A Standard eviction sets generation algorithm

We now briefly present the method to generate eviction sets covering all L2 sets. We start with generating eviction sets with a fixed page offset, which map to L2 sets differed by upper 6 bits. To this end, we sweep a pool of pages to identify new evict targets, and test if the fixed offset into one of them has conflicts with the current eviction set group. If there is no conflict, it means that this evict target maps to a new L2 set whose eviction set is not included in the current group. With this evict target, we use the techniques from Vila et al. [85] to generate a matching eviction set and add it into the group. Finally, for each of the 64 (2^6) eviction sets, we fix the upper 6 bits, and generate eviction sets for every combination of the lower 7 bits for a total of 8192 eviction sets.

B Compound Eviction Sets Generation and Noise Tolerance Tips

Compound eviction sets generation. To generate a compound eviction set ($\mathsf{EV}_{\texttt{a}}$, $\mathsf{EV}_{\texttt{ptr}}$), the attacker must solve two problems. First, they must identify the address of `a` as well as valid (and quiet) pages to search for `ptr`. Second, they must confirm `ptr` injection to `a`.

For the first problem, both DHKE-2048 (OpenSSL) and Kyber-512 (reference implementation) allocate `a` in the same 4GByte region as the `dyld` cache, which is an ideal target for `ptr`. The virtual address of the `dyld` shared library is only randomized by macOS at boot time and the attacker can recover it with another unprivileged process by running `vmmap`. RSA-2048 (Go) and deterministic Dilithium-2 (CIRCL) allocate `a` in a stable address region beyond `0x14000000000`.[23] Pages in this region are always valid even with ASLR, which makes it an ideal target for `ptr`.

For the second problem, in RSA-2048 (Go), as long as the ciphertext c is smaller than p and q, `ptr` will be preserved in `a`. In DHKE-2048 (OpenSSL), the first window of secret, s_0, is always 1. Hence, the attacker can inject the `ptr` to `a` for the first iteration by solving Equation (2) with $E = 1$. In Kyber-512 (reference), `ptr` can be injected by correctly encrypting message m with `ptr`. Dilithium-2 (CIRCL) is tricky as the attacker cannot confirm `ptr` injection to `y` (`a` in Dilithium), but has a pool of messages from which a subset correctly injects `ptr`. Moreover, the so-called semi-confirmation in Dilithium significantly increases the compound eviction set search space. To address this, the attacker can decouple $\mathsf{EV}_{\texttt{a}}$ and $\mathsf{EV}_{\texttt{ptr}}$ by first targeting `sig.z`, where the attacker can confirm `ptr` injection. Note that the compound eviction set to `sig.z` shares the same $\mathsf{EV}_{\texttt{ptr}}$ with that of `y`, thus having the right $\mathsf{EV}_{\texttt{ptr}}$ makes generating $\mathsf{EV}_{\texttt{a}}$ for `y` efficient.

Noise tolerance. We observed several sources of noise or failure when checking for the existence of `ptr` in `a`.

First, the background noise of the Prime+Probe channel could result in false positives. To address this, we take 32 latency observations (Sections 6 and 7) and apply the following strategies for our cryptography targets. To start off, during the attack process, the attacker also performs the background test accesses by sending random messages. Having these redundant measurements interleaved with normal test accesses establishes confidence that it is the DMP causing high latencies in the normal test accesses. Second, an attacker can detect errors in RSA-2048 (Go) and DHKE-2048 (OpenSSL), and is able to roll back and redo the experiment in such cases. In RSA (Go), if one bit is wrong 0/1, the ciphertext c will always be smaller/larger than p, resulting in the attacker recovering consecutive 1/0 bits, an unlikely pattern in practice. In DHKE-2048 (OpenSSL), if an erroneous s_{i-1} is chosen at the i-th window, the attacker will not observe any DMP signal for the next window, because the challenge c for subsequent windows is based on correctness of s_{i-1}. This method is not applicable for Kyber-512 (reference) and Dilithium-2 (CIRCL), because the recovery of each coefficient in Kyber/Dilithium is independent of the others. An attacker can always repeat the attack several times and take a majority vote.

Second, `a` may change its virtual address at runtime, rendering $\mathsf{EV}_{\texttt{a}}$ ineffective and causing false negatives. To detect this, the attacker must check known-good `ptr` injection to infer the validity of the current compound eviction set. As long as this happens infrequently, the attacker can then re-generate the compound eviction set.

Third, the interval between each load to `a` may be shorter than traversing $\mathsf{EV}_{\texttt{a}}$. One solution is to decrease the size of $\mathsf{EV}_{\texttt{a}}$ until it matches that of a standard eviction set. If traversing a standard eviction set is too expensive, a possible solution is to degrade the performance of the victim program [10].

[23] This specific address is a function of the target program.

CacheWarp: Software-based Fault Injection using Selective State Reset

Abstract

AMD SEV is a trusted-execution environment (TEE), providing confidentiality and integrity for virtual machines (VMs). With AMD SEV, it is possible to securely run VMs on an untrusted hypervisor. While previous attacks demonstrated architectural shortcomings of earlier SEV versions, AMD claims that SEV-SNP prevents all attacks on the integrity.

In this paper, we introduce CacheWarp, a new software-based fault attack on AMD SEV-ES and SEV-SNP, exploiting the possibility to architecturally revert modified cache lines of guest VMs to their previous (stale) state. Unlike previous attacks on the integrity, CacheWarp is not mitigated on the newest SEV-SNP implementation, and it does not rely on specifics of the guest VM. CacheWarp only has to interrupt the VM at an attacker-chosen point to invalidate modified cache lines without them being written back to memory. Consequently, the VM continues with architecturally stale data. In 3 case studies, we demonstrate an attack on RSA in the Intel IPP crypto library, recovering the entire private key, logging into an OpenSSH server without authentication, and escalating privileges to root via the `sudo` binary. While we implement a software-based mitigation proof-of-concept, we argue that mitigations are difficult, as the root cause is in the hardware.

1 Introduction

In recent years, trusted execution environments (TEEs) have become available on many x86 desktop and server CPUs. While Intel SGX was the first widely-available TEE, it is limited to smaller microservice workloads and requires significant changes to the code running inside the TEE. The next generation of TEEs, specifically AMD SEV and Intel TDX, secure entire virtual machines (VMs). In this threat model, trusted VMs can run on an untrusted hypervisor. The hypervisor can ideally neither read (confidentiality) nor modify (integrity) any content of the VM. Cloud providers, such as Microsoft Azure, Google Cloud, and Amazon Web Services already support AMD SEV [4, 21, 40]. With AMD SEV-SNP, AMD extended SEV to support full integrity protection [6], mitigating previous attacks on the integrity of SEV and SEV-ES VMs [15,35,42,47,57]. AMD also acknowledges that well-known software-based side-channel attacks, such as Prime+Probe are possible against all versions of AMD SEV [6].

In this paper, we present CacheWarp, a new software-based microarchitectural fault attack on AMD SEV-ES and SEV-SNP, targeting memory writes. We show that creating an incoherent view of the memory is possible, causing inconsistencies between the cache and the memory. Specifically, we commit a subset of data writes to memory while dropping changes to other memory locations using the `invd` instruction. Consequently, the VM memory state is only partially updated and the VM uses stale memory. CacheWarp is fully deterministic and allows fine-grained dropping of memory writes from the hypervisor. In contrast to previous attacks [34, 36], CacheWarp is independent of the weaknesses of the AES-XEX encryption used in AMD SEV. Moreover, the hypervisor does not need read or write access to any encrypted VM page. In addition to dropping arbitrary writes, we introduce 2 generic techniques to exploit such dropped writes in a generic fashion. With *Dropforge*, dropping implicit and explicit writes of functions can change function parameters and behavior. With *Timewarp*, the implicit push of the return address caused by a function call can be dropped to divert the control flow to the call site of an *earlier* function call with the return value of the *current* function.

CacheWarp has several advantages over previous attacks that violated the integrity of the guest VM. Most importantly, CacheWarp can be mounted against SEV-SNP. It is, therefore, to the best of our knowledge, the only software-based attack violating the integrity of SEV-SNP. Moreover, even for SEV-ES, CacheWarp has advantages over previous attacks. It does not have to change any memory mappings [35, 42, 47] add malicious I/O devices [47], or build encryption oracles [57]. CacheWarp only needs to evict modified data from the cache that should not be dropped. This can either be done in parallel to the execution of the VM using targeted eviction sets, or

by interrupting the VM at two attacker-chosen points. On the first interrupt, the attacker commits all outstanding memory writes to memory, e.g., using the `wbnoinvd` instruction. On the second interrupt, the attacker reverts a subset of the outstanding memory writes to old, now stale, values using the `invd` instruction.

While CacheWarp can be mounted "blindly", precise control over the time when it is mounted improves the reliability. In contrast to SGX [52] where single-stepping an SGX enclave has been well explored, AMD SEV runs an entire operating system beneath the victim code, making it difficult to precisely target a specific instruction at which the VM should be interrupted. Interrupting an AMD SEV VM requires storing and loading an entire VM state, resulting in many unrelated instructions with unpredictable timings, making triggering interruptions after a specific instruction difficult. Hence, we introduce a robust execution-control framework for VMs running on AMD SEV that is based on page faults and timer interrupts. Conceptually, it is similar to SGX-Step [52] and SEV-Step [56], i.e., using the APIC timer to generate interrupts constantly. However, we introduce additional techniques for reliable stepping to account for the unpredictable runtimes of saving and restoring the VM state. We rely on uncacheable memory for the VM save area and the `wbinvd` instruction for bringing the cache into a known state, resulting in highly-predictable runtimes for stopping and resuming VMs, significantly improving stepping. Additionally, for SEV-ES, we introduce a new technique using register-state feature arrays to reliably detect progress in the VM despite the encrypted register state and to synchronize our attack with the victim. For SEV-SNP, we rely on the progress detection of SEV-Step [56].

We demonstrate CacheWarp and our stepping framework in 3 case studies. In the first case study, we mount a Bellcore attack [10, 12] on the RSA-CRT implementation of the Intel IPP crypto library. Our attack recovers the full private RSA key from an AMD SEV-protected VM within 6 s. Even without single stepping, we achieve a success rate of 90 %. In the second case study, we show that CacheWarp diverts the control flow to the call site of a previous function with the return value of a previously called function. We use this capability to break the authentication of an OpenSSH server running inside a guest VM, allowing an attacker to log into the VM. In the final case study, we demonstrate that an attacker with unprivileged code execution in the VM, i.e., after exploiting the OpenSSH server, can perform privilege escalation by using CacheWarp on the `sudo` binary. Although SEV-ES is already known to provide incomplete protection, we rely on SEV-ES as a "prototyping platform" for the attacks, as reliable stepping is simpler due to the visibility of the register state. Hence, the exploit-development time, including debugging, is significantly reduced. However, as the underlying vulnerability is the same for SEV-SNP, the resulting exploits can be mounted on SEV-SNP as well, as we demonstrate for the Bellcore attack.

Mitigating CacheWarp purely in software is difficult as it exploits a memory-coherence problem that a malicious hypervisor can create. AMD could update the microcode, disabling the `invd` instruction if AMD SEV is active, or change its behavior to first write back any modified data to the memory, similar to the `wbinvd` instruction. Such behavior is in line with the behavior on Intel CPUs, which disable `invd` if SGX is active. Additionally, we propose a software-only compiler-based mitigation that prevents exploiting CacheWarp. Programs compiled with this mitigation ensure that every write is committed to the memory, making it impossible for the attacker to drop writes without being detected.

CacheWarp demonstrates an efficient software-based method of violating the integrity and, consequently, the confidentiality guarantees of AMD SEV. As the root cause is in hardware, fixing CacheWarp requires firmware or hardware changes. Moreover, further research is required for effective and efficient software mitigations.

Contributions. The main contributions of this paper are:

1. We present CacheWarp, a software-based fault attack on AMD SEV-ES and SEV-SNP that allows dropping arbitrary writes, reverting selected cache lines to a previous (stale) value.
2. We introduce two new attack techniques to change the behavior of function calls and to return to a previous call site with a different return value.
3. We demonstrate CacheWarp in 3 case studies: Extracting the private key from the IPP RSA implementation, logging into an OpenSSH server without credentials, and escalating privileges to root using the `sudo` tool.
4. We propose a compiler-based software-only mitigation that reliably prevents exploitation of CacheWarp.

Outline The remainder of this paper is organized as follows. We provide the required background information in Section 2. Section 3 analyzes the behavior of cache invalidation instructions on Intel and AMD. Section 4 introduces our software-based fault injection attack and the techniques used. Section 5 presents the building blocks used in our case studies in Section 6. Section 7 discusses countermeasures. Section 8 discusses limitations and related work. Section 9 concludes.

Responsible Disclosure We responsibly disclosed our findings to AMD on April 25th, 2023. AMD acknowledged our findings on June 27th, 2023 and assigned CVE-2023-20592. AMD confirmed that they will mitigate CacheWarp for SEV-SNP via a microcode patch and an SEV firmware update for Zen 3 EPYC Milan CPUs. The source code of the framework and the proof-of-concepts are open-sourced at `https://github.com/cispa/CacheWarp`

2 Background

This section provides the background information to complement the rest of the paper.

2.1 Virtual Memory

CPUs support virtual memory to isolate processes and translate virtual addresses to physical addresses, i.e., locations in DRAM. The prevalent implementation of virtual memory uses multi-level page tables. The translation unit of page tables is a page and is usually 4 kB in size. While the CPU handles address translation, the operating system configures multi-level page tables to define each process's virtual memory mapping. Alongside the mapping, the operating system stores access permissions and additional meta information for each page mapping in the page table. To extend virtual memory to VMs, AMD-V (AMD Virtualization) supports nested page tables [2]. With nested page tables, the guest VM configures a page table translating from Guest Virtual Address (gVA) to Guest Physical Address (gPA). Furthermore, the hypervisor provides an additional page table mapping from gPA to Host Physical Address (hPA). On each memory access, the composition of those page tables is used to translate from gVA to hPA. Nested paging allows running multiple VMs and isolating their memory without requiring any modifications to the operating systems used by the VMs.

2.2 AMD Cache Hierarchy

Most modern CPUs use a cache hierarchy to reduce the latency of memory accesses. AMD and Intel CPUs have a per-core L1 and L2 cache and a shared last-level cache (LLC), partitioned into slices and Core Complexes on AMD. Usually, the L1 is split into data- and instruction-caches [2, 25]. If a data load can be served from any level of the cache, it has a lower latency. Otherwise, it is fetched from DRAM and usually stored in the cache hierarchy for subsequent accesses. Data may not be written to DRAM directly on write accesses, but an existing cache line may be modified and marked as dirty in the metadata.

Eviction. As caches are limited in size, loading a cache line may require evicting another line based on the eviction strategy. Dirty cache lines must be written back to DRAM if evicted to keep a coherent memory view.

Core Complex (CCX). Starting with the Zen microarchitecture, AMD relies on a modular chiplet design for their multi-core CPUs [7] that are divided into one or more Core Complexes (CCXs) [14]. A CCX consists of up to 8 CPU cores alongside private caches and an LLC cache shared amongst cores in the same CCX [3]. Additionally, AMD relies on non-inclusive cache hierarchies [28]. The CCXs are interconnected with AMD's proprietary infinity fabric and interface with a shared I/O die, responsible for handling DRAM accesses, PCIe communication, and other I/O operations [3,5].

2.3 Software-based Fault Attacks

A fault attack involves intentionally introducing errors or faults into a system to observe its behavior and extract sensitive information. While fault attacks have been well studied in the context of a physical attacker [11, 20], two prominent examples of software-based fault attacks are Rowhammer [30] and software-based undervolting [29, 43, 46]. Both of these attacks rely on the physical properties of the underlying system. Rowhammer exploits disturbances in DRAM memory created by specific access patterns to induce bit flips. Undervolting brings the CPU into an unstable state where specific computations (most prominently multiplications) lead to incorrect results. These attack primitives lead to powerful attacks undermining the security guarantees of the victim system. However, as they both depend on the hardware and environmental properties of the system under attack, the extent to which they can be exploited is highly dependent on the specific DRAM module (Rowhammer) or CPU (undervolting) of the victim.

2.4 Secure Encrypted Virtualization

AMD Secure Encrypted Virtualization (AMD SEV) protects VMs running under an untrusted hypervisor [2]. All versions of AMD SEV support encrypting guest memory using AES-XEX [49], an AES mode of operation tailored towards full disk encryption. The per-guest AES keys are generated and stored on a secure co-processor and are not accessible. The CPU handles encryption and decryption when a guest accesses encrypted memory. Building on AMD-V [2], SEV also uses nested paging.

With AMD SEV-ES (Encrypted State) [9], AMD introduced protection for the saved VM state on transitions to the hypervisor. The VM State Save Area (VMSA), which contains the guest's state, is no longer part of the Virtual Machine Control Block (VMCB) but rather stored in encrypted memory, guaranteeing confidentiality. Additionally, a checksum over the VMSA is stored in a protected memory area, so malicious hypervisors cannot modify information such as register contents. Whenever the CPU transitions from hypervisor to guest, the checksum is verified, and if the checksum is invalid, an exception is raised, ensuring the integrity of the VM state.

Finally, AMD SEV-SNP (Secure Nested Paging) [6] adds a Reverse Map Table (RMP) to track the ownership of each guest page. The RMP verifies the gPA to hPA mapping on each memory access, blocks hypervisor writes to guest pages and ensures that each page is mapped to only one gPA. Thus, AMD SEV-SNP mitigates memory-mapping attacks by a malicious hypervisor [57]. For instance, an attacker can no longer revert a page to a previous version, as is possible with AMD SEV-ES, by reading the encrypted page content and writing

it back later. Although AMD SEV-SNP protects integrity and confidentiality, a malicious hypervisor can still read the encrypted memory and distinguish unique ciphertexts, except for the VMSA, which is protected with *freshness* [34]. Therefore, Wichelmann et al. [55] propose a software-based mitigation to include freshness in each memory encryption block.

3 Cache Invalidation

In this section, we analyze the behavior of the root mechanism in CacheWarp on Intel and AMD CPUs, the cache-invalidation instructions `invd` and `wbinvd`. We show that these privileged instructions have undesirable effects when used by an attacker, which is possible in the threat model of TEEs (Section 3.1). We demonstrate previously undocumented behavior that allows violating the consistency of the memory view, leading to architectural data changes inside TEEs (Section 3.2). Finally, we show that non-coherent memory types are allowed on some AMD client CPUs (Section 3.3).

Setup. For our evaluation, we test on different microarchitectures, namely AMD Rome (AMD EPYC 7252, microcode `0x8301055`), Zen (AMD Ryzen 5 2500U, microcode `0x810100b`), Zen+ (AMD Ryzen 5 3550H, microcode `0x8108102`), and Zen 3 (AMD Ryzen 9 5900HX, microcode `0xa50000c`). For the analysis of the instructions independent of the TEE, we rely on Ubuntu 20.04 with kernel 5.15.0. For the experiments on AMD SEV, we use Ubuntu 22.04 with kernel 6.1.0 on the hypervisor, and Ubuntu 20.04 with kernel 5.15.0 inside the VM.

3.1 Availability

Both Intel and AMD CPUs [2, 25] support the `invd` instruction to invalidate all levels of the internal cache, including the data and instruction cache. Crucially, invalidating the cache containing modified data irreversibly destroys these changes, essentially reverting data modifications to the previous stale state. In contrast, the `wbinvd` instruction writes back any modified cached content to memory before invalidating the cache. In addition, there is the `wbnoinvd` instruction that only writes back modified cache contents to the main memory but does not invalidate the cache. Unlike `wbinvd` and `wbnoinvd`, `invd` has a very limited use case and should only be used if memory consistency is not required and caches are not shared between threads or cores [1]. However, in the threat model of TEEs, the `invd` instruction can be abused by a privileged attacker.

On AMD, `invd` is, by default, converted to `wbinvd`. This behavior can be changed by clearing bit 4 of MSR (`0xc0010015`) [1]. We additionally check the availability of `invd` instructions inside VMs with QEMU v7.2.0. KVM intercepts all invalidation instructions. Hence, CacheWarp can only be mounted via the hypervisor but not from within other VMs.

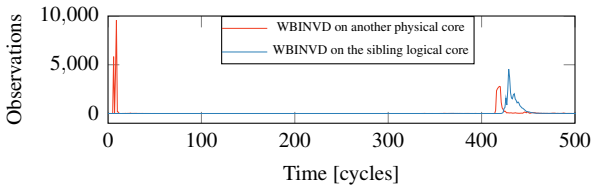

Figure 1: Access time for reloading data from different domains after executing `wbinvd`/`invd`.

Intel explicitly documents that the `invd` instruction is unavailable if Intel SGX is enabled [27, §3.6.5]. More precisely, this instruction raises a general protection fault if processor-reserved memory protection is activated. Consequently, this is also the case for Intel TDX, as TDX crucially relies on the Intel SGX-based quoting enclave as the root of trust [26]. We experimentally verify that the behavior of the `invd` instruction matches the documentation. Thus, CacheWarp is not possible on Intel CPUs.

3.2 Scope

In addition to the availability of the instructions, we analyze their scope, i.e., *which* cache lines are affected, to understand the impact of these instructions on AMD. For the private caches, i.e., L1 and L2, the `invd` and `wbinvd` instructions are limited to a physical core. Hence, they only invalidate data of the current logical and sibling logical core. Although not documented, our experiments show that the LLC part within a CCX is invalidated by the `invd` and `wbinvd` instructions.

Private Caches To measure the effect of the `invd` instruction on different cache levels, we rely on eviction to control the cache state. We rely on eviction sets for the L1 cache to reliably bring data into a specific cache set of the L2. To ensure that data resides in the L2 but not in the L1, we rely on an L1 eviction set that evicts the data from the L1 but not from the L2. Accessing the eviction set is fast as long as the eviction set stays in the respective cache. Hence, if data is invalidated, we observe an increased eviction time. For each cache level, we measure the average access time while executing the `invd` instruction versus executing no instruction on the sibling core. As a second experiment, we measure the eviction timing after executing the `invd` instruction on a different physical core within the CCX. To get precise timing measurements, we rely on the `rdpru` instruction [37]. As shown in Figure 1, executing `wbinvd` or `invd` on another physical core does not affect data within the private caches. However, data in the shared cache is invalidated to memory, exhibiting a red peak on the right side. To conclude the first analysis, `invd` invalidates the private caches on the physical core.

Figure 2: The scope of `wbinvd` and `invd` within a CCX that consists of 2 physical CPUs with 4 CPU cores. The boxes stand for different cache domains. The orange-shaded areas represent the scope of the `invd` instruction.

Shared Cache To understand the scope of the `invd` instruction on the shared non-inclusive LLC, we rely on L2 eviction. The LLC eviction is independent of the L2 eviction, as the LLC is non-inclusive. However, the addresses in the LLC eviction set share their cache set index with those in the L2 eviction set. We can extend an eviction set only for the LLC into one that additionally works for the L2 by accessing 8 more addresses mapping to the same set, as an L2 cache set has 8 ways. As bits 6-8 of the physical address determine the slice [18], a minimum of 28 physical addresses with the same bits 6 to 19 is required to achieve effective LLC eviction. Additionally, Figure 1 shows that the data in the LLC is invalidated, independent of the core within the CCX where the `invd` instruction is executed. Hence, this shows that the `invd` instruction invalidates the entire LLC shared within a CCX but does not affect other CCXs. Figure 2 summarizes our results.

Cache-line State The execution time of the `invd` and `wbinvd` depends on the number of modified, i.e., dirty, cache lines of the affected cache. We experimentally evaluate that by varying the number of dirty cache lines from 0 to 512 and measuring the average execution time over 10 000 repetitions. We observe a clear linear relationship between the number of dirty cache lines and the timing of the instruction.

3.3 Non-coherent Memory

In addition to manually triggering inconsistencies using the `invd` instruction, memory type range registers (MTRRs) on AMD can also violate memory consistency. Both on Intel and AMD, each physical core has its own MTRRs to configure the memory type of physical address ranges. The main idea is to have different memory types on different CPU cores for the same physical address. While Intel does not have non-coherent memory types due to the self-snoop feature, the uncacheable (UC) and write-combining (WC) memory types are documented as non-coherent on AMD [2].

Experimental Setup We map two virtual addresses to the same physical address on two different cores. As the default memory type is write-back (WB), we mark the memory range as UC on one of the cores by using MTRRs. We experimentally confirm that writing to uncacheable memory does not trigger cache updates or invalidations. If two cores write to the same memory and both writes occur on the WB memory type prior to writes on the UC memory type, the writes stored in the cache may later overwrite the writes to the UC memory if a write-back of the cache line is triggered. Our experiments show that this coherency violation also applies to virtualization on AMD client CPUs, ranging from Zen to Zen 3 microarchitectures. In this context, if the guest VM writes to the memory, the hypervisor can discard or "drop" those writes. However, when performing this experiment on an AMD server CPU that supports AMD SEV, the hardware enforces the use of coherent memory types. As a result, the non-coherent memory type, i.e., UC, is converted to the forced coherent memory type, cache disable (CD). If the cache line is in a modified state, writes on CD memory cause the cache line to be written back before being invalidated. Moreover, accesses to a dirty cache line are performed after the invalidation is finished. Hence, a simple attack using a non-coherent memory type for guest access is impossible for AMD SEV.

4 CacheWarp

In this section, we introduce CacheWarp, a software-based fault-injection attack on AMD SEV-ES and SEV-SNP. CacheWarp is based on our analysis of the `invd` instruction, which shows that invalidating dirty cache lines without triggering a write-back is feasible on AMD CPUs, even if AMD SEV is enabled. Specifically, a malicious hypervisor can selectively drop any writes of an AMD SEV-ES and SEV-SNP guest that occurred at an attacker-chosen point. The consequence of such a drop is that the VM architecturally uses stale data.

4.1 Threat Model

In line with previous work [35,42,47,57] and AMD's whitepaper [6], we assume a privileged attacker, i.e., a malicious hypervisor for AMD SEV. Such an attacker executes privileged code outside the VM. The attacker has full control of the scheduling and can pin the virtual CPUs to a logical CPU and offline other cores within the same CCX. Moreover, the attacker can influence the allocation of memory. Lastly, as the attacker can execute privileged code, the attacker can modify model-specific registers (MSRs) and write to APIC registers. However, the attacker has no control over the code or data inside the VM. These capabilities are all in the threat model of AMD SEV and we do not assume knowledge of the guest physical address (gPA) of the target function in the AMD SEV VM [36].

We evaluate the attack on an 8-core AMD EPYC 7252 CPU for SEV-ES and AMD EPYC 7313P and 7443 CPUs for SEV-SNP. As suggested by AMD [8], on AMD EPYC 7252, the host OS, QEMU, and OVMF are built with the master branch (Linux kernel 6.1.0, QEMU v7.2.0-2-g5204b499a6, OVMF

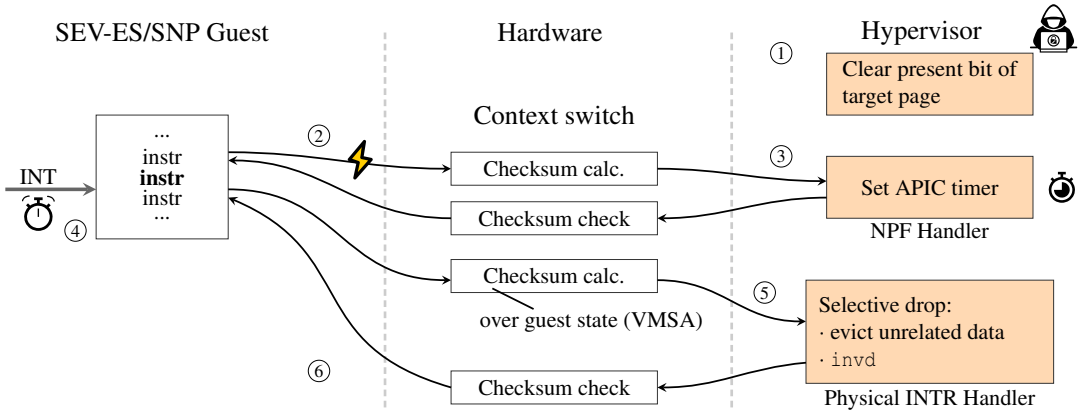

Figure 3: Overview of CacheWarp. The attacker clears the present bit (①) of the page containing the targeted store that should be dropped. Thus, the CPU induces a fault (②) when the guest execution reaches this page. In the fault handler, the attacker sets the APIC timer (③) to let the guest continue execution until the target instruction. When the timeout is reached, the guest is interrupted (④) and the attacker can selectively drop writes of the guest (⑤). The attacker evicts unrelated data from the cache, and drops all other modified data using the `invd` instruction. The guest then continues (⑥) with the dropped stores.

commit `cda98df`, firmware 0.24.15). For AMD SEV-SNP, we use the *snp-latest* branch (commit `ad91624`, firmware 1.54.01). The victim VMs are configured with a single virtual CPU and 4 GB of main memory. The victim system is running Ubuntu 20.04 LTS (Linux kernel 5.15.0).

4.2 Attack Overview

In this section, we present a high-level overview of CacheWarp. The goal of an attacker is to drop a guest write at a precise attacker-chosen point so that the guest architecturally uses stale data in the subsequent execution. Such writes can be explicit, e.g., local variables on the stack, but also implicit, e.g., return addresses of a `call` instruction. We show that both cases lead to powerful attacks. With Dropforge (Section 4.3), we change the behavior of functions. With Timewarp, (Section 4.4) we redirect return values to an earlier point in the program's control flow.

To locate a potential target, we introduce our framework for execution control. We rely on page faults and timer interrupts to interrupt guests at a specific state, dropping all writes not committed to the memory. Additionally, on AMD SEV-ES, we achieve reliable single-stepping using an uncacheable VMSA and register-state tracking (Section 5.1). To maintain the memory consistency of unrelated dirty cache lines, the hypervisor can selectively evict them into the memory (Section 5.2). This step guarantees that CacheWarp does not lead to a failed integrity check for an SEV guest. Figure 3 outlines each step of CacheWarp.

4.3 Dropforge

The main idea of Dropforge is to selectively drop writes during a function call to modify the behavior or result of a target

```c
int victim(int a, int b) {
    int ret = 0;
    ret += a * 10 + b;
    return ret;
}

int main() {
    ...
    do {
        ret = victim(1, 1);
        reset = victim(2, 5);
    }
    while(ret == 11);
    ...
}
```

```
1  victim:
2      push   %rbp
3      mov    %rsp,%rbp
4      mov    %edi,-0x14(%rbp) ; param
5      mov    %esi,-0x18(%rbp) ; param
6      movl   $0x0,-0x4(%rbp)  ; var
7      mov    -0x14(%rbp),%edx
8      mov    %edx,%eax
9      shl    $0x2,%eax
10     add    %edx,%eax
11     add    %eax,%eax
12     mov    %eax,%edx
13     mov    -0x18(%rbp),%eax
14     add    %edx,%eax
15     add    %eax,-0x4(%rbp)  ; var
16     mov    -0x4(%rbp),%eax  ; ret
17     pop    %rbp
18     retq
```

Figure 4: The toy example for dropping implicit writes introduced by the compiler. Depending on which write we drop, i.e., passed parameters, the initialization of local variables, or the assignment of local variables, we observe different return values for the program.

function. If an attacker drops a write from a function, the value is effectively reverted to the previous state, and the function works with a stale value. Writes that can be dropped are not only explicit writes but also writes introduced by the compiler. Compilers commonly introduce writes to the stack for exchanging register contents, i.e., the register content is written to the stack and then read into another register.

To illustrate the power of this attack primitive, Figure 4 shows a toy example containing both explicit and compiler-introduced writes. In this toy example, we show that passing parameters, the initialization of local variables, and the assignment of local variables can all be dropped. The guest VM keeps calling the function `victim` in a loop as long as the return value is correct. The second invocation of `victim` resets the stack frame with different values. Hence, once a

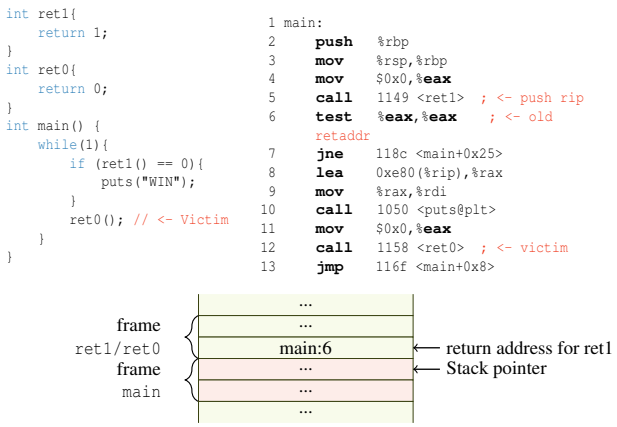

Figure 5: A toy example illustrating the Timewarp primitive. By dropping the implicit write of the `call ret0` instruction, we jump back to the call site of `ret1`. This effectively looks like `ret1` returned '0' and the program outputs "WIN".

drop occurs in the first invocation of `victim`, some different stale values are used. This reset also ensures that the observed return value is not a result of multiple dropped writes across multiple function invocations. In this toy example, most writes fall into the same cache line. Hence, when "blindly" dropping writes, it is highly likely that all writes are dropped. However, an attacker can use single-stepping to target individual writes, even if they fall into the same cache line.

In our example (compiled with GCC 9.4.0), an attacker can drop the writes from the compiler-generated prologue of the function, and the explicit write to the variable, which is used as the return value. We confirm that each instruction that performs a write operation (marked with a comment) can be skipped. Depending on the exact write that is dropped, we observe different return values in the calling function. While we can also drop the value that is pushed onto the stack by the `push %rbp` instruction, the next invocation of `victim` has the same stack frame. Hence, using the old value of `rbp` does not make a functional difference.

4.4 Timewarp

The main idea of Timewarp is to reuse a stale return address of a previous function to redirect control flow. Timewarp essentially jumps back to the call site of this previous function with the return value of the current function. Timewarp exploits that on x86, the return address is implicitly written to the stack on a function call and that stack frames are reused across function calls.

To illustrate Timewarp, Figure 5 shows a toy example. The main function calls two functions, `ret0` and `ret1`. Their expected return values are '0' and '1', respectively. Note that the loop is not strictly necessary. It only enables an attacker to repeat the attack arbitrarily often without having to restart the application and without requiring single stepping. For a realistic attack (cf. Section 6.2), we do not rely on such a loop. In Line 5, `ret1` is called (`call ret1`), which pushes the return address `main:6`, i.e., the address of the instruction following the call, onto the stack. When returning from `ret1`, the `ret` instruction at the end of the function reads the saved return address from the stack. The CPU jumps to this location by setting the instruction pointer to the address.

To modify the return value of `ret1`, we target the call to `ret0` (`call ret0` instruction) at Line 12. A `call` instruction consists of an implicit `push` and a `jmp` instruction. The `push` instruction writes the return address, i.e., the address of the instruction following the call, onto the stack. In this example, the return address is `main:13`. After the call, and before the function returns, the attacker can invalidate the write of the return address. Thus, as the stack frame is reused from the previous call to `ret0`, the old return address `main:6` is still on the stack. As a result, `ret0` returns to `main:6` instead of `main:13`, effectively resetting the instruction pointer to an earlier state. However, the return value stored in `rax` is defined by the function `ret1`. Consequently, the call site of the previously-invoked function `ret1` is re-executed, but this time with the return value of `ret0` instead of `ret1`. For the program, it looks like `ret1` returned the value '0' and it continues execution from there. As the stack-related registers `rbp` and `rsp` are callee-saved [39], this re-use of the stale return address does not have any side effects on the stack layout.

5 CacheWarp Building Blocks

In this section, we introduce two building blocks to provide precise control over which writes to drop (cf. Section 4.2). First, we present our page-fault and interrupt-based framework for execution control. For AMD SEV-ES guest VMs, the framework additionally allows single-stepping the VM reliably. Unlike prior work [36], we rely on MTRRs to assign uncacheable memory for VMSA and `wbinvd` to clean the cache before interrupts, resulting in a stable cache state during a context switch. As a result, the runtime of resuming guest VM demonstrates negligible fluctuations, allowing reliable single stepping. Second, based on the result of constructing eviction sets (cf. Section 3.2), the irrelevant dirty data that resides in other cache sets can be evicted proactively. These two building blocks ensure the reliability of CacheWarp.

5.1 Stepping

CacheWarp needs precise control over guest execution, as dropping irrelevant data can have disastrous side effects for the attacker, such as freezing the entire system. Hence, the main challenge of our framework is to minimize the noise of stepping, achieving reliable single-stepping. Previous work did not have to deal with this problem, as attacks were often repeatable without the potential to crash the system. For Intel

SGX, SGX-Step [52] configures the APIC timer such that a malicious OS can single-step the execution of victim enclaves to leak secret information [38, 41, 45, 48, 50, 53]. Compared to SEV, the context switch to and from SGX is relatively fast and nearly constant time, leading to reliable stepping. For AMD SEV, a malicious hypervisor can also hijack the APIC timer, forcing the guest VM to interrupt its execution. While Li et al. [36] show that they can achieve the execution control of AMD SEV-ES VM on a near instruction level, the internal call flow of each stepping is still unclear. Moreover, the malicious hypervisor needs to dynamically calibrate the interval of APIC interrupts, as the context switch from guest to host is not constant-time, resulting in imprecise control. As a result, multi-stepping may occur frequently instead of single-stepping. While a multi-step is endurable in ciphertext side-channel attacks by repeating measurement, this is not the case for CacheWarp.

Overview The framework is implemented as a modified hypervisor that is controlled by user-space controller in the host. The user-space controller communicates the fixed APIC interval, the number of steps to be performed, and a flag to signal the initiation of stepping. After this flag is set, the hypervisor clears the present bit of all guest pages. As a result, any attempt to fetch code from the guest triggers a nested page fault (NPF) due to the missing present bit of the code page. By reading the *exit_info* in the unencrypted VMCB, the hypervisor gets the faulting gPA. The hypervisor's NPF handler then iterates over the nested page table and resets the present bit in the page-table entry for this faulted page. Before resuming guest execution, the hypervisor sets an APIC interval to determine how much progress the guest can make during this stepping. Since the hardware disables interrupts during the context switch [2], an interval lower than a threshold always results in zero-steppings, i.e., the APIC timer interrupt arrives before the guest commits the first instruction. Conversely, an interval exceeding the threshold ensures that the guest retires one or more instructions, known as single-stepping and multi-stepping [52]. To ensure consistent conditions for every stepping, the hypervisor always clears the present bit of the last fault page when handling the APIC timer interrupt, i.e., an NPF is always triggered before the next APIC interrupt.

Similar to the NPF handler, the hardware takes over the context switch when the local APIC timer interrupt arrives. Since AMD SEV-ES, the CPU encrypts the sensitive guest register values before storing them in the VMSA. In addition, guest-state consistency checks are performed before resuming guest execution. While the guest registers are encrypted, the hypervisor can observe the ciphertext of the guest's RIP register to differentiate between zero-step and non-zero-step, i.e., the hypervisor can determine if the guest made progress. Besides, observing the change of other registers helps to infer whether a non-zero-step is single-step or multi-step. Section 8 discusses alternatives to the RIP register as AMD SEV-SNP obfuscates the register ciphertexts preventing localization over the VMSA.

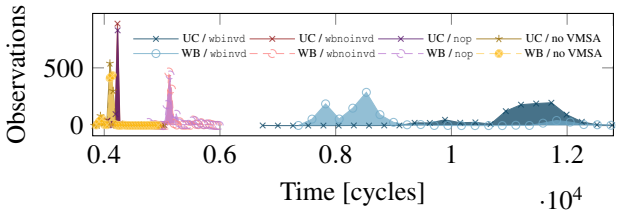

Figure 6: Timing of context switch (zero-step) with different strategies. 'UC' means the hypervisor marks VMSA as uncacheable, and 'WB' marks VMSA as write-back. 'no VMSA' means the hypervisor does not observe the guest `RIP` in VMSA but only sets a tiny APIC interval to guarantee zero-step.

Table 1: The threshold of APIC interval to get single-step.

Uncachable			Write Back		
`nop`	`wbinvd`	`wbnoinvd`	`nop`	`wbinvd`	`wbnoinvd`
74 cycles	146 cycles	78 cycles	114 cycles	146 cycles	114 cycles

Reliability Improvements As shown by Li et al. [36], single stepping is not reliable on AMD SEV-ES due to the non-constant time context switch. The main reason for the observed timing variations are cache effects when loading and storing values to the VMSA memory. Hence, to eliminate the effect of the cache state, we mark the VMSA memory as uncacheable using MTRRs. While we expect a longer time window for a context switch, the consistency check and guest state loading are actually faster, around 900 cycles. Besides, the hypervisor always observes the same VMSA encrypted state even with a large APIC interval that is more than 100 000 cycles. This behavior strongly resembles the observed memory inconsistencies on AMD client CPUs, as shown in Section 3.3.

According to the AMD manual [2], the hypervisor should flush the guest data from all CPU caches before it reads the ciphertext. We hypothesize that when the VMSA page is write-back, reads from the hypervisor force the cached guest data to be encrypted and written back to the memory. However, when the VMSA page is uncacheable, memory coherency is not enforced between the hardware and the hypervisor for this page. The secure processor always saves the plaintext of guest registers into the cache, while the hypervisor reads the stale encrypted VMSA value from memory and no longer flushes the dirty cache lines. The hypervisor always observes the same VMSA value, which leads to a "zero-step".

To experimentally verify this, the hypervisor performs the `wbnoinvd` instruction before reading the encrypted guest-register state to obtain the latest view of the VMSA. We successfully demonstrate the capability of the hypervisor to

observe the variations in the ciphertext of the VMSA. To further investigate the effect of cache state on the stepping, we separately perform `nop`, `wbinvd`, and `wbnoinvd` before resuming VMs while marking the VMSA page as uncacheable or write-back. For each stepping, the hypervisor reads the guest RIP in VMSA after timing the context switch (zero-step). Figure 6 shows the timing of the context switch with different strategies. The threshold of APIC interval to get a single-step is shown in Table 1. When the VMSA is write-back, the timing of the context switch is short only if there is no access from the hypervisor. Moreover, if the hypervisor ensures a clean cache state by executing `wbinvd` before the context switch, the stepping takes longer with an uncacheable VMSA. Thus, by relying on uncacheable memory, we can avoid additional flushes caused by reads from the hypervisor before the context switch. As a result, the runtimes of `VMRUN`, i.e., loading guest state and checksum calculation, is highly-predictable, resulting in a significant improvement in stepping. Additionally, the window of APIC intervals that exclusively results in zero- and single-step is extended to dozens of cycles.

Note that before resuming the execution of the guest, a field in VMCB indicates whether the host has passed an interrupt to the guest. Specifically, the guest OS can handle some specific virtual interrupts, e.g., the APIC timer interrupt, before executing the first instruction. However, to ensure that the attacker always zero/single-steps on the target instruction, the malicious hypervisor can choose not to inject such events.

Evaluation. To evaluate the reliability of single-stepping, Figure 8a in Appendix A shows a benchmark program that modifies a different register for each instruction. The `nop` instruction is also used to demonstrate the performance of the precise control of our framework, as it does not have any dependency. For each stepping, we use a bit vector of changes to guest registers as a fingerprint of the current progress of the victim. According to the layout of VMSA, certain registers are grouped in pairs and coexist within a single 16 byte block, which is the encryption unit. Figure 8b illustrates a subset of the registers we include. Each bit represents a modification of this block in the current stepping. Depending on the value of the vector, we can confirm that a multi-step occurs when the changing pattern does not match the expected sequence and ideally recover how many instructions are executed in the multi-step as well. Note that in realistic scenarios, we cannot directly recognize a multi-step as the guest instruction sequence is unknown to the attacker. While fingerprinting could work, here we just use the benchmark program to evaluate the reliability of single-steps. We observe 10 000 single-steps with 1951 zero-steps and 0 multi-steps, using a fixed interval of 220 cycles as the APIC interval. Concurrent work [58] uses performance counters to distinguish zero-, single-, and multi-steps on SEV-SNP, guaranteeing reliable single-stepping as well. This technique could also be added to our framework.

5.2 Selective State Drop

As the second building block, we show how the hypervisor can selectively drop dirty cache lines, i.e., partially writing back the cache before its invalidation. This step is indispensable, ensuring the passing of the integrity check of the VMSA. Our experiments show that the checksum calculation is always finished before the hypervisor takes over the execution. When the hypervisor executes the `invd` instruction after zero-stepping, the AMD SEV VM can still resume its execution afterward. However, if the chosen interval leads to a single-step or multi-step, the register state of the guest within the VMSA (at least the block containing the guest RIP) changes and is in the modified cache state. Thus, the hypervisor cannot simply execute the `invd` instruction after single/multi-steps, as it immediately leads to a crash of the guest VM.

To achieve a selective state drop, the attacker must keep the dirty cache lines that the attacker intends to discard in the cache but evict all other cached data back to memory. Hence, the attacker first allocates the eviction buffer for all cache sets. Note that this step only needs to be performed once, e.g., before the VM creation. If the write the attacker wants to drop resides in the private cache, i.e., L1 or L2 cache, an eviction on the L2 cache must first be performed due to the non-inclusive shared LLC. To ensure all irrelevant dirty cached data within the scope of `invd` is written back to memory in advance, the attacker performs an L2 eviction for all L2 sets except for the target set. Next, as the unrelated data is now evicted into the LLC cache, the attacker performs an LLC eviction to write back these modified values to the memory.

While the exact target address is unknown to the hypervisor, the hypervisor can track it on a page level. Similar to how the page address for a code fetch is recorded, the hypervisor can retrieve the gPA of an NPF triggered by a write operation. By iterating over the nested page table, the hPA for the fault page, which determines the cache index, can be read to refine the potential cache indexes of the target address.

Finally, to avoid a race condition between writes from other physical cores and cache invalidation, the attacker can offline the other physical cores within the CCX. To ensure there is no other dirty data in the internal cache of the logical sibling core, the attacker can disable hyperthreading. Moreover, the attacker can also disable hardware prefetchers and interrupts as well as fix the CPU frequency during eviction to obtain a denoised environment. After evicting all the dirty cached values the attacker wants to keep, the attacker executes the `invd` instruction to drop the remaining writes.

Evaluation. We evaluate the accuracy of selectively dropping writes on a single L2 cache set both on AMD SEV-ES and SEV-SNP. The test program in the VM first allocates a 2MB huge page to ensure that it occupies memory belonging to all L2 sets. We randomly choose an address within the range and pass it to the for-loop code as listed in Figure 7. The code executes a read-add-write pair for the given address

```
1  for (int i = 0; i < 10000000; i++) {
2      asm volatile (
3      ".rept 4000\n"
4      "movq (%0), %%r11\n"
5      "addq $1, %%r11\n"
6      "movq %%r11, (%0)\n"
7      ".endr\n"
8      :: "r"(addr) : "memory");
9  }
```

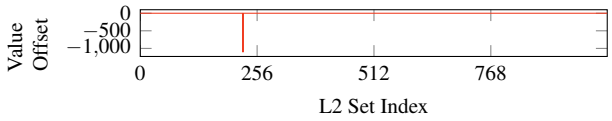

Figure 7: Evaluation for selectively dropping memory writes. For each L2 set, 1000 steppings are repeated separately, followed by invalidation on the entire L2 set per step. The L2 set index of the target address is 225. Only when the correct L2 set remains in the cache, the writes are dropped.

in each iteration, iterating a total of 4000 times. We use the `O2` optimization flag, such that the loop counter resides in a register instead of utilizing stack memory. Hence, the only point where we can drop the modified cache state is `movq %%r11, (%0)` (Line 6).

We choose the APIC interval that leads to multi-stepping. For each stepping, the guest can approximately complete one iteration of memory read and write before the context switch caused by the interrupt. For example, on AMD EPYC 7252, the L2 cache entry of the target can potentially be stored in one of the 16 LLC sets following L2-prime. Hence, to drop the dirty cached data in a different L2 cache set each time, the hypervisor performs a complete LLC eviction for all LLC sets except for 16 specific LLC sets in each measurement. Note that the LLC eviction needs to contain the step of L2 eviction, due to the non-inclusive LLC cache. The hypervisor only requires more LLC eviction addresses as they have the same bits with L2 eviction addresses for the L2 cache index. As there are 1024 L2 cache sets, we assume that the hypervisor can observe the value offset only in one measurement when the target data resides in that L2 cache set that is dropped. Figure 7 shows that only when the correct L2 set remains in the cache, the writes are dropped. Otherwise, the data is written back and updated in the memory before the cache invalidation.

6 Case Studies

In this section, we present 3 end-to-end attacks using CacheWarp as our case studies. In Section 6.1, we demonstrate an attack on the RSA-CRT implementation of the Intel IPP cryptographic library, extracting the full private key within 10 s on average. In Section 6.2, we show that CacheWarp can break the password authentication of the OpenSSH server, resulting in full (unprivileged) access to the guest VM. In Section 6.3, we show that the `sudo` binary can further be exploited using CacheWarp to escalate the privileges of the attacker.

6.1 Breaking RSA-CRT via Bellcore Attack

In the first case study, we show that CacheWarp can perform a Bellcore attack [10, 12] on RSA-CRT, fully recovering the private key given a single faulty signature.

RSA and Bellcore Attack In an RSA signing scheme, the signature S is computed via the modular exponentiation $S = x^d \pmod N$, with x the message, d the secret signing exponent, and N the public modulus. As the involved numbers typically have multiple thousand bits, this exponentiation is computationally expensive. To improve performance, the computation can be split into two parts $S_1 = x^d \pmod p$ and $S_2 = x^d \pmod q$, with p and q the secret prime factors of $N = p \times q$. The final signature S can then be constructed from S_1 and S_2 via the Chinese Remainder Theorem (CRT) [44].

While more efficient than a standard RSA implementation, RSA-CRT is especially vulnerable to fault attacks [10, 12]. A single fault that occurred during the computation of S_1 but not during the computation of S_2 is sufficient to recover the private key (p,q). Given two signatures, one such faulty signature $\hat{S}$ and one correctly-computed signature S over the same message, an attacker can compute the private-key part q as $gcd(S-\hat{S},N) = q$ and subsequently $p = \frac{N}{q}$. This equation holds as $S = \hat{S} \pmod q$ but $S \neq \hat{S} \pmod p$. Hence, such a fault allows an attacker to forge arbitrary signatures.

Threat Model In line with the AMD SEV threat model, our victim is a VM guest protected by AMD SEV running on an attacker-controlled hypervisor. The victim provides an interface to get the signature of data. We do not make any assumptions on the signed data; we only require that the same data can be signed twice. The attacker does not have to choose the data or know the data that is signed. For our attack, the victim uses the RSA-CRT implementation of the Intel IPP cryptography library, as also shown in previous microarchitectural attacks [38,43,54]. The goal of the attacker is to extract the private signing key of the victim.

Attack Flow The attacker queries a non-faulty signature S for an arbitrary message, which is used later to recover the private key. For the attack, the attacker uses CacheWarp to drop the write to a cache line containing the RSA private key during the RSA-CRT computation. This dropped write has the effect that the computation uses stale data instead of the private key. Note that for the Bellcore attack, it does not matter how the computation is faulted. Hence, any stale data is sufficient for getting a faulty signature. Still, the attacker

has to ensure that only one of the partial signatures S_1 and S_2 contains a fault. An attacker has 2 options to achieve that. The clean way is to rely on our single-stepping framework (cf. Section 5.1). With single-stepping, the attacker has fine-grained control over which write is dropped. As a result, an attacker can reliably induce the desired fault. However, in practice, it is sufficient to "blindly" drop (multiple) cache lines. Due to the robustness of the Bellcore attack, such a non-synchronized attack is possible. As the attacker only has to induce a single fault and can retry the attack arbitrarily often, only limited precision is needed. Therefore, targeted eviction strategies for unrelated data are unnecessary.

Results and Implications We successfully mount the Bellcore attack on an SEV-ES machine and an up-to-date SEV-SNP machine (AMD EPYC 7313P), both running Ubuntu 22.04 with Linux kernel 6.1.0. Note that no extra steps are needed to adapt the Bellcore attack to SEV-SNP, as it does not rely on single-stepping. The victim VM runs Ubuntu 20.04 and the newest Intel IPP library 2021.8 from July 27, 2023 (commit `36e76e2`). For SEV-ES, we mount the attack 10 times and check whether the resulting signature has changed.[1] In 9 tries, we drop a write that leads to a faulty signature. 100 % of these faulty signatures allow us to correctly recover the private key using the Bellcore attack. Hence, the average overall success rate is 90 %. As one try takes on average 6 s, we get an expected success rate of 99 % after 12 s. The recovery time using the Bellcore attack is negligible, with on average below 0.1 s. For SEV-SNP, we perform 100 "blind" drops, i.e., we do not use single-stepping but mount CacheWarp at randomes times. Of these tries, 28 result in an exploitable faulty signature and only one causes a system crash. The remaining 71 tries have no effect. Given that each attempt takes less than 2 s, an attacker can easily replicate this attack.

In contrast to other software-based fault attacks, such as Rowhammer [30] and undervolting [29, 43, 46], CacheWarp does not rely on manufacturing differences of hardware. Moreover, CacheWarp can accurately choose the time of the fault as well as the location of the fault. Thus, CacheWarp deterministically works on all vulnerable host machines. Similarly to this attack on RSA-CRT, all cryptographic schemes vulnerable to a fault injection during memory load can be attacked using our primitive. As related work indicates, fault attacks can be a powerful primitive against symmetric [20] and asymmetric [11, 12] cryptographic implementations. Therefore, we highly encourage exploring the impact of our primitive in the context of fault attacks, especially as faulting to stale data is typically not a fault model that is considered [17, 23, 31].

[1] The attacker randomly chooses one or multiple cache lines to drop after a 500 cycles multi-step.

6.2 Bypassing OpenSSH Authentication

In this second case study, we use CacheWarp to log into a password-protected OpenSSH server in a VM guest protected by AMD SEV without knowing the password.

Threat Model In line with the AMD SEV threat model, our victim is a VM guest protected by AMD SEV running on an attacker-controlled hypervisor. The attacker does not have code execution in the victim VM. We assume that an OpenSSH server runs in the victim VM. We assume that the SSH server allows authentication via a password, although we strongly suspect public-key authentication to be vulnerable as well. The attacker runs as the VM host with hypervisor privileges and can request an SSH connection to the victim, either directly from the hypervisor or from a different machine. The goal of the attacker is to connect to the VM without possessing valid SSH credentials.

Attack Flow To bypass the SSH authentication, the attacker mounts CacheWarp on the `sys_auth_passwd` function in OpenSSH. If this function returns '1', the user is authenticated, and the SSH connection is established. More precisely, the attacker uses the Timewarp primitive from Section 4.4 to force a password comparison to always succeed. Appendix D shows the relevant parts of the code. By invoking a Timewarp at the `xcrypt` call (Line 9), the control flow is transferred to the return point of the last function call, which is the `shadow_pw` call (Line 5). The `xcrypt` call returns a pointer to the hashed user input on success, and the attacker can provide an arbitrary nonempty input to `xcrypt` by using a password of their choice. Using the Timewarp primitive, the attacker jumps to the return of the `shadow_pw` call overwriting the `pw_password` variable with the return value from the previous xcrypt call. Therefore, from this point on, it holds that `pw_password` = `encrypted_password` as only the first two characters of the salt are relevant which are always the same. At this point, an attacker is authenticated with a wrong password and can execute arbitrary code in the VM.

Challenges While the basic flow of the attack is simple to understand, its execution remains challenging. Most importantly, the Timewarp primitive must be invoked precisely at the `call` instruction responsible for calling the `xcrypt` function. To single-step to this exact location, we utilize a combination of a page-fault attack and register-usage detection (cf. Section 5.1) to find the correct trigger point. By performing a page-fault attack, we can identify when the control flow reaches the code page containing `sys_auth_passwd`. As this code page can also contain other code, we utilize register-usage detection to identify a register usage pattern that only occurs before the `xcrypt` call. This combination of page-fault attack and register-usage detection allows us to precisely identify the point at which the `xcrypt` function is called.

Results We perform the end-to-end attack on an AMD EPYC 7252, running Ubuntu 22.04. The victim VM runs Ubuntu 20.04 and the OpenSSH server version 8.2p1 which is currently the default version. Our attack succeeds in 10 of 10 test runs. A theoretical failed attack means locating the target instruction fails due to potential multi-steps occurring in the locating period. Thus, the cache is not invalidated, resulting in no crash and the possibility for the attacker to retry the attack. In addition, the entire attack takes less than 10 s, making it highly practical. As VM guests typically expose an SSH connection to allow users to connect to them, this attack presents a high-risk factor for AMD SEV-enabled VMs and completely breaks their security guarantees.

6.3 Bypassing Sudo Authentication

In this third case study, we demonstrate how CacheWarp can be exploited to escalate unprivileged code execution in a guest VM to privileged code execution. Such a scenario is realistic after exploiting, e.g., an OpenSSH server using CacheWarp (cf. Section 6.2) or any other attack. In this scenario, a typical next step for an attacker is to escalate privileges on the machine, thus gaining full control over the system. We demonstrate that an attacker can reliably exploit `setuid` binaries using CacheWarp, and, by that, elevate privileges to the superuser. We demonstrate such an exploit on `sudo` version 1.8.31 as found on Ubuntu 20.04.

Threat Model We assume that the attacker has unprivileged native code execution in the AMD SEV VM. Additionally, in line with the AMD SEV threat model, the attacker controls the hypervisor. We assume that the `sudo` Linux utility is installed in the VM, which is common for Linux distribution.

Attack Flow The general idea is to trick the user check in the `sudo` utility, such that the executing user seems to be the root user, skipping any other checks. On a high level, the `sudo` utility works as follows: The program first queries information about the currently executing user, e.g., their EUID, RUID, and GUID. The `sudo` program uses the stored information to look up the user's permission in the sudoers file. If the permission checks based on the retrieved information pass, `sudo` executes the command specified by the user as root.

For the exploit, we target the code that retrieves the information about the currently executing user. Listing 1 in Appendix B shows the assembly code responsible for retrieving and storing this information. After each query of a user-related ID, the information is stored in a zero-initialized C struct. This struct is accessed by a single write to the corresponding offset for each entry. In our exploit, we drop the write for the real user ID (RUID). As the memory is zero-initialized, this results in an RUID of zero, which reflects the RUID of the root user. The `sudo` program does not require additional checks if it is already running as the root user. Thus, `sudo` allows the user to execute arbitrary commands with the highest privileges.

Challenges Compared to the other case studies (cf. Section 6.1 and Section 6.2), the primitive required for this exploit, including the setup, is much simpler. The main challenge is finding the exact point in time to drop the write. For this, we inspect the register usage of the glibc implementation of `getuid` and search for exactly this pattern using our single-stepping framework. Once we identify the pattern, we can count the remaining few instructions before the desired write instruction to drop it.

Results We evaluate our exploit on an AMD EPYC 7252 with Ubuntu 20.04 running Linux kernel 5.15.0 in AMD SEV. We observe a success rate of 99 % for 100 executions. If the exploit fails, the attacker can just mount the exploit again by restarting the `sudo` binary. We observe that our exploit finishes within 20 seconds. Compared to the Rowhammer-based `sudo` exploit from Gruss et al. [22], which takes more than 44.4 h, our attack is practical and achieves a speedup of 4 orders of magnitude.

7 Countermeasures

In this section, we discuss potential mitigations for CacheWarp on the hardware, firmware, and software layer.

Hardware Ultimately, CacheWarp has to be fixed on the hardware level. One solution is to prevent the `invd` instruction from being used if AMD SEV is enabled. CacheWarp requires this specific privileged instruction that is only necessary for a few very specific scenarios [25]. However, none of these scenarios should occur under the regular use of AMD SEV, and we did not find any use of this instruction in the Linux kernel or Xen hypervisor. Hence, making the use of `invd` and AMD SEV mutually exclusive would prevent CacheWarp. On Intel CPUs, the `invd` instruction is mutually exclusive with Intel SGX, i.e., if SGX is enabled, `invd` simply raises an exception. Such a hardware change also ensures backward compatibility, as `invd` is still available to legacy systems that do not support SGX.

Alternatively, if the `invd` instruction should still be available with AMD SEV, the CPU could automatically write back the cache state on VM interrupt. Similar to TLB flushes, the AMD SEV VM could set a bit in VMSA to indicate the hardware needs to write all modified cache lines back to the main memory. While the writes to the VMSA could still be dropped, there is an integrity check over the whole VMSA during the `vmrun` instruction, already preventing this case.

Firmware In contrast to hardware fixes, firmware workarounds can act as short-term mitigations against

CacheWarp. Such firmware updates can be done using microcode updates via the BIOS or the operating system. Microcode updates can hook instructions to change their behavior [13, 33]. Such a hook can be used to prevent the `invd` function from invalidating the cache if AMD SEV is active. While such a hook leads to a slight performance penalty for the instruction, we expect this to not be a problem, as this instruction is nearly never used.

Alternatively, a microcode update could hook the access to bit 4 of MSR (`0xc0010015`). This bit controls whether the `invd` actually invalidates cache content or acts the same as the not-exploitable `wbinvd` instruction (cf. Section 3.1). As microcode can introduce new MSRs [32], we expect such a change to be possible. Hence, a microcode update could prevent changing the `invd` behavior if AMD SEV is used.

Software We implement a proof-of-concept software-only mitigation for guest VMs in LLVM's *clang*. Appendix C details the compiler's implementation and security analysis. The main idea is to ensure that writes end up in the main memory before they are used again. This can be ensured by forcing a write-back of a modified value using the unprivileged and untrapable `clwb` instruction. In contrast to `clflush`, this instruction writes back the modified cache line without flushing it from the cache. However, there is still a race condition if the hypervisor interrupts the guest VM between the write and the `clwb` instruction. Hence, the compiler must add a read-back of the value *after* the `clwb` to ensure that the write was not dropped before the `clwb` instruction. If the read value is not the same as the written value, the VM can abort, as this is not possible under normal bug-free execution.

Our mitigation is inspired by Intel's compiler-based LVI mitigation for SGX [31, 51] that had to solve a similar problem. While the LVI mitigation has to prevent speculative execution after any load, our mitigation has to write back and verify every write. Still, with this strong attacker model of AMD SEV, we do not see any other software-only mitigation that is effective in the presence of a malicious hypervisor. We evaluate the overhead of our proof-of-concept mitigation on *nbench* [16, 19, 31] compiled with the `O0` optimization flag so that most writes are explicit. An average overhead of factor 193.51 over the benchmarks is introduced by protecting explicit writes and `push` instructions in the prolog. We leave it to future work to implement a feature-complete version of the compiler (Appendix C), as this engineering effort is out of the scope of this paper. We experimentally verify our compiler mitigation against *selective write dropping* (Section 5.2) and no longer observe write drops. Finally, the presence of the `clwb` instruction is already drastically reducing the probability of injecting a fault.

8 Discussion

Limitation AMD addressed the Cipherleaks side channel [36] in AMD SEV-SNP by adding freshness to the VMSA when storing the register context in memory, obfuscating the ciphertext. Thus, we can no longer rely on *register changing* patterns (Section 5.1) to evaluate steppings and identify target instructions as they are no longer constant based on the registers. However, the performance counters are accessible to track the runtime information for each stepping [58]. Other patterns with some chosen events can be used to identify target instructions, which only requires engineering effort as reliable single-step was demonstrated on SEV-SNP [58].

Differences between SEV-ES and SEV-SNP for CacheWarp The underlying vulnerability of CacheWarp is the same for SEV-ES and SEV-SNP. While SEV-SNP introduces new hardware-based security features, most side channels, including page faults and Prime+Probe [6], are not mitigated. As a result, on SEV-SNP, an attacker can still selectively drop dirty cache lines for each stepping (Section 5.2) using eviction. Similarly, since the `wbinvd` instruction and MTRRs are available on SEV-SNP, an attacker can adopt the same strategy as used on SEV-ES to improve stepping. The only difference between CacheWarp on SEV-ES and SEV-SNP is the method for precisely locating the drop target, i.e., the technique for single-stepping.

Related Work Before the introduction of AMD SEV-SNP, several attacks have been proposed. Hetzelt and Buhren [24] showed the first flaws in the design of AMD SEV already before it was widely available in CPUs. They demonstrated control-flow modifications via the back-then unencrypted VM control block (VMCB). Morbitzer et al. [42] exploit the fact that before the introduction of SEV-SNP, a malicious hypervisor could control page mappings in the VM. They tricked the VM into decrypting sensitive memory and returning it to the attacker as the content of a legitimate request posted to a web or SSH server in the victim VM. As the underlying victim operating system relies on the correctness of the provided address mapping, the content of the sent memory pages is not further checked before transmitting them to the attacker. Radev and Morbitzer [47] manipulate external hypervisor-controlled interfaces to an AMD SEV VM degrading hardware randomness in the victim machine, injecting and exfiltrating data, and finally gaining code execution in the victim VM. Wilke et al. [57] show that using an encryption oracle attacker-controlled data can be injected into the victim VM, again leading to code execution for the attacker. Li et al. [35] abuse the information leakage on address translation faults to leak pages from inside of the AMD SEV-protected VM to an attacker. In contrast to our work, these discussed attacks either break with the introduction of AMD SEV-SNP [24, 42, 57] or only theoretically discuss applications on SEV-SNP [35, 47].

Li et al. [36] showed that even with confidentiality and integrity guarantees, the confidentiality of VMs can be violated using side-channel attacks on the ciphertext. While their work violated the confidentiality of the AMD SEV-SNP VMs, our attack additionally breaks the integrity of the VMs as we achieve arbitrary code execution. With hardware access to the hypervisor, Buhren et al. [15] showed that the endorsement keys can be extracted, allowing an attacker to fake remote attestation reports. In contrast to them, we target the software in the VM directly and do not require hardware access.

9 Conclusion

In this paper, we presented CacheWarp, a new software-based fault attack on AMD SEV-ES and SEV-SNP that enables architectural rollbacks to previous (stale) states. Unlike previous attacks, CacheWarp is not mitigated on the newest SEV-SNP implementation, and it does not rely on the specifics of the guest VM. We introduced a robust single- and zero-stepping framework for synchronizing attacker and victim, which we use in 3 case studies. We demonstrated a full key recovery of RSA-CRT in the Intel IPP crypto library, authentication-less login to an OpenSSH server, and privilege escalation via the `sudo` binary. Although we devised a proof-of-concept compiler-based software mitigation, we argue that only hardware, and possibly firmware, mitigation can efficiently mitigate CacheWarp.

Acknowledgment

We want to thank our shepherd and the anonymous reviewers for their guidance, comments and valuable suggestions, as well as Leon Trampert and Moritz Lipp for helpful feedback on this work. Ruiyi Zhang thanks Xinyue Shen for fruitful discussions and suggestions that helped improving the paper. This work was supported in part by Semiconductor Research Corporation (SRC) Hardware Security Program (HWS).

A Register-changing Observation

Figure 8a shows a benchmark program that modifies a different register for each instruction. Figure 8b illustrates a subset of the registers we included. We evaluate the reliability of single-stepping on SEV-ES by observing the register-changing pattern of the benchmark program.

```
300f: nop              ; 0x0
3010: push   %r11      ; 0x1
3012: add    $0x1,%r11 ; 0x80
3016: add    $0x1,%r9  ; 0x40
301a: add    $0x1,%rdx ; 0x10
301e: add    $0x1,%rcx ; 0x8
3022: add    $0x1,%rax ; 0x4
3026: sub    $0x1,%rax ; 0x4
302a: sub    $0x1,%rcx ; 0x8
302e: sub    $0x1,%rdx ; 0x10
3032: sub    $0x1,%r9  ; 0x40
3036: sub    $0x1,%r11 ; 0x80
303a: pop    %r11      ; 0x1
303c: jmp    300f      ; 0x0
```

(a) Register-changing pattern used in the benchmark program

B Sudo Gadget

Listing 1 shows the exploited assembly code in the `sudo` case study Section 6.3.

```
[...]
xor  %edi, %edi
call getsid
mov  %eax, (user_details_struct.sid)
call getuid
mov  %eax, (user_details_struct.ruid) ; <-- drop
call geteuid
mov  %eax, (user_details_struct.euid)
call getgid
mov  %eax, (user_details_struct.rgid)
[...]
```

Listing 1: Assembly code responsible for retrieving information about the currently executing user in the `sudo` program.

C Compiler Mitigation

In this section, we detail the proof-of-concept compiler to mitigate CacheWarp. We implement the compiler in the LLVM framework as a machine function pass and iterate over all assembly instructions to check if the instruction is an explicit store or `push`. Figure 9a shows the emitted instructions to protect a store instruction. First, the compiler inserts a `clwb` instruction to write back the dirty cache line. Second, we emit a comparison instruction between the memory operand and the original register. Finally, if the values are not equal, we are under attack and abort further execution. We focus only on the store instructions in the proof-of-concept. However,

the compiler can be extended to additional instructions like `call` but this engineering effort is out-of-scope for this work.

We assume an attacker with single-stepping capabilities can inject the `invd` instruction after each instruction in the victim. Figure 9b shows the first case when the `invd` arrives after the store and drops the dirty cache line. However, the comparison detects this due to the mismatch of the memory and the desired register value and aborts further execution. Figure 9c shows the second case when the invd arrives after the `clwb` instruction. Here the `invd` has no effect as the cache line's content is already written back. In this case, the victim cannot detect that the attacker tried to fault attack the program since no fault was injected. We experimentally verify these two cases and confirm that the first is detected by the compare instruction and the second is ineffective.

```
1    mov   %rcx,(%rdi)
2    clwb  (%rdi)
3    cmp   %rcx,(%rdi)
4    jne   _abort
5
```

(a) The compiler protects the store in Line 1 by inserting instruction in Lines 2 to 4.

```
1    mov   %rcx,(%rdi)
2    invd  // HV injected
3    clwb  (%rdi)
4    cmp   %rcx,(%rdi)
5    jne   _abort
6
```

(b) The injected `invd` in Line 2 effectively drops the current dirty cache line. However, the comparison with the original register value detects the fault attack.

```
1    mov   %rcx,(%rdi)
2    clwb  (%rdi)
3    invd  // HV injected
4    cmp   %rcx,(%rdi)
5    jne   _abort
6
```

(c) The injected `invd` in Line 3 is ineffective as the content is already written back to the main memory.

Figure 9: The compiler-generated code to protect a store instruction and the possible attack scenarios a malicious hypervisor could exploit in the AMD SEV threat model.

D OpenSSH Gadget

Listing 2 shows the exploited source code in the `OpenSSH` case study Section 6.2.

```
1  // Returns 1 if user authenticated 0 else
2  int sys_auth_passwd(struct ssh *ssh, const char *password) {
3    [...]
4    char *encrypted_password, *salt = NULL;
5    char *pw_password =  shadow_pw(pw);
6    [...]
7    if (authctxt->valid && pw_password[0] && pw_password[1])
8      salt = pw_password;
9    encrypted_password = xcrypt(password, salt);
10   return encrypted_password != NULL &&
11       strcmp(encrypted_password, pw_password) == 0;
12 }
```

Listing 2: Simplified source code of the `sys_auth_passwd` function from OpenSSH.

MOAT: Towards Safe BPF Kernel Extension

Abstract

The Linux kernel extensively uses the Berkeley Packet Filter (BPF) to allow user-written BPF applications to execute in the kernel space. The BPF employs a verifier to check the security of user-supplied BPF code statically. Recent attacks show that BPF programs can evade security checks and gain unauthorized access to kernel memory, indicating that the verification process is not flawless. In this paper, we present MOAT, a system that isolates potentially malicious BPF programs using Intel Memory Protection Keys (MPK). Enforcing BPF program isolation with MPK is not straightforward; MOAT is designed to alleviate technical obstacles, such as limited hardware keys and the need to protect a wide variety of BPF helper functions. We implement MOAT on Linux (ver. 6.1.38), and our evaluation shows that MOAT delivers low-cost isolation of BPF programs under mainstream use cases, such as isolating a BPF packet filter with only 3% throughput loss.

1 Introduction

It is common to extend kernel functionality by allowing user applications to download code into the kernel space. In 1993, the well-known Berkeley Packet Filter (BPF) was introduced for this purpose [7]. The classic BPF is an infrastructure that inspects network packets and decides whether to forward or discard them. With the introduction of its extended version (referred to as eBPF) in the Linux kernel, BPF soon became more powerful and is now utilized in numerous real-life scenarios, such as load balancing, system tracing, and system call filtering [24, 30, 37, 63, 71, 72].

To ensure security, BPF is equipped with a *verifier* [9]. The verifier performs a variety of static analyses to ensure the user-supplied code is secure. For instance, the verifier tracks the bounds of all pointers to prevent out-of-bound access. Given that BPF code runs directly within the kernel, the verifier becomes crucial for BPF security. Nevertheless, as pointed out by recent studies [32, 43, 44, 61, 69], the current verifier has various limitations and is insufficient for the overall security of BPF. First, the current BPF ecosystem supports a variety of functionalities, such as packet forwarding and kernel debugging [10, 31]. Supporting all these functionalities in the verifier results in a complicated verification process. Though the verifier has been partially verified via formal methods [68], the unverified part and the gap between abstraction and implementation still result in vulnerabilities [47–51, 53, 54, 56]. Second, due to the rapid expansion of BPF capabilities, the verifier is frequently updated, and it is inherently difficult to update a complex static verification tool without introducing new vulnerabilities [55]. To date, the BPF subsystem has been repeatedly exploited. For instance, two privilege-escalation vulnerabilities have been discovered in `bpf_ringbuf`, a recent BPF feature introduced in 2020 [7]. Further, the verifier's register-value tracking is quite complex and often bypassed via corner-case operations (e.g., sign extension) [47–50].

Given the increasing security threats in BPF and the challenge of enforcing safe BPF programs with merely static verification, we seek to employ hardware extensions to sandbox untrusted BPF programs. In particular, we leverage Intel Memory Protection Keys (MPK) [11], an emerging hardware extension that partitions memory into distinct permission groups by assigning up to 16 keys to their Page Table Entries (PTEs). With the aid of MPK, we present MOAT, which isolates untrusted BPF programs in a low-cost and principled manner. For instance, two MPK protection keys K and E can be assigned to the kernel and the BPF programs, respectively. When the kernel transfers control to a BPF program, it can set K as access-disabled to prevent the potentially malicious BPF program from tampering with kernel memory.

Despite its promising potential, using MPK to enforce BPF isolation is not straightforward. In designing MOAT, we faced and overcame *two major technical hurdles*. First, MPK provides a maximum of 16 keys. Thus, supporting numerous BPF programs with this limited number of keys is challenging. Existing workarounds like key virtualization [62] heavily rely on scheduling and notification mechanisms that are only available to user space; our tentative observation shows that

† Shuai Wang and Fengwei Zhang are the corresponding authors.

