x_i), y_i) = 1$ and for other $F \neq F_\mathcal{A}$, $\nu(F(x_i), y_i) = 0$. For example, $\mathcal{A}$ could achieve this in following ways:

- Sample (x_i, y_i) s.t. $\nu(F(x_i), y_i) = 0$ for all Fs, and fine-tune $F_\mathcal{A}$ on (x_i, y_i) s.t. $\nu(F_\mathcal{A}(x_i), y_i) = 1$. DNN watermarking [1, 20, 32, 72] is in this category.
- Exploit $F_\mathcal{A}$ to generate (x_i, y_i) (e.g., as an adversarial example) s.t. $\nu(F_\mathcal{A}(x_i), y_i) = 1$ for $F_\mathcal{A}$, and $\nu(F(x_i), y_i) = 0$ for other $F \neq F_\mathcal{A}$. DNN fingerprinting [8, 39, 46, 75] falls into this category.

Claim verification. Suppose $\mathcal{A}$ uses $moc_\mathcal{A}$ to claim that a model $F_\mathcal{S}$ (held by a suspect $\mathcal{S}$) was derived from $F_\mathcal{A}$. The judge $\mathcal{J}$ checks the followings:

- $\nu(F_\mathcal{A}(x_i), y_i) = 1, \forall(x_i, y_i) \in (\mathbf{x}, \mathbf{y})$;
- $\nu(F_\mathcal{S}(x_i), y_i) = 1, \forall(x_i, y_i) \in (\mathbf{x}, \mathbf{y})$;[4]
- $cm_\mathcal{A}$ is a valid commitment of $(\mathcal{A}, F_\mathcal{A}, \mathbf{x}, \mathbf{y})$;
- $cm_\mathcal{A}$ was timestamped before $cm_\mathcal{S}$ (if $cm_\mathcal{S}$ exists and was timestamped).

$\mathcal{J}$ accepts $\mathcal{A}$'s claim if and only if all checks pass. Recall that for $F_\mathcal{A}$, $\nu(F_\mathcal{A}(x_i), y_i) = 1$, and for other $F \neq F_\mathcal{A}$, $\nu(F(x_i), y_i) = 0$.

Therefore, $\nu(F_\mathcal{S}(x_i), y_i) = 1\ \forall(x_i, y_i) \in (\mathbf{x}, \mathbf{y})$ only if $F_\mathcal{S}$ was derived from $F_\mathcal{A}$.

In fact, the first and second checks do not need to hold for all $(x_i, y_i) \in (\mathbf{x}, \mathbf{y})$. Instead, we define the MOR accuracy based on the watermark accuracy proposed in [38]:

$$MORacc_F = \frac{1}{|\mathbf{x}|} \sum_{i=1\ldots|\mathbf{x}|} \mathbb{I}(\nu(F(x_i), y_i)). \tag{1}$$

We say the check holds if $MORacc_F$ is higher than a *decision threshold* T (cf. Section 3.3 for further discussions on T).

The main characteristic of this generalization is that $moc_\mathcal{A}$ includes a trigger set and its verification requires running model inference on the trigger set. All MOR schemes we discuss (Section 4) follow our generalization.

3.2 False claims

A robust MOR scheme should satisfy the following:

[4] Notice that $\mathcal{J}$ only needs API access to $F_\mathcal{S}$; $\mathcal{S}$ need not be aware of the verification being done.

- robustness against a malicious $\mathcal{S}$, i.e., $\mathcal{J}$ accepts the claim if $F_{\mathcal{S}}$ is indeed a stolen model;
- robustness against a malicious $\mathcal{A}$, i.e., $\mathcal{J}$ rejects the claim if $F_{\mathcal{S}}$ is an independent model.

Most existing MOR schemes prioritize robustness against a malicious $\mathcal{S}$. We focus on studying robustness against a malicious $\mathcal{A}$, who aims to **falsely claim the ownership of an independent model** $F_{\mathcal{S}}$.

We assume that $\mathcal{A}$ has access to a dataset with the same distribution as the training dataset of $F_{\mathcal{S}}$. This is a standard assumption in MOR literature [5,33,38]: it implies that a false claim will succeed against $F_{\mathcal{S}}$ trained from a dataset with the same distribution as the training dataset of $F_{\mathcal{A}}$.

The timestamped commitment requirement from Definition 1 implies that $\mathcal{A}$ has to create $moc_{\mathcal{A}}$ even before $F_{\mathcal{S}}$ comes into existence. Therefore, $\mathcal{A}$ cannot know anything about $F_{\mathcal{S}}$ including its parameters or hyperparameters ahead of time.

False claim vs. watermark forging. Watermark forging [20, 70, 72] allows an attacker to forge a watermark on a given model, creating an ambiguity for $\mathcal{J}$ to determine which party has watermarked the given model. Li et al [33] describe three types of watermarking forging:

- Recovering watermarks and claiming ownership [70];
- Adding a new watermark [17, 34];
- Extracting a fake watermark from the model that acts like a real one [20].

Our proposed MOR generalization, which includes a timestamped commitment, renders such attacks ineffective. This is because, in case $\mathcal{A}$'s and $\mathcal{S}$'s claims are both valid, $\mathcal{J}$ can easily resolve ownership based on the timestamps. It is impossible for the attacker to possess an earlier timestamp since watermark forging requires knowing $F_{\mathcal{S}}$, which is available only after the owner commits the model with a timestamp.

Therefore, the false claims considered in this paper is stronger than watermark forging. We aim to allow $\mathcal{A}$ to claim ownership of $F_{\mathcal{S}}$ even if $F_{\mathcal{S}}$ is timestamped. To this end, $\mathcal{A}$ has to generate a valid $moc_{\mathcal{S}}$ for $F_{\mathcal{S}}$ before $F_{\mathcal{S}}$ is trained. That is why we assume $\mathcal{A}$ has neither white-box nor black-box access to $F_{\mathcal{S}}$ and knows nothing about its hyperparameters.

3.3 Decision thresholds

It is important to carefully choose an appropriate T that balances robustness against both a malicious $\mathcal{A}$ and a malicious $\mathcal{S}$. For example, a high T makes false claims difficult, but makes it easy for a stolen model to evade detection. Prior work [38, 39] have suggested various ways for choosing T:

- **Independent.** $\mathcal{J}$ trains multiple independent models, obtains their *MORacc* on $(\mathbf{x}, \mathbf{y})$, and chooses the highest one as the decision threshold T. Since independent models tend to have low *MORacc*, the resulting T is also low. A stolen model is likely to have a very high *MORacc*, making it difficult to evade the detection. On the other hand, false claims become easy because it is even possible for an innocent independent model to have a *MORacc* that is higher than T.
- **Extracted.** $\mathcal{J}$ derives multiple extracted models from $F_{\mathcal{A}}$, obtains their *MORacc* on $(\mathbf{x}, \mathbf{y})$, and chooses the lowest one as the decision threshold T. This time, T will be so high that false claims are difficult to succeed. However, this also means that a stolen model can be easily manipulated to have a lower *MORacc* than T, allowing it to evade the detection.
- **Mixed.** $\mathcal{J}$ calculates the average *MORacc* of multiple independent and extracted models This can be considered as a middle-ground approach.

The mixed threshold is the most sensible choice in realistic deployments, but the extracted threshold is the least favourable to a malicious $\mathcal{A}$. Notice that the decision threshold should be uniform for all claims and $\mathcal{J}$ needs to determine it before receiving any claim. Therefore, to determine a decision threshold, $\mathcal{J}$ needs to act as $\mathcal{A}$: trains its own $F_{\mathcal{A}}$, and generates its own trigger set $(\mathbf{x}, \mathbf{y})$ according the MOR scheme it adopts.

4 MOR: Survey

In this section, we survey 16 MOR schemes and describe five well-known schemes under our generalization.

4.1 Taxonomy

Table 2 lists 16 MOR schemes, including 11 watermarking schemes collected from four survey papers [5, 33, 38, 53], and 5 fingerprinting schemes. The watermarking schemes are categorized according to the taxonomy proposed in [38]:

- **Model-Independent.** The watermark is embedded into the model functionality and is independent of the model itself. For example, it could be an independent backdoor embedded into the source model by adding extra samples to the training set.
- **Model-Dependent.** The watermark is embedded into the model functionality and depends on the model. For example, it could also be a backdoor embedded into the source model, but the backdoor is generated based on the source model.
- **Active.** The watermark is embedded into the model functionality during inference, which means that it is only activated when the model is used to make predictions. Therefore, this approach only considers situations where attackers have black-box access to the source model.
- **Parameter-Encoding.** The watermarking schemes in this category are known to be not robust [68]. We refer to Section 9 for more details.

One common characteristic of watermarking schemes is that they require modifications to the source model or its inference process. Such modifications inevitably result in a loss

of model accuracy. In contrast, model **fingerprinting** extracts a unique identifier (i.e., fingerprint) from the source model as its trigger set, without any changes to the model itself. This allows the original model to be preserved, maintaining its accuracy and functionality.

Table 2: MOR schemes.

Category	MOR scheme
Model-independent watermarking	Adi [1] Zhang [72] Li (a) [32] Guo [20] Namba [44] Xu [70]
Model-dependent watermarking	Frontier-Stitching [31] Blackmarks [11] EWE [24] Li (b) [34]
Active watermarking	DAWN [59]
Fingerprinting	Lukas [39] AFA [75] IPGuard [8] Metav [46] DI [43]

4.2 Generalization

All the MOR schemes surveyed in Section 4.1 follow our generalization: the model ownership claim (*moc*) in each scheme includes a trigger set and the claim verification requires running the model inference on the trigger set. Next, for each category, we pick exemplary schemes and describe them under our generalization. We refer to a scheme by its first author's name for ease of presentation, unless it is known under a different name.

4.2.1 Model-independent: Adi [1]

The *moc* of Adi contains a set of out-of-distribution images $\mathbf{x}$. The label y_i for each x_i is randomly sampled over all classes excluding its true label. The source model $F_{\mathcal{A}}$ needs to be fine-tuned on $(\mathbf{x},\mathbf{y})$. If $F_{\mathcal{S}}$ shows a similar behaviour as $F_{\mathcal{A}}$ on $(\mathbf{x},\mathbf{y})$, then $F_{\mathcal{S}}$ is likely derived from $F_{\mathcal{A}}$.

- **claim generation.** $\mathcal{A}$ generates $moc_{\mathcal{A}}$ as follows:
  1. samples out-of-distribution $\mathbf{x}$ and assigns a wrong label y_i to each $x_i \in \mathbf{x}$, i.e., $f(x_i) \neq y_i$ where $f()$ is the ground-truth function;
  2. fine-tunes $F_{\mathcal{A}}$ on $(\mathbf{x},\mathbf{y})$;
  3. commits $(\mathcal{A}, F_{\mathcal{A}}, \mathbf{x}, \mathbf{y})$ as $cm_{\mathcal{A}}$ and timestamps.
- **claim verification.** $\mathcal{J}$ checks the following:
  1. $\frac{1}{|\mathbf{x}|}\sum_{i=1\ldots|\mathbf{x}|}\mathbb{I}(F_{\mathcal{A}}(x_i)=y_i \text{ and } f(x_i)\neq y_i) > T$;
  2. $\frac{1}{|\mathbf{x}|}\sum_{i=1\ldots|\mathbf{x}|}\mathbb{I}(F_{\mathcal{S}}(x_i)=y_i \text{ and } f(x_i)\neq y_i) > T$;
  3. $cm_{\mathcal{A}}$ is a valid commitment of $(\mathcal{A}, F_{\mathcal{A}}, \mathbf{x}, \mathbf{y})$;
  4. $cm_{\mathcal{A}}$ was timestamped before $cm_{\mathcal{S}}$.

$\mathcal{J}$ accepts $\mathcal{A}$'s claim iff all checks pass. The verification function ν could be represented as

$$\nu(F(x_i), y_i) := \mathbb{I}(F(x_i) = y_i \text{ and } f(x_i) \neq y_i). \quad (2)$$

Other model-independent watermarking schemes differ from Adi [1] only in how $(\mathbf{x},\mathbf{y})$ was sampled; all other parts are the same as Adi [1]. In Zhang [72], all samples in $\mathbf{x}$ are from the same class and perturbed with a secret mask, or they are sampled from a different domain unrelated to the source model's domain. In Li (a) [32], all samples in $\mathbf{x}$ are masked with a small filter consists of three colors: image pixels under the white pattern pixels are changed to a very large negative number, image pixels under black pattern pixels are changed to a very large positive number, and pixels under gray pattern pixels stay unchanged. Guo [20] samples $(\mathbf{x},\mathbf{y})$ s.t. $f(x_i) \neq y_i$ $\forall(x_i,y_i) \in (\mathbf{x},\mathbf{y})$, and embeds an n-bit message into each x_i. Namba [44] samples $(\mathbf{x},\mathbf{y})$ s.t. $f(x_i) \neq y_i$ $\forall(x_i,y_i) \in (\mathbf{x},\mathbf{y})$ and imprints them with greater force and cause the model to learn them profoundly. Xu [70] samples $\mathbf{x}$ but labels them with a serial number. Therefore, all such schemes follow our generalization.

4.2.2 Model-dependent: EWE [24]

Recall that $\mathbf{x}$ sampled in Adi [1] are out-of-distribution. The watermarked features learnt by $F_{\mathcal{A}}$ are different from the task distribution and can thus be easily removed through compression or other forms of knowledge transfer. EWE [24] embeds watermarks that are entangled with legitimate data to $F_{\mathcal{A}}$, so that removing such watermarks will sacrifice performance on legitimate data. To this end, EWE uses the soft nearest neighbor loss (SNNL) [27, 55] as an additional loss during training to entangle feature representations of the watermark with the training data. The data samples contained in *moc* are in-distribution samples from the same class $(\mathbf{x},y)$, and these samples will be perturbed by a small mask called trigger.

- **claim generation.** $\mathcal{A}$ generates $moc_{\mathcal{A}}$ as follows:
  1. samples in-distribution $(\mathbf{x},y)$ s.t. $f(x_i)=y$ $\forall x_i \in \mathbf{x}$, for simplicity, we represent it as $f(\mathbf{x})=y$;
  2. samples a trigger t, computes $x'_i := x_i + t$ $\forall x_i \in \mathbf{x}$;[5]
  3. samples y' with $y' \neq y$;
  4. fine-tunes $F_{\mathcal{A}}$ on $(\mathbf{x}',y')$;
  5. commits $(\mathcal{A}, F_{\mathcal{A}}, \mathbf{x}', y')$ as $cm_{\mathcal{A}}$ and timestamps.
- **claim verification.** $\mathcal{J}$ checks the following:
  1. $\frac{1}{|\mathbf{x}'|}\sum_{i=1\ldots|\mathbf{x}'|}\mathbb{I}(F_{\mathcal{A}}(x'_i)=y' \text{ and } f(x'_i)\neq y') > T$;

[5] The trigger is an input mask which can be arbitrarily chosen by $\mathcal{A}$. And the trigger location is determined as the area with the largest gradient of SNNL with respect to x_i.

2. $\frac{1}{|\mathbf{x}'|}\sum_{i=1\ldots|\mathbf{x}'|}\mathbb{I}(F_{\mathcal{S}}(x'_i)=y' \text{ and } f(x'_i)\neq y')>T$;
3. $cm_{\mathcal{A}}$ is a valid commitment of $(\mathcal{A},F_{\mathcal{A}},\mathbf{x}',y')$;
4. $cm_{\mathcal{A}}$ was timestamped before $cm_{\mathcal{S}}$.