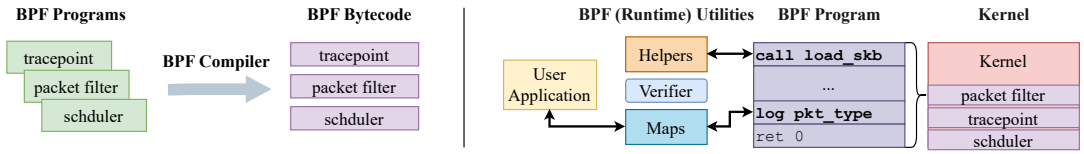

Figure 1: BPF overview. We illustrate the BPF compilation procedure and execution context of a sample BPF packet filter.

directly reusing them in the kernel may largely block kernel threads. To address this hurdle, we propose a novel two-layer isolation scheme to protect both the kernel and the benign BPF programs from malicious BPF programs. MOAT also utilizes a contemporary hardware feature named process context identifier to minimize the incurred overhead. Second, while MPK-based isolation mitigates malicious BPF programs, *helper functions* provided by the BPF subsystem may still be exploited by attackers. On the one hand, MOAT should allow benign BPF programs to use these helpers freely. On the other hand, MOAT must be cautious enough with these helpers to ensure that they are not abused. However, designing security policies for each of them requires non-trivial engineering effort and might result in a bloated codebase. To prevent abuse, we design two defense schemes that do not rely on the specific design of helper functions. We show that each of them applies to a wide range of helpers (see Appendix. C).

We systematically examine how MOAT mitigates the attack on the BPF ecosystem and the potential threats to MOAT itself. We also empirically analyze all recent CVEs within MOAT's application scope. The result shows that MOAT successfully mitigates each CVE. We evaluate the performance overhead brought by MOAT across a variety of micro and macro benchmark settings, and MOAT achieves low performance overhead across all settings. In particular, we evaluate MOAT with the common use cases of BPF in network applications, and the maximum performance penalty from MOAT is 3% among these cases. We also test MOAT's overhead on system tracing, another important BPF use case. On average, MOAT brings a performance loss of 5.5% in this setting. Furthermore, we evaluate MOAT's performance when using BPF for system call filtering [12]. In this case, the performance loss brought by MOAT is less than 3%. Thus, we conclude that MOAT's overhead is reasonably low, especially given its security benefits. In sum, we have made the following contributions.

- Instead of merely relying on the BPF verifier to statically validate BPF programs, this paper, for the first time, advocates isolating BPF programs with an emerging hardware extension, Intel MPK, effectively ensuring the memory safety of BPF programs.
- Technically, MOAT is properly designed to address domain-specific challenges, including limited hardware keys and preventing helper abuse in the BPF ecosystem. MOAT features a two-layer isolation scheme to protect both the kernel and the benign BPF programs from malicious BPF programs and incorporates various design considerations to deliver a security guarantee on memory safety at a low cost.
- We implemented a prototype of MOAT on Linux 6.1.38[1] and thoroughly evaluated its security over different attack scenarios (including all memory-relevant BPF CVEs in the past decade) and performance using various benchmark datasets. The evaluation shows that MOAT delivers a principled security warranty with minimum overhead.

2 Background

2.1 Berkeley Packet Filter (BPF)

BPF Overview. BPF [7] was originally introduced to facilitate flexible network packet filtering. Instead of inspecting packets in the user space, users can provide BPF instructions specifying packet filter rules, which are directly executed in the kernel. BPF allows configurable packet filtering without costly context switching and data copying. Modern Linux kernel features extended BPF (eBPF), a Linux subsystem which supports a wide range of use cases, such as kernel profiling, load balancing, and firewalls. Popular applications such as Docker [46], Katran [31], and kernel debugging utilities like Kprobes [10] utilize or are built directly on top of BPF.

Fig. 1 depicts an overview of how BPF programs are compiled and deployed. The BPF subsystem offers ten general-purpose 64-bit registers, a stack, BPF customized data structures (often called BPF maps), and a set of BPF helper functions. To use BPF (e.g., for system tracing), users first write their own BPF programs (in C code) to specify the functionality, which, in turn, are compiled into bytecode and loaded into the kernel. Given that BPF code is written by untrusted users, the kernel employs a verifier to conduct several checks during the bytecode loading stage (see below). By default, the verified bytecode is further compiled into native code by an in-kernel Just-In-Time (JIT) compiler for better performance. Additionally, on platforms without the JIT support, the bytecode is alternatively executed by the BPF interpreter. The BPF program is then attached to certain kernel components based on its specific end goal. For instance, as shown in Fig. 1, a BPF program attaches to the kernel as the packet filter, monitoring network traffic and sending statistics back to the user space via a BPF map.

BPF Verifier. BPF programs are written in C and compiled into a RISC-like instruction set. As aforementioned, the kernel

[1]We release the codebase of MOAT on our site [14]. We will maintain MOAT to benefit the community and follow-up research.

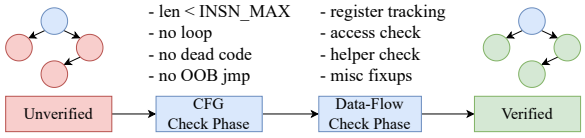

Figure 2: BPF verification process.

strictly verifies the BPF programs upon loading to ensure they are safe to execute. Fig. 2 illustrates the verification process in a holistic manner. First, a BPF program is parsed into a control flow graph (CFG) by the verifier, which performs a CFG check phase to ensure four key properties: 1) the program size is within a limit; 2) there are no back edges (loops) on its CFG; 3) there is no unreachable code; and 4) all jumps are direct jumps and refer to a valid destination.

The verifier then tracks the value flow of every register to deduce its value ranges conservatively. With these ranges, the verifier decides if a pointer accesses safe memory and if a parameter is valid. Since this analysis is performed statically, it is possible for a malicious BPF program to exploit a vulnerability to bypass it [47–51, 53, 54, 56].

BPF Helpers. The kernel also limits the functions a BPF program may call. Those functions are dubbed BPF helpers, as shown in Fig. 1. To date, there are over 200 helpers provided by the kernel [4]. Depending on the task, a BPF program can usually call a group of relevant helpers. For example, a BPF packet filter can call `skb_load` to read packet data, but is not allowed to call any helper related to system tracing.

BPF Maps. Out of security concern, the kernel also sets a strict space limit on BPF programs. Each program, by default, can only use up to 512 bytes of stack space and 10 registers, which is far from enough for certain BPF programs. To address this problem, BPF maps can be allocated to provide additional space for BPF programs. To date, there are over 30 types of maps supported by kernel [8]. Based on the isolation requirements, they can be roughly categorized into two types. The first type is maps that own a memory region. The most commonly used maps, hash maps and array maps, belong to this category. BPF programs use them to store data and communicate with user space. Therefore, a proper access permission has to be set for these maps (see MOAT's solution in Sec. 4.1). The second type holds references to other kernel resources (e.g., file descriptors). BPF programs are restricted to using helpers to interact with this type of map. Thus, MOAT forbids BPF programs from directly accessing them.

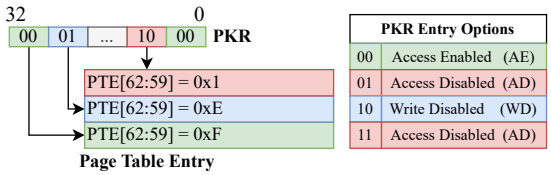

Figure 3: Intel MPK overview.

Classic BPF (cBPF). cBPF specializes in tasks like syscall filtering (e.g., `seccomp-BPF`) and has more restrictions than eBPF. We clarify that MOAT supports both of them. We also evaluate MOAT using `seccomp-BPF` with cBPF in Sec. 6.2.2. In this paper, we use BPF to refer to both cBPF and eBPF, as the kernel internally converts cBPF to eBPF.

2.2 Hardware Features in MOAT

Intel MPK. Intel introduced MPK [11] to provide efficient page table permissions control. By assigning an MPK protection key to the page table entries (PTEs) of one process, users can enable intra-process isolation and confidential data access control [23, 45, 62, 67]. As illustrated in Fig. 3, MPK uses four reserved bits `[62:59]` in each PTE to indicate which protection key is attached to this page. Those three PTEs in Fig. 3 are assigned with keys `0x1`, `0xE` and `0xF`, respectively. Since there are only 4 bits involved, the maximum number of keys is 16. Then, a new 32-bit register named Protection Key Register (PKR) is introduced to specify the access permission of these protection keys. Each key occupies two bits in PKR, whose values flag the access permission of the page. In Fig. 3, the access permissions of the three pages are `01` access-disabled (AD), `10` write-disabled (WD), and `00` access-enabled (AE), respectively. By writing to certain bits in PKR, the access permission of corresponding pages can be configured efficiently without having to modify the PTEs.

Clarification and Notations. There are actually two versions of MPK. One applies to the user space, while the other applies to the kernel space. For brevity, we refer to these two versions in their conventional abbreviations as Protection Key Supervisor (PKS) and Protection Key User (PKU), respectively. Most existing works [23, 34, 45, 62, 67] are based on PKU. In MOAT, we use PKS instead since our goal is to isolate in-kernel BPF programs. The logistics behind these two versions are mostly identical with slight variations. For instance, the permission configuration register in PKS is a Model Specific Register (MSR) named `IA32_PKRS`, which is inaccessible from user space, whereas in PKU, this role is assigned to a dedicated register `PKRU`. To avoid confusion, the rest of the paper refers to MPK leveraged by MOAT as PKS.

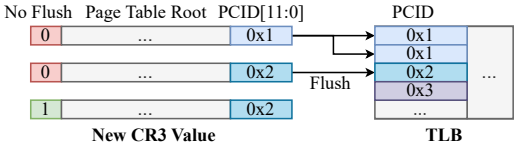

Figure 4: PCID overview.

Process Context Identifier (PCID). MOAT uses PCID to reduce the overhead of address-space switching (Sec. 4.2.2); we introduce PCID here. On the x86 platform, the CR3 register holds the page table root of the current process. Modifying the CR3 register causes a complete Translation Lookaside Buffer (TLB) flush and is therefore costly. Fortunately, Intel introduced PCID to address this issue. As shown in Fig. 4, the lower 12 bits `[11:0]` of CR3 register are PCID, identify-

ing the owner of the page table, while the highest bit of the new CR3 value controls the flushing behavior of TLB. If the highest bit is 1, this modification does not flush TLB at all; if the highest bit is 0, then this modification only flushes the TLB entries of the PCID in this new CR3 value. This feature enables fast address-space switch without costly TLB flush. Since there are only 12 reserved bits for PCID, it supports up to 4096 different processes with isolated TLB entries.

3 Motivation and Threat Model

3.1 Motivation

In this section, we discuss the typical threats to the BPF verifier, the restriction on unprivileged BPF brought by these threats, and lastly, the motivation for our research.

Fast Feature Evolving. As a fast-developing technology, threats may come from the inconsistency between the constantly expanding BPF capabilities and the rigorous static verification process imposed on them [51, 55]. It is a common practice to add corresponding verification procedures simultaneously when introducing new features to BPF programs. However, it is difficult to implement a verifier that supports all these features yet still does not miss any edge case, which already has over 10K LoC with various functionalities [9].

Challenging Register-value Tracking. Second type of threats originates from the complexity of the register-value tracking. Although the soundness of such a tracking mechanism is formally proved [68], there exist gaps between the actual implementation and abstraction of the register-value tracking, especially in some corner cases, such as sign extension, truncation, and bit operators [47–51, 53, 54, 56].

Unprivileged BPF. BPF was originally designed as a restricted interface for *unprivileged* users to extend kernel functionality. It comes with a fine-grained privilege system [6] that allows users to tune a specific part of the kernel without root. However, numerous vulnerabilities [47–50] indicate that the verifier is not reliable, and consequently, major distributions have banned unprivileged users from loading BPF programs [38, 65]. Despite this, there is still a long-lasting desire for unprivileged BPF in the community. For example, the `seccomp-BPF` users have been asking for unprivileged BPF support for a long time [5].[2] Moreover, there have been continuous efforts (from 2016 to 2023) in the community to re-emerge unprivileged BPF again [1, 3, 13]. Unfortunately, these efforts fail as they only focus on enhancing the verifier itself, which is already over-complicated and error-prone.

Motivation. Overall, seeing BPF's potential and its current restriction, we propose MOAT as an isolation scheme complementary to the BPF verifier. On the one hand, this isolation scheme shall make BPF more accessible to unprivileged users whilst maintaining security. On the other hand, even for privileged users, MOAT provides the security guarantee that the BPF programs obtained from a potentially untrusted source are isolated from the kernel. Overall, we aim to provide a more secure and accessible BPF ecosystem, thereby promoting its development and adoption in the community.

[2] We clarify that `seccomp` already supports classic-BPF (cBPF), which lacks expressiveness and no longer updates [2]. BPF here refers to eBPF.

3.2 Threat Model

Our threat model considers a practical setting that is aligned with existing BPF vulnerabilities [47–51, 53, 54, 56]. Attackers can load their prepared BPF code into the kernel space to launch exploitation. In particular, we assume attackers are *non-privileged users* with BPF access since a root user already has control over almost the entire kernel. MOAT isolates user-submitted BPF programs and prevents them from accessing kernel memory regions. As will be introduced in Sec. 4, a BPF program is given only the necessary resources and privileges to complete its task. We present the threat models of major components in our research context as follows.

BPF Programs. We assume that malicious BPF programs are able to bypass checks statically performed by the verifier; they may thus behave maliciously during runtime. Our threat model deems BPF programs as *untrusted*.

BPF Helper Functions. These helpers act as the intermediate layer between the BPF subsystem and kernel. Certain malicious BPF programs can abuse these helpers to perform attacks, and therefore, we assume they are also *untrusted*. MOAT mitigates risks raised by adversarial-manipulated helper functions with practical defenses.

Out of Scope. The main objective of MOAT is to mitigate memory exploitation performed by BPF programs. Other subtle attacks (not relevant to memory exploits), such as speculation, race condition, and Denial of Service (DoS) toward the BPF subsystem [57, 58] are not considered. They do not specifically exist in BPF [22, 26], and are addressed by relevant research [21, 29]. We thus treat them as orthogonal. Also, BPF subsystem comes with a set of user-space facilities such as `libbpf`; bugs in them are not considered by MOAT. Note that MOAT mitigates information leakage that is due to out-of-bounds memory access; if the leakage is due to issues like speculation [58], then it is out of the scope of MOAT.

We clarify that MOAT focuses on the kernel memory exploitation via BPF, its most prevalent threat. The vulnerabilities mitigated by MOAT typically receive high threat scores in vulnerability databases [47–51, 53–56] with public PoC exploits [66], whereas above-precluded vulnerabilities often lack exploits [27].

4 Design

MOAT Overview. As described in Sec. 3.1, the current security design against malicious BPF programs solely relies on the static analysis performed by the BPF verifier, which

is seen as a weak point and exploitable by non-privileged users. MOAT instead delivers a principled isolation of BPF programs from the rest part of the kernel using PKS and prevents bypasses.

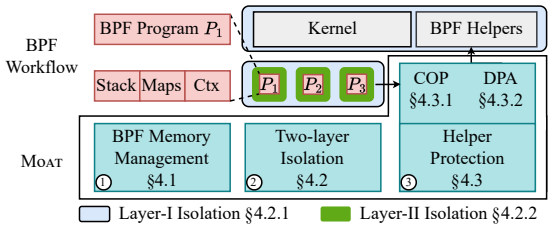

Figure 5: MOAT overview.

Fig. 5 depicts an overview of MOAT and how it is integrated into the workflow of BPF programs. ① Given a user-submitted BPF program *P*, MOAT statically allocates the necessary memory regions the program needs, such as stack, maps, and context based on *P*'s metadata (Sec. 4.1). ② When the kernel invokes *P*, MOAT isolates *P* from the kernel using PKS (Layer-I in Sec. 4.2.1), and constrains *P* in its isolated address space (Layer-II in Sec. 4.2.2). ③ On the occasions that *P* calls helpers, depending on the helper types, MOAT adjusts the involved memory region permissions (Sec. 4.3.1) and validates the helper parameters (Sec. 4.3.2) to prevent the helpers from being abused.

4.1 BPF Memory Management in MOAT

Further to the overview in Fig. 5, we introduce how MOAT manages the BPF memory. The BPF memory refers to the memory regions a BPF program needs to function properly, including descriptor tables, stacks, maps, and runtime context.

Descriptor Tables. On x86 platforms, Global Descriptor Table (GDT) and Interrupt Descriptor Table (IDT) are essential for basic operations like interrupt. These structures are assigned to a shared region that all BPF programs can access. To prevent tampering, they are made read-only when shared.

Stack. BPF programs use a 512-byte stack space to store local variables and function frames. The verifier determines if a program makes out-of-bounds access toward the stack. Thus, if the BPF program passes the static checks, its stack is directly allocated from the kernel stack. However, as discussed in Sec. 3.1, certain vulnerabilities may allow BPF programs to bypass this check. Thus, MOAT needs to allocate the stack as a part of BPF memory and swap stacks to prevent the BPF programs from tampering with the kernel stack.

Maps. As described in Sec. 2.1, maps are utilized by BPF programs to store data and communicate with the user space. Linux provides a set of helper functions for BPF programs to interact with maps. For example, `bpf_map_look_up_elem` returns the pointer of an element so that the program can modify its value. This means that BPF programs must have access to these elements' memory. Thus, MOAT allocates these maps as a part of BPF memory. Note that we do not allocate the metadata of these maps inside BPF memory since they contain exploitable structures like function pointers.

Runtime Context. The context refers to BPF program parameters, which vary depending on the BPF program types. We investigated the BPF contexts of common BPF program types and summarized our findings in Table 1. Most of these contexts are local objects on the kernel stack and are passed to BPF programs as parameters, such as `bpf_cgroup_dev_ctx`. For this type of BPF context, MOAT allocates them on the BPF stack instead so that the BPF programs can still access them without the permission to access the kernel stack. However, there also exist contexts that are not local objects on the stack but persistent kernel structures. For example, `sk_buff` holds the network packet received by a socket and is also passed to BPF socket filter programs as context. For this type of persistent context (denoted in the fourth column of Table 1), MOAT dynamically maps the physical page of the corresponding context into the BPF memory. The reason why we choose to map instead of creating a local copy is that `sk_buff` is typically hundreds of bytes. Our preliminary experiment shows that syncing between the local copy and the actual kernel object brings non-trivial overheads. Furthermore, network-related BPF contexts (e.g., `bpf_sock_ops`) may contain nested pointers to other kernel structures (denoted in the fifth column of Table 1). Including only these pointers in BPF memory triggers a false alarm, as these nested structures are not included. We clarify that BPF programs only access limited fields of these nested structures. Thus, MOAT reserves a part of BPF memory to mirror these nested fields efficiently so that they can be accessed by the BPF programs.

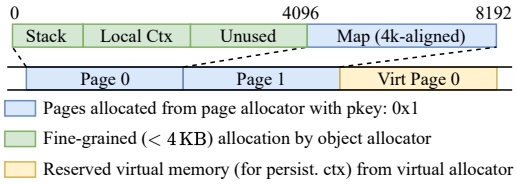

Figure 6: BPF memory allocators.

BPF Memory Allocators. As shown in Fig. 6, MOAT provides three types of allocators to manage these BPF memory regions. When loading a BPF program, the page allocator first allocates physical pages (Page 1) for its BPF memory; these pages are given the protection key `0x1` and become a part of its BPF memory. The object allocator handles fine-grained allocations from the allocated pages (Page 0) that are less than the page size (4 KB), e.g., the BPF stacks (512 bytes). Lastly, the virtual allocator controls the virtual memory that is not backed with concrete physical pages. For instance, it reserves a part of virtual BPF memory (Virt Page 0) to map persistent BPF contexts (e.g., `sk_buff`). Note that we also modify the implementation of BPF maps to use MOAT's allocator.

Table 1: BPF context of common program types.

Category	Program Type	Context Type	Persistent	Nested	Note
Network	Socket Filter	`sk_buff *`	Yes	Yes	Socket packet buffer
	Socket Ops	`bpf_sock_ops *`	No	Yes	Socket events (timeout, retransmission, ...)
	Socket Lookup	`bpf_sk_lookup *`	No	Yes	Packet information for socket lookup
	XDP	`xdp_md *`	No	Yes	Metadata of `xdp_buff`
Tracing	Kprobe	`pt_regs *`	No	No	Register status on probed location
	Tracepoints	Depending on tracepoint types	No	No	Relevant tracepoint information
	Perf Event	`bpf_perf_event_data *`	No	No	Perf. event (register status, sample period)
Cgroup	Cgroup Socket Filter	`sk_buff *`	Yes	Yes	Socket packet buffer under specific cgroup
	Cgroup Device	`bpf_cgroup_dev_ctx *`	No	No	Device ID, access type (read, write)

4.2 Two-layer Isolation

Challenge. In theory, we can assign each BPF program with a unique key to achieve low-cost BPF isolation. However, PKS only supports up to 16 regions (i.e., keys). If we assign each BPF program with a unique key, these keys would soon be exhausted as there could be over 16 BPF programs in the kernel. It is challenging to isolate an unlimited number of BPF programs with only 16 protection keys.

Solution. We propose a novel two-layer isolation scheme using PKS and isolated address spaces. Though isolating address spaces is less efficient than PKS, we manage to reduce its overhead to a minimum using a contemporary hardware feature named PCID; We use PCID as a complement to PKS to support the isolation of numerous BPF programs.

4.2.1 Layer-I: Lightweight Isolation Domain via PKS

The main objective of MOAT is to isolate the kernel from malicious BPF programs. Thus, we use PKS as a lightweight isolation primitive between kernel and BPF programs. Specifically, we use PKS to build three isolated domains: the BPF domain, the kernel domain, and the shared domain.

As depicted in Fig. 7, all BPF programs reside in the BPF domain with the protection key `0x1`. MOAT grants a BPF program access (i.e., access-enabled; AE) to the BPF domain (`0x1`) when executing the program by setting its PKR bits to `00` (flagging AE). The kernel domain holds all kernel pages with the protection key `0x0` and is only accessible by the kernel itself. When entering a BPF program, this kernel domain (`0x0`) becomes access-disabled (AD) by setting its PKR bits to `01` (flagging AD). However, the shared domain (`0x2`) comprises memory regions like IDT and GDT. These regions are crucial for low-level routines like interrupts. Thus, they are made write-disabled (WD) instead of access-disabled for BPF programs by setting the PKR bits to `10` (flagging WD).

This domain design only needs three (out of 16) keys from PKS yet effectively mitigates malicious BPF programs targeting the kernel. For these malicious programs, a modus operandi is to introduce an unsanitized kernel pointer by exploiting a verifier vulnerability. Then, the malicious BPF program arbitrarily tampers the kernel using that pointer, leading to a full-blown exploitation. Isolating BPF programs from the kernel effectively stops such attacks, as all malicious kernel access directly from BPF programs is prevented by PKS.

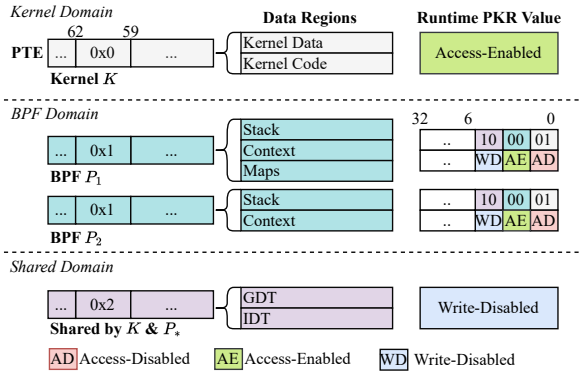

Figure 7: PKS-enforced domains of MOAT.

4.2.2 Layer-II: Isolated BPF Address Space

In Sec. 4.2.1, we have discussed how MOAT prevents BPF attacks targeting the kernel. However, MOAT only uses PKS to build isolation between the kernel and BPF programs. All BPF programs still share the same PKS domain, allowing a malicious BPF program to tamper with the memory of benign BPF programs. Inspired by prior works in user-space isolation [70], we set up an isolated address space for each BPF program to prevent such tampering. Consequently, when a malicious BPF program tries to access the memory regions of another BPF program, a page fault occurs, and the malicious BPF program is immediately terminated.

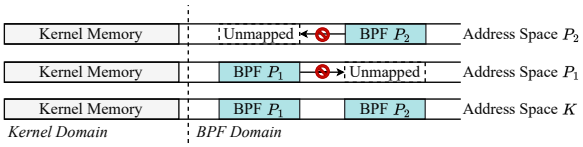

Figure 8: Isolated address spaces of BPF programs.

Fig. 8 illustrates the isolated address spaces of two BPF programs, P_1 and P_2. In the address space of P_1, the mapping of P_2 does not exist. Similarly, the mapping of P_1 does not exist in the address space of P_2 either. This effectively prevents BPF programs from accessing each other and addresses the abovementioned issue. To avoid the high TLB flush overhead (and TLB misses) from the address-space switching, we use PCID to keep the TLB entries from different BPF programs isolated. Since BPF programs are usually smaller than user applications, MOAT allocates a non-overlapped virtual address space with a unique PCID for each of them. In the rare cases where over 4,096 BPF programs are running in the

same kernel, MOAT has to flush the TLB when two BPF programs (with the same PCID) run consecutively. Since there are 4,096 PCIDs available, we expect such conflicts to be rare, especially considering that the kernel also periodically flushes TLB, thus clearing the conflicting entries. Even when such cases occur, MOAT only flushes the TLB entries of the conflicting PCID and leaves other TLB entries intact.

Why Intra-BPF Isolation. One may question the necessity for the isolation between BPF programs, as most existing BPF exploits target the kernel. However, since BPF maps are the only bridge between the BPF programs and the user space, the configurations of a BPF program have to be saved in its maps so that users can change its behavior without reloading it. This paradigm makes cross-BPF attack a noticeable threat [17]. For example, an attacker may load a malicious BPF program to change the behavior of another program by tampering with its configuration maps, disrupting resources accounting, or even nullifying security checks. Intra-BPF isolation is essential for preventing such attacks.

4.3 Helper Security Mechanism

As mentioned in Sec. 2.1, the kernel provides a set of helper functions for BPF programs. As these helpers act as the interfaces between the kernel and BPF programs, they can also be abused by malicious programs to launch attacks. MOAT needs to protect the helpers from such abuse.

Our investigation of existing BPF vulnerabilities shows that the malicious BPF programs typically abuse the BPF helpers in two ways: ① the helper contains a defect, which is exploited by the malicious programs [52]; ② the helper itself is correct, but the malicious programs pass invalid parameters to abuse it [55]. For ①, a typical case is that the helper itself contains defects such as heap overflow. These defects are leveraged by malicious programs to overwrite the sensitive fields (e.g., function pointers) of BPF-related kernel objects. For ②, since the helper by itself is correct, the malicious programs are typically restricted to leaking kernel pointers (by passing invalid parameters) and cannot conduct full-blown exploitation. Notably, in most cases, since the helper parameters are checked by the BPF verifier, the malicious programs still need to leverage the register-value-tracking vulnerabilities in the verifier (Sec. 3.1) to bypass this check [47–51, 53, 54, 56].

Challenge. However, protecting these BPF helpers is not trivial. First, the BPF helpers, by design, need to access BPF-related objects in the kernel memory; blindly isolating helpers using PKS leads to spurious alarms and impedes benign programs. Second, there are over 200 BPF helpers in the kernel, so MOAT's design must be generic enough to apply to most of these helpers (see Appendix. C for the supported helpers).

Design Consideration and Solution. To prevent such abuse, we aim to identify and guard sensitive BPF-related objects (instead of all BPF-related objects) from the defective BPF helpers. Besides directly protecting sensitive objects, since the attackers need to deliver malformed parameters to conduct helper abuse, we also wish to ensure the validity of the helper parameters at runtime. To this end, we designed the following two defense schemes: Critical Object Protection (COP) and Dynamic Parameter Auditing (DPA). COP protects sensitive BPF-related objects from being tampered with, while DPA dynamically checks if the arguments of the helpers are within legitimate ranges. To clarify, COP and DPA should be enabled together to deliver protection. DPA only constrains the arguments to their expected ranges. This stops most exploitation attempts [47–51] but may not ward them off completely in the presence of a buggy helper [52]; COP, in this case, prevents the buggy helper from accessing sensitive objects.

4.3.1 Critical Object Protection (COP)

Although BPF helpers have to access BPF-related kernel objects to complete their tasks, the sensitive BPF-related objects should still not be accessed by any helper. For example, `array_map_ops` is a function pointer in the BPF array maps that should *only* be accessed from system calls. However, `array_map_ops` is close to other helper-needed objects in the address space, making it a potential victim of the abused helpers. Based on this, we designed the COP scheme. As shown in Fig. 9, instead of treating the entire kernel domain as a whole, we divide it into a normal domain and a critical-object domain. Permissions of these critical objects are managed via an extra page and protection key. When entering helper functions, instead of setting the entire kernel space as access-enabled (AE), those critical objects remain access-disabled (AD), preventing the helpers from accessing them. To identify these objects, we first review BPF CVEs and find all objects that have been exploited. Then, we manually search for similar objects in the kernel and check that these found objects indeed contain sensitive fields (e.g., function pointers). It took two authors about half a month to conduct the above procedure individually and cross-check results, which ensures the credibility of our research to a great extent. We identified a total of 44 critical objects (see Appendix A); these objects could either leak the sensitive base address of the kernel (e.g., `iter_seq_info`) or even be tampered with to launch a full-blown exploit (e.g., `array_map_ops`). In addition to these 44 identified objects, we set MOAT itself and `cred` as critical objects. The former contains sensitive data of MOAT (e.g., the saved state of `IA32_PKRS`), while the latter tracks the privilege of a process. We believe protecting the identified critical objects provides a practical security guarantee for the BPF helpers. Nonetheless, unidentified critical objects could exist; we will discuss their potential threat in Sec. 8. Moreover, it is always feasible to extend COP to protect other kernel objects.

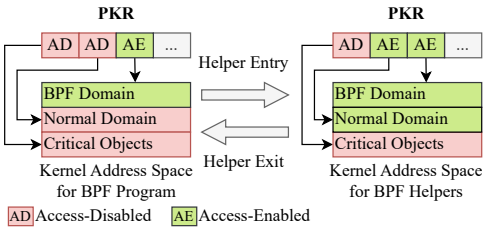

Figure 9: Critical object protection (COP).

4.3.2 Dynamic Parameter Auditing (DPA)

To further regulate the helpers, we propose Dynamic Parameter Auditing (DPA), which leverages the information obtained from the BPF verifier to dynamically check if the parameters are within their legitimate ranges. As illustrated in Fig. 10, the verifier can deduce the value range of each register via static analysis (aligned with the uncovered verifier inaccuracies [49, 53]; our DPA design tolerates even *invalidly* deduced value ranges; see clarification below). MOAT logs such value ranges and instruments the BPF programs to insert checks before helper calls. During runtime, these checks ensure that the provided parameters of the helpers are within the verifier-deduced value ranges during runtime. In our example, we can check if `r0==0x10; r1==0x11` when `BPF_HELPER` is called. If the parameter runtime values do not match with the static analysis results, the BPF program is terminated immediately.

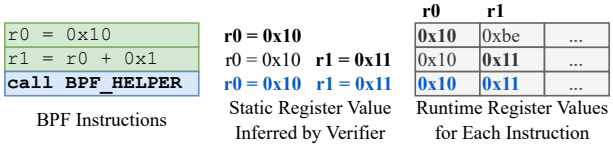

Figure 10: Register value tracking of the verifier.

Clarification. In this DPA strategy, one may wonder if the "value ranges" deduced by the verifier are wrong [49, 53]. To clarify this, we list possible cases of a BPF variable v's value range and the corresponding system states in Table 2; our discussions are as follows.

Table 2: Four cases of a BPF variable v's value ranges. R denotes the runtime value of v, D denotes the verifier's deduced value of v, E denotes verifier's *expected* legitimate value range of v, while T denotes the *ground truth* legitimate value range of v. The last column denotes this case is safe (✓), mitigated by verifier ($✓_V$), mitigated by MOAT ($✓_M$), or unsafe (✗)

	R	D	E	T	State
1	0x10	0x10	[0,0x20]	[0,0x20]	✓
2	**0xba**	0xba	[0,0x20]	[0,0x20]	$✓_V$
3	**0xba**	**0x10**	[0,0x20]	[0,0x20]	$✓_M$
4	**0xba**	**0xba**	**[0,0xba]**	[0,0x20]	✗

Case 1 illustrates the value range of a variable v in a benign BPF program. The runtime value aligns with verifier's deduction which further falls within the *expected* and *true* legitimate value ranges simultaneously ($R = D \in E = T$, see the caption of Table 2). Case 2 demonstrates the value range of variable v in a malformed BPF program. The runtime value `0xba` is out-of-bounds, and this invalid value is detected by the verifier through static analysis. Therefore, this program is rejected by the verifier, and the system remains safe ($R = D \notin E = T$). Case 3 shows the value range of v in a malicious BPF program. The runtime value `0xba` is out-of-bounds. However, due to the incomplete analysis caused by vulnerabilities, the verifier deduces that v's value is `0x10`, which is within the verifier's expectation. Since DPA operates in the runtime and checks whether the runtime value actually matches the verifier's deduction, this mismatch is then detected by DPA, and this malicious BPF program is terminated ($R \neq D \in E = T$).

While the above three cases cannot be exploited, Case 4 implies a scenario where DPA fails and the helper is abused. The verifier's *expected* value range differs from the *ground truth*, legitimate value range. This discrepancy allows an out-of-bounds value `0xba` to be passed as an argument to a helper for exploitation. For this to occur, the following conditions must be satisfied simultaneously: ① The verifier has an *incorrect* expectation (i.e., $E \neq T$). ② The incorrect expectation E is *unsafe* (i.e., $T - E$ overlaps an exploitable structure). ③ The BPF program is carefully tweaked to be aligned with D and evade DPA (i.e., $R = D$). For BPF programs, It is usually straightforward for the verifier to obtain E statically (e.g., E encodes the array size). It is thus hard to satisfy ① and ② simultaneously. For today's known BPF exploits (all of which fall into Case 3), the verifier has the correct expectation $E = T$ but makes the incomplete deduction $R \neq D$; therefore, the discrepancy $E \neq T$ is never encountered in practice.

4.4 Design Comparison

In this section, we compare MOAT's design with other works in kernel isolation. This helps highlight the contribution of MOAT, in comparison to previous research.

Virtualization. There is a line of research works on isolating kernel components via virtualization [16, 59, 60]. However, among these prior works, lightweight solutions like SKEE [16] are not compatible with the low-level routines (e.g., interrupt) in Linux. SKEE disables the interrupt upon entry, but disabling the interrupt will significantly impede BPF's network performance. To incorporate with low-level routines in the kernel, non-trivial modification to the system is often needed. For example, LVD and LXDs [59, 60] require a hypervisor and an implanted micro-kernel to manage the isolated components. MOAT, on the one hand, leverages PKS to enforce lightweight isolation between kernel and BPF; this ensures efficient interrupt handling. On the other hand, MOAT re-uses the kernel memory subsystem to enforce intra-BPF isolation without the additional hypervisor or micro-kernel.

SFI-based Solutions. Prior works also proposed Software Fault Injection (SFI) for kernel security [20, 41]. SFI inserts checks before memory access to ensure that they fall into valid ranges. However, inserting checks for memory access often brings higher overheads (see Sec. 6.3 for an empirical

comparison with MOAT). MOAT uses PKS to ensure memory safety and only inserts checks before helpers. Since the number of helper calls is much smaller than that of memory access, this design largely reduces the overhead of MOAT.

5 Implementation

MOAT is implemented on Linux 6.1.38, and consists of 2,911 lines of C code. We explain the key points below.

Kernel Interrupt Handling. MOAT has to cooperate with many low-level routines inside the kernel. For instance, during the execution of BPF programs, an interrupt may occur and take over the control flow to its handler. Note that most interrupt handlers require access to kernel memory, and as a result, the PKS would presumably raise spurious alerts. Thus, we need to temporarily disable PKS inside these handlers and re-enable it once the handlers finish. To avoid the overhead when there is no BPF program, we use a per-CPU variable `in_bpf` to identify whether the processor is executing a BPF program. Since BPF programs only occupy a tiny fraction of kernel execution time, we observe little performance loss due to this, even under cases where interrupt frequently occurs (e.g., intensive network activity in Sec. 6.2.2).

Granularity of PKS. As protection keys are associated with PTEs, MOAT only protects memory in the granularity of a page (i.e., 4 KB). However, the objects used by BPF programs may not be aligned to 4 KB, which means they could interleave with critical kernel structures. Therefore, granting BPF programs access to these objects also enables access to those kernel structures and leads to exploitation. To prevent this, we have modified BPF-related objects (e.g., maps) so that they are page-aligned and not interleaved with other structures.

DPA Check Generation. To deploy DPA from Sec. 4.3.2, we modify the BPF JIT compiler (`bpf_jit_comp.c` with about 2500 LoC) to instrument BPF programs. As shown in Fig. 11, our modified JIT compiler receives a set of expected ranges from the verifier. Then, for each parameter, the JIT compiler emits assembly instructions to check whether the parameter is within the expected range. If not, we terminate the program (`bad` label in Fig. 11). This prevents malicious programs from passing invalid parameters to abuse BPF helpers.

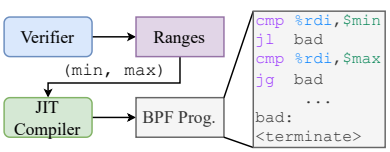

Figure 11: DPA Check Generation.

6 Evaluation

To evaluate MOAT, we first analyze how MOAT mitigates various attack interfaces and then benchmark its CVE detectability in Sec. 6.1. We then assess the performance of MOAT under different BPF program setups in Sec. 6.2.

6.1 Security Evaluation

6.1.1 Analysis of Attack Mitigation

We systematically analyze how MOAT mitigates the representative attacks on the BPF ecosystem as well as the potential threats to MOAT itself. Our analyses are illustrated in Fig. 12.

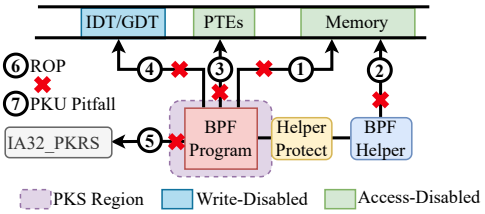

Figure 12: Analysis of attack mitigation.

① Arbitrary Kernel Access. Currently, the most prevalent threat to the BPF ecosystem is the ability of malicious BPF programs to arbitrarily modify kernel memory. In order to accomplish this, these BPF programs typically employ corner-case operations to deceive the verifier during the loading phase and to behave maliciously during runtime. This type of attack is effectively mitigated due to the fact that MOAT derives the necessary memory regions of each BPF program and uses PKS to prevent any runtime access beyond this region (Sec. 4.2), mitigating such illegal access.

② Helper Function Abuse. Apart from launching an attack directly from BPF programs, a malicious BPF program may carefully prepare parameter values and pass them to abuse certain helpers. To prevent such abuse, MOAT deploys security enforcement schemes (Sec. 4.3) to dynamically audit helper parameters and also protect critical kernel kernel objects during the execution of these helpers. Thus, the attacker can no longer take advantage of these helpers.

③ PTE Corruption. A page's PKS region is configured via its PTE. Consequently, a malicious BPF program may attempt to tamper with the PTEs to disable MOAT. However, this is impossible since MOAT sets these PTEs as access-disabled; they are thus protected by PKS like other kernel resources.

④ Descriptor Table Tampering. Descriptor tables like GDT and IDT are essential for segmentation and interrupt handling. Therefore, blindly setting them as access-disabled would cause system crashes. However, since these descriptor tables are only accessed in a read-only manner, MOAT sets them as write-disabled, thus preventing malicious BPF programs from using them to compromise the kernel.

⑤ Hardware Configuration Tampering. Besides memory-based attacks, attackers may also directly disable PKS through hardware configurations. As described in Sec. 2.2, `IA32_PKRS` is a critical register for configuring PKS. One may disable PKS by modifying `IA32_PKRS`. However, this register can only be modified via special instructions, and

BPF instruction sets do not include any of these. Thus, a BPF program with these instructions is rejected immediately. Since the BPF programs are set to $W \oplus X$ (meaning write and executable permissions are not simultaneously enabled), adding these instructions via self-modification is also impossible.

⑥ **Return-Oriented Programming.** Two properties of the BPF instruction set prevent potential control-flow hijacking attacks like return-oriented programming (ROP). First, BPF only supports jump instructions with *constant and instruction-level* offsets. This means the destinations of jumps are trivially known during the compile time, and there are no *unintended ROP gadgets* (jumps between instructions) like x86 [19]. Secondly, as a specialized instruction set, BPF does not include any instructions that may modify hardware configurations such as `XRSTOR` and `WRMSR`. These two properties allow MOAT to reliably detect invalid instructions and prevent BPF programs from tampering with hardware settings.

⑦ **Attacks in PKU Pitfalls.** We carefully examined attacks mentioned in PKU Pitfalls [25], which focus on breaking PKU, the user variant of MPK. Their noted attacks can be roughly categorized into three types. The first type manipulates memory mappings through certain system calls (e.g., `mremap`) to subvert PKU, such as modifying user-space PTEs and creating mutable backup. However, BPF programs are incapable of launching such attacks, as there is no helper that can manipulate kernel memory mappings. The second type involves tampering with the saved state of `PKRU` and disabling PKU entirely upon restoration. Unlike PKU, MOAT exclusively manages the saved state of `IA32_PKRS`, making these attacks infeasible. The third type relies on mechanisms that are exclusive to the user space (e.g., using `seccomp` to intercept system calls) and is not applicable to MOAT.

6.1.2 Real-world CVE Evaluation

We surveyed the BPF CVEs in the past ten years. A total of 26 CVEs are memory exploits (Appendix. B) and thus fall within the scope of MOAT. We tested MOAT's effectiveness on all of these CVEs. For CVEs with publicly available PoC, we ported and ran the PoC on MOAT-enabled kernel. For CVEs without PoC, we studied the fixes and ensure that MOAT mitigates them. In sum, we report that MOAT successfully mitigates *all* of them. We now present the following case studies.

CVE Case Study. To better explain how MOAT mitigates these CVEs, we elaborate on the exploit paths for three of them, 2022-23222, 2020-27194, and 2021-34866.

CVE-2022-23222 is a pointer mischeck vulnerability introduced via a rather new BPF feature, `bpf_ringbuf`. This new feature was brought to BPF in 2020, along with a new pointer type named `PTR_TO_MEM_OR_NULL`. However, the verifier had not been updated to track the bounds of this new type, resulting in this vulnerability. As shown in Fig. 13a, the malicious payload first retrieves a `nullptr` via `ringbuf_reserve` (line 1), which returns this newly added pointer type named `PTR_TO_MEM_OR_NULL`. Since this new type is not tracked by the verifier, the payload can bypass pointer checks by tricking the verifier that `r1` is `0x0` when it is `0x1` (line 3). `r1` can then be multiplied with any offset to perform arbitrary kernel access (line 6). However, such access violates PKS and is terminated by MOAT (line 7).

CVE-2020-27194 is a vulnerability due to incorrect truncation. As in Fig. 13b, the user first inputs an arbitrary value in the range of `[0,0x600000001]` (line 1). Then, the conditional clause helps the verifier to determine its value range (line 3). However, when tracking the `BPF_OR` operator, the verifier performs a wrong truncation on its upper bound. After the truncation, the user-controlled `r5` is viewed by the verifier as a legitimate constant `0x1` (line 5), which is later used as the offset to perform arbitrary access to the kernel (line 6). Similarly, such access is stopped by MOAT.

CVE-2021-34866 is a helper-abuse vulnerability. As shown in Fig. 13c, the malicious payload tries to pass an invalid map to the `ringbuf_reserve` to cause heap overflow (line 3). However, since the runtime value of `r5` does not match the argument of `ringbuf_reserve`, DPA prevents such a mismatched helper call (line 2). Moreover, supposing that the DPA is not enabled, and the helper tries to tamper with exploitable kernel objects (e.g., `array_map_ops`). COP protects these objects and thus prevents the helper from accessing them (line 3). Lastly, even if neither COP nor DPA is enabled, and the abused helper manages to return a leaked kernel pointer, accessing the leaked pointer violates PKS, and the malicious program is terminated by MOAT (line 4).

```
1 r0 = ringbuf_reserve(fd, INT_MAX, 0)
2 r1 = r0 + 1              // R:r0=0;r1=1 V:r0=r1=?
3 if (r0 != nullptr)       // R:r0=0;r1=1 V:r0=r1=?
4  exit(1)
5 off = <bad off>       // R:r0=0;r1=1 V:r0=r1=0
6 off = off * r1        // R:off=<bad off> V:off=0
7 *(ptr+off) = 0xbad    // PKS violation
```

(a) Code snippet of CVE-2022-23222

```
1 r5 = <bad addr>
2 r6 = 0x600000002
3 if (r5>=r6||r5<=0) // R&V:0x1<=r5<=0x600000001
4  exit(1)
5 r5 = r5 | 0       // R:r5=<bad addr> V: r5=0x1
6 *(ptr+r5)=0xbad   // PKS violation
```

(b) Code snippet of CVE-2020-27194

```
1 r5 = <bad map fd>
2 <DPA checks>                      // DPA violation
3 r0=ringbuf_reserve(r5,INT_MAX,0)// COP-guarded
4 *(r0+ptr_off) = 0xbad             // PKS violation
```

(c) Code snippet of CVE-2021-34866

Figure 13: CVE case study. `R` denotes variable runtime statuses. `V` denotes verifier-deduced values of variables.

6.2 Performance Evaluation

Evaluation Setup. We assess MOAT performance on Linux v6.1.38 and a 5-core Intel 8505 processor with PKS support. To reduce variance, hyper-threading, turbo-boost, and frequency scaling are disabled. All evaluated BPF programs are executed in the JIT mode, given that BPF JIT is enabled by default on all supported platforms. Moreover, both COP and DPA (Sec. 4.3) are enabled; COP is configured to protect the critical objects identified in Sec. 4.3.1. We manually inspected the CPU utilization to ensure it is close to 100%, and that the overhead is not hidden by the increased CPU load.

6.2.1 Micro Benchmark

For the micro benchmark, we measure the CPU cycles of four key operations in MOAT. We list the four operations in Table 3. `set_pkrs` changes region permissions by changing `IA32_PKRS` via `WRMSR`. `get_pkrs` returns the current permission configuration by reading `IA32_PKRS` via `RDMSR`. `bpf_{entry/exit}` is the total cost of entering/exiting a BPF program, which includes operations like swapping stack, managing BPF context, and configuring region permissions with `set_pkrs`. `dpa_check_args` is the cost of checking helper parameters. Each operation is measured by averaging ten runs of one million invocations to eliminate randomness. Since Intel has introduced the concept of "performance core" and "efficient core", we measure their cycles independently.

As shown in Table 3, the overall switching cost of MOAT is less than 200 cycles, which is negligible for most BPF programs (see Sec. 6.2.2 for details). Notably, setting and getting the region permissions (`set_pkrs`/`get_pkrs`) in PKS is more expensive than its user-space variant in `libmpk` [62] (see the caption of Table 3). We presume that this is because, in PKU, the region permission is controlled via a dedicated register named `PKRU` with two special instructions `RDPKRU`/`WRPKRU`, whereas in PKS employed by MOAT, its region permission is stored in an MSR named `IA32_PKRS` without any special instruction. To configure the permission in `IA32_PKRS`, one has to use the `RDMSR`/`WRMSR` instructions with the MSR ID `0x6E1`. Moreover, although the cost of `dpa_check_args` varies based on the checked range type (e.g., value point `[0x1, 0x1]` costs less than value range `[0x1, 0x10]`), we report that these costs are all less than ten cycles. Lastly, we observe that the operations of MOAT are not substantially affected by the difference between performance and efficient cores.

Table 3: Micro benchmark results. We use P to denote the cycles of performance cores and E for the efficient cores. As a reference [62], user-space `RDPKRU`, `WRPKRU` take 0.5 and 23.3 cycles, respectively.

Operation	#Cycles		Note
`get_pkrs/RDMSR`	P:36	E:43	Get region permissions
`set_pkrs/WRMSR`	P:111	E:112	Set region permissions
`bpf_{entry/exit}`	P:154	E:173	Entry/exit BPF program
`dpa_check_args`	P:≤10	E:≤10	Check helper arguments

MOAT's Overhead vs. #BPF Programs. To show MOAT supports that numerous BPF programs, we prepare the following experiments. We attach 1, 10, 32, 64, and 128 BPF programs to trace `execve`[3], run a program that continuously creates processes for one minute, and measure the number of processes created. In this setting, each invocation of `execve` stresses MOAT to constantly switch between the BPF programs. Moreover, we craft each BPF program as succinct (programs that directly return) so that MOAT's relative overhead is not "dominated" by the overly lengthy BPF programs.

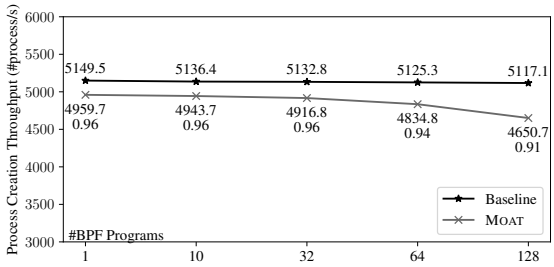

Figure 14: MOAT's overhead with respect to #BPF programs.

We report our results in Fig. 14. Since we use simple BPF programs, the baseline performance (without MOAT) is not observably affected by the number of BPF programs; we expect that in real-world cases, the baseline performance would also drop as the number of BPF programs increases. MOAT's overhead stays largely the same (4%) when there are 1, 10, or 32 BPF programs and then slowly increases with the number of BPF programs. It eventually incurs 9% overhead with 128 BPF programs. With further inspection, we find that over 64 BPF programs with isolated TLB entries pose heavy stress to TLB, resulting in increased overhead. However, having over 64 BPF programs attached to the same place is extremely rare (if it occurs at all). Nonetheless, even in such cases, MOAT incurs a performance penalty of less than 10%.

To complement the above experiment, we prepare the following experiment where BPF programs are attached to different kernel locations. There are, in total, 685 BPF tracepoints of system calls in Linux [15]. Following a similar setting as above, we attach each of these tracepoints with a simple BPF program and run UnixBench [42] to measure the overall system performance. In sum, there are nearly 700 BPF programs in the kernel with diverse invocation patterns. Thus, this setting stresses the system in a manner distinct from the previous experiment. We report that in such settings, the average UnixBench baseline score is 4936.3, MOAT's score is 4720.8, and thus, the incurred overhead is about 5%.

From these two experiments, we interpret that the overhead of MOAT is slightly affected by the number of BPF programs due to the TLB stress. Nevertheless, MOAT's overhead falls in a reasonable and promising range (4%~9%), even for cases

[3]We clarify that one BPF tracepoint only supports up to 64 programs [18], so we attach to both entry and exit tracepoints of `execve` in these experiments.

that are much heavier and rarely seen in real-world ones.

6.2.2 Macro Benchmark

For the macro benchmark, we set up three mainstream BPF use cases: network, system tracing, and system-call filtering. On the network cases (i.e., Socket and XDP), we use the smallest applicable packet size because BPF operates on each packet. Thus, under the same bandwidth, smaller-sized packets will incur higher throughput (i.e., more packets) and lead to more invocations of BPF programs, eventually putting more stress on MOAT.

Network — Socket. To evaluate MOAT's overhead on the network applications, we simulate a traffic monitoring scenario. A traffic generator sends UDP packets for one minute, with a packet size of 16 bytes, to our tested device. A server on the tested device receives these packets. Both the sender and receiver have a 1 GbE network interface controller. As for the tested BPF programs, we use five socket filtering programs from the Linux source tree, similar to previous works [39]:

- `drop`: directly ignores the packet.
- `byte`: monitors the traffic in bytes from each protocol.
- `pkt`: monitors the traffic in packets from each protocol.
- `trim`: only keeps the packet header to the socket.
- `flow`: monitors the network traffic based on protocol, interface, source, destination, and port.

We attach a socket to the receiver's network interface and set up these BPF programs to monitor the network traffic over the socket. In addition to the evaluation of each program, we also conduct a full-on experiment where five BPF programs are attached simultaneously to stress MOAT.

Table 4: MOAT's traffic monitoring performance in Thousand Packets per Second (TPPS). The full-on experiment is denoted as "all". The "vanilla" throughput without BPF program is 596.3 TPPS; the relative throughput is denoted in parentheses, e.g., (99.73%).

Throughput (TPPS)	drop	byte	pkt	trim	flow	all
Baseline	594.39 (99.70%)	594.67 (99.73%)	594.26 (99.66%)	594.74 (99.73%)	594.39 (99.68%)	587.22 (98.47%)
MOAT	593.10 (99.46%)	594.31 (99.66%)	594.43 (99.68%)	594.69 (99.73%)	593.10 (99.46%)	575.33 (96.48%)

As shown in Table 4, MOAT incurs negligible overhead (<1%) for all BPF programs if they are solely executing in the kernel. Even in the full-on experiment, which forces MOAT to constantly switch between these BPF programs, MOAT brings only a very small throughput drop of 2%.

Network — XDP. Besides processing packets from a socket buffer, BPF provides a direct way to control the network — eXpress Data Path (XDP). XDP processes packets at an early stage in the network stack to achieve fast packet processing. Following the settings in the socket experiment, we simulate a packet processing scenario. Similar to prior works [39], we run five XDP programs from the Linux source tree:

- `xdp1`: parses the IP header, keeps packets count in a BPF map, and drops the packets.
- `xdp2`: same as `xdp1`, but re-sends the packets.
- `adj`: trims the packets into ICMP packets, sends them back, and keeps packet count in a BPF map.
- `rxq1`: counts and drops the packets in each receive queue.
- `rxq2`: same as `rxq1`, but re-sends the packets.

Unlike socket filters, XDP programs require packets to be over a certain size, so we tune our traffic generator to send packets that go through the maximum possible execution path of the tested programs. We send packets of 64 bytes for `xdp1` and `xdp2` and packets of 100 bytes for `adj`, `rxq1`, and `rxq2`.

Table 5: MOAT's XDP performance in TPPS. The "vanilla" throughput without XDP program is 532.9 TPPS with 100-byte packets, and 561.5 TPPS with 64-byte packets; the relative throughput is denoted in parentheses, e.g., (99.55%).

Throughput (TPPS)	xdp1	xdp2	adj	rxq1	rxq2
Baseline	560.58 (99.84%)	557.78 (99.34%)	531.11 (99.66%)	528.36 (99.15%)	530.52 (99.55%)
MOAT	560.15 (99.76%)	557.76 (99.33%)	530.65 (99.58%)	527.57 (99.00%)	527.66 (99.05%)

As illustrated in Table 5, MOAT incurs negligible performance penalties (<1%) when executing XDP programs.

System Tracing. System tracing is another mainstream BPF use case. To evaluate MOAT's overhead on system tracing, we prepare 11 BPF programs to trace frequent system events like page faults, process creation, context switch, and file operations. These programs collect relevant system statistics for user-space analysis. Then, we run UnixBench [42] to measure the overall system performance. UnixBench includes the following tests: ① execl throughput, ② file copy, ③ pipe throughput, ④ pipe-based context switching, ⑤ process creation, ⑥ shell scripts, and ⑦ system call.

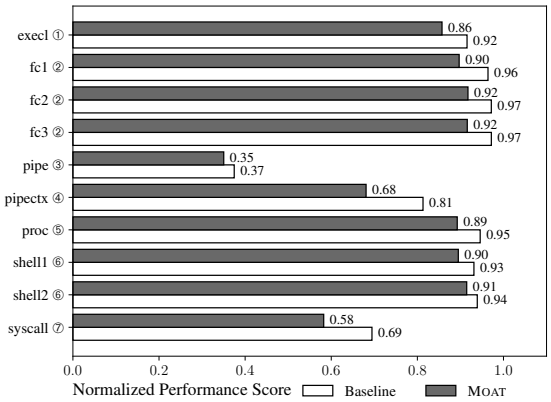

Figure 15: UnixBench normalized scores with respect to the "vanilla" scores without BPF tracepoints. The "fc* ②" and "shell* ⑥" are file copy tests and shell tests with different settings.

We report the results in Fig. 15. We find that MOAT imposes a small slowdown ($\leq 6\%$) for most UnixBench tests.

The maximum performance loss brought by MOAT is 13% in test ⑦. Such overhead seems moderate. However, note that the BPF programs without MOAT already bring a non-trivial performance penalty (e.g., 63% slowdown in test ③). Therefore, the performance loss brought by MOAT (<13%) is reasonably low for system tracing.

Syscall Filtering. BPF is also used to enhance software security [12, 28, 36]. `seccomp-BPF` allows filtering the system calls of a process with BPF. `sysfilter` [28] is an automated tool that analyzes a program, creates the set of system calls the program needs, and restricts the program using `seccomp-BPF`. We use `seccomp-BPF` and `sysfilter` to evaluate MOAT's overhead in such a use case. We apply the MOAT-hardened filter to Nginx and benchmark it using `wrk` [33] with one, two, and three client processes; each sends requests for one minute with 128 connections. Nginx is configured with the same number of worker processes. To clarify this setting: the number of processes for Nginx typically shall not exceed the number of cores, and adding more processes does not increase the throughput due to the context-switch cost. All requests are sent over the loopback (`lo`) to minimize network interference.

Table 6: Nginx throughput in Thousands of Request per Second (Treq/s). The relative throughput is in the parentheses, e.g., (95.6%).

Throughout (Treq/s)	1 worker	2 worker	3 worker
Vanilla (no `seccomp-BPF`)	148.1 (100%) ±12.81	179.5 (100%) ± 8.35	165.2 (100%) ±4.72
Baseline	147.2 (99.4%) ±9.56	171.3 (95.4%) ±8.08	160.5 (97.2%) ±5.28
MOAT	142.3 (96.1%) ±8.77	166.3 (92.6%) ±6.70	158.0 (95.6%) ±4.48

As shown in Table 6, MOAT incurs an additional throughput drop of 3%. Moreover, the standard deviations of throughput are within the normal range. Therefore, MOAT does not introduce fluctuation to Nginx throughput.

6.3 Additional Evaluation

In addition to the above experiments, we also evaluate MOAT's memory footprints, instrumentation cost from DPA, and compare MOAT's performance with a prior work [41].

Memory Footprint. As mentioned in Sec. 5, MOAT aligns BPF-related objects (e.g., maps) to 4 KB to ensure that they do not interleave with other kernel structures, introducing extra memory footprints. We provide a detailed breakdown of MOAT's memory footprints in Table 7. Specifically, MOAT uses four pages to set up the page table of isolated address-spaces, one page for the stack and one for the context. As for critical objects identified in Sec. 4.3.1, MOAT uses an extra page to toggle their permissions independently. Additionally, the memory used by the BPF program binaries and BPF maps is aligned up to a multiple of page size.

Though MOAT's memory footprints seem non-trivial from Table 7, we clarify that they are static and thus do not grow dynamically during the runtime. Even if there are thousands of BPF programs, MOAT's memory footprints are merely a few megabytes, which is negligible for modern systems.

Table 7: Breakdown of MOAT's memory footprint. AS: Address Space; ST: Stack; Ctx: Context; CO: Critical Objects. P and M denote #pages of program and map, respectively.

Type	AS	ST	CO	Ctx	Prog	Map
#Page	4	1	1	1	$\lceil P \rceil$	$\lceil M \rceil$

Helper Instrumentation Cost. As described in Sec. 4.3.2, MOAT instruments the BPF programs to insert DPA checks. Table 8 shows the number of helper calls and memory access made by the BPF programs[4] in Sec. 6.2.2. The former reflects the number of DPA checks inserted by MOAT, while the latter reflects the number of checks from SFI-based solutions. We report that, in most cases, the number of DPA checks is smaller than that of SFI-based solutions, let alone that SFI only offers memory safety, which is offered by PKS in MOAT.

Table 8: The number of checks of DPA and SFI-based isolation. Note that the tracepoint (marked with *) consists multiple BPF programs, and we report their average number of inserted checks.

Name	drop	byte	pkt	trim	flow	xdp1	xdp2	adj	rxq	tracepoint*
#Helper	0	1	1	0	2	3	3	5	3	6.4
#Mem.	0	4	3	1	61	16	29	53	37	6.9

Comparison with SandBPF. As far as we know, SandBPF [41] is the only work on BPF isolation at the time of writing. In this section, we compare MOAT with SandBPF. Technically, SandBPF enforces isolation by inserting software runtime checks into the memory access of BPF programs. As a result, it shall incur a relatively higher overhead than hardware-based methods. To substantiate this observation, we conduct the following direct comparative study. The authors of SandBPF conduct an evaluation with Phoronix Test Suite [40]; we reproduce the same experiments on MOAT. Note that the source code of SandBPF is not public at the time of writing, so we directly refer to their data in Table 9.

Table 9: Comparison with SandBPF [41]. We provide MOAT's relative overhead (Rel.) and SandBPF's overhead (Ref.).

Test #Conn (req./s)	XDP				Socket Filter			
	Base	MOAT	Rel.	Ref.	Base	MOAT	Rel.	Ref.
Apache 20	34,303	33,689	2%	**0%**	40,666	40,286	**1%**	4%
Apache 100	31,929	30,726	**4%**	8%	37,998	36,546	**4%**	4%
Apache 200	27,751	26,657	**4%**	5%	32,652	31,344	4%	**3%**
Apache 500	24,786	24,439	**1%**	7%	30,262	29,423	**3%**	7%
Apache 1000	24,597	24,470	**1%**	6%	29,545	28,961	**2%**	7%
Nginx 20	22,688	21,892	**3%**	7%	23,359	23,530	**0%**	10%
Nginx 100	21,492	20,689	**4%**	7%	22,870	22,482	**2%**	8%
Nginx 200	19,972	19,216	**4%**	6%	21,562	20,984	**3%**	8%
Nginx 500	18,470	17,814	**4%**	6%	19,421	18,713	**4%**	7%
Nginx 1000	17,024	16,735	**2%**	3%	17,392	17,098	**2%**	6%

As shown in Table 9, MOAT's overhead is lower than SandBPF in most testcases (Rel. v.s. Ref.). The MOAT's highest overhead is 4%, while SandBPF's is 10%. Again, we interpret the advantage of MOAT is attributed to the reduced

[4] The BPF programs in syscall filtering scenario are cBPF programs and thus do not support helper functions; we do not include them here.

number of inserted checks compared to SFI-based approaches.

7 Related Work

In this section, we discuss other related works on MPK and BPF. We already reviewed highly relevant works on kernel isolation and compared MOAT's design with theirs in Sec. 4.4.

MPK-based Isolation. Prior to PKS, Intel first announced its user-space variant PKU. Consequently, most existing works [35, 62, 70] using MPK focus on user-space isolation. To better utilize PKU as an isolation primitive, Park et al. [62] proposed `libmpk`, which resolves the semantic discrepancies between PKU and conventional `mprotect`. VDom and EPK [35, 70] aim to provide unlimited keys in the *user space* via key virtualization. Despite the similarity, we clarify that isolating BPF programs in the *kernel* is a distinct scenario and comes with its own challenges. This is why we have proposed the lightweight two-layer design to efficiently isolate BPF programs. Apart from using PKU to isolate user applications, efforts are made to isolate trusted applications in SGX via PKU [23, 45]. SGXLock [23] establishes mutual distrust between the kernel and the trusted SGX applications, while EnclaveDom [45] enables intra-isolation within one enclave. PKU has also been used for kernel security. IskiOS [34] applies PKU to kernel pages by marking them as user-owned.

BPF Security. There are prior works [32, 43, 44, 61, 69] on securing the BPF ecosystem. Most of them use formal methods to enhance the following BPF components: the verifier, the JIT compiler, or the BPF program. To enhance the BPF verifier, Gershuni et al. [32] propose PREVAIL based on abstract interpretation, which supports more program structures (e.g., loops) and is more efficient than the standard verifier. PRSafe [44], on the other hand, designs a new domain-specific language, whose ultimate goal is to build a mathematically verifiable compiler for BPF programs. Jitk [69] offers a JIT compiler whose correctness is proven manually, and Nelson et al. [61] generate automated proof for real-world BPF JIT compilers. Lastly, Luke Nelson [43] build proof-carrying BPF programs, requiring developers to provide a correctness proof with the program before loading it into the kernel.

8 Limitations

In this section, we discuss the limitations of MOAT, including the unidentified critical objects, issues brought by the granularity of PKS, and potential barriers to deploying MOAT.

Unidentified Critical Objects. In Sec. 4.3.1, we manually identified the critical objects in the BPF subsystem that have been exploited in the wild or similar to the ones that have been exploited. Despite two authors' rich experience, there might still exist unidentified critical objects. However, to exploit these unidentified objects, one still has to find a BPF helper that can be abused to access these critical objects and bypass the parameter checks (i.e., DPA) enforced by MOAT. Thus, even if few unidentified critical objects exist, they would be hard, if at all possible, to exploit due to DPA.

Page-size Granularity. MOAT leverages PKS to enforce isolation, which only supports 4 KB granularity. Though we carefully adjust BPF-related objects so that they are page-aligned, there still exist few corner-cases where PKS does not apply. In particular, BPF programs shall only access certain fields of the context `sk_buff`, which is enforced via the static checks by the verifier. However, applying PKS to these fields would significantly bloat `sk_buff` due to the granularity. MOAT thus cannot use PKS to constrain the access of BPF programs. As a result, `sk_buff` might have some bits leaked to BPF programs if the verifier's static checks are bypassed. Fortunately, BPF programs only receive a copy of `sk_buff` and cannot tamper with the original structure. Therefore, the consequence of such leakage, per our observation, seems trivial.

Barrier to Deploying MOAT. To deploy MOAT on other platforms or systems, there exist several barriers. First, MOAT requires a hardware feature like PKS that can provide page-level isolation. Fortunately, major platforms already support security features with similar capability. For example, on RISC-V, a prior work [64] implements a PKS-like feature named Donky, which could be used to support MOAT. Therefore, we expect MOAT to be deployable on other platforms with moderate engineering effort. Second, as we mentioned in Sec. 6.3, MOAT introduces additional memory footprints. Though the introduced footprints are only a few pages and negligible for modern systems, it might still create obstacles for some embedded systems, where memory is a scarce resource. Third, MOAT consists of about 3,000 lines of C code, which requires moderate engineering effort to port to other platforms.

9 Conclusion

Despite using BPF to extend kernel functionality, malicious BPF applications can bypass static security checks and conduct unauthorized kernel accesses. We present MOAT to isolate potentially malicious BPF applications from the kernel. MOAT delivers practical and extensible protection with a low cost, in compensation to contemporary BPF verifiers.

Acknowledgments

Appendix A: Critical Objects

We list the critical objects identified by us in Table 10. We categorize the objects in Table 10 based on their locations. Despite different location (i.e., map and iterator), both of them are used to implement dynamic dispatching in the kernel.

Table 10: Critical objects in the BPF subsystem.

Location	Critical Object
Map	array_map_ops, percpu_array_map_ops, prog_array_map_ops, sock_map_ops, cgroup_storage_map_ops, htab_map_ops, htab_percpu_map_ops, htab_lru_map_ops, htab_lru_percpu_map_ops, trie_map_ops, task_storage_map_ops, dev_map_ops, sk_storage_map_ops, cpu_map_ops, xsk_map_ops, perf_event_array_map_ops, queue_map_ops, stack_map_ops, bpf_struct_ops_map_ops, ringbuf_map_ops, bloom_filter_map_ops,cgroup_storage_map_ops, cgroup_array_map_ops,array_of_maps_map_ops, stack_trace_map_ops, htab_of_maps_map_ops, user_ringbuf_map_ops, inode_storage_map_ops

Abstract

In recent years, heap-based exploitation has become the most dominant attack against the Linux kernel. Securing the kernel heap is of vital importance for kernel protection. Though the Linux kernel allocator has some security designs in place to counter exploitation, our analytical experiments reveal that they can barely provide the expected results. This shortfall is rooted in the current strategy of designing secure kernel allocators which insists on protecting every object all the time. Such strategy inherently conflicts with the kernel nature.

To this end, we advocate for rethinking the design of secure kernel allocator. In this work, we explore a new strategy which centers around the "atomic alleviation" concept, featuring flexibility and efficiency in design and deployment. Recent advancements in kernel design and research outcomes on exploitation techniques enable us to prototype this strategy in a tool named `SeaK`. We used real-world cases to thoroughly evaluate `SeaK`. The results validate that `SeaK` substantially strengthens heap security, outperforming all existing features, without incurring noticeable performance and memory cost. Besides, `SeaK` shows excellent scalability and stability in the production scenario.

1 Introduction

In the Linux kernel, exploitation targeting heap vulnerabilities such as use-after-free, heap out-of-bound write and read, and uninitialized heap is very prevalent. In the Google and Alphabet Vulnerability Reward Program held in 2022 [36], 42 revealed Linux kernel exploits are all against the kernel heap. In the Pwn2Own contest since 2020, all nine showcased Linux kernel exploits target the kernel heap, with awards reaching up to $300k. In addition, from a variety of sources including industry summits like BlackHat and personal blogs of famous whitehat hackers (*e.g.*, [1, 9]), we collected public exploits, PoCs, and write-ups over the past five years, and found that 143 out of 173 Linux kernel exploits are against the kernel heap. Hence, securing the heap is of paramount importance for kernel protection.

Though there are security features in place in the Linux kernel to counter heap-based exploitation, they can barely provide the expected protection. On one hand, the features that are enabled by default in most distros are overly specific to certain exploitation techniques, making them bypassable. Consider freelist randomization as an example: by design, it only works for exploits leveraging spatial corruption, like heap out-of-bound write and read, and falls short in defending against temporal corruption, such as use-after-free. On the other hand, the features that are disabled by default have intrinsic weaknesses and fail to deliver the promised security improvements. To enumerate, structure layout randomization faces challenges in securely storing the random seed, while, based on our experiments, KFENCE rarely achieves its goal of separating kernel objects.

In parallel, in the user space, the design of secure allocators has been well researched [19, 45, 57, 59], introducing features like red zones, poisoning, user tracking, and ad-hoc sanity checks. These features can be found in a kernel mechanism named slub_debug. Unfortunately, slub_debug is regarded primarily as a debugging feature and serves as the building block for sanitizers like KASAN, due to its high cost.

In this work, we conducted a multi-faceted measurement of existing security features, revealing the fundamental obstacle in designing a kernel secure allocator: the allocator is the core kernel subsystem and is invoked with high frequency. Given the current strategy in security feature design, which insists on protecting every object all the time [51], performance and memory overhead accompany each allocation and free. This level of overhead is unacceptable for the kernel as it must offer services for user space with high efficiency but does not have unlimited memory.

Since the obstacle is intrinsic to the kernel nature, we advocate for rethinking the design of kernel secure allocators. In this work, we explore a new strategy which centers around the "atomic alleviation" (AA) concept. One AA offers the most granular level of exploit alleviation by separating a specific type of kernel object. We can orchestrate particular sets of AAs to meet distinct security needs, focusing only on critical

objects instead of every object indiscriminately. Besides, the enforcement and retirement of AAs do not bother to recompile and reboot the kernel, supporting continuous protection upgrading.

This strategy had been previously infeasible until recent advancements in the extended Berkeley Packet Filter (eBPF) [29, 35, 49, 54, 66, 71, 72]. Using eBPF, we prototyped this new strategy in a tool named `SeaK`, representing **Se**cure **a**llocator for **K**ernel. We further developed techniques that can automatically identify allocation and free sites of objects selected for separation in a certain scenario, and synthesized eBPF programs that construct separation at runtime. The separation is shipped with guard pages and up to 43 entropy randomization.

This strategy wouldn't be reliable security-wise without the outcomes of research on exploitation techniques in recent years. We applied `SeaK` to two scenarios to illustrate how it enhances kernel heap security. Given that not all objects are worth protecting, recent works [21, 22, 65] have been focusing on identifying security-sensitive objects in the Linux kernel. Advancements in this direction pave the way for deploying `SeaK` to separate and protect these critical objects. In another scenario where the kernel patching process is lengthy, we showcase how `SeaK` can separate corruptions introduced by N-day vulnerabilities, thereby protecting the kernel from potential exploitation before patches are available.

We evaluated `SeaK` in terms of security improvement, performance and memory overhead, and scalability, by using real-world cases. Our experimental results validate that `SeaK` can effectively thwart state-of-the-art kernel heap exploitation, even the newest DirtyCred attack [44], outperforming existing security features. In the meanwhile, the performance overhead of a single AA is negligible - less than 1% on average when separating the most frequently used object; and the memory overhead is not noticeable when separating the most durable object. `SeaK` is scalable as there is no obvious increase in performance overhead and memory overhead when more than 64 AAs are orchestrated.

To our knowledge, `SeaK` is the first practical secure allocator in open-source kernels. `SeaK` has been deployed on the authors' machine, having supported daily research and education activities for 2.5 months, and running stably to date. In summary, this work makes the following contributions:

- A multi-faceted measurement to disclose the inherent obstacles of designing a secure allocator for OS kernel.
- The introduction of a new and practical strategy to secure kernel heap and its core concept - atomic alleviation.
- Open-source design and implementation of the strategy in `SeaK` which is the first practical secure kernel allocator. `SeaK` can remediate vulnerability before patches are available.
- A comprehensive evaluation of `SeaK` which validates the effectiveness and efficiency of the new strategy.

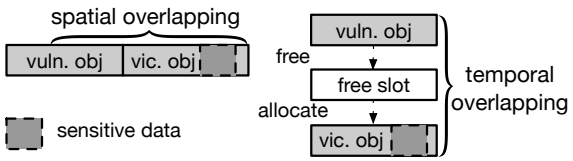

Figure 1: Kernel heap exploitation which creates overlapping between spatial/temporal memory corruption from the vulnerable object and sensitive data in the victim object.

2 Background

In this section, we will describe the heap management and heap exploitation techniques in the Linux kernel.

2.1 Kernel Heap Management

In the Linux kernel, the term of heap often refers to the memory located in the direct mapping region which has 64TB in total and maps all physical memory. The heap is coordinately managed by the buddy allocator and the SLAB/SLUB allocator, which roughly work as follows.

Buddy Allocator. The buddy allocator partitions physical memory into pages and manages objects larger than one page. During allocation, if the requested size (*e.g.*, 2 pages) is unavailable, a larger chunk (*e.g.*, 8 pages) is repeatedly halved (*e.g.*, 8 pages to 4 pages to 2 pages) until a chunk of the exact size is produced. The two halves are referred to as buddies: one satisfies the allocation request and the other remains free. When the allocated buddy is later freed and its counterpart buddy is not used, they will be merged back and reclaimed (*e.g.*, two 2-page buddies back to one 4-page chunk).

SLAB/SLUB Allocator. The SLAB/SLUB allocator manages small objects by acquiring pages from the buddy allocator. These pages are known as slab caches and are divided into slots - each slot aims to hold one object. Objects stored in the same slab cache either share the same type or have a similar size. When slots are free, they are linked in a singly-linked list called the freelist. The freelist works in a LIFO (Last In, First Out) fashion: retrieving the first slot in the freelist for allocation and adding the slot back to the beginning of the list during free. If all slots in these pages are freed, the SLAB/SLUB allocator returns these pages to the buddy allocator.

2.2 Kernel Heap Exploitation

In recent years, exploitation techniques against the kernel heap have been thoroughly discussed in both academia [21, 22, 67, 68, 70] and industry [38]. Due to the space limit, we won't elaborate on concrete exploits but instead summarize the common ideas behind various exploitation techniques.

Create Overlapping. Figure 1 illustrates an essential step in exploitation which is to create overlapping between heap corruption and sensitive data such as function pointers and credentials. The overlapping can be categorized into spatial overlapping and temporal overlapping according to the nature of vulnerabilities. To exploit heap out-of-bound write/read, attackers manipulate heap layout [22,68] to place victim objects that contain sensitive data adjacent to the vulnerable object. By triggering the vulnerability, the corruption has a spatial overlapping with the sensitive data, allowing attackers to tamper with it and achieve IP control or privilege escalation. To exploit use-after-free, attackers first free the vulnerable object which still has a dangling pointer referring to it. The freed slot is recycled back to SLAB/SLUB allocator. Then, attackers spray victim objects containing sensitive data to reclaim the same memory, leveraging the LIFO feature. By dereferencing the dangling pointer, attackers tamper with sensitive data in the victim object and obtain exploitable primitives.

Cross-cache Exploitation. If the victim object and the vulnerable object are in the same slab cache, it is often referred to as within-cache exploitation. Cross-cache exploitation stands for the situation where the victim object and the vulnerable object are in different slab caches. To exploit a heap out-of-bound write/read in a cross-cache exploitation manner, attackers manipulate the heap layout at the buddy allocator level, ensuring that two pages — the one containing the victim object and the other containing the vulnerable object are adjacent though they belong to distinct caches. To exploit a use-after-free in a cross-cache exploitation manner, attackers first free all vulnerable objects within the same cache so that the cache is reclaimed to the buddy allocator. Then, they allocate a number of victim objects, forcing the buddy allocator to re-halve the just reclaimed slab cache pages - previously storing vulnerable objects - for storing victim objects instead. Thus, there is a temporal overlapping between the vulnerable and victim objects.

Same-type Exploitation. In most exploits, regardless of within-cache or cross-cache, the vulnerable object and the victim object are of distinct types so the difference between their semantics allows successful tampering. However, the newest DirtyCred attack [44] demonstrates that vulnerable objects and victim objects can be of the same type in exploitation. Technically, two objects of the same type (*e.g.*, `struct cred` but carrying different privilege levels (*e.g.*, `cred.uid == 1000` and `cred.uid == 1000`) can be overlapped to achieve privilege escalation. This attack bypasses all existing security features in the kernel allocator, even slub_debug.

3 Obstacles in Existing Designs

The newest security features in the Linux kernel allocator are in three categories: (C1) features that are enabled by default in mainstream Linux distros such as Ubuntu and CentOS; (C2) features that are designed for protection but are disabled by default in most distros; (C3) features that are commonly employed in user space secure allocators and integrated into slub_debug [37].

In this section, we will evaluate the security and overhead of these features, followed by investigation into the particular obstacle in secure kernel allocator design.

3.1 Security Analysis

By-default Enabled Features (C1). In this category, ❶ freelist randomization [26] randomizes the order of slots in the freelist of the SLAB/SLUB allocator so that attackers can hardly accurately predict the slab cache layout. ❷ The freelist obfuscation [27] aims to hinder attackers from manipulating the allocator into returning a memory under the attackers' control. ❸ The heap zeroing [52] on allocation initializes the slot during allocation so that attackers cannot read sensitive information belonging to the object that previously occupied the slot. These features raise the bar of exploitation but are too specific to certain vulnerabilities and attack techniques and thus can be easily bypassed [2–4, 7, 10]. Taking freelist randomization as an example, it is designed only against vulnerabilities that cause spatial overlapping like out-of-bound write, and doesn't work for vulnerabilities that cause temporal overlapping like use-after-free. Even for spatial overlapping, it can be bypassed through heap grooming [39].

By-default Disabled Features (C2). In this category, ❶ structure layout randomization [25] shuffles the field orders in structures each time the kernel boots up so that attackers cannot predict the offset between sensitive data and the start of corruption. However, the kernel must reveal the random seed to support compiling third-party kernel modules. How to securely store the seed continues to be a challenge nowadays [33]. Besides, it only randomizes structures that contain only function pointers and cannot cover all structural types. ❷ KFENCE allocates objects from a pre-reserved pool. Each object takes pages and is surrounded by red zones and guard pages, which can detect out-of-bound access. When the object is freed, the corresponding page is unmapped so that use-after-free can also be detected. However, to reduce overhead, KFENCE randomly samples objects for separation, no matter whether the object is security-related or not. Further, the sampling only happens in the fast path of allocation and it only samples one object in a certain time window. Thus, in our experiment, KFENCE can only protect 0.005% - 0.35% sensitive objects even after its capability is maximized. Features in this category are designed for protection but fall short of providing assured security improvement, presumably the reason why they are disabled by default.

Lightweight "Debugging" Features (C3). This category includes ❶ slub_debug which is primarily regarded as a debugging feature. It provides a full spectrum of security fea-

tures typically found in userspace secure allocators: red zones around objects enabled by Z flag, poisoning and user tracking of freed memory by P and U flags respectively, and additional sanity checks by F flag. Compared with KASAN, slub_debug is lightweight but for protection, it is too heavy. We will show this in the following.

3.2 Overhead Measurement

Benchmarks and Settings. We use two benchmarks to evaluate the overhead of existing security features. One is LMbench [47] which is a micro-benchmark widely used for system call level measurement. Another is Phoronix Test Suite [11] which is a macro-benchmark. It runs real-world applications and we use it to measure the impact of `SeaK` on the overall system. In particular, from Phoronix Test Suite, we choose seven applications: OpenSSL, 7zip-compress, FFmpeg, Redis, SQLite, and Apache as representatives of different workloads to comprehensively test processor, OS, and system.

Our experiments were conducted using a bare-metal machine running Ubuntu 22.04 LTS with an Intel(R) Core(TM) i7-6700 CPU @ 3.40GHz and 16GB RAM. We built a vanilla kernel image as the baseline using the Linux kernel v5.15 - the latest Long-term support (LTS) version at the time of experimentation. The vanilla kernel doesn't contain any security features described in this section. Then, we built another three images: one with all three features in C1, one with the two features in C2, and one with slub_debug in C3. To minimize fluctuation and rule out outliers, we repeatedly ran benchmarks until the overhead of the recent five executions had a coefficient of variation smaller than 3.5% - a default setting in Phoronix. Between each round, we rebooted the whole system to ensure a clean environment for the benchmark.

Performance Overhead. Table 1 presents the performance overhead. Though a recent study [55] reveals that freelist randomization in C1 showcases 45% peak overhead in certain situations (*i.e.*, big-select and big-fork) because of poor locality, our measurement over both LMbench and Phoronix indicates that the overall overhead of C1 is not obvious: -2.74% to 3.91% which is within reasonable fluctuation range. For the two features in C2 that are disabled by default, their overhead is slightly noticeable: -1.88% to 5.25% for LMbench, and -1% to 1.34% for real-world applications in Phoronix. While this extent of overhead is tolerable, as we discussed in the security analysis (Section 3.1), both features in C2 have inherent weaknesses that prevent them from producing the expected secure enhancement.

For slub_debug in C3, its overhead is prohibitively high, reaching 177.22% for LMbench and 57.58% for Phoronix. Note that, in the table, some benchmarks (*e.g.*, 7zip-compress) show negative overhead because their execution time predominantly takes place in user space with minimal kernel involvement. These negative numbers shouldn't be mis-interpreted as indicating that slub_debug has no overhead. In fact, for benchmarks that are dependent on kernel services, the overhead arises significantly.

LMbench	**C1**	**C2**	**C3**
Simple syscall	0.35%	1.06%	0.90%
Simple read	0.98%	3.73%	0.70%
Simple write	0.41%	1.71%	2.46%
Select on 100 fd's	-0.64%	1.21%	0.04%
Signal handler install	-1.35%	-1.88%	-1.17%
Signal handler overhead	0.75%	3.29%	169.16%
fork+exit	0.60%	1.76%	168.17%
fork+execve	2.42%	1.56%	177.22%
fork+/bin/sh -c	1.21%	2.32%	151.55%
UDP latency	3.91%	4.97%	144.34%
TCP/IP connection	-2.74%	5.25%	129.81%
AF_UNIX bandwidth	-0.20%	0.27%	52.16%
Pipe bandwidth	0.80%	1.16%	-1.98%
Phoronix	**C1**	**C2**	**C3**
Sockperf (Msgs/sec)	-0.27%	-0.61%	57.58%
OSBench (Ns/Event)	-0.08%	-1.00%	6.25%
7-Zip Compress (MIPS)	-0.34%	0.54%	-0.39%
FFmpeg Live (FPS)	-0.14%	0.28%	1.25%
OpenSSL SHA256 (B/s)	0.01%	0.04%	0.01%
Redis SET (Reqs/sec)	-0.37%	0.47%	0.55%
SQLite Speedtest (sec)	0.52%	1.34%	4.05%
Apache 100 (Reqs/sec)	-0.50%	-0.42%	46.29%

Table 1: Performance overhead of security features in different categories. See Section 3.1 for more details of each category.

Memory Overhead. Figure 2 presents the memory overhead when running LMbench (Phoronix's result are moved to [18] due to space limit). From the figure, we can observe that vanilla, C1, and C3 exhibit similar memory usage while C2 consumes an additional 400 MB of memory. This is because KFENCE in C2 allocates objects from a pre-reserved pool and each object separated by KFENCE occupies pages that are surrounded by red zones and guard pages.

3.3 Behind Security / Overhead Trade-off

Summarizing from security analysis and overhead measurement, existing security designs in the Linux kernel allocator either fail to provide substantial security enhancement (C1 and C2) or are impractical due to excessive memory and performance overhead (C2 and C3). To have a deeper understanding of the root obstacle, we selected Apache from Phoronox - a case with noticeable overhead - as our target and conducted a case study.

Table 2 presents the statistics collected by bpftrace during the execution of Apache. From the table, we can observe that,

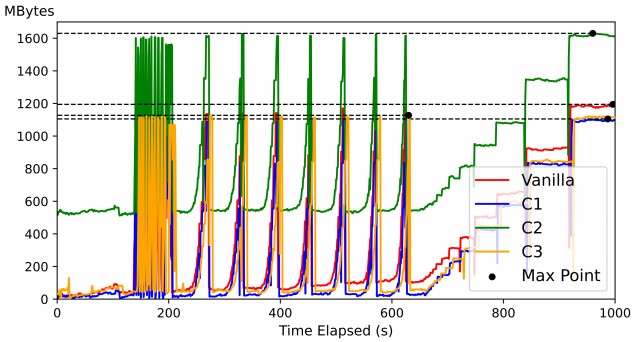

Figure 2: Increase of memory usage of existing security features when running LMbench.

	Vanilla	C1	C2	C3
Inst. # (million)	1,661,099	1,641,186	1,673,330	2,708,439
Invoked #/sec	324,194	321,347	321,634	214,793
Time Proportion	17.1%	17.1%	17.7%	41.4%
Time Per Req (μs)	17.8	17.7	17.7	33.2

Table 2: Statistics collected through the Apache Benchmark in five minutes. "Inst. # (million)" indicates the # of instructions executed within the kernel, represented in millions. "Invoked #" is the # of times the allocator is called. "Time Proportion" is the fraction of time spent within the allocator inside the kernel. "Time Per Req" averages time required to handle a request.

in a given time, the kernel with security features executes a substantially higher number of instructions, particularly for C3 which exhibits a 63.1% increase compared to vanilla. This is attributed to C3's most complete spectrum of security features, which introduces numerous additional instructions to the kernel allocator. Further, we observed that the kernel allocator is invoked very frequently, reaching 214,793 to 324,194 times per second. As a result, in C3, the time proportion dedicated to the allocator doubles, jumping from 17.1% to 41.4%. This bloating not only decelerates the kernel, as evidenced by the reduced number of allocator invocations in a given time, but also impacts the entire system, leading to longer response times for Apache to handle a request.

Conclusion. Based on our analytical experiments, we have the following conclusion. First, the allocator is a core subsystem in the kernel and is frequently used. Second, each time the kernel invokes the allocator, it incurs the overhead associated with executing the additional code introduced by security features. Given these facts, the current strategy of protecting every object all the time can hardly work within the kernel which must offer services for user space efficiently.

4 Design Overview

Drawing on lessons learned from evaluating existing features, a more realistic strategy would be conserving resources on critical objects rather than protecting every object indiscriminately. We explored this new strategy and prototype it in the design of `SeaK`. In this section, we will first describe the eBPF ecosystem on top of which we build `SeaK`, followed by the threat model and the design overview.

4.1 The eBPF Ecosystem

The extended Berkeley Packet Filter (eBPF) is an in-kernel virtual machine that allows **privileged** users to run programs in the kernel space. The eBPF programs are written in the C language and compiled to bytecode using the LLVM eBPF backend. Privileged users can install the compiled eBPF programs into the kernel and attach them to arbitrary instructions, monitoring and modifying kernel behaviors.

The **safety** of eBPF programs is guaranteed by a static verifier which establishes three properties: (1) memory safety, ensuring that the program only accesses pre-defined memory locations, (2) information flow security, ensuring that no secret kernel state is exposed, and (3) all execution must terminate. Over decades of development, eBPF has significantly improved in **expressiveness**. The eBPF helper functions allow the installed eBPF programs to interact with other kernel subsystems. The BPF maps can store arbitrary data. They allow eBPF programs to communicate with each other and with privileged userspace processes by looking up and updating the stored data through keys. For the sake of **efficiency**, a variety of optimization techniques has been adopted in the eBPF ecosystem. For instance, the eBPF bytecode is executed by a Just-In-Time (JIT) engine rather than a slow interpreter to achieve native-machine code level performance. Further, the instructions once attached, are overwritten to `call` or `jmp` instructions instead of the previously used `int3` interrupt. As such, the time spent on switching context to eBPF programs is saved.

eBPF for Security. The eBPF ecosystem has undergone swift evolution across commodity OS kernels, including Linux, Windows, FreeBSD, and macOS [5, 6]. In the security area, PET [66] instruments eBPF programs to error sites, preventing kernel vulnerabilities from being triggered. Sifter [32] filters malicious syscall with eBPF to make attack surfaces in security-critical kernel modules unreachable. RapidPatch [31] allows RTOS developers to hot-patch embedded device firmware using eBPF.

4.2 Threat model

`SeaK` has the following assumptions about the capabilities of attackers and defenders.

Attacker. Attackers possess a vulnerability that corrupts the kernel heap. This vulnerability can be exploited using the newest kernel exploitation techniques. It can be present in any kernel subsystem, including the eBPF subsystem on top

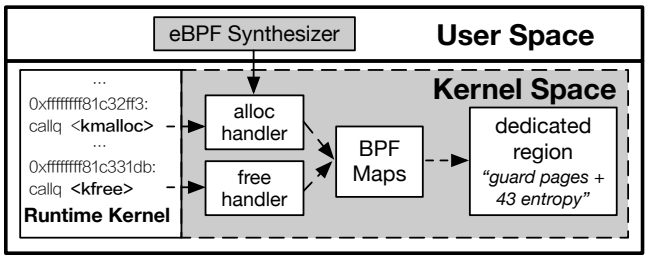

Figure 3: Overview of one atomic alleviation (AA) in SeaK. The eBPF program synthesizer in the userspace installs an eBPF program with alloc handlers and free handlers into the kernel space, separating objects of interest.

```
1  // essential utilities
2  int alloc_handler(struct pt_regs* ctx,
3      u64 kpi_type) {...}
4  int free_handler(struct pt_regs* ctx,
5      u64 kpi_type) {...}
6
7  SEC("kprobe/?") // attach to allocation site
8  int probe_alloc_? (struct pt_regs* ctx) {
9      return alloc_handler(ctx, ?);

Listing 1: The snippet of synthesis template. Once the "?" is filled in, it can be directly compiled and installed into the kernel space.

of which SeaK is built, as long as the eBPF programs can be installed. Further, we assume attackers are unprivileged users so that they cannot directly disable SeaK.

Defender. Defenders are privileged users or system administrators so that SeaK is granted the right privilege to install eBPF programs into the kernel. The installed eBPF programs are free from bugs and their safety is guaranteed by the sound verified. We assume that defenders are aware of the vulnerability threat by either catching its exploit in the wild or obtaining necessary information (*e.g.*, vulnerability reports) from public resources including the dashboard of Syzkaller – the most widely used kernel fuzzer developed by Google, the National Vulnerability Database, and more.

4.3 SeaK at a Glance

The **atomic alleviation** (AA for short) is the key concept in SeaK. One AA is responsible for separating a specific type of kernel objects - objects of interest. Figure 3 illustrates the design of one AA in SeaK.

In user space, the eBPF synthesizer first analyzes the kernel source code to pinpoint the allocation and free sites for objects of interest. Then, it investigates debug information to map the source-code-level sites into corresponding binary addresses of `call` instructions that invoke memory allocation and free functions (*e.g.*, `kmalloc/kfree`). After this, the synthesizer produces an eBPF program that can be installed into kernel space to achieve alleviation.

In the kernel space, the eBPF program shoulders a complete allocation and free logic for objects of interest: The alloc handler attached to the allocation sites intercepts the original allocation and obtains memory from a dedicated region that is separated; the free handler attached to the free sites prevents the memory in dedicated regions from being directly returned to the buddy system and recycles memory only for objects that are allowed by the security policy. The status of dedicated regions is maintained by BPF maps. If one dedicated region runs out of space, additional memory will be assigned. When the threat landscape changes and the AA is no longer useful or requires updates, the eBPF program can exit gracefully and be reinstalled later if needed again.

Like secure allocators in user space (*e.g.*, [19,45,57,59]), to prevent spatial overlapping, the dedicated region is equipped with guard pages and randomization with up to 43 entropy. To prevent temporal overlapping, SeaK currently enforces the most restrictive separation policy to deal with the newest exploitation techniques (Section 2.2): only recycle within objects that are allocated from the same site, having the same size, carrying the same privilege level, and in the same zone.

Advantages. SeaK is flexible from the following perspectives. ❶ Design-wise, one AA offers the most granular level of alleviation. We can strategically orchestrate different sets of AAs to meet distinct security needs. It allows efficient use of resources by focusing on crucial objects, rather than an indiscriminate separation. ❷ Deployment-wise, AAs can be enabled on the fly without disrupting running computation services, thus maintaining system availability. ❸ Evolution-wise, The separation policy enforced in AA can be dynamically upgraded when new exploitation techniques are disclosed. In comparison, the implementation of existing solutions is fixed once integrated.

5 Technical Details

In this section, we will present more technical details of AA in SeaK, from the eBPF synthesizer in the user space to the runtime separation in the kernel space.

5.1 eBPF Program Synthesis

To separate objects of interest, an eBPF program is generated. The essential elements needed to construct the eBPF program include the binary addresses of the allocation site and free site, as well as the prototype of the kernel function that is called for allocation or free. Readers can refer to List 2 in Appendix for the illustration of a synthesized program.

Synthesis Template. List 1 shows the template SeaK uses to synthesize eBPF programs. All the "?" in the template represent the elements that need to be customized per site. In line 7 and line 11, SEC decoration denotes the locations of the allocation and free sites in the format of func+offset. In this format, func is the symbol of the kernel function where allocation and free are called, offset represents the offset of the call instruction from the start of func. We use func+offset instead of the absolute address of the call instruction (*i.e.*, 0xffffffff81c331db) because of Kernel Address Space Layout Randomization (KASLR) [28] which randomizes the base address of kernel image during boot time. Using func+offset, the eBPF program can work across machines with different base addresses without further modification.

In lines 8 and 12, the "?" serves as a placeholder for a unique identifier to differentiate multiple allocation sites and free sites. In line 9 and 13, the "?" is used to differentiate prototypes of allocation and free functions being called. This Kernel Programming Interface (KPI) information (kpi_type) is needed so that the eBPF programs (line 1-5) can determine how to obtain the requested size of the allocation and the address of object to be freed from the run-time context. For example, we differentiate kmalloc and kmem_cache_alloc because the allocation size is stored in the 1st parameter of kmalloc but in the 2nd parameter of kmem_cache_alloc, passed through $rdi and $rsi, respectively, by the x64 convention.

Determining Allocation and Free Sites. Given the object type, SeaK finds the allocation sites and free sites by first searching at the source code level and then converting the sites into the corresponding binary addresses in the format of func+offset.

At the source code level, the SLAB/SLUB allocator uses two series of kernel functions for allocation and free. One is kmalloc/kfree series for objects in the general cache. The other is kmem_cache_alloc/kmem_cache_free series for special cache. For the buddy system, the functions for allocation and free are alloc_pages/free_pages series. The code lines that call these functions are allocation and free sites. We further narrow down the scope and identify the sites specific to the objects of interest by analyzing the return values or arguments of these function calls. Because their return values or arguments are always pointers referencing the objects allocated or freed, by analyzing them, we can easily figure out whether the object is of interest. Technically, we perform a use-def analysis and resolve memory alias. Along the use-def chain of returned value or arguments, we track instructions relevant to typecasting, pointer dereferencing, and argument passing. The operands of these instructions explicitly reveal the type of variables. By using this information, we can easily infer and conclude the type of each allocated or freed object.

At the binary level, sites in the source code that allocate or free objects of interest are mapped to binary addresses via debugging information in the kernel image. Note that, kmalloc/kfree series functions at the source code level are occasionally inlined into kmem_cache_alloc/kmem_cache_free series at the binary level through compiler optimization. Therefore, we synthesize the kpi_type part in the eBPF programs according to the series used in the kernel image rather than the source code to eliminate inaccuracies.

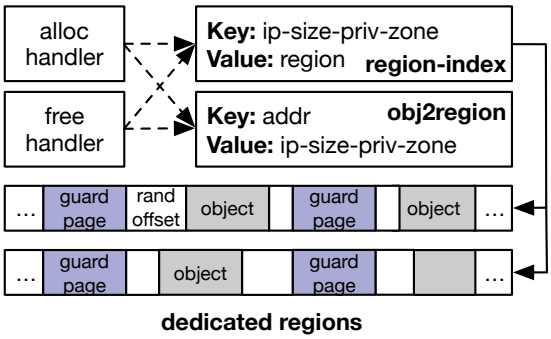

Figure 4: Run-time separation in the kernel space. The attached malloc handlers and free handlers leverage two BPF maps to manage dedicated regions.

5.2 Run-time Separation

Here, we delve into more details of how eBPF programs and BPF maps separate objects of interest.

Data Structures. As illustrated in Figure 4, in one AA, an alloc handler is attached to each allocation site, and a free handler is attached to each free site. The synthesizer described in Section 5.1 is responsible for identifying these sites and synthesizing the corresponding handlers.

To track the status of dedicated regions that store separated objects, each AA has two BPF maps: region-index and obj2region. The region-index map is used to locate dedicated regions. Its key is customized according to the security policy. Its value represents the dedicated region which is the address of either a struct kmem_cache object if the requested size is smaller than one page or a struct page object if the requested size is larger than one page. The key of the obj2region map is the address of an individual object that is separated into dedicated regions. Its value indicates which region the object belongs to and can be used to index the region-index map.

Evolving with Exploitation Techniques. In Figure 4, we use ip-size-priv-zone as the key to index the dedicated region. As such, the memory is recycled only within objects that are allocated from the same site (*i.e.*, ip), with the same size, carrying the same privilege level, and in the same zone. It is the most restrictive policy that can alleviate the newest exploitation techniques that have been disclosed thus far. As new exploitation techniques evolve in the future, this policy can be strengthened accordingly.

Guard Page and Randomization. Each separated object occupies multiple pages. Even for the object the real size of which is smaller than one page, it takes over at least one page. These pages are further surrounded by guard pages that are not mapped. The offset of the object from the start of the pages is randomized. The randomization entropy within the page is 7, considering pointer alignment in x64. Since the dedicated region can be located anywhere in the direct mapping area, the overall entropy is 21 for the 16 MB DMA zone or 43 for the 64TB normal zone, which is much higher than the widely-used KASLR which is 8. Given such a high entropy, the chance for attackers to brute-force the address of separated objects in one shot is nearly zero.

Workflow. Now, we describe how the aforementioned designs are used through the life cycle of an object that is separated.

When the object is allocated, the alloc handler will be executed. According to the security policy, it obtains the execution context: (1) the address of allocation sites from `$rip` register, (2) the request size from `$rdi` for `kmalloc`, `$rsi` for `kmem_cache_alloc`, `$rsi*PAGE_SIZE` for `alloc_pages`. (3) the privilege level of the current process through the helper function, (4) the requested zone which is specified in GFP flags - `$rsi` for `kmalloc`, `$rdx` for `kmem_cache_alloc`, `$rdi` for `alloc_pages`. This context information is concatenated to form the key. The alloc handler uses the key to look up the region-index map to examine if there is already a dedicated region that fits. If no dedicated region is available, the alloc handler creates a new slab cache or a new buddy through the helper function and records related information in the region-index map. Otherwise, the alloc handler retrieves the slab cache or buddy structure from the region-index map, storing the object and setting guard pages through help functions. Following this, the address of the object is used as the key to update the obj2region map. Finally, the alloc handler overwrites the return address to directly jump to the next instruction of allocation `call` and thus skip the original allocation.

When the object is freed, the free handler will be executed. It first obtains object's address from the `$rdi` register and looks it up in the obj2region map to determine if the object to separated. If not, the kernel continues the routine free operation. Otherwise, the free handler looks up the region-index map, obtains the dedicated region, and frees the object from the region using a helper function. Note that, this free operation does not indeed return the memory. Instead, the memory is recycled for the subsequent allocations of objects with the same `ip-size-priv-zone` key, as the security policy requires.

Concurrency and Exit. Since objects of interest can be allocated and freed at many kernel sites, the alloc handlers and free handlers attached to these sites will concurrently access the shared region-index and obj2region maps. Therefore, it is essential to ensure the atomicity of map read and write. Fortunately, the current eBPF ecosystem provides a spin lock per key and a read-copy-update (RCU) counter per value in BPF maps to achieve concurrency control.

When one AA is no longer needed or a stronger policy is developed, it exits gracefully without causing memory leakage. More specifically, `SeaK` creates a kernel task that periodically scans the entire kernel memory to check for pointers referring to the separated objects indexed in the obj2region map. If no more pointers refer to the separated objects, the occupied memory can be safely returned to the buddy system. Otherwise, the AA stays in the kernel until the obj2region map becomes empty.

6 Application

In this section, we showcase how to orchestrate a set of AAs to meet security requirements in different scenarios.

6.1 Separating Security-Sensitive Objects

Given not all objects are security-sensitive, protecting each one indiscriminately is unnecessary. Kernel objects such as `cred`, `msg_msg`, and `key_payload` are well-known to be security-sensitive because they contain data like credentials and function pointers. Separating them is one key task in prior works, including xMP [53], kalloc_type [30], AutoSlab [40], and slab_virtual [64]. `SeaK` can complete this task in a straightforward way: each AA separates one specific sensitive type.

A series of research efforts have been undertaken to identify security-sensitive objects in the Linux kernel: SLAKE [22] collects objects with function pointers; ELOISE [21] focuses on elastic objects that can provide stronger write and read primitives; AlphaExp [65] finds objects based on within-cache exploitation scheme. As exploitation techniques evolve, more objects will be identified as security-sensitive. By constructing and installing more AAs, `SeaK` can easily adapt to these newly discovered objects. This flexibility is a significant advantage over prior works because their design and implementation are fixed. Moreover, `SeaK` can enforce separation on the fly while prior works require recompilation and rebooting which disrupts system availability.

6.2 Separating Vulnerability Corruptions

Due to the lack of manpower and design complexity, the patching process is quite lengthy for the Linux kernel. A study two years ago [61] revealed that the average patching window in the Linux kernel was 66 days, and the situation is getting worse [8]. During this time window, patches are not available for these N-day vulnerabilities and attackers have the full freedom to develop exploits and launch attacks.

To mitigate this threat, we can construct AAs to separate corruptions introduced by vulnerabilities, thereby limiting the damage. For vulnerabilities such as heap out-of-bound write and read, corruption happens when there is beyond-boundary

access. One AA can be installed to separate the overflowed object. Thus, guard pages can catch the spatial overlapping caused by the vulnerability, and due to randomization, the overlapping cannot precisely tamper with targeted kernel data. For vulnerabilities such as use-after-free, corruption happens when a dangling pointer dereferences a freed object. After separating the freed object using one AA, the heap memory is recycled only for objects that are allowed by the separation policy, which is restrictive enough to fail newest exploitation attempts. Furthermore, SeaK creates a task that periodically scans the entire kernel memory to check for the existence of dangling pointers and starts recycling only when there is no dangling pointer. Presented with multiple N-day vulnerabilities, we employ a set of AAs to protect the kernel until patches for these vulnerabilities are released.

7 Implementation

The implementation of SeaK includes 416 lines of C code for eBPF templates, 152 lines of C code for the new helper functions in the kernel, and 649 lines of Python code for eBPF program synthesis and framework integration. In addition, SeaK has 3998 lines of C++ code based on LLVM infrastructure, to pinpoint allocation and free sites for objects of interest and support the scenario of separating vulnerability corruption by identifying vulnerable objects. SeaK is implemented over Linux and can be migrated to other open-source kernels thanks to the consistent design of the eBPF ecosystem across platforms. SeaK is open-source in GPLv2 Licence[1].

eBPF Program Synthesis. Given the type of objects for separation, SeaK analyzes the kernel image with debug information to pinpoint allocation sites and free sites in order to synthesize eBPF programs. We use LLVM infrastructure to search for these sites of interest at the source code level and use Binary Ninja to map the results to binary addresses. More specifically, we provide a list of kernel allocation and free KPIs (*e.g.*, `kfree`, `kmem_cache_free`, `kfree_skbmem`, etc) for Binary Ninja. Binary Ninja can get the addresses of all symbols, cross-reference them to their call sites, retrieve the address of each call site, and then write them into a file. After that, each address in this file is passed to `llvm-symbolizer` to create an allocation site mapping between the kernel image binary and the source code. The mapping itself is stored as a Python dictionary within a `.pickle` file. We can easily look up the mapping for the exact `call` instructions that allocate and free objects of interest. All the steps and sub-steps mentioned above are wrapped in a Python script to fully automate the entire analysis workflow.

New Helper Functions & BPF Maps. To support separating objects of interest, we extend the eBPF mechanism by adding new helper functions, including `bpf_create_slab_cache` and `bpf_create_buddy` to create dedicated regions, `bpf_get_zone` to obtain the requested zone (*e.g.*, normal zone or DMA zone), `bpf_cache_alloc` and `bpf_buddy_alloc` to allocate memory in the dedicated regions, and `bpf_set_pt_present` to set guard pages. The two BPF maps, region-index and obj2region, used in the eBPF program are both of type `BPF_MAP_TYPE_HASH`, which supports quick lookup and update. The maximum number of entries for both maps is set to 2^{14}, allowing the management of up to 16,384 dedicated regions. Our implementation is based on v5.15 the latest Long-term support (LTS) kernel version when we did our experiments. It can be easily migrated to other versions with minor modifications. We leverage the LLVM toolchain to compile eBPF programs.

Support for Loadable Kernel Modules (LKMs). In some corner cases, objects of interest are allocated and freed by loadable kernel modules. Without loading these modules, the attached address cannot be determined. To deal with this issue, we first install an eBPF program that attaches to the `load_module()` kernel function to monitor which module is loaded. Once the module is loaded, it sends out signals, allowing separation-purposed eBPF programs to be installed. Note that SeaK does not need the absolute address of the kernel module as the attached sites are based on symbols.

Support for Application Scenarios. To identify vulnerable objects that introduce corruption, we employ the approach in prior work [43] to analyze reports generated by sanitizers such as KASAN, KMSAN, KCSAN, and more. We pay special attention to the soundness of our analysis by including situations not previously considered. More specifically, some kernel objects are ordinary arrays and do not belong to any structure or union type (*e.g.*, `char* p = kmalloc(0x10)`). If we naively treat `char*` as the vulnerable type, SeaK will inevitably isolate a number of irrelevant arrays in the kernel, resulting in unnecessary overhead. Through investigation, we observe that these arrays are either referenced by a pointer field in a structure (*e.g.*, `bitmap_ip.members`) so that they can be used across system calls, or used as a temporary buffer that will be passed as a function argument, which can be tracked by our analysis. Therefore, for each array in the analysis, we create an anonymous type `type_name+offset` for differentiation. Here, `type_name` indicates the associated structure type (*e.g.*, `struct bitmap_ip`) and `offset` records the offset of the pointer field (*e.g.*, `members`). we patch the LLVM compiler to dump bitcodes before any optimization passes, thus preventing compiler optimization from influencing the accuracy of our analysis.

8 Evaluation

In this section, we use real-world cases to evaluate SeaK in terms of security improvement, performance and memory overhead, as well as scalability and stability.

[1] https://github.com/a8stract-lab/SeaK

Exploits	Sensitive Object Type	C1	C2	C3	SeaK

Table 3: Results of SeaK's security improvement for separating security-sensitive objects. The "Exploits" column includes CVE IDs and the internal exploit ID from Google. The "Sensitive Object Type" means the type of objects misused in the exploit. ○ indicates failing to prevent exploitation, ◑ stands for working occasionally due to the sampling nature, ● means succeeding in preventing exploitation.

8.1 Security Analysis

To evaluate the security improvement of SeaK, we draw a comparison between it and existing security features, no matter whether they are enabled by default or not.

Dataset & Criteria. We built two datasets corresponding to the two illustrative scenarios. The first dataset is for the scenario of separating security-sensitive objects. It includes seven exploits collected by Google and Alphabet Vulnerability Reward Program [36]. We didn't include all cases because the remaining lacks publicly available, functional exploit code. We selected this program as the data source because the program report clearly specifies which security-sensitive object is used in each case, which saves our time and avoids inaccuracies in identifying which type of object for separation.

The second dataset is for the scenario of separating vulnerability corruption. This dataset is constructed using vulnerabilities reported by Syzkaller [15]. Every case from Syzkaller encompasses a report, a configuration file, and a PoC program, all aiding in the reproduction of the vulnerability. We randomly selected 50 vulnerabilities reported after kernel version v4.15 [2], successfully reproducing 46 of them. These include 30 reported by KASAN, 1 by KMSAN, 1 by UBSAN, 5 by BUG_ON macro, 2 by GPF, and 7 by WARNING macro. The diversity within these vulnerabilities ensures that the dataset is representative.

Separating Security-Sensitive Objects. Table 3 shows the results of separating security-sensitive objects against the first dataset. In general, SeaK outperforms C1 (*i.e.*, freelist randomization + freelist obfuscation + heap zeroing), C2 (*i.e.*, structure layout randomization + KFENCE), and also C3 (*i.e.*, slub_debug=UFPZ).

For C1, all exploits can bypass by-default enabled features in it. First, freelist randomization essentially cannot prevent temporal corruption based exploitation (*e.g.*, exp1, exp3, exp9, exp13, exp15) and is bypassed using heap grooming [39] in the exploitation of spatial corruption based exploitation (*e.g.*, exp4, exp6). Second, freelist obfuscation and heap zeroing are not activated because no exploit tampers with freelist pointer and relies on uninitialized value for KASLR bypassing. Instead, they use the read capability introduced by the vulnerability to leak kernel base address.

For C2, structure layout randomization fails to prevent all exploits because it only randomizes structures with every field as a function pointer. None of the sensitive objects misused in the exploit fall into this category. KFENCE samples objects for separation. During the experiment, we maximized the capability of KFENCE by minimizing its sampling interval to 1 ms and expanding its memory pool to its limit of 512 MB. We discovered that it can protect only 0.005% - 0.35% sensitive objects in Table 3.

For C3, slub_debug successfully thwarts most exploits except for exp15. This exploit performs DirtyCred attack [44] which overlaps two cred carrying different levels of privilege, thereby evading detection through red zone, poisoning, and user tracking.

In comparison, SeaK prevents all exploits, showcasing the strongest security improvement. On one hand, guard pages and offset randomization hinder exploitation utilizing spatial overlapping, achieving the same effect as slub_debug. On the other hand, SeaK only recycles objects allocated from the same site, having the same size, carrying the same privilege level, and in the same zone. Therefore, it can handle not only common temporal overlapping attacks but also the newest same-type exploitation like DirtyCred. Moreover, when new attacks emerge in the future, SeaK supports updating the recycling policy correspondingly to keep pace with the evolving threat landscape.

Separating Vulnerability Corruption. Table 4 shows the sampled results for separating vulnerability corruption against the second dataset. The results share a similarity with the first scenario: C1 cannot restrict corruption, so is structure layout randomization in C2; KFENCE in C2 works occasionally if the vulnerable object is sampled. slub_debug can separate all corruptions when proactive attacks are not present.

FP and FN. To separate vulnerability corruption, SeaK identifies the vulnerable object and its allocation and free sites. During this process, SeaK can have False Positive (FP) - identifying objects that are not vulnerable or sites that allocating irrelevant objects, and False Negative (FN) - missing vulnerable objects or sites that allocate vulnerable objects. SeaK can accommodate FP by separating more objects at the cost of a minor increase in overhead, thanks to its scalability (See Section 8.2). The elimination of FN relies on the soundness of the analysis. To achieve this, we used the state-of-the-art techniques in implementation (See Section 7). However, it is important to note that, to date, no whole-program analysis is sound when applied to real programming languages [46]. Therefore, thouogh empirically SeaK didn't overlook any vul-

[2] LLVM is unable to compile kernel earlier than this version, and many eBPF features used in SeaK did not exist at the time.

SYZ Title	C1	C2	C3	Type of Identified Vulnerable Object	SeaK

Table 4: Sampled results of SeaK's security improvement for separating vulnerability corruption. More results can be found in Table 9. The "SYZ Title" column is the bug report title minus an uninformative preposition. Structures in bold in "Type of Identified Vulnerable Object" column are ground truth. The remainings are FPs. SeaK has no FN in all test cases. ○ indicates failing to prevent corruption from damaging other kernel objects, ◑ stands for working occasionally due to the sampling nature, ● means succeeding in separating corruption.

nerable object in all test cases (See Table 4 and 9), we must caution users about the risk of FNs - SeaK might occasionally fail to separate vulnerable objects.

Comparison with Other Works. Beyond C1, C2, C3, in Section 6.1, we mentioned several works also for object separation purpose. Among them, xMP [53] and kalloc_type [30] are comparable to SeaK security-wise. However, AutoSlab inadvertently simplifies cross-cache exploitation [40] because it separates kernel objects per slab cache which eases recycling at the buddy system level. Google slab_virtual's newest implementation [63] prevents temporal-corruption-based exploitation but partially works for spatial-corrution-based exploitation. Besides, it cannot handle DMA objects which must reside in DMA zone. On a different note, PET [66] prevents vulnerability triggering, focusing on a different stage of the exploitation chain from SeaK. It can miss vulnerabilities triggered through different paths or at different sites [43].

8.2 Overhead Measurement

Benchmarks and Settings. We employed identical benchmarks and settings including variances for measuring the overhead of SeaK as those utilized for the existing security features outlined in Section 3.2. In addition to the vanilla kernel image, we built a hardened kernel image incorporating the SeaK extensions. Both images have the BPF JIT engine enabled. Note that, we needn't build a different kernel for each individualAA. Once the SeaK extension is there, any number of AAs can be installed.

We used bpftrace to profile the lifespan of kernel objects for 20 minutes in two situations - no workload and running LMbench. The profiling revealed that most kernel objects are allocated and freed quickly while a small fraction of objects have long lifespan. No objects have both a long lifespan and frequent operations, as this combination would result in a substantial amount of objects lingering in memory, thus easily exhausting kernel memory.

Based on the profiling results, we consider three representative situations - Cold, Hot, and Durable. "Cold" refers to an object whose allocation and free rarely happen. We use KASAN-uaf-l2cap_chan_close [60] from the dataset for separating vulnerability corruption as an example of this situation, because its vulnerable object - `struct l2cap_chan` is allocated only in function `l2cap_chan_create` in the Bluetooth module. "Hot" indicates that the object is frequently allocated and freed, but has a short lifespan. Our profiling shows that `struct seq_operations` is the hottest in both no workload situation and running LMbench situation - allocated 32.7 times and 47.34 times per second respectively. "Durable" stands for an object that has a long lifespan and a moderate operation frequency. Our profiling suggests `struct cred`, `struct sk_filter`, `struct fdtable`, because they have 5s, 20s, and 30s lifespan. Further, we include `struct file` into our measurement because "Everything is a file".

Performance Overhead. Table 8.2 presents the performance overhead of the three representative situations. Intuitively, one would anticipate the overhead of "Hot" is the highest, given the correlation between performance and the frequency of allocation and free. However, the data illustrates that "Hot" doesn't show any significant increase compared to the other situations. Specifically, the overhead ranges from -2.42% to 2.70% for LMbench, and -1.73% to 1.64% for Phoronix, which is within reasonable margin of fluctuation and aligns with the data for "Cold" and "Durable". Therefore, we conclude that SeaK has negligible overhead, regardless of the benchmark and the use frequency of objects that are separated.

To further validate our conclusion and have a deeper understanding of SeaK's performance, we measured the latency caused by critical operations in SeaK. The potential overhead, if there is any, will come from eBPF program execution and

LMbench (ms)	Vanilla	Cold	Hot	Durable			File
Simple syscall	0.1942	-1.68%	-0.67%	0.06%	0.08%	-0.29%	-0.94%

Table 5: Performance overhead of `SeaK`. Vanilla indicates the baseline. The "Cold", "Hot", and "Durable" columns are three representative situations explained in Section 8.2. Especially, three columns in "Durable" indicate `cred`, `sk_filter`, and `fdtable` from left to right.

Operations	Time (ns)	Operations	Time (ns)
create region	13,320.93	idle handler	1,479.55
allocate from region	1,545.04	alloc handler	7,108.49
free to region	121.03	free handler	1,597.02
set guard page	280.64		

Table 6: Latencies of critical operations in `SeaK`. The idle handler represents an empty eBPF program; the alloc handler refers to the time in eBPF programs minus allocation helper function; the free handler is time in eBPF programs minus free helper function.

the creation of dedicated regions. Therefore, we inserted `rdtsc` instructions before and after these operations to collect the data. The results are presented in Table 6. As we can see, all latencies are below 0.02 ms, significantly smaller than the minimum time required for a system call - 0.1942 ms for simple syscall in Table 8.2. Among all operations, the most time-consuming one is "create region", taking 0.013 ms. It occurs only when a dedicated region is created - the AA performs allocation for the first time. Such a small overhead is unlikely to impact real-world applications - as doubly confirmed in Table 8.2.

Memory Overhead. The additional memory brought in by `SeaK` comprises the guard pages and the unused memory within the page(s) that hold the object. As two separated objects can share one guard page, the maximum memory wastage is 8KB for each 16B object. However, such extreme memory inflation is very rare, as our profiling indicates that 87.2% objects in the kernel are at least 64 bytes. Figure 5 presents the increased memory usage for various situations when running LMbench. Unlike existing features (Figure 2),

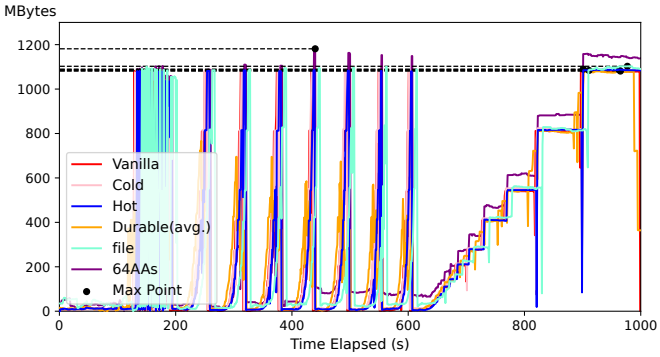

Figure 5: Increased memory usage of `SeaK` when running LMbench. The lines of all situations almost completely overlap with each other, except for 64 AAs (in purple). Durable (avg.) averages memory usage of `cred`, `sk_filter`, and `fdtable`.

the memory usage lines for "Cold", "Hot", and 'Durable (avg.)' almost completely overlap with Vanilla. On the one hand, it is because AA offers the most granular level of separation rather than indiscriminately protect every object all the time. Therefore, itself doesn't impose excessive memory overhead. On the other hand, no kernel object has a long lifespan while also being frequently allocated. Therefore, the memory consumed by `SeaK` is either quickly reclaimed, as seen in "Hot" and "Cold", or sufficiently small to remain unnoticeable, as in"Durable".

Comparison with Other Works. Besides C1, C2, C3, Section 6.1 mentioned several protections from academia and commercial products that are also for object separation. While the performance of kalloc_type [30] and AutoSlab [40] can not be evaluated due to their closed-source nature, a comparison can be made among `SeaK`, xMP [53], slab_virtual [63], and PET [66], based on publicly available results and our measurement in the same setting: xMP's average overhead for isolating `cred` using LMbench is 22.34% (calculated from paper's data), exceeding Seak's 1%. The Phoronix results of both are negligible. The average performance overhead of slab_virtual is 1.09% which is larger than SeaK-64 case's 0.4%. PET's performance overhead is 3% and memory overhead is 5.6% (915MB/16GB), as shown in the paper, while Seak's overhead is minimal in both.

8.3 Scalability & Stability Analysis

To deploy `SeaK` in the real world, it is essential to evaluate its scalability when multiple AAs are used. To measure this, we gathered all AAs from our security analysis and randomly selected additional security-sensitive objects identified in [65], to obtain in total of 64 unique AAs. We increased the number of installed AAs exponentially, without any specific order, and presented the averaged performance overhead in Table 7 (More complete results are in Table 8 in Appendix). The performance shows no noticeable degradation as the number

LMbench	2 AAs	4 AAs	8 AAs	16 AAs	32 AAs	64 AAs
Avg.	-0.32%	0.0%	-0.55%	0.01%	0.20%	0.04%
Phoronix	**2 AAs**	**4 AAs**	**8 AAs**	**16 AAs**	**32 AAs**	**64 AAs**
Avg.	-0.28%	-0.74%	-0.33%	-0.31%	0.71%	0.22%

Table 7: Performance of SeaK scaling up to 64 AAs. More detailed results are in Table 8.

of AAs grows, regardless of the benchmark used. This is because one single AA, no matter for cold or hot objects, has negligible overhead. Regarding memory overhead, Figure 5 shows that the memory usage of 64 AAs is on par with Vanilla, with occasional variances up to 100MB. Such intermittent overhead is negligible for modern OS which has access to the entire physical memory - often multiples of 4GB - owing to SDRAM technology. To conclude, SeaK is scalable when multiple AAs are present.

Regarding stability, we enabled all 64 AAs on the machine used for daily research and education activities, including Overleaf, Outlook, Zoom meetings, ChatGPT, Docker containers for CTF challenges, and plugining/unplugining peripherals. Over nearly 2.5 months, the machine maintained consistent stability without encountering any issues.

9 Discussion & Future Directions

eBPF Alternatives and Security Issues. SeaK employs the eBPF ecosystem because it is safe, expressive, efficient, and only privileged users can install eBPF programs. Without considering these advantages, there are alternatives of eBPF ecosystem like Kprobe. Kprobe stores raw data rather than structures data in kernel memory and relies on a userspace process to be in charge of data sharing between modules. Starting from Kprobe, we need to reinvent the wheels already provided by the eBPF ecosystem. This requires significant engineering efforts and inevitably incurs higher performance overhead due to additional kernel-user switches for data sharing.

A recent work EPF [34] reveals that attackers can misuse BPF code as gadgets for code reuse attacks. Furthermore, the eBPF ecosystem was previously reported to contain vulnerabilities [12–14]. Though addressing these security issues are orthogonal to SeaK, it remains worthwhile to pay attention to the downsides of eBPF in the deployment of SeaK.

Hardware Support. SeaK relies on randomization and guard pages to separate objects within dedicated regions. While the entropy stands strong at 43, it can be further strengthened through hardware features or hypervisor features if present. Some promising memory protection features include Intel MPK, Arm protection domain, and RISC-V Donky [58], and Xen. However, considering that many devices, especially embedded ones, lack these features, we choose not to integrate them into SeaK at this time to maintain its broad applicability. In the future, we will release new versions to leverage these features specific to different platforms.

Extending to stack. Though SeaK is designed as a kernel secure allocator, it can be extended to prevent stack attack. For example, we can attach eBPF programs to functions where stack overflow might happen, recording the value of the return address in BPF maps at the function entry and examining its integrity at the function exit. We will integrate this extension into SeaK in the future.

10 Related Works

Heap security features from the upstream kernel have been evaluated in Section 3 and those from academia and commercial products have been compared with SeaK in Section 8.

The remaining related works are secure allocator in user space, which employs safe design principles and randomized mechanisms to mitigates heap vulnerabilities. Typically, these allocators separate in-place metadata from the object and randomize both the allocation and reuse of memory. Notable examples include DieHard [19] and its successor DieHarder [48], which rely on abundant memory space to allocate more memory than required and randomize object locations. FreeGuard [59] enhances performance by integrating the security features of BIBOP-style allocators with the rapid allocation capabilities of freelist-style allocators. Guarder [57] refines FreeGuard by fine-tuning the level of entropy, while SlimGuard [45] improves memory efficiency through fine-grained memory class management. While SeaK benefits from its user-space counterparts, certain features are not applicable to kernel space. For example, the kernel doesn't have infinite memory which is commonly assumed in these works.

In addition to general-purposed secure allocators, there are specialized allocators focusing solely on mitigating use-after-free vulnerabilities. Cling [50] ensures that freed objects are reused only if their types match, identified through runtime call stack analysis. MarkUs [17] employs garbage collection principles to free objects when no dangling pointers reference them. Oscar [62] and FFmalloc [20] operate under the assumption of unlimited memory space, allocating objects once and never reusing them. Vik [23] assigns IDs to allocated objects and permits only pointers with matching IDs to access the object, optimizing overhead through ARM hardware features. These specialized allocators are generally unsuitable for kernel space because their assumptions do not apply there. Besides, they are overly specific to certain vulnerability type while SeaK generally works.

11 Conclusion

This work presents SeaK, the first practical secure allocator in the kernel that substantially strengthens heap security without

introducing noticeable overhead. It is anchored in a new strategy of designing a secure kernel allocator, centering around the "atomic alleviation" concept. This new strategy is derived from in-depth analyses of existing kernel heap security features and is further validated by comprehensive evaluation of SeaK in terms of security improvement, performance and memory overhead, scalability, and stability.

Table 8: Complete results for the performance of SeaK scaling up to 64 AAs. Corresponding sampled results are in Table 7.

A Additional Results

Due to the space limit, we only present sampled results in the text. In Google Sheet [18], we present more results regarding memory usage of existing features and SeaK when running Phoronix. In addition, Table 8 presents more complete results regarding SeaK's scalability in performance. Table 9 shows the FN and FP results of static analysis for separating vulnerability corruption. List 2 shows an example of synthesized eBPF program.

Abstract

Recently, a novel method known as Page Spray emerges, focusing on page-level exploitation for kernel vulnerabilities. Despite the advantages it offers in terms of exploitability, stability, and compatibility, comprehensive research on Page Spray remains scarce. Questions regarding its root causes, exploitation model, comparative benefits over other exploitation techniques, and possible mitigation strategies have largely remained unanswered. In this paper, we conduct a systematic investigation into Page Spray, providing an in-depth understanding of this exploitation technique. We introduce a comprehensive exploit model termed the DIRTYPAGE model, elucidating its fundamental principles. Additionally, we conduct a thorough analysis of the root causes underlying Page Spray occurrences within the Linux Kernel. We design an analyzer based on the Page Spray analysis model to identify Page Spray callsites. Subsequently, we evaluate the stability, exploitability, and compatibility of Page Spray through meticulously designed experiments. Finally, we propose mitigation principles for addressing Page Spray and introduce our own lightweight mitigation approach. This research aims to assist security researchers and developers in gaining insights into Page Spray, ultimately enhancing our collective understanding of this emerging exploitation technique and making improvements to the community.

1 Introduction

The Linux operating system, known for its complexity, has gained widespread popularity in today's world. It serves as the foundation for critical real-world components, including cloud systems, infrastructure web servers, and various customized operating systems.

To defend Linux against potential threats, developers and designers have implemented a range of protective and mitigation techniques, such as SMEP [21], SMAP [41], and KASLR [14], operating at different levels. In response to these defensive measures, security researchers have innovatively introduced new exploitation techniques and made assessments, such as Elastic Objects [3], K(H)eaps [46], and DirtyCred [30], to circumvent these security "barriers" during exploitation.

As the field of exploitation techniques continues to evolve, there remains an ongoing discourse on refining and enhancing control over kernel-heap granularity. Among these techniques, Linux Kernel Heap Object Spray stands out as the predominant method. Heap Object Spray has found utility in exploiting a variety of common vulnerabilities, including Use-After-Free (UAF) [13], Double Free (DF) [12], and Out-of-Bounds (OOB) [10, 11] vulnerabilities. These traditional approaches primarily center around the manipulation of heap object granularity.

In recent times, a page-level exploitation technique has made its appearance in high-quality exploits, which differs from traditional object spray in control granularity. The capability to control and execute data spraying at the page level introduces new possibilities, not only for offensive security researchers but also for defense and mitigation designers approaching security challenges from various angles.

Despite being an emerging technique in Linux kernel exploitation, the security impact of Page Spray has been underestimated, and Page Spray has been considered obsolete to modern Linux systems. Prior Page Spray attacks [45][1] only work under constrained memory environments (hundreds of MBs memory) where the Linux operating system will allocate kernel-freed physical pages for user-space memory requests when the system is under memory pressure. Such situation unlikely happens in modern Linux systems as memory increases significantly and that modern Linux operating systems will kill a memory-intensive user-space process to handle extra user-space memory requests under memory pressure. Therefore, prior Page Spray attacks no longer work in modern Linux operating systems.

However, we discover that Page Spray can still work through new methods. The original page attack relies on user pages for spraying, which will not work in currently normal scenarios due to the separate allocation of user pages and SLUB pages in distinct memory zones. Previous research

[1] This paper names Page Spray physmap-based attacks. We use the term "Page Spray" in this paper since this name is more broadly used in the Linux kernel security community.

indicated that during periods of intense memory pressure, the page allocator might allocate user pages to the kernel page zone, facilitating page-level reuse. However, this practice is no longer feasible due to the increase in device memory, posing a risk of destabilizing the kernel and triggering OOM kill. In contrast, the method in our study works effectively under current standard conditions without stressing kernel memory. Instead of leveraging user-space memory allocation, it uses kernel-space callsites to invoke Page Spray within the kernel.

Furthermore, the contribution of our work is **not only to analyze the methodologies of Page Spray, but also is a comprehensive study on many aspects of it that have not been studied before**, such as its root cause, exploitation effectiveness & stability, and how it can be mitigated with existing approaches as well as our own proposed approach.

To this end, we systematically unravel and formalize its exploitation model, accounting for various scenarios and circumstances.

Moreover, we delve into the origins of this technique by scrutinizing kernel code across different subsystems, ultimately identifying three root causes: Raw Page-Level Buffer, Non-linear Page Frags Buffer, and Mmap & Zero Copy Calls. These root causes unveil inherent security risks at the design level within the Linux Kernel. We propose an analysis model and develop an LLVM-based analyzer to facilitate the identification of potential and potent Page Spray invocations within the Kernel. Leveraging these analysis tools, we successfully pinpoint 21 callsites within the Kernel that can be used in Page Spray exploitation.

Additionally, we demonstrate Page Spray's distinctive advantages, highlighting its unique attributes concerning exploitability, stability, and compatibility through real-world evaluations. Furthermore, we delve into the principles of mitigating Page Spray, introducing our lightweight mitigation approach. Our research uncovers intriguing insights, such as Page Spray's ability to transform seemingly challenging-to-exploit or even previously unexploitable vulnerabilities into viable targets for security researchers. At a practical level, **we have successfully applied this technique to various contexts, including Desktop Ubuntu, Android Kernel [31], and Cloud Environment in Google kCTF [22], won the novel exploitation award, and some of which have involved zero-day exploits.**

In summary, this paper makes the following contributions:

- We provide a well-structured and comprehensive formalization of the Page Spray exploitation technique. Our model showcases the compatibility and adaptability of Page Spray across various vulnerability types.
- We conduct a methodical evaluation of the exploitability and stability of the Page Spray exploitation technique. This emerging and promising technique has been relatively unexplored, making our study a valuable addition to the understanding of Page Spray.
- We systematically analyze the root causes of Page Spray Exploitation within the Linux Kernel. Our analysis identifies key design-level security risks, categorizing these into three distinct root causes. We also introduce an analysis model, and implement it as a LLVM-based analyzer for Page Spray to identify the occurrences of such root causes in the kernel.
- To raise awareness within the community, we discuss and evaluate general and potential mitigation techniques for countering Page Spray exploitation. Additionally, we introduce a lightweight mitigation approach.

2 Background

2.1 Kernel Heap Allocator

To enhance memory performance and reduce fragmentation, the Linux kernel has incorporated the concept of an object-based allocator for managing kernel heap objects.

Among various heap allocators [1, 7, 34], the SLUB allocator is the most common one in Linux. From a higher-level perspective, the heap allocator in the Linux kernel can be conceptualized as a cache size-based allocator, closely linked to the page allocator, which will be comprehensively discussed in the subsequent subsection. The "cache" serves as the meta-structure for managing various heap objects within the allocator. At the cache granularity level, the kernel allocates memory pages from the page allocator and divides them into uniform-sized fragments, each serving as a memory slot for maintaining a heap object. Throughout the cache's lifecycle, as the available memory within a cache is being exhausted, the kernel allocates additional pages from the page allocator and assigns them to the heap allocator to supplement the memory pool. Conversely, when a specific cache is no longer in use, i.e. there are no more in-use objects within the cache, the kernel prioritizes the recycling of allocated pages, returning them to the page allocator for potential reuse.

2.2 Kernel Page Allocator

Kernel page allocator serves as the underlying foundation for kernel heap allocator. This interaction comes into play when the heap allocator either recycles or reclaims pages. The buddy system, which has emerged as a prominent algorithm for memory allocation within the page context, operates by dividing the available memory into blocks. These blocks adhere to a uniform size, with each block possessing dimensions that are exact powers of two.

Linux kernel implements distinct memory zones, each carrying specific attributes aimed at optimizing page allocation. Within each zone, a reserve of free memory is maintained to facilitate page allocation. In free memory areas, free pages are organized into separate linked lists based on their size and attributes, with each list representing pages of a specific size and attribute. When a page allocation request is initiated,

the kernel identifies the most suitable match of free pages by considering the allocation attributes and the required size.

Moreover, the node within the `kmem_cache` serves as a structural component monitoring partially full and full slabs within a specific node in a NUMA system. For instance, if a newly allocated object is the final available object within the CPU slab, then the associated "active" slab is transferred to the full list corresponding to its node. Simultaneously, the first slab from the CPU slab's partial list is newly designated as the "active" slab.

GFP (Get Free Pages) flags. GFP flags serve as a means to characterize the attributes of page allocation. Different GFP flags, assigned by higher-level components, have the potential to yield different fundamental behaviors. For example, when utilizing `GFP_DMA` and `GFP_DMA32` flags, the kernel is instructed to ensure that the allocated memory is accessible by hardware with limited addressing capabilities in DMA.

Fallback operation. During the allocation process, beginning at the zone level, the kernel diligently scrutinizes the selected memory zone to ensure a close match with the desired attributes. A comprehensive evaluation is conducted to determine the suitability of the chosen zone for the allocation. In instances where the assessed zone is found to be unsuitable, the memory allocator may proceed to revert or fallback to alternative memory zones for allocation.

3 Threat Model

In our established threat model, we assume that, in a real-world exploitation scenario, an adversary gains access to unprivileged permissions within the Linux environment and aims to exploit a kernel vulnerability related to heap memory corruption such as UAF, DF, and OOB as a means to escalate their privileges. It is important to note that we take into consideration typical security protections and mitigations that are enabled on most real-world Linux systems, including KASLR [14], SMEP [21], SMAP [41], KPTI [35], FREELIST RANDOM [16], HARDENED FREELIST [37], CFI [15]. For Android cases, we also include KCFI [17], and Memory Tagging [47] on Pixel devices.

Mitigations that are not integrated in the mainline Linux kernel at the time this paper was written, such as AUTOSLAB and SLAB VIRTUAL, are not included in our threat model. However, to provide a comprehensive study, their effectiveness against Page Spray's exploitability is still studied, dicussed and analyzed in Section 9.2.

Furthermore, we make the explicit choice to exclude any hardware-level vulnerabilities or side-channel mechanisms that might be leveraged to facilitate the exploitation process. Finally, we do not account for variations in architecture codes within the Linux kernel as part of our analysis.

4 Page Spray Exploit Model Analysis

In this section, we provide a high-level overview of the exploitation model associated with Page Spray, drawing from our extensive analysis. We break down the Page Spray technique into four main steps, showing how it operates during the exploitation of kernel heap vulnerabilities. Furthermore, we showcase the versatility of Page Spray by demonstrating its applicability to different types of vulnerabilities.

4.1 Basic Exploitation Model

We now introduce a foundational exploitation model for Page Spray, which we denote as DIRTYPAGE. This model is presented at a high level to offer a clear understanding without delving into excessive technical intricacies.

DIRTYPAGE operates by employing three key types of heap objects: (1) *padding objects* are responsible for occupying specific positions in the heap memory, (2) *vulnerable object* corresponds to the case-specific object capable of triggering the vulnerability, (3) *victim object* represents the object that is intended to be corrupted by the end of DIRTYPAGE. In our model, *padding objects* and *victim object* can be chosen independently of the vulnerability. However, in order to easily adapt DIRTYPAGE to different vulnerabilities and increase stability, we choose *padding objects* that have controllable size and can be sprayed rapidly on a desired slab cache (such as `msg_msg`, `iovec`, `user_key_payload`, etc.).

Much like a UAF vulnerability that results in a dangling reference to a freed heap object, DIRTYPAGE aims to achieve a dangling reference to a freed memory page from a reference to the *victim object*, leveraging the primitives provided by the *vulnerable object*, by triggering vulnerabilities such as Double Free, Invalid Free, UAF, and others. In Figure 1, we illustrate the DIRTYPAGE model for exploiting a Double Free vulnerability.

In the first step, we initiate a series of allocations to occupy a slab S in a designated slab cache with a specific pattern of objects: *padding objects* - *vulnerable object* - *victim object* - *padding objects*, in a way that the *vulnerable object* and the *victim object* reside in the same page P. To achieve this arrangement, we spray *padding objects* twice - once before the allocation of the *vulnerable object* and *victim object*, and once after. Suppose there are N objects per slab in this cache, we now have S populated with one *vulnerable object*, one *victim object*, and $N-2$ *padding objects*.

To achieve a dangling reference to a freed page P, we must ensure that S is to be discarded so that all the memory pages it contains are returned to the page allocator. This requires the deallocation of exactly N objects within S, while still maintaining a reference to the *victim object*. We accomplish this by initially freeing all $N-2$ *padding objects* and then exploiting the Double Free vulnerability to free the *vulnerable object* twice. This operation results in the slab allocator recognizing two separate deallocations, coupled with the $N-2$ deallocations of the *padding objects*, resulting in a total of N deallocations within S. Importantly, the *victim object* remains unaffected and its reference is preserved.

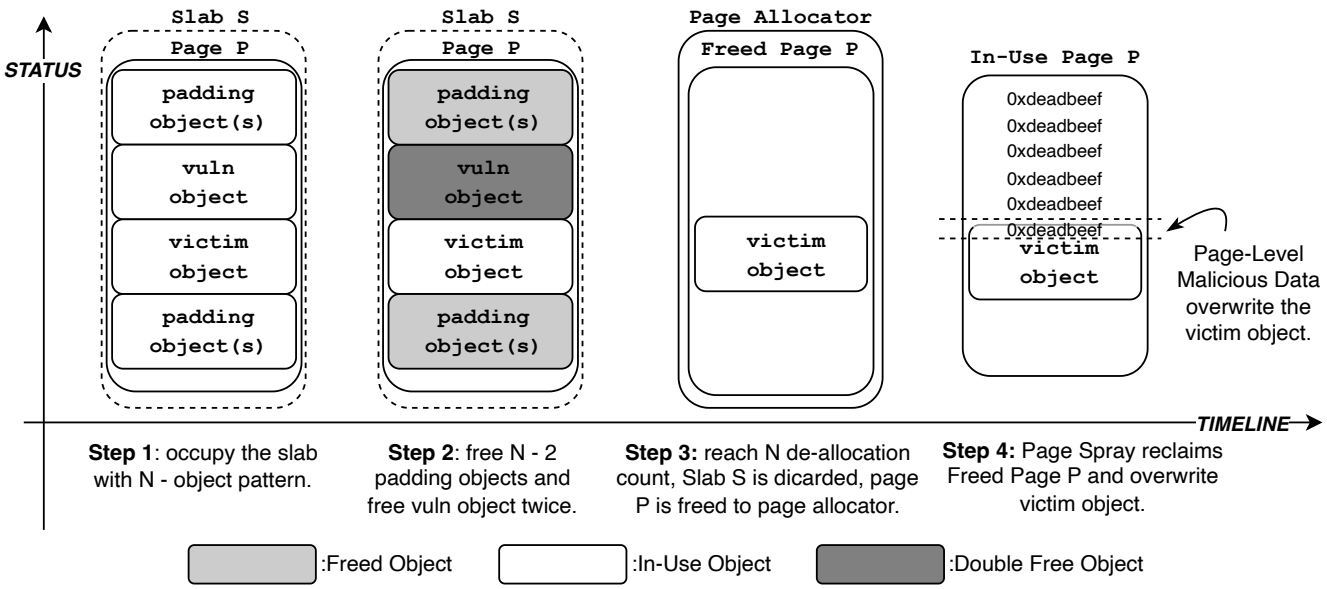

Figure 1: Page Spray Exploit Model for Double Free.

Subsequently, *S* is discarded, initiating the page recycling process, which returns *P* within *S* to the page allocator. Following the recycling of pages, we initiate page-spraying operations from the user space that are capable of triggering direct page allocations (they will be referred to and explained in Section §5 as *page-spraying callsites*). Simultaneously, in the kernel space, corresponding page allocations are substantially sprayed, effectively reclaiming the slab pages freed in the previous step, including *P*. This operation facilitates the direct injection of malicious page-level data into the kernel. Notably, regarding *P*, the maliciously crafted page-level data overwrites the data within the *victim object*. For instance, if the *victim object* is a `pipe_buffer`, the adversary gains control over the `ops` field, which is a pointer to its operations function table.

4.2 Model Variants

In different scenarios, the DIRTYPAGE technique can adapt to various variants. When dealing with a UAF vulnerability, it is possible to optimize the model by having the *victim object* and the *vulnerable object* as a single object. This optimization arises from the fact that the UAF object can be inherently freed, eliminating the need for deceiving the allocator and simulating the freeing of all objects. Instead, we can efficiently free all the objects within the slab and still naturally maintain a reference to the freed UAF object.

Moreover, straightforward privilege escalation can be achieved (we achieved this in CVE-2022-2588 [9]). To accomplish this, we make adjustments to the specific data used in the Page Spray process, focusing on the `cred` object. After constructing a fake `cred` object in user space, during the page reclamation step, we employ Page Spray to inject a multitude of these fake `cred` objects, overwriting the real credentials in memory pages by writing to pipe pages. Once the target credential is hijacked, the privilege escalation process succeeds.

Finally, cross-cache technique can also be integrated into the DIRTYPAGE model as a plug-in component, depending on the specific object being exploited or the nature of the *vulnerable object*.

4.3 Model Adaptability

The model described in the preceding subsections is noteworthy because it relies solely on the fundamental nature of the vulnerability itself. Whether it involves an extra free operation in the case of a Double Free or Invalid Free bug, or a dangling reference to a freed object in the case of a UAF, the model remains agnostic to the specific characteristics of the *vulnerable object*. This key feature allows Page Spray to be independent of the attributes of the *vulnerable object*, making it an orthogonal approach to addressing vulnerabilities.

This characteristic presents a significant advantage of Page Spray when compared to traditional methods such as heap object spraying. The exploitability of these conventional methods is heavily influenced by the level of control that can be exerted over the *vulnerable object*. In contrast, Page Spray enables attackers to reuse the entire model with minimal modifications when targeting different vulnerabilities of the same type. This flexibility and independence from the specific attributes of the *vulnerable object* enhance Page Spray's effectiveness in exploiting a wide range of kernel vulnerabilities.

5 Root Cause of Page Spray

In this section, we focus on analyzing the root cause of the Page Spray exploitation technique. Additionally, we provide real-world case analysis to aid in understanding.

5.1 Existence of Fast Page-level Operations

Based on the high-level exploitation model shown in Figure 1, page spraying in the Linux kernel heavily depends on the use of *page-spraying kernel callsites* to achieve Step 4. The primary distinction between page-spraying callsites and regular page-allocation functions lies in the control they offer over data within kernel pages. Page-spraying callsites not only allocate pages but also provide opportunities for attackers to manipulate page-level memory spaces directly (compared to indirect operations like SLUB subsystem), allowing them to place malicious page-level data as desired.

After diving into the kernel codebase and analyzing concrete patterns that allow attackers to control page allocation and its content, we categorize page-spraying callsites into two main types: Copy-Write Calls and Remapping Calls. The design of these two types of calls primarily revolve around enhancing system performance. Specifically, during periods of high memory demand in the system, the smaller non-page-level buffers prove insufficient for promptly storing the substantial data volume. Consequently, the system requires the rapid allocation of larger page-level buffers, leading to direct page-level allocations.

As for the scenario in remapping (zero-copy) callsites. Considering the sensitivity of performance-critical functionality, performing multiple data copies between user space and kernel space incurs significant performance overhead. As a result, the concept of zero-copy design emerged, where the kernel dynamically allocates page-level buffers at runtime and shares these memory regions with the user space as needed in order to reduce the aforementioned overhead and increase data handling capacity.

These designs play irreplaceable roles in ensuring the kernel's performance and reliability. Their presence is essential for maintaining high availability and enhancing overall performance. Consequently, it is impossible to eliminate or reduce them as part of any mitigation strategy within the kernel. In other words, the root cause of Page Spray cannot be eliminated.

5.2 Copy-Write Call Mode

To elaborate on this call mode, we can identify two sub-types of copy-write operations. It's essential to note that both of these sub-types of calls can be employed with Page Spray techniques. However, it's crucial to highlight that their low-level design intricacies differ within the Linux Kernel.

Raw Page-Level Buffer. In consideration of the kernel's design, several subsystems incorporate a function that initially sets up a buffer and subsequently triggers and writes to this buffer as needed. An example of this can be observed in the code snippet shown in List 1, which is part of the pipe subsystem.

```
1  struct pipe_buffer {
2          struct page *page;
3          unsigned int offset, len;
4          const struct pipe_buf_operations *ops;
5          ...
6  };
7  static ssize_t
8  pipe_write(..., struct iov_iter *from) {
9  for (;;) {
10     if (!page) {
11         page = alloc_page(GFP_HIGHUSER | __GFP_ACCOUNT);
12         ...
13     }
14     buf->page = page;
15     copied = copy_page_from_iter(page, 0, PAGE_SIZE,
       ↪  from);
16     }
17 }
```

Listing 1: Copy-Write implementation in Pipe subsystem.

Within the pipe subsystem, a meta-control structure responsible for buffer management is referred to as `pipe_buffer`. This structure employs a pointer to page(s) to locate and access the actual buffer when there's a buffer-write request originating from user space. In the `pipe_write()` function's operations, after simplification, it's evident that the kernel's intention is to first allocate multiple pages as required. Subsequently, these allocated pages are assigned to the page buffer pointer inside the corresponding `pipe_buffer` object. Finally, the function `copy_page_from_iter()` is invoked to carry out the specific copy-write operations.

It's worth mentioning that when the `pipe_buffer` is generated and initialized, the page buffer is not allocated and assigned immediately in practice. Instead, the kernel defers the allocation of page buffers until a buffer's copy-write request is received and processed. This represents a delay-allocation strategy employed by the kernel for page buffers.

Non-linear Page-Frags Buffer. Within the networking subsystem, the structure known as `sk_buff` [25] is responsible for representing network packets. To focus solely on relevant details, we concentrate on the buffer aspects and omit unrelated components. In this context, the design of the buffer can be divided into two types: linear buffer and non-linear buffer.

The linear buffer is allocated at the early stage of `skb` creation and primarily serves to hold protocol headers and a portion of actual data. Page allocation does not occur at this initial stage. On the other hand, the non-linear buffer comes into play when the linear buffer is unable to provide sufficient memory space for data storage. The organization of the non-linear buffer resembles multiple fragments, with each fragment maintaining a specific page as the data buffer. The kernel employs copy-write operations to transfer data from user space to these continuous page fragments.