$\mathcal{J}$ accepts $\mathcal{A}$'s claim iff all checks pass. The verification function ν is also Equation 2.

4.2.3 Model-dependent: Li (b) [34]

Li (b) aims to prevent watermark forging by enforcing the trigger set to be indistinguishable from the original samples in the training set. To achieve this, it employs an encoder and a discriminator, both trained based on the source model, to construct the trigger set. A malicious $\mathcal{A}$ who does not have access to the encoder cannot generate a trigger set that works well for the victim model. However, as we will show in Section 5.1.3, it is still possible for $\mathcal{A}$ to falsely claim a $F_{\mathcal{S}}$.

- **claim generation.** $\mathcal{A}$ generates $moc_{\mathcal{A}}$ as follows:
  1. samples in-distribution $(\mathbf{x},\mathbf{y})$ s.t. $f(\mathbf{x})=\mathbf{y}$;
  2. generates a triggered $x'_i:\ \forall x_i\in\mathbf{x}$ through the encoder and discriminator;
  3. samples $y_i{}'$ with $y_i{}'\neq y_i,\ \forall y_i\in\mathbf{y}$;
  4. fine-tunes $F_{\mathcal{A}}$ on $(\mathbf{x}',\mathbf{y}')$;
  5. commits $(\mathcal{A},F_{\mathcal{A}},\mathbf{x}',\mathbf{y}')$ as $cm_{\mathcal{A}}$ and timestamps.
- **claim verification.** $\mathcal{J}$ checks the following:
  1. $\frac{1}{|\mathbf{x}'|}\sum_{i=1\ldots|\mathbf{x}'|}\mathbb{I}(F_{\mathcal{A}}(x'_i)=y'_i \text{ and } f(x'_i)\neq y'_i)>T$;
  2. $\frac{1}{|\mathbf{x}'|}\sum_{i=1\ldots|\mathbf{x}'|}\mathbb{I}(F_{\mathcal{S}}(x'_i)=y'_i \text{ and } f(x'_i)\neq y'_i)>T$;
  3. $cm_{\mathcal{A}}$ is a valid commitment of $(\mathcal{A},F_{\mathcal{A}},\mathbf{x}',\mathbf{y}')$;
  4. $cm_{\mathcal{A}}$ was timestamped before $cm_{\mathcal{S}}$.

$\mathcal{J}$ accepts $\mathcal{A}$'s claim iff all checks pass. The verification function ν is also Equation 2.

In Frontier-Stitching [31], $(\mathbf{x},\mathbf{y})$ are generated as adversarial examples w.r.t. $F_{\mathcal{A}}$. Due to transferability, they are also adversarial examples to the independent models of $F_{\mathcal{A}}$. Then, $\mathcal{A}$ updates $F_{\mathcal{A}}$ with $(\mathbf{x},\mathbf{y})$ using adversarial training, so that $F_{\mathcal{A}}$ and the models derived from $F_{\mathcal{A}}$ will perform differently from other independent models on $(\mathbf{x},\mathbf{y})$. Blackmarks [11] is similar to Frontier-Stitching [31] except that all class labels are clustered into two groups; the adversarial examples are generated s.t., for randomly selected samples from one cluster, $F_{\mathcal{A}}$ predicts labels from the other cluster.

Both Frontier-Stitching [31] and Blackmarks [11] follow our generalization: the *moc* includes a trigger set and the claim verification requires running model inference on the trigger set.

4.2.4 Active: DAWN [59]

DAWN is designed to be integrated into the prediction API of a model so that it can survive model extraction. It works by dynamically watermarking a small fraction of client queries, altering the model's prediction responses for these queries. The watermarked queries act as a trigger set in case an adversarial client attempts to train an extracted model using the prediction responses. Using this trigger set, $\mathcal{A}$ can demonstrate ownership as in other DNN watermarking schemes.

- **claim generation.** $\mathcal{A}$ generates $moc_{\mathcal{A}}$ as follows:
  1. samples $(\mathbf{x},\mathbf{y})$ s.t. $F_{\mathcal{A}}(\mathbf{x})=\mathbf{y}$;[6]
  2. samples a model-specific key k;
  3. for each $x_i\in\mathbf{x}$, computes $y'_i:=\pi(\text{HMAC}(k,\mu(x_i)),y_i)$, where $\pi()$ is a keyed pseudorandom permutation that that permutes the label from y_i to y'_i, and $\mu()$ is a mapping function that ensures $\mu(x)=\mu(x+\delta)$ for a small perturbation δ[7];
  4. commits $(\mathcal{A},F_{\mathcal{A}},\mathbf{x},\mathbf{y},\mathbf{y}')$ as $cm_{\mathcal{A}}$ and timestamps.
- **claim verification.** $\mathcal{J}$ checks the following:
  1. $y'_i:=\pi(\text{HMAC}(k,x_i),y_i),\forall x_i\in\mathbf{x}$;[8]
  2. $\frac{1}{|\mathbf{x}|}\sum_{i=1\ldots|\mathbf{x}|}\mathbb{I}(F_{\mathcal{S}}(x_i)=y'_i \text{ and } f(x_i)\neq y'_i)>T$;
  3. $cm_{\mathcal{A}}$ is a valid commitment of $(\mathcal{A},F_{\mathcal{A}},\mathbf{x},\mathbf{y},\mathbf{y}')$;
  4. $cm_{\mathcal{A}}$ was timestamped before $cm_{\mathcal{S}}$.

$\mathcal{J}$ accepts $\mathcal{A}$'s claim iff all checks pass. The verification function ν is also Equation 2.

4.2.5 Fingerprinting: Lukas [39]

Recall that model fingerprinting extracts a persistent, identifying code (i.e., fingerprint) from the source model. Lukas [39] uses the adversarial examples specific to the source model as the fingerprint. They hypothesize that there exists a subclass of targeted, transferable, adversarial examples that transfer only to stolen models but not to independent models. To achieve this, they train a set of independent models and extract a set of surrogate models from the source model. They then find a set of adversarial examples that minimize the loss for $F_{\mathcal{A}}$ and its extracted models but maximize the loss for independent models.

- **claim generation.** $\mathcal{A}$ generates $moc_{\mathcal{A}}$ as follows:
  1. $\mathcal{A}$ trains a set of extracted and independent models:
     - extracted models are trained on data labeled by $F_{\mathcal{A}}$;
     - independent models are trained on ground-truth labels.
  2. samples $(\mathbf{x},\mathbf{y})$ s.t., $f(\mathbf{x})\neq\mathbf{y}$;
  3. for each $x_i\in\mathbf{x}$, perturb it into x'_i s.t., the loss of (x'_i,y_i) is minimized for $F_{\mathcal{A}}$ and its extracted models, but is maximized for the independent models;
  4. commits $(\mathcal{A},F_{\mathcal{A}},\mathbf{x}',\mathbf{y})$ as $cm_{\mathcal{A}}$ and timestamps.

[6] In fact, $\mathbf{x}$ was received from an API client.

[7] Without $\mu()$, a malicious client receiving different predictions for x and $x+\delta$ can discard both x and $x+\delta$ from its training set to avoid the watermark.

[8] The DAWN [59] paper did not explicitly mention this verification, as robustness against malicious $\mathcal{A}$ is not their focus. We add this verification because we want to consider the most difficult condition for false claims.

- **claim verification.** $\mathcal{J}$ checks the following:
  1. $\frac{1}{|\mathbf{x}'|}\sum_{i=1\ldots|\mathbf{x}'|}\mathbb{I}(F_{\mathcal{A}}(x'_i)=y_i \text{ and } f(x'_i)\neq y_i)>T$;
  2. $\frac{1}{|\mathbf{x}'|}\sum_{i=1\ldots|\mathbf{x}'|}\mathbb{I}(F_{\mathcal{S}}(x'_i)=y_i \text{ and } f(x'_i)\neq y_i)>T$;
  3. $cm_{\mathcal{A}}$ is a valid commitment of $(\mathcal{A}, F_{\mathcal{A}}, \mathbf{x}', \mathbf{y})$;
  4. $cm_{\mathcal{A}}$ was timestamped before $cm_{\mathcal{S}}$.

$\mathcal{J}$ accepts $\mathcal{A}$'s claim iff all checks pass. The verification function ν is also Equation 2.

AFA [75] is a concurrent and independent work with Lukas [39]: it also generates the adversarial examples specific to the source model. IPGuard [8] is similar to Lukas [39] except that it uses a different way to find adversarial examples *near* the decision boundary of $F_{\mathcal{A}}$: they start from an initial data point and iteratively move it along the gradient of the objective function. Metav [46] is an extension of Lukas [39]: besides generating $(\mathbf{x}', \mathbf{y})$ in the same way as in [39], it also trains a verifier; the concatenated outputs of $F_{\mathcal{S}}$ on $(\mathbf{x}', \mathbf{y})$ will be input to the verifier, which then determines if $F_{\mathcal{S}}$ is a stolen model. Therefore, both IPGuard [8] and Metav [46] follow our generalization.

4.2.6 Fingerprinting: DI [43]

The key observation for DI is that all models derived from $F_{\mathcal{A}}$ will contain direct or indirect information from the training set of $F_{\mathcal{A}}$, hence model ownership can be resolved by showing that the suspect model was trained (at least partially or indirectly) on the same dataset as the source model. DI measures $F_{\mathcal{S}}$'s prediction margins (distances from the samples to the model's decision boundaries) for both $F_{\mathcal{A}}$'s training set and public samples. If $F_{\mathcal{S}}$ has different prediction margins for them, it is deemed to be stolen; otherwise the model is deemed independent.

- **claim generation.** $\mathcal{A}$ generates $moc_{\mathcal{A}}$ as follows:
  1. samples $\mathbf{x}$ from the training dataset of $F_{\mathcal{A}}$; extracts the feature embeddings for $\mathbf{x}$ that characterizes its "prediction margin" (i.e., distance from the decision boundaries) w.r.t. $F_{\mathcal{A}}$; and labels them as "inside" ($b=1$);
  2. samples $\mathbf{x}'$ from an unseen publicly available dataset; extracts the feature embeddings for $\mathbf{x}'$ w.r.t. $F_{\mathcal{A}}$; and labels them as "outside" ($b=0$);
  3. using the embeddings and the ground truth membership labels (i.e., b), trains a regression model $g_{\mathcal{A}}$, which is to predict a (proxy) measure of confidence that a sample is in the training set of $F_{\mathcal{A}}$.
  4. commits $(\mathcal{A}, F_{\mathcal{A}}, (\mathbf{x},1), (\mathbf{x}',0), g_{\mathcal{A}})$ as $cm_{\mathcal{A}}$ and timestamps.
- **claim verification.** $\mathcal{J}$ checks the following:
  1. extracts the feature embeddings for $\mathbf{x}$ and $\mathbf{x}'$, w.r.t. $F_{\mathcal{A}}$; inputs the embeddings to $g_{\mathcal{A}}$, gets the confidence scores, and checks if there is a significant difference between the two sets of confidence scores;
  2. extracts the feature embeddings for $\mathbf{x}$ and $\mathbf{x}'$, w.r.t. $F_{\mathcal{S}}$; inputs the embeddings to $g_{\mathcal{A}}$, gets the confidence scores, and checks if there is a significant difference between the two sets of confidence scores;
  3. $cm_{\mathcal{A}}$ is a valid commitment of $(\mathcal{A}, F_{\mathcal{A}}, (\mathbf{x},1), (\mathbf{x}',0), g_{\mathcal{A}})$;
  4. $cm_{\mathcal{A}}$ was timestamped before $cm_{\mathcal{S}}$.

$\mathcal{J}$ accepts $\mathcal{A}$'s claim iff all checks pass. DI still follows our generation as it requires running a model on the "trigger set" to generate embeddings. However, it differs from other MOR schemes in that it does not verify each sample separately; instead, it verifies the trigger set as a whole, calculating the effect size or p-value between the confidence scores of $\mathbf{x}$ and $\mathbf{x}'$, and comparing it with a threshold T.

5 Transferable Adversarial Examples Against MOR

Recall that most of the samples in the trigger set $(\mathbf{x}, \mathbf{y})$ satisfy: $\nu(F_{\mathcal{A}}(x_i), y_i) = 1$ for $F_{\mathcal{A}}$ and $\nu(F(x_i), y_i) = 0$ for other independently trained $F \neq F_{\mathcal{A}}$. To falsely claim the ownership of an independent model F, $\mathcal{A}$ could just generate (x_i, y_i) in a way s.t. $\nu(F(x_i), y_i) = 1$ for most $(x_i, y_i) \in (\mathbf{x}, \mathbf{y})$. Our key observation is that $\mathcal{A}$ can achieve this by leveraging the transferability of adversarial examples. Recall that we assume $\mathcal{A}$ has access to a dataset that has the same distribution with $F_{\mathcal{S}}$'s training set. Then, we could have $\mathcal{A}$ train $F_{\mathcal{A}}$ using this dataset and generate a malicious trigger set $\hat{\mathbf{x}}$ as transferable adversarial examples for $F_{\mathcal{A}}$. Then, $\nu(F(\hat{x}_i), y_i) = 1$ for most $(\hat{x}_i, y_i) \in (\hat{\mathbf{x}}, \mathbf{y})$, holds for the independent models of $F_{\mathcal{A}}$.

5.1 Attacks in detail

For each exemplary scheme from Section 4, we show how a malicious $\mathcal{A}$ generates $moc_{\mathcal{A}}$ so that it can falsely claim ownership of an independent model. The underlined text describes $\mathcal{A}$'s misbehaviour. For all attacks, the training sets of $F_{\mathcal{A}}$ and $F_{\mathcal{S}}$ are distinct but follow the same distribution.

5.1.1 Model-independent: Adi [1]

Recall that Adi [1] fine-tunes $F_{\mathcal{A}}$ on $(\mathbf{x}, \mathbf{y})$, where $f(x_i) \neq y_i$ $\forall (x_i, y_i) \in (\mathbf{x}, \mathbf{y})$; models derived from $F_{\mathcal{A}}$ have good performance on $(\mathbf{x}, \mathbf{y})$. $\mathcal{A}$ could generate $(\mathbf{x}, \mathbf{y})$ as adversarial examples so that $F_{\mathcal{A}}$ performs well on $(\mathbf{x}, \mathbf{y})$. Due to transferability, models that are independent of $F_{\mathcal{A}}$ also perform well on $(\mathbf{x}, \mathbf{y})$. Then, $\mathcal{A}$ can claim ownership of these models.

- **claim generation.** $\mathcal{A}$ generates $moc_{\mathcal{A}}$ as follows:
  1. samples $\mathbf{x}$ and assigns a wrong label y_i to each $x_i \in \mathbf{x}$, i.e., $f(\mathbf{x}) \neq \mathbf{y}$;
  2. for each $x_i \in \mathbf{x}$, perturbs it into $\hat{x}_i$ s.t., $F_{\mathcal{A}}(\hat{\mathbf{x}}) = \mathbf{y}$.
  3. commits $(\mathcal{A}, F_{\mathcal{A}}, \hat{\mathbf{x}}, \mathbf{y})$ as $cm_{\mathcal{A}}$ and timestamps.

- **claim verification.** $\mathcal{J}$ checks the following:
  1. $\frac{1}{|\hat{\mathbf{x}}|}\sum_{i=1\ldots|\hat{\mathbf{x}}|}\mathbb{I}(F_{\mathcal{A}}(\hat{x}_i)=y_i \text{ and } f(\hat{x}_i)\neq y_i)>T$;
  2. $\frac{1}{|\hat{\mathbf{x}}|}\sum_{i=1\ldots|\hat{\mathbf{x}}|}\mathbb{I}(F_{\mathcal{S}}(\hat{x}_i)=y_i \text{ and } f(\hat{x}_i)\neq y_i)>T$;
  3. $cm_{\mathcal{A}}$ is a valid commitment of $(\mathcal{A}, F_{\mathcal{A}}, \hat{\mathbf{x}}, \mathbf{y})$;
  4. $cm_{\mathcal{A}}$ was timestamped before $cm_{\mathcal{S}}$.