```
typedef struct bio_vec skb_frag_t;
static int packet_snd(struct socket *sock, struct
  ↪ msghdr *msg, size_t len) {
    ...
    skb = packet_alloc_skb(sk, hlen + tlen, hlen, len,
     ↪ linear, msg->msg_flags & MSG_DONTWAIT, &err);
    ...
    err = skb_copy_datagram_from_iter(skb, offset,
     ↪ &msg->msg_iter, len);
}
```

Listing 2: Copy-Write implementation in Packet Address Family.

In the relevant function `packet_snd` (as seen in List 2), an `skb` is generated by `alloc_skb_with_frags()` in lower level, which is called to allocate page fragments as buffers. Subsequently, the `skb_copy_datagram_from_iter()` function manages the copy-write process by invoking `copy_page_from_iter()`. When the kernel initiates the copy-write procedure, the page fragments are transformed into real page addresses using the `skb_frag_page()` function.

5.3 Remapping Call Mode

In this subsection, we discuss another major type of Page Spray calls, remapping calls. To demonstrate the Page Spray's ingenious invoking mode, we also introduce code segments to illustrate its nature and particularized implementation in kernel. We will discuss the copy-write and zero-copy design in Linux Kernel, then explore in depth the model.

Mmap & Zero Copy Calls. Typically, when a user-space application executes a `mmap()` call to establish a new mapping in the virtual address space of the calling process, the kernel primarily grants access rights to the virtual address as the return value of this call.

When we delve into the kernel implementation, we found the zero-copy mechanism facilitated by memory mapping opens up opportunities for Page Spray. Where data copy operations occur between a user process and kernel space, the boundary between these two memory address spaces often necessitates checks for operation validity and data reconstruction in the kernel space. Therefore, copy operations that traverse the boundary between user processes and kernel space can raise significant performance concerns, especially in subsystems that prioritize performance, such as the networking subsystem. To address this challenge and improve overall system performance, Linux incorporates a zero-copy design. With zero-copy, data transfer between kernel space and user processes reduces the additional overhead introduced by memory copies.

In this design, user-space processes explicitly set (ring) buffer attributes, and the allocated pages are organized into multiple page-related structures. When a process from user space perform a `mmap()` call, its detailed implementation and execution are redirected by the corresponding kernel function tables based on the socket's attributes. For instance, when

```
1  static int packet_mmap(..., struct vm_area_struct
   ↪ *vma){
2  ...
3  for (i = 0; i < rb->pg_vec_len; i++) {
4      struct page *page;
5      void *kaddr = rb->pg_vec[i].buffer;
6      int pg_num;
7      for (pg_num = 0; pg_num < rb->pg_vec_pages;
        ↪ pg_num++) {
8                  page = pgv_to_page(kaddr);
9                  err = vm_insert_page(vma, start, page);
10         ...
11         }
12     }
13 }
```

Listing 3: Example codes of mapping in packet mmap.

setting up a packet ring buffer in PF_PACKET, the `mmap()` call is executed by the `packet_mmap()` function in the kernel (as seen in List 3). In this implementation, the page-related structure it introduces is page-vector, which can be used to maintain a reference to a valid page and akin to the previously discussed skb page-fragments. The kernel first transforms a page-vector to a raw page reference in Line 8 3. Subsequently, in the next line, `vm_insert_page()` is invoked to insert the target page into the virtual address mapping space of the user space process. After this insertion, the user space process gains the right to achieve direct memory write operations to the page. In other words, at this stage, the related user process becomes capable of spraying data onto pages which allocated by the kernel space.

The zero-copy mapping mechanism leads to a page of memory explicitly shared between kernel space and user space, allowing bad actors to overcome previous limitations. What sets zero-copy mapping apart from other methods is that it inherently allocates pages for data (ring) buffers and makes them accessible to user space. In this scenario, user space gains flexible control over memory allocation and writing behaviors. For example, user space can explicitly call `packet_set_ring()` to specify the number of pages to allocate (as shown in List 4), where the `req` variable represents the ring buffer configuration request sent from the user process.

Furthermore, zero-copy mapping introduces kernel virtual address space overlaps between slab pages and zero-copy pages, providing a fundamental support for Page Spray. This means that a page discarded by the kernel heap's slab allocator can be reclaimed through zero-copy operations and remapped to the memory space of the user space process.

6 Static Analysis Model

To understand the extent to which Page Spray impacts the security of the kernel, it is crucial to comprehend the prevalence and generality of Page Spray in the Linux kernel. While manually identifying all potential call sites is the most straightforward approach to consider, the intricacy of the Linux kernel

```
static struct pgv *alloc_pg_vec(struct tpacket_req
  ↪ *req, int order){
    unsigned int block_nr = req->tp_block_nr;
    pg_vec = kcalloc(block_nr, sizeof(struct pgv),
     ↪ GFP_KERNEL | __GFP_NOWARN);
    for (i = 0; i < block_nr; i++) {
        pg_vec[i].buffer = alloc_one_pg_vec_page(order);
        ...
    }
}
```

Listing 4: Example codes of page allocation in packet ring-buffer setting.

codebase makes manual selection relatively impractical and inadequate for supporting a large-scale comprehensive study.

To tackle this challenge and offer a systematic comprehension, we introduce our static analysis model designed to scrutinize the Linux kernel codebase. Furthermore, leveraging this model, we develop an automated static analyzer tool and apply it to the kernel codebase.

In this section, we introduce our static analysis model aimed at pinpointing the crucial page-spraying call sites within the Linux Kernel through a combination of control-flow analysis and data-flow analysis.

6.1 Static Analysis Methodology

Copy-Write Callsites. To identify Copy-Write page-spraying callsites, our approach involves the analysis from root interfaces, which we categorize into two distinct types: allocation and copy root interfaces.

Allocation root interfaces primarily serve the purpose of executing direct page allocation or functioning as wrapper functions within specific subsystems to accomplish such allocations. It is worth noting that, although some page allocations occur in the kernel heap slab allocator, we do not consider those as the qualified callsites for Page Spray. The distinction here arises from the granularity of operations within the slab allocator, which operates at the object-level rather than the page-level, and in Page Spray, we consider direct page-level allocation.

On the other hand, copy interfaces are mainly associated with copy-write functions in the kernel. These interfaces are capable of transferring of data from user space to the kernel's page buffers. Through these operations, user processes gain the capability to manipulate data at the page level. Because our data copy are based on the "benign" operations, such as copying a data to kernel space networking buffer and so on, it natively will not trigger any defense or mitigation like SMAP which is designed for enhancing islation between user space and kernel space.

To systematically identify callsites, we build a global-level callgraph in the kernel to capture inter-function control flow information. Each function call is represented as a node within this graph. We initiate our search by tracing backward from two root interface call nodes: one pertaining to allocation and

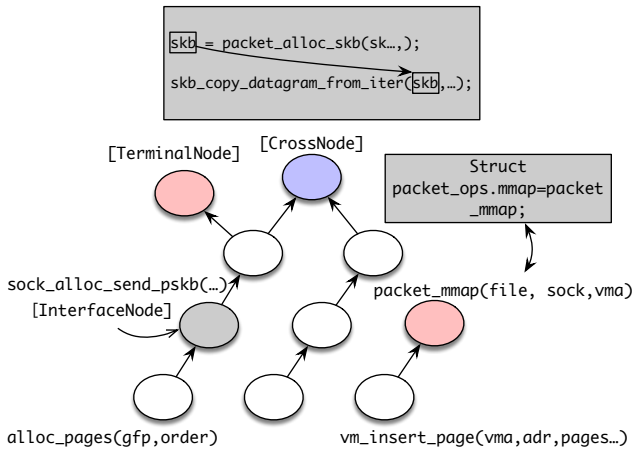

Figure 2: Page Spray Invocation Model. Each node indicates a specific function in the overall CallGraph. `skb` is the structure which is binded with page frags.

the other to copy operations. As we traceback paths from root interfaces, we identify nodes where the paths intersect. These nodes are marked as potential callsites at the control flow level.

Then, to enhance the accuracy, we employ fine-grained data flow analysis. This entails conducting data flow analysis inside individual nodes. Our data flow analysis is guided by two specific instruction points. We ensure that the allocation instruction precedes the copy-write operation. Subsequently, we proceed to a search process from the allocation points to the copy-write points, with the aim of ascertaining whether the corresponding data transmission occurs between them. Specifically, if the allocation operation allocates pages and assigns them to a certain position in a control structure, and the subsequently corresponding copy-write operation writes data to that same position of the structure, we recognize this as a valid callsite.

Remapping Callsites. On the contrary, when examining zero-copy calls, these are tightly linked to the function tables of specific subsystems, such as the `packet_ops`, in various protocol families. Therefore, in our analysis, we start by traversing the structures of these function tables at an early stage and gather pertinent information regarding function pointer members. Of particular interest is the mmap-related function pointer, which directs the mmap-execution-flow to the actual implementation in the kernel. Much like in our previous analysis, zero-copy mmap calls also contain memory remapping root interfaces. For instance, `vm_insert_page()` is responsible for inserting a single page into a user's virtual memory area, and `remap_pfn_range()` facilitates the remapping of kernel memory for sharing with user space processes.

In the zero-copy mapping model analysis, these root interfaces are also treated as nodes at the control flow level. During our analysis, we trace back from these nodes. When we encounter a specific `*_mmap` function that aligns with the

mmap function within a function pointer found in our collected function tables, we preliminarily consider it as a zero-copy remapping callsite. Furthermore, at the data flow level, we apply forward dataflow analysis and backward dataflow analysis. We backtrack from the allocation root interfaces to ascertain whether the same control structure is employed both in allocation and remapping. If we identify a structure that connects allocation with remapping, we recognize the callsite as a valid zero-copy remapping type page-spraying callsite.

Optimization. As illustrated in Figure 2, the interface nodes represent the starting points for one-time search. While there are some raw nodes positioned beneath these interface nodes, we have opted to exclude these nodes to simplify the backtrace process. Like the pruning operation, the terminal nodes point to functions that we've encountered during the analysis but are not intended to be traced back to their higher parent function nodes. The introduction of this is necessary for several reasons. Firstly, in the slab allocator, there are functions that rely on the page allocator but do not directly trigger page allocation, like `kmalloc()`. Although indirect allocation may occur when a new slab allocation is executed, it does not align with the scenarios capable of triggering Page Spray. Secondly, the backtrace operations may have reached their maximum limit, so they terminate as we expect. Lastly, there are sections of code within the kernel that are exclusively available on specific architectures or hardware. In such cases, we dissociate the results from these code segments to ensure accuracy and relevance.

It is crucial to note that during the process of remapping invocation, there might be instances where there is no "Crossing Node." This occurs because the remapping `mmap()` function often follows a separate execution path from allocation. To fit this situation, we set the related "Terminal Node" for it. For example, when a `mmap()` call is made in the user space for a packet page buffer, it is typically executed by `packet_mmap()` ↪ in kernel. Therefore, `packet_mmap()` is considered a "Terminal Node". If the analyzer encounters this point during backtrace, it immediately stops and proceeds to analyze allocation interfaces to determine if the data flow between allocation and remapping aligns appropriately. As for allocation, we backtrace from the direct page allocation points, like `__get_free_page()`. Considering the multiple reference and the depth of invocation chains for these lower direct page allocation calls, when we find the tracing enter the related subsystem which is the same as previous mmap invocation, we will reset the root interface into the function in corresponding subsystem, and searching the control structure in this given subsystem. If the same control structure is found, we will compare with the control structure of the mmap operations.

Design and implementation. Due to the page limit, we discuss the details of our implementation in Appendix A.2.

6.2 Dynamic Test and Analysis

To ensure the effectiveness of the callsite analysis, we deployed the state-of-the-art and most widely used kernel fuzzer, Syzkaller [19]. In order to enable Syzkaller to report the corresponding callsites' reachability, we insert `WARN_ON(1)` as the panic function in each callsite. The Syzkaller will generate syscall sequences to reach and trigger the callsite, once it reaches, the kernel will experience an error by warning messages and stack dump information. In the following steps, Syzkaller will try to reproduce the related panic then output a minimized input. It should be emphasized that Syzkaller is performed based on syscall templates to generate the fuzzing input and dynamically test the kernel. For some kernel modules and logics, the templates have not yet been supported well to fit the corresponding part by Syzkaller. In these kinds of situation, we confirm the callsite manually with our crafted trigger programs. During our dynamic test, manually check only happens for `tap_skb_alloc` callsite.

For configuration of Syzkaller, we set 8 processes with qemu-based instance in bare-mental machine. Every instance we set 2 CPUs with 2G memory.

6.3 Analysis Result

As shown in Table 1, by our analyzer, we have identified 21 page-spraying callsites within the Linux kernel source code. These results illustrate that the page-spraying callsites are distributed across several crucial subsystems in the Linux Kernel, including Networking, Pipe, io_uring and so on. Notably, the networking subsystem in Linux Kernel exhibits a higher frequency of these page-spraying callsites. Upon closer examination, we have observed that this frequency can be attributed to the data transmission model employed in the networking subsystem.

When transmitting data or messages via various protocols in Linux Kernel, non-linear buffers may be allocated and utilized for data storage. The commonly used kernel function `alloc_skb_with_frags()` is responsible for allocating kernel pages from the page allocator to store data received from user space. Furthermore, we have identified memory remapping-related callsites within the networking/pipe subsystem and the *io_uring* subsystem. These callsites, along with their respective subsystems, are designed to share memory spaces with user space during the early stages of constructing (ring) buffers. This approach aims to reduce the overhead associated with cross-space data copying and writing, ultimately improving system performance, as we discussed previously.

Moreover, we conducted a dynamic analysis of each callsite identified by the static analyzer as validation. We perform a Syzkaller test in kernel level for all callsites. For our results, Syzkaller automatically triggers 20 of 21 in our callsites. For callsite `tap_alloc_skb()` which is actually inlined in `tap_get_user()`, we find that Syzkaller has trouble triggering it. After investigating the information from syzbot-assets [18]

of Syzkaller, we learn that Syzkaller has a low coverage in tap.c file. Due to this reason, only for this callsite, we use our crafted program based on the testcase from Linux v6.1 selftests [32] to trigger it manually.

Beyond the current findings, our static analyzer can be utilized for continuous integration. As the Linux kernel continues to evolve, incorporating new functionalities and features, we can re-employ the analyzer to detect recently added page-spraying callsites.

7 Effectiveness Evaluation

In this section, we will discuss the design and results of several experiments conducted to measure the effectiveness of the Page Spray technique in the context of various real-world kernel vulnerabilities. To gain a comprehensive understanding, we categorize "effectiveness" into two distinct attributes: "exploitability" and "stability". The results of exploitability evaluation are shown in Table 2, and the stability evaluation results are in Table 3.

CVE-ID	Type	Object Spray	Page Spray
CVE-2016-4557	UAF	✔	✔

7.1 Experiment Design & Methodology

We have executed a series of experiments to investigate the practicality of employing the Page Spray technique in the exploitation of real-world kernel vulnerabilities. These experiments underscore the inherent complexity of real-world vulnerabilities exploitation, which can be attributed to several key factors.

Firstly, the subsystem within the kernel where vulnerabilities manifest can significantly influence the contexts of the exploitation process. An effective exploitation method should ideally be versatile enough to overcome or mitigate the influence of these context-specific variations, with as few adjustments as possible. Secondly, the nature of the vulnerable object plays an imperative role in shaping the exploitation strategy. Objects of different sizes and behaviors require distinct approaches to achieve successful exploitation. Lastly, the patterns exhibited by vulnerabilities, such as Use-After-Free, Double-Free, Invalid-Free, and Out-of-Bound, introduce further complexity. Attackers must select appropriate exploitation methods that align with these specific patterns in order to effectively exploit the vulnerabilities.

Based on the outcomes of these experiments, the effectiveness of Page Spray in the context of real-world vulnerabilities is evaluated. Additionally, a comprehensive analysis is conducted to evaluate how proficiently Page Spray performs when applied to the exploitation of these vulnerabilities.

In our evaluation, we systematically assess a selection of real-world Linux kernel CVEs, adhering to the methodology outlined in K(H)eaps [46]. Furthermore, we introduce several up-to-date CVEs and real-world vulnerabilities into our assessment. Our criteria for CVE selection focus on kernel heap data-related corruptions that align with the principles

Type	CVE	Slab-Cache	Single-Thread Spray	Multi-Process Spray	Page Spray	Subtypes
			In IDLE State			
UAF	CVE-2016-4557 †	Kmalloc-256	100%	100%	100%	eBPF
UAF	CVE-2016-8655 †	Kmalloc-2048	99.4%	99.3%	100%	Race

Table 3: Exploit Stability Evaluation of Page Spray under Idle State and Busy State generated by `stress-ng`, compared to Single-Thread Spray and Multi-Process Spray. The † symbols represent cases Page Spray achieves better or comparable results as the traditional approaches.

established in K(H)eaps. These CVEs are rigorously verified for their reproducibility within the Linux kernel and their capacity to induce kernel crashes.

Our collection of CVEs encompasses a total of 15 real-world Linux kernel CVEs, as presented in Table 2. Our collection incorporates a set of 9 native Use-After-Free bugs, 3 Double-Free bugs, and 2 Out-Of-Bound bugs. This diverse set of vulnerabilities includes various subtypes such as race conditions, eBPF-related issues, and cross-cache attacks [33, 39].

Exploitability Evaluation. To evaluate the exploitability of Page Spray, we adopt a straightforward approach. We create a Page Spray proof-of-concept (PoC) for each of the CVEs within our dataset. Subsequently, we execute these PoCs to ascertain how many of the CVEs can be successfully exploited using Page Spray with a reasonable success rate. In instances where our initial PoC fails, we conduct an in-depth examination to identify the underlying reasons and try to adapt the PoC to the specific circumstances. In cases where no modifications yield successful exploitation, we draw the conclusion that Page Spray is incapable of exploiting that particular vulnerability and provide a detailed explanation for this outcome.

Stability Evaluation. Our stability evaluation experiments involve running exploits for a subset of the CVEs that are exploitable by Page Spray from the exploitability evaluation for a 1000 iterations under two distinct system operational states: the idle working state and the busy working state. The idle state represents a moderate kernel heap activity environment on the machine. This state mirrors the conditions that one would typically encounter on a standard local user's machine. Conversely, the busy state aims to simulate a more extreme operational setting where many intensive applications and stressors are running concurrently, providing a comprehensive context to limit test the capability of the Page Spray technique. We simulate this busy working state by utilizing a benchmark program called `stress-ng` [40]. Due to the space limit, we describe the detail of the environment used for evaluation in Appendix A.1.

Under these varying working conditions, we conduct a comparative analysis involving several practical state-of-the-art kernel heap exploitation techniques, including Page Spray, Single-Thread Heap Spray, and Multi-Process Heap Spray, as analyzed in K(H)eaps. This analysis serves to reveal the potential advantages or disadvantages of the Page Spray technique in the context of real-world environments.

The exploits are developed by first collecting publicly available and approved PoCs for each CVE. Then, we modify them into corresponding variants (Page Spray, Single-Threaded/Multi-Process Heap Spray) following the method we propose in Section 4. To ensure fairness, the only difference between each exploitation variant is the spraying technique itself, based on the same setups. Different types of

vulnerabilities have slight differences compared to our proposed method in Section 4.1, as discussed in Sections 4.2 and 4.3. A step-by-step detail of one such exploits can be found in Section 8 and Appendix A.3.

7.2 Experiment Results

Exploitability Evaluation. The outcome of our experiment is presented in Table 2. Page Spray demonstrated successful exploitation in 14 out of 15 vulnerabilities within our dataset. These successful exploits encompassed all three vulnerability types: UAF, OOB, and Double Free. Notably, Page Spray also effectively exploited a vulnerability on a mobile device (CVE-2022-20409) and executed cross-cache attacks (CVE-2022-2585, CVE-2022-29581).

Specifically, in the case of CVE-2022-2585, which is a relatively recent kernel heap vulnerability, traditional object spray method is unable to successfully exploit it due to the lack of precise control over the entirety of a vulnerable object and insufficient kernel information leakage. In contrast, Page Spray excels in this scenario. It effectively exploits CVE-2022-2585, and we'll delve into this in more detail in Section 8, where we explore how Page Spray shines in addressing recent real-world vulnerabilities.

On the other hand, in the case where Page Spray failed, we conducted a deep analysis to find out the root cause. In CVE-2016-10150, the vulnerability is triggered in KVM kernel's module. The UAF's allocation and free happen during a single invocation to `ioctl()`. This situation introduces a challenging race condition with a very narrow time window. This is a corner case for Page Spray, since as demonstrated in Section 4, the page layout manipulation and page spraying must occur after the vulnerable object is allocated and before it is freed to effectively exploit the vulnerability. However, the stringent time constraints imposed by this case make it exceedingly difficult to set up the necessary conditions for Page Spray to be successful.

Stability Evaluation. As evident from our observations of the experiment result in Table 3, in an idle system environment, the Page Spray technique demonstrates remarkable effectiveness, surpassing both the Single-Thread Heap Spray and Multi-Process Heap Spray methods. It consistently achieves an impressively high success rate, often approaching 100%, particularly in scenarios involving UAF vulnerabilities. This robust performance is noteworthy because real-world kernel heap exploits commonly occur on systems with moderate workloads. For instance, when jailbreaking mobile devices, one of the common applications of kernel exploitation, the jailbreaker typically has complete control over the device's workload and can reduce it to a minimum. This level of workload can also be expected on a standard local user's machine, which is a common target by attackers for exploitation. Furthermore, in attacks on busy remote servers like web servers or cloud servers, attackers can monitor the server's workload and strategically time their exploits during periods of lower activity, such as late at night.

In contrast, when operating within extremely stressed environments, it is expected that the success rates of Page Spray, as well as the other compared techniques, would experience a decrease. Nevertheless, Page Spray maintains a superior success rate in comparison to the Single-Thread Heap Spray method, and it delivers results comparable to those achieved with Multi-Process Heap Spray. Notably, in specific circumstances, Page Spray even performs on par or significantly better than Multi-Process Heap Spray, as exemplified by CVE-2017-10661, CVE-2017-15649, CVE-2018-6555, CVE-2017-8890, and CVE-2022-2588. The forthcoming subsection will delve into the conditions under which Page Spray excels and elucidate the rationale behind its performance.

In summary, the outcomes of both evaluations illustrate that Page Spray is a robust and effective approach that can serve as a valuable complement to conventional object spray methods. When used in the correct scenarios, these techniques cover each other's limitations, leading to a broader range of vulnerabilities that can be exploited and ultimately enhancing the stability of successful exploits.

7.3 Result Discussion

Root Cause of Instability. In order to explain and have a better understanding of the evaluation results and subsequent comparisons, it is imperative to first understand the key factor that influences the success rate of exploitation techniques and how they differentiate between Page Spray and conventional object spray approach. In the context of object spraying, in order to reclaim the vulnerable object's slot, the object must be in the active slab. Consequently, the exploit program has to race against the unpredictable and random allocations coming from the busy kernel with the goal to reclaim that specific slot for the desired object.

In contrast, page spraying can mitigate this issue, by spraying the target cache with spray objects until the current slab is full, and another slab is allocated as the active slab, all before freeing the vulnerable object. In this case, all the unpredictable allocations from the kernel are directed into the active slab, while the freed vulnerable object resides in another slab, remaining untouched. This is possible because in this technique, the goal is not to reclaim the individual object, but rather to target the entire page for reclamation. However, it is worth noting that the stability concern in the context of page spraying arises during the actual spraying process itself. The key requirement for the pages to be recycled to the allocator is that all objects within the entire slab containing the vulnerable object must be freed. Consequently, there must be no unpredicted allocation within the same slab, as this would impede this requirement.

This characteristic is an advantage for Page Spray under certain conditions. For instance, in the case of CVE-2017-10661, Page Spray shows an remarkable advantage over traditional

approach, boasting a success rate of 98.1% compared to the traditional method's 78.3%. A similar trend is observed in CVE-2017-8890, where Page Spray achieves a success rate of 49.0% compared to the traditional approach's 27.8%. We specifically examined these cases and it became evident that they have one important thing in common: the vulnerable objects are freed in RCU [42]. This means that the vulnerable objects undergo a grace period before they are returned to the allocator. Importantly, the duration of this grace period is not visible to the exploit program. Therefore, the common solution is to let the process sleep for a few seconds before attempting to reclaim the vulnerable object's slot. As mentioned above, the race to reclaim this slot is the most critical source of instability for the traditional heap spraying approach. Therefore, the longer the process remains in the sleep state after the object has been freed, the lower the likelihood of successfully reclaiming it, thus explaining the low success rates observed. Page Spray does not suffer from this problem as the reclamation stage is not the critical source of its instability.

8 Case Study: Refurbish Intractable Exploit

In this section, we demonstrate how Page Spray make improvements to certain hard-to-exploit vulnerability case, and enhance the exploitability. To achieve this, Page Spray employs two novel approaches, kernel information leakage by new channel, and halting the CPU execution to improve exploitability. We successfully apply Page Spray into a real world zero-day bug (CVE-2022-2585 [8]) and achieve privilege escalation.

Vulnerability Background: The vulnerability in question resides within the Posix CPU Timer Subsystems of the Linux Kernel. It pertains to a `CLOCK_THREAD_CPUTIME_ID` timer, which is utilized to measure the amount of CPU time consumed by a thread. When the function `timer_settime()` is invoked, the timer is marked as "armed." If there exists a user-defined time interval, once that interval elapses, the timer is triggered. To provide further context, Linux manages a linked list of timer-associated structures, `struct k_itimer`, within `struct posix_cputimers`. When a timer interrupt is raised, the kernel checks whether a specific thread has consumed a sufficient amount of CPU time. If the conditions are met, the timer expires and is placed into a firing linked list. Subsequently, all timers within this firing linked list are utilized to trigger the `posix_timer_event`, leading to the issuance of signals to the program.

This UAF vulnerability manifests in scenarios where a thread establishes a thread CPU timer and then invokes `execve()`. When `execve()` is called, a clean-up operation is executed on behalf of the process, which involves freeing all timers associated with that process. However, the crucial oversight lies in the failure to remove the reference to the timer within the `struct posix_cputimers`. In essence, if the timer was already armed before the `execve()` operation, the kernel proceeds to free the timer while still maintaining a reference to it within the doubly linked timer list. Consequently, when the designated time arrives, the kernel traverses the linked list, locates the timer, adds it to the firing linked list, and attempts to trigger the timer, thereby leading to a UAF vulnerability.

Kernel Information Leakage: In this scenario, we initiate a timer UAF vulnerability within a process and prepare the page vectors for subsequent Page Spray exploitation using `AF_PACKET`. Following these preparations, we create a child process directly through a `fork()` operation. Within the child process, we monitor the release of the slab page, which eventually returns to the page allocator. The parent process triggers the freeing operation. After the page is freed, we allocate and remap the vulnerable timer page to user space. This remapping is achieved through memory remapping operations, as illustrated in Listing 3, performed by the `packet_mmap()`. At this stage, the user gains access to the timer's page; however, it's important to note that the kernel still maintains a reference to this timer. Consequently, any modifications made to the timer's memory data will be immediately reflected in the user space, and vice versa.

In the next step, we initiate an exit process operation. Specifically, the "timer queue" utilized here is, in fact, an RB-Tree rather than a traditional queue structure. During the execution of the exit operation, the kernel invokes `timerqueue_del()` to remove the timer from the RBTree and label it as a "dangling node." This marking is achieved through `node->__rb_parent_color = node (RB_CLEAR_NODE)`, indicating that the operation associated with process termination adds a kernel heap pointer that points back to the process's own memory region. Consequently, we can read the remapped memory region from user space, allowing us to easily obtain a kernel heap address.

Finally, we release the sprayed pages back to the page allocator and proceed to spray `msg_msg` objects in order to reclaim the pages. At this stage, the kernel heap address we previously leaked serves as the address of a `msg_msg` object.

To summarize the previous paragraphs, Page Spray during exploitation introduces a novel channel for leaking kernel information. This is achieved by remapping kernel-allocated pages directly to user space. In essence, this means that by sharing pages with kernel space, users can efficiently monitor and access certain kernel data. This approach eliminates the need to copy data from the kernel space to the user space, thereby simplifying the exploitation process and improving its effectiveness.

Trapping CPU Execution. After successfully leaking kernel information and running on CPU0, we can trigger the vulnerability once more and reclaim the freed pages using Page Spray. However, it's important to note that, at this stage, we modify the payload used for Page Spray to trap CPU0. This involves manipulating the `k_itimer` structure in the payload with the following key modifications: (1) setting the `it_requeue_pending` field to a large value, (2) faking the `sigq` field to point to the leaked `msg_msg` address minus 0x20, (3)

faking the cpu_timer's head field within the related k_itimer, to reference the kernel heap address we previously leaked. These modifications are made to trap the execution of CPU0, allowing us to further control its behavior.

When the timer is triggered, we initiate a search within the previously remapped memory region in user space, with the objective of identifying the specific timer. This identification is achieved by examining the firing field associated with the relevant k_itimer. Importantly, following this identification, a modification made to the head field results in the entrapment of CPU0 within an infinite loop during RBTree operations. As a consequence, we switch execution to CPU1 to carry out the subsequent steps.

This enforced halt serves two minor yet noteworthy purposes. Firstly, it affords us the necessary time to mitigate potential locking issues by resetting the corresponding member within the k_itimer structure. Secondly, it ensures that the modified timer is not immediately reintroduced to the firing list, thus preventing any potential corruption of the kernel state. Instead, the timer is scheduled to trigger after a 2-second delay. Once these adjustments are completed, we can return to CPU0 and resume execution. With the manipulation of the sigq and it_requeue_pending fields, subsequent write operations effectively overwrite critical fields within the msg_msg structure, resulting in the leakage of kernel base information.

Page Spray, as evident in this context, possesses a remarkable capability for precise page-level control. This unique ability empowers us to effectively suspend or trap CPU execution, making it exploitable. Without Page Spray, at this time, the kernel's internal state would likely undergo corruption, making exploitation exceptionally challenging or even unattainable.

9 Mitigation Discussion

9.1 General Principles

As we have extensively explained in Section 4, Page Spray primarily involves reusing pages at the page level. These pages are recycled back to page allocators while slabs are discarded, and then the slab pages are reclaimed from page allocators and overwritten through page-level write/copy operations. To address this issue, the key is to prevent the overlap happening between the pages used for slab objects and the pages used for page-level data buffers. In simpler terms, the idea is to introduce a mechanism that isolates or divides these two sets of pages, ensuring that the same pages are not used both in the SLUB system and for direct page allocation.

9.2 Rethinking Memory Reuse

To further clarify our discussion on mitigation approaches, we illustrate two real-world examples. In one example, the lightweight solution goes to use GFP flag to separate memory allocation area, while in the other, modifying the slub system within the Linux Kernel.

Our Lightweight Mitigation. As we discussed earlier in Section 2.2, different GFP flags can influence the allocation zones in the Linux Kernel. One straightforward approach involves adjusting the GFP flags at the points where Page Spray is invoked, directing the allocation to a different memory area that does not overlap with the previous slab memory. Although some other GFP flags can be leveraged to achieve the isolation, to select appropriate flags, it's essential to understand the allocation fallback mechanism. In scenarios where the memory areas best suited for the allocation flags are unavailable for upper-level components, the fallback mechanism is triggered to allocate in the next available zones. At the end of this fallback sequence, the DMA region cannot further fall back to another memory area.

Given that no specific ZONE is initially designated as a reserved isolation area for against Page Spray, we make adjustments to the allocation attributes within the Page Spray callsites in the Linux Kernel. We attach GFP_DMA to the Page Spray allocation points in kernel, which finally reclaims pages from DMA region, instead of general region. This redirection of allocation operations effectively separates Page Spray allocation from the freed slub pages and eliminates the overlapping. It's important to emphasize that our aim here is to validate the feasibility of this principle, and it's not intended for application in a production environment.

Slab Virtual. Slab Virtual, a mitigation technique designed by Google and currently maintained outside the Linux Source Code Tree, addresses concerns related to object reuse and cross-cache attacks. This approach extends prior work, such as AUTOSLAB [29] by Grsecurity and PartitionAlloc [6] by Chromium, by taking a more comprehensive approach. Originally, AUTOSLAB is not enough to mitigate Page Spray, since it only isolates objects at object level, page reuse can still happen if the attacker chooses the same type of object for *padding objects* and *vulnerable object*.

Conversely, Virtual-Slab operates by creating a new, dedicated virtual memory region (previously an unused hole in the address space). In this region, slab objects are allocated, isolating them from the regular memory allocation process. Additionally, adjustments are made to functions like virt_to_phys() to ensure that the mapping between virtual and physical slab memory becomes permanent. This step is crucial because it prevents the possibility of evading UAF attacks in the physical address space. By combining these measures, Virtual slab significantly reduces the potential for overlap between Page Spray allocations and freed slab pages. However, it introduces incompatibility (e.g. compilation and/or runtime conflicts with common defenses such as KFENCE and KASAN), and noticeable overhead compared to our direct mitigation. Furthermore, it is important to note that as of now, Virtual slab has not been integrated into the Linux Mainline, and therefore the current Linux kernel can still be exploited with Page Spray.

Benchmark	Slab-Virtual	Direct-Mitigation
Sys-RAM (MB/s)	2.26%	-0.43%
Sys-CPU (Events/s)	-0.95%	-4.08%
FFmpeg (s)	-0.95%	0.11%
OpenSSL (Verify/s)	3.43%	-2.72%
OpenSSL (Sign/s)	2.78%	1.18%
PHPBench (Score)	3.33%	0.40%
PyBench (ms)	11.70%	-1.29%
GIMP (s)	10.19%	5.57%
PostMark (TPS)	7.67%	1.00%
Apache (Req/s)	3.80%	1.43%
Memcached(Ops/s)	10.64%	1.93%
Redis(Req/s)	3.68%	-0.82%
Nginx(Req/s)	-3.14%	-1.62%
Geo-Mean	4.09%	0.02%

Table 4: The Overhead on Phoronix Benchmarks.

Macro-Performance Overhead. To assess the macro-performance impact of the aforementioned patches, we implemented both of them in Linux version 6.1. We conducted our experiments on a bare-metal machine equipped with 32GB of memory, a 200GB SSD storage drive, and a 4-core 11th Gen Intel i7 processor running at 2.90GHz. The performance evaluations were executed using Phoronix-Benchmarks [36]. For each specific benchmark case, we ran the tests five times and calculated the average results. The outcomes of our measurements are summarized in Table 4. Notably, the introduction of Virtual SLUB seems to result in an approximate 4% macro-overhead in these benchmarks. In contrast, the Hardened patch introduces minimal and practically negligible performance overhead.

10 Related Work

This paper primarily focuses on conducting a systematic study for an exploitation technique for the Linux kernel exploitation. In this section, we provide an overview of these related works and highlight the distinctions between their approaches and the scope of our paper.

Exploitability Assessment & Improvement. FUZE [44], aims to strengthen the evaluation of kernel UAF vulnerability exploitability and guide the manipulation of vulnerable object, by combining kernel fuzzing along with symbolic execution. KOOBE [2] emphasizes the automated exploit generation (AEG) on Linux Kernel Heap Out-Of-Bound vulnerabilities, including a novel capability-guided technique, to achieve more comprehensive analysis for the capability of real-world kernel OOB vulnerabilities. These two works are state-of-the-art in automatic generation of traditional kernel heap exploits, however, they are different from our work, which is a comprehensive study on a lesser known technique itself. ExpRace [28] provides the insight of augmenting time-windows to improve the success rate on race condition vulnerability exploitation, by performing inter-process interrupts. PSPRAY [27] creatively proceeds to utilize a timing side-channel attack based technique, increasing the success probability of exploitation. Xu et al. [45] conducts a systematic study on how to exploit use-after-free vulnerabilities in Linux kernel based on the difficulties that mainly come from the uncertainty of the kernel memory layout. Target on kernel vulnerable object, ELOISE [4] clarifies the exploitability of object with adjustable size, and how it facilitates the kernel vulnerability exploiation. SLAKE [5] benefits the community through constructing a kernel object database for heap-based vulnerabilities, and demonstrates its capability of memory layout manipulation. KEPLER [43] points out the communication between kernel space and user space can be used for kernel stack ROP, by stack canary leakage and payload injection. KHEAPS [46] retrieves several traditional heap-based exploitation techniques, and builds combination-exploits from them to comprehensively measure the difference of exploitation stability. We consider KHEAPS [46] as the most related state-of-the-art work currently, and had a systematic comparison with it in Section 7.

Exploitation Approaches & Techniques. ret2usr [24] mentions the importance of isolation between the user space and kernel space, to circumvent the inadequate mitigation, kGuard is introduced as a insight to counter it. ret2dir [23], making a constructive move, elaborates to us how implicit memory sharing can be maliciously leveraged to compromise the isolation technique. DirtyCred [30] proposes a new and general exploitation method. They concentrate on launching attacks by Linux Kernel's privileged object which can be artfully used to replace a vulnerable object and fulfill the privilege escalation. Reshetova et al. [38] retrieves the kernel eBPF JIT Spray exploitation. While they develop two different JIT Spray attack approaches by eBPF subsystem, and prove that the existing measures implemented in the upstream kernel are not enough to stop JIT Spray attack. He et al. [20] involves malicious eBPF program in kernel space to break container boundary, through hijacking the user space process which has been granted to high privilege. Kirzner et al. [26] dwells on the speculative type confusion vulnerabilities in Linux Kernel eBPF subsystem, and conducts a study on existing general mitigations, including system-level, compiler-level, and hardware level.

In essence, our work stands apart from the aforementioned studies. While those studies focus on kernel heap-based exploitation or side-channel attacks, our work advances further by concentrating on page-level control. To the best of our knowledge, although page-level spraying technique is not a novel exploitation method, our work is the first to systematically investigate and examine it. Through real-world case studies, we aim to showcase the potential and effectiveness of this approach.

11 Conclusion

In conclusion, our systematic study reveals that Page Spray as a page-level exploitation method complements existing techniques in the field. Page Spray offers a viable alternative with comparable even superior exploitability and stability in real-world scenarios. Notably, in terms of compatibility, Page Spray exhibits greater versatility, serving as an easily adaptable method during exploitation. The general model of Page Spray, DIRTYPAGE, demonstrates compatibility with multiple variants, underscoring its flexibility. Our investigation into the root causes of Page Spray has revealed its close association with certain mechanisms in the Linux Kernel's design. Addressing these root causes and mitigating Page Spray should be a priority for future developments. This may involve introducing enhanced memory isolation designs at the page level to enhance security measures. In essence, Page Spray emerges as a promising and powerful addition to Linux kernel exploitation techniques, offering a unique set of advantages. However, its potential risks and implications should not be underestimated, and proactive measures are warranted to safeguard against Page Spray attacks in kernel security.

A Appendix

A.1 Detail of Experiment Setup

Environment used for evaluation. We run the experiments on a PC equipped with 12th Gen Intel Core i7-12700 @ 4.8GHz (20 cores in total) and 32GB memory, running Ubuntu 22.04 LTS. For each vulnerability, we re introduce it into v4.15 Linux kernel, compile the corresponding kernel and disk image and run the system in QEMU virtual machine (VM). The VM is configured with 2 CPUs and 2GB RAM.

VM vs. bare-metal machine. Admitted that the success rate of each exploit we obtain from VMs may be different from that on bare-metal machines, we argue that the relative difference of stability between different techniques and the change of success rate (e.g., improvement or degradation) is consistent. Therefore, by observing the results from VMs, we can safely draw conclusions.

Busy environment simulation. For the busy setting created by `stress-ng`, it enables a high degree of control over the type and quantity of stressors to run. In our specific experiment, we opted to engage two stressors for each of the following stressor types, including CPU, sock, shm, and timerfd. The CPU stressors consistently maintain CPU usage close to 100%. Concurrently, the other stressors target kmalloc cache usage, affecting distinct kmalloc cache sizes. For instance, sock stressors allocate a considerable number of skbuff structs, thereby stressing kmalloc-2048. Similarly, the shm stressors allocate shminfo structs, pressuring kmalloc-64. Timerfd stressors create timerfd structs, focusing on kmalloc-256, while additional kmalloc caches also undergo stress from other structures generated by these stressors.

A.2 Design & Implementation

Preparation. We implemented our analyzer based on LLVM. The analysis tool takes kernel bitcode as input. To avoid the bitcode from being optimized and lose critical dataflow information, we used a customized clang to generate bitcode before any code optimization is invoked. The first thing we perform in early stage is to scan every modules and build the global context, in this phase, we collect related global level object, structs, and functions information. Specifically, when we found certain member in a data structure, we go through each field of it, and check if it is a related subsystem's mmap function, we record and insert into a mmap-function-list. We also build the invocation information in this phase, which maintains a global level call graph.

Cross Analysis. As we mentioned in Copy-Write call model in Section 5.2. A copy-write callsite is constructed with an allocation and a copy. Due to this, we perform a cross tracking from the allocation root interfaces and copy root interfaces. This process works based on the previous collected invocation information. Then, two invocation chains are built for the Copy-Write callsite. After we idnetify the chains, we analyze whether there are any intersections between these two call chains. Assume no intersections are found, we exclude the case and mark as invalid for copy-write type page spray. If an intersection is found we mark as potential copy-write callsite. For those potential callsites, we apply the corresponding dataflow analysis to them. The intention of dataflow analysis at this time is to check if they two chains can be traced back to the same control structure. In two chains' intersection function, we apply a forward analysis to check the control struct of the presence spot in intersection function(the instruction in the intersection function for allocation) is able to reach the corresponding position in the instruction function for data copy.

Remapping Analysis. When it comes to analyze remapping callsites, it is worth to emphasize that the biggest difference compared to copy-write callsites is that the allocation chains and remapping chains probably don't have an intersection, which require more detailed dataflow analysis. First, we also build invocation chain for remapping(mmap) from root interfaces. In the following step, we search from the lowest level page allocation function with a BFS queue, to find if a potential page allocation can be invoked in the corresponding remapping's subsystem. Once we successfully find an upper root interface in subsystem, we mark it as potential allocation root interface for previous remapping chain. After that, we perform backward dataflow analysis to remapping point, the goal of it is to find a potential control structure for remapping behaviors in related subsystem. Correspondingly, to find out the control structure for allocation, we execute forward dataflow analysis. By integrating the results from the previous dataflow analysis. We are able to have a allocation control structure and remapping control structure. At last, we apply a nest-analysis for two structure to figure out whether one of the control structures is a childfield of another control structure. We confirm as valid remapping point when they have the same control structure in the same subsystem, or the two control structures have a parent-child relationship in the same subsystem.

Technical Discussion. By using analyzer, we identify 21 callsites for page spray based on our invocation model. We compare these callsites with those randomly sampled and manually confirmed, and find our manually audited callsites are a subset of those pinpointed by analyzer. We understand this discovery cannot directly conclude zero false negatives because the kernel's scale limits our ability to manually audit all potential callsites. However, it implies the false negatives of analyzer are minimal under the potential callsites of our invocation model. To provide more systematic understanding, we need to calrify that if there are some other callsites out of our current callsite model, it could also lead to extra false negatives. On the other hand, for false positive, we perform dynamic test to verify and trigger them by Syzkaller in Section 6.2 , and illustrate some of them have related limitation in Table 1.

A.3 A basic step-by-step Page Spray exploit

In this Appendix Section, we will demonstrate a detailed step-by-step exploit for one of the CVEs that we used in our evaluation as an example for a generic Page Spray exploit against a UAF vulnerability. The PoCs for other CVEs follow the exact principles that we explain in this section, albeit for a vulnerability in a different subsystem. The CVE we choose to demonstrate is CVE-2018-6555, which is a UAF vulnerability in the IrDA subsystem of the Linux kernel. We will describe in details the steps that are needed to achieve the kernel heap layout similar to the one introduced in Section 4. However, the internals of the IrDA subsystem are out of the scope of this paper and will not be explained in details.

The vulnerability. The `irda_setsockopt` function in `net/irda ↪ /af_irda.c` and later in `drivers/staging/irda/net/af_irda. ↪ c` in the Linux kernel before 4.17 allows local users to cause a UAF on the `ias_object` object. In the public PoC that we collected, this UAF is triggered by first creating 3 IrDA sockets using `socket(AF_IRDA, SOCK_STREAM, 0)` and bind them using the function `irda_bind`. Subsequently, calling the function `irda_set_ias(fd, "\x00")` on 2 of the 3 sockets will corrupt the `ias_object` queue and later trigger a UAF when closing the 3 sockets. Finally, creating and binding a 4th socket will overwrite the target pointer, and calling `setsockopt` with the right arguments will execute the function pointer that has been overwritten.

Initial setup. Before setting up the kernel heap for Page Spray and for triggering the vulnerability, we utilized some commonly used technique to make the exploit more stable. Firstly, we pin the process to a specific CPU, so that all our objects will be allocated from a single CPU. This is a requirement for a slab to be discarded after all objects inside it are freed. Secondly, we defragment the heap by allocating many *padding objects*, in this case, we chose the *padding objects* to be the `msg_msg` objects. This step is not always necessary, but it helps against very busy environments. Thirdly, we prepare beforehand the *page spraying callsite* that we will use to reclaim the vulnerable page. This callsite is chosen amongst the callsites that we found in Section 6.3. In most of our PoCs, we choose the `pipe_write` callsite for generality and ease of implementation, therefore, in this step, we prepare multiple `pipe` objects that we can later write to, in order to spray page allocations.

Page Spray setup. Since this is a UAF vulnerability, our *vulnerable object* and *victim object* can be the same object, which in this case is the `ias_object`. As mentioned above, we choose our *padding objects* to be `msg_msg`. Since `ias_object` resides in kmalloc-96, we can spray `msg_msg` objects of size 48 (to account for the extra 48-byte header of `msg_msg` objects). With the Page Spray objects in mind, these are the steps to create a kernel heap layout similar to the one we introduced in Section 4 for CVE-2018-6555:

1. Spraying our first set of `msg_msg` *padding objects*.
2. Creating and binding 3 IrDA sockets using `socket(AF_IRDA ↪ , SOCK_STREAM, 0)` and `irda_bind`.
3. Reinserting the middle `ias_object` and corrupting the queue by calling the function `irda_set_ias(fd, "\x00")` on 2 of the 3 sockets.
4. Spraying our second set of `msg_msg` *padding objects*. At this point, we have achieved a vulnerable `ias_object` in the middle of 2 sets of `msg_msg` padding objects.
5. Closing all 3 sockets to trigger a free on the vulnerable `ias_object`.
6. Freeing all 2 sets of `msg_msg` padding objects. At this point, the slab containing the vulnerable `ias_object` will be discarded.

Page Reclaim. To reclaim the page containing the vulnerable/victim object, we simply write to the pipes that we have prepared in the initial setup step. The content of the data that we use to write will be an array of 8-byte values that are all equal to `0xffffffffdeadbeef`. This way, we can recognize a successful Page Spray exploit be parsing the crash report, i.e. a successful exploit will crash at RIP equals to `0xffffffffdeadbeef`.

Trigger UAF. After corrupting the victim `ias_object`, we can execute one of if its function pointer by creating and binding a 4th IrDA socket, and calling `setsockopt`. The corrupted pointer will be executed and the kernel will crash at RIP equals to `0xffffffffdeadbeef`, resulting in a successful Page Spray exploit and hijack the kernel's execution flow.

SafeFetch: Practical Double-Fetch Protection with Kernel-Fetch Caching

Victor Duta Mitchel Josephus Aloserij Cristiano Giuffrida

Vrije Universiteit Amsterdam

Abstract

Double-fetch bugs (or vulnerabilities) stem from in-kernel system call execution fetching the same user data twice without proper data (re)sanitization, enabling TOCTTOU attacks and posing a major threat to operating systems security. Existing double-fetch protection systems rely on the MMU to trap on writes to syscall-accessed user pages and provide the kernel with a consistent snapshot of user memory. While this strategy can hinder attacks, it also introduces nontrivial runtime performance overhead due to the cost of trapping/remapping and the coarse (*page-granular*) write interposition mechanism.

In this paper, we propose `SafeFetch`, a practical solution to protect the kernel from double-fetch bugs. The key intuition is that most system calls fetch small amounts of user data (if at all), hence *caching* this data in the kernel can be done at a small performance cost. To this end, `SafeFetch` creates per-syscall caches to persist fetched user data and replay them when they are fetched again within the same syscall. This strategy neutralizes all double-fetch bugs, while eliminating trapping/remapping overheads and relying on efficient *byte-granular* interposition. Our Linux prototype evaluation shows `SafeFetch` can provide comprehensive protection with low performance overheads (e.g., 4.4% geomean on LMBench), significantly outperforming state-of-the-art solutions.

1 Introduction

The operating system (OS) kernel is the bedrock of modern systems. To provide service, the kernel includes a syscall interface, an explicit boundary between *untrusted* OS processes and the *trusted* kernel. Hence, it is crucial for the kernel to properly sanitize data that flows through this boundary (e.g., syscall arguments). Failure to do so may lead to (kernel) *double-fetch bugs* [15]. Such bugs occur when the kernel fetches (i.e., reads) the same/overlapping data from user space twice—a common kernel design pattern—without properly (re)sanitizing data on the second fetch. In essence, double-fetch bugs introduce a race condition, which attackers can exploit to mount *time-of-check to time-of-use* (TOCTTOU) attacks—changing user data between the two fetches. This is to bypass sanity checks and typically escalate privileges. Such bugs are both common (as they involve skipping seemingly "redundant" kernel checks [15]) and elusive (as they normally escape testing with production sanitizers [9]).

Prior research [18, 23, 26, 31] has mostly sought to detect and report several double-fetch bugs [2–7]. However, prior detection tools are imprecise and thus unsuitable to mitigate double-fetch bugs in production. More recently, Midas [15] proposed the first mitigation to offer protection (rather than detection) guarantees against double-fetch bugs. Midas relies on the MMU and `copy-on-write` mechanics to expose consistent snapshots of user pages to each syscall. To this end, Midas traps writes to each fetched user page, copies the page, and exposes the new (old) page to the writer (syscall). While this approach structurally prevents double-fetch exploitation, it also incurs nontrivial overhead due to the cost of trapping, remapping, and copying pages as well as operating at the coarse page granularity (causing overtrapping and overcopying due to *false sharing* [15]). Finally, due to the complex and costly operations Midas whitelists a number of syscalls (including the kernel-fetch heavy `execve`), ultimately reducing protection coverage.

In this paper, we propose `SafeFetch`, a practical protection system against kernel double-fetch bugs. The key idea is to move the core instrumentation from writes to kernel fetches, with the kernel maintaining per-syscall *caches* to serve kernel fetches. Indeed, our design has been inspired by Linux kernel developers seeking a practical double-fetch bug mitigation by "*performing some kind of kernel-side caching of user space memory*" [8]. `SafeFetch`'s design prevents concurrent (attacker-controlled) writes from corrupting data exposed to kernel double fetches—which instead hit the previ-

ously populated kernel-fetch cache by construction. As we will show, the vast majority of syscalls only copy a few bytes from user space, hence caching kernel-fetch data per-syscall can be done in a *simple* and *inexpensive* way. In contrast to Midas' *write-side* instrumentation strategy, `SafeFetch`'s *fetch-side* strategy eliminates the need for costly MMU-based instrumentation (as writes run uninstrumented), false sharing and overcopying (as the cache operates at the byte rather than page granularity), and syscall-based whitelisting (as individual problematic kernel fetches can be whitelisted as needed). As a result, `SafeFetch` significantly improves both the performance and the security (protection coverage) of state-of-the-art solutions at a fraction of the complexity.

To support our claims, we implemented `SafeFetch` on Linux and evaluated our prototype, along with a number of caching-centric optimizations, against a number of standard benchmarks. Our evaluation shows that `SafeFetch` provides comprehensive protection at a fraction of the overhead incurred by Midas, despite the higher protection coverage (i.e., a single kernel fetch vs. three major syscalls whitelisted). For instance, `SafeFetch` incurs geomean performance overheads consistently below 5% across standard kernel benchmarks (i.e., LMBench, OSBench, and Phoronix). On the same benchmarks, Midas reports much higher geomean overheads (i.e., as high as ≈15% on OSBench and ≈36% on LMBench). Moreover, Midas incurs a single-benchmark worst-case overhead of 279% (vs. 22% for `SafeFetch`).

Contributions. We make the following contributions:

- We investigate common kernel fetch patterns during syscall execution and use the resulting insights to design a per-syscall kernel-fetch cache.
- We present `SafeFetch`, an implementation of our design to structurally mitigate *double-fetch* bugs in the Linux kernel. We show `SafeFetch` can be seamlessly integrated into existing kernel code paths, resulting in a practical implementation.
- We evaluate `SafeFetch` on a number of standard benchmarks, confirming that it can comprehensively mitigate double-fetch bugs with low performance overheads (e.g., 4.4% geomean on LMBench).

2 Background

2.1 User/kernel Memory Isolation

Modern operating systems rely on virtual memory support to enforce user/kernel memory isolation, that is preventing user (kernel) execution from accessing kernel (user) memory. This is typically done by using a joint virtual memory address space—where both user and kernel memory mappings coexist during user/kernel execution—and features offered by modern memory management units (MMUs) to enforce isolation. Specifically, on x86 platforms, the kernel can set (unset) the User/Supervisor bit in the Page Table Entries (PTEs) for user (kernel) memory mappings. This prevents user execution from accessing kernel memory. It also prevents the reverse (i.e., kernel execution accessing user memory) assuming Supervisor Mode Access/Execution Prevention features (SMAP and SMEP, respectively) are enabled.

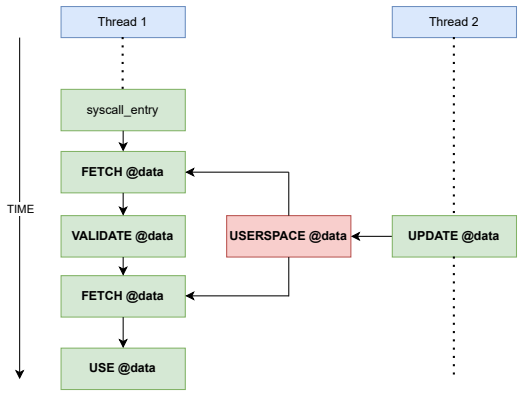

Figure 1: Workflow of a double-fetch exploit.

While important for memory isolation, SMAP complicates the implementation of common operations such as *kernel fetches*, that is user-to-kernel data transfers often issued by the kernel as part of syscall handling (e.g., copying a message from user memory to be sent over the network). To ease their implementation, modern operating systems typically support special kernel *transfer functions* in order to safely transfer data between user and kernel. For example, the Linux kernel offers two user-to-kernel (i.e., `copy_from_user` and `get_user`) and two kernel-to-user (i.e., `copy_to_user` and `put_user`) transfer functions, which temporarily disable SMAP and copy data from/to user memory (respectively).

2.2 Double-fetch Bugs

A kernel *double fetch* occurs in presence of kernel fetches transferring the same user data twice, that is with multiple user-to-kernel transfer function invocations for the same (or overlapping) user data on Linux. This pattern is normally benign and used to simplify or optimize common types of (e.g., deep or variable-length [26]) user-to-kernel data transfers. However, if the kernel assumes the data to be invariant and only validates data on the first fetch, the second fetch originates a *double-fetch bug*. Such bugs are particularly insidious as they introduce a race condition that may never cause any harm during normal execution. However, an attacker can exploit such

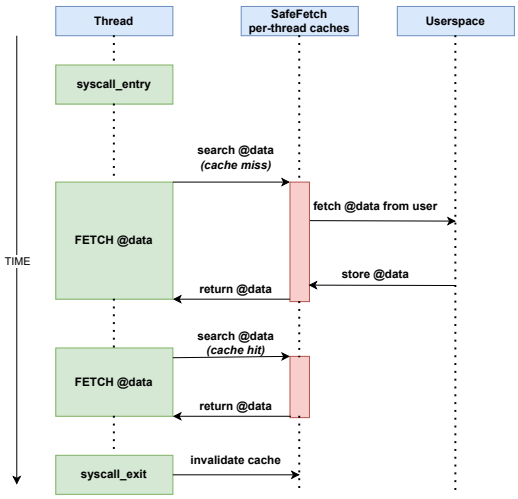

Figure 2: `SafeFetch` hindering a double-fetch exploit.

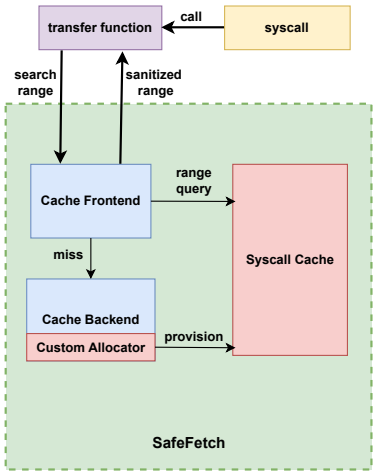

Figure 3: `SafeFetch`'s high-level architecture.

bugs by racing against kernel execution from another user thread and corrupting the (unsanitized) data exposed to the second fetch. Such *time-of-check to time-of-use* (TOCTTOU) attack can bypass sanity checks and often kickstart a privilege escalation exploit [26].

Figure 1 depicts the workflow of a typical double-fetch exploit. In response to *Thread 1* executing a syscall, the kernel first fetches and validates some user **@data**. Shortly after, another attacker-controlled *Thread 2* concurrently modifies the **@data** in user space. In *Thread 1*, the kernel then proceeds to fetch **@data** again without (re)validation. This allows the attacker to bypass validation checks and mount a TOCTTOU attack. Prior work has largely focused on *detecting* such bugs with reasonable accuracy [18, 23, 26, 31]. In this paper, we instead focus on *protecting* the kernel from zero-day double-fetch bugs, while proposing a much simpler and more efficient design than the state-of-the-art protection system [15].

3 Threat Model

We assume a typical local exploitation threat model, with an unprivileged user-space attacker seeking to exploit a kernel double-fetch bug. Other classes of vulnerabilities are out of scope, e.g., addressed by orthogonal mitigations. The attacker ultimately aims to mount a TOCTTOU attack for a variety of different purposes, e.g., privilege escalation, info leak, denial of service, etc.

4 Overview

To hinder exploitation of kernel double-fetch bugs, `SafeFetch` guarantees that, during the lifetime of each syscall, kernel fetches to the same user data will return the same value. To this end, `SafeFetch` caches data read by kernel fetches at the per-thread and per-syscall granularity, as illustrated in Figure 2. As shown in the figure, when a syscall fetches some user **@data** for the first time, `SafeFetch` proxies the fetch to user memory and stores the fetched data in a per-thread in-kernel cache. When the syscall fetches the same **@data** again, `SafeFetch` retrieves the data from the cache. As such, double fetches are always consistently served with the initial version of the data regardless of any concurrent updates to user memory. At the end of the syscall lifecycle, the cache is invalidated to implement per-syscall caching semantics.

Internally, `SafeFetch` includes two core components, as shown in Figure 3. The **`Cache Frontend`** intercepts each kernel fetch, i.e., (user-to-kernel) transfer function invocation, and returns a *sanitized* range (i.e., a contiguous, immutable user memory block) in output. To this end, the frontend queries the current *syscall cache* for the range. In case of a hit, a (sub)range is served directly from the cache. In case of a miss, the frontend notifies the **`Cache Backend`**. The latter provisions the cache to store the missing (sub)range (fetched from user memory) by means of a *custom allocator*.

Challenges. While `SafeFetch`'s design is conceptually simple, there are several challenges involved in its realization. First, the need for an in-kernel cache may lead to a nontrivial TCB impact, affecting security. We will later show it is feasible to efficiently implement our design with small TCB impact. Second, the need to interpose on all fetch operations may lead to protection coverage (and thus security) issues. We will later show it is feasible to produce a (nearly) full-coverage implementation on modern operating systems such as Linux, faring even better than the state of the art (Midas). Third, our fetch-side instrumentation strategy may end up copying

more data than Midas' write-side strategy in case user data is never changed during syscall execution. We will later show such cost is marginal compared to that of MMU-based instrumentation, resulting in consistently better performance. Finally, our design require instrumenting the kernel's fast path (i.e., transfer functions). As such, its instrumentation and data structures need to be carefully designed to efficiently support typical kernel fetch patterns. We will show it is possible to capture a variety of different fetch patterns with relatively simple data structures. In the next sections, we first analyze the patterns relevant to our design. Then, we use the insights gathered from our analysis to detail our design.

5 Profiling Kernel Fetches

While our syscall caches are superficially similar to other kernel caches since they may support similar range queries, our design requirements are fairly unique. For instance, the VMA cache is a classic example of a kernel cache supporting range queries, however, its lookup patterns are wholly different from ours (lookups on locality-friendly memory management operations vs. lookups on kernel fetches) and so are its scope (process vs. syscall) and data storage requirements (fixed- vs. variable-sized data). As such, to make optimal design decisions, we need to learn more about typical patterns for kernel fetches, including their frequency, data transfer size, etc.

To this end, we developed a simple profiler to gather kernel-fetch statistics. Specifically, our profiler interposes on syscall execution and records the following statistics: the total number of ranges a syscall transfers from user space, the average size of ranges transferred by a syscall, and the total amount of data a syscall fetches from user space. Moreover, for each process executed during profiling, we also gather the number of syscalls that transfer data from user space. We use various benchmarks (e.g., LMBench, OSBench) and popular user applications (e.g., Nginx, Apache) to generate a workload to sample syscall execution. In total, our workload generated around 317 million syscall samples, exercising 165 individual syscalls ($\approx$ 52% of all defined syscalls for Linux `x86_64`). Our main profiling results are depicted in Figures 4, 5, 6, 7, 8. We elaborate on the results in the next sections, using the gathered insights to motivate our design.

6 Cache Frontend

To provide the kernel with a consistent view of user memory, the cache frontend interposes on all user-to-kernel *transfer* function invocations requesting a specific user range. In response, the frontend queries the syscall cache for the range by means of the user (virtual) address and the length of the range. After the query completes, the frontend performs a query resolution step, fetching parts of the range from user space into the cache if needed (i.e., if not cached) and then forwarding a sanitized range to the original transfer function.

The frontend considers a user range A *sanitized* if and only if: for any sub-range B of contiguous user addresses, such that $B \subseteq A$, and B was previously fetched during the execution of the syscall (i.e., via a previous transfer function) then B must consist of the same bytes as when it was first fetched. When querying the cache, the frontend uses a predetermined *search policy* to locate the range in the cache. The search policy is subject to the (meta)data structure used to bookkeep the user ranges in the cache.

6.1 Efficient Range Queries

Given a user start and end address (i.e., a range) `SafeFetch` needs to find all cached chunks that overlap with this input range. Since a range may only partially overlap with an existing range (or multiple cached ranges), we are interested in finding the optimal data structure that can service this operation efficiently. For this purpose, other kernel subsystems use either linked lists (for small caches) or red-black trees (for large caches). The Virtual Memory Area (VMA) cache is case in point, generally serving address range queries via a per-process red-black tree. However, the VMA cache's fast path uses a linked list for the few recently used VMAs.

We experimented with both types of data structures in the context of `SafeFetch`. In both cases, a node contains *metadata* recording the start/end address of the range and a reference to the cached *data*. Clearly, in the case of many cached ranges, we expect linked-list-based queries to perform poorly, with a worst-case search complexity of O(n). In the same vein, we expect red-black trees to be more efficient, with a worst-case search search complexity of O(log(n)) due to constant-time rebalancing. Indeed, we experimentally verified that after around 100 cached ranges, the average search time of a linked list is slowed down by a factor of two compared to a red-black tree. However, when the cache contains only a few elements we observed the linked list significantly outperforming a red-black tree. On top of more lightweight search logic, a small linked list has another important performance edge over a small red-black tree on the insertion path (i.e., when adding a new user range into the cache). Indeed, due to rebalancing, insertions in the red-black tree are always around 10 orders of magnitude slower than in a linked list. Since according to our profiling results, double fetches are rare (occurring once every 1,277 sampled syscalls), insertions are frequent and are thus important to consider for performance. For more detailed double fetch statistics from our profiling results,

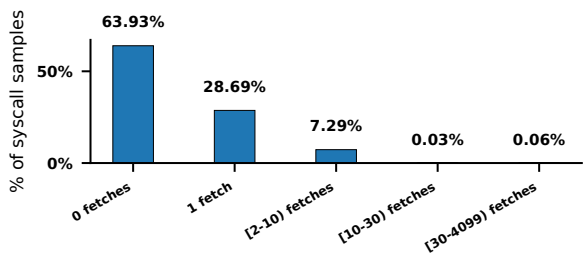

Figure 4: Percentage of syscall samples vs. number of ranges they fetch.

we refer the interested reader to Appendix A.

Selecting the ideal data structure. To select the ideal candidate between our two data structures, we turn to our profiling results. Figure 4 shows the percentage of syscall samples that fetch N ranges from user memory across all the profiled benchmarks. As shown in the figure, most samples ($\approx 64\%$) do not fetch user ranges at all, while the vast majority of those which do, fetch at most one range ($\approx 28.7\%$ of samples). Even so, a nontrivial number of samples ($\approx 7.32\%$) fetch at most 30 ranges, while only $\approx 0.06\%$ samples fetch over 30 ranges. As our results suggest, a (small) linked list seems the ideal candidate to support range queries for the vast majority of syscall samples. However, we also observed samples fetching as many as $\approx 4{,}000$ ranges. In those cases, the linked list has very poor performance and the red-black tree is a vastly better option.

To optimize for all possible syscall scenarios, we ultimately opted for an `adaptive` search policy. In other words, the search policy uses a linked list by default until the number of ranges in the cache reaches a predetermined threshold. When the threshold is exceeded, `SafeFetch` switches to a red-black tree implementation. We detail how we experimentally selected a good threshold in Section 9.3. To convert the linked list into a red-black tree, `SafeFetch` uses an efficient algorithm that constructs a balanced red-black tree from an ordered linked list. This is done by first copying the pointers to ranges in a vector and then iterating over the vector in a binary breath-first search fashion. To keep the algorithm efficient, we need to initiate the conversion when the list contains a number of ranges of the form $2^N - 1$.

6.2 Query Resolution

When processing the result of the query, the **`Cache Frontend`** makes different decissions depending on whether it found a cached user range colliding with the queried range (**cache hit**) or not (**cache miss**).

In case of a miss, no subrange from the queried range was previously fetched from user space. As a resolution, the frontend fetches the range from user space and instructs the backend to allocate storage to insert the range into the cache. It then also indexes the new range by inserting new metadata into the linked list or red-black tree with with O(1) complexity—by piggybacking on the result of the previous query.

Cache hits can either be *perfect* or *partial*. A perfect hit means that the frontend found a cached range which contains the entire range it queried for. In this case, the frontend forwards the sane range from the cache without performing any fetch from user space. A cache hit is partial if the frontend finds a cached range that collides with the range it queried for, but does not contain the entire range. In this case, the queried range may collide with multiple cached ranges previously fetched from user space and the frontend needs to first execute a range defragmentation step to determine the sanitized range. Let B be the queried range and let $M = \{A_i | A_i \in cache \wedge A_i \bigcap B \neq \emptyset\}$ containing all cached ranges that collide with B. Defragmentation involves computing a new range C such that $C = \cup_{i=1}^{n} A_i \cup (B \setminus \cup_{i=1}^{n} A_i)$. In other words, the defragmented range C contains all bytes from the cached ranges colliding with B, while the sub-ranges of bytes that are not cached yet are fetched from user space. The frontend instructs the backend to replace all colliding ranges in the cache with the newly defragmented range C, after which it can service the sanitized range from C. Defragmentation piggybacks on the result of the previous search, because all colliding ranges can be found by using the previous search's iterator. To support this, insertion in the linked list and red-black tree preserves the virtual address ordering of cached ranges.

7 Cache Backend

The **`Cache Backend`** is responsible with managing the backing memory for the syscall cache. Specifically, its main goals are to efficiently manage the lifecycle of ranges in the cache and exploit CPU cache locality as much as possible. The latter can be achieved by stacking together ranges in memory for data locality and thus better CPU cache utilization, which speeds up range queries. The former involves enforcing policies for range allocation/deallocation and storage provisioning/relinquishing techniques to keep cache operations optimal.

To achieve its goals, the backend maintains one cache for each in-transit syscall (at the per-thread granularity) and adheres to a cache organization specifically tailored to maximize data locality when performing range queries through the cache. Additionally, the backend enforces a series of range lifecycle management policies to efficiently oversee cache lifespan. To support this overall strategy, the backend relies on a custom memory allocator.

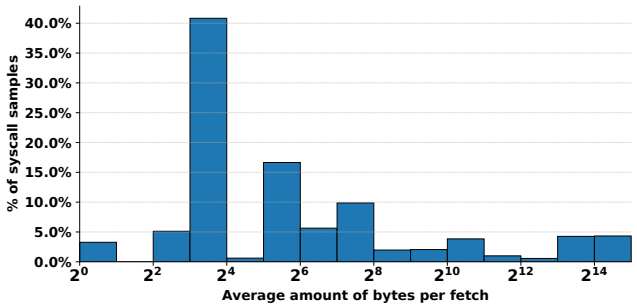

Figure 5: Percentage of syscall samples vs. average size of data they fetch.

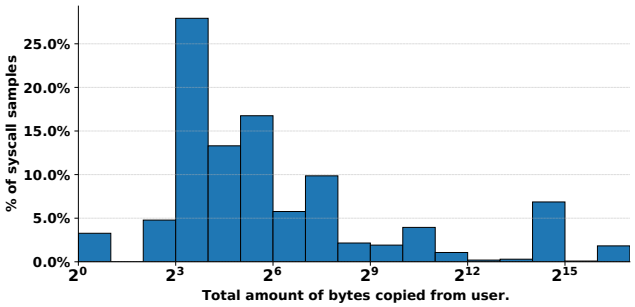

Figure 6: Percentage of syscall samples vs. total amount of data they fetch.

7.1 Custom Allocator

A naive allocation policy would be to create an object in the cache every time a syscall fetches a new range, by using an of-the-shelf kernel allocator (e.g., slab) to accommodate range data and metadata. However, standard kernel allocators do not give control over where objects are placed in (virtual) memory, so we cannot assure locality to improve the performance of range queries. Moreover, for an off-the-shelf allocator the allocation and deallocation logic might cause non-trivial overhead when syscalls transfer many ranges from user space, which happens in practice (see Figure 4).

A better approach is to service kernel memory in larger chunks to fit multiple ranges, i.e., using a *region-based allocation* scheme [13]. In such a scheme, a *region* consists of one or more *buffers* (contiguous memory blocks) with the same data lifetime. In a region, memory objects are allocated one after another in memory (in the current buffer) and get deallocated all at once (by flushing all the buffers), once the lifetime of all the objects in the region ends. As such, region-based allocation allows us to pack ranges together in memory to improve locality. Moreover, it reduces the number of calls to the underlying allocator when allocating ranges. On the fast path, an allocation involves only bumping a pointer to the next slot in the current buffer. Finally, it can efficiently deallocate all the allocated objects in one blow.

`SafeFetch` uses a custom region-based allocator, which services kernel memory at the granularity of a region, every time the backend requests more storage to hold ranges. To understand how well `SafeFetch` can benefit from region allocation's locality-friendly design, we turn again to our profiling results. Figure 5 shows the percentage of syscall samples that fetch an average size S of user data across all the profiled benchmarks. As shown in the figure, the majority (i.e., 65%) of syscall samples fetch ranges that are on average less than 64 bytes, confirming a high degree of data locality in a region in the common case. `SafeFetch` also benefits from the fast deallocation path of region-based allocation, efficiently deallocating all the ranges in the region when the syscall terminates. As an optimization, `SafeFetch` does not discard the buffers once the region is deallocated, but adds them to a pool for (fast) reuse in new regions created by future syscalls.

The next question is the buffer size one should use. As Figure 5 suggests, small allocation requests are common suggesting small buffers are desirable. Moreover, Figure 6 shows the percentage of syscall samples that fetch a total amount of B bytes of user data across all the profiled benchmarks. As shown in the figure, although a moderate portion of syscalls transfer much data (even above 8 pages), the vast majority transfer far less than a page of data. As a result, `SafeFetch` uses a single 1-page buffer by default in each new region (syscall) and elastically adds buffers as needed in the edge cases—many fetches per syscall or fetches transferring over 4 KB of data.

7.2 Dual Region Design

A naive approach would be to store the user memory ranges and the metadata necessary for range queries as a standalone object in one single per-syscall region. However, this approach would lead to metadata fragmentation and poor locality because metadata would be intermixed with data bytes. While most fetched ranges are small, we saw that syscalls can transfer larger ranges as well (Figure 5). To maximize data locality for range querying, the `Cache Backend` partitions the syscall cache in two separate regions: a *data* region stores all byte ranges copied from user space while a *metadata* region stores the bear bone necessities to perform queries over ranges. Consequently, for each user range, the backend maintains two objects: a) a *data* object storing the range of bytes copied from user space and b) a *metadata* object storing the properties of the range used when querying (e.g., user virtual address, length, pointer to the data object, and

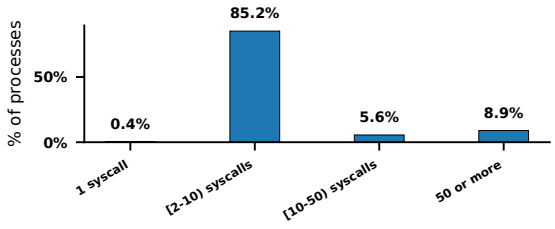

Figure 7: Percentage of processes vs. number of syscalls fetching user data.

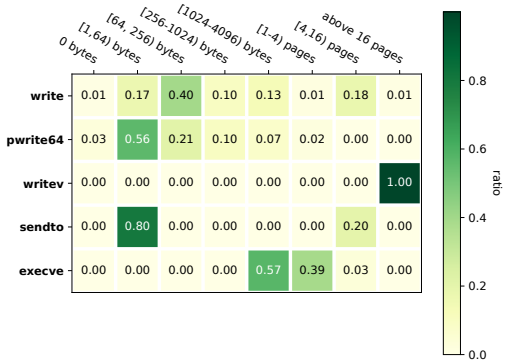

Figure 8: Heatmap showing the total amount of user data fetched by fetch-heavy syscalls.

a field used to link into a red-black tree or linked-list).

The size of *metadata* objects is fixed and small, allowing one to provision metadata regions with buffers smaller than a page. Nonetheless, we chose to serve 1-page buffers to metadata regions as well because this leads to better CPU cache coloring (and utilization) [19]. Despite the same default buffer size, the two regions provision their buffers from separate memory pools (i.e., slab caches) to further improve locality.

7.3 Lifecycle Management

Range allocation policy. A range is allocated in the cache every time the frontend encounters a cache miss while performing a range query. Our profiling data (e.g., Figure 4) suggests that most fetches are not double fetches, hence we expect frequent range allocations in the cache. Our custom allocator helps reduce the pressure on the (less efficient) underlying allocator, because many ranges can be allotted from the same region buffer.

Allocating ranges entails creating metadata and data objects in the appropriate regions. To this end, the backend uses a `region accounting` structure, which keeps track of all buffers allotted to the referent region. To speedup object creation, the `region accounting` structure stores a pointer to a region head buffer and favors servicing allocations from this buffer. As region heads get depleted at some point, new buffers are added to the region when appropriate and region heads get updated.

If an object cannot be created from the region head, the `Cache Backend` goes on the slow path iterating over all buffers allotted to the region until it finds one with enough space to service the request. As shown in Figure 6, some syscalls can transfer large amounts of user data, thus it is possible that a region can hold many depleted buffers. While this is more likely for *data* regions, it can also occur for *metadata* regions when syscalls execute many fetches. To optimize the slow path, the `region accounting` structure keeps a `freelist` containing only the buffers that are not yet depleted and can still service allocations. Lastly, if an object cannot be serviced on the slow path, then the backend leverages the custom allocator to create a new buffer in the referent region.

Cache invalidation policy. When a system call terminates, all ranges currently held in the cache can be deallocated. As a result, one could relinquish all storage held by cached ranges on syscall exit. This strategy reduces the memory footprint and also yields a simple deallocation path flushing all the buffers held by metadata and data regions. Moreover, as discussed, syscalls do not fetch many ranges, thus on average we need not free many buffers. However, as shown in Figure 7, our profiling data shows that 99.6% of the processes that incur fetches do so across at least two syscalls. In other words, if a process issues a syscall that fetches user data, it is likely to issue other syscalls that do the same.

Given our profiling results, it may be tempting to preserve all the allocated region buffers across syscalls. However, while this strategy minimizes the number of calls to the underlying allocator (improving performance), it may also significantly increase the steady-state memory footprint. That is particularly the case for threads issuing syscalls that fetch a lot of user data (even more than 8 pages, as shown in Figure 6). Given these observations, our cache invalidation policy is to preserve the head buffers, for both metadata and data regions, across the syscalls of a given thread but release all the other buffers held by each region, on syscall exit. Additionally, on each syscall exit, we invalidate the bookkeeping structure used by our frontend when performing range queries. Finally, on thread exit we release the residual head buffers.

Cache initialization policy. Given that our two head buffers persist across syscalls of the same thread, the next question is when to allocate such buffers. An option would be to simply allocate the head buffers at thread (i.e., `task_struct`) creation time. However, as shown in Figure 4, syscalls rarely fetch user data, e.g., $\approx 64\%$ of the syscalls do not issue any fetches. Hence, eager head

buffer allocation at thread creation time may lead to unnecessary memory overhead. As a result, the backend allocates the two head buffers (and the two regions) *lazily*, on the first user fetch that a thread incurs.

Zero-copy optimization. Given that most syscalls fetch little data, storing data into the cache is generally inexpensive. However, some syscalls are fetch-heavy and copy large amounts of data. In such scenarios, copying data into the cache incurs a nontrivial cost (as shown later in our evaluation), so it is desirable to eliminate as many such extra copies as possible. To investigate optimization avenues, we isolated all syscalls in our profiling results that copy more than a page of data from user space. Figure 8 presents our results in a heatmap.

As shown in the figure, many of these syscalls (with the exception of exec) are I/O bound. To avoid resource contention, I/O bound syscalls rely on the kernel `iov_iterator` functionality to copy dozens of large chunks of user data into kernel staging buffers. Such buffers (and their copied data) persist unchanged until the hardware (e.g., network card, hard disk) becomes available to complete the I/O transfer. To optimize out expensive copies to the cache, we use the kernel staging buffer itself as a data cache for all the `iov_iterator` copies fetching one or more pages. To delay deallocation of such staging buffers until syscall exit, we increase the reference count on the underlying pages. When enabling this *zero-copy* optimization (`SafeFetch` default), our cache invalidation policy also releases the staging buffers on syscall exit.

8 Implementation

We implemented a `SafeFetch` prototype for Linux kernel v5.11 (matching Midas' version for a fair comparison). The `Cache Frontend` adds the logic for cache lookups and fetch sanitization by instrumenting all kernel transfer function variants (i.e., `raw_copy_from_user` and all the `get_user` macro variants).

To manage the cache lifecycle for in-transit syscalls, the `Cache Backend` stores the accounting structures for (metadata and data) caches as structures in a thread's `task_struct`. Similarly, the bookkeeping structure used (for cache lookups) by the frontend is also referenced by the thread's `task_struct`. The custom region allocator uses two global slab caches (`kmem_caches`) to service region buffers efficiently to in-transit syscalls. We implemented cache invalidation by instrumenting the epilogue of the `do_syscall_64` kernel function and the `do_exit` function. Additionally, we instrumented all `clone` variants to initialize the `SafeFetch` logic in newly created threads. Finally, we implemented the zero-copy optimization by instrumenting the `copyin` kernel function used for `iov_iterator`-based user-to-kernel transfers.

Maintainability. While our design and implementation are optimized based on our syscall profiling data, we efficiently support a variety of syscall patterns. As such, even assuming applications change some of their syscall patterns in the future, we expect only minor (if any) modifications to our implementation. To facilitate the process, SafeFetch already supports runtime changes for all its core parameters, similar to other workload-sensitive kernel features (e.g., KSM, THP, etc.). In other words, with its ability to support many syscall patterns, its small codebase, and compliance to standard kernel design patterns (e.g., use of standard kernel data structures, standard hooking points, etc.), we expect `SafeFetch` to be highly maintainable moving forward.

9 Evaluation

In this section, we experimentally evaluate the security and performance of `SafeFetch`.

9.1 Security

CVE analysis. As `SafeFetch` hinders double-fetch bugs by construction, similar to Midas [15], we verify it can correctly mitigate a known double-fetch vulnerability. `CVE-2016-6516` is a known double-fetch vulnerability introduced in Linux kernel version 4.5. This vulnerability can be triggered via an ioctl syscall in combination with the `FIDEDUPERANGE` flag. This particular syscall attempts to deduplicate the memory pages between the source and its respective destination files. The source and destinations are supplied as parameters in a `file_dedupe_range` structure which the syscall copies from user space. However, before the syscall can fetch the structure it first needs to compute its size by using a count variable located inside the user space structure. After acquiring the count from user space, and performing sanity checks, the syscall fetches the entire structure into kernel memory overwriting the count field in the process, as can be seen in Listing 1. A double fetch vulnerability can emerge if between the first fetch (line **2**) and second fetch (line **17**) the count field is modified in user space. As a result, `vfs_dedupe_file_range` would operate on a malicious count value. This vulnerability was patched within Linux kernel v4.7 by copying back the old value into the data structure (line **23**) after the second fetch.

To evaluate whether `SafeFetch` can defend against this particular double fetch we modified Linux kernel version 5.11 by adding an additional check that verifies if a double fetch has occurred (lines **19-20**) prior to the proposed fix. In order to reproduce the bug