  The first check holds because $(\hat{\mathbf{x}}, \mathbf{y})$ are adversarial examples generated for $F_{\mathcal{A}}$. The second check holds because $(\hat{\mathbf{x}}, \mathbf{y})$ can transfer to $F_{\mathcal{S}}$.

In fact, the labels $\mathbf{y}$ can be chosen based on the perturbation of $\mathbf{x}$, i.e., untargeted adversarial examples. This makes the adversarial optimization easy to converge.

Other model-independent watermarking schemes differ from Adi [1] only in how $(\mathbf{x}, \mathbf{y})$ was sampled, hence false claims can be done in the same way as in Adi.

5.1.2 Model-dependent: EWE [24]

False claims for EWE [24] are similar to Adi [1], except that $\mathcal{A}$ needs to generate targeted adversarial examples this time. Specifically, in EWE [24], all samples in $\mathbf{x}'$ have the same label y'. Then, $\mathcal{A}$ can no longer determine the label based on the perturbation of $\mathbf{x}$. Instead, it has to perturb each x_i for a target label. Targeted adversarial examples can be generated in the same way, but its transferability becomes weaker. In Section 5.2, we describe a way for enhancing its transferability.

- **claim generation.** $\mathcal{A}$ generates $moc_{\mathcal{A}}$ as follows:
  1. samples $(\mathbf{x}, y)$ with $f(\mathbf{x}) = y$;
  2. samples a trigger t, computes $x'_i := x_i + t,\ \forall x_i \in \mathbf{x}$;
  3. samples y' with $y' \neq y$;
  4. for each $x'_i \in \mathbf{x}'$, perturbs it into $\hat{x}_i$ s.t., $F_{\mathcal{A}}(\hat{\mathbf{x}}) = y'$.
  5. commits $(\mathcal{A}, F_{\mathcal{A}}, \hat{\mathbf{x}}, y')$ as $cm_{\mathcal{A}}$ and timestamps.
- **claim verification.** $\mathcal{J}$ checks the following:
  1. $\frac{1}{|\hat{\mathbf{x}}|}\sum_{i=1\ldots|\hat{\mathbf{x}}|}\mathbb{I}(F_{\mathcal{A}}(\hat{x}_i)=y' \text{ and } f(\hat{x}_i)\neq y')>T$;
  2. $\frac{1}{|\hat{\mathbf{x}}|}\sum_{i=1\ldots|\hat{\mathbf{x}}|}\mathbb{I}(F_{\mathcal{S}}(\hat{x}_i)=y' \text{ and } f(\hat{x}_i)\neq y')>T$;
  3. $cm_{\mathcal{A}}$ is a valid commitment of $(\mathcal{A}, F_{\mathcal{A}}, \hat{\mathbf{x}}, y')$;
  4. $cm_{\mathcal{A}}$ was timestamped before $cm_{\mathcal{S}}$.

  The first check holds because $(\hat{\mathbf{x}}, y')$ are adversarial examples generated for $F_{\mathcal{A}}$. The second check holds because $(\hat{\mathbf{x}}, y')$ can transfer to $F_{\mathcal{S}}$.

5.1.3 Model-dependent: Li (b) [34]

Recall that Li (b) claims that a malicious $\mathcal{A}$ who does not have access to the encoder cannot generate a valid trigger set. However, this claim does not take into account the possibility of transferable adversarial examples. That is, a malicious $\mathcal{A}$ without knowing the encoder can still generate a set of transferable adversarial examples as the trigger set, with the condition that the adversarial examples are within an L_ϵ neighborhood of the original samples to satisfy the indistinguishability requirement between the trigger set and its original samples.

- **claim generation.** $\mathcal{A}$ generates $moc_{\mathcal{A}}$ as follows:
  1. samples in-distribution $(\mathbf{x}, \mathbf{y})$ s.t. $f(\mathbf{x}) = \mathbf{y}$;
  2. generates a triggered x'_i : $\forall x_i \in \mathbf{x}$ through the encoder and discriminator;
  3. samples $y_i{}'$ with $y_i{}' \neq y_i,\ \forall y_i \in \mathbf{y}$;
  4. for each $x'_i \in \mathbf{x}'$, perturbs it into $\hat{x}_i$ s.t., $F_{\mathcal{A}}(\hat{\mathbf{x}}) = \mathbf{y}'$.
  5. commits $(\mathcal{A}, F_{\mathcal{A}}, \hat{\mathbf{x}}, \mathbf{y}')$ as $cm_{\mathcal{A}}$ and timestamps.
- **claim verification.** $\mathcal{J}$ checks the following:
  1. $\frac{1}{|\hat{\mathbf{x}}|}\sum_{i=1\ldots|\hat{\mathbf{x}}|}\mathbb{I}(F_{\mathcal{A}}(\hat{x}_i)=y'_i \text{ and } f(\hat{x}_i)\neq y'_i)>T$;
  2. $\frac{1}{|\hat{\mathbf{x}}|}\sum_{i=1\ldots|\hat{\mathbf{x}}|}\mathbb{I}(F_{\mathcal{S}}(\hat{x}_i)=y'_i \text{ and } f(\hat{x}_i)\neq y'_i)>T$;
  3. $cm_{\mathcal{A}}$ is a valid commitment of $(\mathcal{A}, F_{\mathcal{A}}, \hat{\mathbf{x}}, \mathbf{y}')$;
  4. $cm_{\mathcal{A}}$ was timestamped before $cm_{\mathcal{S}}$.

  The first check holds because $(\hat{\mathbf{x}}, \mathbf{y}')$ are adversarial examples generated for $F_{\mathcal{A}}$. The second check holds because $(\hat{\mathbf{x}}, \mathbf{y}')$ can transfer to $F_{\mathcal{S}}$.

False claims for Frontier-Stitching [31] and Blackmarks [11] are easy: $\mathcal{A}$ can simply generate $(\mathbf{x}, \mathbf{y})$ s.t. $f(\mathbf{x}) = \mathbf{y}$; then all independent models will behave the same as $F_{\mathcal{A}}$.

5.1.4 Active: DAWN [59]

Similar to EWE [24], $\mathcal{A}$ again needs to generate targeted adversarial examples to attack DAWN [59].

- **claim generation.** $\mathcal{A}$ generates $moc_{\mathcal{A}}$ as follows:
  1. samples $(\mathbf{x}, \mathbf{y})$ s.t. $F_{\mathcal{A}}(\mathbf{x}) = \mathbf{y}$;
  2. samples a model-specific key k;
  3. for each $x_i \in \mathbf{x}$, computes $y'_i := \pi(\text{HMAC}(k, \mu(x_i)), y_i)$;
  4. for each $x_i \in \mathbf{x}$, perturbs it into $\hat{x}_i$ s.t., $F_{\mathcal{A}}(\hat{\mathbf{x}}) = \mathbf{y}'$.[9]
  5. commits $(\mathcal{A}, F_{\mathcal{A}}, \hat{\mathbf{x}}, \mathbf{y}, \mathbf{y}')$ as $cm_{\mathcal{A}}$ and timestamps.
- **claim verification.** $\mathcal{J}$ checks the following:
  1. $y'_i := \pi(\text{HMAC}(k, \mu(\hat{x}_i)), y_i), \forall x_i \in \hat{\mathbf{x}}$;
  2. $\frac{1}{|\hat{\mathbf{x}}|}\sum_{i=1\ldots|\hat{\mathbf{x}}|}\mathbb{I}(F_{\mathcal{S}}(\hat{x}_i)=y'_i \text{ and } f(\hat{x}_i)\neq y'_i)>T$;
  3. $cm_{\mathcal{A}}$ is a valid commitment of $(\mathcal{A}, F_{\mathcal{A}}, \hat{\mathbf{x}}, \mathbf{y}, \mathbf{y}')$;
  4. $cm_{\mathcal{A}}$ was timestamped before $cm_{\mathcal{S}}$.

  The first check holds because $\mu(x_i) = \mu(\hat{x}_i)$[10]. The second check holds because $(\hat{\mathbf{x}}, \mathbf{y}')$ can transfer to $F_{\mathcal{S}}$.

Recall that DAWN changes the prediction results of $F_{\mathcal{A}}$ instead of $F_{\mathcal{A}}$ itself. Therefore, a source model $F_{\mathcal{A}}$, trained by an honest accuser, should in principle have a low performance on the committed samples. Based on this observation, we

[9] In principle, $\mathcal{A}$ cannot modify $\mathbf{x}$ as it is supposed to be received from an API client. However, without some additional means of validation, $\mathcal{A}$ can simply claim that $\hat{\mathbf{x}}$ was received from an API client (cf. Section 7).

[10] In our experiments, we took $\mu()$ from the open-sourced implementation of DAWN and it shows that more than 88% of the adversarial examples satisfy $\mu(x_i) = \mu(\hat{x}_i)$. Furthermore, $\mathcal{A}$ can discard the $\hat{x}_i$s that do not satisfy this condition.

could prevent the above attack by introducing an additional check during verification: $\mathcal{J}$ checks the performance of $F_{\mathcal{A}}$ on the committed samples. However, this again can be attacked. Namely, after Step 4, a malicious $\mathcal{A}$ could update $F_{\mathcal{A}}$ with $(\hat{\mathbf{x}}, \mathbf{y})$ in a way like adversarial training.

5.1.5 Fingerprinting: Lukas [39]

Recall that Lukas [39] uses adversarial examples specific to the source model as the fingerprint: they train a set of extracted models and independent models, and perturb the adversarial examples to minimize the loss for the extracted models but maximize the loss for independent models. We could simply omit the part of maximizing loss for independent models, then the adversarial examples will transfer to independent models.

- **claim generation.** $\mathcal{A}$ generates $moc_{\mathcal{A}}$ as follows:
  1. samples $(\mathbf{x}, \mathbf{y})$ s.t., $f(\mathbf{x}) \neq \mathbf{y}$;
  2. for each $x_i \in \mathbf{x}$, perturbs it into $\hat{x}_i$ s.t., $F_{\mathcal{A}}(\hat{\mathbf{x}}) = \mathbf{y}$;
  3. commits $(\mathcal{A}, F_{\mathcal{A}}, \hat{\mathbf{x}}, \mathbf{y})$ as $cm_{\mathcal{A}}$ and timestamps.
- **claim verification.** $\mathcal{J}$ checks the following:
  1. $\frac{1}{|\hat{\mathbf{x}}|} \sum_{i=1\ldots|\hat{\mathbf{x}}|} \mathbb{I}(F_{\mathcal{A}}(\hat{x}_i) = y_i \text{ and } f(\hat{x}_i) \neq y_i) > T$;
  2. $\frac{1}{|\hat{\mathbf{x}}|} \sum_{i=1\ldots|\hat{\mathbf{x}}|} \mathbb{I}(F_{\mathcal{S}}(\hat{x}_i) = y_i \text{ and } f(\hat{x}_i) \neq y_i) > T$;
  3. $cm_{\mathcal{A}}$ is a valid commitment of $(\mathcal{A}, F_{\mathcal{A}}, \hat{\mathbf{x}}, \mathbf{y})$;
  4. $cm_{\mathcal{A}}$ was timestamped before $cm_{\mathcal{S}}$.

  The first check holds because $(\hat{\mathbf{x}}, \mathbf{y})$ are adversarial examples generated for $F_{\mathcal{A}}$. The second check holds because $(\hat{\mathbf{x}}, \mathbf{y})$ can transfer to $F_{\mathcal{S}}$.

Again, $\mathcal{A}$ can choose $\mathbf{y}$ based on the perturbation of $\mathbf{x}$, as untargeted adversarial examples.

AFA [75], IPGuard [8] and Metav [46] can be attacked in the same way as Lukas [39], except that in Metav [46] the adversarial optimization needs to be based on the verifier.

5.1.6 Fingerprinting: DI [43]

Recall that $\mathcal{A}$ in DI needs to include a regression model $g_{\mathcal{A}}$ in $moc_{\mathcal{A}}$. Therefore, to falsely claim a model in DI [43], $\mathcal{A}$ could simply manipulate $g_{\mathcal{A}}$ s.t. it always shows significant differences even for independent $F_{\mathcal{S}}$. Recall that we assume $\mathcal{A}$ has access to a dataset with the same distribution as $F_{\mathcal{S}}$'s training set. We could have $\mathcal{A}$ train $F_{\mathcal{A}}$ with this dataset and "adversarially" perturb each sample in $\mathbf{x}$ with a small amount of noise such that the "prediction margin" (distance between $\mathbf{x}$ and the decision boundaries) w.r.t. $F_{\mathcal{A}}$ are larger. Due to the transferability of our adversarially perturbed samples, $F_{\mathcal{S}}$ will also have a larger "prediction margin" on $\mathbf{x}$. Then if $g_{\mathcal{A}}$ was trained with the embeddings of this perturbed $\mathbf{x}$ and public $\mathbf{x}'$ w.r.t $F_{\mathcal{A}}$, it will output significantly different confidence scores when it takes the embeddings of $\mathbf{x}$ and $\mathbf{x}'$ w.r.t. $F_{\mathcal{S}}$.

- **claim generation.** $\mathcal{A}$ generates $moc_{\mathcal{A}}$ as follows:
  1. samples $\mathbf{x}$ from the training dataset of $F_{\mathcal{A}}$; perturbs $\mathbf{x}$ s.t. the "prediction margin" w.r.t. $F_{\mathcal{A}}$ are larger; extracts the feature embeddings for $\mathbf{x}$ that characterizes this "prediction margin"; and labels them as "inside" ($b = 1$);
  2. samples $\mathbf{x}'$ from an unseen publicly available dataset; extracts the feature embeddings for $\mathbf{x}'$ w.r.t. $F_{\mathcal{A}}$; and labels them as "outside" ($b = 0$);
  3. using the embeddings and the ground truth membership labels (i.e., b), trains a regression model $g_{\mathcal{A}}$, which is to predict a (proxy) measure of confidence that a sample is in the training set of $F_{\mathcal{A}}$;
  4. commits $(\mathcal{A}, F_{\mathcal{A}}, (\mathbf{x}, 1), (\mathbf{x}', 0), g_{\mathcal{A}})$ as $cm_{\mathcal{A}}$ and timestamps.
- **claim verification.** $\mathcal{J}$ checks the following:
  1. extracts the feature embeddings for $\mathbf{x}$ and $\mathbf{x}'$, w.r.t. $F_{\mathcal{A}}$; inputs the embeddings to $g_{\mathcal{A}}$, gets the confidence scores, and checks if there is a significant difference between the two sets of confidence scores;
  2. extracts the feature embeddings for $\mathbf{x}$ and $\mathbf{x}'$, w.r.t. $F_{\mathcal{S}}$; inputs the embeddings to $g_{\mathcal{A}}$, gets the confidence scores, and checks if there is a significant difference between the two sets of confidence scores;
  3. $cm_{\mathcal{A}}$ is a valid commitment of $(\mathcal{A}, F_{\mathcal{A}}, (\mathbf{x}, 1), (\mathbf{x}', 0), g_{\mathcal{A}})$;
  4. $cm_{\mathcal{A}}$ was timestamped before $cm_{\mathcal{S}}$.