```
// first fetch, fetch count from user space
if (get_user(count, &argp->dest_count)) {
 ret = -EFAULT;
 goto out;
}

// use count to compute size of second fetch
size = offsetof(struct file_dedupe_range
   __user, info[count]);

// sanity check
if (size > PAGE_SIZE) {
 ret = -ENOMEM;
 goto out;
}

// second fetch
same = memdup_user(argp, size);

if (same->dest_count != count)
 printk("Double fetch Occurred\n");

// patch fix, write first fetched count back
same->dest_count = count;

// use second fetch
ret = vfs_dedupe_file_range(file, same);
```

Listing 1: CVE-2016-6516 Double-fetch vulnerability in ioctl_file_dedupe_range

we used the publicly available exploit[1] which runs the `FIDEDUPERANGE` ioctl in one thread, while constantly modifying the `dest_count` field in another thread. After running this exploit for 11 iterations on the vulnerable kernel, each iteration exploiting the double-fetch vulnerability one million times, we observed the double-fetch bug at least 10 times per iteration. When we subsequently ran the same experiment on a vulnerable kernel that deployed the `SafeFetch` defense, we did not observe a single double-fetch bug. This shows that `SafeFetch` is capable of mitigating kernel double-fetch vulnerabilities.

Security guarantees. `SafeFetch`'s ability to provide the expected security guarantees depends on the correctness of the implementation. To this end, we focus our analysis on TCB impact and protection coverage. As for the former, we note that, despite the carefully optimized implementation, our prototype has a small TCB impact. In total, our solution adds ≈1,750 LOC to the Linux kernel, ≈250 of which are for the region allocator (which the Linux kernel currently does not provide, but is on the list of kernel developers). Moreover, the TCB impact is comparable to that of Midas (1,100 LOC).

As for the latter, `SafeFetch` relies on hooking standard user-to-kernel transfer functions to interpose on kernel fetches, providing full protection as long as the kernel complies to standard interfaces. We found this to be (nearly) always the case for the core Linux kernel. The nonstandard `unsafe_get_user` wrapper—only used to implement `strnlen` semantics—is the only exception we could find. Nonetheless, in rare cases, some third-party drivers may bypass such interfaces, impacting protection coverage and also breaking standard features such as SMAP in the process [10]. This (minor) limitation is shared by Midas, which also needs to instrument standard user-to-kernel transfer functions. Furthermore, whitelisting some patterns may also reduce protection coverage. For instance, as also observed by Midas, `futex` requires whitelisting for correct behavior. Indeed, in `SafeFetch` we had to whitelist a single kernel fetch in `futex` (and no other syscall), yielding nearly full protection coverage. In contrast, Midas provides lower protection coverage by entirely whitelisting three major syscalls. We also noticed Midas' prototype does not protect fetches issued by interrupt handlers, while `SafeFetch` does.

9.2 Performance

Evaluation setup. To evaluate the performance of `SafeFetch`, we tested it on a server comprising of an i7-6700 CPU, 32 GB of RAM and a 120GB SSD, running on a Ubuntu 22.04 operating system. Our comparison baseline is a vanilla kernel version 5.11 on which we build the `SafeFetch` prototype. We evaluate `SafeFetch`'s default configuration, which uses an adaptive strategy that switches from a `linked list` to a `red-black tree` after 63 ranges are cached (see later for details on how we experimentally derived the threshold). The region allocator services 1-page region buffers to per-thread caches (for both metadata and data regions). Furthermore, the **default** `SafeFetch` config uses the zero-copy optimization for `iov_iterator` transfers above 4 KB. To get an idea on how `SafeFetch` directly affects core kernel building blocks, we analyze its performance on two OS benchmarks, namely `LMBench` [21] and `OSBench` [11]. Furthermore, we evaluate `SafeFetch` against popular applications from the `Phoronix` [12] test suite, to see how the prototype performs under various real-world workloads. For each result presented, we evaluated the corresponding benchmark 11 times and then reported the median. To get an estimate of `SafeFetch` performance relative to current state-of-the-art defenses, we compare our prototype against Midas—also deployed on Linux kernel version 5.11. As Midas incorporates a syscall whitelist, we made sure to also perform the same experiments on a `SafeFetch` variant that uses exactly the same kind of whitelisting (**whitelist** configuration).

`LMBench`. is a popular solution for system benchmarking as it focuses attention on many core kernel subsystems and has widely been used to pinpoint perfor-

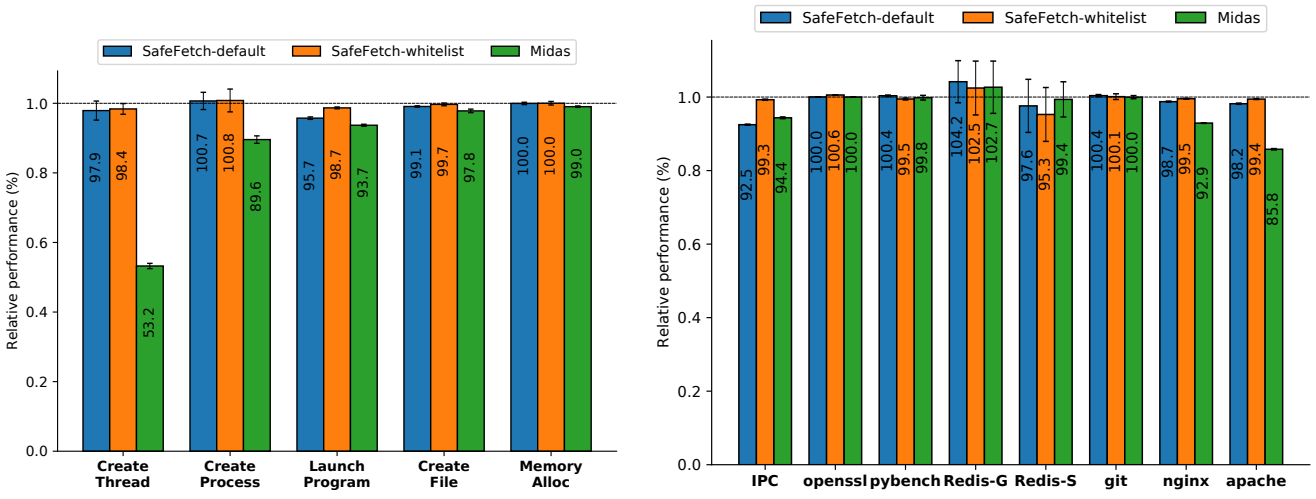
mance bottlenecks in OSes [16]. LMBench comprises of a series of latency benchmarks for a series of system calls that are commonly used by user applications and bandwidth benchmarks for relevant I/O related kernel facilities. In Table 1, we report the latency benchmark results of `SafeFetch-default`, `SafeFetch-whitelist`, and Midas relative to the baseline.

From the table we can observe that `SafeFetch-default` is able to provide comprehensive protection with marginal penalty to syscall latency for most syscalls tested by LMBench. The median geometric overhead across all latency benchmarks is around 4.4%. However, there are some syscall outliers that incur a larger penalty due to `SafeFetch`'s protection.



For example, the latency increase, when selecting over a small number of fds, is around 15% and 13%, on file and tcp descriptors, respectively. As the baseline latency is already small (less than half a microsecond), our defense wastes extra clock cycles copying the fd sets and `timespec` structure into `SafeFetch`'s cache from user space. Taking a deep dive in the main source of the overhead, we see that select benchmarks are mainly impacted by the extra downtime when allocating the head region buffers for metadata/data regions, rather than the actual copies into the cache.

Signal handling is also a major overhead outlier when using `SafeFetch-default`. Handling a signal is generally fast, executing with less than one microsecond downtime. However, `SafeFetch` adds extra overhead due to a series of user copies needed to setup and restore a `sig_return` frame, a stack frame used to restore the program context after calling the signal handler. The largest part of the overhead is spent on calls to memcpy when copying the signal frame into the data cache, as the frame can be around 160 bytes in size. At the same time, our results show that Midas reports significant overhead, incurring around 36% geomean overhead across all benchmarks. Signal handling and selecting on file descriptors is particularly slow and in some cases, Midas can triple the latency of these benchmarks.

We attribute our performance edge over Midas due to in-kernel caching being much more efficient than MMU-based instrumentation in the typical case of syscalls copying limited number of data (if any) from user space. Even in the case of the fork+shell microbenchmark, which can copy even a couple of hundred user space ranges, `SafeFetch` manages to outperform Midas in terms of latency, even though Midas whitelists the *execve* syscall.

The standard deviation relative to the baseline (the **stddev** column), suggests that our results are stable across measurements. One exception for `SafeFetch` is the TCP connection benchmark, which has moderate standard deviation due to one single (high) outlier. Lastly, we also noticed that applying whitelisting does not typically provide much performance gain for `SafeFetch`. However, for fetch-heavy benchmarks, such as fork+shell, whitelisting does completely eliminate the incurred overhead. This trend is even more noticeable in our LMBench bandwidth benchmark results, which we report in Table 2. As shown in the table, `SafeFetch-default`'s overhead on those benchmarks is again generally low (≈ 3.5% geometric mean overhead) and whitelisting completely eliminates the overhead for the outliers for `SafeFetch`—and to a lesser extent for Midas.

`OSBench`. We also evaluate `SafeFetch` on OSBench benchmarks. OSBench uses libc wrappers to evaluate basic kernel functions such as: process creation (e.g., `fork`, `waitpid`), thread creation (e.g., `pthread_create`, `pthread_join`), launching programs (e.g., `exec`), file creation (e.g., `fopen`, `fwrite`), and memory allocation (e.g., `malloc`, `free`). The results are shown in Figure 9, which reports the performance relative to the baseline

(a) OSBench

(b) Phoronix

Figure 9: `SafeFetch` performance on OSBench and Phoronix benchmarks relative to the baseline kernel. Standard deviations are reported relative to baseline performance.

kernel for `SafeFetch-default`, `SafeFetch-whitelist`, and Midas. Performance is expressed as the inverse of the time spent executing each benchmark.

These results show that creating threads and processes for the default `SafeFetch` configuration is marginal, i.e., ≈ 2% for thread creation and ≈ -1% for process creation. Interestingly, Midas does incur a significant performance loss on these benchmarks and some results significantly deviate from those reported in the original Midas paper (e.g., ≈ 88% vs. ≈ 5% slowdown for the "Create Thread" benchmark). We verified that the standard deviation is small for all the configurations (lower than 3% relative to the mean for `SafeFetch` and at most 2.7% for Midas), which confirms Midas' overheads are consistent in our environment. We attribute the deviations to Midas being particularly environment-sensitive. For instance, a trivial change in the allocator behavior may introduce/eliminate false sharing and significantly change Midas' performance characteristics. As detailed later, false sharing as well as other sources of overhead such as TLB shootdown are more likely to occur in a multi-threaded scenario. This is consistent with Midas' overhead being higher when creating threads.

Creating files is typically an I/O bound task and we expected `SafeFetch-default` to incur more overhead from the extra writes to the caches. However, the file creation benchmark creates small 32-byte files to prevent saturation of the underlying storage, thus imposing fairly low pressure on the caches. Across all benchmarks from OSBench, `SafeFetch` offers competitive performance with a negligible 1.3% geomean performance penalty, especially when compared to Midas's geomean performance impact of ≈ 15.4%. The overhead outlier for `SafeFetch` is the program launching benchmark (≈ 4.3%), as it relies on the fetch-heavy `exec` system call. Midas's performance penalty on OSBench is ≈ 15%, mostly because of thread creation. Looking at `SafeFetch-whitelist` performance, we observe that the geomean overhead on OSBench approaches 0%, as whitelisting completely eliminates the overhead on exec syscalls.

`Phoronix Test Suite.` The Phoronix Test Suite comprises of a wide range (> 600) of open-source benchmarks to evaluate application or OS performance under various workloads. We selected a range of benchmarks that evaluate popular user applications, each exhibiting various levels of kernel activity. From the chosen benchmarks, OpenSSL, is mainly compute bound and thereby its performance is mostly OS-agnostic. Therefore, we chose OpenSSL as a representative example for the best case scenario, assessing whether `SafeFetch`'s OS instrumentation perturbs user space performance. The other benchmarks vary from single-threaded (e.g., pybench) to multi-threaded (apache) and multi-process (nginx) workloads. We also chose the IPC benchmark to highlight the worst-case scenario, as it spends most of the time in I/O syscalls (`writev`) to transfer multiple 128 byte chunks between processes, via TCP.

For benchmarks that report throughput, we compute the ratio relative to the baseline and, for benchmarks that report execution time (e.g., pybench, git), we compute the inverse ratio relative to the baseline. The speedup of each benchmark relative to the baseline for `SafeFetch`

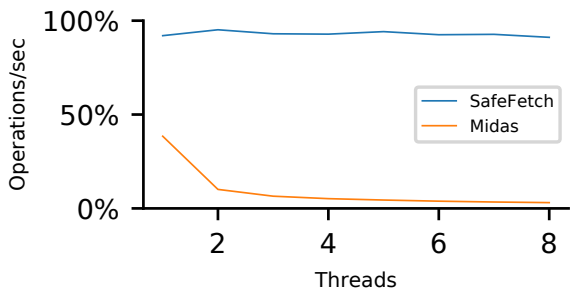


Figure 10: Relative throughput to the baseline when fetching from concurrent threads

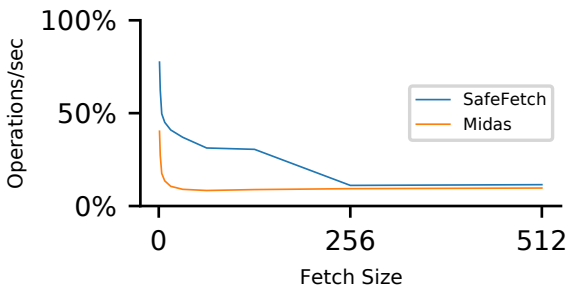

Figure 11: Relative throughput to the baseline when fetching user buffers of increasing sizes

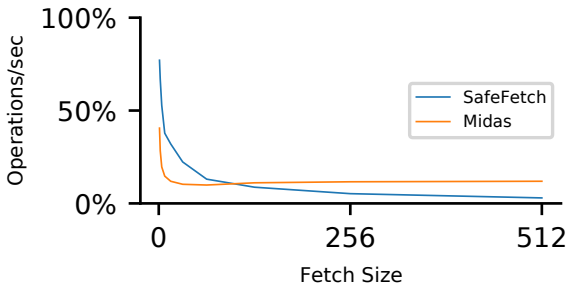

Figure 12: Relative throughput to the baseline when fetching user buffers one 1-page fetch at the time

(default and whitelist configs) and Midas is shown in Figure 9. On benchmarks that do not rely much on syscalls (e.g., pybench, openssl, git), `SafeFetch-default`'s performance is nearly equivalent to that of the baseline. Interestingly enough, benchmarking git revealed that some git commands can copy a couple of 1-page buffers from user space (during `write` syscalls). Even so, the performance of our default configuration is slightly faster than that of the baseline. This shows that caching is not necessarily a bottleneck even when storing large user ranges, provided that this does not happen frequently. Redis uses `recvfrom` and `sendto` syscalls when processing key store requests and responses. As Redis relies on pipelining to batch multiple client requests in a single response, the `sendto` syscall can cache large user space ranges (e.g., 8 pages). This would explain why `SafeFetch-default` scores 2.4% throughput degradation on *Set* benchmarks. Midas performs slightly better on this benchmark, having around ≈1% throughput degradation.

In contrast to the other benchmarks, the Apache and Nginx web servers heavily rely on I/O syscalls to respond to requests over the network and perform logging on the file system. Yet, `SafeFetch-default` scores only 1.3% and 1.8% throughput degradation on Nginx and Apache (respectively), while Midas scores 7.1% on Nginx and 14.2% overhead on Apache. As we will see in the next section, `SafeFetch`'s zero-copy optimization provides a large benefit on these benchmarks reducing the throughput degradation by nearly a factor of 5 compared to caching large `iov_iterator` copies. On the IPC benchmark, our default `SafeFetch` configuration scores 7.5% throughput degradation. Although the IPC benchmark exercises syscalls that can leverage the zero-copy optimization, these syscalls fetch buffers smaller than a page and thus never trigger the optimization. Whitelisting does not provide much benefit on Phoronix with the exception of the IPC benchmark, where whitelisting writev syscalls reduces the throughput degradation to 1%.

Overall, across all Phoronix benchmarks the default `SafeFetch` configuration has around 1.2% overhead and, when applying the same whitelisting as Midas, `SafeFetch` overhead again approaches the 0%. Conversely, Midas scores around 3.2% overhead (more than **2x** overhead vs. `SafeFetch`) even though it whitelists three major system calls. Across all the Phoronix benchmarks, the standard deviation is small, with the exception of Redis benchmarks which reported higher values (around 7% for both Midas and `SafeFetch`). The higher standard deviation matches that reported by others for multi-core systems, where Redis performance relies on the NUMA configuration of the system [1].

`Microbenchmarks.` To better understand the performance characteristics of `SafeFetch` and Midas, we devised microbenchmarks that repeatedly cause the kernel to fetch data from a user process. The goal is to evaluate throughput (number of fetches per second) as (i) the number of threads that fetch the same data increases or (ii) the size of the fetched data increases.

For the first scenario, our microbenchmark repeatedly issues a syscall to fetch a single 32-byte user buffer (the median fetch size in our profile) from multiple concurrent threads. We ran our microbenchmark for different number of threads (1 to 8, matching our core count).

Figure 10 reports the average per-thread throughput we measured relative to the baseline. As shown in the figure, SafeFetch's throughput is stable as we increase the thread count, with a 7.1% degradation on average. This is because kernel-side caching scales efficiently with no interferences across threads. In contrast, Midas' throughput progressively degrades as we increase the thread count, with a degradation as high as ≈97% with 8 concurrent threads. A number of factors contribute to the heavy performance penalty.

First, Midas' MMU-based instrumentation introduces nontrivial costs on the fast path: (i) software page table walks to retrieve and mark PTEs in protected state and (ii) TLB misses after transitioning pages from/to read-only state. Such costs are noticeable even in a single-threaded scenario, where Midas already reported a significant 62% throughput degradation. Second, transitioning pages to/from protected state adds extra (e.g., page table) locking to the fast path, leading to higher lock contention and lower performance as we increase the number of threads. Third, changing page protections in a multi-core setting introduces increasingly expensive TLB shootdowns as we increase the number of threads. Last, false sharing effects are generally more prominent as we increase thread count. To synthetically simulate these effects, we configured each thread in our microbenchmark to interleave fetches with writes to the same page as the fetched data. When rerunning our microbenchmark, we observed no noticeable throughput differences for SafeFetch. In contrast, Midas' throughput further dropped by ≈3% on average, due to false sharing inducing additional page fault and (over)copying overhead.

For the second scenario, our microbenchmark uses a single thread (best-case scenario for Midas) repeatedly issuing a syscall to fetch user data of a given size. We ran our microbenchmark for different sizes (1 to 512 pages) of a user buffer transferred by a single fetch. Figure 11 reports the average throughput we measured relative to the baseline. As expected, both SafeFetch and Midas experience significant throughput degradation as the user buffer grows larger and larger. However, SafeFetch consistently outperforms Midas and even by a wide margin up to 256-page buffers. This shows that the costs associated to page protection (Midas) are consistently higher than those of copying data (SafeFetch), especially when the buffer is in the CPU caches. To further stress our implementation, we also repeated our experiment when distributing the user buffer transfer over multiple fetches per syscall (1 page fetched at the time). Figure 12 presents our results. As shown in the figure, only the heavier pressure on SafeFetch's cache lookups at a large number of fetches (128 pages and beyond) gives Midas a performance edge. Nonetheless, it is rare for syscalls to copy such large amounts of data over many fetches. For instance, we only recorded 2,350 samples in our profile (out of ≈317 million syscall samples) that fit this pattern.

Table 3: SafeFetch-induced memory utilization.

Benchmark	SafeFetch raw memory utilization					
	cache provisioning			zero-copy pins		
	avg.	99^{th}	peak	avg.	99^{th}	peak
LMBench	**8.02 KB**	**8 KB**	**236 KB**	**0.65 KB**	**0 KB**	**9.6 MB**
OSBench	**8.04 KB**	**12 KB**	**12 KB**	**0 KB**	**0 KB**	**0 KB**
Phoronix	**8.04 KB**	**8 KB**	**44 KB**	**5.82 KB**	**16 KB**	**128 KB**

Memory utilization. We show per-syscall raw memory utilization in times of storage provisioned to caches and pages pinned by the zero-copy optimization across all benchmarks in Table 3. The table depicts average, peak, and 99^{th} percentile utilization, only for syscalls that use the SafeFetch defense at all. On average, syscalls use at most 3 pages for the cache storage and pin at most 2 pages of memory (e.g., Phoronix). While peak utilization is higher on LMBench and Phoronix the 99^{th} percentile results suggest that this trend is isolated to only a couple of executed system calls, for both storage provisioning and zero-copy pinning. On Phoronix, we observed that the calling thread's resident memory size is increased on average by ≈0.12% due to provisioning in-transit syscall caches. Overall, our results show that, even at (short-lived) peak utilization, SafeFetch only marginally impacts the system memory footprint, demonstrating realistic overheads for a practical solution.

9.3 Design Breakdown

In this section, we discuss the optimal configuration for SafeFetch's adaptive cache lookup algorithm as well as the performance benefits of SafeFetch's core design decisions (i.e., using a region allocator, preserving head region buffers across syscalls, and the zero-copy optimization for iov_iterator copies).

Adaptive search algorithm. SafeFetch uses an adaptive search algorithm which switches from a linked list to a red-black tree after a threshold of cached ranges is reached. We have determined the optimal conversion threshold experimentally. To this end, we performed repeated experiments (101 times), with each experiment performing 100 1-byte fetches from a set of random virtual addresses while using a given data structure (linked list or red-black tree). We ensured the addresses were nonoverlapping (no double fetches), thereby simulating the most common scenario we uncovered during profiling.

Figure 13 reports the average time (search+insert time) of each fetch as the number of cached ranges grows, for the linked list and red-black tree configurations. The

Figure 13: Average normalized time for each fetch vs. number of cached ranges.

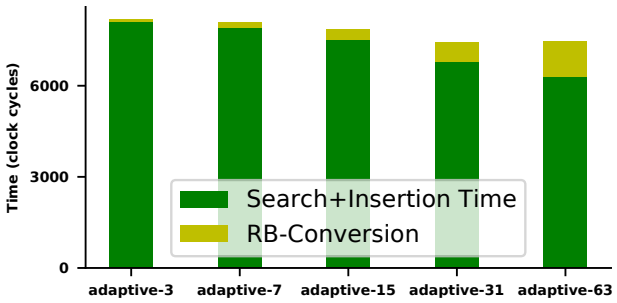

Figure 14: Cumulative times of the first 64 fetches for different adaptive configurations of `SafeFetch`. The conversion cost is marked on top of each bar.

average times are normalized with respect to the largest observed value. As shown in the figure, after ≈ 50 cached ranges the red-black tree is more efficient than the linked list. To establish the most efficient conversion threshold, we also need to consider constraints of the conversion algorithm. As mentioned earlier, our algorithm is most efficient if a dataset contains $2^N - 1$ entries, which, according to our results, suggests a threshold of 31 or 63.

To determine the optimal one, we compared average cumulative search+insert times for the first 64 fetches in our experiments with all possible conversion thresholds smaller than 63. Figure 14 reports our results, highlighting the cost of conversion with yellow bars. While the 31 and 63 configurations offer similar performance, `SafeFetch` uses the latter by default. This is to delay conversion as much as possible, which is beneficial for (more common) syscalls with a lower number of fetches.

Benefits of region allocation. We used LMBench to understand how region-based allocation speeds up syscall performance for `SafeFetch`. As a baseline, we use our default `SafeFetch` prototype, equipped with a region allocator which relies on 4 KB buffers for data/metadata provisioning. The baseline also preserves region heads across syscalls (executed from the same thread). We compare the baseline against a `SafeFetch` version invoking a standard kernel allocator (i.e., kmalloc) when a syscall needs to add ranges into the cache and freeing all the objects on syscall exit (the **noregion** configuration). Moreover, to determine the benefits of preserving buffers across syscalls, we also compare the baseline against a region-enabled `SafeFetch` version not preserving region heads across syscalls (the **noheads** configuration).

For brevity, we focus on LMBench results. Across all the LMBench benchmarks, the **noheads** configuration adds 3.1% geomean overhead compared to the baseline, with the select benchmarks being the worst offender. Select on 500 file descriptors is 18% slower on the **noheads** configuration compared to the baseline. This is somewhat expected as the select syscall can be interrupted (e.g., by a signal), which may prompt the application logic to restart the syscall. The **noregion** configuration, in turn, adds a 5% geomean overhead compared to the baseline, showing that region allocation significantly speeds up syscall performance for `SafeFetch`. The delta is even more evident if we look closely at the worst-case overheads. Major overhead offenders for the **noregion** configuration are select on file descriptors (as high as 30% slowdown compared to the baseline), signal handling ($\approx$ 21% slowdown), and exec calls ($\approx$ 4.3% overhead when spawning a shell).

Zero-copy optimization. To understand the benefits of the zero-copy optimization, we evaluate two `SafeFetch` configurations: the default `SafeFetch` configuration (/w zero-copy) and the same configuration with the zero-copy optimization disabled (/wo zero-copy). We compare our two configurations against the baseline Linux kernel on a series of I/O benchmarks. To showcase the worst-case scenario, we used the `AF_UNIX` socket stream bandwidth and the pipe bandwidth benchmarks part of the LMBench suite. To show the gains of zero-copying on real-world applications, we used the `Apache` and `Nginx` web servers which are known to exercise I/O syscalls. Table 4 presents our results, with the `SafeFetch`-induced throughput degradation compared to the baseline.

As shown in the table, without the zero-copy optimization, the throughput degradation is significant. For instance, `AF_UNIX` throughput is reduced by $\approx$ 39% while pipe throughput is reduced by $\approx$ 16%. This is because,

Table 4: SafeFetch-induced throughput degradation.

Benchmark	SafeFetch /wo zero-copy (%)	SafeFetch /w zero-copy (%)
AF_UNIX	**39.1%**	**8.4%**
Pipe	**16.1%**	**5.1%**
Nginx	**5.9%**	**1.3%**
Apache	**9.3%**	**1.8%**

without zero-copy optimizations, SafeFetch copies large chunks of user data to the data cache, incurring significant overhead. For instance, avoiding unnecessary copying reduces the throughput degradation to 8.4% and 5.1% on the AF_UNIX and pipe benchmarks, respectively. Copying large chunks of user data impacts performance of real-world applications as well: Nginx and Apache have their throughput reduced by 5.9% and 9.3% compared to the baseline (respectively). Enabling the zero-copy optimization reduces throughput degradation for both web servers to below 2%. Our results confirms the zero-copy optimization is key to good I/O benchmark performance.

10 Related Work

While double-fetch or TOCTTOU (Time-of-Check-to-Time-of-Use) vulnerabilities affect different interfaces and components (e.g., enclaves [17, 25], sandboxes [22], compilers [29], and compartments [14]), we focus here on closely related research on operating system kernels. Serna [24] was the first who coined the name "*double-fetch vulnerability*" to describe an instance in the Windows kernel. Since then, research has focused on finding double-fetch bugs (through static and dynamic program analysis) or even mitigating these issues.

Static analysis. On the static analysis front, Wang et al. [26] leverages pattern matching analysis on source code to find double-fetch bugs in the Linux kernel. DFTinker [20] extends such pattern-based approach to increase double-fetch coverage and reduce false positives. While pattern-matching techniques proved effective in uncovering new double-fetch bugs, they still produce a high rate of false positives and negatives and are fundamentally limited to detecting only specific bug patterns.

DEADLINE [31] and DFTracker [27] improve static detection of double fetches by means of compiler-level symbolic execution. While these approaches can be applied more broadly (e.g., to detect compiler-induced double fetches [28,30]) and are generally better suited for vetting false positives, symbolic execution introduces other limitations (e.g., path explosion) and does not completely remove false reporting (e.g., due to imprecise memory modeling or incomplete code coverage). DEADLINE, for example, does not detect double fetches in inline assembly, which is widely used in the kernel.

Dynamic analysis. On the dynamic analysis front, Jurczyk and Coldwind [18] propose Bochspwn, which instruments memory access callbacks in an x86 emulator to trace double-fetch patterns. Coupled with fuzzing, their technique found a series of exploitable double fetches in the Windows kernel. However, Bochspwn incurs high overheads because its tracing instrumentation affects the emulator's fast path. Wilhelm [28] uses a similar approach to Bochspwn and found double-fetch vulnerabilities in the Xen hypervisor, one of which was introduced through compiler optimizations. Schwarz et al. [23] use a fuzzer in conjunction with concurrent user memory accesses to detect double fetches through a cache covert channel. However, such a solution is reliant on hardware features (e.g., caches), which vary across microarchitectures and are subject to noise. While dynamic techniques are often more precise than static approaches, they are fundamentally subject to code coverage and limited to finding double-fetch bugs only on executed code paths.

Mitigations. Midas [15] is the first proposed mitigation to protect the operating system kernel against double-fetch vulnerabilities. Midas relies on MMU-enabled Copy-on-Write semantics to create snapshots of user pages accessed by the kernel during syscall execution. As a result, Midas incurs nontrivial runtime performance overhead due to the cost of trapping/remapping and the coarse (page-granular) write interposition mechanism. Additionally, Midas whitelists some syscalls, most notably the fetch-heavy *exec* syscall. In contrast, SafeFetch eliminates the need for MMU-based instrumentation and offers comprehensive protection at a fraction of Midas' cost. Moreover, our solution is simple and seamlessly integrates with existing kernel code paths. Indeed, SafeFetch's high-level design is inspired by the "*kernel-side caching of user space memory*" on the wishlist of Linux kernel developers to address double-fetch vulnerabilities [8].

11 Conclusion

We presented SafeFetch, a practical double-fetch bug protection system which caches kernel fetches at the syscall granularity and serves subsequent fetches of the same data from the cache, thus ensuring that user data never changes across fetches. We showed that SafeFetch offers comprehensive protection at a fraction of the cost of state-of-the-art solutions such as Midas with marginal memory overheads and geometric performance overheads consistently below 5% across various OS benchmarks (e.g., 4.4% on LMBench and 1.3% on OSBench) and real-world workloads (e.g., 1.2% on Phoronix).

Availability

To encourage adoption, we have open sourced `SafeFetch` at https://github.com/vusec/safefetch. We are also actively engaging Linux kernel developers to seek mainline inclusion.

A Double Fetch Statistics

In this section, we present detailed statistics related to fetch and double fetch occurrences across our benchmarks. Table 5 presents our results. For both generic fetches and double fetches (i.e., fetches that transfer data overlapping with a previous fetch within the same syscall) we detail: the rate of (double) fetches relative to the total number of syscall samples collected for the benchmark (the **Rate** column), the total number of distinct syscalls that executed a fetch during the benchmark (the **Syscalls** column). Additionally, we report the minimum, average, and maximum number of (double) fetches executed by one single syscall sample. The last row in the table refers to syscalls executed by background applications. As shown in the table, each benchmark has a nontrivial (e.g., up to 21 for Phoronix) number of syscall types with double fetches. Moreover, the number of double fetches performed by double-fetch syscalls greatly varies (e.g., ranging from 1 to 218 for Phoronix).

Table 5: Statistics for (double) fetch rates.

Benchmark	Statistic	Fetches	Double Fetches
LMBench	**Rate**	**1/2**	**1/273457**
	Syscalls	**38**	**7**
	Min/Avg/Max	**1/1/459**	**1/50/67**
OSBench	**Rate**	**1/3**	**1/80**
	Syscalls	**17**	**5**
	Min/Avg/Max	**1/6/134**	**1/42/43**
Phoronix	**Rate**	**1/4**	**1/5993**
	Syscalls	**47**	**21**
	Min/Avg/Max	**1/1/661**	**1/1/218**
Background	**Rate**	**1/2**	**1/644**
	Syscalls	**93**	**20**
	Min/Avg/Max	**1/2/4099**	**1/130/467**

Across all benchmarks, syscalls are likely to execute fetches (around 1 in 3 syscalls fetch user buffers), but more often they will fetch only a small number of user buffers (e.g., on average syscalls fetch 6 user buffers on OSBench). This prompted us to use a linked list as the default data structure for efficient caching. However, across all benchmarks, there are occurrences of fetch-heavy syscall executions (e.g., with up to 661 fetches on Phoronix), motivating the need for an adaptive strategy that resorts to a red-black tree to handle fetch-heavy scenarios. Moreover, the striking difference between fetch rates and double fetch rates across all benchmarks, with double fetches being far less frequent, suggests that cache insertions happen often and thus it is crucial to factor in insertion time when determining the optimal threshold to convert to a red-black tree.

Looking more closely at the variability of the number of fetches a syscall makes—across the syscalls that fetch data in our profile—we observed that ≈55% have a stable fetch rate (i.e., they fetch the same number of user buffers every time). Most syscalls with stable fetch rates perform either 1, 2 or 3 fetches, with the exception of sendmmsg which performs 6 fetches all the time. From the syscalls that have variability in the number of executed fetches, 45 system calls execute between 1 and at most 8 fetches while only 5 system calls execute more than 8 fetches. Special cases are 3 system calls, i.e., pwrite64, execve, and write that have high variability and execute 1-255, 1-1411 and 1-4,099 fetches, respectively. Again, this variability motivates the need for an adaptive strategy for cache lookups. Looking instead more closely at the variability of the number of double fetches—across the syscalls that fetch data twice in our profile—we observed that ≈60% execute only one double fetch, while 33% execute either 1 or 2 double fetches and the sendmsg syscall may execute between 3 and 6 double fetches. The execve syscall is again an exception and can execute between 1 and as many as 467 double fetches.

LanDscAPe: Exploring LDAP Weaknesses and Data Leaks at Internet Scale

Abstract

The Lightweight Directory Access Protocol (LDAP) is the standard technology to query information stored in directories. These directories can contain sensitive personal data such as usernames, email addresses, and passwords. LDAP is also used as a central, organization-wide storage of configuration data for other services. Hence, it is important to the security posture of many organizations, not least because it is also at the core of Microsoft's Active Directory, and other identity management and authentication services.

We report on a large-scale security analysis of deployed LDAP servers on the Internet. We developed LanDscAPe, a scanning tool that analyzes security-relevant misconfigurations of LDAP servers and the security of their TLS configurations. Our Internet-wide analysis revealed more than 10k servers that appear susceptible to a range of threats, including insecure configurations, deprecated software with known vulnerabilities, and insecure TLS setups. 4.9k LDAP servers host personal data, and 1.8k even leak passwords. We document, classify, and discuss these and briefly describe our notification campaign to address these concerning issues.

1 Introduction

The Lightweight Directory Access Protocol (LDAP) is the standard technology to query information stored in directories. These directories may contain sensitive personal data such as usernames, email addresses, and passwords. LDAP is also used as a central organization-wide storage of configuration data for other services. LDAP instances manage data within the directory and allow the authentication of individuals and services seeking access to it [48]. LDAP is used in various domains, including email services [6, 43] such as Microsoft Exchange [34], publishing Public Key Infrastructure (PKI) information [29], and enabling Single-Sign-On solutions [24, 56]. LDAP servers are often an integral part of more comprehensive directory services, notably Apple's Open Directory [4], Microsoft's Active Directory (AD) [7,28], and Red Hat's Directory Server [42]. In some cases, these services are intended for public use and hence meant to be exposed to and accessible over the Internet. More frequently, however, they hold private or sensitive data that should be only accessible to a small group of principals or within an organization's backend network. The secure configuration of these private LDAP servers is of critical importance.

In this paper, we take a closer look at the security configurations and the directories of LDAP servers publicly accessible on the Internet. To the best of our knowledge, despite it being the industry standard, there is no prior study of LDAP at Internet scale besides DDoS amplification analyses using LDAP over UDP [1]. In fact, LDAP has been mostly studied in terms of isolated vulnerabilities rather than as an ecosystem. Consequently, there are no tools dedicated to large-scale evaluation. Existing software to analyze LDAP settings is also usually limited in scope [32, 51, 54].

For our study, we built a custom tool, LanDscAPe, that identifies public LDAP servers on the Internet, assesses their configuration, including TLS setup, and samples the hosted directories. Concretely, the tool scans the IPv4-wide Internet for hosts with common LDAP ports in an open state. It then sends LDAP probes to determine if the service indeed speaks LDAP. LanDscAPe tries all standard-conforming ways of anonymously (without using passwords) binding to servers and, if successful, collects configuration information and requests directory samples. It analyzes the samples for personal data, sensitive configuration values, and possible passwords. Finally, LanDscAPe examines the TLS configurations of LDAP servers. Note that the scanning and analysis methods behind LanDscAPe, in particular those that take and analyze directory samples, are built to minimize harm to affected users. For example, we only take small directory samples, even if the server is willing to return larger samples or even the full directory, and delete all samples after analysis.

LanDscAPe found 3.7 million IPv4 addresses responding on LDAP ports 389 or 636; about 82.1k IPs sent valid LDAP responses. 12,179 IPs (14.83%) respond with personal data, and out of those, only 1,392 (11.4%) use a recommended

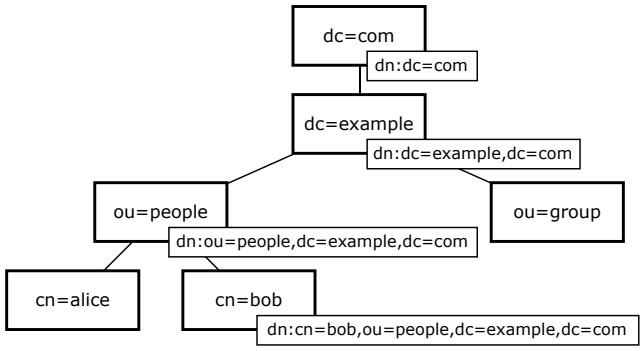

Figure 1: LDAP DIT example.

cipher suite and have a valid certificate chain. This means that the vast majority of LDAP servers exposing personal data insufficiently protect the confidentiality and authenticity of personal data. Furthermore, 616 IPs (0.75%) run an LDAP server version that is linked to at least one CVE and 9,731 IPs (11.85%) leak possibly sensitive internal information. In combination, these findings mean that it is trivial for attackers to obtain valuable information about organizations. Personal data in LDAP directories often resembles contact information of employees; these may even leak the organization's structure, which is valuable reconnaissance information.

Even worse, our sampling revealed that 1,817 IPs (2.21%) leak passwords, either hashed or plaintext. To further minimize harm to users, we develop a method for counting the total numberount of passwords within a directory without actually downloading them. In total, the affected servers leak 3.9 million passwords. For technical, ethical, and legal reasons, we cannot validate whether these passwords are (still) valid, and for many LDAP servers, we do not know which organizations and services the directories are part of. Still, we fear that the sheer amount of leaked passwords implies that a sizable number is used in real-world services.

Contributions. In summary, our contributions are:

- We introduce LanDscAPe, enabling semi-automated and Internet-wide security analysis of public LDAP servers.
- We analyze technical opportunities and limits of the LDAP protocol as well as ethical considerations for Internet-wide LDAP security analysis.
- We uncover thousands of LDAP servers that host personal data and use a subpar security configuration, including TLS ciphers and certificates. We find 1.8k LDAP servers that leak hashed or plaintext passwords, posing a high risk for affected organizations and users.
- We describe our coordinated disclosure campaign and its effectiveness.

2 Background

2.1 The Lightweight Directory Access Protocol (LDAP)

Data access using the Lightweight Directory Access Protocol (LDAP) assumes an X.500 directory structure, which uses a hierarchical tree structure called Directory Information Tree (DIT), as shown in Fig. 1. Every entry within this directory system is identified by a distinct Distinguished Name (DN). This DN consists of the entry's name and the path leading back to the root entry—also known as the directory path. Additionally, entries have attributes with a predefined type and a value. The type determines the syntax, semantics, and characteristics of the value. Attribute types are uniquely identified internationally by their Object Identifier (OID) [25, 26].

The Directory System Agent (DSA)'s DSA-Specific Entry (DSE) is the root node within the DIT [57]. Clients can access this entry through a search operation specifying the desired attributes of the DSE. These attributes hold a unique significance, as they encompass essential information about the server, such as supported controls, extensions, features, LDAP versions, SASL mechanisms, and more [57].

2.2 LDAP Authentication and Authorization

Clients authenticate to an LDAP server by attempting a bind operation. A connection between the client and the server is established if the bind is successful [16, 48]. As part of the bind request, the client chooses an authentication method and, if necessary, supplies authentication credentials. LDAPv3 supports four types of authentication: simple, anonymous, unauthenticated, and SASL authentication [16].

Simple Authentication is performed when the client transmits the fully qualified DN of a user and a cleartext password. This method necessitates an encrypted channel, such as TLS, as transmitting the password in plaintext exposes it to the network [16].

Anonymous Authentication uses empty values for both the username and password or sends a request without a prior bind operation. The client is then authenticated as an anonymous user. This anonymous bind is a mandatory part of the protocol [16].

Unauthenticated Authentication is a simple authentication with a username and an empty password. The client is then bound as an unauthenticated user. It's worth noting that RFC 4513 [16] recommends disabling this method by default for clients and servers. This is due to the unexpected nature of users being able to bind without supplying a password, which may cause security issues.

SASL. SASL supports a wide range of authentication methods, such as username/password, Kerberos, and digital certificates. Anonymous and plaintext SASL authentication is

not commonly used in LDAP [17]. While some are notably robust, others have been identified as insecure [58].

Authorization, or access control, is not documented within the LDAP Standards [48]. Consequently, LDAP server vendors often autonomously develop their own access control mechanisms. OpenLDAP uses Access Control Lists (ACLs) [33, 37] for this purpose [15].

LDAP as an Authentication Provider. LDAP is frequently used as a central component of single sign-on systems. For this purpose, most implementations follow a specific workflow: Initially, a search operation is initiated for the provided username to retrieve the DN of the user's LDAP entry. For this, LDAP servers must either allow unauthenticated searches or the application must use an authorized service account. Without the initial search, user sign-in becomes cumbersome because the user needs their Distinguished Name (DN), such as `CN=John Doe, OU=Users, DC=example, DC=com`. After the search, the system proceeds to bind using the DN and the provided password.

2.3 Data Retrieval from LDAP Servers

The search operation is a fundamental feature of LDAP, enabling the retrieval of entries from an LDAP server. The search is performed relative to a base object entry, which the client specifies using a DN. This can also be the root entry of the LDAP directory. Additionally, the scope of the search can be restricted. This allows limiting the search to the specified entry, to the immediate subordinate level of the specified entry, or to its entire subtree.

The search criteria are determined by specifying search filters, based on which the search is conducted. For example, the filter `sn=Doe` searches for an entry where the attribute `sn` (surname) contains the value Doe. Multiple filters can be combined using logical operators such as AND, OR, or NOT. Additionally, searching for any value in an attribute is permissible by specifying an asterisk (*e.g.,* `sn=*`). Furthermore, the LDAP protocol allows for the specification of attributes in the search request that should be exclusively returned in the event of a match. It is possible to determine whether only the attribute names or both the attribute names and values should be returned.

Another option that can be specified in the search request is the size limit. This allows the client to determine the maximum number of results to be returned by the server in the event of a match. In addition to client-side size limits, various LDAP servers allow for server-side size limits to be configured to restrict the number of entries returned in a search request. Different LDAP server manufacturers establish different default values for size limits. For example, the default size in OpenLDAP is set at 500 entries, while Apple's Open Directory Server sets it at 11,000 entries.

3 Methodology for Analyzing LDAP Security

3.1 Threat Model

We assume that the attackers access publicly available LDAP servers on common ports, *e.g.,* by connecting to the IP address of a public LDAP server with a standard LDAP browser. The attackers send standard-conforming packets to retrieve data from LDAP servers and do not attempt to circumvent deployed access controls. Further, we assume they take educated guesses about default configurations—including administrator usernames and attribute names commonly observed.

When analyzing the security of TLS configurations, we assume that network attackers act as active Meddler-in-the-Middle (MitM) between the LDAP client and server. These attackers aim to exploit weak TLS configurations or downgrade the connection to plaintext to steal the LDAP client's credentials and other sensitive data.

3.2 LanDscAPe Analysis Pipeline Overview

LanDscAPe uses a set of modules for the analysis illustrated in Fig. 2. This section gives a brief overview of the analysis pipeline. The *scanning module* performs Internet-wide port scans, resulting in a dataset of IPs responding on well-known LDAP ports. It also collects information on TLS configurations on LDAP servers. Upon detecting an open LDAP port on either of the targeted ports, LanDscAPe's *confirmation module* sends LDAPv2, LDAPv3, or unspecified LDAPv4 messages to provoke an LDAP response. The *sampling module* then attempts to connect to identified LDAP servers and performs information requests through standard-conforming connection and anonymous authentication methods. If a connection succeeds, the *sampling module* requests configuration settings and metadata. Additionally, it requests a subset of LDAP entries from the server for further analysis and stores the data on an internal analysis server.

The two final stages analyze the collected data. The *data classification module* analyzes the configuration details and collected samples for exposed personal data, sensitive data shortcomings, and leakage of credentials. The last stage is the *network analysis module*, which analyzes the security of LDAP servers' TLS configurations. The system examines the supported cipher suites and the trust chain. The pipeline was executed in January 2024, and we base our evaluation on the data gathered from this run.

3.3 Scanning Module

Our *scanning module* begins by scanning the entire routable IPv4 space on ports TCP/389 and TCP/636 with ZMap [9]. The former port is used for plain LDAP and for the in-band upgrade with StartTLS, the latter port for LDAP over TLS. This gives us a list of IPv4 addresses where these ports are

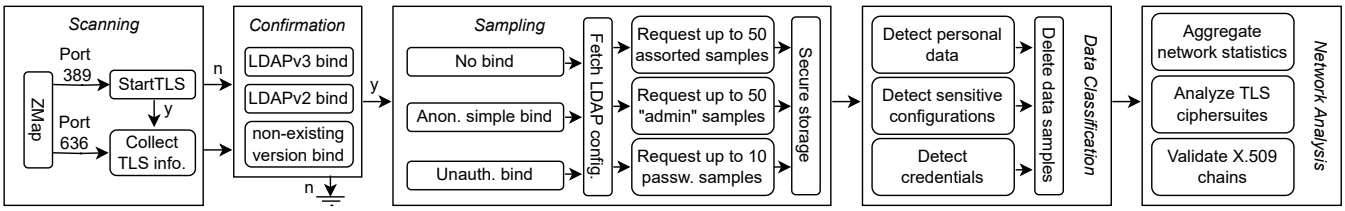

Figure 2: LanDscAPe analysis pipeline.

open. Previous work [27, 44] shows that many middleboxes will make a port seem open, meaning that the true number of LDAP servers can only be determined by following through with a higher-layer connection, *i.e.,* plain LDAP, LDAP and an in-band upgrade to TLS via StartTLS, or a TLS connection over which an LDAP connection runs. These are implemented as submodules that execute within 24 hours of the scan. This means that IP churn can lead to us missing an LDAP host that was still visible in the ZMap scan. We tested the churn and found that it is at most between 1-5% per day; *e.g.,* our TLS scans always cover at least 95% of all IP and port combinations (IP:port) for which we also ran successful LDAP queries. To enable StartTLS for LDAP on port 389, we extend Goscanner [11] with this form of in-band upgrade to collect connection properties and certificates. On port 636, we connect directly with Goscanner and do a TLS handshake. Goscanner is configured to offer TLS versions from 1.3 down to 1.0, in that order. A server that supports a more modern version of TLS should hence select it from our scanner's offer. Similarly, we configured the cipher suites we offer according to the best current practices [50], ordered from highly secure to less secure. However, we do not attempt multiple connections to determine all cipher suites that LDAP servers support to avoid undue load on them. Note that some servers support both TLS-protected and plain LDAP sessions. In our analysis, we treat this case as two distinct ways of accessing a server.

3.4 Confirmation Module

The *confirmation module* ties directly into the scanning module, but we describe it separately here. It verifies that the candidate IP:port combinations collected in the previous steps actually serve the LDAP protocol. To determine this, we send three anonymous simple bind requests with varying versions to each server. First, a normal LDAPv3 bind to check for general LDAP support. Second, an LDAPv2 bind, testing for backward compatibility and outdated servers. Finally, a bind with a non-existing version (v4) to provoke a "BindResponse where the resultCode is set to protocolError" [48].

If a server does not return a valid LDAP response within five seconds, we abort the attempt. Conversely, if the server replies with an RFC 4513-conforming LDAP message [17], we classify the service as an LDAP server. If no protocol error is encountered, we assume that the server supports the respective LDAP version.

After this step, for each IP:port tuple, we know if they are standard LDAP servers, which LDAP versions and connection security they support, and which TLS certificates are used.

3.5 Sampling Module

The *sampling module* gathers information in a three-step process: connecting to an LDAP server, fetching configuration data and metadata, and collecting sample entries.

Connecting to Servers. For each server with each supported connection type (port 389 with and without StartTLS, and port 636 with implicit TLS), we initially request information without bind, leading to an anonymous authorization identity, according to Section 4 of [17]. Subsequently, it executes a simple bind request with both username and password fields left empty, aligning with the specifications in Section 5.1.1 of [17]. The third approach involves an unauthenticated bind, as outlined in Section 5.1.2 of [17], using an arbitrary username (we chose `cn=*`) and an empty password field. We do this for all available connection types per IP address as it may serve different LDAP services or configurations on each.

Fetching Configurations. Next, we collect configuration information and metadata from the server. We first request the root DSE that contains information on supported LDAP controls, extensions, features, and versions. Additionally, it contains the server's naming contexts. Based on this, we request the server's schema, size limit, and password policies.

Collecting Samples. To assess the data the server publicly exposes, we collect a specific number of entries from the server. To retrieve entries from an LDAP server, the client sends an LDAP `SearchRequest` and gets the result via the server's `SearchResultEntry` response.

For our analysis, we request random, admin, and password samples. We request random samples by sending a query filtering for `objectClass=*` and admin samples by filtering for `cn=*admin*`. To prevent the server from sending excessive data, we limit each search to a maximum of 50 entries. For password samples, we request the following fields: `userpassword`, `password`, `sambantpassword`,

sambalmpassword, krbprincipalkey, clearpassword, goimappassword, lmpassword, and ntpassword. Here, we limit each request to a maximum of ten results. For ethical reasons, we do not make further requests and accept a smaller sample size if the server responds with less.

Secure Data Storage. Even though we only sample public LDAP servers, collected data samples may contain sensitive information as critical as user credentials. To protect these samples, this module moves them from the scanning server to an internal server that is only accessible via VPN by the researchers involved in this analysis.

3.6 Data Classification Module

The *data classification module* tries to identify the types of data samples collected in earlier stages. Particularly, it aims to detect personal data, internal information, and credentials within our samples. In its final step, all samples are deleted, and only metadata indicating the type of data found per server is kept to prevent possible harm from unauthorized access.

Detect Personal Data. We analyze our samples for typical personal data attributes such as names, email addresses, or certificates. We follow Art. 4 of the GDPR here that defines personal data as any information relating to an identified or identifiable natural person [12, Art. 4]. To identify personal data, we first aggregate semantically identical attributes of our samples (max. 50 samples per server, less if the server sends less), *e.g.,* attributes such as surname, sn and lastname (see Table 12 for more details). We then group by this aggregation and count the servers containing personal data.

Detect Sensitive Configurations. We try to identify potentially insecure servers and confidential information on servers. Therefore, we first categorize LDAP servers into usage scenarios and common products. This categorization uses three indicators: OIDs, the root DSE vendorName and vendorVersion fields, and random sample attributes with hints such as the msExch prefix referencing an AD. Since some servers communicate their exact version, we look up the corresponding version number on [46]. However, this is only a weak indicator that the vulnerability is exploitable and harms the overall security.

Furthermore, we look at SASL (Simple Authentication and Security Layer) mechanisms supported by servers. While some mechanisms are notably secure, *e.g.,* using salts or providing memory or CPU hardness, others are not. If LDAP servers act as authentication servers, a strong Simple Authentication and Security Layer configuration is important.

Moreover, we consider servers exposing internal information related to LinuxUserManagement, Microsoft Active Directory, DICOM, and passwordPolicies having a sensitive configuration. If this information is publicly accessible (*e.g.,* gidNumber, uidNumber), it might be utilized by attackers.