  The first check holds because $\mathbf{x}$ are "adversarially" perturbed w.r.t. $F_{\mathcal{A}}$. The second check holds because $\mathbf{x}$ can transfer to $F_{\mathcal{S}}$.

5.2 Transferability enhancement

We borrow an idea of Lukas [39] to enhance the transferability. Recall that $\mathcal{A}$ aims to generate $(\hat{x}, y)$ in a way s.t. $\nu(F(\hat{x}), y) = 1$ for all independent models of $F_{\mathcal{A}}$. We could have $\mathcal{A}$ generate a set of independent models, and perturb the adversarial examples to minimize the loss of these independent models for $\nu(F(\hat{x}), y) = 1$.

To generate an untargeted adversarial example, $\mathcal{A}$ just needs to *maximize* the following loss function:

$$\mathcal{L}(\hat{x}, y) = L(F_{\mathcal{A}}(\hat{x}), y) + \sum_{F \in \mathcal{F}} \beta_F L(F(\hat{x}), y), \tag{3}$$

where y is the true label, $L()$ denotes the cross-entropy loss, $\mathcal{F}$ denotes a set of independent models, β_F is a weight [11] for F. We use Iterative Fast Gradient Sign Method (IFGSM) [30] to find a solution that both maximizes $\mathcal{L}(\hat{x}, y)$ and minimizes the perturbation:

$$\hat{x} := Clip_{\hat{x},\varepsilon}\{\hat{x} + \alpha sign(\Delta_{\hat{x}} \mathcal{L}(\hat{x}, y))\},$$

where $Clip_{\hat{x},\varepsilon}()$ is a function that performs per-pixel clipping for $\hat{x}$. We use $\alpha = 0.03$ and select the number of iteration to

[11] We set $\beta_F = \frac{1}{|F|}$ in our experiments.

be 100 to make the adversarial examples reach the edge of the ε max-norm ball. It ensures that the generated adversarial example $\hat{x}$ will be in $L_\infty\varepsilon$-neighborhood of the original input x. Notice that the per-pixel perturbation bound ε balances the false claim effectiveness and the perturbation visibility.

To generate a targeted adversarial example, $\mathcal{A}$ needs to *minimize* the loss function (i.e., Equation 3), where y becomes the target (wrong) label. The iteration step is similar to that in the untargeted case:

$$\hat{x} := Clip_{\hat{x},\varepsilon}\{\hat{x} - \alpha sign(\Delta_{\hat{x}}\mathcal{L}(\hat{x}, y))\}.$$

This enhancement is generally applicable and we have implemented it for all of our benchmarks in Section 6. We remark that our main contribution is to show that defending against false claims is as challenging as preventing transferable adversarial examples. Any method for generating transferable adversarial examples is pluggable into our attacks. There are many methods for transferability enhancement; it is only necessary to show that our attack works with one such method.

6 Evaluation

We now empirically evaluate our attacks against Adi [1], EWE [24], Li (b) [34], DAWN [59], Lukas [39] and DI [43].

6.1 Setup

For Adi and EWE, we use the Watermark-Robustness-ToolBox[12] to reproduce their results; for Li (b)[13], DAWN[14] and DI[15], we use their open-sourced implementations; as the source code of Lukas[16] is based on TensorFlow (whereas all others are in Pytorch), we re-implemented their scheme in Pytorch [52].

We consider all three kinds of decision thresholds we discussed in Section 3.3. For the extracted models, we use fine-tuning based extraction, a.k.a. Fine-Tune All layers (FTAL) [64][17].

For datasets, we consider CIFAR-10 [29], ImageNet [15], and a face attributes dataset named CelebA [37]. When we measure the *MORacc* on CIFAR-10 and ImageNet, we consider the following three cases:

1. "different structures & different data": $F_\mathcal{A}$ and $F_\mathcal{S}$ use different model structures and training data.
   - We divided CIFAR-10 into two non-overlapping subsets to train $F_\mathcal{A}$ and $F_\mathcal{S}$ respectively. The model structure for $F_\mathcal{A}$ is ResNet 28×10 [71] and it achieves an accuracy of 89.3%; the model structure for $F_\mathcal{S}$ is ResNet-34 [21] and it achieves an accuracy of 86.3%.
   - We randomly selected ten classes from ImageNet to form an ImageNet-10 dataset, and divided ImageNet-10 into two non-overlapping subsets to train $F_\mathcal{A}$ and $F_\mathcal{S}$ respectively. The model structure for $F_\mathcal{A}$ is ResNet-18 [21] and it achieves an accuracy of 82.0%; we use VGG-13 [57] for $F_\mathcal{S}$ and it achieves an accuracy of 85.9%.
2. "same structure & different data": $F_\mathcal{A}$ and $F_\mathcal{S}$ use the same model structure (ResNet 28× 10 for CIFAR-10 and ResNet-18 for ImageNet), but different training data (as described in case 1).
3. "different structures & same data": $F_\mathcal{A}$ and $F_\mathcal{S}$ use the same training data, butdifferent model structures (as described in case 1).

We aim to use CelebA to train a model (i.e., $F_\mathcal{A}$) to falsely claim the model behind Amazon Rekognition API [54], which detects face features of uploaded images. The model structure for $F_\mathcal{A}$ is Resnet-18 [21] and it achieves an accuracy of 97.8%. We have no knowledge about the training dataset or the model architecture of Amazon Rekognition, except that we have black-box access to the model via the API. Therefore, the setting for CelebA is "different structures & different data".

For all three datasets, we set the trigger set size as 100. $F_\mathcal{A}$'s *MORacc* on the trigger sets are near 100% for all MOR schemes except DAWN, which has a *MORacc* of 0 because its $F_\mathcal{A}$ is independent of its trigger sets. For all experiments, we set the per-pixel perturbation bound, (i.e., maximal value allowed for per-pixel perturbation) as 16.

Recall that we use independent models to enhance transferability (cf. Section 5.2). We train 10 independent models for CIFAR-10, 8 independent models for ImageNet, and 2 independent models for CelebA.[18]

All reported results are averages of 5 runs; all reported run times were obtained using (single) Tesla V100 GPUs. We refer to our research report version for more details of our experiments.

[15] https://github.com/cleverhans-lab/dataset-inference

[16] https://github.com/ayberkuckun/DNN-Fingerprinting

[17] FTAL comprises two steps: it first queries $F_\mathcal{A}$ with a set of samples and obtains the predicted labels; it then uses this set to fine-tune $F_\mathcal{A}$ with a smaller learning rate. The model extracted through FTAL is very similar to $F_\mathcal{A}$, hence it provides the most challenging threshold for false claims. Indeed, FTAL is the most effective one among several model extraction methods we have tried.

[18] We began with two independent models in each case. With CelebA, two models were enough to get high *MORacc*. On CIFAR-10 and ImageNet, the *MORacc* with two models were not high enough, hence we tried increasing the number of independent models until a sufficiently high *MORacc* was reached: 10 for CIFAR-10 and 8 for ImageNet. However, training models on CIFAR-10 and ImageNet is not as expensive as in CelebA.

Table 3: Decision thresholds (we refer to Section 3.3 for an explanation of the decision thresholds; the column of DI shows the normalized effect size (%) instead of *MORacc*).

Dataset	Threshold type	Adi	EWE	Li (b)	DAWN	Lukas	DI
CIFAR-10	independent	10.0	1.8	23.0	1.0	28.0	90.0
	mixed	29.0	32.9	61.5	38.5	57.5	81.4
	extracted	48.0	64.0	100.0	76.0	87.0	72.8
ImageNet	independent	15.0	12.0	30.0	3.0	14.0	76.5
	mixed	23.5	37.5	65.0	42.5	30.0	69.6
	extracted	32.0	63.0	100.0	82.0	46.0	62.6
CelebA	independent	25.7	3.7	55.0	7.0	21.0	20.0
	mixed	42.4	2.9	55.5	26.0	28.5	14.1
	extracted	59.0	2.0	56.0	45.0	36.0	8.2

Table 4: False claim effectiveness (the bold number means *MORacc* is higher than the mixed threshold and the underlined number means *MORacc* is higher than the "extracted" threshold).

Dataset	Model configurations ($F_{\mathcal{S}}$ vs. $F_{\mathcal{A}}$)	Adi	EWE	Li (b)	DAWN	Lukas	DI
CIFAR-10	different structures & different data	**94.3**	**69.3**	**94.3**	**69.3**	**94.3**	**100**
	same structure & different data	**98.0**	**100.0**	**98.0**	**100.0**	**98.0**	**99.1**
	different structures & same data	**99.0**	**78.3**	**99.0**	**78.3**	**99.0**	**98.6**
ImageNet	different structures & different data	**72.6**	**87.6**	**72.6**	**87.6**	**72.6**	**100**
	same structure & different data	**93.7**	**97.0**	**93.7**	**97.0**	**93.7**	**100**
	different structures & same data	**84.6**	**89.0**	**84.6**	**89.0**	**84.6**	**100**
CelebA	different structures & different data (Amazon Rekognition API)	**68.4**	**68.0**	**68.4**	**68.0**	**68.4**	**99.9**

6.2 False claim effectiveness

Table 3 presents the decision thresholds and Table 4 presents $F_{\mathcal{S}}$'s *MORacc* for all three datasets. It demonstrates that, for a realistic configuration of MORs using the mixed threshold, our false claims can succeed against all MOR schemes on all datasets. Even for the extracted threshold (least favorable to a malicious $\mathcal{A}$), false claims still succeed against all except Li (b). We also show that in scenarios where $F_{\mathcal{A}}$ and $F_{\mathcal{S}}$ are trained with either the same model structure or the same dataset, false claims become much easier.

Recall that the *moc*-generation procedure for Adi, EWE, Li (b), DAWN and Lukas are similar: generating adversarial examples that transfer to $F_{\mathcal{S}}$. The untargeted adversarial examples generated by Adi, Li (b), and Lukas result in identical *MORacc*. In contrast, EWE and DAWN's targeted adversarial examples yield a different *MORacc* value. The distinguishing factor lies in the decision thresholds of each scheme.

Recall that DI calculates the effect size or p-value between the confidence scores of training samples and public samples, and compares it with a threshold, hence the last column in Table 3 and 4 shows the normalized effect size instead of *MORacc* (using normalized effect sizes is equivalent to using the p-values directly). Different from other MOR schemes, DI treats $F_{\mathcal{S}}$ as stolen as long as $F_{\mathcal{S}}$ was trained with the same data as $F_{\mathcal{A}}$, even if it was trained independently. It is possible that the model behind Amazon Rekognition API was trained from CelebA as well, in which case it is not independent from our $F_{\mathcal{A}}$ in terms of DI. Therefore, we tested DI (without our attack) on Amazon Rekognition API and obtained a normalized effect size of 0.0 indicating that there was likely no overlap between CelebA and the training data used for Rekognition API.

Figure 1 shows a comparison between an original image in the trigger sets and its noised version with the per-pixel perturbation bound of 16. It is evident that the original content of the image is clearly perceptible. Table 6 in (Appendix B in our research report) shows the original and our perturbed versions of some images from the same class of CelebA,

and their corresponding confident scores from the Amazon Rekognition API.

We also measure the *MORacc* with different per-pixel perturbation bounds. The results are in Figure 2. The *MORacc* roughly increases with the perturbation bound and becomes stable when the *MORacc* is high enough. When generating untargeted adversarial examples on CIFAR-10, the untargeted label y for all Fs in Equation 3 tend to be the same one that near the true label. As a result, the *MORacc* of untargeted adversarial examples (Adi, Li (b) and Lukas) on CIFAR-10 are higher than the targeted ones (EWE and DAWN). This is not the case for ImageNet, as different Fs have different untargeted labels, leading to a relatively lower *MORacc*. As there are only two labels in CelebA, the targeted and untargeted adversarial examples are essentially the same, hence, their *MORacc* are simliar to each other.

Our attack can succeed even if $F_{\mathcal{A}}$ is of much lower quality than $F_{\mathcal{S}}$. We conducted additional experiments with CIFAR-10 and ImageNet to see what $F_{\mathcal{A}}$ accuracy is needed for a successful attack against an $F_{\mathcal{S}}$:

- On CIFAR-10, $F_{\mathcal{S}}$ achieves 86.3% accuracy; we can break the mix thresholds of all schemes with $F_{\mathcal{A}}$ reaching only 75.0% accuracy; (with $F_{\mathcal{A}}$ reaching 80% accuracy, we can break the extracted thresholds of all schemes except Li(b) and Lukas).
- On ImageNet, $F_{\mathcal{S}}$ achieves 85.9% accuracy; we can break the mix thresholds of all schemes with $F_{\mathcal{A}}$ reaching only 71.3% accuracy; (with $F_{\mathcal{A}}$ reaching 76.3% accuracy, we can break the extracted thresholds of all schemes except Li(b) and DAWN).
- While we do not know the precise accuracy of the model behind the Amazon Rekognition API, it undoubtedly surpasses that of our $F_{\mathcal{A}}$, given its status as a well-known commercial service.

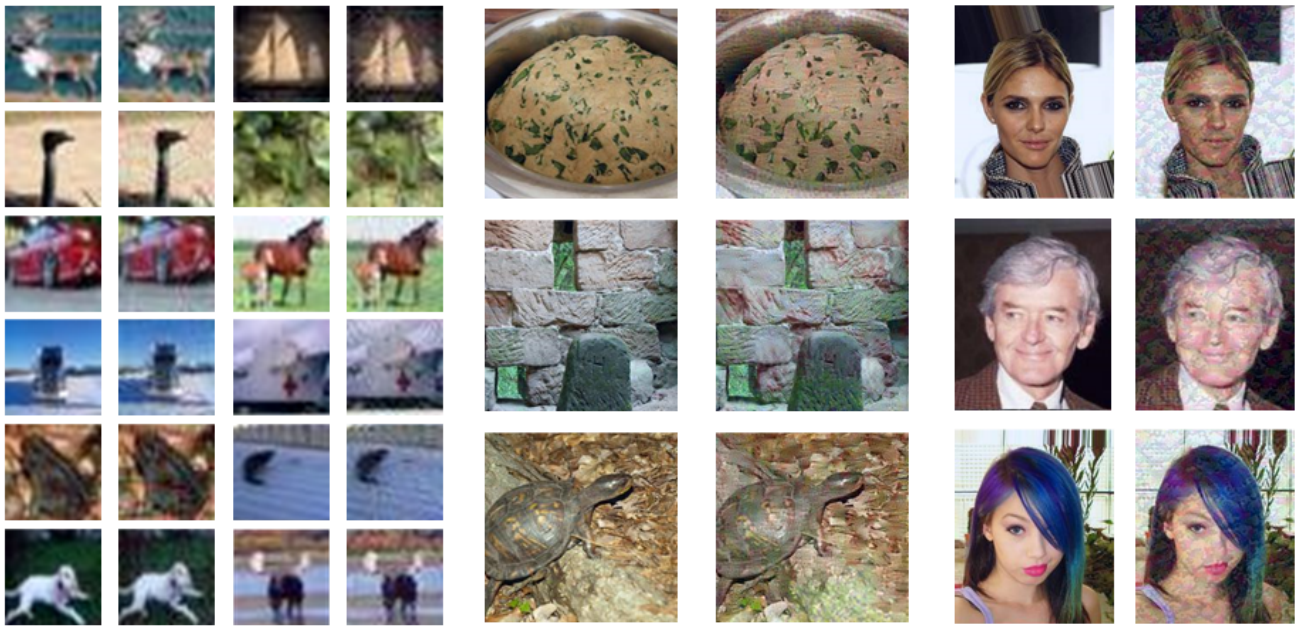
6.3 False claim efficiency

Table 5 displays the time usages in minutes for generating the adversarial trigger sets. Note that a malicious $\mathcal{A}$ needs to run this process only once; therefore the computational cost of our false claims is essentially negligible.

Table 5: Attack runtime in minutes (the reported results does not include the time for training independent models; training an independent model takes 18 min on CIFAR-10, 11 min on ImageNet and 67.5 min on CelebA).

	Adi	EWE	Li (b)	DAWN	Lukas	DI
CIFAR-10	13.6	14.1	13.6	14.1	13.6	13.6
ImageNet	11.1	19.1	11.1	19.1	11.1	11.1
CelebA	8.8	10.7	8.8	10.7	8.8	8.8

7 Countermeasures



In this section, we present four kinds of countermeasures that have the potential to defend against our false claims. Three of them are generic and can be applied to all MOR schemes, while the fourth is specific to a particular scheme. We also examine the feasibility and potential pitfalls associated with each countermeasure.

$\mathcal{J}$-verified trigger sets. We remark that the root cause of our false claims is the ability of a malicious $\mathcal{A}$ to deviate from the trigger set generation procedure specified by a MOR scheme. Then, a straightforward countermeasure it to have $\mathcal{J}$ verify if the trigger set was generated correctly.

At first glance, achieving this goal seems easy via *verifiable computation* (VC) [3, 51], which enables efficient verification of complex function execution through a VC-proof. Namely, we could have $\mathcal{A}$ use VC to prove that the trigger set was indeed generated by following the MOR scheme. Unfortunately, this is not applicable to watermarking, because its trigger set sampling cannot be captured by the VC-proof. For example, in the claim generation of Adi (cf. Section 4.2.1), $\mathcal{A}$ could generate an adversarial $(\mathbf{x}, \mathbf{y})$ in Step 1) and then generate the VC-proof from Step 2) onwards, allowing the false claim to succeed even with a valid VC-proof. For fingerprinting, VC is applicable, since its trigger sets are generated based on $F_{\mathcal{A}}$. To be secure, the VC-proof in fingerprinting must include the training stage of $F_{\mathcal{A}}$, otherwise, $\mathcal{A}$ could still generate an adversarial trigger set by manipulating the source model. However, including the training stage in VC will be overwhelmingly expensive for the proof generation. We further remark that VC is not applicable to DI due to the fact that *moc*-generation in DI relies not only on $F_{\mathcal{A}}$, but also on its training set, which can be manipulated in advance.

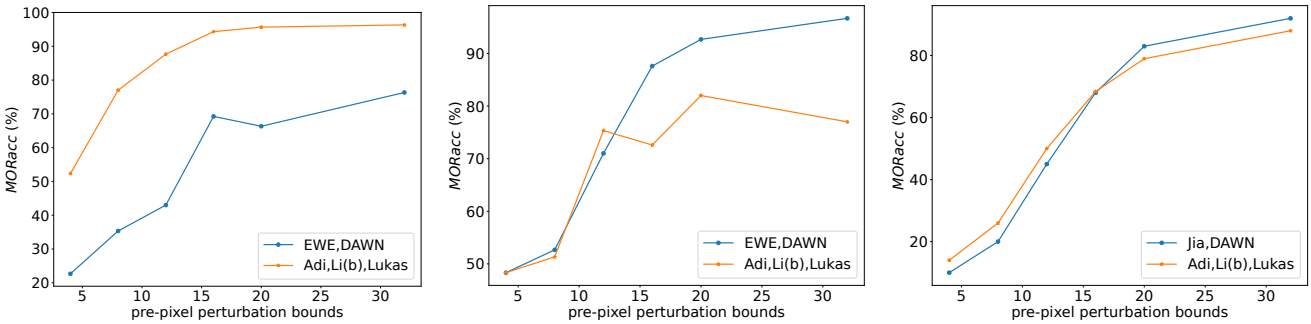
A more effective way to verify the trigger set is to have $\mathcal{J}$ train multiple independent models by itself and run them on the trigger set; if $\mathcal{J}$'s claim verification check deems all such known independent models as stolen, $\mathcal{J}$ can reject $moc_{\mathcal{A}}$ as adversarial. One caveat is that $\mathcal{A}$ could use black-box model extraction to extract these models and generate the trigger sets that can cause $\mathcal{J}$ to deem them as independent; $\mathcal{A}$ could also create black-box adversarial examples directly against these models. While such attacks may be expensive and resource-intensive, it is crucial to take them into consideration. Therefore, $\mathcal{J}$ has to rate-limit and/or raise the cost of dispute requests from $\mathcal{A}$s, which is reasonable since dispute rarely happens.

$\mathcal{J}$-generated trigger sets. Instead of verifying the trigger set, we could have $\mathcal{J}$ generate the trigger set by itself. For model-independent watermarking, $\mathcal{J}$ can simply choose a trigger set and return it to $\mathcal{A}$. For model-dependent watermarking, $\mathcal{A}$ needs to submit $F_{\mathcal{A}}$ to $\mathcal{J}$ first, who can then choose the trigger set based on $F_{\mathcal{A}}$. In either case, $\mathcal{A}$ needs to interact with $\mathcal{J}$ for each deployed model, even if no dispute happens. For fingerprinting, it is enough for $\mathcal{J}$ to get involved and generate

(a) CIFAR-10 (b) ImageNet (c) CelebA

Figure 1: Comparison between original images and the noised versions (the per-pixel perturbation bound is 16; the original images are on the left-hand side and the noised images are on the right-hand side).

the trigger set only when dispute happens. It is worth mentioning that such a countermeasure is not applicable to DI or DAWN. For DI, again, the training dataset can be manipulated so that $moc_{\mathcal{A}}$ can be adversarial even if it is generated by $\mathcal{J}$. For DAWN, the trigger set is generated dynamically based on the queries submitted by the clients.



Defending against transferable adversarial examples. Notice that preventing false claims can be reduced to preventing transferable adversarial examples. If we have an effective way for detecting transferable adversarial examples [16, 36, 69], we could have $\mathcal{J}$ use it to determine if the trigger set is adversarial. Similarly, if we have an effective way for adversarial training [6, 19, 56], we could have $\mathcal{S}$ use it to make $F_{\mathcal{S}}$ more robust against transferable adversarial examples. However, how to prevent transferable adversarial examples is still an open problem and it is orthogonal to our paper. On the other hand, any advance in generating transferable adversarial examples will also enhance our false claims.

We evaluate the effectiveness of adversarial training against false claims (untargeted adversarial examples in particular) on CIFAR-10. We use PGD [42] as the adversarial training algorithm and run it for 20 epochs with a perturbation bound $\varepsilon = 16$. *MORacc* decreases from 94.3% to 32.5%. However, the model accuracy also decreases from 86.3% to 83.1%. Therefore, adversarial training can be effective against false claims, but at the cost of a drop in utility. Therefore, adversarial training can be effective against false claims, but at the cost of a drop in utility. Furthermore, it takes 3-30 times longer to train a robust model with adversarial training than training a non-robust equivalent. This longer training time implies a higher cost in computational resources, which is particularly undesirable in the era of large models. However, note that $\mathcal{A}$ can use a large ε to invalidate adversarial training. In some settings, $\mathcal{J}$ can easily detect trigger set entries that are adversarial examples computed using a large ε. How to use adversarial training as a broadly applicable, effective defense against false claim attacks remains an open problem.

Scheme-specific countermeasures. Recall that in DAWN, the trigger set consists of clients' queries; if such queries are signed by clients, $\mathcal{A}$ can no longer perturb them. However, $\mathcal{A}$ could collude with a client to submit perturbed queries. To discourage such collusion, we could have $\mathcal{J}$ punish the client who signed perturbed queries (instead of $\mathcal{S}$) when $F_{\mathcal{S}}$ is deemed stolen. This may not always be realistic. Furthermore, signing each query separately is expensive. We would need to resort to having clients sign aggregate queries (e.g., in the form of a Merkle tree root) periodically.

8 Discussion

False claims for non-timestamped models. As we mentioned in Section 3.1, most MOR schemes do not explicitly require the commitment to be timestamped. This is partially because timestamping is a strong assumption as it requires another trusted third party (or a blockchain) to run the service

(a) CIFAR-10 (b) ImageNet (c) CelebA

Figure 2: *MORacc* with different per-pixel perturbation bounds.

for timestamping. To the best of our knowledge, none of the existing models is timestamped. That means we can falsely claim an existing model without considering timestamping.

If timestamping is not enforced, our false claim becomes much easier, as $\mathcal{A}$ no longer has to create $moc_{\mathcal{A}}$ before $F_{\mathcal{S}}$ comes into existence. That means $\mathcal{A}$ can directly query $F_{\mathcal{S}}$ to create adversarial examples, and such adversarial examples do not need to be transferable. As a result, some of the countermeasures presented in Section 7 are no longer valid. For example, we cannot rely on $\mathcal{J}$ to train independent models to verify the trigger sets, because $\mathcal{A}$ can make the adversarial examples only work for $F_{\mathcal{S}}$ (instead of transferring to other independent models) by leveraging the idea of Lukas [39].

Deferred trigger set generation. Given that most model owners are unlikely to initiate MOR disputes, trigger set generation constitutes an unnecessary upfront cost, especially if we use the $\mathcal{J}$-generated trigger set countermeasure (Section 7). Fortunately, in fingerprinting schemes, the trigger set is generated after $F_{\mathcal{A}}$ being fixed. Therefore, one can *defer* trigger set generation until a MOR dispute arises. In this case, the certified timestamped commitment $cm_{\mathcal{A}}$ covers only $\mathcal{A}, F_{\mathcal{A}}$; $\mathcal{J}$ will need to either generate or verify the trigger set in the event of a dispute.

9 Related Work

Parameter-Encoding. Recall that the main characteristic of our generalization (in Section 3.1) is that $moc_{\mathcal{A}}$ includes a trigger set and its verification requires running model inference on the trigger set. One kind of MOR schemes that do not follow our generalization is parameter-encoding-based watermarking, such as Uchida [64], DeepMarks [10] and DeepSigns [14]. Instead of embedding the watermark into the model functionality, they embed the watermark into the model parameters or the activations of its hidden layers; and their claim verifications require accessing the model parameters. For example, Uchida [64] embeds a message into the weights of some target convolutional layer, by adding an embedding loss during training that regularizes the model and is minimized when the message can be extracted successfully.

Such schemes are known to be *not* robust [38]: one can easily remove the watermark via weight shifting, retraining, or transfer learning [68]. Furthermore, when the suspect model is not white-box accessible, IP infringement cannot be detected.

Passport-based watermarking. A special kind of parameter-encoding-based watermarking embeds a passport into the model to link the model to its owner's identity. For example, Fan et al. [18] introduce a passport layer to regulate the performance of the model: the model owner can use a secret passport to compute the affine factors of the passport layer. They claim that an attacker cannot add a substitute passport while maintain the model performance. However, Chen [12] et al. show that this is feasible, based on the observation that the model can achieve a high accuracy even with different affine factors of the passport layer. This attack can also be considered as a false claim, but they did not consider the situation where timestamped commitment is enforced.

We remark that, to link the model to its owner's identity, the owner can simply add its identity to the (timestamped) commitment, as we did in our generalization (in Section 3.1).

False positives in DI. Szyller et al. [61] showed that DI suffers from false positives when an independent $F_{\mathcal{S}}$ happens to be trained from a dataset with the same distribution as $F_{\mathcal{A}}$'s training set. This explains why DI has very high independent thresholds (cf. Table 4). For example, for an honest trigger set, the normalized effective size of an independent model trained from CIFAR-10 can be as high as 90%.

While Szyller et al. [61] discovered the naturally occurring false positives, we further show that a *malicious* $\mathcal{A}$ can intentionally increase the normalized effective size to 100%.

Proof-of-learning. Jia et al. [25] proposed an alternative MOR scheme dubbed proof-of-learning (PoL), which allows $\mathcal{A}$ to claim ownership of its model by proving integrity of the training procedure. Its $moc_{\mathcal{A}}$ includes a set of intermediate models recorded during training, together with the corresponding data points used to obtain each recorded model. With such

a $moc_{\mathcal{A}}$, $\mathcal{J}$ can replicate the path all the way from the initial model to the final model to be fully confident that $\mathcal{A}$ has indeed performed the computation to obtain the final model.

Nevertheless, as a MOR scheme, PoL has three problems. Firstly, PoL only helps if $F_{\mathcal{A}}$ and $F_{\mathcal{S}}$ are identical, i.e., it is not robust against the thief making minor changes to the stolen model. Secondly, the authors of PoL only claimed that $\mathcal{S}$ cannot generate a valid $moc_{\mathcal{A}}$ with a lower cost than that made by $\mathcal{A}$, i.e., it is not robust if $\mathcal{S}$ wishes to pay that much cost to generate $moc_{\mathcal{A}}$. Lastly, Zhang et al. [74] have shown that, even with less cost than that made by $\mathcal{A}$, $\mathcal{S}$ can still generate a valid $moc_{\mathcal{A}}$.

10 Conclusion

There has been a steady stream of works that have demonstrated that model theft is a real concern and MOR schemes are needed. The recent flurry of works that showed how large language models can be inexpensively bootstrapped off of prominent, expensive, models like GPT-4 have underscored this problem.

In this paper, we described a systematic shortcoming in all existing MOR schemes that permits false accusations to succeed, impacting the robustness, and hence the trustworthiness, of those schemes. Although we outlined several possible generic countermeasures, they can incur significant costs. Developing an efficient generic countermeasure, or identifying effective countermeasures specific to individual MOR schemes remain open problems.

Furthermore, we assume that the malicious accuser has access to a surrogate dataset that is in the same distribution as the suspect model's training set, which may preclude false claims on valuable models trained on rare or private datasets. Evaluating the feasibility of false claims without this assumption is left for future work.

Landscape More Secure Than Portrait ?
Zooming Into the Directionality of Digital Images With Security Implications

Benedikt Lorch

Rainer Böhme
University of Innsbruck

Abstract

The orientation in which a source image is captured can affect the resulting security in downstream applications. One reason for this is that many state-of-the-art methods in media security assume that image statistics are similar in the horizontal and vertical directions, allowing them to reduce the number of features (or trainable weights) by merging coefficients. We show that this artificial symmetrization tends to suppress important properties of natural images and common processing operations, causing a loss of performance. We also observe the opposite problem, where unaddressed directionality causes learning-based methods to overfit to a single orientation. These are vulnerable to manipulation if an adversary chooses inputs with the less common orientation. This paper takes a comprehensive approach, identifies and systematizes causes of directionality at several stages of a typical acquisition pipeline, measures their effect, and demonstrates for three selected security applications (steganalysis, forensic source identification, and the detection of synthetic images) how the performance of state-of-the-art methods can be improved by properly accounting for directionality.

1 Introduction

Images are *directional* if horizontal pixels sequences have different statistical properties than vertical sequences. Directionality has multiple causes. It can originate from scene content, unintentional asymmetries in image processing, or technological choices that appeal to human visual perception. While the effect of directionality has so far been neglected in security applications that depend on images, we show that directionality impacts the security of image steganography, forensic source identification, and the detection of synthetic images (aka "fake-or-real").