```python
def generic_query(prefix):
    results = []
    for letter in alphabet:
        filter=f"(&(cn={prefix + letter}*)(
            ↪ userPassword=*))"
        try:
            result=ldap_connection.search(filter,
                ↪ attributes=[])
        except SIZELIMIT_EXCEEDED:
            result=generic_query(prefix + letter)
        results.extend(result)
    return results
```

Listing 1: Prefix search to count LDAP entries.

Credentials Detection. To detect user credentials on LDAP servers, we examine our fetched password samples (max. 10 samples per password field, less if the server sends less, see section 3.5) and evaluate their values. We automate this process using tags according to [15] and pattern recognition (*e.g.,* BCRYPT). If we detect encodings such as base64, we try automatically to decode and restart the evaluation process. If the password type of a value was not recognizable (*e.g.,* password was masked with asterisks), we excluded the server from further analysis. To assess the extent of leaked passwords, we proceed by reconnecting to the server and counting the number of entries that contain a non-empty password field without transferring any further sensitive information by restricting the attributes returned by the server to the DN. We do this by setting the requested attribute list to empty as shown in Listing 1. We have taken these steps to transfer minimal sensitive information minimizing the risk for users.

Data Deletion. The module only collects and retains information about the type of data available on any public LDAP server. To minimize risk for organizations and users, we delete all collected samples when this module finishes.

3.7 Network Analysis Module

This module analyzes TLS cipher suites and the X.509 certificate chains in the TLS handshakes; it also provides access to aggregate statistics enriched with third-party data sources, such as IP2Location[1] to determine the geographical location and hosting situation of an LDAP instance. For the purpose of this paper, we present only analyses for LDAP servers with security-relevant properties, *e.g.,* those that support authentication via the SASL framework or host personal data or user credentials. Such servers should use secure TLS configurations: even if the data can be queried anonymously, it may cross other networks and should hence be protected against privacy-invasive monitoring (*e.g.,* queries to a public address

book will reveal the communication behavior of individuals). We define "secure" by referring to the best-practice recommendations for TLS in RFC 9325 [50] for connections and X.509 certificate chains. The server chooses the cipher suite from a list the client offers; we can obtain the chosen cipher suite from the handshake.

The certificates need to be validated against root stores that contain the public keys of recognized certificate issuers, *i.e.,* Certificate Authorities (CAs). For the Web PKI, such certificate stores are well-known and can be downloaded for browsers and operating systems. For LDAP, no defined set of CAs exists. Hence, we check against a "meta root-store" and validate the LDAP certificates against the combined root stores from Apple, Microsoft, Google, CCADB (Mozilla), and Oracle (Java). Together, these are known to cover the majority of TLS user agents for web users [31]. We define a valid chain as one that is valid for at least one root store.

Various problems with certificate chains have been found, initially for the Web [8,22] and later for other communication protocols, especially email [21]. The use case of LDAP is different from these protocols: both the Web and email servers are, almost by definition, meant for public access. LDAP is commonly used in ways that are internal to an organization. Hence, there are two choices to configure X.509: either by using a certificate from a globally acting CA or by running a custom, "in-house" CA. The former method has the advantage that it is thoroughly documented and certificates are available at no cost from CAs like Let's Encrypt. The latter method also avoids costs, but it comes with more administrative overhead as the local CA must be operated securely by the organization (tooling is available in some environments, *e.g.,* Microsoft Windows servers) and its root certificate deployed to client software. In theory, self-signed certificates could also be used to replace an in-house CA; in this case, one would need to ship the self-signed certificate with the client (and possibly alter the software to accept such certificates).

We call certificate chains *globally invalid* if the root CA is not in the root store. This means that our estimate for the number of valid certificates is a *lower bound* (and an upper bound for the number of invalid chains). Custom CAs can be expected to issue relatively few certificates (as there are few servers per organization). Independently of these considerations, we always call a chain invalid if there is a cryptographic problem, *e.g.,* use of the deprecated SHA1 algorithm for certificate signatures. Our validator uses the standard Go library, which rejects such certificates as invalid.

Note that we cannot validate the names in the certificates, as the domain names that resolve to an IP are unknown.[2]

[2]While some large DNS datasets exist (*e.g.,* OpenINTEL), these do not cover subdomains, which are likely names for LDAP servers.

Version Support	Port 389		Port 636		Any	
Any	80,968	(100.00%)	34,095	(100.00%)	82,129	(100.00%)
v2	48,362	(59.73%)	21,162	(62.07%)	56,798	(69.16%)

None	41	(0.05%)	20	(0.06%)	55	(0.07%)

Table 2: Identified LDAP servers with supported versions.

4 Results

Using the pipeline described above, we aim to answer two main questions: What sensitive data do publicly accessible LDAP servers expose, and how protected are the connections a client can establish to them?

The structure of this section follows the same analysis pipeline as Section 3 by presenting the results of each module in Fig. 2. An overview of the results is given in Table 1.

4.1 Scanning

Our ZMap scan identified 3,704,816 hosts responding to the SYN scan on port 389 and 3,763,310 hosts on 636. We collected 67,498 distinct TLS certificates from 50,970 hosts on port 636 and 35,707 hosts on 389 via StartTLS, including non-static hosts. In pilot studies, we observed that LDAP servers usually run on static IP addresses, observing a churn rate as it is commonly observed for other protocols as well [35].

4.2 Confirmation

We determined that 80,968 servers on port 389 and 34,095 servers on port 636 (82,129 distinct IP addresses in total) respond to our LDAPv2 bind or LDAPv3 bind with an LDAP result message as defined in Section 4.1.9 in [48]; we classified them as LDAP servers (Table 2). Nearly all LDAP servers support LDAPv3, with slightly over half accepting LDAPv2 binds; however, this does not necessarily indicate that the server actually supports LDAPv2. For instance, OpenLDAP documentation [15] states that OpenLDAP does not support LDAPv2 but accepts LDAPv2 bind requests for legacy reasons. Nevertheless, we observed 177 servers on port 389 and 32 on port 636 that only accept LDAPv2.

During the confirmation process, we observed that a few LDAP servers delivered a `protocolError` either during an LDAPv2 or LDAPv3 bind. However, using the respective other version, our connection experiences a timeout (two seconds) or receives a connection reset. The occurrence of a `protocolError` indicates that the server is an LDAP server; however, it does not support the requested protocol version.

4.3 Sampling

We established a total of 115,063 connections (`IP:port`), as shown in Table 2. We found that many connections were willing to send data without a bind request. For example, we retrieved the root DSE entry 92,588 times: 95.04% without a bind, 4.93% with a simple bind, and 0.03% with an unauthenticated bind. This means that in some cases, we were able to request additional information from the server via simple bind and unauthenticated bind Table 3. However, according to RFC 4513 [17], the server should be in the same state as without binding. This hints at misconfigurations and faulty assumptions regarding the authorization and authentication mechanisms LDAP provides.

Alarmingly, we identified entries[3] with credential attributes on 2,935 connections (`IP:port`), highlighting a significant security concern.

5 Data Analysis

This section describes the results of the data analysis module described in Section 3.6.

5.1 Vendor and Type of LDAP Server

In total, we categorized 10,740 servers using supported controls, vendor information, and attribute combinations.

Using the supported controls (OIDs) during our scans, we were able to categorize 5,938 hosts (of 35,083 hosts that expose them)—predominantly Active Directory servers, Sun Java, and iPlanet directory servers (`OID` in Table 11).

Only a small set of hosts (2,382) expose the `vendorName` and `vendorVersion` attributes, which allows us to identify 23 different LDAP server types (`Version` in Table 11).

We attempt to map all of the 3,668 unique attributes observed in the samples to a server type. As a result, of the 16,218 hosts for which we have samples, 5,577 hosts could be categorized (`Attributes` in Table 11). Predominantly, this allowed identifying servers used for Linux user management and servers with Active Directory support for Apple.

Merging all the described categorization approaches results in the LDAP server types shown in Table 11. Note that servers can be categorized into multiple categories—*e.g.,* a server that uses a specific server software and is used for Linux user management.

5.2 Detected Sensitive Configurations

We found several sensitive server configurations that potentially are vulnerable to security flaws or expose sensitive data.

[3] Note that not each entry contains actual user credentials (cf. Section 5).

Bind Type	Root DSE	Schema	Naming Context	Passw. Policy	Samples		
					Rand.	Admin	Passw.
Total	92,588	35,658	90,265	1,432	17,283	11,715	2,935
No bind	95.04%	87.28%	94.97%	99.93%	84.02%	99.74%	99.18%
Only Simple bind	4.93%	12.69%	5.00%	0.07%	15.98%	0.26%	0.82%
Only Unauth. bind	0.03%	0.03%	0.03%	0.00%	0.00%	0.00%	0.00%

Table 3: Summary of sampling result per IP:port combination.

SASL Mechanism	# IPs	Plaintext only	TLS config	
			w/ issues	w/o issues
Total	26,464	7,962	13,418	5,084
Hash	87.95%	31.67%	47.53%	20.80%
CR	87.68%	32.57%	47.57%	19.86%
GSSAPI	57.52%	14.63%	58.13%	27.24%
Plain	32.63%	3.56%	80.68%	15.76%
External	6.05%	10.74%	68.66%	20.60%
Anonymous	4.61%	8.52%	66.99%	24.49%
Proprietary	0.37%	29.59%	68.37%	2.04%

Table 4: Supported SASL Mechanism Types. Percentages are based on Mechanism Type. Servers commonly support multiple mechanisms.

Supported SASL Mechanism. Table 4 lists the SASL mechanisms supported by servers. In total, 26,464 servers support SASL authentication; however, less than one-fifth of them allow authentication over a secure connection. This is especially glaring for the servers supporting plain authentication, of which more than four-fifths do have issues within the TLS configuration—potentially leaking plaintext credentials to a MitM attacker. The categorization of issues with TLS configurations is explained in Section 6.

We also find it worrying that a large share of servers support challenge-response and hash-based authentication only allow plaintext connections (32.57% and 31.67% respectively). This puts the sole trust in the confidentiality provided by SASL.

CVE Check. We found 616 servers with known vulnerabilities (identified by CVEs). Eight servers use a version of the `UnboundID LDAP SDK for Java` that might be vulnerable to CVE-2018-1000134—an authentication bypass using unauthenticated bind with a CVSS of 9.8. Additionally, we detected two known vulnerabilities in servers identified as `389-Directory Servers`: 608 servers might be vulnerable to CVE-2020-35518—an information disclosure on the directory structure with a CVSS of 5.3—and 413 might be vulnerable to CVE-2018-10935—a denial of service with a CVSS of 6.5. The rather low number of servers with known vulnerabilities does not necessarily indicate that these servers are well maintained. On the contrary, we assume that we could not identify a large share of vulnerable servers due to missing product and version information.

Internal Information. Based on the categorization explained in Section 3.6, we could identify hosts exposing settings or parameters that, if accessed by unauthorized users, can lead to security breaches or data leaks.

As shown in Table 11, we found 5,180 hosts that are used for Linux user management and 4,465 hosts that can be identified as Microsoft Active Directory. Neither of these should be exposed to the Internet.

Additionally, there are 283 hosts that expose password policies. These, for example, contain information about the minimum length of a password and thus provide conclusions about the strength of the passwords, which in turn helps in the creation of dictionary attacks. A notable risk involves the potential for targeted account lockouts [49]. Malicious actors can exploit this by issuing bind requests with incorrect passwords, thereby intentionally locking out individual or multiple accounts. This becomes an issue if user enumeration is possible and lockout policies are in place.

Further sensitive information in the form of hosts with Digital Imaging and Communications in Medicine (DICOM) configurations could be found. The DICOM standard for the storage and transport of medical radiologic images proposes the usage of LDAP for configuration data [36, Part 15, H.1]. DICOM's standardized secure authentication methods are often not supported in commercial products and rarely used in productive systems [10]. One common way of securing access is the usage of the Application Entity Title (AET) as a password in a way that the client must provide the correct AET before the connection is allowed by the server. The DICOM configuration data in the LDAP scheme contains, besides the medical institution name, device name, and software version of the DICOM device, the AET title. We found 145 publicly accessible LDAP servers with DICOM configuration values. The publication of the AET title on a public LDAP server is, to the best of our knowledge, not meaningful, and if the AET is used for authentication, a severe security vulnerability.

Personal Data	# IPs	Plaintext only	TLS config

Table 5: Personal data attributes exposed by LDAP servers. Percentages based on the corresponding number of IPs.

5.3 Detected Personal Data

LDAP servers are commonly used to manage users. These servers provide user authentication or serve as public or internal address books. Therefore, it is plausible that these servers contain personal data such as names or email addresses. The question arises as to how many servers provide us with personal data and what form of data is accessible. The *Sampling Module* collected a limited sample set (see Section 3.5) from 16,218 LDAP servers, which serves as the basis for the investigation in this section.

The samples can be used to determine which server makes which type of personal data publicly available. We divided the attributes we observed in our sample set that potentially hold personal data into groups. We have listed these groups together with the number of servers that provide us with the corresponding personal data in at least one sample in Table 5. A complete mapping of all LDAP attributes to a group can be found in Table 12 in Appendix C.

We identified a total of 12,179 servers publishing one piece of personal information. We also categorized the number of servers from which the corresponding information can only be transmitted in plain text on port 389. If a server offers TLS, we have listed how many servers have issues with TLS configuration for the transmission. The classification of issues in TLS configurations is explained in Section 6.

In addition to the names and email addresses, LDAP servers also hold public keys. This category includes S/MIME certificates, which usually contain the certificate owner's name. Since LDAP servers are often used within a PKI to distribute S/MIME certificates, the publication of this information is common. More concerning, we found that some LDAP servers return entries with a date of birth, a photo, or even a social security number. Although management of such information in an LDAP directory is plausible, the publication of such information may indicate a misconfigured LDAP server.

In particular, servers that publish attributes such as name, address, city, country, email, or telephone number can only transmit the data in plain text in at least a third of cases. Even the servers that can transmit this information via TLS use TLS configurations with issues in more than a third of cases.

	Passw.	Passw. & Hash
Total #IPs	32	28
Plausible Credentials	18	15
Numerical Credentials	2	-
Sample size 1	6	11
Implausible Credentials	6	2

Table 6: Manual analysis results of servers exposing over 1,000 credentials.

5.4 Detected Credentials

As LDAP can serve authentication services, it is a common practice to store credentials on these servers. In this chapter, we analyze the security implications that arise from misconfigurations by admins, posing a risk to stored credentials. Our analysis reveals that such misconfigurations lead to exposed credentials on 1,817 (2.21%) of the LDAP servers we examined. RFC 4519 [45] recommends storing passwords in the `userPassword` field as plaintext strings without any form of encryption. We speculate that this recommendation may have contributed to a substantial proportion of servers (0.71%) exposing plaintext passwords.

Verification of Credential Leaks. In our investigation of servers that may leak credentials to unauthorized entities, we faced the challenge of verifying the authenticity of these credentials. A first analysis of the data samples indicated that the exposure of a potentially sensitive attribute does not mean the information is actually sensitive. As a result, we eliminated a proportion of servers (26.7%) where passwords were displayed in a redacted form (*e.g.,* partially masked by asterisks). To reduce potential harm to users as much as possible, we limit credential sampling to 10 entries per password attribute and server, even if a server is willing to return more. This intentionally small sample size made further automated evaluation challenging.

An analysis of the credential distribution indicates that the vast majority of credentials were stored on relatively few servers. This prompted a *manual* examination of our samples of all servers harboring over 1,000 credentials. Table 6 shows that the majority of servers (18) expose only plausible plain-

Field	# IPs	# of Leaks
Total	1.8k	3.9m
userPassword	1.4k (78.8%)	3.2m (80.5%)
sambaNTPassword	343 (18.9%)	187k (4.8%)
sambaLMPassword	268 (14.8%)	157k (4.0%)

Table 7: Top three fields (potentially) leaking credentials.

Network usage type	Total IPs	Leaks	
		Credentials	Personal data
Total	92,109 (100%)	1,817 (100%)	12,179 (100%)
Data Center	48.17%	49.04%	39.63%
ISP	39.02%	26.97%	41.18%
Commercial	7.32%	14.91%	9.24%
Educational	4.16%	6.60%	8.19%

Table 8: Network types where LDAP servers are located.

text credentials within our samples, while 15 servers expose plausible plaintext credentials mixed with hash values. We suspect that this is due to the migration of some servers, for example, from plaintext to salted hashes. We also classified some servers as implausible when the sample consisted of very few, repeating identical hash or password values.

The Scope of Credential Exposure. To reduce potential harm for users, we only requested samples of user credentials from LDAP servers with a hard limit of ten entries. That way, we can detect *if* an LDAP server exposes credentials, but not *how many*. However, to determine the risk a credential-leaking server poses, we need to estimate the number of credentials on the server. We accomplished this by performing an enumeration of entries (as outlined in Section 3.5) containing at least one of the identified sensitive attributes (*e.g.,* `userPassword=*`), but only requesting the `DN` of these entries, ensuring minimal data exposure. The returned `DN`s are then counted and discarded.

The outcomes of this enumeration are presented in Table 7. We found that more than 3.9 million credentials were publicly accessible at the time of our data collection in January 2024. Moreover, very few servers expose the majority of credentials.

For ethical reasons, we chose not to download the entire dataset of passwords, and we therefore checked the plausibility of the credential samples. Table 6 summarizes our efforts to check the plausibility and distribution of plaintext and hash values of these passwords.

6 Network Analysis

We analyze data on the network configuration of LDAP instances and the Transport Layer Security (TLS) configuration of LDAP servers. We say an LDAP server's TLS configuration is "without (potential) issues" when it fulfills two conditions: it has a valid X.509 chain, signed by a known root certificate of a Certificate Authority (CA) from a root store, and it follows the respective recommendations from RFC 9325 [50] guidelines for connection security.

Hosting. We use the IP2Location dataset to determine in which countries and networks LDAP instances are deployed and summarize this in Table 1. More than 50% of LDAP servers are hosted in the US, Germany, France, Poland, Russia, or China. As shown in Table 8, nearly half of the instances are located in networks that IP2location classifies as data centers, *i.e.,* a form of hosting. Interestingly, 39.02% are located in network ranges classified as Internet Service Providers (ISPs). This classification *may* indicate self-hosting situations. We note, however, that these categories are rather broad, with blurry boundaries as ISPs often have multiple network ranges for various purposes, which also change over time. Hence, we take this classification with a grain of salt. We also find a sizable number of LDAP servers in commercial settings (7.32%) or education (4.16%). Outside the top four, we also find some deployment in government networks (0.40%) or military networks (0.01%). In all categories, we find servers associated with leaked passwords and personal data—including some in government or military networks.

TLS Cipher Suites. Our Network Analysis Module aggregates all IPs that successfully negotiated a TLS connection with the TLS server certificate, forming a TLS-enabled subset of 48.2k servers (58% of all identified LDAP servers).

TLS defines several cipher suites, indicating the symmetric cipher, encryption mode, hash algorithm, and the key exchange method. We evaluate the established TLS connections against the best practices and recommended cipher suites from RFC 9325 [50]. As described in detail in Appendix D, only 65.92% of the hosts use a recommended TLS cipher suite. This number decreases with servers that leak credentials (36.59%), expose personal data (44.20%), or expose internal information (61.42%).

Servers that leak credentials use recommended cipher suites significantly less frequently (see Table 13 in Appendix D). The same is true for servers for which we find at least one CVE and, to a lesser degree, also for servers that contain personal data. Servers that provide support for Simple Authentication and Security Layer or hold internally relevant, security-critical information, however, tend to fare better, but the situation is still not satisfactory. For example, around 40% of these servers still use other cipher suites than recommended by the RFC. Overall, this paints a picture where weaker cryptography correlates with sensitive data leakages.

TLS 1.3 experienced a fast deployment on the Web, in part

LDAP Client	Total	Rec.	Other	CBC mode
Apache LDAP Studio	38,269	71.82%	28.18%	11.97%
LDAP Administrator	38,545	69.98%	30.02%	13.15%
ldapsearch	37,775	69.86%	30.14%	12.44%
Outlook	38,771	70.69%	29.31%	12.27%
Thunderbird	38,560	66.18%	33.82%	11.89%

Table 9: Simulating the outcome of cipher suite negotiations using the cipher suites preferred by common LDAP clients.

because of the widespread use of cloud hosting [23]. After just a few years, the deployment already exceeded 30% on popular domains. For LDAP today, 36.67% of all our identified TLS-enabled servers support TLS 1.3. Once again, the numbers are significantly lower for servers that leak sensitive information.

X.509 Chain Validation. We find that over 50% of the X.509 chains are *globally invalid* as per our definition. The most common reasons for invalid chains are the use of self-signed certificates, expired or not yet valid certificates, and an unknown root certificate. For the latter case, we note the caveat of in-house CAs—we cannot detect these with our methodology, and hence this number needs to be treated as an upper bound. We note that self-signed certificates can be used in very bespoke situations to bypass the need for an in-house CA, *e.g.,* private servers used by one or very few clients. We summarize our results in Table 13. We find very few cases where chains are invalid for other reasons (less than 1%) (*e.g.,* self-signed certificates used to sign other certificates, too many intermediate certificates in the chain, violating path length constraints [5], or improper use of critical extensions).

Cipher Suites Chosen by LDAP Clients. After our initial analyses, we also ran reconfirmation scans to understand how well our scanning methodology approximates the cipher suite negotiation that common LDAP clients would achieve. We chose the five common LDAP implementations: Apache LDAP studio [3], LDAP Administrator [52], *ldapsearch* [40], Microsoft Outlook, and Thunderbird. We extract the cipher suite string they use in the handshake and use these in our scanner to determine which cipher suites LDAP servers would select. On inspection, we found that our Go library does not support some cipher suites that the clients do, so we do not test them. However, these do not offer a more secure connection than our library offers. However, servers should always choose recommended cipher suites, and we find that the servers do not reject our connection attempts due to a failure to negotiate a cipher suite. Therefore, clients should always be able to negotiate the same connection security our scanner can. Hence, we conclude that our method of simulating common LDAP clients is a good approximation.

We summarize the results of these tests in Table 9, reusing our categorization of recommended ciphers. A more detailed description of the results is presented in Appendix D. We find that the numbers are within a small margin of our previous scans, and in general, the percentage of recommended cipher suites negotiated is actually slightly higher. As these reconfirmation scans took place five months after the original scans, this could simply be due to servers that have received updates meanwhile rather than any difference in the cipher suite negotiation. Our conclusion is that our scanning methodology approximates the behavior of real LDAP clients very well.

7 Discussion

Following, we will discuss the implications of our results for the overall security of the Internet-wide LDAP landscape.

7.1 Personal Data and TLS

The analysis uncovered 12k public LDAP servers exposing personal data. Because of ethical and legal considerations and because of the large number of affected servers, we cannot ultimately determine if this data is supposed to be public. But even if it is supposed to be public, access to it should be encrypted. Take an LDAP server providing access to a public address book as an example. The people within this address book agreed to be listed there, so this information is not confidential. However, people accessing this address book may not want to reveal their searches in the address book because it leaks with whom they are communicating. Moreover, an active MitM could return fake contact results to the client, for example, to intercept the subsequent communication.

We found that out of 12k public LDAP servers exposing personal data, only 1,392 servers (11.4%) run a TLS configuration without issues that LDAP clients can use to authenticate the server and encrypt queries. Given that it is widely accepted that strong transport encryption is mandatory from a security viewpoint and easy to deploy, this is another indicator that LDAP has yet to receive wide attention from security professionals within organizations. Furthermore, the number drops substantially for servers that leak credentials (a mere 10%) or personal data (about 13%). It increases when servers are used for authentication or hold sensitive internal information. Servers that leak credentials or store personal data have particularly often poor configurations, both in terms of cipher suites and certificates. The strong correlation we see between weak cryptography and older TLS versions on the one hand, and data leakages and vulnerable LDAP implementations on the other hand, supports the hypothesis that the more weakly configured servers have not been updated in several years.

7.2 Public Directories vs. Social Engineering

Knowledge about the internal structure of organizations and, in particular, information about employees is an important

indicator for the success of social engineering or phishing attacks. Collecting intelligence from open sources is complex and time-consuming because it involves a multitude of techniques and tools.[4] Overall, our analysis found that more than 12k organizations leak their organizational structure, configuration values of other services, or even detailed personal data about employees. These servers provide this information to attackers essentially for free. Even if organizations intentionally expose such information, it is questionable whether they are aware of the possible consequences.

7.3 Fast Track to Admin

Our analysis uncovered 1,817 servers leaking 3.9 million possible user credentials. As an example, the analysis uncovered that a university exposed more than 30,000 credentials, including email addresses and plaintext passwords, via a public LDAP server. This security lapse compromised a wide array of accounts, including those of IT administrators.

Even worse, we found 526 servers leaking passwords where at least one username contained the substring "admin". While it is not necessary for privileged users to have this substring in the username, it is a strong indicator that these servers indeed leak the credentials of privileged users. This is quite dangerous for the affected organizations as many modern ransomware cyberattacks exfiltrate and then encrypt victims' data to demand a ransom from victims. For this, the attackers not only need initial access to the victims' networks, but also privileged user accounts to get read and write access to data or to destroy backups by lateral movement. It is well-known that attackers may give up even if they have network access to a victim if they cannot get privileged user access. Our findings are hence relevant with respect to modern cyber-attackers: there is a substantial risk for organizations if they expose privileged user credentials via LDAP.

7.4 Current Status of Disclosure Efforts

In February 2024, We disclosed the list of credential-leaking servers to a national CERT, which then contacted the operators via email. To check the effectiveness of our disclosure campaign, three months later, we sent probes to the 1,817 server IPs previously found leaking credentials. These probes are limited to finding only one entry containing at least one of the password fields (see section 3.5). As in the previous analysis, we instructed the server not to transfer any data besides the `DN`. Out of the original 1,817 servers, 475 (26.1%) are no longer available. Five servers remain reachable but now require authentication. While we observed a significant reduction in password-leaking LDAP servers, a substantial amount remains online.

[4] See the MITRE ATT&CK about the "Reconnaissance" tactic (https://attack.mitre.org/tactics/TA0043/).

8 Ethical Considerations and Disclosure

Our overarching goal was to carry out an Internet-wide security analysis of public LDAP deployments to uncover and responsibly disclose security risks to affected operators. The nature of this work and the characteristics of LDAP led us to carefully consider the balance between improving the overall security of LDAP deployments and introducing potential harm or risk to others in the course of our work. We hence designed our steps and analyses carefully to prevent any unnecessary risks. For example, by interacting with LDAP servers, potentially sensitive data is transferred between our scanners and the scanned targets. In extreme cases, public LDAP servers may even be configured to return the full directory when prompted with a simple, standard LDAP query. To minimize the impact on users, we designed LanDscAPe specifically to only request and process very few samples from each LDAP server—even if the servers were configured to send more. To understand the grave problem of leaked credentials, we developed a method to count such credentials on a server *without* actually transferring them.

A further risk of our method lies in our scanning infrastructure becoming an attractive target itself, as attackers may aim at a cumulative view of our raw analysis results, including a list of LDAP servers leaking credentials. To mitigate this, the processing of the data samples happens on an internal server whose access is restricted by VPN to the authors of this paper. After finishing the classification of a sample, we *delete* it and only keep *metadata* for the disclosure campaign.

As a result, our analysis uncovered more than 1,800 LDAP servers that leak user credentials to anyone. We note that the bar for this is as low as knowing how to use a standard LDAP client. This is a potentially serious risk for well over 3 million users with data on these servers. On balance, we believe our minimally invasive testing is justified as it allows warning affected operators. Downloading a small sample set of credentials was necessary to reduce the rate of unnecessary reports to operators that do not expose real credentials or personal information (see Section 3.6). We conducted a responsible disclosure campaign with a national CERT. Our focus was on notifying those operators responsible for LDAP servers that leak highly critical information such as user credentials or sensitive internal information. Three months after our initial disclosure, more than one-fourth of the credential-leaking servers are no longer exposed to the Internet.

In our measurements, we followed standard best practices, as outlined by Durumeric *et al.* [9]. We sent only standard-conforming TCP and LDAP packets and TLS handshakes, using rate limiting, in randomized order of destination addresses to reduce strain on the network and servers. On the scanning IPs, a website gives project details and contact information for opt-out requests. We honored all such requests. Our ISP, national CERT, and university network administrator cleared all scans.

9 Related work

Hassler [19], along with Findlay, [13] Sermersheim [48] and Harrison [18], strongly endorsed using TLS to protect LDAP sessions while also emphasizing the importance of considering the possibility of its removal by adversaries. This is a particular issue when using StartTLS. Recent research by Poddebniak *et al.* highlighted vulnerabilities of in-band upgrades to TLS [41]. In this context, we note that security factors can change even during an LDAP session, necessitating additional considerations by servers [13, 18, 48]. Further security risks result from the absence of standardized access control mechanisms in LDAP, requiring each server to implement its own custom approach [13, 19]. In our work, we do not exploit any of these vulnerabilities, nor do we aim to find new ones. Our framework focuses on the analysis of a large set of LDAP servers on the Internet. It analyzes their network security and takes samples (ethically) to assess whether sensitive information is leaked.

Obimbo and Ferrima [39] demonstrated a Denial of Service (DoS) attack on LDAP, highlighting how the protocol can be abused. In 2017, the Project Sonar study by Rapid7 [47] investigated the prevalence of LDAP services on the Internet and fingerprinted them based on the root DSE. The study aimed to identify remote services using the Connectionless LDAP (CLDAP) protocol and also included LDAP scans on TCP ports 389 and 636. They found 300,663 servers on TCP port 389 and 91,842 servers on port 636 speaking LDAP. In our work, we found 80,968 servers on port 389 and 34,095 servers on port 636, indicating significant changes in this area over the past years. Additionally, their analysis assessed the effectiveness of CLDAP in Distributed Reflection Denial of Service (DRDoS) attacks. Srinivasa *et al.* [53] employed honeypots to study malicious intrusion attempts with various purposes, demonstrating that the protocol constitutes an attack surface that is quite commonly targeted by attackers. Our work does not use honeypots nor study DoS attacks; however, we focus on LDAP configurations and publicly accessible data, which may correlate with attack vectors as well, indicating the need for further scrutiny. Furthermore, our methodology employs a broader classification approach, considering additional parameters such as OIDs and LDAP attributes rather than solely relying on the root DSE to categorize LDAP services.

The X.509 PKI has been the subject of numerous publications, with multiple weaknesses identified for the Web as well as other communication protocols, often due to poor cipher suites and invalid certificate chains [2, 8, 21, 22]. Other studies indicated that TLS deployment is difficult even for expert users [30]. More recently, attention has focused on the root stores as well. Ma *et al.* investigated the root stores' operational ecosystem and exposed bad practices of multipurpose root stores and concentration in a root store [31]. Our analysis focuses on the deployment of certificate chains. A standard root store for LDAP does not exist; we hence relied on a combination of the ones available for the Web, which comprises all commonly recognized Certificate Authorities.

Compared to existing LDAP analysis tools, LanDscAPe is primarily designed to detect misconfigurations of LDAP servers at Internet-scale while at the same time transferring as little data as possible for ethical and performance reasons. Tools such as ldapsearch [40] and nmap's LDAP script [38] are designed to simplify communication with LDAP servers; however, they lack server analysis. Windapsearch [14], ldapper [54], and LDAPPER [51] focus on the enumeration of AD, while LanDscAPe minimizes harm by fetching samples instead and is applicable to all LDAP server types. Furthermore, LanDscAPe allows us to analyze servers by only transmitting small data samples using a novel counting algorithm (see section 3.6). Our tool also differs in connection modes. It connects to LDAP servers via anonymous, simple, and unauthenticated bind, while the other tools rely on authentication or switch to anonymous bind. Moreover, LanDscAPe can detect personal data, examine password policies, and find configuration files, whereas previously mentioned tools focus on pen-testing active directories. pbis [20] aims to integrate non-Windows devices into AD to extend security policies, which is outside the scope of our work.

10 Conclusion

We present the first study on public LDAP servers deployed on the Internet. The analysis uncovered more than 80k public LDAP servers, with 12k exposing personal data. Even worse, well over one thousand servers expose hashed or even cleartext passwords of users, resulting in a total of around 3.9 million exposed user credentials. Furthermore, we found that more than 10k servers expose possibly sensitive internal information, and more than 600 servers are linked to some CVE, suggesting they contain security vulnerabilities. We also found that although LDAP supports TLS, either implicit via port 686 or using StartTLS over port 389, the vast majority of LDAP servers supporting TLS have issues in the TLS configuration. This is either because it uses deprecated TLS versions or cipher suites, or because the certificate is self-signed, does not validate against common trust chains, or has expired. Interestingly, the TLS configuration of servers leaking personal data or user credentials is much worse than the TLS configuration of LDAP servers that may be used for user authentication. This indicates that servers leaking personal data or user credentials are not meant to be public.

Overall, the analysis strongly suggests that a surprisingly large number of organizations run LDAP servers leaking highly critical information, running non-optimal configuration values, and subpar TLS configurations. These LDAP servers are a treasure trove for cyberattackers, giving them important insights and possibly even access credentials to privileged users. Affected organizations need to quickly mitigate these risks by securing their LDAP server or removing

them from the public Internet. We believe that this analysis sets the ground for future analyses in the security of the LDAP landscape on the Internet.

Acknowledgments We thank the USENIX reviewers and the USENIX Security Research Ethics Committee for their insightful comments on this paper. Furthermore, we thank Samson Umezulike and Marvin Dölzer for designing the database used for the statistical evaluations. We also thank Thomas 'Balu' Walter and Martin Renner for fruitful LDAP and Active Directory discussions. Special thanks to the German BSI CERT for the responsible disclosure efforts. unavailable	1	1	-	1
unwillingToPerform	44	68	97	93

Table 10: LDAP error result codes.

Table 10 shows the errors for failed LDAPv2 and LDAPv3 binds. We observe that the majority of LDAPv2 bind requests were met with a `protocolError` response, indicating dwindling legacy support. Servers also commonly disallow anonymous binds (`inappropriateAuthentication`) or mark empty credentials as invalid (`invalidCredentials`).

Server Types	Total	OID	Version	Attributes
Linux User Man.	5,180	0	0	5,180

DICOM	145	0	0	145
HL7	141	0	0	141

Table 11: Overview of the top 10 categorized server types and the categorization methods.

B Categorization of Servers

We have categorized the LDAP servers based on the OIDs they expose, their version number, and the attributes they use. Table 11 shows the top 10 list of all categorized server types.

C Personal Data Attribute Groups

We have extracted all attributes from the LDAP samples that potentially contain personal data and categorized them into general groups. The classification of the identified attributes into groups is shown in Table 12.

D Analysis of TLS and X.509

Only about 60% (56k) of the candidate hosts respond to our scans with a successful TLS connection. This is expected: recent findings by Sattler *et al.* [44] and Izhikevich *et al.* [27] show that many IPv4 addresses respond to a SYN packet but do not follow through with a full TCP handshake.

TLS Versions. TLS 1.3 experienced an unusually fast deployment on the Web, in part because of the widespread use of cloud hosting [23]. After just a few years, the deployment already exceeded 30%. We also find substantial deployment of this version (which mandates many strong security features) also for LDAP, with deployment at nearly 37% of all analyzed hosts. Once again, the numbers are significantly lower for the servers that leak information—and better for those that support authentication. Still, TLS 1.2, which has come under significant pressure in recent years, is still by far the most widely deployed version, especially for servers with data leakages.

Cipher Suites. Numerous cipher suites are defined for use in TLS. They indicate the symmetric cipher, block mode (if applicable), and the hash algorithm for the Message Authentication Code (MAC). In addition, they indicate how the session key for the symmetric cipher is to be derived. In our evaluation, we generally refer to RFC 9325 [50], which defines best practices for TLS. In particular, this means that the key exchange should be ephemeral Diffie-Hellman (DHE) to enable forward security, ideally on elliptic curves. Classic finite-field Diffie-Hellman is discouraged for TLS 1.2, and non-ephemeral Diffie-Hellman is generally viewed as too weak. Using RSA in the key exchange means that forward secrecy is not possible; the RFC advises strongly against this.

RSA can be used for authentication. In this case, the RFC requires the key to be at least 2048 bit long. Concerning block ciphers, the RFC views GCM (Galois Counter Mode)

Table 13: Overview of the results of the Network Analysis Module.

as secure, whereas Cipher Block Chaining (CBC) is under pressure due to padding oracle attacks [55] possible in some contexts. This can be mitigated when CBC is negotiated with the "encrypt_then_mac" TLS extension. However, none of the major LDAP clients we tested sent this extension. Therefore, we excluded it from our scans. Older hashing algorithms such as SHA1 are deprecated; the more modern SHA2 and SHA3 or the Poly1305 family of hash functions should be used instead. The effective length of the symmetric session keys should never be less than 128 bits; the RFC explicitly mentions 3DES as an example of a cipher with insufficient key length. We implemented the most relevant parts of RFC 9325 to evaluate the use of TLS in our data set.

Table 13 summarizes our findings. We find that a decent number of connections (around 65%) use one of the recommended cipher suites. Across all TLS-supporting LDAP instances, we find that AES-GCM is widely used, often even with a secure key length of 256 bit. The modern stream cipher ChaCha20 is in significant use as well (20%). However, servers that leak credentials commonly use recommended cipher suites significantly less frequently. The same is true for server versions for which we find at least one CVE and, to a lesser degree, also for servers that contain personal data. Servers that provide support for SASL (Simple Authentication and Security Layer) or hold internally relevant, security-critical information, however, tend to be more commonly configured with better cryptography. Yet, this is still unsatisfactory: for example, 38% of servers that hold information of the latter kind still use cipher suits besides the recommended ones. Overall, this paints a picture where weaker cryptography correlates with leakages of sensitive data.

Analyzing X.509 Chains. We call certificate chains (globally) invalid if the root CA is not in the root store, but also if a CA uses the SHA1 algorithm (as modern libraries such as the Go standard library reject these certificates as invalid).

The use case of LDAP is often different from that of the Web, which is almost by definition a publicly accessible resource. As data on LDAP servers may only need to be accessible to very few clients, it is conceivable that an organization operates a custom in-house CA to issue certificates for the LDAP server and deploys the CA's root certificate only to its clients. Microsoft has tooling for such a purpose, for example. To our analysis, such certificates would appear to have invalid chains as the root CA is not part of any root store. Hence, when we check for valid chains, our numbers are a *lower bound* (and an upper bound for invalid chains). Custom CAs can be expected to issue relatively few certificates (as there are few servers per organization).

Common LDAP Clients and Negotiated Cipher Suites. To understand what cipher suites common LDAP clients would negotiate, we extracted their list of supported cipher suites from the *Client Hello* messages they send. Table 9 shows the results. This analysis was done several months after our initial scans.

Summarizing View. Table 13 gives an overview of what we consider TLS configurations with and without issues, breaking down the reasons into cipher suites (recommended by the RFC vs. others) and certificate chains. We observe that servers that leak credentials or personal data fare worse than the total regarding selected cipher suites and valid X.509 chains. Furthermore, we verified that cipher suite negotiation that major LDAP clients carry out results in very similar results as in our own scans. The correlation we see between weak cryptography and older TLS versions on the one hand, and data leakages and vulnerable LDAP versions on the other hand, would support the hypothesis that the more weakly configured servers have not been updated in several years.

FakeBehalf: Imperceptible Email Spoofing Attacks against the Delegation Mechanism in Email Systems

Abstract

Email has become an essential service for global communication. In email protocols, a Delegation Mechanism allows emails to be sent by other entities *on behalf of* the email author. Specifically, the `Sender` field indicates the agent for email delivery (*i.e.*, the Delegate). Despite well-implemented security extensions (*e.g.*, DKIM, DMARC) that validate the authenticity of email authors, vulnerabilities in the Delegation Mechanism can still be exploited to bypass these security measures with well-crafted spoofing emails.

This paper systematically analyzes the security vulnerabilities within the Delegation Mechanism. Due to the absence of validation for the `Sender` field, adversaries can arbitrarily fabricate this field, thus spoofing the Delegate presented to email recipients. Our observations reveal that emails with a spoofed `Sender` field can pass authentications and reach the inboxes of all target providers. We also conduct a user study with 50 participants to assess the recipients' comprehension of spoofed Delegates, finding that 50% are susceptible to deceiving Delegate information. Furthermore, we propose novel email spoofing attacks where adversaries can impersonate arbitrary entities as email authors to craft highly deceptive emails while passing security extensions. We assess their impact across 16 service providers and 20 clients, observing that half of the providers and all clients are vulnerable to the discovered attacks. To mitigate the threats within the Delegation Mechanism, we propose a validation scheme to verify the authenticity of the `Sender` field, along with design suggestions to enhance the security of email clients.

1 Introduction

Email stands as a significant tool for global communication. In 2023, approximately 347.3 billion emails were generated and transmitted each day, averaging over 4 million emails per second [45]. Unfortunately, due to its convenience and the sensitive information it contains, email has become a preferred tool for network phishing attacks. According to Cofense's annual report [4], malicious email threats bypassing secure email gateways (SEGs) increased by 104.5% in 2023, and email continues to rank first among threat vectors for cybercrime, with 90% of data breaches starting with phish. Consequently, the persistence of email threats poses a formidable challenge to network security.

Among various email threats, email spoofing attacks are particularly concerning. Attackers employ various tactics to impersonate legitimate entities, sending fraudulent emails to deceive recipients and gain their trust. To counter these spoofing emails, researchers have proposed various defensive methodologies. As highlighted in numerous works [3, 11, 36, 47], the email header, which includes vital fields, plays a significant role in assessing the legitimacy of an email. The `From` field, designating the **message's author**, *i.e.,* the individual responsible for composing the email, holds particular significance. Due to its importance, the `From` field is often the primary target of email spoofing attempts, where attackers aim to forge this field in fraudulent emails. Consequently, it is also the central focus of email authentication schemes and protocols [3, 6, 17, 36].

Despite the prevalence of email security mechanisms such as DKIM [6] and DMARC [17] for verifying the authenticity of the `From` field, we identify novel vulnerabilities that can still be exploited in email spoofing attacks. These vulnerabilities arise within what we term *the Delegation Mechanism*, a widely employed strategy that allows individuals to send emails on behalf of the actual author. RFC 5322 [33] specifies the `Sender` field for recording the agent responsible for email delivery (*i.e.*, the Delegate). This field is crucial in the Delegation Mechanism as it denotes the Delegate if different from the email author. However, our observation reveals two significant vulnerabilities: **Vul-1: Sender field Fabrication** - the `Sender` field lacks authentication and can be arbitrarily fabricated by attackers, and **Vul-2: Inconsistent Delegation** - there is no standard protocol for implementing the Delegation Mechanism, resulting in inconsistent implementations across web interfaces and email clients. Attackers exploit these weak-

*Corresponding author: Kaiping Xue, kpxue@ustc.edu.cn

nesses to pass authentications and dispatch spoofing emails to potential victims. Our research introduces a novel email spoofing attack that allows attackers to impersonate legitimate entities, send emails, and evade security checks. By exploiting issues within the Delegation Mechanism, these spoofing emails can reach inboxes of popular service providers without triggering security warnings, making recipients unaware of the spoofing attacks.

This study delves into email authentication issues related to the Delegation Mechanism, with a specific focus on the `Sender` field. While the `From` field undergoes strict verification, the `Sender` field lacks authentication and can be arbitrarily generated by email servers, which raises significant security concerns. Based on the observation above, the primary objective of this paper is to investigate and answer three key research questions:

- **RQ1**: How do mainstream email providers and clients implement the Delegation Mechanism and handle emails with spoofed `Sender` fields?
- **RQ2**: How do mainstream service providers and clients convey the inconsistency between the email author and Delegate to the user? Can users correctly comprehend this inconsistency, especially during spoofing attacks?
- **RQ3**: How can an adversary exploit vulnerabilities within the Delegation Mechanism to craft practical attacks? What measures can mitigate these risks and defend against such attacks?

We conduct comprehensive studies to answer these questions. Firstly, we systematically evaluate the implementations of the Delegation Mechanism across 16 email services and 20 clients, focusing on the effect of the `Sender` field within this mechanism. Our findings reveal that 10 providers have various implementations for the mechanism, while 13 clients solely use the `Sender` field as the Delegate. To understand recipients' sensitivity to such spoofed email Delegates, we conduct a user study involving 50 participants to observe their reactions when encountering emails with various Delegates. Our analysis indicates that deceptive Delegate information misled 50% of the participants into misjudging spoofed emails as legitimate. To explore more effective methods of email spoofing, we propose six distinct email spoofing methods involving the `Sender` field, enabling attackers to impersonate anyone and send spoofed emails to unsuspecting victims without any warnings exposing the attackers' addresses. We also evaluate the efficacy of these attacks across 16 prominent email providers and 20 clients and find half of the providers and all clients vulnerable to these attacks. Finally, we propose a validation scheme for the `Sender` field to enhance the security of email systems.

This paper presents three main contributions:

- We identify the vulnerabilities within the Delegation Mechanism for the first time and highlight the insufficient validation of the `Sender` field by most email service providers.

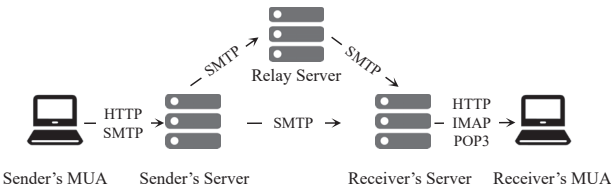

Figure 1: Email Delivery Process.

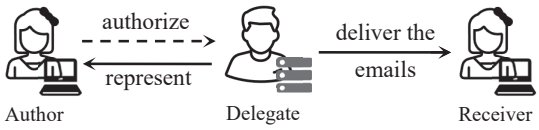
- We conduct a comprehensive user study involving 50 participants to evaluate the effectiveness of forged Delegates on email users, with half of the participants susceptible to misleading email delegate information.
- We propose six distinct email spoofing attacks that exploit the vulnerability within the Delegation Mechanism, allowing the forged `Sender` field to appear as the genuine email author without any security warnings. We also evaluate the efficacy of these attacks across 16 prominent email providers and 20 clients, finding that half of the providers and all clients are vulnerable to these attacks.



This paper is structured as follows: Section 3 provides an overview of our work. In Section 4 and Section 5, we illustrate the implementations of the Delegation Mechanism and the effectiveness of forged Delegates on recipients, respectively. Section 6 introduces the methodologies of email spoofing attacks. Section 7 discusses our main observations, and Section 8 illustrates the defensive measures. Section 9 introduces related works and their differences from ours. Finally, we draw our conclusion in Section 10.

2 Background

2.1 Mail Delivery and Delegation Mechanism

The Simple Mail Transfer Protocol (SMTP) [16] serves as the fundamental protocol for email transmission. An SMTP session begins with the sender initiating the session through the `HELO` command, followed by the `MAILFROM` command, indicating the initiator of the session, primarily verified by SPF authentication [15]. Upon receiving a valid response from the receiver, the sending server transmits the email using the `DATA` command. The entire email delivery process is presented in Figure 1. Initially, the author generates an email using a Mail User Agent (MUA), which may either be a web interface or an email client. Subsequently, the email is transmitted to the transport server via SMTP or HTTP. The email then traverses several forwarding servers before reaching the recipient's server, which delivers the email to the recipient's mailbox through IMAP [24], POP3 [27], or HTTP.

With the development of the modern Internet, major enterprises worldwide have adopted specialized mail servers to centrally process their emails. In such cases, emails from various origins are assembled in these dedicated agents and processed and transmitted collectively. Similarly, email au-

- The **From** field denotes the **Email Author;**
- The **Sender** field denotes the **Delegate;**
- The **Delegation Mechanism:**
  - The **Delegate on behalf of** the **Author** to send emails.

Figure 2: The Delegation Mechanism and Related Fields.

thors may authorize other individuals to represent them in dispatching emails, a scenario referred to as the Delegation Mechanism in email systems (see Figure 2). This mechanism presents a challenge when the email author is inconsistent with the Delegate. Meanwhile, it is necessary to record the address of the delivery agent in emails for possible bouncebacks, along with the original email author. To address this problem, RFC 5322 specifies two fields in the email header: `From` and `Sender`, as shown in Figure 2. The `From` field denotes the email author and is essential in an email. The `Sender` field is an optional field that indicates the agent for delivering the email. When the specialized agent delivers emails from other entities, it must use the `Sender` field to record its own address as the Delegate [33]. The `Sender` field is primarily designed for the Delegation Mechanism and will be ignored if it aligns with the `From` field.

2.2 Email Spoofing and Countermeasures

2.2.1 Email Spoofing Attacks

Email spoofing attacks can be utilized in phishing attempts, aiming to exploit inherent vulnerabilities in email systems and impersonate others to send spoofed emails. Attackers craft emails that resemble those from legitimate entities, deceiving and gaining the trust of potential victims. This method is more elaborate and effective than traditional phishing emails, as spoofed emails closely mimic legitimate ones. Previous research has developed various spoofing methods to bypass authentication and successfully attack popular email service providers and clients [3, 36], highlighting the severe threat of these attacks.

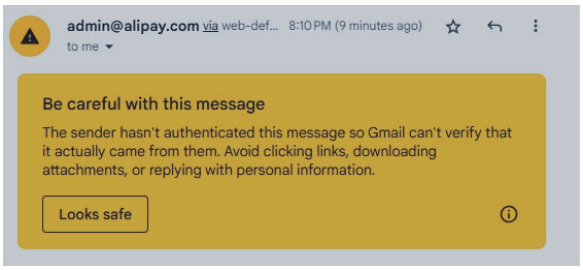
2.2.2 Email Authentication protocols

The original SMTP protocol lacks authentication for the email author, allowing any user on the Internet to impersonate others and send emails. To address these security issues, several extensions have been developed to enhance email transmission security, with the three most widely used being SPF [15], DKIM [6], and DMARC [17].

SPF. The Sender Policy Framework (SPF) [15] allows domain owners to publish a DNS TXT record that specifies which servers are authorized to send emails on behalf of their domain. Upon receiving an email, the receiving server extracts the domain from the `MAILFROM` or `HELO` command, queries the domain's SPF record via DNS, and compares the sending server's IP address with the SPF record. This process enables the receiver to authenticate the email's validity and handle it based on local policies.

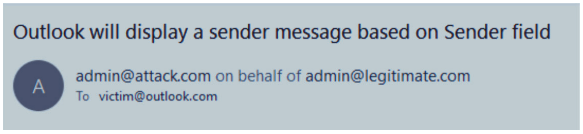
DKIM. DomainKeys Identified Mail (DKIM) [6] employs cryptography to ensure the integrity protection of emails. It enables the email author to choose specific header fields and use a private key to sign them, along with the hash of the email body. Receivers can extract the "selector" entry and the signer's domain from the signature in the email header to query the public key via DNS and then validate the authenticity of the DKIM signatures.

DMARC. Domain-based Message Authentication, Reporting and Conformance (DMARC) [17] is an email security extension built upon SPF and DKIM. DMARC introduces an alignment scheme to ensure that the address in the `From` field aligns with the domain verified by SPF or DKIM. If both SPF and DKIM fail to pass, DMARC authentication fails as well. DMARC also includes a specialized feedback mechanism that allows receivers to report errors or provide suggestions to help develop the domain's DMARC policies.



Combining the above security protocols, an email system ensures that spoofing emails based on the `From` field are easy to verify. However, there is currently no validation method for the `Sender` field, leaving open the possibility of successful spoofing attacks on the `Sender` field.

2.2.3 Client-level Protections



Despite the implementation of security protocols, engineers and researchers have proposed various measures to enhance user-side security. Two commonly used mechanisms are user warnings, which alert users to potentially malicious emails or activities, and exposing the Delegate, which provides information about the actual origin of the email. These mechanisms are extensively employed in email clients and web interfaces.

GUI Warning. Researchers have studied user actions [11, 30, 47] and found that the user's judgment is crucial in email authentication. Due to differences in education and technical backgrounds, recipients may make different decisions when faced with the same email. To assist in verifying suspicious emails, user warnings are vital and widely implemented in email clients and web interfaces. When an email is flagged as phishing or potentially harmful but not directly rejected, a warning prompts the recipient to examine the email carefully, as shown in Figure 3(a).

Exposing the Delegate. As illustrated above, an email contains two distinct "senders": one specified in the `MAILFROM` command within the envelope, and the other in the `From` field of the email header. Since the original transmission protocol does not allow for inconsistency between these two addresses, attackers can exploit this vulnerability to arbitrarily forge the

(a) An Example of User Warning that Gmail.com Displays to the Recipient.

(b) The Outlook Client Displays a Delegate Message Based on the Sender Field.

Figure 3: Two Client-level Protections Employed Worldwide.

`From` field with a controlled domain. In such cases, most email providers will expose the actual transmitter (also referred to as the Delegate) to users, which is defined as a Sender Inconsistency Check (SIC) by Shen *et al.* [36]. Exposing the Delegate is also a defensive measure to prevent email spoofing attacks, as it presents the email's origins to the recipients. As the envelope varies with every SMTP session, RFC 5322 [33] specifies the `Sender` field to record the Delegate's address, as shown in Figure 3(b). However, the absence of authentication for the `Sender` field enables attackers to arbitrarily fabricate this field. This design ambiguity gives rise to additional security issues. Moreover, the lack of a standard protocol for implementing the Delegation Mechanism leads to inconsistent implementations among various providers and clients, raising potential risks.

3 Research Overview

In this work, we primarily investigate the vulnerabilities associated with the email Author and the Delegate within the Delegation Mechanism.

3.1 The Attack Model

The threat model, as depicted in Figure 4, includes three key entities: a trusted email author (Alice) with the mailbox *Alice@legitimate.com*, a victim receiver (Bob) with the account *Bob@victim.com*, and an adversary (Eve) attempting to impersonate Alice and send forged emails to Bob from the domain *@attack.com*. In this model, Alice deploys robust security extensions for the sending domain (SPF, DKIM, and DMARC), as does Eve. It is worth noting that Alice is not influenced by Eve when configuring the security policies and is unaware of these attacks. We also clarify that these addresses presented in

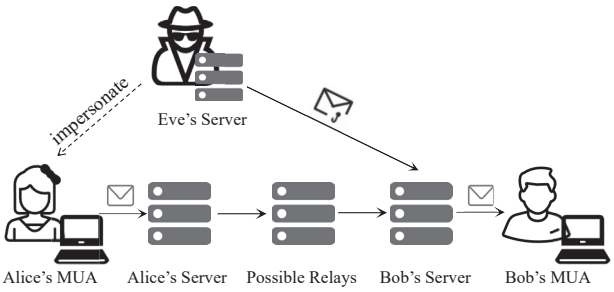


Figure 4: The Model of Email Spoofing Attack.

the model are not actual email addresses but serve as illustrative examples, as well as the attacks mentioned in Section 6. We assume that Eve owns a personal email server and can establish SMTP sessions directly with Bob's receiving server, a task that is easily achieved by attackers [3, 36]. When establishing SMTP sessions, Eve will try to manipulate the email content within the `DATA` command rather than the commands in SMTP interactions, such as `MAILFROM`. This implies that the address specified in the `MAILFROM` command is under the control of the attacker. With this attack model, we can naturally pass the authentication of SPF and DKIM, as the sending domain is fully under our control. The primary factor enabling this is the absence of explicit exposure of the authentication results to users, who are unaware that the verified domain is not aligned with original expectations.

Moreover, the success of an attack in Section 6 is defined by three factors: 1) The forged email successfully enters Bob's inbox; 2) The MUA presents Alice (as indicated in the `Sender` field) as the email author; 3) The attack email closely resembles a legitimate message from Alice, e.g., the MUA displays no warnings or Delegate information exposing the attacker's address. Each attack is repeated, meaning the same attack email is sent twice, and it is considered successful only if both attempts succeed. A demonstration of a successful attack on the Gmail client is presented in Figure 9(a) in the Appendix, while a failed attempt on the Outlook client is shown in Figure 9(b) as a contrast.

3.2 Solution Overview

To address the preceding research questions, we conduct a series of studies comprising three main steps. An overview of our methodology is presented in Figure 5.

We commence with a *Measurement Study* to investigate the implementations of the Delegate Mechanism and the handling of spoofed `Sender` fields in target providers and clients (**Step-1** of Figure 5). We append a spoofed `Sender` field to legitimate emails originating from our domain and dispatch them to target email providers. By checking the email performances on 16 web interfaces and 20 email clients, we discover that most providers lack authentication for the `Sender` field and accept test emails in their inboxes. Moreover, 10 out of 16

providers have various implementations of the Delegation Mechanism, while 13 clients solely display the `Sender` field as the Delegate, as introduced in Section 4.

To evaluate recipients' comprehension of the spoofed Delegate, we conduct a *User Study* involving 50 participants (**Step-2** in Figure 5), as described in Section 5. We carefully craft four types of email Delegates for identical emails and invite each participant to independently assess the validity of one example from the four emails. The observations reveal that misleading Delegates successfully deceive 50% of the participants into recognizing spoofing emails as legitimate, while the remaining half can verify these suspicious emails.

While spoofing email Delegates presents substantial security risks, this simple attack is still identified by 50% of the participants. To achieve more effective spoofing, we employ methodologies that forge the `From` field along with exploiting vulnerabilities within the Delegation Mechanism. Consequently, we propose six email spoofing techniques in **Step-3** that enable attackers to impersonate legitimate entities and send spoofing emails to potential victims without displaying security warnings to expose the attacker's address. Detailed methods are described in Section 6. Our investigations reveal that these attacks successfully deceive half of the providers and all the clients.

Finally, in Section 8, we propose a validation scheme for the `Sender` field along with several security suggestions for email clients and users.

Ethical Considerations and Responsible Disclosure. We have taken several measures to ensure the ethical integrity of our research. One potential risk is the trust credit loss that legitimate domains might suffer if victims receive spoofed emails under those domains. However, our email spoofing targets in the *Spoofing Attack* are fully under our control. We sent only two example emails with addresses beyond our control to demonstrate the concept of our attack (Fig 3(a) and Fig 9). We believe this limited number of emails will not trigger robust defense mechanisms in commercial email systems. Additionally, we reported our findings to relevant email providers, along with our test emails, to help them investigate the vulnerability. In the *Measurement Study* and *Spoofing Attack*, we exclusively used test accounts owned by ourselves, ensuring that no real users were affected by these experiments. We carefully controlled the email-sending rate to be under 10-minute intervals per email to minimize the impact on target servers. We did not request any personal information from participants in our *User Study*. The user study in Section 5 was reviewed by the IRB at the university and received an exempt designation. Our platform implements robust defensive measures to prevent unauthorized access or data leakage. We have responsibly disclosed our findings to all affected email providers in January 2024. As of the submission of this manuscript, we have received feedback from *163.com*, *139.com*, and *coremail.com* that they successfully replicated the attacks and their engineering teams are further investigating the issue. *Evolution* is currently in discussion with us to identify the affected versions. Our further investigation showed that the recently updated version of Evolution is still vulnerable. To prevent malicious attacks by unscrupulous users, we will not disclose the vulnerabilities to the public until 90 days after our final disclosure.

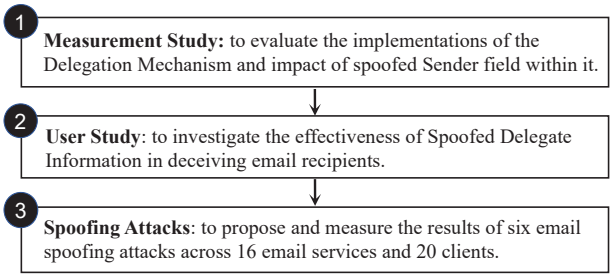

Figure 5: An Overview of Research Methodology.

4 Measurement Study on Implementations of the Delegate Mechanism

Since we observe that the `Sender` field can be modified by attackers, our goal is to explore the implementations of the Delegation Mechanism and how the `Sender` field is presented within this mechanism across widely-used email providers and clients. We conduct a *Measurement Study* involving 16 email providers and 20 clients to examine the performance of emails with a spoofed `Sender` field. The results are presented in Section 4.2.

4.1 Experiment Methodology

Target selection. This study primarily focuses on assessing the impact of the spoofed `Sender` field within the Delegation Mechanism across various email providers and clients. The selection of target providers is based on three specific criteria. Firstly, we choose widely used providers such as *gmail.com* and *outlook.com* since their security concerns and policies affect a larger global user base. Secondly, our study requires an end-to-end experiment involving gathering information from recipients and necessitating direct SMTP connections with target servers, excluding providers like *protonmail.com*, which does not offer SMTP. Thirdly, we need access to the raw email content or email files from testing accounts for further analysis. Consequently, we select a total of 16 email service providers, including platforms like *163.com* and *gmail.com*. Additionally, as claimed by Liu *et al.* [22], the market share of self-hosted email servers has decreased consistently since 2017, with many organizations opting to deploy their email servers with commercial support such as Outlook. We also evaluate the self-hosted email server of a large university supported by *coremail.com*, a popular email server solution deployed on more than 15,000 private servers [5].

Table 1: Target Providers' Implementations of the Delegation Mechanism and the Handling of the Spoofed Sender field.

Email Handling	Gmail	Outlook	Zoho	Naver	139	163	Yandex	QQ	Mailo	Yeah.net	126	Sohu	Sina	Rambler	Coremail.com	Tutanota
Accept in inbox	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓
Modify the spoofed Sender field						✓				✓	✓				✓	
Append a Sender field if necessary						✓		✓		✓	✓				✓	
Policy to expose the Delegate	✓		✓		✓	✓		✓		✓	✓	✓	✓		✓	
Header fields used as the Delegate	Return-Path		Return-Path		X-RM-Sender	Sender		Sender		Sender	Sender	Return-Path	X-Sender		Sender	

Furthermore, we meticulously select popular email clients across five desktop and mobile operating systems, including Foxmail and Apple Mail. In total, we include 20 email clients that collectively serve billions of users worldwide [28]. We believe that the security issues they exhibit are representative of the threats faced by most email users. Refer to Table 1 and Table 2 for more details on our chosen targets.

Measurement procedure. We initially set up a personal email server to establish direct interactions with the servers of target providers. Additionally, we employ robust security extensions (SPF, DKIM, and DMARC) to ensure that legitimate emails sent from our domain successfully pass authentication. Next, we generate test emails originating from our domain, with the `From` field aligning with the `MAILFROM` command, and append a spoofed `Sender` field in the email header (*e.g.*, *admin@google.com*). Subsequently, we configure all selected clients as agents for our email account to assess email performance. Finally, we deliver these crafted emails to target providers and observe their manifestations on the web interfaces and clients. Through careful analysis of the results, we summarize our findings in Section 4.2.

4.2 Experiment Results

More details of the experimental results from target providers and clients are presented in Table 1 and Table 2, respectively. Based on these results, we make three main observations as follows:

Deficient validation of the Sender field by email providers. Our experimental findings reveal that all 16 target providers allow test emails to pass their authentications and reach the recipients' inboxes without displaying any user warnings, as shown in Table 1. Notably, the `Sender` field is spoofed and does not match the address in the `From` field or `MAILFROM` command, demonstrating that attackers can forge this field with accounts of any legitimate entities. Although a few providers perform various processing actions on this field, we conclude that the majority of providers do not authenticate the validity of the `Sender` field.

Modification of the spoofed Sender field by certain providers. Upon comparing the received emails with the original ones, we observe that five of the 16 providers modify the `Sender` field in various situations based on their local strategies. When processing "legitimate" emails with a spoofed `Sender` field only, *126.com*, *163.com*, and *yeah.net* delete the existing `Sender` field, while *coremail.com* modifies it to the address in `MAILFROM`. Given our experimental setup, both modification methods seem reasonable. Moreover, when processing various spoofing attack emails mentioned in Section 6.1, these four providers modify the spoofed `Sender` field to the address in the `MAILFROM` command, which is an effective measure to defend against these attacks. Additionally, these four services, along with *qq.com*, append a `Sender` field in original emails if necessary (and none exists), as shown in Table 1. The modification of the spoofed `Sender` field reveals that these email providers employ basic validation measures to verify this field. However, these countermeasures are not extensively employed, as the remaining 11 providers take no action toward the spoofed `Sender` field. On the other hand, the issue within the Delegation Mechanism is a system-level problem relevant to both email providers and clients. Even for providers that modify the spoofed `Sender` field, it is still possible to conduct spoofing attacks with popular email clients.

Inconsistent implementations of the Delegation Mechanism within web interfaces and clients. Our findings indicate that 13 out of 20 clients and 10 out of 16 providers have employed the strategy to expose the Delegate to the recipients, as shown in Table 1 and Table 2, respectively. Specifically, 10 providers deploy various implementations of the Delegation Mechanism, with half of them parsing the `Sender` field for this purpose. While *outlook.com* does not present the Delegate on the web interface, it stores and labels the address in `Sender` as the email transmitter. Conversely, all 13 clients present the `Sender` field as the Delegate, including popular ones like Outlook and eM Client.

According to the results, the `Sender` field serves as a primary source for email Delegates in 50% of web interfaces and is the sole source in email clients. Considering that four providers modify the spoofed `Sender` field, spoofing the Delegate is practical only on the web interface of *qq.com*. However, since the remaining 11 providers keep the spoofed `Sender` field unchanged, we conclude that attackers can forge Delegate information on all 13 clients.

5 User Study

Motivated by the observations above, we aim to investigate whether users comprehend the inconsistency between the

[1] The subscript A_i identifies the spoofing attacks capable of attacking these clients, which will be discussed in Section 6.1.

email author and the spoofed Delegate. To this end, we conduct a user study involving 50 participants. Analysis of the results reveals that **deceptive Delegate information notably influences 50% of the participants to verify spoofing emails as legitimate, while the other half can identify these emails as fraudulent**.

5.1 Methodology

We initially set up an email platform for our study and invite 50 participants to evaluate their perceptions when presented with emails containing forged Delegates. The participants, who are well-educated college students from different grades, have generally encountered various kinds of phishing emails and possess a certain level of recognition. They are asked to validate and decide how to process (accept or reject) five test emails and provide brief explanations for their judgments. To collect the participants' actions when judging emails, we design our web interface with additional functions beyond traditional MUAs. This setup also streamlines the process for participants to access the web interface, enabling us to better organize the study. Through understanding the participants' actions regarding the test emails, we summarize our key findings in Section 5.2.

Email platform. For better organization and privacy considerations, we initially develop an email platform for the study, consisting of four primary components: the storage module, the controller, the analyzing module, and the web interface. Each participant is allowed to participate in the test only once. The web interface displays test emails with various additional functions for the participants, such as validating the email or marking suspicious portions. Test emails are securely stored in the storage module along with anonymous IDs and hashed passwords. The controller retrieves measuring emails from the storage module, which are later parsed and presented on the web interface. We design our web interface in the style of *gmail.com*, as it remains the most popular email provider worldwide. As most MUAs do, if a `Sender` field is present in the test email, we show it to the participant as the email Delegate; in contrast, if this field is absent, no such information will be displayed, as depicted in Figure 6. During the test, the controller caches the actions performed by each participant and subsequently transmits them to the analyzing module. The analyzing module classifies these actions based on different orientations and provides statistical results for further analysis. This platform is fully under our control, with comprehensive measures to prevent security risks.

Email generation. We investigate the impact of forged email Delegates on users, and a crucial step is to generate emails with distinct `Sender` fields. As the recipients' domain is *victim.com*, we consider four types of Delegates: 1) a domain controlled by the attacker (*attack.com*), which is easily identifiable to recipients; 2) an account from the victim's domain (*e.g.*, *admin@victim.com*), which is most likely to deceive recipients, as it appears to originate from their organization; 3) a domain belonging to a different organization (*organization.com*), which has less potential to mislead recipients than the previous type; 4) no specific Delegate information, acting as a control group.

Each participant is requested to verify five test emails (Emails 1 to 5, as presented in Table 3), with Email 5 focusing on the `Sender` field. To minimize bias, each participant is randomly assigned one of the four types of emails as their final test. The other four emails (Emails 1 to 4), which include three legitimate and one phishing sample, are based on real samples received by our group to ensure participants' basic ability to recognize phishing. Additionally, all emails are desensitized for privacy preservation.

Protocol of the user study. We first inform the participants that our study is an anti-phishing game, where they play the role of an assistant helping a group leader process emails, a commonly used methodology in phishing studies [30, 44, 47]. After account registration with pseudonyms and logging into the web interface, each participant is requested to process five emails, with the final one featuring the spoofed `Sender` field. The web interface provides buttons to process the emails, and participants can also highlight any suspicious parts. Their actions are recorded and subsequently transmitted to the analyzing module for further examination.

After the study, we disclose the actual purpose of the research to the participants to enhance their ability to identify email spoofing. Our main findings are summarized in Table 3.

5.2 Results and Analysis

As shown in Table 3, the experimental results indicate that half of the 18 participants who received emails with deceptive Delegate information (*admin@victim.com*) mistakenly iden-

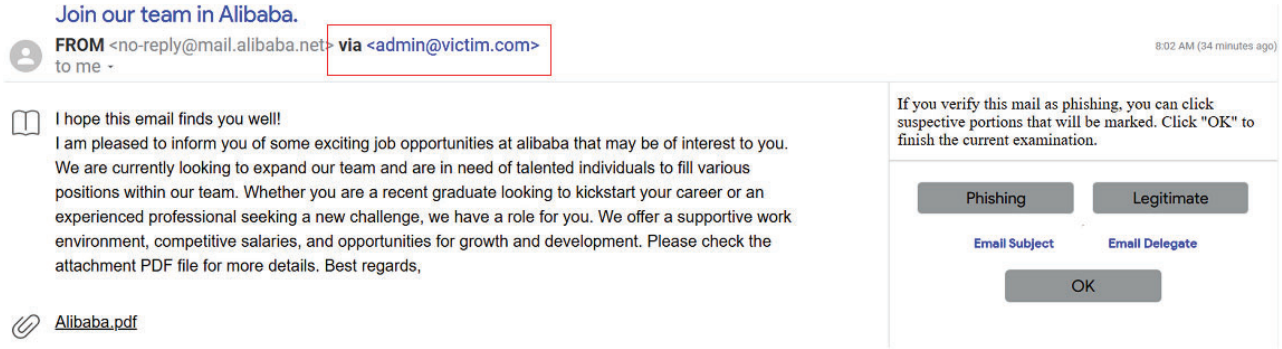

Figure 6: The Web Interface of the User Study, where the Sender Field is Displayed as the Delegate as Marked.

tified them as legitimate. Conversely, the misjudgment rate for identical emails without a spoofed `Sender` field is only 12.5%. For emails with less misleading Delegates (*organization.com*), three out of ten participants incorrectly judged them as legitimate, and only one recipient misjudged the phishing emails with the Delegate *attack.com*. We randomly assign test samples to each participant, resulting in slightly different participant counts across the four groups. However, this inconsistency does not significantly affect our findings, which are more relevant to the experimental setup.

The findings confirm that deceptive email Delegates significantly mislead users into recognizing forged emails as legitimate. Attackers can deceive many users by sending "legitimate" emails with spoofed `Sender` fields, which are accepted by all measured providers. However, this forgery is not always effective, as half of the users recognize the abnormal Delegates and correctly identify the emails as spoofing. Additionally, some participants noted that the deceptive nature of the Delegate itself raised suspicion, leading them to reject such emails.

6 Imperceptible Email Spoofing Attack

The results of the *User Study* reveal that deceptive email Delegates misled half of the participants into trusting spoofed emails, while the other half detected these forgeries. This prompts us to explore more aggressive email spoofing mechanisms. Inspired by previous works [3, 36], we examine various approaches to craft emails with irregular `From` fields and assess their effectiveness in evading security protocols. Consequently, we propose six types of email spoofing attacks and measure their impact across 16 email services and 20 clients. All 20 clients are configured as MUAs for all 16 providers via IMAP, resulting in 336 combinations (including 16 web interfaces of target providers). Detailed demonstrations of these attacks are described in Section 6.1. The experimental results indicate that these spoofing emails can successfully bypass authentication and enter the inboxes of eight target providers. Furthermore, by exploiting issues within the Delegation Mechanism, we demonstrate that all 20 clients display the unauthenticated `Sender` field as the sole email author without any warnings or Delegate information to expose the attacker's address, making these attacks imperceptible to the recipients.

Minimize the bias. This work primarily focuses on the issues within the Delegation Mechanism, which differs from spam filters mainly based on the email body semantics. To minimize the impact of spam filters, we consult an email security expert to create an email body unlikely to be flagged as spam or harmful. Additionally, we use a static IP for our email server and control the sending rate with a 10-minute interval to reduce the impact on target email servers. Considering the billions of daily emails, we believe a low sending rate will not significantly affect target servers. We randomly select pre-sending emails and target providers and send each type of email twice to the same service. An attack is deemed successful only if both attempts succeed. By sending emails randomly, we aim to reduce the impact of prior emails on subsequent ones.

6.1 Email Spoofing with the Sender Field

This section introduces various approaches employed to pass authentications in our email spoofing attacks. Since the `Sender` field is a crucial part of the Delegation Mechanism, all forgery methods are denoted by **"with the Sender field"**. For conciseness, we omit the preceding quotes and use A_i to represent the i-th method. Additionally, to evaluate the `Sender` field's effect on email spoofing, we delete this field from test emails and conduct a comparative trial for each attack. These trials help assess the `Sender` field's impact on the success rate of our attacks.

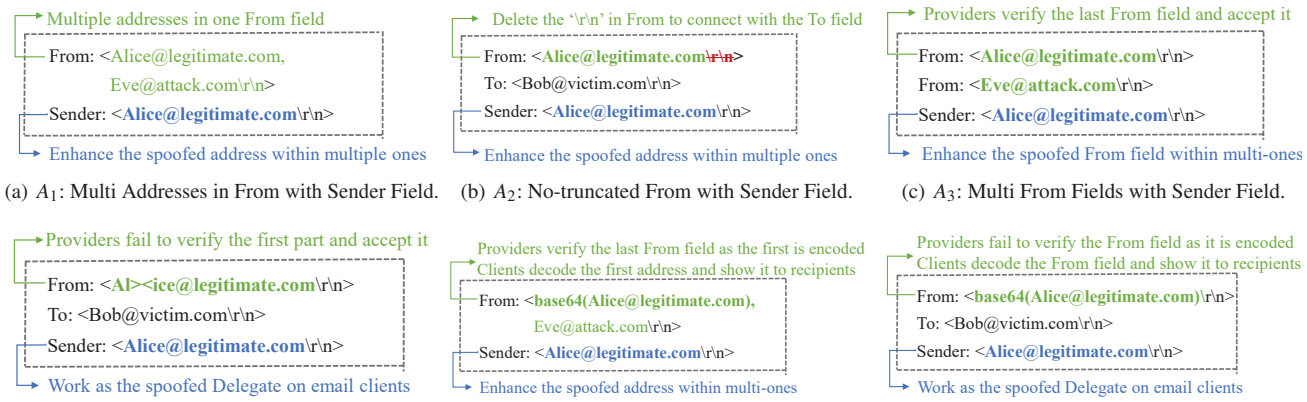
Attack 1: Multiple addresses in one From field (A_1). RFC 5322 allows multiple addresses within one `From` field [33]. In such cases, the `Sender` field must be used to indicate the one responsible for email delivery. However, no security extensions authenticate multiple email authors, enabling attackers to fabricate addresses in `From` casually while utilizing the `Sender` field to enhance the spoofed account's reliability. Figure 7(a) shows the structure of the forged email. The address

Table 3: Experimental Results of the User Study.

Character	Email 1	Email 2	Email 3	Email 4	Email 5			
					Variant 1	Variant 2	Variant 3	Variant 4
Is Phishing	×	×	✓	×	✓	✓	✓	✓
The Link	✓	×	✓	✓	×	×	×	×
Attachment	✓	×	×	×	✓	✓	✓	✓
Sender Field	legitimate	×	×	×	Victim.com	Organization.com	Attack.com	×
Participant Count	50	50	50	50	18	10	14	8
Misjudgment[1]	10	12	13	5	9	3	1	1

[1] Misjudgment refers to the act of participants mistakenly judging phishing emails as legitimate, or identifying legitimate ones as phishing.

in the `Sender` field is consistent with the first one in the `From` field, which is the spoofed account that clients may regard as the primary author and show to the recipient. Instead, receiving servers employ the second address (controlled by attackers) for authentication and consequently accept this email as legitimate.