Figure 1 showcases the loss of not considering directionality in these three applications. The task of *steganalysis* is to attack steganography [92] by detecting hidden messages embedded in innocuous cover images [84]. We embed 0.4 bit per usable sample into JPEG images of size 512^2 using J-UNIWARD [49], a state-of-the art steganography method, resulting in an average payload ratio of 4.3 %. The leftmost graph shows the detection accuracy of an EfficientNet-B0 [97] detector with 4 M parameters trained on the dataset from the ALASKA2 steganalysis competition [16]. It achieves 91 % accuracy (blue bar) for the binary task of distinguishing between stego images and pristine covers. This accuracy drops to 78 % (orange bar) when the test images are rotated by 90 degrees, indicating a lack of robustness to directionality. In terms of error rates, this means that the probability of false accusations increases from 8 % to 37 %. (See Sec. 4 for more details.) A common task in *forensic source identification* is to identify the camera model that was used to acquire a given image [61, 73]. The center graph shows the accuracy of EfficientNet-B5 trained as multi-class classifier on scenes from the Forchheim database [44], which contains images acquired with 27 different smartphone models. Again, the performance drops from 94 % to 85 % when the square-shaped test images are rotated by 90 degrees. (See Sec. 5 for details.) Finally, *image authentication* concerns the task of

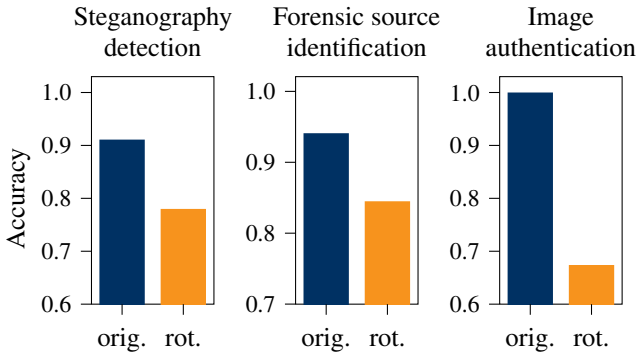

Figure 1: Directionality matters across security applications. The figure summarizes the performance loss of selected state-of-the-art classification tasks when the (square-shaped) test images are rotated by 90 degrees. Note the different scales.

distinguishing real images from forgeries [28]. An increasingly important subtask is the detection of synthetic images, which has received considerable attention through large-scale challenges including ones hosted by Facebook [26] and the IEEE [22]. The rightmost graph shows the performance of EfficientNet-B0 trained on the binary classification task of distinguishing between real images from the ALASKA2 dataset and generated images using the Stable Diffusion XL [81] autoencoder. Once again, the accuracy drops significantly from 100 % to 67 % if the orientation of the test images does not match the training images. (See Sec. 6 for details.) In all examples, we replicate a common experimental setup and train a state-of-the-art CNN detector. The results reveal that images contain directional statistics, which learning-based detectors tend to exploit. This calls for a spotlight on the effect of directionality in security applications.

To give one example for a typical cause of directional artifacts, consider JPEG compression [79]. While this popular [27, 50] lossy compression standard does not favor any direction, common parameter choices do leave directional artifacts. These include the practice to subsample the chroma channels in the horizontal direction only, or the asymmetry in the default quantization table. Some practices can be explained with technological requirements (e.g., interlacing on CRT monitors [56]); others originate from empirical measurements of human visual perception (e.g., contrast sensitivity by spatial frequency [71]). Strikingly, these historically justified practices prevail in contemporary cameras and software libraries. Multiple causes of directionality may coexist, interact with directional biases in the scene content, and therefore require careful analysis. There is no single measure of directionality and causal relationships are not always straightforward.

Contributions This paper takes a comprehensive approach to studying directionality of images in security applications. It makes the following specific contributions:

- We identify and systematize causes of directionality and relate them to technology and human perception.
- We present evidence for the effect of directionality in selected security applications: steganalysis, forensic source identification, and the detection of synthetic images.
- We show how the state of the art in each application can be improved by correctly accounting for directionality.
- We extract guidance on the use of rotation augmentation, which has the potential to generalize across applications.

Implications Our work has at least three important implications. First and foremost, if security techniques are biased towards one direction, then the opponent can have an advantage by choosing images of the opposite orientation. Second, defenders who want to consider directionality face the decision to incur higher cost and complexity (e.g., in terms of trainable weights) or accept limited generalizability across image orientations. This applies in particular to deep learning-based methods, but also to hand-crafted features (as we show in Sec. 5). Lastly, some causes we identify are due to legacy decisions made for technology that is no longer in use (e.g., CRT monitors). Standardization bodies and developers of image processing libraries should revisit these conventions.

Organization Section 2 discusses how directionality can be measured. Section 3 systematizes the causes of directionality and relates them to technology and human perception. The three following sections evaluate the effect on selected security applications: steganalysis (Sec. 4), forensic camera model identification (Sec. 5), and synthetic image detection (Sec. 6). Section 7 reviews related work. Section 8 discusses implications and limitations, and Sec. 9 concludes.

2 Measuring directionality

Tools to detect directional artifacts in images and, where possible, to quantify their strength are a prerequisite for evaluating the effects of directionality. Directional artifacts occur at different stages of the image acquisition pipeline and manifest themselves in different statistical properties. To deal with this variety, we use several methods to measure directionality. We discuss them below, from coarse to fine.

End-to-end effect The three security applications mentioned in the introduction use a learning-based detector with measurable accuracy. An intuitive measure of directionality is to evaluate the detector's sensitivity to rotated test images. If the images were non-directional or directionality did not matter, the detector would naturally generalize to rotated test images. A significant performance drop indicates that the detector is sensitive to directional image statistics, and the magnitude of the drop can be interpreted as effect size.

An advantage of the end-to-end approach is that it measures the effect of directionality for the target application. As learning-based detectors tend to exploit small nuances in image statistics, this approach can pick up subtle directional artifacts, which are difficult to measure directly with other tools. At the same time, the indirect measurement through a specific detector has several limitations. A drop in performance is hardly comparable across applications. Moreover, this approach cannot reveal the cause of directionality.

Visualization Statistical patterns in single images are often difficult to see with bare eyes. A common technique in the forensics community is to visually inspect the power spectrum, where periodic patterns manifest themselves as peaks in the frequency domain [82]. Figure 2 shows an example image (left) and its power spectrum (center left). Horizontal motion

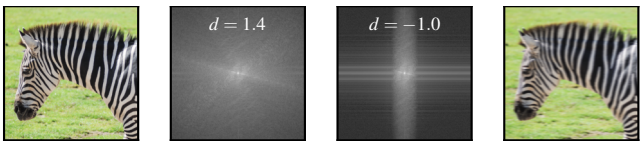

Figure 2: The power spectra (center panels) reveal that the right image has low energy in the high horizontal frequencies. (Motion blur has been applied for illustration.)

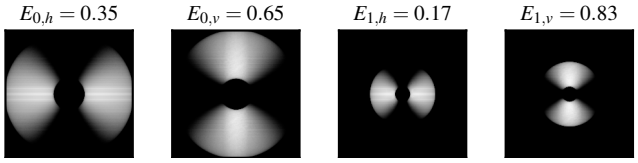

Figure 3: The steerable pyramids directionality score compares the horizontal and vertical energy on two scales.

blur (right) removes high horizontal frequencies, as can be seen in the corresponding power spectrum (center right).

Directional artifacts that are common and synchronous in all images from a particular source or processing operation can be amplified by averaging many images with diverse content. To further suppress the scene content, one can extract a noise residual. The noise residual is obtained by subtracting the image from a denoised version of it. We use the denoising CNN (DnDNN) [107] with pre-trained weights from [20]. Denoising and averaging can also be combined.

Visualization has the advantage that directionality can be visually perceived and its orientation can be determined. Limitations are that subtle artifacts may not be perceptible, and that it is not easy to quantify the strength of directionality.

Quantification by steerable pyramids Ideally, we seek to quantify the directionality of an individual image. A numeric directionality score should have three properties: (1) a score of zero means that directional statistics are unchanged when the image orientation is changed; (2) the sign of the score should indicate the dominant image direction; and (3) the absolute value of the score should reflect the strength of directionality.

The *steerable pyramids* method [93] has these properties. It decomposes the image into several oriented frequency bands at different scales, as shown in Fig. 3. For each scale s, it calculates the difference in energy between the two horizontal wedges $E_{s,h}$ and the two vertical wedges $E_{s,v}$, normalized by their sum. The resulting scores are summed over all scales. Using two scales gives a directionality score in the range $[-2,2]$. A positive score indicates that the image contains more energy in its horizontal frequencies than in its vertical frequencies. Note that summing over the scales may cancel out directional differences at different scales. Summing over absolute values would avoid this problem, but loses the sign of the dominant image direction.

We also experimented with alternative measurements. An intuitive approach is to compute directional edges using first-order derivative filters, such as the Sobel operator [94]. A directionality score can be defined as the difference between the horizontal and vertical absolute-valued derivative image. We found that both detectors can indicate the dominant image direction, but the steerable pyramids are more precise. The comparison is reported in Appendix B.

Steerable pyramids are applicable to individual images and produce a numerical score d, which can be compared to other measurements. For example, the left image in Fig. 2 has a directionality score of $d = 1.4$. The prevalence of horizontal frequencies corresponds to the Zebra's vertical stripes. The right image has a score of $d = -1.0$, because the horizontal blur attenuates the horizontal frequencies and adds vertical frequencies. A limitation is that the method aggregates over the entire spectrum and is therefore less sensitive to directional artifacts in narrow subbands. By design, it cannot detect higher-order dependencies with directionality, e.g., pairwise correlation between horizontally (but not vertically) adjacent pixels that only occurs in certain environments. Only the learning-based detectors of the end-to-end approach are able to exploit this. This justifies our combination of approaches.

3 Causes of directionality

Directionality in images has multiple causes. It can be inherent to the image content or introduced at several stages during the image acquisition, as illustrated in Fig. 4. During image acquisition, the scene is projected through lenses onto a sensor. The sensor turns the incoming light into an electrical current, which is amplified and converted to a raw digital signal. The signal then undergoes a number of raw-to-image conversion steps including demosaicing, denoising, sharpening, color adjustments, gamma correction, quantization, and optionally lens correction. The final image is usually stored in a compressed format, with JPEG still being most popular [27, 51, 78]. All stages can introduce directional artifacts.

The following subsections walk through these stages and explain causes of directionality. Each subsection starts with an observation in a gray box, then presents links to technology, human perception, and prior evidence. At the end of each subsection, we present our own evidence in support of hypotheses derived from previous work. Appendix A gives an overview of the image sources used for the validation experiments.

3.1 Scene content

Scene content. Edges in natural images are predominately horizontal and vertical. In popular image datasets, horizontal edges are more prevalent than vertical edges.

Background Most photographs show visual recordings of our world and therefore inherit the orientation characteristics

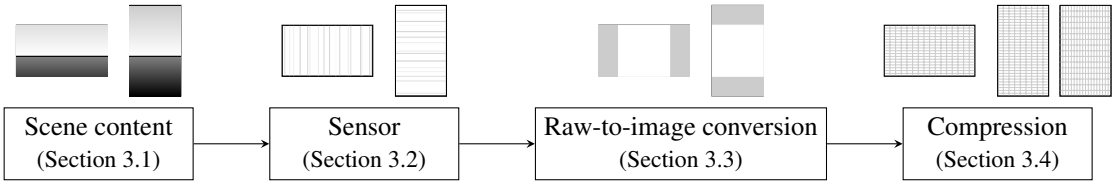

Figure 4: Causes of directionality are present in several stages of the image acquisition.

of the environment. Since the 1970s, researchers have measured the distribution of oriented contours in indoor, outdoor, and natural scene environments. They have found that contours near the cardinal axes, i.e., vertical and horizontal edges, are more prevalent than contours with oblique orientation angles [18, 96]. This holds especially for urban outdoor and indoor scenes, but also for natural scenes. Extensive analyses of horizontal vs. vertical differences support the finding that horizontal lines are more prevalent than vertical lines [45, 58].

The prevalence of cardinal contours is also reflected in human perception. Neurophysiologists have found that humans perceive horizontal and vertical lines more readily than oblique lines. This is known as the *oblique effect* [3]. This bias can be linked to the physiology of the visual cortex, which has more cells processing horizontal and vertical than oblique information [13]. Other work discusses the interaction between the living environment and the development of visual perception. The so-called carpentered world hypothesis suggests that people in urban environments develop stronger preferences for cardinal lines than people from rural areas [89]. Largely independent of the living environment is the visual perception of human faces. A recent study presented filtered versions of human faces to subjects in fMRI brain scanners. It found that stimuli with horizontal frequencies activated the primary visual cortex more than vertical or oblique frequencies [41]. (Examples of the stimulus material are in Appendix F.)

The prevalence of cardinal contours is also present in the art. Analyses of 20th century paintings show that artists prefer horizontal and vertical over oblique lines, which may suggest that human observers find cardinal lines more aesthetically pleasing [66]. In particular, paintings in portrait format contain more vertical lines while paintings in landscape format contain more horizontal lines [66].

Validation We analyze the relative distribution of horizontal and vertical scene content in the BOSSBase, ALASKA2, and ImageNet databases using steerable pyramids. Figure 5 shows the distribution of directionality in the three databases. The directionality score d on the x-axis ranges between -2 and $+2$. Images with negative d contain more horizontal edges, images with positive d contain more vertical edges. While all databases contain diverse images, the distribution is skewed towards images with horizontal edges. These findings are consistent with related work [45]. The number of images

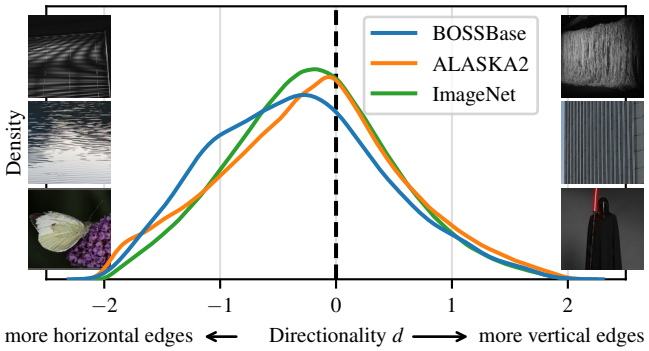

Figure 5: The relative distribution of horizontal and vertical scene content is skewed towards images with more horizontal edges. On the sides are example images from the three databases with very high absolute directionality scores.

with $|d| > 0.5$ ranges between 49 % and 57 %. Through manual inspection, we observe that BOSSBase contains many seascapes with a clear horizon and horizontal edges.

3.2 Sensor noise

The sensor consists of a rectangular array of photo diodes, which convert incoming photons to an electric charge. The charges are collected, read from the sensor, amplified, and eventually converted to a digital signal [34]. Imperfections in this process introduce noise into the resulting output image. The exact sources of noise and its visual manifestation depend on the sensor design, which is usually proprietary. While some sources of noise cause barely perceptible white noise, others lead to banding, which is more perceptible to the human eye. To give one example, we illustrate how the readout of CMOS sensors produces column patterns [2, 37].

Readout noise. Differences between individual column amplifiers in CMOS sensors produce a column pattern.

Background In CMOS sensors, each individual cell converts the charge to a voltage. The voltages are then read line by line after shifting the charges through the column amplifier. Deviations in the column amplifiers introduce a column pattern. This column pattern can be best seen from bias frames.

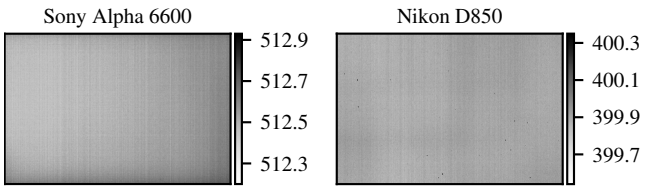

Figure 6: Physical differences between column amplifiers in CMOS sensors produce column artifacts.

Validation To illustrate the column pattern, we recorded 200 raw images with a Sony Alpha 6600 and a Nikon D850 camera in a dark room with the lens cap on. Both cameras save 14 bits per pixel. The exposure time was set to the minimum of $1/4000\,s$ and $1/8000\,s$, respectively. The short exposure time keeps the influence of dark current low and therefore allows us to measure the readout noise only. Figure 6 shows the average over the 200 frames. The column pattern is clearly visible in the average frame, however, its amplitude is rather small. The values fluctuate around 512 and 400, which are the two cameras' black levels.

3.3 Raw-to-image conversion

Linear pattern. Camera model-specific processing steps leave characteristic horizontal and vertical traces.

Background The raw sensor measurements undergo a sequence of processing steps to produce a final image. They include color filter array (CFA) demosaicing, tone mapping, white balancing, denoising, sharpening, and often compression. While the exact process in commercial cameras is proprietary and thus difficult to analyze, its effect can be observed by averaging many frames of the same camera model.

The sensor together with the raw-to-image conversion introduce a so-called linear pattern, which can be obtained as a byproduct of the camera fingerprint estimation. Camera fingerprints are estimated by averaging noise residuals from dozens of images, followed by zero-meaning the rows and columns separately for each channel in the color filter array, and then applying a Wiener filter [34]. The difference between the average noise residual and the final fingerprint gives the linear pattern [15]. It contains artifacts which are shared by cameras of the same model, unlike the fingerprint, which is intended to uniquely identify each sensor [29].

Validation The flat-field frames in the VISION database are particularly suited for studying linear patterns of different cameras [91]. Figure 7 shows four selected examples. Observe that the Apple iPhone 4 leaves strong horizontal banding artifacts. Apple's iPhone 6+ shows an oval shape in the center. The Huawei P9 shows irregular vertical structures, while the Samsung Galaxy Tab A leaves strong vertical

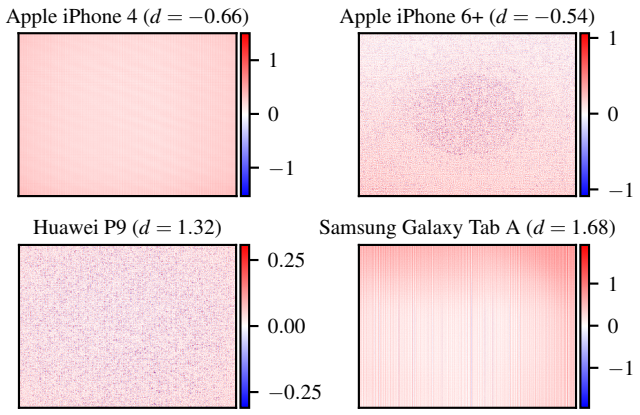

Figure 7: Spatial representation of linear patterns and directionality score d of four cameras in the VISION database.

banding artifacts. The directionality score d, calculated with steerable pyramids, confirms the visual impression. Although it is difficult to pinpoint the exact causes in these proprietary devices, these artifacts contribute to directional statistics in final images. We conjecture that the oval shape of the iPhone 6+ might be related to the correction of geometric lens distortion, another cause of directional artifacts which we discuss next.

Geometric distortion correction. Correcting geometric lens distortion introduces resampling artifacts, which are strongest at the longer ends of rectangular images.

Background An optical lens focuses incoming light onto the camera sensor. An ideal lens would map straight lines onto straight lines. Most practical lenses are not ideal. Their magnification changes with the distance from the optical center [46, Ch. 6.3]. As a result, straight lines appear curved. We distinguish barrel from pincushion distortion, where the magnification decreases or increases with distance from the optical axis, respectively. While this geometric distortion is radial (i.e., non-directional), rectangular sensors capture more distortion at the longer ends of the frame. This raises the question why most cameras have rectangular sensors. For example, DSLR full frame sensors typically measure 36×24 mm. This 3:2 aspect ratio has likely persisted from the 35 mm film.

A simple calculation also shows that rectangular sensors are more economical when photographers prefer rectangular aspect ratios.[1] Lenses produce a spherical projection. Since spherical sensors are difficult to manufacture, a square shape would maximize the area within a spherical projection. However, cropping the square frame to the desired rectangular

[1] Rectangular formats can be related to artistic rules, like the rule of thirds, and the golden ratio. In historical paintings, where artists were allegedly free to choose the aspect ratio, the majority of paintings are rectangular rather than square. https://blog.wolfram.com/2015/11/18/aspect-ratios-in-art-what-is-better-than-being-golden-being-plastic-rooted-or-just-rational-investigating-aspect-ratios-of-old-vs-modern-paintings/ (accessed on 2 Feb, 2024).

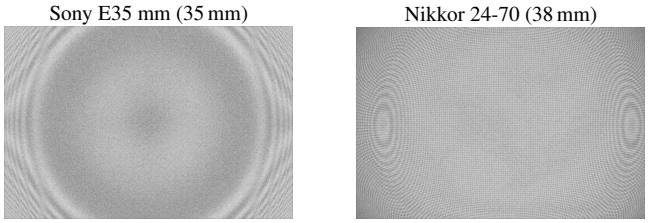

Figure 8: Algorithmic correction of geometric lens distortion may introduce directionality as it treats the long ends of rectangular frames differently than the center area. The figure illustrates this by showing the amount of local correlation for each pixel (brighter means stronger). See text for details.

shape would imply losing resolution. Directly fitting a 3:2 rectangle into the spherical lens projection gives 38 % more area than fitting a square into the same size and cropping to the 3:2 format afterwards.

Most cameras accept geometric distortion on the optical side and correct for it using signal processing. This involves unwarping the image, a geometric transformation that requires interpolation [28, Ch. 4.2]. Interpolation, in turn, leaves statistical measurable correlations between adjacent pixels [82].

Validation For illustration, we take two raw flat-field images with a Sony E 35 mm prime lens and a Nikkor 24–70 zoom lens at 38 mm, and correct for geometric distortion in Adobe Lightroom Classic 12.3. The corrected images are analyzed with a forensic resampling detector [82]. Figure 8 shows the resulting p-maps. Brighter shades in p-maps mean that pixels can be better predicted from their local neighborhood. Known variations in local predictability can be exploited for more reliable forensics and steganalysis [64].

3.4 JPEG compression

JPEG is still the most popular image format supporting lossy compression [27]. It achieves its storage efficiency by discarding visually unimportant information. JPEG compression proceeds as follows [79]. RGB pixel values are converted to the luminance and chrominance color space. The chrominance channels are optionally subsampled. Every channel is split into non-overlapping 8×8 blocks, each of which is transformed to the frequency domain using the discrete cosine transform (DCT). The resulting DCT coefficients are quantized by division with subband-specific quantization factors and subsequent rounding. The 64 quantization factors form a quantization table (QT), which can be different per channel, and is typically derived using the quality factor (QF) parameter in the (useful) range between 50 (low quality, small files) and 100 (all factors set to 1, high quality, but still not lossless). The quantized DCT coefficients are stored using lossless entropy encoding. JPEG decompression works in reverse order. Information discarded after rounding is not recoverable.

Although the standard does not introduce any directional artifacts, we find several sources of directionality in common parameter choices and in popular implementations.

Chroma subsampling. Horizontal chroma subsampling is more popular than vertical chroma subsampling. Moreover, the popular libraries *libjpeg-turbo* and *MozJPEG* introduce horizontal high-frequency artifacts.

Background Human perception is less sensitive to changes in color than to changes in brightness [87, Sec. 4.3.4, p. 221]. JPEG compression exploits this property by optionally reducing the resolution of the chroma channels. There are several common subsampling factors, usually denoted in J:a:b notation [83, Ch. 10]. Here it is sufficient that 4:2:0 halves the chroma channel resolution in both directions, i.e., to $1/4$ of the pixels; horizontal subsampling (4:2:2) halves the horizontal resolution while keeping the vertical resolution; and vertical subsampling (4:4:0) halves the vertical resolution while keeping the horizontal resolution.

Among the directional parameter choices, horizontal subsampling (4:2:2) is more common than vertical (4:4:0). This is probably due to the use of interlacing on cathode ray tube (CRT) monitors, and in accordance with the ITU-R BT.601 recommendation in favor of horizontal chroma subsampling [54]. Interlacing was adopted in the 1930s to double the frame rate without increasing the bandwidth requirements, thereby reducing temporal flickering from low frame rates [11, pp. 426–427]. Interlacing splits the frame into two fields with alternating rows. Only one field is updated at a time. Decompressing a horizontally subsampled field is easy by replicating the previous chroma sample in a row. By contrast, decompressing and displaying a vertically subsampled frame is more involved. As CRT monitors update row by row, additional memory would be required to buffer a row of chroma samples.[2] These are all historical reasons. Today's displays do not use interlacing, memory has become cheaper, and bandwidth has multiplied.

Libjpeg [52], the open-source reference implementation, introduced a high-frequency horizontal artifact during chroma subsampling caused by integer rounding [72]. This artifact, called *chroma wrinkle*, was found in version 6b, which has been in use for about a decade (1998–2009) [7]. From version 7 onwards, *libjpeg* resolved this problem by changing the chroma subsampling implementation to DCT scaling. Yet, the artifact persists until today in popular forks like *libjpeg-turbo* [68], which uses SIMD, and *MozJPEG* [77], which is optimized for web publishers [47].

Validation We analyze the distribution of chroma sampling patterns in native camera images from forensic image

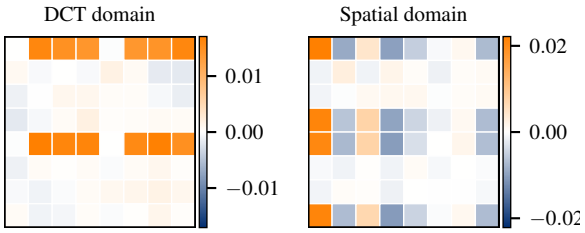
[2] Personal communication with Eric Bourguignat of (formerly) CCETT, a research center in Rennes, France, that contributed to the JPEG standard.

Table 1: Number of cameras in forensic image datasets split by their use of chroma subsampling. Cameras in the "mix" column produce JPEGs with 4:2:0 and 4:2:2 subsampling.

Database	4:4:4	4:2:0	4:2:2 (directional)	mix
Dresden	–	1	26	–
VISION	–	32	2	1
Forchheim	–	21	5	1

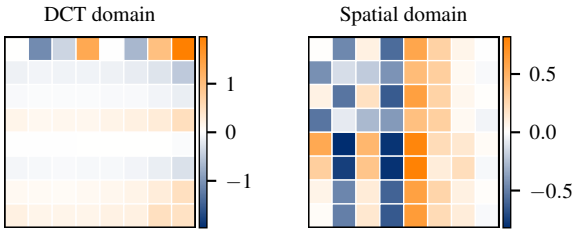
databases. The Dresden database [39] contains JPEG images from DSLR and point-and-shoot cameras. The VISION [91] and Forchheim databases [44] contain smartphone photos. As shown in Tab. 1, 26 out of 27 cameras in the Dresden database use 4:2:2 subsampling. The only exception is the Kodak M1063, which uses 4:2:0 subsampling. In the VISION and Forchheim datasets, 4:2:0 subsampling is more prevalent. Still, some smartphones produce 4:2:2 subsampling.

Libjpeg and its derivatives include the command line tool `cjpeg` for compressing images. Interestingly, *MozJPEG*'s `cjpeg` chooses the chroma subsampling based on the given quality factor. For QF ≥ 90, *MozJPEG* disables chroma subsampling (4:4:4), for $80 \leq$ QF < 90, it subsamples horizontally (4:2:2), and for QF < 80, *MozJPEG* defaults to 4:2:0.



DCT implementation. The integer DCT implementations in *libjpeg* introduce directional rounding artifacts.

Background Since the 2-D DCT is linearly separable, it is commonly implemented as a row-wise 1-D DCT followed by a column-wise 1-D DCT [1]. *Libjpeg* supports three DCT methods. The default, called ISLOW, converts fractional constants to 13-bit integers and uses a fixed-point Loeffler–Ligtenberg–Moschytz (LLM) algorithm, which saves multiplications by using a divide-and-conquer strategy [69]. Fixed-point arithmetic requires descaling (bitwise shifts to the right) followed by rounding.[3] To maintain precision, this happens only after the second (column-wise) DCT. A property of the LLM algorithm is that the 1st and 5th element of the row vectors are not multiplied by fractional constants. These are upscaled by only 2 bits after the first pass, which is why the final descaling leaves stronger rounding artifacts in the 1st and 5th row, but no artifacts in the 1st and 5th elements.



The faster but less accurate IFAST option uses the Arai–Agui–Nakajima (AAN) DCT [79, p. 52] algorithm with fixed-point arithmetic. The implementation processes columns first and rows second. Compared to the ISLOW implementation, fractional constants are converted to only 8-bit integers and intermediate results are descaled immediately.

The more accurate but slower IFLOAT DCT also uses the AAN DCT but with floats. We did not observe any noticeable rounding errors. DCT rounding artifacts are a cause of directionality, which is strongest at quality factor 100 as quantization attenuates these weak traces.

[3] The scaling is explained in *jfdctint.c* in *libjpeg*.

(a) ISLOW DCT

(b) IFAST DCT

Figure 9: Practical DCT implementations in *libjpeg* leave directional rounding artifacts. The top row is the default setting.

Validation We draw 100 000 random symmetric 8×8 blocks. Each block is DCT-transformed using the ISLOW and IFAST DCT methods. We measure the difference between the DCT block and a floating point version which does not have rounding artifacts. Figure 9 shows the average difference of the ISLOW DCT (top) and the IFAST DCT (bottom) in the DCT and the spatial domain. The DC difference is set to zero. Positive differences (orange) mean that the DCT implementation overestimates the corresponding coefficients. The ISLOW DCT overestimates rows 1 and 5 in the DCT domain. The differences are quite small. The IFAST DCT produces stronger artifacts, i.e., in spatial domain it underestimates columns 2 and 4 and overestimates column 5.

Quantization tables. Many quantization tables are asymmetric, including the ones *libjpeg* uses by default.

Background The idea of subband-specific quantization is to attenuate those spatial frequencies that are barely perceptible. The tables are stored in every JPEG file, therefore camera manufacturers and software developers can choose them.

In Annex K, the JPEG standard [53] provides example quantization tables (QTs) for luminance and chrominance components. They are the result of psychovisual thresholding experiments in which study participants were asked to indicate at what intensity the projection of each DCT basis function was discernible from a constant background [71]. Measurements from the original experiment are shown in

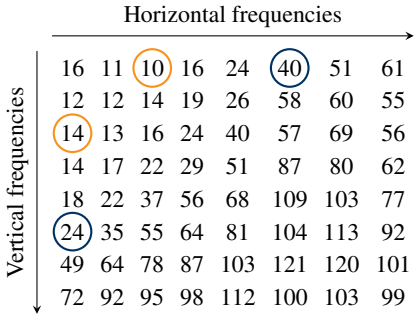


Figure 10: The luminance quantization table from Annex K of the JPEG standard [53] has several asymmetric features.

Table 2: Prevalence of standard quantization tables (QTs) and asymmetric luminance and chrominance QTs in native camera images from popular forensic datasets.

Dataset	Standard QTs	Asymmetric luma QT	Asymmetric chroma QT
Dresden	31 %	96 %	19 %
VISION	50 %	68 %	13 %
Forchheim	52 %	99 %	29 %

Appendix E. Although the JPEG standard emphasizes that these two tables are only examples, their inclusion as defaults in *libjpeg* has made them the de facto standard in many software implementations and in academic research. These QTs are still in use today, although the luminance table has been criticized since the 1990s for its asymmetry and because certain higher frequencies are less quantized than lower frequencies [62].