Experimental results show that five providers (*e.g.*, *mailo.com*, *qq.com*) and 17 clients (*e.g.*, Outlook on Windows) are influenced by this attack. These affected providers accept such emails in the inbox, allowing the attacker to successfully conduct this attack against recipients on the above 17 clients. Conversely, *qq.com* will drop the email without the `Sender` field into the spam folder, and this attack fails to impact seven clients that are initially susceptible (*e.g.*, Foxmail on Windows) due to the lack of the `Sender` field. The supporting details are presented in Table 6(a) in the appendix.

Attack 2: From field none-truncation (A_2). The terminator defined in emails is a character consisting of two ASCII letters named "Carriage-Return Line-Feed" (CRLF). It indicates the end of SMTP commands or the email content, including header fields like `From`. As shown in Figure 7(b), an email with none-truncated `From` deletes the CRLF in `From` and connects it with the subsequent field `To`, with the `Sender` field consistent with the `From` field. When parsing the address in `From`, the server recognizes all the content preceding a CRLF (which contains the receiver's address in `To`) as the message author and validates the email as self-sent. However, email clients may recognize it as multi-address and display the first as the email author, with the `Sender` field enhancing the reliability of the spoofed author. Compared to general multi-address ones (A_1), such emails are more likely to enter the inbox, thereby increasing the success rate of spoofing attacks. According to the measurement results, six email providers (*e.g.*, *163.com*, *139.com*) and nine clients (*e.g.*, Windows Mail, Gmail on iOS) are vulnerable to this attack. Compared to the results in A_1, six service providers accept these messages into the inbox, including the ones that directly reject multi-address emails (*e.g.*, *163.com*, *yeah.net*). This significantly improves the inbox rate and raises more potential risks than attack A_1. In the contrast test, no specific differences are observed in email processing. However, the results change on four clients when handling emails without the `Sender` field. More details are shown in Table 6(b) in the appendix.

Attack 3: Multiple From fields (A_3). It is specified that emails with multiple `From` fields should be directly rejected [33]. However, even for providers that employ various preventive measures, such emails are still allowed to enter the inbox (*e.g.*, *139.com*, *mailo.com*). An example is shown in Figure 7(c). The email contains two `From` fields, and the first one is consistent with the `Sender` field, which is the disguised email author that attackers aim to show to recipients. The address in the second `From` field is controlled by the attacker to pass possible authentications. By utilizing the `Sender` field, attackers convince the receiving servers that the address in the first `From` field is the legitimate author, thus delivering the email to the inbox.

We observe that four email providers (*e.g.*, *sohu.com*, *139.com*) and 15 clients (*e.g.*, Outlook, Gmail on iOS) are affected by this attack. Additionally, *mailo.com* accepts the email in the inbox and displays the address in the `Sender` field as the email author on the web interface, marking it as the only successful attack conducted on web interfaces under our strict criteria. The results show no differences in email processing and the performance of target clients, as detailed in Table 6(c) in the appendix.

Attack 4: Parsing with angle brackets (A_4). The `From` field supports rich text with complex forms, which can lead to incorrect email address parsing. By carefully constructing the `From` field with special characters, attackers can misguide email servers to parse incorrectly and display the wrong address to recipients. We discover that angle brackets ("<>") are particularly effective in this attack, as shown in Figure 7(d). The disguised email author in the `From` field consists of two parts enclosed within two pairs of angle brackets, while the `Sender` field contains the correct address. Receiving servers may authenticate the first part as the email author but fail to parse it correctly. Different service providers employ varying strategies in this scenario. Seven email providers, such as *coremail.com*, accept these emails into the inbox, while *zoho.com* rejects them.

(a) A_1: Multi Addresses in From with Sender Field. (b) A_2: No-truncated From with Sender Field. (c) A_3: Multi From Fields with Sender Field.

(d) A_4: Parsing From with Angle Brackets. (e) A_5: Multi From Fields with One Encoded. (f) A_6: Encoded From with Sender Field.

Figure 7: Demonstration of the Methodologies in Spoofing Attacks.

As for the results on email clients, five of them are susceptible to this attack (*e.g.*, Outlook on Windows, Gmail on Android). Influenced by the `Sender` field, these clients tend to tolerate the illegal address and remove the additional angle brackets in the `From` field, presenting the intact address of Alice to the victim Bob. For the comparison trial, no differences are observed during email processing, but the attack fails when targeting NetEase on iOS due to the lack of the `Sender` field. More details are summarized in Table 6(d) in the appendix.

Attack 5: Multiple addresses with one encoded (A_5). Per Figure 7(e), address encoding is also an effective method for email spoofing. The original SMTP protocol only supports ASCII characters, and to extend support for non-ASCII characters, RFC 2047 [25] defines two encoding algorithms: Base64 and quoted-printable. Unlike typical multi-address emails, attackers can encode the first address with Base64 and place it in the `Sender` field, while the second address belongs to the attackers themselves. Receiving servers may not identify the encoded address and use the second one for authentication. Clients like Foxmail are inclined to decode the first address and recognize it as a multi-address email, thereby displaying the address in the `Sender` field as the primary author. We find that four email service providers (*e.g.*, *qq.com*, *sohu.com*) and six email clients (*e.g.*, Outlook, Apple Mail on iOS) are vulnerable to this attack. As for the comparative test, no providers show a difference in processing these emails, but the attack fails on four out of the six clients (*e.g.*, Outlook and Netease on iOS) due to the lack of the `Sender` field, as shown in Table 6(e) in the appendix.

Attack 6: Address encoding (A_6). Unlike attack A_5, this type of forged email contains only a single address encoded in the `From` field, as shown in Figure 7(f). SMTP servers receiving such emails fail to authenticate the encoded address and deliver them to the inbox. Conversely, email clients typically decode the `From` field and present the decoded address as the email author to the recipients.

The results indicate that seven service providers (*e.g.*, *163.com*, *coremail.com*) and 11 clients (*e.g.*, Foxmail on Windows, Thunderbird on Linux) are vulnerable to this attack. Compared to the original approach in prior works [3, 36], the `Sender` field helps enhance the reliability of the spoofed address, thereby increasing the success rate of the attack. When the `Sender` field is removed from attack emails, the implementation of A_6 fails on five clients that were previously vulnerable (*e.g.*, QQ Mailbox and NetEase on iOS). Refer to Table 6(f) in the Appendix for more details.

We need to clarify that some methods for manipulating the `From` field (A_1, A_3, A_5, A_6) have been mentioned and evaluated in previous works [3, 36]. While these measures share some similarities with prior research, our work primarily focuses on the issues within the Delegation Mechanism and extends beyond the manipulation of the `From` field. We explore various approaches for crafting this field and chose the above six methods for their broader applications and higher success rates.

6.2 Experiment Results and Analysis

The results of the *Spoofing Attack* are illustrated in Table 2 and Table 4. We summarize our experimental findings as follows.

Finding-1: Attack emails can reach the inboxes of half of the email providers but are not significantly effective on their web interfaces. As shown in Table 4, 8 out of 16 email providers are vulnerable to various attacks. These affected providers tend to accept forged emails into their inboxes and present them to the recipients, raising potential risks for corresponding users. However, only one provider is successfully attacked on its web interface. After careful analysis, we identify three reasons for these unsuccessful attempts.

Firstly, 8 resilient providers implement strict security extensions, such as DMARC, which renders most attack emails invalid in authentication, leading to their rejection or identification as spam. Secondly, the operations for presenting the `From` field do not align with the attacker's expectations on the web interfaces. For instance, *qq.com* and *coremail.com* dis-

[2] The "Total" denotes the proportion of all providers that accept any attack emails in the inbox, and the proportion of clients and web interfaces that are susceptible to any attacks.

play the encoded address to the recipients in attack A_6 rather than presenting the decoded results. Lastly, as explained earlier, exposing the Delegate is an effective way to prevent spoofing emails, and all 10 services adopting the Delegation Mechanism correctly expose the attacker's address to the recipients, as shown in Table 1.

We can classify the 10 providers into four types based on their approaches to implementing the Delegation Mechanism when processing attack emails: 1) *qq.com* utilizes the original `Sender` field as the Delegate and adds the actual sending address (*attack.com*) if necessary; 2) Four providers (*163.com*, *126.com*, *yeah.net*, and *coremail.com*) modify (or add) the address in the `Sender` field to match the `MAILFROM` command, and then use the modified field as the Delegate; 3) *gmail.com*, *zoho.com*, and *sohu.com* add a "Return-Path" entry based on the actual sending address and present it as the Delegate while retaining the original `Sender` field; 4) *139.com* and *sina.com* append a specific field (e.g., "X-Sender") in the email header, with the original `Sender` field unchanged. Although these entries resemble the `Sender` field, they can only be parsed on corresponding web interfaces and are ineffective in email clients. As various providers deploy different strategies to implement the Delegation Mechanism, their web interfaces can correctly expose the email Delegate to the recipients.

Finding-2: All 20 clients are vulnerable to various attacks. With the proliferation of mobile devices and personal computers, email clients on various operating systems have garnered the attention of billions of email users due to their portability and convenience. Based on the results shown in Table 2, all 20 clients exhibit weaknesses to various attacks, including popular ones like Gmail and Outlook. Using forgery approaches, attackers can successfully conduct spoofing attacks on users across all clients via appropriate email providers. Compared to web interfaces, email clients are more susceptible to these spoofing attacks for the following reasons:

1) Email clients are more likely to present the `From` field in a way that aligns with the attacker's intentions compared to web interfaces. Due to a smaller display area, email clients are more inclusive of irregular forms of the `From` field, increasing the risks of email spoofing.

2) As shown in Table 1, 10 providers adopt various strategies to expose the correct Delegate to the recipients, including the `Sender` (*e.g.*, *163.com*), `Return-Path` (*e.g.*, *gmail.com*), and other header fields. However, email clients only employ the `Sender` field for this purpose. Some mainstream providers append specific entries with their local strategies, which email clients cannot parse while keeping the original `Sender` invari-

ant. Consequently, email clients can only display the forged Delegate in the `Sender` field rather than the correct one shown on web interfaces. These differences in implementations explain the different Delegates of the same email, thus resulting in various attack outcomes.

3) Moreover, as emphasized above, exposing the Delegate is a significant way to prevent spoofing emails. However, seven out of the 20 clients (*e.g.*, Gmail) do not employ the policy to present the Delegate, making failed attempts on web interfaces practical for these clients. While some providers employ strategies to verify the `Sender` field such as *163.com*, spoofing emails they receive can still successfully attack the recipients using the Gmail client. The absence of the Delegation Mechanism raises potential risks for spoofing attacks on these clients.

Finding-3: The Sender field significantly increases the success rate of attacks, especially when targeting email clients. Due to the standardization of the feature [33], the `Sender` field significantly influences the design of some email clients, thereby increasing the success rate of various spoofing attacks, as shown in Table 5. Specifically, for clients that adopt the policy to expose the email Delegate (*e.g.*, Outlook, NetEase), the spoofed `Sender` field improves the success rate evidently. However, its impact is limited on web interfaces due to their well-established security strategies. This highlights the importance of implementing robust security measures within client applications.

We also identify two reasons that influence the impact of this field on email clients. Firstly, as described in Section 4.2, seven out of 20 clients do not adopt the policy of presenting the Delegate to the recipients. Consequently, the `Sender` field proves inconsequential to attack results on these seven clients.

Another reason is the modification of the `Sender` field by certain providers. As mentioned in Section 4.2, five email providers (*e.g.*, *163.com*) modify or add the `Sender` field in original emails, resulting in consistent email representations regardless of the existence of this field. These providers adopt various strategies to verify the `Sender` field, thereby preventing such spoofing attacks to some extent. However, by exploiting the inconsistencies in the implementation of the Delegation Mechanism between providers and clients, we demonstrate that they are still vulnerable to these attacks.

7 Root Causes and Main Conclusions

7.1 Root Causes

We summarize the root causes of these attacks in three aspects.

First, the `Sender` field, which is defined as the delegation feature in RFC 5322, is mostly neglected by email security mechanisms. This allows the attackers to arbitrarily modify this field, thereby raising potential security issues.

Second, exposing the email Delegate is an effective measure to defend against spoofing attacks. However, various email providers implement the Delegation Mechanism differently on their web interfaces, while major clients only parse the `Sender` field for this purpose. Moreover, some clients do not expose the Delegate to recipients, increasing the potential risks of email spoofing. These inconsistencies within email providers and clients raise the security vulnerabilities of spoofing attacks, especially for client users at scale.

Third, since it is defined in RFC 5322 [33], the `Sender` field enhances the validity of the spoofed address and significantly influences the implementation of most email clients, thereby increasing the success rate of email spoofing on these clients.

7.2 Answers to Research Questions.

We can now address the research questions presented in Section 1.

Answer-1: Our investigations reveal that 10 out of 16 service providers have adopted different strategies to implement the Delegation Mechanism, with half of them using the `Sender` field as the Delegate. When processing attack emails with the spoofed `Sender` field, these five providers will take various measures to verify this field, while the majority do not validate its authenticity. Conversely, 13 out of 20 email clients display the Delegate to users, and all of them parse the `Sender` field for this purpose. Exposing the email Delegate is widely utilized in both web interfaces and clients as a defensive measure against spoofed emails.

Answer-2: To assess recipients' comprehension of the inconsistency between the email author and spoofed Delegate, we conduct a user study involving 50 participants. Our main observation is that deceptive Delegates misled 50% of participants into identifying forged emails as legitimate. However, the remaining half correctly identified such suspicious emails. Moreover, the misleading Delegate information can prompt recipients to scrutinize the email's authenticity more carefully, potentially increasing their vigilance.

Answer-3: Since all clients present the `Sender` field as the Delegate, attackers can deceive many recipients by simply appending a deceptive `Sender` field in spoofed emails. However, this trick is not significantly effective for users. To implement more effective attacks, we propose six email spoofing methods using the `Sender` field, which can bypass the defenses of half the mainstream providers we have measured. By exploiting issues within the Delegation Mechanism, attackers can impersonate any entity to send emails without triggering security warnings, making these attacks imperceptible to recipients. The experimental results indicate that all 20 clients are vulnerable to such attacks, putting billions of users at risk of email forgery.

Our findings demonstrate that vulnerabilities within the Delegation Mechanism pose a significant threat to email security, affecting both email providers and clients. In Section 8, we provide a comprehensive discussion of the countermeasures to address these issues.

8 Defense Suggestions

To prevent vulnerabilities within the Delegation Mechanism, we propose a robust validation scheme for email providers. We also offer several suggestions for clients and users to enhance their security measures.

8.1 Validation Scheme on the Sender Field

As defined in RFC 5322 [33], the `Sender` field indicates the agent responsible for email transmission. Considering possible relays during email delivery, the `Sender` field should be consistent with the `MAILFROM` command in *the first SMTP session* (where the receiving server must be public-trusted). Therefore, we propose implementing an alignment scheme between the `Sender` field and the `MAILFROM` command at the beginning of email transmission. The primary focus of the validation process is to ensure consistency among `Sender`, `MAILFROM`, and `From` under various scenarios utilizing the `Sender` field.

Building upon the concept outlined above, we recommend implementing a rigorous strategy to validate the `Sender` field within the first SMTP session. If the email author does not align with the `MAILFROM` command, or if multiple authors are specified in the `From` field, the receiving server should append a `Sender` entry directly with the address specified in the `MAILFROM` command. Additionally, any original `Sender` field in received emails should be eliminated if it exists. By generating a legitimate `Sender` based on received emails, rather than solely inspecting the original field, we can effectively authenticate the validity of the `Sender` field while ensuring proper parsing of such an added field on email clients.

However, the aforementioned strategy may not be suitable for all real-world scenarios, as organizations may choose to use specialized servers to collectively transmit their emails. In such cases, it is reasonable for these emails to contain a `Sender` field with a reputable domain (the delivery server), and the *first SMTP session* occurs between the organization's server and the dedicated server. It is inappropriate for specialized delivery servers to strictly follow the authentication process. Instead, the common practice is to append a `Sender` field with their domain. Consequently, we emphasize that the authentication strategy should be implemented in two modes, as illustrated in Figure 8. For emails from such organizations, the authenticating server can simplify the validation process by appending a `Sender` field with their domain without checking for inconsistencies within related fields.

8.2 Suggestions for Clients

It is insufficient to take actions only on the providers' side since such vulnerabilities are relevant to the entire email system. Based on our findings, we derive four suggestions for email clients summarized as follows. Firstly, it is essential to

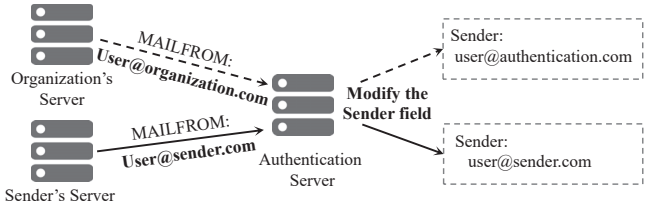

Figure 8: The Validation Scheme on the Sender Field.

display the original content in the `From` field to prevent spoofing email authors in specific formats. Specifically, clients should present all the accounts in multi-address emails (A_1 and A_5) or display the truncated address enclosed in angle brackets for A_4. This approach effectively helps recognize spoofing emails while reducing the payload for processing irregular `From` fields. Secondly, deploying the strategy of exposing the email Delegate in all email clients is crucial. It has proven effective in recognizing phishing and has been adopted by most web interfaces and clients. Thirdly, it is advantageous for clients to parse the entries appended by mainstream service providers within the email header. As mentioned in Section 6.2, providers like *gmail.com* prefer to add a "Return-Path" field to the email header, which could also be parsed similarly to `Sender` and displayed as the Delegate on clients. Lastly, we suggest displaying a warning message to recipients when an email with the `Sender` field is shown, reminding them to carefully verify the authenticity of the email.

8.3 Suggestions for Email Users

For email users, we propose three suggestions to help verify such spoofed emails. Firstly, we recommend checking important emails through web interfaces rather than email clients, as web interfaces of mainstream service providers often deploy well-established security measures and provide more detailed information to help verify emails, such as the raw email content and the authentication results of security extensions. Secondly, for users who prefer email clients, we suggest replying to suspicious emails and observing the return address. This can help verify the legitimacy of important emails and also identify potential phishing attempts. Thirdly, for clients that allow access to fetch the raw email content, such as Thunderbird, we suggest examining the header fields like `From` and `Sender` in the raw email content to identify possible spoofing attacks. We believe that the raw email content significantly helps identify potential spoofed emails.

9 Related Works

Recent research has primarily focused on email security problems from three perspectives.

Email security protocols. The original SMTP protocol lacks

security considerations, making it vulnerable to impersonation attacks. Although security extensions (*e.g.*, SPF, DKIM) have been deployed to mitigate forgery attacks, vulnerabilities within the protocols themselves pose new threats. Due to concerns surrounding these flaws, researchers focus on the problems with email security extensions [8,10,12,39–41]. Additionally, various works concentrate on enhancing the original SMTP protocol [20,32]. Our work primarily addresses issues related to the Delegation Mechanism, an advanced feature in the SMTP protocol that is mostly neglected in the email security literature.

User study within email security. User studies play a crucial role in email security research as they provide realistic data from real-world users, enabling researchers to conduct more accurate analyses. Various user studies have been conducted to address different aspects of email security. Some researchers have recognized the impact of factors such as email presentation [9,23,30,46,47] and text language [11] on phishing recognition. Additionally, various works emphasize the importance of phishing training to improve users' ability to identify phishing emails [1,18,19,21,29,37,42,43]. Our work is partially inspired by their approaches to include a real-world user study to evaluate the effectiveness of forged delegate messages on deceiving email users.

Email spoofing attacks. Email attacks are a severe challenge to cybersecurity, as they allow malicious actors to breach security measures and send harmful emails to unprotected victims. Some research focuses on breaking email encryption or spoofing digital signatures in OpenPGP [2,7,14,26,31,35,38]. Schneider *et al.* explored the issues of email bomb attacks against email system availability [34]. Our work is closely related to the studies that provide new insights into email spoofing [3,13,36]. Such attacks aim to exploit the vulnerabilities inherent in email systems and impersonate others to send spoofing emails. These attacks are more elaborate and effective than original phishing emails, as they significantly resemble those from legitimate entities. Prior research has proposed various email forgery methods. Our work differs in that it concentrates on the authentication issues within the Delegation Mechanism, which is a highly practical threat but is inconsistently handled by popular email service providers and clients, and largely neglected by email security solutions.

10 Conclusion

The Delegation Mechanism is an email service feature that enables users to delegate their permissions to a third party. However, as first presented in this paper, it not only offers convenience but also introduces a new vulnerability by lacking a validation method for the `Sender` field, which is the primary theme in the Delegation Mechanism. This flaw allows malicious attackers to easily manipulate the email Delegates. In this paper, we undertook a comprehensive investigation of the security issues associated with the Delegation Mechanism in three main steps. Firstly, we evaluated the implementations of the Delegation Mechanism within various email providers and clients. The results revealed that email providers and clients have inconsistent implementations of this mechanism. Secondly, we conducted a user study and observed that even exported and trained users can fall victim to spoofed Delegate information. Thirdly, we disclosed six email spoofing attacks that can successfully bypass the security measures of half of the major email providers and affect all the clients. Finally, we presented countermeasures and disclosed these vulnerabilities to the respective service providers.

Limitations and Future Work. Our work has several limitations. Firstly, the diversity of email products presents a significant challenge in measuring the Delegation Mechanism across all platforms. While we selected various mainstream providers and clients as targets for our study, the results may not necessarily apply to other products. Secondly, there are fewer approaches to manipulating the `From` field compared to previous works [3,36], as mainstream email providers have implemented defensive measures to prevent such emails. Although we have explored various methods for crafting spoofed emails, the majority are only effective on certain providers and become useless when targeting others. Future work will expand our research by developing more effective methods for crafting spoofed emails. Additionally, we plan to investigate the security issues within email clients to enhance protections against spoofing attacks.

Appendix A - Demonstration of spoofing attacks

We list the demonstrations of attack A_4 targeting *139.com* in Figure 9. Notably, it has proven successful in executing a spoofing attack on the Gmail client, as shown in Figure 9(a). However, when attempting the same attack on the Outlook client, it encounters failure due to the presence of the Delegate, as illustrated in Figure 9(b). This inconsistency in implementing the Delegation Mechanism among different email clients may lead to varying results for these attacks, emphasizing the necessity of standardizing implementations.

(a) Successful A_4 Attack Targeting 139.com on the Gmail Client.

(b) Failed Attempt of A_4 Targeting 139.com on the Outlook Client.

Figure 9: Demonstrations of Spoofing Attack on Clients.

Appendix B - Results of six spoofing attacks

We summarize the experimental results of the six attacks targeting eight affected services across all 20 email clients in Table 6. The results of each attack consist of two rows: the highlighted row indicates the attack results involving the `Sender` field, while the second row shows the email performance without this field on various email clients. In the results table, a "✓" denotes a successful attack on the clients, and a "×" represents failed attempts. During the measurement, we noticed that some clients failed to fetch emails from certain services due to indefinite configuration errors, and we used "-" to identify these samples.

Table 6: Results of Six Spoofing Attacks Targeting Affected Service Providers on 20 Email Clients.

Abstract

The Domain Name System (DNS) fundamentally relies on glue records to provide authoritative nameserver IP addresses, enabling essential in-domain delegation. While previous studies have identified potential security risks associated with glue records, the exploitation of these records, especially in the context of out-domain delegation, remains unclear due to their inherently low trust level and the diverse ways in which resolvers handle them. This paper undertakes the first systematic exploration of the potential threats posed by DNS glue records, uncovering significant real-world security risks. We empirically identify that 23.18% of glue records across 1,096 TLDs are *outdated* yet still served in practice. More concerningly, through reverse engineering 9 mainstream DNS implementations (e.g., BIND 9 and Microsoft DNS), we reveal manipulable behaviors associated with glue records. The convergence of these systemic issues allows us to propose the novel threat model that could enable large-scale domain hijacking and denial-of-service attacks. Furthermore, our analysis determines over 193,558 exploitable records exist, placing more than 6 million domains at risk. Additional measurement studies on global open resolvers demonstrate that 90% of them use unvalidated and outdated glue records, including OpenDNS and Alibaba Cloud DNS. Our responsible disclosure has already prompted mitigation efforts by affected stakeholders. Microsoft DNS, PowerDNS, OpenDNS, and Alibaba Cloud DNS have acknowledged our reported vulnerability. In summary, this work highlights that glue records constitute a forgotten foundation of DNS architecture requiring renewed security prioritization.

1 Introduction

The Domain Name System (DNS) facilitates Internet communications by translating human-readable domain names into machine-friendly IP addresses. The recursive traversal of a delegation chain from parent to child authoritative nameservers underpins domain name resolution, necessitating that parent domains contain delegation records referencing their subdomains' designated nameservers. However, a paradoxical loop emerges when attempting to resolve a subdomain delegated by its parent domain (e.g. `ns.foo.com` which is delegated by `foo.com`). This inherent recursion is resolved by utilizing *glue records*, which contain nameserver IP addresses stored within the delegating parent's zone file, solely used in referral responses.

The security of delegation records has been widely discussed in the security community. RFC1034 [52] states that authoritative nameserver (NS) records at both parent and child should be "consistent and remain so", but some researchers found significant inconsistencies [4, 64]. Moreover, researchers have conducted extensive measurement studies on abandoned glue records [33, 63] and have analyzed the potential impact of unsigned glue records on DNSSEC [68]. These inconsistent and inappropriate delegation records provide potential attack vectors, allowing attackers to take over domain names by re-registering expired NS domains [3, 4] or obtaining IP addresses [14, 46].

Although some studies and blog posts [30, 46] have mentioned the potential exploitation of glue records to hijack domains, the exploitation of glue records, especially in the case of out-domain delegation, remains unclear. This is due to the differences in their use, compared to typical authoritative records, which can be directly exploited, as presented in [3, 4, 14]. In this paper, we aim to provide a comprehensive analysis of the management and utilization of glue records, evaluating realistic security threats in the wild.

Our study. Our research conducts a thorough examination of the conditions under which glue records are exploited. We propose a new attack vector called *shadow caching* to exploit the massive number of stale DNS glue records in the domain namespace, even under out-domain delegation. Specifically, through comprehensive analysis, we examine 1,096 TLD zone files alongside 9 predominant DNS implementations. Extensive interrogation of zone file data reveals that over 23.18%

* Both authors contributed equally to this work.
✉ Corresponding author.

of existent glue records are outdated yet still served in real-world DNS infrastructure. More troublingly, our software testing reveals manipulable behaviors in mainstream DNS software where they cache and utilize "unvalidated" glue records during resolution, resulting in a phenomenon we term "shadow caching". Once attackers obtain the GlueIP, typically from cloud platforms, they can covertly hijack domains using *shadow caching* even under out-domain delegation. Moreover, if the GlueIP is unobtainable, they can still launch a denial-of-service attack against the target. We have demonstrated the widespread nature of this threat, impacting up to 6M domains.

We empirically assessed the real-world exploitability of stale records utilizing our proposed threat models. The analysis identified 193,558 (9.60%) potentially exploitable stale glue records among the 2,016,516 used glue records examined. Alarmingly, 39,795 (20.56%) of these resided within the Tranco Top 1M domains [57], indicating serious exposure among prominent websites. Overall, we detected 6,398,631 domains vulnerable to hijacking attacks and 784,693 susceptible to denial-of-service, with 496,324 affected by both vectors. Further examination revealed 5,700 impacted domains lie within the Tranco Top 1M, including high-profile companies (e.g., trueconf.net) and ISPs (e.g., i2bnetworks.com), empirically proving the ability to disrupt major providers. Experimental confirmation validated that all tested DNS software and 14 major public resolvers are susceptible, including widely used providers such as BIND [13], Microsoft DNS [51], OpenDNS [15] and Quad9 [59].

We also evaluated the real-world impact of stale records by conducting measurements on open DNS resolvers, selecting only representatives exhibiting stability over two months owing to high churn rates [39]. Over 90% of the tested resolvers exhibited manipulable behaviors with glue records, rendering them susceptible to hijacking exploits. Furthermore, 111,766 resolvers (12.48%) were confirmed to be vulnerable to denial-of-service attacks abusing stale records. Our results provide empirical evidence that the vast majority of DNS resolvers operating in practice are prone to exploitation of stale glue record vulnerabilities. This highlights the seriousness and scale of the threats that have been overlooked by the technical community thus far.

Disclosure and mitigation. We responsibly disclosed the discovered issues to affected TLD registries, resolver vendors, and DNS software. The `.info` and `.org` registry confirmed the issue and began remediating impacted records. Also, we reported the issue to ICANN and are collaborating to assist other registries in resolving this problem. Among DNS providers, Microsoft DNS, PowerDNS, OpenDNS, and Alibaba Cloud DNS acknowledged the threat and have either deployed or are implementing mitigation based on our reports. Moreover, we disclosed the threat to affected domains through our national CERT. This responsible disclosure and ongoing collaboration will raise community awareness and drive the adoption of critical defenses against the overlooked risks of stale glue records.

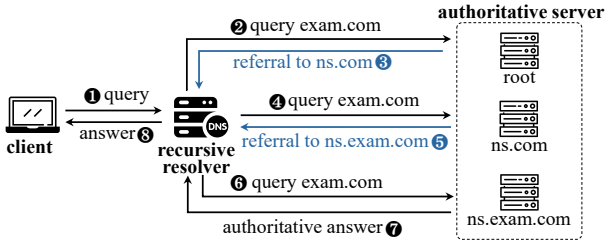

Figure 1: DNS resolution process.

Contributions. Our contributions are outlined as follows:

Systematic analysis of glue records. A systematic analysis of real-world glue record usage from the lens of domain configurations across 1,096 TLDs and 9 major DNS software.

Novel attack. Exploiting our proposed novel attack vector, *shadow caching*, we propose the new exploitation method for stale glue records, especially under out-domain delegation, enabling domain hijacking and denial-of-service attacks.

Comprehensive evaluation of new attacks. Comprehensive threat evaluation proving over 6 million domains are vulnerable. We empirically demonstrate 90% of stable open resolvers and 14 major public DNS providers are susceptible to the newly proposed attacks.

2 Background

DNS resolution process. The domain name space is a tree structure. Each node and leaf on the tree corresponds to a resource set, with the higher and lower zones called parent and child zones. At the top of the DNS tree is the `root` zone, whose child zones are divided into a collection of Top-Level Domains (TLDs), like `.com`, and `.net`. One step down, the child zone of the `.com` zone is a set of Second-Level Domains (SLDs), such as `exam.com.` and `foo.com.`

As shown in Figure 1, the DNS recursive resolver first contacts the `root` zone when it receives a query request from a client (step ❶ and ❷). Since a DNS zone only contains information about its child zones, the `root` returns a *referral response* that informs the resolver of information of the authoritative nameserver for `.com` (step ❸). Iterating through this process (step ❹ and ❺), the resolver eventually retrieves the resource records from the authoritative nameserver of `exam.com.` (step ❻) and returns it to the client.

DNS glue record. The DNS resource record (RR) format defined by RFC 1034 [52] is a 5-tuple: ⟨ *owner, type, class, TTL, RDATA* ⟩. *Owner* describes the domain name that the RR belongs to, *Type* and *RDATA* represent the kind of RR and its value, such as the `NS` record for the authoritative nameserver and `A` record for IPv4 IP address.

Glue records are a specific `A` record in the DNS zone. Theoretically, for the DNS zone, the parent zones can provide all information that is successful in accessing their children's

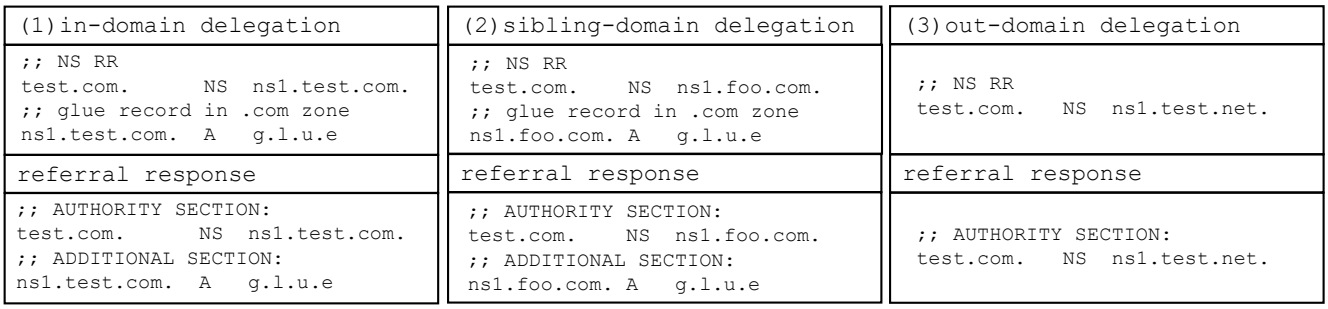

Figure 2: Domain delegation categories.

zones. It is, however, difficult to do this using only the NS RR for children zones. We may encounter a situation where a parent domain is delegated to its child domain (i.e., in-domain delegation), which means that the recursive resolver has to initial the query from the parent domain, causing the DNS resolution loop problem. To fix it, RFC 1034 introduces the glue record, which allows to add non-authoritative data (i.e., the IP address of the NS RR) in the zones [52]. For convenience, we will refer to the domain name of authoritative nameservers in the glue record as GlueFQDN (e.g., `ns1.test.com.` in Figure 2), and the corresponding IP address as GlueIP (e.g., `g.l.u.e` in Figure 2).

In implementation, the provisioning and management of domain names and nameserver delegation records are standardized via the Extensible Provisioning Protocol (EPP) [25–27]. Registrants are not able to interact directly with the EPP servers and can only configure the glue records via the limited interfaces provided by the registrars. Not all registrars support the configuration of glue records; this is determined by the registrars themselves. However, it is worth noting that some famous registrars do provide support for glue records, like GoDaddy [22], and Aliyun [6].

In addition, RFC 1034 requires that glue records are only used as part of a referral response [52]. To do this, depending on the source of the data, different levels of trust are assigned to the RRs, with the glue records having the lowest level of trust [21]. The authoritative data in the `answer` section of the authoritative response is the most trusted, while the trust level of glue records is far below it. DNS software relies on the trust level of resource records to determine which records can be returned to users as `answer` and which records can be cached or updated. Moreover, Li et al. [43] showed that the implementation of record trust levels by different DNS software does not follow the RFC requirements exactly, but the common denominator is a low trust level for glue records.

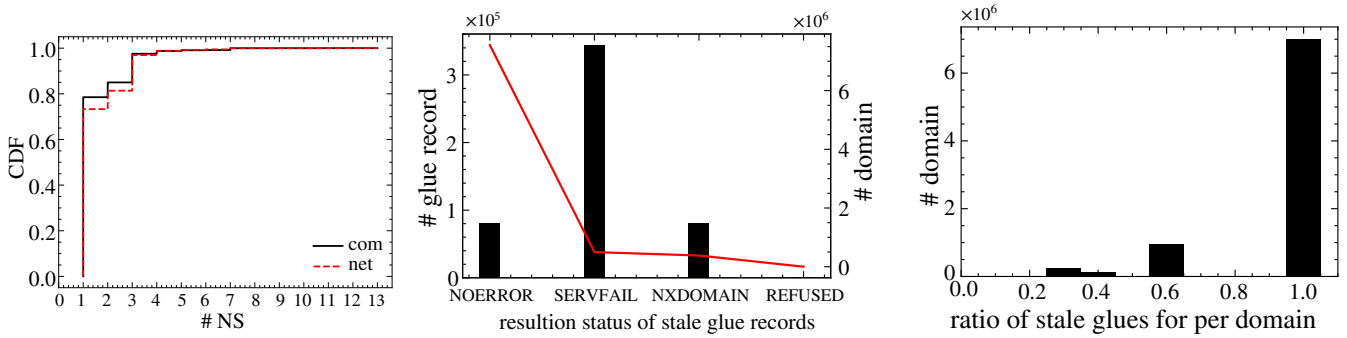
Categories of domain delegation. The domain administrator delegates their domains to a specific server by configuring the delegation NS RR and glue RR (if needed). According to the relationship of NS RR and the domain name, there are three types of delegation, in-domain, sibling-domain, and out-domain delegation. Below, we describe each category of delegation and their corresponding referral response in detail.

In-domain delegation configures the in-domain nameservers that are contained in the delegated zone itself [50], where the glue records are necessary; otherwise, resolution loops will occur. The configuration and referral response for `test.com.` with glue records are shown in Figure 2 (1).

Sibling-domain delegation configures nameservers that are not contained in the delegated zone itself, but in another zone delegated from the same parent [50], where glue records are not required, as shown in Figure 2 (2).

Out-domain delegation sets nameservers that cross the TLD, where glue records are not required. The referral response for `test.com.` that delegated to `ns1.test.net.` is shown in Figure 2 (3).

Summary: Under in-domain delegation, glue records are necessary, otherwise the resolution chain will be broken. For sibling domain delegation, glue records are not necessary. However, the referral response usually contains the glue record. Thus, resolvers typically utilize these glue records to improve resolution efficiency. For out-domain delegation, the resolver cannot obtain glue records from the referral response and is required to actively resolve the GlueFQDN.



3 Characterizing the Use of DNS Glue Records

Due to the special nature of DNS glue records, they are not used directly, unlike authoritative records. They are exclusively used in referral responses and are assigned low trust rank. This unique characteristic makes the exploitation of glue records more challenging.

In this section, we investigated the use of glue records in TLD zone files and DNS software to determine whether the problem is caused by incorrect or manipulable usage.

3.1 Stale Glue Records in Zone Files

To evaluate the use of glue records within zone files, we begin by introducing our dataset and describing the methodology employed to identify stale glue records. Then, we analyze the distribution of glue records in the two largest TLD `.com` and `.net` and quantify stale glue records through our approach.

(a) Domain NS population distribution in `.com` and `.net`.

(b) Statistics of stale glue record resolution status (bar) and served domains (line).

(c) Stale glue record ratio distribution for domains (grouped with an equal interval of 0.1).

Figure 3: Statistics information of glue records.

Table 1: Overview of glue records.

Total glue [1]	**2,827,798**	**GlueFQDN status** [2]	**2,016,516 (100%)**
GlueFQDN	2,518,786	NOERROR	1,438,964 (71.36%)
SLD	975,168	SERVFAIL	385,816 (19.13%)
Used glue	2,283,196	NXDOMAIN	191,160 (9.48%)
Stale glue	529,197	REFUSED	576 (0.03%)

[1]: A single GlueFQDN can correspond to multiple IP addresses. Thus, the number of GlueFQDN is less than that of glue records.
[2]: Only glue records served domains are being considered.

Moreover, we compare differences between legacy and latest IP addresses to reveal the IP changing of stale glue records. Finally, we exhibit the overall delegation distribution.

Dataset. For a comprehensive evaluation of glue records, we downloaded authorized zone files for 1,096 TLDs on August 10, 2023, through ICANN's CZDS [29]. The zone file of a TLD encompasses delegation information for all its associated SLDs, while concurrently housing glue records, DNSSEC signatures, and other pertinent details. From these zone files, we collected a total of 2,827,798 glue records, represented as ⟨ `FQDN, IP` ⟩ pairs, with 2,518,786 distinct GlueFQDNs, spanning across 975,168 SLDs that correspond to 954,971 GlueIPs. Specifically, 2,283,196 glue records (80.74%) are in use, with the rest abandoned and unused by any domain. Note that we have excluded the abandoned glue records from subsequent analysis. Our active resolution results for GlueFQDNs show that nearly 30% of GlueFQDNs cannot obtain IP addresses, as shown in Table 1. Note that an abnormal resolution status doesn't necessarily invalidate a GlueFQDN. For instance, if the resolution response for a GlueFQDN is `NXDOMAIN`, it might be due to the domain name owner forgetting to configure the `A` record of the GlueFQDN in their nameservers. Nevertheless, the GlueFQDN remains valid for in-domain and sibling-domain delegation. Hence, we need a method to determine the real stale glue records.

Methodology. In this paper, we define *stale glue records* as glue records that persist in the zone file but no longer fulfill their domain resolution function. There are several reasons for the occurrence of stale glue records, such as when domain owners change their authoritative server's IP address or when that authoritative server is deprecated. As such, our first step is to identify those glue records where the GlueIP does not align with the `A` record on their authoritative nameservers. Specifically, we begin with extracting all glue records from the zone files. Subsequently, we resolve these GlueFQDNs actively to collect their latest IP addresses. To enhance the precision of our data collection, we obtain data from three distinct measurement points (Hong Kong, Dubai, and Virginia). At each of these points, data is collected independently, and subsequently, the union of the resource records is derived. Next, we compare the actively obtained IP addresses with those retained GlueIP in the zone files. Glue records exhibiting discrepancies in these results are classified as potential stale glue records.

Then, we check if these glue records continue to provide services for the domains delegated to them. For the GlueFQDN with more than 100 domains, we randomly select max(1%,100) as test domains. For those serving less than 100, we test them all. We believe that testing only 1% (100) of the domains when the nameserver is serving a large number of domains provides a representative indicator of its performance while minimizing unnecessary load. This approach also helps reduce the influence of external factors like network instability or potential DNS censorship, ensuring a more accurate assessment of the nameserver's responsiveness. We only consider the glue record as stale if we did not receive a response for all test domains, suggesting it is inactive.

In summary, we identify stale glues by filtering out active records, abandoned glue records, and records that are consistent with authoritative records. The configuration operation of glue records is complicated, and most require registrants to configure manually at the registrar. Thus, the identified stale glue that does not provide any services, fails to meet the requirements of specific configurations, such as load balancing.

Glue record distribution. The use of glue records is very

prevalent, with 75.27% of NS records in the zone files being configured with glue records. We conducted a statistical analysis on the NS configuration in the two largest TLDs `.com` and `.net`, as shown in Figure 3a. We observed that 80% of domains are configured with 2 NS records, yielding an average of 2.42 NS per domain. In addition, we discovered that 95% of the glue records are associated with fewer than 5 IP addresses. This is consistent with common load-balancing strategies, where large enterprises configure multiple primary and secondary servers to provide redundant services, thereby enhancing resolution efficiency and disaster recovery capabilities. However, certain IP addresses are associated with even more than 10,000 glue records, which could be attributed to specific operations by certain registrars [4].

Stale glue records. We found, surprisingly, that *23.18% of glue records are stale*. Utilizing our approach, we identified 529,197 stale glue records (504,851 GlueFQDNs) out of 2,283,196 (2,016,516 GlueFQDNs) actively used. Then, we analyzed the resolution status of these stale glues and the number of domains they serve. In Figure 3b, the bar illustrates the stale glue records across various resolution states (primary Y-axis), while the line depicts the count of domains they serve (secondary Y-axis). Stale glue records in a normal resolution status support the majority of affected domains. We deduced that these stale glue records have transitioned to new service IP addresses, yet the historically deprecated IPs remain preserved in zone files. A domain name can be associated with multiple nameservers; if even one operates correctly, the domain can be resolved normally. Subsequently, we quantified the proportion of stale glue records in each domain's nameservers, as depicted in Figure 3c. The findings indicate that, although some domains depend on both normal and stale records, a significant 83.42% of impacted domains solely rely on stale glue records. We will outline how to exploit them in the following section (Section 4).

Legacy and latest IP addresses of stale glue records across organizations, these migrations not only directly demonstrate the migration of nameservers but also imply that the GlueIP left in the zone files is forgotten. The authoritative IP addresses of GlueFQDN have been migrated to the new IP address, but the old glueIP remains in the zone file. We selected the legacy and latest IP addresses of the stale glue records with service status `TIMEOUT` to draw the Sankey diagram in Figure 4. The left shows the autonomous system organization of legacy IP addresses for stale glue records, while the right displays the distribution of their current IP addresses. The legacy glue IPs contain many IP addresses from cloud platforms. The results of our analysis confirm the tangible risk that attackers could exploit stale glue records to hijack active domains (Section 5). In addition, compared to previous domain takeover methods, taking over domains via stale glue records is subtler and poses challenges for detection through active scanning.

Delegation category. The use of glue records under sibling-domain delegation far exceeds that under in-domain delegation. The TLD's nameserver responses glue records if the delegation is in-domain or sibling-domain. We analyzed the delegation patterns across 1,096 TLDs and found that a mere 0.29% of domains employ in-domain delegation. Moreover, we discovered that over 50% of domain names are configured with sibling-domain nameservers, which is the main usage scenario for glue records.

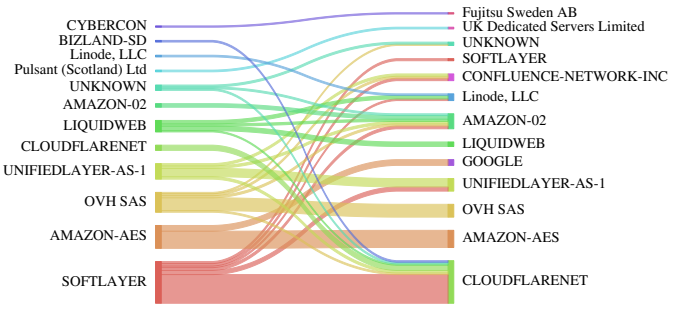


Figure 4: Legacy and latest IP address changes of stale glue records. The left shows the distribution of legacy IP addresses for stale glue records in the zone file, while the right displays the distribution of their current IP addresses.

3.2 Glue Record Use in DNS Implementations

In this section, we present a systematic analysis of the glue records usage of mainstream DNS implementations.

As glue records in the DNS that are permanently ignored and never returned to users, whether they can be successfully exploited depends on how resolver software uses them. Hence, the aim of our analysis is to answer three questions:

Q1: Does DNS software validate glue records before use?

Q2: Whether the software caches unvalidated glue records?

Q3: How does the software handle it when no response is received from the GlueIP?

Particularly, after reviewing previous work [2, 41, 43–45], we collected 9 DNS software after discarding some that are outdated or not downloadable, as shown in Table 2, including two proprietary software for Windows, Microsoft DNS [51] and Simple DNS Plus [62] and other seven have published source code. For open source software, we downloaded the latest version of the source code from their official website, then compiled and installed them in Docker; for Windows software, we tested them in a local virtual machine. Depending on the nature of delegation, we design specific test scenarios and then observe the resolution behaviors of different DNS software to infer their usage characteristics of glue records. Next, we detail the design of test scenarios and results.

Table 2: DNS operational modes for glue records with different responses in mainstream implementations.

DNS Software		Active Glue			Stale Glue Service Status*			
brand	version	use directly[1]	check actively[2]	shadow caching[3]	TIMEOUT	SERVFAIL	REFUSED	NXDOMAIN
BIND [13]	9.18.12	✔	✘	✔	SERVFAIL	SERVFAIL	SERVFAIL	NXDOMAIN
PowerDNS Recursor [58]	4.8.4	✔	✘	✔	SERVFAIL	SERVFAIL	SERVFAIL	NXDOMAIN
Unbound [54]	1.17.1	✔	✔	✔	NOERROR	NOERROR	NOERROR	NXDOMAIN
Knot [37]	5.6.0	✔	✘	✔	SERVFAIL	SERVFAIL	SERVFAIL	NXDOMAIN
CoreDNS [19]	1.10.1	✔	✘	✘	NOERROR	NOERROR	NOERROR	SERVFAIL
Technitium [65]	11.1.1	✔	✔	✘	NOERROR	NOERROR	NOERROR	SERVFAIL
MaraDNS [49]	3.5.0036	✔	✘	✘	NOERROR	NOERROR	NOERROR	TIMEOUT

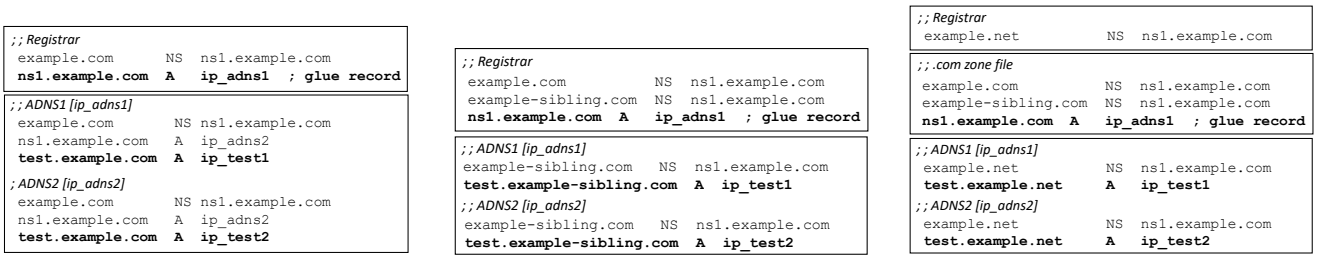
[2]: Whether the software updates glue records actively from their authoritative nameservers. [3]: Whether software uses shadow caching.
*: The header is the response status of GlueFQDNs, and the table shows the response status returned to the client by different software after receiving different response statuses.
✔: Yes ✘: No

Test scenarios for different delegations. We designed three test scenarios to verify the use of glue records under different delegations. To determine whether DNS software validates glue records before use, we configure two different authoritative nameservers (ip_adns1 and ip_adns2) to return different responses for the test domain, as shown in Figure 5. We use ip_dns1 to represent the stale glue record remaining in the zone file, whereas ip_dns2 refers to the IP address that ns1.example.com actively resolves to. Then, through the responses, we verify how the resolver utilizes glue records for both legacy (i.e., ip_dns1) and latest (i.e., ip_dns2) IPs. For in-domain and sibling-domain delegation, the glue record is attached directly to the `additional` section of the referral response from the authoritative nameserver of the TLD. However, the out-domain nameserver scenario does not carry glue records. Therefore, we introduce a domain name with a sibling-domain nameserver to inject glue records into the resolver. We do not use domain names with in-domain delegation for glue record injection because they're not always controllable. It's easier to manage and configure registrable domain names with sibling-domain delegation as we prefer.



Manipulable behaviors of glue records. Most DNS software cache and use glue records without validation, neglecting to ensure the GlueIP matches the authoritative response for GlueFQDN, even when the GlueIP is inactive or returns a negative response. While this behavior does not breach protocol specifications, it is susceptible to abuse.

Caching and using glue without validation. All DNS software trusts and uses the glue record that is in-bailiwick when a response with glue records attached is received, as shown in column *use directly* in Table 2. Under in-domain delegation, this behavior is in line with the RFC 1034, but for sibling-domain and out-domain delegation, this is not the behavior expected [52]. There are still some differences in the way they are implemented in practice. Most of the DNS software trusts the glue records completely without actively resolving, including BIND9 [13], PowerDNS Recursor [58], Knot [37], CoreDNS [19], MaraDNS [49], Microsoft DNS [51] and Simple DNS Plus [62]. However, Unbound [54] and Technitium [65] query the authoritative `A` records of GlueFQDNs actively to update the GlueIP. On the other hand, in DNS RFCs, the trust level of glue records is very low and is required to be used in the resolution process and cannot be returned as the answer to users. However, RFCs do not specify the scope of the resolution process, whether it is limited to the current resolution only or can extend to future resolution tasks. In the out-domain test scenario, we evaluate the use of shadow caching, which refers to cached unvalidated glue records. We found that CoreDNS [19], Technitium [65], and MaraDNS [49] do not use shadow caching across different resolution tasks, while all other software leverages glue records as shadow caching. Note that since Unbound resolves actively glue records, it only utilizes unvalidated glue records when the authoritative responses are inactivated.

Misplaced trust for unvalidated glue records. Most DNS software seems to place too much trust in the unvalidated glue records, as shown in column *Stale Glue Service Status* in Table 2. When receiving a negative response (e.g., `TIMEOUT` and `NXDOMAIN`) from the GlueIP, five out of the nine DNS software adopt a simple retry policy for stale GlueIPs instead of actively resolving GlueFQDNs to obtain authoritative IP addresses, suggesting these software completely trust the unvalidated glue records. Moreover, the `NXDOMAIN` response for stale GlueIPs will cause all DNS software to abort the recursive resolution, resulting in a `NXDOMAIN` response to users.

3.3 Summary

The original intention of introducing glue records was to address the resolution loop issue in in-domain delegation. However, our observations suggest that the current usage of glue records lacks uniform standard practices. Firstly, registries and registrars incorrectly handle stale glue records, resulting in an abundance of outdated glue records in the zone files.

(a) In-domain nameserver test configuration. To answer whether or not the resolver will unconditionally trust the attached glue records under the in-domain delegation.

(b) Sibling-domain nameserver test configuration. To answer whether or not the resolver will unconditionally trust the attached glue records under the sibling-domain delegation.

(c) Out-domain nameserver test configuration. To answer whether or not the resolver caches and uses the non-validation glue records to resolve the test domain.

Figure 5: Test configuration of different delegations.

Furthermore, most DNS software exhibits correct-but-can-be-abused behaviors when handling glue records, even though such behavior does not violate protocol specifications. They cache and use unvalidated glue records, including BIND, PowerDNS Recursor, Knot, CoreDNS, MaraDNS, Microsoft DNS, and Simple DNS Plus. Such behavior provides an opportunity for attackers to exploit stale glue records.

4 Attack Overview

In this section, we first describe the technical concept of *shadow caching*. Then, we introduce the threat models of our domain takeover and DoS attacks, and describe the workflows of the two attacks. Finally, we compare our threat models with the previous work.

4.1 Shadow Caching

According to RFC1034 [52], DNS glue records are only allowed to be used in the referral response of the same TLD, i.e., under in-domain or sibling-domain delegation. Under out-domain delegation, the referral response of the TLD response does not contain glue records, as shown in Figure 2(3). Once glueFQDN (e.g., ns1.test.net) is actively resolved, the resolver will get the authoritative record (the correct record) of the glueFQDN instead of the glue record.

To exploit the glue records under out-domain delegation, we introduce *shadow caching*, a glue record cache resulting from carefully constructed delegation records. According to the analysis in Section 3, mainstream DNS software caches the glue records in the referral response (as shown in Figure 2(1) and (2)) and utilizes them for future resolution. Therefore, we can create sibling-domain delegation to inject specific stale glue records into the target resolver in advance, as shown in the preparation phase in Figure 8. Specifically, we register a domain with the same TLD as the stale glue (i.e., `attack.com`), configuring its NS to `ns1.vulner.com` (i.e., the target stale glueFQDN). When querying `attack.com`, the target resolver will cache the glue records in the referral response, leading to the *shadow caching*.

In general, an attacker can easily implement shadow caching by registering a domain name with the same TLD as the target glueFQDN and configuring NS records. Moreover, the test results in Section 3 show that 6 mainstream DNS software is affected by this problem.

4.2 Threat Model

Domain takeover. Figure 6 illustrates the threat model of the domain takeover. We assume that the GlueFQDN `ns1.vulner.com.`, on which `victim.net.` depends, is stale and remain in *.com* zone file. Moreover, when the recursive resolver receives a referral response from the authoritative nameserver of the TLD, it applies *shadow caching* directly. To complete the domain takeover, the following requirements need to be fulfilled.

(1) Exploitable stale glue records. Most gTLD zone files are publicly accessible and can be acquired from their registries, like .com of Verisign. Moreover, ICANN developed the CZDS to simplify the process of applying for zone data access [29]. Once attackers had access to the zone files, they were able to discover a large number of potentially exploitable stale glue records, as we showed in Section 5.1.

(2) Assignable cloud IPs. The attacker is capable of obtaining IP addresses released by other users on cloud platforms by continuing to allocate and release. Prior studies showed the feasibility of milking the cloud platform IP pool from the perspective of an external attacker [14, 46]. Moreover, a recent study [56] uncovered the cloud squatting problem within a cloud platform, further revealing the severity of cloud IP reuse issues.

DoS attack. When the GlueIP is unobtainable, although attackers cannot directly hijack the target domain, they can still launch a denial-of-service attack against it. Figure 7 illustrates the threat model of the DoS attack. We assume that the stale glue record stops service for the target domain name, and the

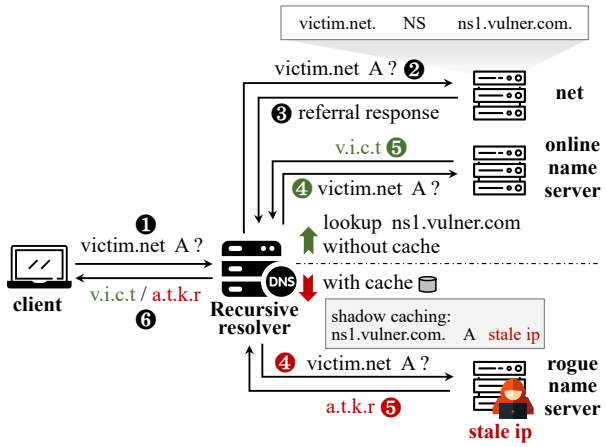


Figure 6: Threat model of domain takeover by stale glue records.

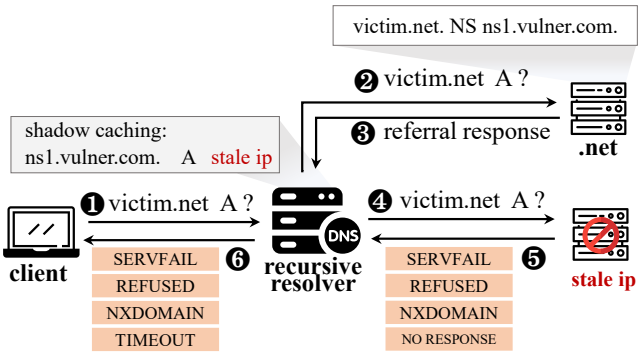

Figure 7: Threat model of DoS attack by stale glue records.

attacker can not get hold of the GlueIP because it is assigned or not a cloud IP. And the target resolvers can be accessed, so the attacker is able to inject the *shadow caching*. Moreover, the target domain configures out-domain nameservers and all GlueFQDNs of nameservers are stale. We found through large-scale experiments that this configuration is very common, making them vulnerable to potential attacks (Section 3). On the other hand, we assume that the recursive resolver uses the *shadow caching* directly.

4.3 Attack Workflow

Figure 8 presents steps of our domain takeover and DoS attack via stale glue records. In the preparation stage (i.e., causing the *shadow caching*), the attacker collects the exploitable glue records (e.g., `ns1.vulner.com.`), whose GlueIP is assignable (domain takeover) or stops authoritative services (DoS). Next, we require injecting the *shadow caching* into the resolver. To achieve this, we first registered a domain with the same TLD as the stale glue (i.e., `attack.com`), configuring its NS to `ns1.vulner.com`. Note that this step does not require the cooperation of `vulner.com`; attackers can complete it independently. Subsequently, the attacker queries `attack.com` to a target resolver, causing it to cache the glue records in the referral response, leading to the *shadow caching*. In the next stage, the attacker can conduct the domain takeover and DoS attack leveraging the above cache.

Domain takeover attack. The part two of Figure 8 illustrates the steps of the domain takeover attack via stale glue records. First, a client queries the domain (e.g., `victim.net`) to the target resolver (step ❶), where `victim.net` is delegated to `ns1.vulner.com`. After receiving the referral response from `.net` nameservers (step ❸), the resolver resolves the domain from rogue nameservers controlled by the attacker due to the *shadow caching* is not expired (step ❹). Finally, the resolver returns the fake resource records to the client (step ❻).

DoS attack. The part three of Figure 8 presents the step of DoS attack by stale glue records. Similar to the domain takeover, when the client queries the domain name to the target resolver, the resolver requests the resource records leveraging the *shadow caching* (step ❶ ∼ ❹). When multiple retries fail to obtain a valid response, the resolver returns a failed response to the client (step ❹ and ❺).

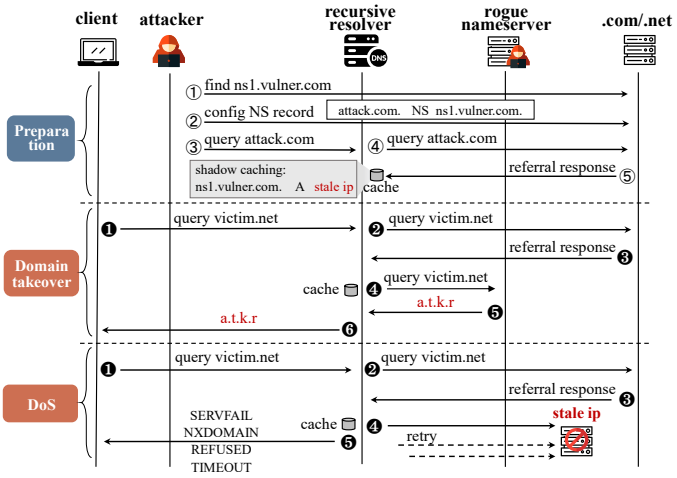

Figure 8: Workflow of domain takeover and DoS attacks.

4.4 Comparison to Prior Work

Similar to previous work on domain takeover [3, 14, 46, 70], our threat model leverages the stale resource records to hijack target domains. However, our threat model differs from these studies by exposing a long-standing overlooked and broader attack surface related to the usage mechanism of glue records, even threatening a large number of active domains, not just expired domains. By analyzing the usage of glue records in DNS software, we introduce the *shadow caching* to address a significant gap in glue record security research, i.e., the exploitation of glue records under out-domain delegation. Compared to prior work [14, 46], the *shadow caching* broadens the range

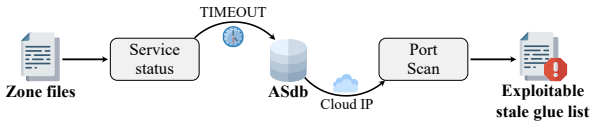

Figure 9: Identifying potential exploitable stale glue records from zone files.

of impact and increases the flexibility of attacks. Attackers can target any domain name delegated to stale glue records by means of meticulously crafted delegation records, even in out-domain delegation. Furthermore, our findings reveal more affected domains than previous studies. From the 1,096 TLD zone files, we identified 193,558 directly potentially exploitable glue records, impacting 6,687,000 domains.

5 Evaluating the Impact of Stale Glue Records

In this section, we demonstrate that the risks of stale glue records in the wild are widespread and underplayed. We first evaluate the impact scope of our threat models by analyzing vulnerable glue records in zone files. Subsequently, we conduct comprehensive experiments and measurements to understand the real-world implications of stale glue records, encompassing both open DNS servers and prominent public DNS services.

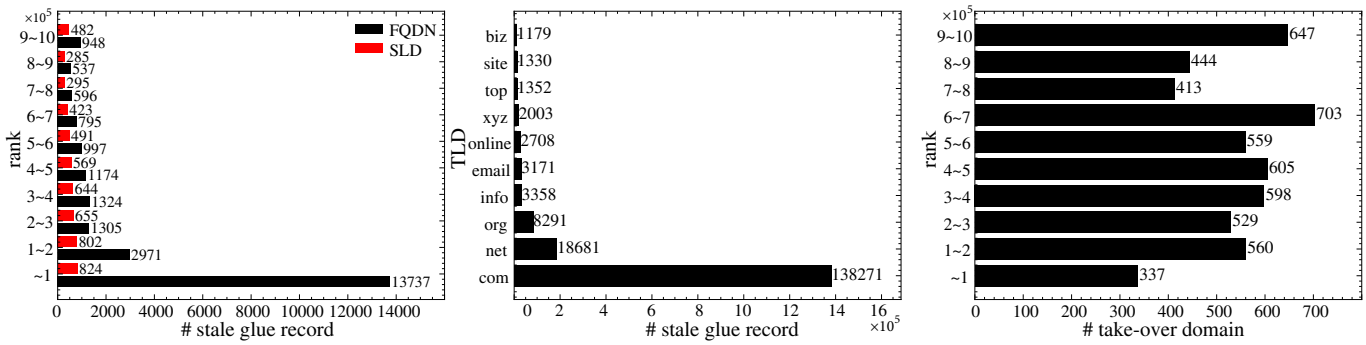
5.1 Domain Takeover

5.1.1 Methodology

In this part, we propose a novel methodology that finds potential exploitable stale glue records in zone files.

Technical challenges. Glue records can be valid but not resolvable. A glue record works as long as it is submitted to zone files [52]. However, a glue record will only be resolvable if its parent domain has added an `A` record for the glue record on its authoritative nameservers. Otherwise, the glue record will be invisible in DNS, present only in zone files, and unavailable through active resolve. On the other hand, invalid glue records are not necessarily exploitable, so careful verification is required to confirm whether attackers can acquire the GlueIP. As a result, identifying exploitable stale glue records poses a significant challenge.

Identifying potential exploitable stale glue records from zone files. We extract all glue records from zone files regardless of their resolvability, delineating our analysis scope and reducing complexity. Moreover, the prerequisite that a glue record can be exploited is that it is outdated and assignable, suggesting attackers can obtain it. Therefore, based on the previous studies [14], we develop our approach to identify the potential exploitable stale glue records, as shown in Figure 9.



First, we select GlueFQDNs from the stale glue records found by Section 3 exhibiting a service status of `TIMEOUT`, indicating that the record no longer furnishes authoritative services for any domain. Next, we leverage the ASdb [71], a research dataset that maps public autonomous systems (identified by ASN) to organizations and industry types, to locate the GlueIP belonging to cloud platforms. Finally, we examine the GlueIPs to determine if they are offline and assignable by conducting a port scan on the 33 most commonly used TCP and UDP ports [14], as shown in Table 6 (in Appendix A). When the service status of a GlueFQDN is `TIMEOUT`, and the GlueIP is offline and assignable, we mark it as a potential exploitable stale glue record.

5.1.2 Results

Leveraging our approach to zone files from August 10, 2023, we identified *193,558* exploitable stale glue records mapping to 100,258 cloud IPs. *39,795 (20.56%)* of these glue records (5,615 SLDs) are present with Tranco Top 1M, as shown in Table 3. Figure 10a shows the ranking distribution of these stale glue records FQDN and SLD. From a TLD perspective (Figure 10b), the highest number of exploitable stale glue records are found under `.com`, followed by `.net` and `.org`. Moreover, the number of exploitable stale glue records we found far surpassed statistics on orphan and abandoned records in prior research, indicating that the security risks of stale glue records remain largely unaddressed and growing.

These glue records are scattered throughout the DNS space, posing an extensive yet pressing issue requiring resolution. However, the distribution of SLDs partially accounts for stale glue: undocumented registrar operations caused glue records to remain in the zone files. Similar to the operation observed by Akiwate et al. [4], we speculate that some of the stale glue records may also originate from an undocumented operation by registrars. Specifically, when a domain expires, registrars should remove all associated records. However, some instead rename and keep the glue records of expired domains in zone files. One specific example is that for the SLD `directideleteddomain.com`, we identified 1,967 stale glue records, which map to 1,491 IP addresses. Moreover, from the stale glue records, it is possible to identify the domain names before they are renamed. For example, the stale GlueFQDN `zeus1.smmdeyiz.com.directideleteddomain.com` and domain name before renamed `zeus1.smmdeyiz.com`. We successfully traced the historical mapping relationships between the domains and GlueIP using passive DNS data.

Furthermore, we identified *6,398,631* domain names delegated to exploitable stale glue records susceptible to takeover. Of these, 5,947,669 (92.95%) domain names are active. Among these domains, 5,395 ranked in Tranco Top 1M, and Figure 10c shows their ranking distribution. For example, the domain `trueconf.net` (ranked 2,138), a leader in enterprise video conferencing and collaboration in Europe, has

(a) Distribution of stale glue records' FQDN and SLD rank.

(b) TLD distribution of affected stale glue records.

(c) Ranking distribution of domain names that could potentially be taken over.

Figure 10: Exploitable stale glue records information.

Table 3: Potential exploitable stale glue record statistics.

	# (in Tranco)	# SLD (in Tranco)
Stale glue record	193,558 (39,795)	99,373 (5,470)
Takeover domain	-	6,398,631 (5,395)
DoS domain	-	784,693 (1,576)

modified the nameserver on their authoritative server but failed to remove the discarded NS RR `ns7.trueconf.net`. Other domain names include the largest U.S. pharmacy chain `walgreens.com`, and even ISP `i2bnetworks.com`.

5.1.3 Discussion

The proportion of stale glue in a domain's nameservers influences the performance of the domain takeover. Two factors must be considered to evaluate the impact of stale glue records on the target domain: the number of NSes configured for the domain and the number of stale GlueIP associated with each NS. We assume that if a domain name is configured with N NS records, then the probability of each NS being selected is $1/N$. Moreover, each NS has M GlueIPs, of which m are stale. Then, the formula to calculate the degree of impact on the domain is as follows:

$$Hijacking\ ratio = 1/N * \sum_{i=0}^{N} m_i/M_i$$

Where N represents the number of NS for the domain. M_i and m_i respectively represent the number of GlueIPs and stale GlueIPs under the *ith* NS.

We have calculated the hijacking ratio of affected domains and discovered that half of the traffic for 84% of these domains could be taken over by attackers, and Figure 12 shows the CDF of hijacking ratio (in Appendix B). Subsequently, we examine whether these stale glues are cleaned up in time. We tracked the lifecycle of exploitable stale glue records within zone files, including whether they are still present in zone files and whether they are still being used by domain names. The results demonstrate that with few glue records removed within a month, attackers have a substantial time window to operate. Figure 11 shows the monthly change in stale glue records identified. The blue dashed line experiences a trough on August 13th, which is attributed to the partial loss of `.net` zone files during our data processing.

Another challenge of hijacking a domain is obtaining cloud IPs. However, a lot of work has been done to prove the feasibility of this [14,46,56]. Liu et al. [46] and Borgolte et al. [14] collected IP pools from different cloud service vendors by applying and releasing, while Pauley et al. [56] examined cloud IP reuse from the internal perspective of a cloud platform, proving that cloud IPs are frequently acquired by other users after release. Following the method of previous work [14,46], we utilize the Amazon Cloud API `allocate_address` and `release_address` to automate the allocation and release of cloud IPs [9] at a very low rate to prove stale GlueIPs could be obtained by attackers. As for attackers, they can apply for a large number of IPs in a short time. Within two weeks, we successfully applied for 27 GlueIPs, costing $2.3 total. We released IPs immediately after allocation, so there is no actual impact on domains. Moreover, we also reported to domain owners to remind them of the risk of their domains.

5.2 DoS Attack

Attack condition. Analysis of DNS software behavior (Section 3.2) shows that most DNS software misplaces trust in unvalidated glue records. Exploiting stale glue records, attackers can perform a denial-of-service attack on some domains. When domain names meet the following conditions, they may be affected: (1) the domain configures out-domain nameservers; (2) all the GlueFQDNs of nameservers are stale.
Results. While the attack conditions may seem stringent, we still managed to identify a substantial number of affected domain names. And we exclude domain names that cannot

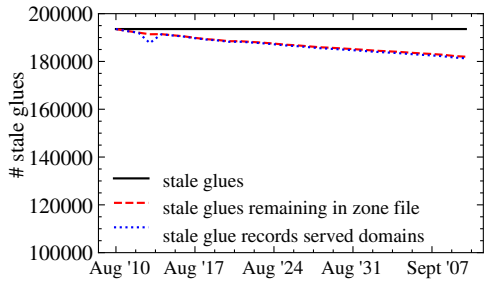


Figure 11: Number of exploitable stale glue records over time in zone files (August 10-September 10).

be resolved as they hold no value for the attack. As a result, we identified *784,693* active domains meeting the conditions, including 1,576 popular domain names in Tranco Top 1M.

Discussion. After the cache expires, attackers need to reinject stale records into the target resolver again. Here, we are discussing the negative cache TTL, glue record TTL, and the maximum cache TTL of the software. The implementation of negative cache TTL depends on the software itself, but it typically does not exceed the maximum value specified in the standards [10], which is 300 seconds. Moreover, we conducted a statistical analysis on the TTL of 2.8M glue records and found that they have a fixed value of 172,800 (2 days). In addition, Li et al. [41] analyzed the Maximum cache TTL of mainstream DNS software and found that all popular software has a maximum cache TTL of more than one day and 3 of them have a maximum over 6-day TTL by default (BIND9 [13], Simple DNS Plus [62], and Knot [37]).

Table 4: Open DNS resolver statistics.

	# IP	%
DNS resolver on Apr. 03 2023	1,846,535	
DNS resolver alive on Jun. 10 2023	895,674	100%
Domain Takeover*		
in-domain delegation	834,644	93.19%
sibling-domain delegation	830,146	92.68%
out-domain delegation	218,942	24.44%
portion stale glue	201,607	22.51%
Domain Denial-of-Service		
misplaced trust in unvalidated glue records	111,766	12.48%

*: Number of resolvers that use unvalidated glue records directly on different delegations.

5.3 Evaluating DNS Resolvers in the Wild

In this part, we perform extensive experiments to evaluate the impact of stale glue records in the wild. Due to ethical considerations, we evaluate glue record usage under different delegation categories for resolvers to infer the impacts of stale glue records. The primary external factor in our threat models is how resolvers use glue records, so this evaluation is reasonable. Moreover, we conduct DoS attack experiments on controlled domains to identify their impact on open resolvers. Meanwhile, we also measured open resolvers' non-standard behavior. This behavior of resolvers can expand the attack surface of our threat model.

5.3.1 Collecting DNS Resolver

Our test DNS resolvers include not only public DNS providers but also a large number of stable open resolvers.

Public DNS providers. We collect a famous public DNS provider list, whose users are distributed all over the world, and they are used in prior works as well [2, 31, 32, 35, 36, 47, 48, 60], like Google Public DNS, Cloudflare DNS.

Stable and open resolvers. Some studies have demonstrated significant churn of open DNS resolvers [39]. Hence, our measurements focus on stable DNS resolvers. To this end, we scanned the entire IPv4 address space on April 3rd and June 3rd, 2023, using XMAP [42] respectively, then took the intersection of the two results as our measurement subjects (i.e., open resolvers that stably exist for two months), and the detailed statistics are listed in Table 4.

5.3.2 Measurement Setup

This section aims to measure resolvers' usage of unvalidated glue records and assess whether such usage can lead to domain takeover or DoS attacks. To comprehensively evaluate resolver behavior, we employed different configurations, including in-domain, sibling-domain, and out-domain scenarios, as detailed in Section 3.2. Moreover, T1 and T2 were introduced to investigate specific out-domain configurations further. Here, we denote the authoritative `A` records actively queried by the resolver as QR.

T1: Outage QR, and Online GlueIP. The QR is offline, and the service of GlueIP is normal. We registered four new test domain names to configure different QR and GlueIP. GlueIP provided normal resolution services for these four domain names, while QR returned different error status codes, including `SERVFAIL`, `NXDOMAIN`, `REFUSED`, and without response.

T2: Online QR, and Online and Outage GlueIP. We set up another four new test domain names to avoid the cache effect of open resolvers. One GlueIP and QR provided normal responses to these four domain names, while the other GlueIP returned different error status codes.

Furthermore, special configurations were implemented to assess the impact of DoS attacks. We configure two new domain names, `dos-test.com` and `inject-cache.net`. Among them, all glue records (`ns1.vulner.net` and `ns2.vulner.net`) of `dos-test.com` are stale, making it vulnerable to DoS attack. The `inject-cache.net` is used to cause shadow caching in the target resolver. It is also delegated to `ns1.vulner.net` and `ns2.vulner.net`.

Each experiment is repeated three times to comprehensively and accurately evaluate the behavior of open DNS resolvers. In each experiment, we first inject glue records into resolvers

Table 5: Glue usage of public DNS resolver.

using the domain name under the same TLD as GlueFQDN and then query different test domain names, respectively.

5.3.3 Measurements and Results

Most of the stale open resolver lacks validation for glue records. As listed in Table 4, under in-domain and sibling-domain delegation, over 90% of resolvers cache and use unvalidated glue records. While for out-domain delegation, *24.44% of resolvers blindly trust shadow caching.* On the other hand, 410,406 resolvers resolve actively glue records in each of our tests. Of these, however, 67% resolvers exhibited non-standard behavior. When the service of validated NSes is abnormal, they fall back to using the glue records.

After repetitious experiments, we show that *all 14 public DNS are vulnerable to domain takeover* because they unconditionally cache and use glue records, like Open DNS and Quad9. Although Google Public DNS and Cloudflare DNS only trust the records they resolve actively instead of using glue records under out-domain delegation, they are still affected under in-domain and sibling-domain delegation. Moreover, these public DNS are affected to varying degrees by their complex multi-backend and multi-cache architecture [60], as shown in Table 5. Three Public DNS (Alibaba Cloud DNS, Quad9, and DNSPod) will continue to make full use of glue records under the sibling-domain delegation, but other public DNS are using glue in some of the tests (i.e., partial use). There are two reasons for this phenomenon: 1) the public DNS backend is multi-cache, and our test domain name just happened to miss the glue records we injected. 2) The backend implementations of one public DNS are different, resulting in a difference in their behavior when using glue records. Even so, attackers can still take over part of the target domain name traffic. In addition, we discover that *five public DNS (OpenDNS, Quad9, CleanBrowing, DNSPod, and Baidu DNS) misplaced trust unvalidated glue records*, who are vulnerable to our DoS threat model.

5.4 Ethical Considerations

Our experiments involve large-scale open DNS resolver scanning, DNS software implementation analysis, and attack effect evaluation against different public DNS and open resolvers. Hence, we have considered many ethical considerations in the experimental design. We strictly follow the existing ethical principles of Menlo Report [34] and best practices of network measurements [38, 39].

First, for large-scale open DNS resolver scanning, to minimize the impact on DNS resolvers, we strictly limit the scan rate. In addition, we limit the number of DNS queries for each resolver in each round of testing.

Second, we perform controlled experiments. We use newly registered experimental domain names to evaluate the effect of attacks. All domain names and authoritative servers are under our control. To avoid the impact of cache and different service statuses, we registered more than 15 new domain names under different TLDs. These new domains have no real-world impact as they are only used in our experiments.

Third, we report vulnerabilities to all relevant domain owners and resolver vendors for responsible disclosure.

6 Discussion and Mitigation

In this section, we discuss the lessons learned from new threats. Then, we propose mitigation measures. Finally, we describe our responsible disclosure.

6.1 Lessons Learned

When RFC 1034 introduced glue records, they aimed to assist in domain name resolution under in-domain delegation and were prescribed for use in referral responses. Nevertheless, as DNS has progressed, such foundational guidelines no longer suffice for the multifaceted applications of DNS. Currently, the management and utilization of glue records are predominantly determined by individual registrars, registries, or resolver software, leading to a noticeable absence of a comprehensive and unified guideline.

Due to a lack of awareness and concern regarding the security risks of glue records, over time, a large number of legacy glue records are left in the TLD zone file, leading to deterioration in the usability and credibility of glue records. On the other hand, the usage of glue records by most DNS software also deviates from their initial design intent. They utilize glue to enhance resolution efficiency, irrespective of whether it's sibling-domain or even out-domain delegation. However, the configuration of glue records is typically distinct from that of conventional `A` and `NS` records. Domain owners are required to manipulate specific functions provided by the registrars. This might pose confusion to ordinary users, thereby leading to operational errors or forgetting previous configurations.

Thus, the behavior of DNS software is risky. Our work highlights that glue records constitute a forgotten foundation of DNS architecture. We advocate for thoroughly reassessing security threats for glue records and establishing standardized guidelines for their usage scenarios, with renewing security prioritization.

6.2 Mitigation

The core issue of the stale glue threat lies in managing glue records by registrars and registries. Upon the registrar's comprehensive cleanup of all invalid glue records, attackers will lose their avenue of attack. Therefore, we recommend that registrars and registries establish or refine their strategies to promptly clean up stale glue records. On the other hand, the undocumented and improper operations of registrars on expired domain names have introduced direct attack vectors into TLD zone files. These operations should be standardized, and the incorrectly introduced glue records should be removed.

For resolver software, validating glue records is complex and may reduce efficiency. However, sacrificing security for speed is not advisable. Thus, we recommend that mainstream resolver software actively query the glueFQDN to obtain an authoritative response and use it when encountering a glue record under sibling-domain and out-domain delegation. In the experiments, we observed that Unbound and Technitium have implemented similar strategies. They prioritize glueFQDN's authoritative response over the glueIP.

6.3 Disclosure and Responses

We have reported vulnerabilities to all relevant vendors and DNS software for responsible disclosure and are discussing the mitigation with them.

Regarding resolver software, we understand that given the complexities of domain dependencies, resolver software must consider multiple factors to balance security and performance. Nonetheless, we have submitted reports to mainstream DNS software and public DNS services, recommending the deployment of mitigation measures. As a result, Microsoft DNS confirmed the vulnerability and ranked it as `important`, with plans to release a patch in April 2024, along with a $1,000 bonus. PowerDNS acknowledged the threat but thought that fixing this issue may impact resolution performance, and we are discussing an optimized solution. Moreover, OpenDNS and Alibaba Cloud DNS have acknowledged the threat and are preparing to implement mitigation based on our reports [16].

Furthermore, we have contacted the respective TLD registries to explore more effective mitigation strategies. `.org` and `.info` have acknowledged the issue and are collaborating with us on a cleanup plan. We have also reported the issue to ICANN and are working together to assist other registries in resolving this problem. Given the impact on 6 million affected domains, it is not feasible for us to individually report to each one. Thus, we disclosed the information through our national CERT and await their response.

7 Related Work

DNS Misconfiguration. Although RFC 1034 requires that the delegation data from parent and child zones should be consistent, inconsistent delegation caused by complex DNS configurations is prevalent in practice [12, 61], which is the main reason for the generation of legacy records. Back in 2004, Pappas et al. [55] found that 15% of DNS zones had inconsistent delegation. Kalafut et al. [33] noticed that some glue records remained in the TLD zone even though their parent domains had expired. They referred to these records as orphan records and found that some orphans were evidently used for malicious purposes. In 2020, Sommese et al. [63] reviewed orphan records again. They observed a significant decrease in `.com` and `.net`, suggesting that TLD operators had implemented policies to mitigate this. However, in some new gTLDs, this phenomenon showed an upward trend, such as `.info` and `.mobi`. Moreover, under the common gTLDs (i.e., .com, .net, and .org), Sommese et al. [64] have shown that almost 8% of domain name delegations are inconsistent. They are concerned about how it could affect DNS operations, such as improper load balancing among the nameservers. To mitigate this problem, RFC 7477 [24] proposes a new record type (CSYNC) to synchronize delegation information between parent and child zones. However, actual deployment is rare. These previous works have identified a large number of inconsistent delegation records (NS RR), our work further proposes a novel exploitation method of DNS glue records and systematically evaluates the real-world threat it poses.