While the chrominance table is symmetric, the luminance table (shown in Fig. 10) has different values for horizontal and vertical frequencies. For example, at 2/2 cycles per block, the horizontal quantization factor is 10, whereas the vertical factor is 14 (orange circles). Conversely, at 5/2 cycles per block, the horizontal factor is 40, whereas the vertical one is 24 (blue). These seemingly minor differences affect JPEG steganography methods, such as J-UNIWARD [49] and UERD [43], which embed more into coefficients with lower quantization factors.

Validation We analyze the JPEG images of three forensic image databases[4] for the ratio of asymmetric QTs. Table 2 shows that across all databases, the majority of luminance tables are asymmetric. Conversely, the majority of chrominance tables are symmetric. Furthermore, we had access to 99 677 user-supplied JPEG images [78]. Our own reanalysis revealed 1 169 distinct luminance QTs including the standard tables ranging from QF 1 to QF 100. Out of these 1 169 luminance QTs, 997 (85 %) are asymmetric.

Libjpeg calculates QTs by scaling the standard table [105]. The only QF leading to a symmetric QT is 100, where all entries are 1. *Libjpeg-turbo* uses the same luminance QTs. *MozJPEG* supports several QTs, including the standard tables. However, the default has changed to a symmetric table,[5] which refines a previous proposal [62]. On Ubuntu systems, the popular image libraries Pillow and OpenCV link against *libjpeg* version 6b and *libjpeg-turbo* version 8. Hence, software built with these packages introduces chroma wrinkles and uses asymmetric QTs.

Lossless rotation Most cameras produce JPEGs with a fixed orientation and store the sensor orientation with respect to the ground as EXIF metadata. This lets the viewer rotate the image after decompression [57]. JPEG images can also be rotated without decompression, e.g., using the command line tool `jpegtran`. This also rotates the directional traces.

4 Effect on steganalysis

Having discussed the causes of directionality, we move on to implications for security applications. We start with steganalysis, the task of detecting steganography [8]. We show for several steganography methods that state-of-the-art CNN-based detectors may fail if the stego images are rotated (Sec. 4.1). We present and evaluate mitigations (Sec. 4.2), and link the effect to specific causes of directionality (Sec. 4.3).

4.1 Sensitivity to rotated test images

The ALASKA2 database is split into three disjoint subsets: 80 % of the images are used for training, 10 % for validation, and 10 % for testing. All images have a resolution of 512^2 pixels and are compressed using *libjpeg-turbo* 2.1.0 with quality factor 75 and no chroma subsampling (4:4:4). The corresponding QT is roughly the standard QT shown in Fig. 10 divided by two. Steganography is simulated using the three state-of-the-art JPEG steganography methods nsF5 [36], UERD [43], and J-UNIWARD [49] with embedding rate 0.4 bits per non-zero AC coefficient (bpnzAC) into the luminance channel. This setup and rate corresponds to a commonly chosen evaluation setting in contemporary papers [17, 103, 104].

We use the AdamW optimizer to train an EfficientNet-B0 with ImageNet-pretrained weights [12], batch size 32, dropout rate 0.25, and learning rate 10^{-4}. The training images in the *no-rot* setup were randomly flipped on the horizontal and vertical axis for data augmentation, but not rotated by 90 or 270 degrees in order to preserve the directionality.

[4] We do not include the steganalysis databases because their original images are never compressed.

Table 3: Sensitivity of steganalysis to directionality (top section). The first two columns report the accuracy for quality factor 75, the last two columns for an artificially asymmetric QT blending quality factors 60 and 80.

		QF 75 (Section 4.1)		QF 80\60 (Section 4.2.2)	
Setup	Stego.	org.	rot.	org.	rot.
no-rot	nsF5	0.977	0.879	0.976	0.665
	UERD	0.922	0.893	0.927	0.557
	J-UNIWARD	0.884	0.801	0.893	0.492
Effect of rotation augmentation (Section 4.2.1)					
aug-rot	nsF5	0.978	0.976	0.977	0.975
	UERD	0.926	0.925	0.914	0.913
	J-UNIWARD	0.897	0.897	0.893	0.873
base-rot	nsF5	0.986	0.864	0.984	0.671
	UERD	0.927	0.876	0.938	0.543
	J-UNIWARD	0.911	0.780	0.908	0.505

The top section of Tab. 3 (*no-rot*, QF 75) reports the accuracy on the original test images (org.) and after rotating the test images by 90 degrees (rot.). Comparing the three steganography methods on the original orientation, nsF5 is least secure and J-UNIWARD is most difficult to detect. This confirms related studies [10,12,55]. Importantly, if the test images are rotated, the performance of all three detectors drops between 2.9 and 9.8 %-pts. This means that steganographers can gain an advantage by transmitting rotated images.

4.2 Mitigation with rotation augmentation

Data augmentation attempts to reduce overfitting by training on multiple variants of the existing samples. A popular augmentation practice is to rotate the decompressed training images by multiples of 90 degrees [10, 55, 101, 106]. Since image statistics are directional, rotating the test images can prevent a CNN from exploiting directional embedding traces. To validate this, we add two experimental setups.

4.2.1 Standard quantization table

The second setup, denoted *aug-rot*, is identical to the first, but the images are randomly rotated by multiples of 90 degrees in the spatial domain during training, as is typical for data augmentation. Hence, the detector must generalize to both the original and the transposed QT.

In the third setup, *base-rot*, we create three additional copies of the database, where the cover images are rotated by 90, 180, and 270 degrees prior to compression. The stego images are created from the rotated covers. This dataset has four times the number of cover and stego images.

Table 3 reports the test accuracy for all setups and embedding methods. Both rotation setups slightly improve the detection accuracy over the *no-rot* setup, presumably because the CNNs are exposed to a greater variety of images. In the *aug-rot* setup, the detectors generalize to rotated images, because they have seen both orientations during training. This mitigates the weakness and removes the steganographer's advantage from sending rotated images.

The highest accuracy on the original test images is achieved by training with the *base-rot* setup. The gain in accuracy compared to the *aug-rot* training ranges between 0.1 and 1.4 %-pts. Although our gains are small, they are within the range of improvements that have been reported in recent publications. For example, tweaking the EfficientNet-B0 architecture by removing pooling promises gains below 1 %-pt., but at the cost of tripling FLOPs and memory [103]. Unsurprisingly, the detectors in the *base-rot* setup experience the largest drop in accuracy when tested with rotated images. This is probably because they have learned directional traces in the training data that have been introduced by JPEG compression.

4.2.2 Artificial QT with amplified asymmetry

Although the standard QT contains many asymmetric features, the table as a whole does not exhibit a dominant direction. Stronger quantization in one horizontal coefficient might be compensated by another vertical coefficient. In order to link the drop in performance to directionality caused by JPEG compression, and to rule out alternative explanations, we repeat the experiments with a QT that has artificially strong directionality. Our artificial QT blends the QTs for QF 60 in the upper and QF 80 in the lower triangle, and their average on the diagonal. We chose this combination because it is close to QF 75. Note that the performance cannot be compared directly to the results for QF 75, because the difficulty of the steganalysis task significantly depends on the QT. Everything else is unchanged.

The two rightmost columns in Tab. 3 (QF 80\60) report the test accuracies for this experiment. As before, in the *no-rot* and *base-rot* setups, the CNNs do not generalize to rotated images. However, the performance drops are more pronounced. The accuracy on UERD and J-UNIWARD gets close to random guessing. We interpret this as evidence that the directionality picked up by the CNN is to a large extent introduced during JPEG compression, and specifically by the directionality in the QT. Again, the *base-rot* CNNs show improvements over the *aug-rot* CNNs between 0.7 and 2.4 %-pts.

4.3 Overfitting to dataset directionality

Popular image databases, including the steganalysis databases BOSSBase and ALASKA2, are dominated by images with

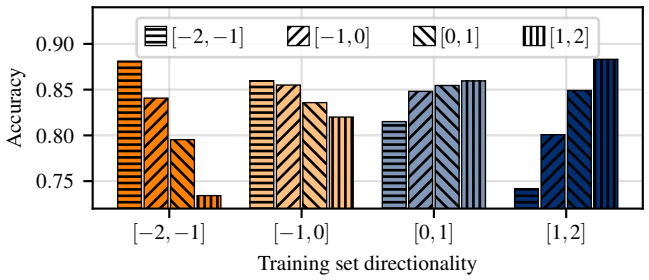

Figure 11: Effect of dataset directionality on steganalysis. Each set of bars refers to one detector trained on artificially biased data with directionality scores in the reported interval. Hatched bars report the resulting accuracy on test data with varying directionality. Observe the overfit on the outer bins.

more horizontal than vertical edges (cf. Fig. 5). When training on such biased databases, a learning-based steganalysis detector might overfit to the prevalent direction. We demonstrate this first on an artificial dataset and then on BOSSBase.

Artificial dataset For the first experiment, we chose the ALASKA2 database because it is larger than BOSSBase. The ALASKA2 database is split into 50 % for training and 50 % for testing. Both subsets are split by directionality into four bins with the directionality scores $[-2,-1]$, $[-1,0]$, $[0,1]$, and $[1,2]$. From each bin, we randomly select the maximum number of images such that all bins have the same size (2484 training and 2592 test images). We then train a steganography detector with images from a single bin, and evaluate its test accuracy on all bins separately. To isolate the effect of the directionality of the scene content, we suppress the directional bias from JPEG compression by using a symmetrized variant of the QF-75 QT and the floating-point DCT method. Like before, we embed steganography into the luminance channel using J-UNIWARD with 0.4 bpnzAC. Since we have too few images for training a CNN-based detector, we use feature-based steganalysis. We extract the popular Gabor filter residual (GFR) [95] features from the luminance channel and train an ensemble classifier with ≈ 100 Fisher linear discriminants as base learners, as suggested in the literature [65].

Figure 11 shows the results. Each set of bars shows one ensemble classifier trained on one bin. The individual bars represent the accuracy on the individual test bins. When training with an extremely directional training set, i.e., $[-2,-1]$ and $[1,2]$, the classifier achieves the highest accuracy on images with the same directionality. The accuracy drops when the test images contain a less pronounced or opposite directionality. When training with a moderately directional training set, i.e., $[-1,0]$ and $[0,1]$, the classifier shows higher accuracy for images of the same directionality than for the opposite direction. This experiment on an artificial subset of ALASKA2 demonstrates that even featured-based steganalysis is sensitive to a directionality bias in the training data.

Table 4: Effect of the directionality bias in the BOSSBase steganography benchmark dataset on detection accuracy.

Steganography method	Steganalysis features	Test all d	Test $d<0$	Test $d>0$
# images		5000	3417	1583
nsF5	GFR	0.993	0.993	0.991
	PHARM	0.987	0.989	0.980
UERD	GFR	0.894	0.900	0.879
	PHARM	0.860	0.868	0.841
J-UNIWARD	GFR	0.895	0.899	0.888
	PHARM	0.870	0.878	0.854

BOSSBase Typical datasets are more diverse in their directionality than the one in the previous experiment. Now we demonstrate that the directionality bias in BOSSBase may impair into a steganography detector's generalizability. The BOSSBase images are split into 50 % for training and 50 % for testing. All images have a resolution of 512^2 pixels and are compressed using *libjpeg-turbo* 2.1.0 with the symmetric QF-75 QT and the floating-point DCT method. Steganography is simulated using nsF5 [36], UERD [43], and J-UNIWARD [49] with an embedding rate of 0.4 bpnzAC. In this experiment, we use two popular steganalysis feature descriptors: the phase-aware spatial rich models (PHARM) [48] and the Gabor filter residuals (GFR) [95]. Both feature sets do not merge horizontal and vertical orientations and can thus capture directional traces. We use the same ensemble classifier as before [65].

The left column in Tab. 4 shows the test accuracy over all test images. Additionally, we break down the test set by the directionality score d. The detector consistently achieves higher accuracy on test images with negative d. Although the difference is small, this result on a database that has served as a benchmark for many publications [10,35,43,48,49,65,95,101] confirms that the detector works better on images that follow the database bias. We repeated this experiment on the original ALASKA2 database, but did not observe any significant differences in accuracy. This relates to the observation in Fig. 5, where we found that the directionality distribution in ALASKA2 is less skewed than in BOSSBase. ALASKA2 seems to be a better benchmark than BOSSBase in this regard.

5 Effect on forensic source identification

Linking a photo to a camera make or model is a common forensic task relevant to law enforcement [61]. This is possible because cameras differ in the technical implementation of the acquisition pipeline (cf. Fig. 4). While recent advances in camera model identification propose CNNs [9,44,86], feature-based classifiers [75,76] are still used, presumably because

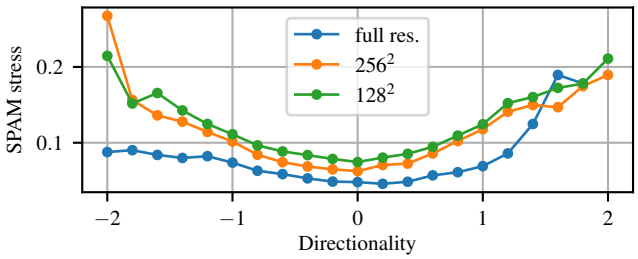

Figure 12: Relation between directionality and "stress" in the original SPAM feature space. Higher values indicate more information loss due to symmetrization. Our proposed variant removes this stress at the expense of greater dimensionality.

they are established, explainable (if necessary in court), and require fewer training images than CNNs. In this section, we show how considering directionality can improve the classification accuracy of feature-based methods. The results for the CNNs used in Fig. 1 are in Appendix C.

A popular feature descriptor for capturing camera model artifacts is the *subtractive pixel adjacency model (SPAM)* [75, 76]. SPAM features compute noise residuals and count co-occurrences between adjacent pixels. Both happens in horizontal and vertical direction. To decrease the feature dimensionality, certain horizontal and vertical co-occurrences are averaged [80]. This removes directional information. We show that feature-based camera model identification benefits from keeping directional image statistics separate.

Similar to previous work [75], we randomly select 10 camera models with at least two devices from the Dresden database [39]. To ensure that the classifier learns model-specific rather than device-specific traces, images from only one device are used for training. The other devices are used for testing. To properly account for potential lossless rotation (cf. Sec. 3.4), we verify that 17 (out of 18) camera models store the images with a canonical orientation. One camera model rotated the images prior to compression. We also use its images as stored, because this preserves the compression direction. We randomly select the same number of images from each camera model, such that training and test sets are class-balanced. To avoid leakage from the scene content, 80 % of the scenes are exclusively used for training and the remaining 20 % are used for testing.

We extract the SPAM features from each image. The original feature descriptor with directional averaging has 338 dimensions. Removing the directional averaging yields 676 dimensions. The feature extraction is repeated for the full-resolution images and for center crops with a size of 256^2 and 128^2. Normalized features are used to train a linear support vector machine (SVM), as suggested in previous work [75]. The regularization hyper-parameter of the SVM is set via a grid search with five-fold cross validation.

Table 5 shows the classification accuracy for this 10-class task. The results are averaged over five training runs with randomly selected camera models. At the full image resolution, both feature descriptors attain the same near-perfect accuracy. For the more challenging task on smaller image patches, the classifier benefits from the directional information in our extended feature descriptor. At size 128^2, our non-symmetrized variant outperforms the original by 3 %-pts. We observed similar results when using only the straight submodel or the diagonal submodel and with different classifiers.