Domain Takeover. In essence, the DNS provides a resource mapping service. If the mapping is not purged when the service expires or is terminated, it can be exploited by attackers. Liu et al. [46] proposed four types of exploitable dangling DNS records (Dare), showing that Dare is a real and prevalent threat. Moreover, Borgolte et al. [14] discovered a significant number of stale DNS records pointing to available IP addresses in clouds, introducing a new attack vector. Akiwate et al. [3] utilized comprehensive collections of both active and passive DNS measurements to investigate and quantify the risks of lame delegation and showed that lame delegation in some zone files affected 14% of domains. In addition, Alowaisheq et al. [8] investigated a new category of stale NS records that reside in the domain zone (instead of the TLD zone) for an active domain, which can cause a stealthier hijacking of target domains. Houser et al. [28] have shown that authoritative nameserver deployments in government domains still contain a non-trivial number of configurations that do not comply with RFC requirements and that more than 1,000 domains are vulnerable to hijacking because of these configurations. Unlike previous research, our work introduced the concept of *shadow caching* enabling domain takeover or

DoS under out-domain delegation.

DNS Cache Measurement. DNS depends on extensive caching for good performance, and numerous studies have contributed to DNS cache measurements. Klein et al. [36] proposed methodologies for efficiently discovering and enumerating the caches of the DNS resolution platforms to shed light on architectures and configurations of the caches in DNS resolution platforms. And, Al-Dalky et al. [5] presented a characterization and classification of the multiple recursive resolver pools and showed the pools exhibit a wide range of behaviors. Randall et al. [60] developed the Trufflehunter tool, which models the complex behavior of large multi-layer distributed caching infrastructures, and used it to infer the caching strategies of four popular public DNS resolvers. Moreover, Li et al. [41] measured the caching and transmission mechanism of DNS software and open resolvers. Previous work has only focused on conventional resource records such as the A record, ignoring the glue record hidden in the reference response. As a result, the security community currently lacks a clear understanding of the usage behavior of glue records in the wild. Our work evaluates the caching and usage behavior of glue records by open resolvers and mainstream DNS software, revealing manipulable behavior in mainstream implementations. Exploiting this, we propose new threat models.

8 Conclusion

In this paper, we systematically measure and assess the security risks of glue records, especially under out-domain delegation, proving that they are real and prevalent. We empirically identify that 23.18% of glue records are stale in the zone files of 1,096 TLDs. In addition, through reverse engineering 9 mainstream DNS implementations (e.g., BIND 9 and Microsoft DNS), we reveal the risky behaviors of glue records. Moreover, we identified 193,558 exploitable glue records. These affect over 6M domain names that are vulnerable to takeover or DoS attacks. To evaluate the real-world implications of stale glue records, we perform large-scale measurements toward stable open resolvers and 14 well-known public DNS resolvers. The experimental results show that over 90% of resolvers and all surveyed public DNS cache and use unvalidated glue records, including Quad9, and OpenDNS. To initiate the remediation process, we have notified the affected vendors and actively followed up on the deployment of the mitigation solutions. Our work provides a thorough picture of glue record threats and hopes to inspire the enthusiasm of registrars, registries, and DNS software for the security threats of glue records.

Acknowledgments

We sincerely thank all anonymous reviewers and our shepherd for their valuable comments to improve the paper. We also thank Ruixuan Li, Zhijie Xie, and Weijing Liang for their help with the paper. A Common TCP and UDP ports

We selected 13 UDP and 20 TCP ports associated with common protocols, as shown in Table 6. These ports have been utilized in previous studies for the purpose of verifying whether an IP address is currently in use [14].

Table 6: Most frequently used TCP and UDP ports [14]

	Protocol (port)
UDP	FTP (21), SSH (22, 2222, 22022), Telnet (23), SMTP (25, 587), DNS (53), Kerberos (88), POP3 (110), IMAP (143), LDAP (389), MYSQL (3306)
TCP	FTP (21), SSH (22, 2222, 22022), Telnet (23), SMTP (25, 587), WHOIS (43), DNS (53), HTTP (80,8000,8080), Kerberos (88), POP3 (110), IMAP (143), LDAP (389), HTTPS (443, 8443), MS SQL (1433), MYSQL (3306)

B Hijacking scope of affected domains

Figure 12 displays the cumulative distribution of the hijack ratio for affected domains. For the majority of affected domains, attackers can capture half of their traffic.

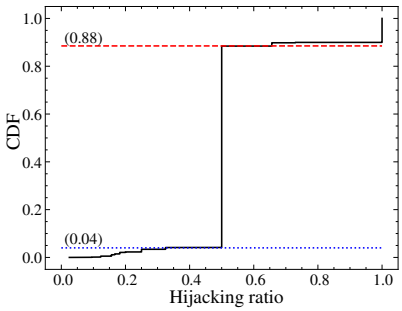

Figure 12: Hijacking ratio for each domain. Half of the traffic for 84% of affected domains can be taken over by attackers.

EVOKE: Efficient Revocation of Verifiable Credentials in IoT Networks

Abstract

The lack of trust is one of the major factors that hinder collaboration among Internet of Things (IoT) devices and harness the usage of the vast amount of data generated. Traditional methods rely on Public Key Infrastructure (PKI), managed by centralized certification authorities (CAs), which suffer from scalability issues, single points of failure, and limited interoperability. To address these concerns, Decentralized Identifiers (DIDs) and Verifiable Credentials (VCs) have been proposed by the World Wide Web Consortium (W3C) and the European Union as viable solutions for promoting decentralization and "electronic IDentification, Authentication, and trust Services" (eIDAS). Nevertheless, at the state-of-the-art, there are no efficient revocation mechanisms for VCs specifically tailored for IoT devices, which are characterized by limited connectivity, storage, and computational power.

This paper presents EVOKE, an efficient revocation mechanism of VCs in IoT networks. EVOKE leverages an ECC-based accumulator to manage VCs with minimal computing and storage overhead while offering additional features like *mass* and *offline revocation*. We designed, implemented, and evaluated a prototype of EVOKE across various deployment scenarios. Our experiments on commodity IoT devices demonstrate that each device only requires minimal storage (i.e., approximately 1.5 KB) to maintain verification information, and most notably half the storage required by the most efficient PKI certificates. Moreover, our experiments on hybrid networks, representing typical IoT protocols (e.g., Zigbee), also show minimal latency in the order of milliseconds. Finally, our large-scale analysis demonstrates that even when 50% of devices missed updates, approximately 96% of devices in the entire network were updated within the first hour, proving the scalability of EVOKE in offline updates.

1 Introduction

Today, there are 15 billion Internet of Things (IoT) devices connected worldwide [46], generating an enormous amount of data that paves the way for novel applications. In such settings, the lack of *trust* [35] is one of the major concerns that limit the full usage of data and collaboration among different entities. Third-party organizations do not rely on external data for decision-making and devices do not trust each other. Therefore, increasing trust in IoT networks would remarkably contribute to leveraging a larger amount of data, leading to the development of next-generation services [43].

Centralized Approaches. At the state-of-the-art, Public Key Infrastructure (PKI) is the most widespread technology adopted to identify devices and establish mutual trust [22, 23]. In this, digital identities are traditionally issued and managed by centralized certification authorities (CAs). However, centralized approaches present several concerns and limitations, including scalability, lack of control over own information, single point of failure, and limited interoperability.

Decentralized Approaches. To address these concerns, decentralized approaches are increasingly attracting the interest of the industry and academia. In this direction, the World Wide Web Consortium (W3C) has formalized and standardized Decentralized Identifiers (DIDs) [54] and Verifiable Credentials (VCs) [55] as viable solutions for promoting decentralized identification. A DID is a unique identifier that resolves to a DID Document containing public keys, enabling the proof of ownership over specific data. On the other hand, a VC is a statement about an entity that can be cryptographically verified by a third party. VCs offer an alternative to traditional digital certificates for establishing trust and verifying the authenticity of attributes. Indeed, interest in DIDs and VCs has seen remarkable growth in recent years as they have laid the groundwork for innovative identity solutions like digital healthcare passports [15]. Such a trend can also be observed in several initiatives that are emerging worldwide with many countries that are starting to use these technologies [26, 40, 51].

For instance, VCs are considered a key technology by the European regulation for "electronic IDentification, Authentication, and trust Services" (eIDAS) to ensure secure and remote identity proofing [38]. Furthermore, DIDs and VCs

have the potential to efficiently implement the concept of Identity of Things (IDoT) [25] introduced by the Kantara Initiative. Each device is assigned a DID that enables proving certain capabilities, through VCs, to other devices.

Problem Definition. A critical operation for the trust of the whole network depends on the efficient revocation of VCs for malfunctioning or compromised devices. A notable example is the chip vulnerability on RSA key generation, as highlighted in CCS'17 by Namec et al. [37], which resulted in the revocation of more than 700K certificates for devices using that chip. In IoT networks, the presence of heterogeneous devices, some with limited computing and storage capabilities, adds complexity to the revocation process. Additionally, an IoT setting can be constrained as well and characterized by limited bandwidth, low transmission range, dynamic topology, and unreliable connectivity. These factors pose challenges to the adoption of traditional revocation mechanisms like the Online Certificate Status Protocol (OCSP) [42] and Certificate Revocation Lists (CRLs) [10], which respectively assume reliable connections and large amounts of memory. Despite the growing interest in DID and VCs [20, 33], the development of efficient approaches for VC revocation remains in its early stages as evidenced by the lack of a dedicated W3C standard [53].

EVOKE. Motivated by the growing interest in DID and VCs, coupled with the inherent challenges posed by IoT devices, in this paper, we introduce EVOKE, a novel solution to address the efficient VC revocation in IoT settings. Our approach allows devices to establish trusted interactions while minimizing computing and storing overhead. To achieve this, EVOKE leverages an Elliptic Curve Cryptography (ECC)-based accumulator [52], which efficiently aggregates multiple data into a unique element called accumulator value, whose size remains constant regardless of the number of accumulated elements. An additional significant characteristic is that proving membership in the accumulator value also demands constant verification time. These characteristics ensure that EVOKE maintains efficiency even when the number of credentials and devices within the network grows.

Implementation and Evaluation of EVOKE. We implemented and evaluated a prototype of EVOKE, assessing its effectiveness and applicability across various scenarios. First, to validate its feasibility in real-world environments, we evaluated EVOKE on commodity IoT devices. To the best of our knowledge, it is the first tool to enable using VCs on IoT devices. However, due to the restrictions imposed by vendors, as end-users, we were not allowed to run our code directly on them. Thus, to broaden the scope of our analysis and encompass a wider range of scenarios, we extended our evaluation to include hybrid networks that combine both IoT devices and Raspberry Pis. This setup allowed us to create the typical IoT deployment scenarios like star or mesh topologies that require the IoT devices' interaction with each other. Last but not least, we conducted scalability tests by simulating a large-scale network consisting of thousands of devices.

The experimental results demonstrate that EVOKE can be supported by off-the-shelf IoT devices easily, demanding only minimal requirements in terms of storage and computing resources. Remarkably, each device only needs to allocate approximately 1.5 KB of space for storing verification information, i.e., the accumulator value and proof of inclusion (witness). The constant size of the accumulator value, combined with the low latency introduced by the verification operations, significantly enhances the scalability of EVOKE and it enables *mass revocation*. Our mechanism also offers *offline revocation*, whereby devices that fail to receive revocation updates can still be updated by trustworthy devices that have received the updates. Even in the extreme case where 50% of devices miss updates in a network of one million devices, EVOKE is capable of updating almost the entire network through a limited number of interactions.

Contributions. The main contributions of the paper can be summarized as follows:

- We present a novel and efficient revocation mechanism for VCs in IoT networks. Our approach offers a direct application to device-to-device trust establishment, significantly enhancing revocation efficiency while enabling the capability for mass revocation of VCs.
- EVOKE supports offline revocation and effectively reduces network overhead. In cases where a device misses updates (i.e., accumulator value and witness), EVOKE allows for the updating of the device by leveraging interactions with other devices in the network.
- EVOKE ensures that each device stores only a minimal amount of data necessary for validating other VCs and establishing trusted communications. This design minimizes storage requirements while maintaining the integrity of the system.
- To comprehensively evaluate the effectiveness and performance of our approach, we conducted a series of experiments that include direct evaluations of EVOKE also on several commodity IoT devices. To the best of our knowledge, this work represents the first solution and design of a VC revocation scheme specifically tailored for IoT technologies.

Organization. The remainder of this paper is structured as follows: Section 2 provides the background for DID, VCs, and cryptographic accumulators. Section 3 presents the EVOKE system model and threats. Section 4 describes the revocation mechanism. Section 5 analyzes the security of our proposal. Section 6 evaluates our revocation mechanism and presents experimental results. Section 7 compares EVOKE to other approaches. Section 8 covers related work, and Section 9 concludes the paper.

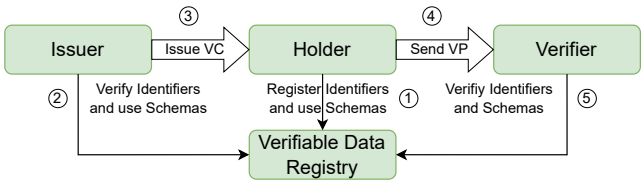

Figure 1: Overview of VC main actors.

2 Background

In this section, we provide the needed background to understand the data structure that enables revoking VCs in our proposal.

2.1 Decentralized Identifiers (DIDs) and Verifiable Credentials (VCs)

DIDs have revolutionized identification in decentralized identity frameworks [34]. A DID uniquely identifies a DID Subject, whether human or non-human entities. It comprises three elements: the Uniform Resource Identifier (URI), the specific DID method identifier, and the method-specific DID identifier. Additionally, a DID URL extends the basic DID by incorporating additional URI components for precise resource location. Each DID resolves to a machine-readable JSON-LD document called DID Document, containing cryptographic public keys, service endpoints, authentication parameters, timestamps, and metadata. DIDs eliminate the need for identity providers and centralized authorities, allowing entities to prove ownership through private keys corresponding to the embedded public keys in the DID Document. Verification is facilitated by accessing the public DID Document, shared via a verifiable data registry usually implemented using distributed ledger technologies (DLTs).

VCs are another W3C specification, providing an interoperable data structure for representing cryptographically verifiable and tamper-proof claims. VCs play a significant role in an ecosystem that includes holders, issuers, verifiers, and a verifiable data registry. Holders are entities with control over one or more VCs, while issuers create new VCs. In an IoT environment, issuers may be the manufacturer of devices. Verifiers obtain VCs for establishing trust, e.g., smart locks requesting trusted data from smoke detectors to facilitate building evacuation. The verifiable data registry mediates the creation and verification of identifiers, keys, credential schemas, and other relevant data. A VC comprises elements such as the subject URI, the issuer's URI, unique credential identifiers, claim expiration conditions, and cryptographic signatures. Moreover, the W3C VC Working Group introduced Verifiable Presentations (VPs), defining methods for signing and presenting VCs by holders. Figure 1 sketches the main actors within the ecosystem of VCs.

2.2 Cryptographic Accumulators

The academic interest in cryptographic accumulators dates back to 1994 when they were initially proposed as solutions for eliminating trusted central authorities [3]. Accumulators are used to cryptographically produce a short binding commitment to a set of elements called accumulator value, proving the membership of data in the dataset through short proofs. An accumulator is defined as a family of *one-way hash functions* that satisfy the capability of being *quasi-commutative*. A one-way hash function h is a function that takes an input value v of arbitrary length and produces a fixed-size output named hash value $h(v)$. The one-way property of the hash function means that given $h(v)$, it is computationally infeasible to recover the original input. The quasi-commutative property makes the accumulator independent from the order of values accumulated. These properties allow accumulators to be used for condensed representing a set of elements and efficiently verify membership. To test if a v_i is included in the accumulator value, one needs to calculate its corresponding witness w_i, which is obtained by accumulating all the values except v_i. Accumulators that enable verifying the inclusion of elements via *membership witnesses* are called *positive*, while those that allow verifying if elements are not accumulated through *non-membership witnesses* are referred to as *negative*. Accumulators that support both functionalities are known as *universal*.

Different types of accumulators have been proposed over the years. Extensive studies [29, 50, 56] have demonstrated that ECC-based accumulators outperform alternative solutions such as RSA-based accumulators and Merkle Trees (MTs) [47]. ECC-based accumulators offer several advantages, including smaller proofs of membership (witnesses) and efficient verification, thanks to the reduced number of mathematical operations needed.

In this paper, we leverage the features of a positive ECC-based accumulator [52] that supports batch operations, including witness generation. In contrast, the size of the accumulator value in an RSA-based accumulator is determined by the size of the modulus used in the RSA encryption scheme. The modulus size is directly related to the security level of the RSA accumulator. Thus, RSA demands larger module sizes to achieve the same security level as ECC. In MTs, the proof size increases logarithmically with the size of the committed data, which can make it grow considerably when considering a large set of data. This can be a disadvantage regarding storage space and computation time when dealing with large amounts of data.

3 System and Threat Model

In this paper, we consider IoT networks $\mathcal{N}$ that comprise issuers I, accumulators $\mathcal{ACC}$, a distributed ledger b, and IoT devices $\mathcal{D}$. In real-world scenarios, devices interact within

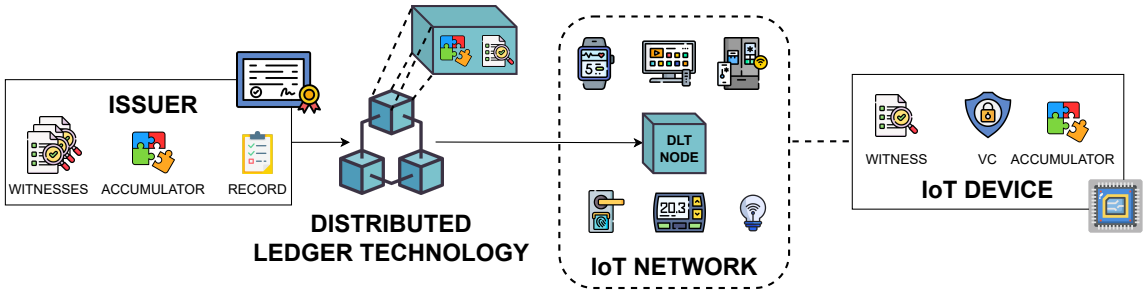

Figure 2: EVOKE architecture. The dotted lines represent a closer examination of revocation information shared on the DLT and data maintained by each IoT device.

Table 1: EVOKE Notation.

Symbol	Description
$\mathcal{N}$	Set of IoT Networks
I	Set of issuers
$\mathcal{ACC}$	Set of accumulators
j	Geographical area
A_j	Single accumulator
a_j	Single accumulator value
i_j	Single issuer
D_j	Set of IoT devices in j
d_i	Single IoT device
W_j	Set of witnesses in j
w_i	Witness of device d_i
b	DLT

specific geographical areas, whose boundary depends on several factors such as administrative divisions, technological infrastructure, or network coverage (e.g., Wi-Fi networks). For instance, a geographical area can be mapped into a 5th-generation network cell.

Without loss of generality, we assume that a geographical location j represents an IoT network $n_j \in \mathcal{N}$. Each IoT device $d_i \in D_j \subset \mathcal{D}$ in n_j has a VC issued by the issuer $i_j \in I$. To manage VCs, i_j accumulates all the valid VCs of j, i_j accumulates them in $a_j \in A_j \in \mathcal{ACC}$. Table 1 summarizes the notation used in the EVOKE system model and security analysis. In the design of EVOKE, we make the following assumptions:

1. The issuer i_j possesses sufficient computing capabilities, including an adequate level of processing power, memory, and necessary software/tools and mechanisms, to successfully build the accumulator value a_j, remove VCs, generate witnesses W_j for all $d_i \in D_j$, and disseminate updates (i.e., accumulator and witnesses) through the DLT. i_j provides VCs only to authenticated and properly functioning devices that have not been compromised.
2. Each device d_i is initially provided with a valid VC, a_j, w_i, its cryptographic material and the public key of i_j, which has issued the VC. Through the public key of i_j, d_k can establish secure and authenticated communications.
3. There are devices in n_j that have full connectivity, intended as a reliable connection to the DLT to receive the updates. Updated revocation information is disseminated in n_j through a publish/subscribe paradigm.

3.1 Components

In this section, we provide a detailed explanation of EVOKE's components, whose architecture is depicted in Figure 2.

- *Issuer*: The issuer i_j is responsible for issuing and revoking VCs. It records all issued VCs and IoT devices within the network. The issuer operates independently from the rest of the network and only communicates through the DLT. We assume it possesses sufficient computing capabilities for managing VCs, including the generation and update of the accumulator value a_j and witnesses W_j.
- *DLT*: b serves as a secure, distributed data source for exchanging updates (i.e., a_j and W_j), between the i_j and D_j. DLTs are secure due to the use of cryptographic techniques like digital signatures and hash functions, along with the resilience to single points of failure and the adoption of consensus mechanisms. In the highly improbable case of being compromised, the availability of updates may be affected, but the updates' integrity remains intact. Updates are included in VCs signed by i_j, thus only the issuer can generate them. Each n_j has at least one DLT node equipped with adequate resources to maintain a consistent and up-to-date version of b. In our work, we utilized a directed acrylic graph (DAG)-based ledger, DAG for brevity. The adoption of a DAG offers transparency and immutability of shared data while exhibiting enhanced performance in terms of latency and energy consumption that make it ideal for IoT environments [17].
- *IoT Device*: $d_i \in D_j$ vary in computational power, resource consumption, storage capacity, and networking capabilities. Each IoT device d_i is equipped with sufficient storage for essential components such as the a_j,

d_i, a VC, DID, and associated information. Additionally, each d_i possesses the minimum cryptographic functions necessary to establish trust within the IoT network n_j. Devices communicate with each other through their networking technologies, while only devices with sufficient networking capabilities can interact with b.

3.2 Threat Model

The security of our scheme relies heavily on the secure implementation of the proposed system. We assume that the a_j has been computed securely, ensuring its collision resistance. To assess the security of our system, we employ the Dolev-Yao model adversary [14], who possesses the capability to eavesdrop on, intercept, or inject an arbitrary number of messages. Furthermore, we also consider that the attacker can compromise the entities composing n_j. The primary objective of the adversary is to acquire a valid VC, thereby gaining the ability to establish trusted communications. This goal can be accomplished by compromising i_j, D_j, or communication links. In the following, we highlight the primary threats of a scenario where an issuer furnishes VCs for IoT devices:

- **Compromised Issuers**: Gaining control over the issuer i_j gives the adversary the capability to arbitrarily issue valid VCs as well as revoke valid ones. The attacker can generate VCs with false or misleading claims, improperly granting permission to entities within the system. Furthermore, the adversary may invalidate legitimately issued VCs, resulting in a denial of services (DoS) or disruption of the established trust relationship.
- **Compromised IoT Devices**: IoT devices D_j act as the entry point to IoT networks and can be vulnerable to a range of attacks if compromised by adversaries. The attacker may identify vulnerabilities in the firmware of IoT devices to gain unauthorized access or control over other devices. Devices can be compromised in a variety of ways, such as malware distribution through firmware updates or the devices may have already been manufactured with compromised hardware or software components in case the adversary has direct access.
- **Compromised Communication**: In n_j, D_j are not obligated to implement encryption mechanisms, making it relatively easy for the adversary to eavesdrop on the traffic. For example, the attacker may use the intercepted VC to spoof the identity of the device and establish trust on its behalf.

4 EVOKE Protocol

The proposed approach allows IoT devices D_j to securely communicate with minimal overhead. Specifically, each device d_i maintains the accumulator value a_j, which comprises all the valid VCs, and a witness w_i that demonstrates the validity of its credential. a_j and the witnesses W_j are computed by the issuer i_j and initially provided to all $d_i \in D_j$. However, when a VC is revoked both a_j and W_j have to be updated. Using just two values, which require only a few bytes, remarkably reduces the revocation management overhead both in terms of storage and distribution. The remainder of this section provides the full details of our method.

4.1 Preliminaries

The accumulator value a_j is the key element of our proposal that enables efficient management of VCs. In this subsection, we provide all the details related to its usage in EVOKE.

Proof of membership: When using a revocation list, two devices d_i and d_k that have to authenticate each other present their VCs and verify whether the received one is included in the list. Similarly, to use a_j to revoke VCs, d_i needs to present proof of membership named witness. In this way, the receiver applies a verification function that allows it to state whether the VC has been included in a_j.

Inputs of the accumulator: Values in a_j are derived from the hash conversion of the valid VCs. Therefore, the security of a_j relies heavily on the chosen hash function. In our case, we use the widely adopted SHA-256 hash function, which is considered to be secure and collision-resistant.

Functions: The following functions are used to implement the proposed approach:

- $a_{info} \leftarrow \mathsf{Setup}(\mathsf{K})$: setups the parameters of $\mathsf{a_j}$ by taking a set of public values K, which represent the random generators of the elliptic curve.
- $a_j \leftarrow \mathsf{ComputeAccumulator}(\mathsf{a_{info}}, \mathsf{V})$: accumulates a set of valid verifiable credentials V by mapping them onto the curve. This function is also executed to update a_j when V is modified, as VCs can be revoked and newly valid ones can be issued.
- $a_j^t \leftarrow \mathsf{RevomeFromAccumulator}(\mathsf{a_{info}}, \mathsf{a_j^{t-1}}, \mathsf{V})$: removes a set of invalid verifiable credentials V. This function is also executed to update a_j.
- $w \leftarrow \mathsf{ComputeWitness}(\mathsf{a_j}, \mathsf{vc_i})$: generates a witness value $\mathsf{w_i}$ for a valid verifiable credential $\mathsf{vc_i}$, providing proof of its membership within $\mathsf{a_j}$.
- $0,1 \leftarrow \mathsf{Verify}(\mathsf{a_j}, \mathsf{vc_i}, \mathsf{w_i}, \mathsf{pk_i})$: $\mathsf{d_i}$ presents $\mathsf{vc_i}$ by signing it with its secret key $\mathsf{sk_i}$. The verifier executes this function to authenticate $\mathsf{d_i}$. It verifies whether $\mathsf{w_i}$ provided by $\mathsf{d_i}$ is accumulated in $\mathsf{a_j}$. The verifier uses the device's public key $\mathsf{pk_i}$ to ensure that $\mathsf{vc_i}$ is associated with $\mathsf{d_i}$.
- $a_j^t \leftarrow \mathsf{UpdateAccumulator}(\mathsf{a_{info}}, \mathsf{a_j^{t-1}}, \mathsf{V})$: removes a set of invalid verifiable credentials V through the $\mathsf{RevomeFromAccumulator}()$ function. In case, a new set of valid verifiable credentials V is released, they are included in a_j using the $\mathsf{ComputeAccumulator}()$ function.
- $w^t \leftarrow \mathsf{UpdateWitness}(\mathsf{a_j^t}, \mathsf{vc_i})$: updates the witness corresponding to a valid verifiable credential $\mathsf{vc_i}$. When $\mathsf{a_j}$ is

updated, previously disseminated W_j^{t-1} become invalid. This function takes the updated value a_j^t, a verifiable credential vc_i, and returns a valid witness w_i^t corresponding to vc_i.

4.2 Protocol

This subsection describes the main phases of our protocol, which uses the features of the positive accumulator presented in [52]. These capabilities are leveraged by EVOKE to verify whether a VC has been revoked or not, i.e., checking if the corresponding witness is included in the accumulator value. Given two IoT devices d_i and d_k, they can validate each other as long as the accumulator value a_j and their respective witnesses, w_i and w_k, are updated. To securely share a_j among all $d_i \in D_j$, i_j includes the accumulator value a_j, as well as the witnesses W_j, in self-signed VCs and publishes them on b. This approach enables D_j to verify the authenticity before updating. Furthermore, if d_i is outdated and cannot directly download the freshly issued a_j and w_i, the updated d_k can share the refreshed VCs needed to establish mutual trust. The proposed protocol supports mass and offline revocation, which are defined as follows:

Definition 1 (Mass Revocation) *Mass revocation is the capability of efficiently revoking a large number of VCs without impacting the issuer and device overhead. A protocol designed for mass revocation ensures that the memory size of the underlying data structure to manage VCs as well as the verification time remain unaffected by the number of revoked VCs.*

Definition 2 (Offline Revocation) *Offline revocation refers to the capability of devices to receive and apply updates even when they have been disconnected from the network, without burden on network resources. A protocol that supports offline revocation is designed to minimize the amount of data transmission overhead required to facilitate these updates.*

Setup. In the setup phase, i_j securely generates the accumulator's parameter K and initializes a_j by executing the Setup() function. Valid VCs are accumulated into a_j through the ComputeAccumulator() function. For each valid VC, i_j generates a hash value, which serves as a unique identifier, which is then used to obtain the corresponding representation on the curve. After computing the final a_j, i_j generates the witnesses $w_i \in W_j$ for each valid VC by using the ComputeWitness() function. W_j provides cryptographic proof of the inclusion of the VC in a_j. Initially, each d_i receives a_j, a valid VC, and its corresponding w_i. These components are essential for subsequent operations.

Authentication. During the authentication, d_i initiates the communication with d_k by sending the timestamp of a_j. The issuer associates a timestamp with the accumulator value that

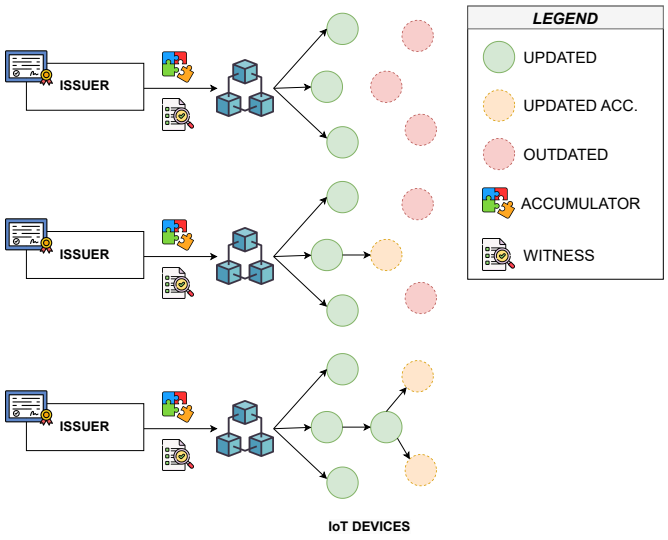

Figure 3: Updating accumulator value and witnesses.

serves as a means to synchronize the devices and ensure consistency. Device d_k compares the received timestamp with that of its accumulator value. Matching timestamps indicate that both d_i and d_k are operating with the same version of a_j, and they can proceed with the authentication. However, if the timestamps differ, it implies that one of the devices has an outdated a_j. In this case, the device with the older timestamp updates its a_j to the latest version.

Once synchronized, d_i and d_k exchange signed VCs and the corresponding witnesses, namely w_i and w_k. Both devices verify that the received VC has been issued by i_j, if the verification is successful they hash them and utilize the Verify() function to check if the VC belongs to that device and if the hash has been included in a_j.This verification step ensures that the VCs are valid and have not been tampered with. If both VCs are found within a_j, it indicates their membership and authenticity. Consequently, the devices can trust each other and establish a secure and trusted communication channel.

Update. Over time, the issuer i_j may need to revoke certain VCs due to device compromise or faults. Revoking VCs entails updating the accumulator value a_j and the corresponding witnesses W_j for the IoT devices that are still functioning correctly. Figure 3 offers a high-level overview of our protocol while updating an IoT network. To revoke VCs, i_j executes the UpdateAccumulator() function that removes invalid credentials from a_j.Once the updated a_j is obtained, i_j uses the novel version to generate a new W_j for the remaining valid VC. The UpdateWitness() function is employed to calculate the updated witnesses based on the modified a_j. Subsequently, i_j embeds the updated information, including the newly generated W_j, within VCs signed by i_j to ensure their authenticity. These modified VCs, containing the refreshed witnesses, are

then shared through a DAG b. By distributing the updated VCs with their corresponding witnesses, other devices in the network can be informed about the revoked credentials and have access to the latest valid set. This mechanism ensures that all devices have an up-to-date view of the trusted credentials within the system, promoting secure and reliable communication.

In an IoT network n_j, offline updates are essential for devices with intermittent connectivity or power-saving hibernation. EVOKE leverages VCs to share a_j and W, enabling devices to update even when not directly connected. When an updated device d_i encounters an outdated device d_k, it can facilitate the update process by sharing a VC that contains a more recent version of a_j. Depending on the networking capability of d_k, there are two possible approaches: *direct retrieval* and *indirect retrieval*. If d_k supports direct retrieval, it has sufficient networking capabilities to directly retrieve the corresponding w_k from b. Otherwise, it obtains w_k from d_i or another device with satisfactory network connectivity. This indirect retrieval process ensures that d_k receives the necessary w_k to accompany the updated a_j. Once d_k acknowledges having an outdated version of new a_j, it disables trusted communications until it will not receive updates. This precautionary measure prevents the authentication of other devices that may attempt to leverage an outdated version of a_j. Importantly, both a_j and w_k should be included within a VC to facilitate the sharing process. By utilizing VCs to share a_j and W, the EVOKE system ensures that updates are always trusted, even if not directly provided by i_j. Algorithm 1 shows how updates are handled in n_j.

Algorithm 1 `HandleUpdates`: Function executed to update $d_i \in D_j$. If d_i becomes outdated, it can still receive revocation information from updated devices.

Input: D_j, b
Output: Updated D_j
for each $d_i \in D_j$ **do**
    d_i interacts with some $d_k \in D_j$ with $i \neq k$
    if a_j^i is older than a_j^k **then**
        $a_j^i \leftarrow a_j^k$
        if d_i has sufficient connectivity **then**
            $w_i \leftarrow DirectRetrieval(b, d_i)$
        else if d_k has sufficient connectivity **then**
            $w_i \leftarrow IndirectRetrieval(b, d_k, d_i)$
        else
            disable trusted communications for d_i
        end if
    else if a_j^k is older than a_j^i **then**
        $a_j^k \leftarrow a_j^i$
        if d_k has sufficient connectivity **then**
            $w_k \leftarrow DirectRetrieval(b, d_k)$
        else if d_i has sufficient connectivity **then**
            $w_k \leftarrow IndirectRetrieval(b, d_i, d_k)$
        else
            disable trusted communications for d_k
        end if
    end if
end for

Discussion. EVOKE's ability to handle intermittent connectivity and hibernation ensures that IoT devices D_j can remain up-to-date with a minimal delay, thereby maintaining the system's integrity and security. However, when two previously offline devices, d_i and d_k, interact, it is important to consider two possible scenarios that require further attention.

- *Consistent Accumulator Value Version*: If both devices d_i and d_k share the same version of the accumulator value a_j, which happens to be outdated, they are unable to detect any missed updates. In this case, devices may incur misbehaved authentication if one of them has a revoked VC. As soon as these devices encounter a device with a fresher accumulator version and one of them supports direct retrieval, updates are applied, and their correct behavior is re-established. Let us note that this situation is unlikely to occur. Additionally, it is worth noting that this undesired condition has a time limitation. As shown in Subsection 6.4, the majority of the devices are updated within the first hour, reducing this risk.
- *Mismatching Accumulator Value Version*: When both the devices have a mismatching version of a_j, additional steps are required. Let us assume that d_k has the older version of a_j. If d_k can implement direct retrieval, it retrieves w_k and recognizes that it corresponds to a fresher version of a_j than what was exchanged. As a result, d_k obtains the associated novel version of a_j and updates itself accordingly. On the other hand, if indirect retrieval is necessary, d_i collects w_k and performs a similar verification process. Eventually, d_i acquires the latest version of a_j and the corresponding witnesses and updates d_k accordingly. If both devices lack direct retrieval, they temporarily disable their trusted communications while waiting for updates in subsequent iterations. In Subsection 6.4, we demonstrate that nearly the entire network is updated within the first hour, even if 50% of devices missed updates.. By following this procedure, devices ensure that their accumulator values and witnesses are synchronized, allowing for consistent and trusted communication.

These scenarios highlight EVOKE's adaptability, allowing D_j to reconcile differences in accumulator value versions and update each other for consistency. Through these mechanisms, EVOKE promotes seamless communication and guarantees the overall security and reliability of the IoT network n_j.

5 Security Analysis

In this section, we consider the threats introduced in Subsection 3.2 and analyze how they are mitigated in an environment where EVOKE is employed as a revocation mechanism. It is worth noting that threats linked with the issuer (e.g., secure private key storage), generally refer to any trusted entity responsible for managing VCs or certificates. Therefore, they are not directly mitigated by revocation mechanisms, including EVOKE. Additionally, revocation mechanisms are not responsible for detecting compromised devices while they have to manage their revocation upon a device being marked as compromised.

5.1 Security of Issuer

The issuer i_j is the primary target of the adversary as it manages the accumulator, which is the key data structure for handling VCs. We examine three potential attack scenarios and corresponding countermeasures:

Securing the Issuer's Environment. i_j is deployed in a secure environment that imposes restrictions on direct external communication. Valid VCs are accumulated within the issuer's secure perimeter, and a_j is shared with n_j through a DAG b. This setup makes it significantly challenging for the attacker to gain unauthorized access a_j from external sources.

Compromise of Accumulator Security Measures. Despite robust defense mechanisms in place, the adversary may still attempt to compromise the security measures protecting a_j and acquire the setting parameters $\mathsf{a}_{\mathsf{info}}$. However, even if the adversary gains access to these parameters, it does not provide them with an advantage in attacking the revocation management process. To undermine our approach, attackers would need to obtain the key pair associated with the issuer DID and use it to sign fraudulent VCs that comprise the accumulator value a_j and witnesses W_j.

Key Pair Compromise. If an adversary successfully obtains the issuer's key pair, immediate action must be taken to mitigate the risk. This includes migrating i_j to a new server and providing it with a fresh DID and key pair. By replacing the compromised key pair, the system maintains the integrity and security of VCs, preventing unauthorized access and fraudulent activities.

5.2 Security of IoT Devices

The adversary can compromise an IoT device $d_i \in D_j$, enabling them to launch various attacks within the IoT network n_j. d_i provided with a valid VC and w_i can establish trusted communications with other entities that place trust in i_j. Therefore, i_j is responsible for identifying and detecting malicious activities, ensuring that VCs associated with compromised devices are removed from a_j. Several approaches have been proposed to detect compromised devices and malicious activities [8, 32]. However, the detection of compromised devices lies beyond the scope of this paper. We assume that the issuer can employ different methods and tools available in the literature for these purposes. i_j updates W_j and a_j, distributing them to D_j. As a result, malicious $d_i \in D_j$ will not be provided with valid witnesses, thereby preventing the attacker from successfully bypassing the revocation mechanism using a compromised d_i or its stolen VC.

5.3 Security of Communication

In n_j, the traffic may not be encrypted, thus, further broadening the attack surface. We consider two possible attack scenarios and corresponding countermeasures occurring during the update phase:

Selective VC Forwarding. One attack scenario involves the attacker intentionally not forwarding the VC containing the updated version of the accumulator value a_j to outdated devices. As a result, outdated devices may continue to trust devices whose VCs are no longer valid. However, it is important to note that an outdated device can still be updated by an honest device during communication initiation. Additionally, to address the concern of the adversary providing an outdated version of a_j, devices only update the value of a_j if the associated timestamp is fresher than the previous one. By incorporating timestamp-based checks, devices can ensure that updates are only applied when newer information is available, mitigating the risk of relying on outdated VCs.

Furthermore, compromised devices instead of sharing the latest version of a_j with benign devices, which includes their revoked VC, may provide another outdated version that does not include their revoked VC but is still fresher than the one held by the benign device. As described previously, given the mismatch between the version of the accumulator value, if the benign device supports direct retrieval, it can detect deceptive attacks when collecting the updated witness directly. However, in cases where direct retrieval is not supported, the device will accept the witnesses corresponding to that version of a_j, establishing mutual trust. It is important to note that while this scenario poses a significant threat, which also affects other approaches like CRL that lack real-time revocation freshness, the risk posed is time-limited. This is evidenced by the observation that most devices are updated within the first hour, as highlighted in Subsection 6.4. Once devices receive the updated accumulator, they become immune to deception, as the revoked VC will no longer be included in the accumulator value.

VC Theft and Masquerading. The attacker can steal the VC comprising the updated w_i of d_i, attempting to masquerade as the legitimate device. However, since the adversary does not possess the key pair associated with d_i, they cannot prove the ownership of the VC and establish trusted communication. Furthermore, in case of transmissions that involve sensitive

information, data can be encrypted using the public key of the receiving device.

6 Evaluation

In this section, we present a detailed evaluation of our approach. We designed a series of experiments to thoroughly assess the effectiveness and applicability of EVOKE. In particular, we considered the following scenarios:

- **Commodity IoT Devices**: To gauge the practicality of implementing EVOKE in real-world scenarios, we conducted experiments on various off-the-shelf IoT devices.
- **Hybrid Network Settings**: Since not all commodity devices support running customized code directly, we performed a set of experiments on an IoT network that comprises both off-the-shelf devices and Raspberry Pis to explore more customizable and broader scenarios.
- **Large-scale Analysis**: As it would be impractical to evaluate our proposed approach on thousands of devices, we devised a set of experiments to simulate a large-scale IoT network and evaluate the scalability of EVOKE.

The results of these experiments, along with detailed explanations, are provided in the subsequent subsections. Through this comprehensive evaluation, we aim to demonstrate the effectiveness, feasibility, scalability, and versatility of EVOKE in various IoT deployment scenarios.

6.1 Implementation Setup

We developed a prototype of EVOKE to evaluate its runtime performance and test its core functionalities. We utilized JavaScript and WebAssembly (WASM) [4] for the implementation in commodity IoT devices. To ensure consistency across all experiments, the same functions were also employed in all scenarios. To enable cryptographic operations, we leveraged the `crypto-wasm-ts` library developed by docknetwork [13]. This library provides a comprehensive set of cryptographic primitives and algorithms implemented using WASM. It ensures efficient and performant execution of cryptographic tasks within EVOKE. For managing DIDs and VCs, we utilized the `identity-wasm/web` library from IOTA [24]. This library offers robust functionality for creating, managing, and verifying DIDs and VCs. Finally, to handle the DLT, we employed the IOTA Tangle [41], a DAG that is specifically designed to cater to the unique requirements of IoT applications [57, 58]. All the results have been averaged over 1K runs. To ensure transparency and reproducibility, we have made our prototype implementation, along with all the experiments, available on GitHub[1].

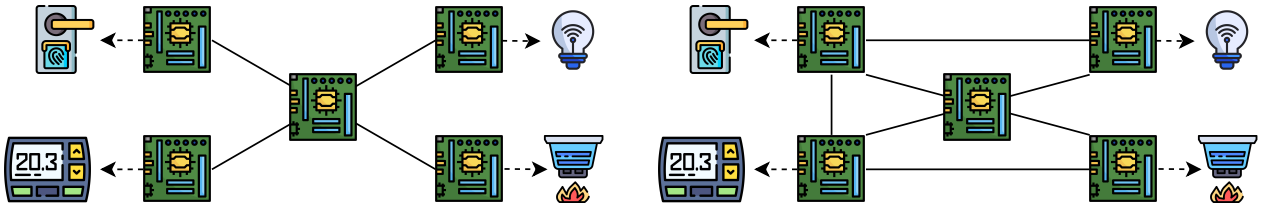
[1] https://github.com/evokevc/EVOKE

Table 2: Commodity IoT devices used in the experiments and their specifications.

Device	Type	Processor	Memory	Operating System
LG Smart TV	Smart TV	LG Quad Core Processor	1.5GB RAM	WebOS
Amazon Echo Show 5	Home Assistant	MediaTek MT8163	1 GB RAM	Linux
Apple iPhone 12	Smartphone	Apple A14 Bionic	4GB RAM	iOS 16
Oculus Quest 2	Virtual Reality Headset	Qualcomm Snapdragon XR2	6GB RAM	Oculus OS

Table 3: Performance evaluation of EVOKE operations on commodity IoT devices.

Operation	LG Smart TV	Amazon Echo Show	Apple iPhone 12	Oculus Quest 2
Verify valid VC	477.44 ms	499.70 ms	12.62 ms	48.69 ms
Verify revoked VC	476.89 ms	498.67 ms	12.58 ms	47.89 ms



6.2 Commodity IoT Devices

In these experiments, we aim to evaluate the feasibility of using EVOKE on commodity IoT devices. For this, we set up an IoT network, which represents a modern smart home comprising different types of off-the-shelf IoT devices. Table 2 reports the specifications of the considered devices, which feature varying resources and operating systems. In our study, we considered devices capable of running EVOKE's code directly. Specifically, all the devices support JavaScript and WASM. To ensure compatibility with various devices, we realized different approaches. For instance, we developed a basic application using the LG WebOS developer framework [1, 48] for the LG Smart TV. For other devices, the code was provided through a Python web server.

Table 3 presents the results. In particular, we highlighted the performance of key operations across a range of commodity IoT devices. The results show that the iPhone 12 runs at about 13ms, while the Amazon Echo Show and LG Smart TV exhibit relatively slower performance. Nonetheless, all the devices verify VCs in under half a second. It is important to note that the size of the information is independent of the specific device used. The storage requirements for maintaining the accumulator value and the witness are approximately 1.5 KB. Notably, these values, along with the execution time of the main operations, remain consistent regardless of the number of VCs involved. This demonstrates the scalability and efficiency of EVOKE across different commodity devices in terms of resource utilization and execution time.

6.3 Hybrid Network Settings

In most cases, commodity devices do not provide direct access for running custom code. However, they often offer APIs that allow developers to control and interact with them. In this scenario, we considered a hybrid IoT network within a smart home, consisting of both off-the-shelf devices and Raspberry

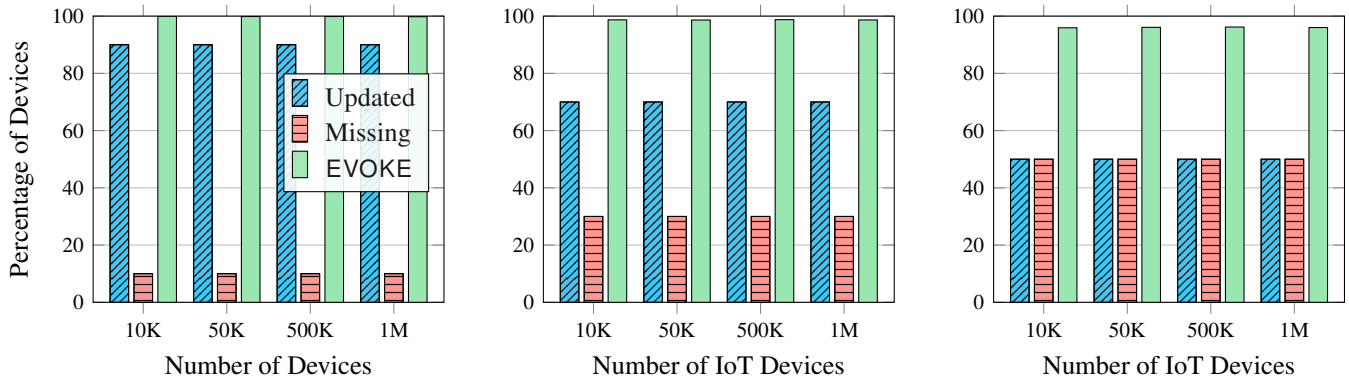
(a) Star network topology

(b) Mesh network topology

Figure 4: Topologies used in our hybrid network experiments.

Pi, serving as controllers for the devices that only provide APIs. By leveraging the capabilities of Raspberry Pi, we were able to perform EVOKE's other operations. The Raspberry Pi devices act as intermediaries, enabling the execution of EVOKE functionalities on behalf of the devices. This approach allowed us to overcome the limitations imposed by the off-the-shelf devices' restricted programmability and harness the power of EVOKE's features. Moreover, this setup ensured the seamless integration of EVOKE operations across a range of devices, expanding the potential applications and scalability of the system. In modern smart homes, advanced integration and connectivity between devices enable enhanced safety and convenience features. For instance, consider a scenario where a smart lock is intelligently linked with a smoke detector. EVOKE allows establishing trust among the devices, enabling it to automatically unlock the door to facilitate the evacuation of occupants during a fire emergency.

In our experiments, we evaluated the performance of EVOKE in two popular network topologies for IoT protocols (i.e., Zigbee and Z-Wave) and scenarios [59]. Specifically, we considered star network topology and mesh network topology, whose deployments are depicted in Figure 4. These scenarios represent real-world use cases and provide valuable insights into the effectiveness and applicability of EVOKE in real IoT environments. The star topology (Figure 4a) consists of a central hub or controller connected to multiple peripheral devices. In a smart home scenario, it is usually represented by a home assistant (e.g., Amazon Alexa or Google Home). All communication flows through the central hub, which acts as a centralized point of control and coordination. This topology offers simplicity in management and facilitates efficient communication between devices and the central hub. However, it can pose limitations in terms of scalability and fault tolerance, as the entire network relies on the central component.



The mesh topology (Figure 4b) involves interconnecting multiple devices in a decentralized manner. Specifically, we considered a fully connected network, a particular case of a mesh network where each device can communicate directly with all the other devices. This topology provides robustness and redundancy, as there are multiple paths for data transmission. It can adapt well to dynamic environments and enables better fault tolerance. However, the complexity of managing and coordinating communication among numerous devices increases with the size of the network. By considering both the star and mesh topologies in our experiments, we aimed to assess the performance and suitability of EVOKE in different network configurations.

Table 4: Performance evaluation of EVOKE operations on commodity IoT devices with different network topologies.

Topology	Approach	Total Latency (Verify + Transfer)	E2E Latency
Star Network	EVOKE	1152.7 ms	948.3 ms
	Baseline	967.7 ms	705.5 ms
Mesh Network	EVOKE	545.2 ms	307.5 ms
	Baseline	97.4 ms	91.7 ms

To evaluate the performance of the two network topologies, we implemented them using a local cluster consisting of five Raspberry Pi4 provided with 8GB RAM. All Raspberry Pis were connected to the same Wi-Fi network, ensuring a controlled environment for our experiments. This setup allowed us to observe the network configurations and measure latency with precision. However, due to the inherent variations in clock accuracy among different devices, it was essential to synchronize their timestamps accurately to obtain reliable metrics in our experiments. To achieve this, we utilized the Network Time Protocol (NTP) [36], a widely adopted networking protocol specifically designed for clock synchronization in distributed networks.

In Table 4, we present the results for the two network topologies examined in our study. We focus on the key metrics: total latency and end-to-end (E2E) latency. The total latency encompasses the overall delay in establishing trust between two updated devices. On the other hand, E2E latency specifically captures the time taken for the verification data to traverse between devices. As expected, the star network exhibits latency more than double that of the mesh network. This discrepancy arises due to the higher number of devices involved in interactions within the star network. Notably, network overhead, including synchronization delay introduced by NTP, is the main factor that affects the overall latency. To evaluate the EVOKE's overhead, we compared it to a *baseline*, which represents latencies when sending a minimal amount of data across the same network configurations without perform-

(a) 10% devices missing updates (b) 30% devices missing updates (c) 50% devices missing updates

Figure 5: Percentage of updated IoT devices by EVOKE with varying the number of devices that miss updates with 5 interactions per device per hour.

ing any operations. It is worth noting that since the baseline only involves a minimal amount of data, it is expected to have better performance than any other revocation mechanism. EVOKE operations for verifying VCs only contribute a few milliseconds per device, posing minimal impact on total latency. Therefore, the increased latency between EVOKE and the baseline, in both configurations, is due to the transfer of revocation information. However, EVOKE's required size is much lower than existing approaches.

6.4 Large-scale Analysis

To conduct a scalability evaluation of EVOKE, an extensive number of devices would be required. However, due to practical limitations, we implemented a large-scale network simulation of IoT devices. The simulation was run on an 11th Gen Intel(R) Core(TM) i7-11370H @ 3.30GHz equipped with 4 cores and 16GB of RAM. The configurations we considered involved scaling the number of devices from 10,000 up to 1 million over a simulated week.

In addition to assessing scalability, our experiments also focused on evaluating the effectiveness of offline updates. To achieve this, we categorized devices as either updated or outdated, with varying percentages of devices missing updates. Additionally, an outdated device can be normal or constrained, the former supports direct retrieval, while constrained devices can only be updated indirectly. We adopted a revocation share of approximately 0.028% of VCs per day (almost 10% yearly), based on similar studies [27] that addressed PKI-certificate revocation. This estimation was derived from the impact of the Heartbleed bug on certificates [31]. When the issuer revokes a VC, the accumulator value and witnesses are updated and disseminated through the Tangle. However, due to various circumstances such as lack of connectivity or devices being in power-saving hibernation mode, a portion of IoT devices may not receive these updates. In our simulations, we considered different missing shares of 10%, 30%, and 50% in different experiment executions to understand the impact of outdated devices on the system. The number of interactions among devices depends on several factors including purpose, communication protocols, and the nature of the data being processed. For our evaluation, we consider the same network set-up of [27], where each device in a satellite network communicates with 5 random devices within an hour. Further experiments and considerations are presented in Appendix. During the interactions, devices exchange their accumulator values implementing the protocol described in Section 4. Therefore if a device has an outdated witness, the node with the older version requests an updated witness from the Tangle node or the interacting device if the capabilities are not sufficient.

Table 5: EVOKE's communication overhead to update offline devices with 5 interactions per device per hour.

Number of Devices	% Devices Missing Updates	Network Overhead (Accumulator + Witnesses)
10K	10	1.49 MB
	30	4.42 MB
	50	7.19 MB
50K	10	7.45 MB
	30	22.03 MB
	50	36.05 MB
500K	10	74.51 MB
	30	220.44 MB
	50	360.70 MB
1M	10	155.43 MB
	30	452.13 MB
	50	721.67 MB

In Figure 5, we highlight the percentage of updated IoT devices in one hour by EVOKE while varying the number of devices missing updates. The `Updated` bars indicate the percentage of devices that have received the novel accumulator value and witnesses, while the `Missing` bars denote the

percentage of devices missing such information. As clearly shown, the percentage of updated devices is not affected by the number of devices. The experimental results demonstrate that EVOKE can update the whole IoT network in the first hour when the number of devices missing updates is 10%. By increasing the number of disconnected devices to 30% and 50%, the percentage of updated devices in the network reached approximately 98% and 96%, respectively. Table 5 presents the network overhead, defined as the amount of data exchanged to updated devices that failed to receive updates. As expected, the overhead grows with both the number of devices and devices missing updates. This increase is due to the higher number of interactions that occur in the network.

Figure 6 illustrates, on a log scale, the three primary overheads encountered on the issuer side: the generation of the accumulator value, the production of witnesses for the included VCs, and the updating of the accumulator value. This latter comprises the removal of VCs and the generation of witnesses, which are obtained by the latest valid accumulator value. The update of the accumulator value was analyzed under various scenarios, considering different percentages of revoked VCs: 10%, 25%, and 50%. Evaluating EVOKE while revoking half of the issued VCs demonstrates its efficiency in handling mass revocations: the store requirements are not affected, while as the revoked VC percentage rises, the accumulator value time decreases due to fewer witnesses generated. This result is because updating the accumulator value involves the removal of VCs, which in turn reduces the number of witnesses to be generated. The graph highlights that the generation of witnesses is the most time-consuming operation. As demonstrated [5], the number of operations needed to generate w witnesses requires at least $\Omega(w)$ operations. However, even when generating 1 million witnesses, the process only requires 80K ms. It is important to note that issuers typically have more computational power, enabling a significant reduction in this overhead.

6.5 Discussion of Results

In this section, we present further considerations regarding the conducted experiments. As previously mentioned, to ensure consistency across all scenarios, including those involving commodity IoT devices, we implemented all experiments using the same JavaScript and WASM libraries. It is worth noting that employing diverse implementations and programming languages could potentially yield improved performance outcomes. These variations could lead to optimized execution and better resource utilization. Moreover, any revocation protocol is affected by the characteristics of the region in terms of latency and bandwidth. However, EVOKE's efficiency consists of minimizing storage and verification time on devices, hence, its performance is independent of the considered geographic area.

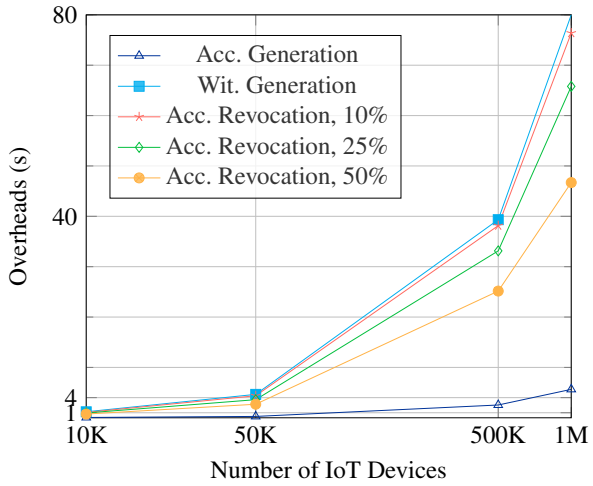


Figure 6: Large scale analysis: Issuer overhead for managing VCs.

Commodity IoT Devices. Vendors typically restrict end users from directly running code on their devices. To demonstrate the compatibility of EVOKE with commodity devices, we developed a JavaScript/WASM application. In this approach, a device sends a request to a server, which responds with an HTML page containing our JavaScript code. This allows the execution of the primary EVOKE operations on the device itself. It is important to note that we had to consider commodity devices with a browser connection to run EVOKE through JavaScript/WASM. Nevertheless, we demonstrated that vendors have the opportunity to integrate EVOKE into their products. The results reported in Tables 3 and 4 demonstrate that EVOKE already achieves remarkable performance when implemented in JavaScript. This underscores its potential for enhanced performance if vendors permit its native execution on devices. Additionally, the ECC-based accumulator used by EVOKE requires very limited storage and efficient verification times, making it particularly suitable for devices with constrained capabilities.

Hybrid Network Settings. The adoption of a hybrid network, which combines both off-the-shelf devices and single-board computers such as Raspberry Pis, provides a holistic approach to exploring the potential of our solution. This setup not only demonstrates the versatility of EVOKE but also broadens its scope, making it applicable in contexts where different types of devices coexist and require efficient and secure management of VCs. Through this set of experiments, we demonstrated the applicability of EVOKE even when the code is not executed directly on the target device but rather on the controlling board. This flexibility opens up new possibilities for deploying our solution in diverse environments. Moreover, the introduction of a controller in the network further expands the potential applications of EVOKE. By incorporating a controller into the system, we can extend the utilization

of VCs and, consequently, the use of EVOKE to encompass more resource-constrained devices. This capability becomes especially relevant for incorporating small sensors that lack the computational power to handle VCs or any revocation mechanisms directly.

Large-Scale Analysis. This set of experiments allowed us to demonstrate two important features of EVOKE that can be achieved through the accumulator: mass and offline revocation. The size of the accumulator value does not increase with the number of devices, thus, it can be employed for massively revoking VCs in any IoT network. The information stored by each device for the accumulator value and witness is always in the order of 1.5 KB. Including the accumulator value within a VC signed by the issuer and the reduced size of the accumulator value itself enable updated devices to update the ones that missed fresh revocation information. Also when 50% of devices are missing updates, after 1 hour, around 96% of the whole network has been successfully updated. As shown in Section 7, the amount of data related to revocation of EVOKE is minimal compared to other approaches. Figure 6 demonstrates that the main overhead is given by the generation and dissemination of witnesses. However, the issuer has the necessary resources to efficiently compute them. Notably, these overheads do not impact the EVOKE's performance in terms of storage and verification time on devices, which is the primary objective of our revocation scheme.

7 Comparison to Other Approaches

This section compares EVOKE to the state-of-the-art techniques in the revocation space and V'CER [27], which we consider the closest work in the literature. It is worth noting that these approaches are applied to PKI certificates, but they can be extended to VCs. An overview of the approaches discussed in this section is reported in Table 6. The storage column indicates the size required per device to store the whole revocation information of 1 million certificates or VCs, according to the focus of the work.

OCSP. In OCSP [42], the verifier sends a request to the issuer to check the validity of the presented VC. The traditional OCSP approach assumes the verifier has a fast and reliable connection to the issuer. However, this assumption may not hold in IoT networks due to the network overhead and the limited connectivity capabilities of certain devices. OCSP Stapling offers a more efficient alternative. It shifts the responsibility of querying the issuer from the verifier to the presenter of the VC. The presenter periodically queries the issuer and appends a time-stamped OCSP response, which is signed by the issuer. Thus, the verifier can obtain the necessary information about the VC's validity without additional communication. While OCSP Stapling provides a more efficient approach, it is worth noting that the stapled OCSP responses have a limited validity period and do not guarantee information freshness, which is a key advantage of this protocol. Furthermore, each OCSP request typically consumes around 4 KB of data [31], which exceeds the 1.5 KB required by EVOKE. Recently, TinyOCSP [22] managed to reduce the size by approximately 70%; however, meeting this requirement while maintaining a reliable connection remains challenging in many IoT networks.

Table 6: Comparison of EVOKE to other approaches

Work	Storage 1M Cert/VC	Mass Revocation	Offline Revocation
EVOKE	1.5 KB	✓	✓
V'CER [27]	3 KB	×	✓
Revoc. List 2020 [53]	125 KB	×	×
CRLite [45]	112.5 KB	×	×
Let's Revoke [30]	70 KB	×	×
TinyOCSP [22]	×	×	×

CRLs. When using CRL [10], devices need to store the whole list. However, in IoT networks comprising many devices and VCs, the amount of data to memorize can be extremely large. A CRL that contains only strictly necessary information for 1 million certificates would require at least a few MBs of storage [31].

Concerning VCs, the only revocation mechanism proposed by W3C is the draft namely Revocation List 2020 [53]. It associates each VC with a position in a bitstring managed by the issuer. If the binary value at a specific position is set to 1, the VC is considered revoked; otherwise, it is considered valid. With 1 million VCs, this would result in approximately 125 KB of storage. However, the use of a bitstring offers the advantage of high compressibility since a significant number of credentials often remain unrevoked, leading to long sections of repetitive bits. By employing compression techniques like ZLIB [12], the compressed size of the bitstring can be nearly halved, assuming an average compression ratio of 50% in case of mass revocation. Although a lower percentage of revoked VCs would yield a higher compression ratio, the memory storage would still exceed that of EVOKE. Indeed, EVOKE always requires that each device only stores 1.5 KB, even though the number of devices in the network may be larger. There are ongoing research efforts, such as CRLite [45] and Let's Revoke [30], aimed at reducing the storage and update overhead specifically for the Web's Public Key Infrastructure PKI. These solutions can reduce the size of the CRL to hundreds of kilobytes.

V'CER. In the literature, we find V'CER as the closest work to EVOKE. V'CER aims to tackle the challenge of efficient trust establishment on constrained networks using PKI certificates. V'CER adopts Sparse Merkle Trees (SMTs) [11], a type of MT that contains all possible hash values. Similar to our approach, V'CER concatenates valid certificates to create a hash root, which can be considered analogous to the final value of the accumulator in EVOKE. However, V'CER employs a small set of hashes called co-path as witnesses, which represents all sibling nodes on the path to the root and serves

as proof of inclusion. The size of this proof is $O(\log(n))$, where n is the number of leaves. Consequently, the storage required by devices may increase with the number of certificates. For instance, when dealing with 1 million certificates, the storage demand is approximately 3 KB. Although V'CER offers a valuable solution tailored for constrained devices, it demands twice the amount of data per device when compared to EVOKE. However, it offers the advantage of enabling devices to distributively repair their proofs in certain cases, without relying on CAs or delegates and supporting offline revocation. In contrast, EVOKE is the most efficient in terms of storage requirements since it demands around 1.5KB of storage and facilitates mutual assistance among devices to update.

Mass and Offline Revocation. Traditional approaches and their enhancements are unsuitable for IoT networks due to their storage and connection requirements, lacking adequate support for mass and offline revocation. By leveraging the features of the accumulator, EVOKE meets the requirements of mass revocation (Definition 1). On the contrary, related works do not meet them due to the usage of data structures whose size grows with the increase of the number of revoked VCs in the network, resulting in a longer verification time.

According to Definition 2, to support offline revocation, a revocation scheme must minimize the amount of data transmission to facilitate the sharing of revocation information. Other approaches employ bigger data structures that cause remarkable bandwidth overhead and make them unsuitable for constrained networks. For example, CRLs demand roughly two orders of magnitude greater than EVOKE for data transmission. Additionally, in the event of missed updates, these methods always rely on devices directly contacting the issuer or their delegates. In contrast, the very limited storage requirements of EVOKE as well as the use of VCs to share revocation information empower updated devices to bring outdated ones up to date.

8 Related Work

Despite the growing interest in VCs, there is a limited research that focuses on developing novel and efficient approaches for their revocation. In this section, we reviewed the existing literature on the revocation of VCs and related works for certificates/credentials, which can be eventually extended to VC, with a particular emphasis on IoT networks.

Verifiable Credential Revocation. Most studies lack a specific emphasis on constrained environments and use traditional revocation mechanisms [9]. For instance, Abraham et al. [2] proposed to revoke VCs by including them in a revocation list. To allow offline verification, nodes (i.e., issuers and users) can generate attestations for valid VCs. These attestations enable verifiers to determine the freshness of the presented credential, ensuring its validity. Recently, Fotiu et al. [18] introduced a lightweight revocation mechanism for VCs tailored for IoT environments, inspired by the W3C draft [53]. The proposed approach involves maintaining a revocation list, where each VC is assigned a position. The position information is embedded within each VC. If the corresponding position is set to 1, the VC is revoked. It is worth noting that this mechanism is most suitable for scenarios with a restricted number of VCs. A similar approach is also presented in [19], wherein in a group of IoT devices, each member is allowed to participate through a VC. The revocation list is included in a TXT DNS record a retrieved is identified through DNS resolution. This solution specifically refers to group member revocation and may not be suitable for use cases where devices are not clustered in groups.

Accumulator-based Approaches. Cryptographic accumulators have long been recognized as an efficient solution for revoking anonymous credentials and PKI certificates [6, 21]. However, most of the existing literature has primarily focused on user-centric revocation rather than efficient revocation in constrained networks. For example, in the protocol recently proposed by Parameswarath et al. [39], the accumulator is used to revoke user policy. The unique characteristics of accumulators, such as their constant memory size and verification time, harness them to design novel revocation schemes specifically tailored for IoT networks [7, 56]. In this direction, the most relevant related work is V'CER [27], an efficient certificate validation in constrained networks. V'CER adopts SMTs, a form of a hash-based accumulator, for performing revocation. The proposed approach achieves remarkable storage efficiency, requiring less than 3KB per node to store 1 million certificates, while also supporting offline updates.

DLT-based Approaches. Numerous studies [28, 44, 59] have highlighted the potential of DLTs in revolutionizing PKI-based authentication and authorization schemes. One particular area where blockchain technology has shown promise is in the management of certificates, with initial applications focusing on storing certificate updates and revocation information [16]. However, implementing a blockchain-based revocation system for IoT devices presents several challenges, including long latency, high energy consumption, and low transaction throughput. To address these challenges, innovative approaches [49, 57] leveraging DAG-based ledgers have emerged as a viable alternative for IoT networks. DAG-based ledgers offer a lightweight solution that maintains the same level of security as traditional blockchains while addressing the specific requirements of IoT environments.

Differences from Existing Works. While several existing approaches can be adapted for revoking VCs, they are often not suitable for constrained environments of IoT networks. In this context, EVOKE stands out as the first revocation scheme specifically designed for VCs in IoT networks. EVOKE offers offline revocation capabilities similar to V'CER, but with even lower storage overhead. Each device only requires less

than 1.5KB to store the accumulator value and the witness. Furthermore, EVOKE introduces the advantage of supporting mass revocation. Unlike traditional schemes, the size of the accumulator value and witness remains constant regardless of the number of included VCs.

9 Conclusion

VCs offer a promising solution to enhance trust among IoT devices. However, ensuring the efficient revocation of VCs in IoT networks remains a critical challenge that is still in its early stages of research. Our work lays the foundation for future research and developments in this field.

In this paper, we presented EVOKE, an innovative solution that addresses the efficient revocation of VCs in IoT networks. EVOKE harnesses the power of ECC-based accumulators to efficiently manage VCs with minimal computational and storage overhead. It also provides essential features like mass and offline revocation, making it a scalable and efficient revocation scheme for IoT networks. To comprehensively validate its effectiveness, we conducted extensive experiments comprising commodity IoT devices, hybrid network settings, and large-scale analysis. The results showcased the efficiency and practicality of EVOKE in real-world scenarios. Each device only demands 1.5 KB of storage for verification information. The experiments conducted in the hybrid network settings showed an overhead in the order of milliseconds for performing key operations. Finally, the large-scale analysis demonstrated its feature to update devices that miss revocation information.

(a) 10% devices missing updates (b) 30% devices missing updates (c) 50% devices missing updates

Figure 7: Percentage of updated IoT devices by EVOKE with varying the number of devices that miss updates with 1 interaction per device per hour.

Table 7: EVOKE's communication overhead to update offline devices with 1 interaction per device per hour.

Number of Devices	% Devices Missing Updates	Network Overhead (Accumulator + Witnesses)
10K	10	1.26 MB
	30	3.05 MB
	50	3.75 MB
50K	10	6.77 MB
	30	15.66 MB
	50	18.61 MB
500K	10	67.53 MB
	30	157.36 MB
	50	186.91 MB
1M	10	134.58 MB
	30	315.16 MB
	50	375.76 MB

Appendix

This section provides additional experiments and results for the large-scale analysis presented in Subsection 6.4.

A.1 Additional Experiments

To show how EVOKE performs in scenarios with lower interaction rates, we conducted additional experiments by setting the number of interactions per device per hour to 1. It is worth noting that EVOKE would perform even better in scenarios with higher interaction rates. Therefore, we did not consider configurations that foresee more than 5 interactions per hour. For consistency with the experiments reported in Subsection 6.4, we maintained the revocation share and the percentage of devices missing updates unchanged. Figure 7 depicts the percentage of updated IoT devices in one hour by EVOKE while varying the number of devices missing updates when the number of interactions per hour is set to 1. Similar to previous observations outlined in Subsection 6.4, the percentage of updated devices does not depend on the number of devices.

The experimental findings demonstrate that even in scenarios with lower interaction rates, EVOKE exhibits remarkable performance in updating the entire IoT network in the first hour when 10% of devices miss updates. However, as the number of disconnected devices increases to 30% and 50%, the percentage of updated devices decreases to approximately 91% and 75%, respectively. This demonstrates the robustness of EVOKE in updating the network despite a decrease in interaction frequency. Further insights into EVOKE's performance are presented in Table 7, detailing its communication overhead for updating offline devices in the examined configuration. As expected, the network overhead decreases with the number of interactions per device per hour.

DNN-GP: Diagnosing and Mitigating Model's Faults Using Latent Concepts

Abstract

Despite the impressive capabilities of Deep Neural Networks (DNN), these systems remain fault-prone due to unresolved issues of robustness to perturbations and concept drift. Existing approaches to interpreting faults often provide only low-level abstractions, while struggling to extract meaningful concepts to understand the root cause. Furthermore, these prior methods lack integration and generalization across multiple types of faults. To address these limitations, we present a fault diagnosis tool (akin to a General Practitioner) DNN-GP, an integrated interpreter designed to diagnose various types of model faults through the interpretation of latent concepts. DNN-GP incorporates probing samples derived from adversarial attacks, semantic attacks, and samples exhibiting drifting issues to provide a comprehensible interpretation of a model's erroneous decisions. Armed with an awareness of the faults, DNN-GP derives countermeasures from the concept space to bolster the model's resilience. DNN-GP is trained once on a dataset and can be transferred to provide versatile, unsupervised diagnoses for other models, and is sufficiently general to effectively mitigate unseen attacks. DNN-GP is evaluated on three real-world datasets covering both attack and drift scenarios to demonstrate state-to-the-art detection accuracy (near 100%) with low false positive rates ($< 5\%$).

1 Introduction

Deep Neural Networks (DNN) have become integral to pushing the envelope of decision making performance in an increasing number [16] like health [8, 21], transportation [32, 44], and security-sensitive areas [46]. However, they have been demonstrated to make blunders, often due to issues related to Adversarial Robustness [12, 13, 33] and Concept Drift [18, 35]. A persisting challenge mitigating the effect of these blunders is the ability to interpret why these fault decisions were made and identify the the root cause [51].

Research Gaps. Despite the significant strides made in understanding the DNN-related errors, two salient gaps persist, the low-level abstraction of interpreting faults, and the lack of an integrated approach to resolving different faults.

Low-level Abstraction of Interpretations. Current techniques, such as Grad-CAM [15, 50], visualize the importance of image features to decision making with heat maps at the individual pixel-level per instance. While detailed, this approach does not reveal the high-level *root causes* of the misclassification. Effective interpretations necessitate operating at a higher level of abstraction, for example at a conceptual level [3, 7, 28, 36]. Unfortunately, these conceptual approaches have been developed to operate on tabular attribute data, posing significant challenges in extracting meaningful concepts from high-dimensional data, like images. An alternative approach involves using autoencoders [54] to transform high-dimensional input into an interpretable latent space. However, such free-form one-to-one mappings are hard to reliably capture consistent, recurring, and global features in the data. Thus, it is difficult to construct a comprehensive concept space.

Lack of Defense Integration. Existing solutions are always narrow-focused approaches to address specialized vulnerabilities or achieve particular generalizations of a given attack. Due to the arms-race development of machine learning attacks and their respective defenses, these proposals have not sought the breadth to concurrently address an array of vulnerabilities. A quintessential solution should boast the versatility to diagnose a myriad of models across diverse faults, solely equipped with knowledge of the clean or original dataset. For instance, a diagnostic methodology crafted to tackle adversarial perturbations should be equally adept at addressing semantic transformations leading to model inaccuracies. Moreover, the crux of the diagnostic process lies not just in identifying faults but in using this insight as a springboard to bolster fault mitigation, ultimately fortifying model resilience.

Research Question. Given these gaps, research question is *"to propose an interpreter that can develop a conceptual space to diagnose model's faults caused by adversarial/semantic attacks, and data drift, then to guide efficient mitigation."*

Motivation. To this end, we propose DNN-GP, an integrated interpreter to diagnose various types of vulnerabilities and

faults using latent conceptual interpretation. The motivation behind DNN-GP is threefold:

Global Consistent Conceptual Space. Our strategy relies on mapping high-dimensional input to a low-dimensional latent conceptual space that is both consistent and informative. Here, a global concept codebook plays a pivotal role in preventing free-form latent representations derived from ordinary autoencoders. It helps to direct the encoder towards a set of fixed, globally shared concepts (one-to-standard). Every concept in the global codebook essentially serves as a prototype, encapsulating a cluster of similar features from the dataset. One strength of the concept codebook is its ability to self-learn from training data, eliminating the need for prior domain-specific knowledge. This provides a compact and summarized representation of the data while ensuring that the latent space is interpretable through concepts, with each codebook concept offering insights into underlying patterns of the dataset.

Comprehensive Diagnosis. By deploying the encoder alongside the global concept codebook, we can seamlessly diagnose samples. This is achieved by encoding each sample into its latent representation, followed by aligning this representation with the global concepts from the codebook. Consequently, both the aligned concept index and the associated alignment distance serve as diagnostic indicators, effectively quantifying how the sample deviates from the established norms in the original dataset based on the hypothesis testing. We then apply further diagnostic methodologies to dissect samples stemming from existing adversarial attacks, semantic attacks and data drifting issues, named probing samples. As shown in Figure 1, DNN-GP provides three-tiered diagnostics: *(i)* Concept Patterns of Usage and Alignment: DNN-GP's encoder maps the input into a 2D latent representation, such as the aligned concept index matrix coupled with the corresponding alignment distance matrix. This enables the identification of aberrant distance distribution patterns and the detection of unusual or susceptible concept usages (red concepts and bars of Figure 1). *(ii)* Spatial Patterns in Latent Space: The 2D latent representation can also reveal abstract spatial patterns. For example, by comparing the average alignment distance matrices of original and attack datasets, we can unearth the underlying causes of model misclassifications. Visualization of these patterns suggests that perturbations causing misclassifications in gender often resemble makeup applications in facial areas. *(iii)* Pixel Pattern via Reconstruction: DNN-GP is adept at converting non-structural perturbations at the pixel level into structured patterns in the pixel space via reconstruction. These discernible patterns serve as a valuable reference to assist in understanding attacks.

Effective Mitigation. Utilizing the diagnostic insights from DNN-GP, we can devise conceptual strategies to bolster a model's resilience. For instance, feature selection can be applied to the latent conceptual representation to detect malicious or anomalous samples from benign ones. These subsequent mitigation strategies boast the benefits of being model- and attack-agnostic. As DNN-GP's countermeasures are rooted in the foundational latent conceptual representations derived from the original dataset, it sidesteps the vulnerabilities of current interpretation methods, which are susceptible to adversarial manipulations.

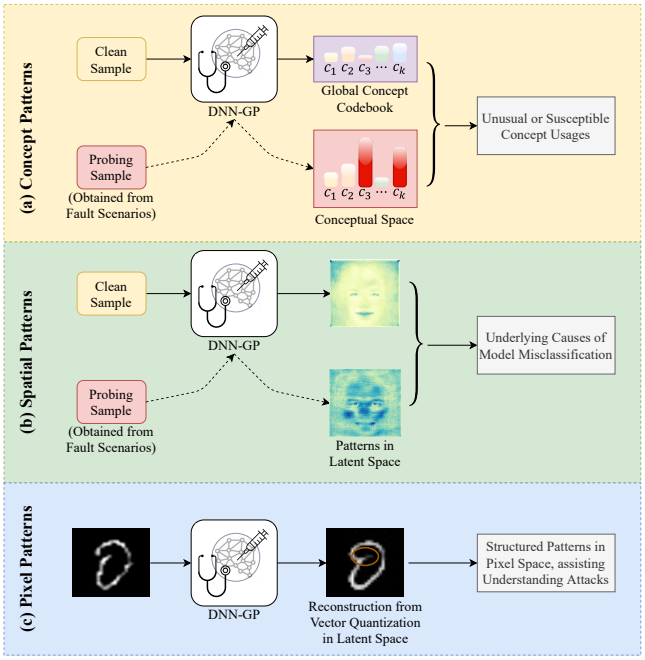

Figure 1: An illustration of DNN-GP's three-tiered approach to diagnose DNN faults and data quality issues.

Contributions. Key contributions are summarized as follows:

(i) Benchmark Dataset. We curate a benchmark dataset with a wide spectrum of model vulnerabilities, including adversarial attacks, semantic attacks, and data drift instances.

(ii) Integrated Diagnostic Tool. Introducing DNN-GP, a open diagnostic tool that elucidates DNN faults using patterns in the conceptual space. Once trained on a dataset, DNN-GP offers a continuous, versatile, and unsupervised diagnosis and mitigation across various models and faults.

(iii) Innovative Perspective. DNN-GP introduces a fresh lens to anchor probing samples within a consistent conceptual space, moving beyond instance-level model interpretations. This allows a handful of probing samples to catalyze insights into the underlying causes of model's faults to inform decisions on vulnerability evaluations, strengthen resilience, and/or formulate adversarial tactics.

(iv) Resilience Detection. We introduce an approach that harnesses latent concept representation to bolster model robustness through detection. This detection mechanism achieves state-of-the-art performance, nearing 100% with minimal false positives. It excels in an unsupervised, fault-agnostic, model-independent, and streamlined fashion. Notably, our method adeptly identifies even advanced attacks with minimal perturbations, outperforming existing solutions.

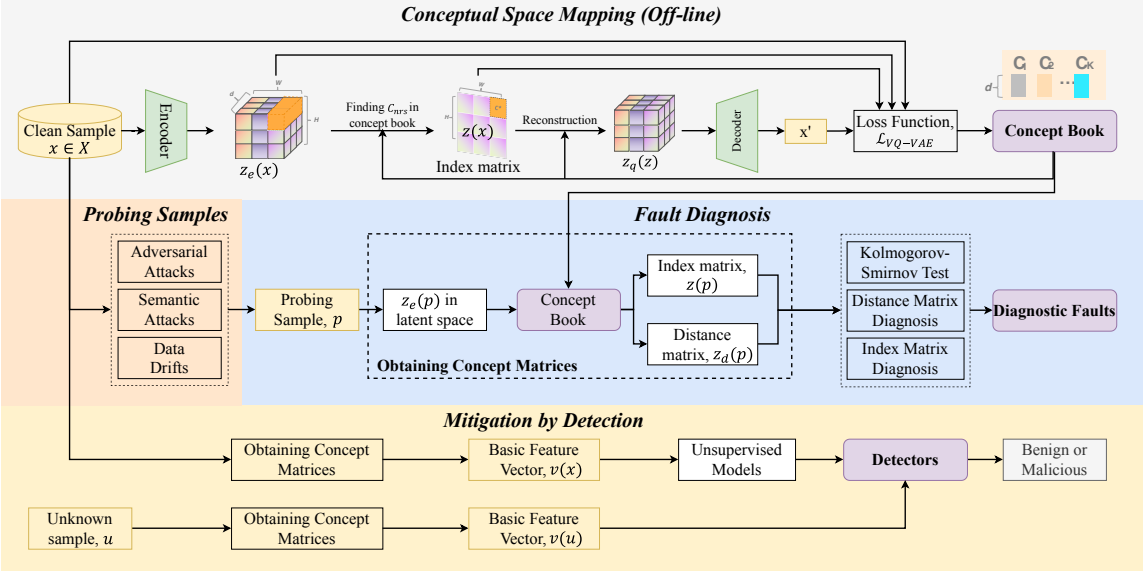

Figure 2: Functional overview of the DNN-GP. Observe how DNN-GP establishes a learned aligned concept book from a data distribution, leverages probing samples to diagnose a range of faults, and uses latent concept alignments to mitigate faults.

2 DNN-GP

Our system comprises four components in Figure 2.
***(i)* Probing Samples.** To unravel the intricacies of DNN behavior, we delve into three distinct fault scenarios from which we derive our 'probing samples'. The scenarios span Adversarial Examples, Semantic Attacks, and Data Drift.
***(ii)* Conceptual Space Mapping.** Leveraging Vector Quantization, we train an encoder and establish a global codebook from the original dataset. This framework allows us to craft latent conceptual representations for samples, achieved by aligning their encoded embeddings to global concept markers. This process is enriched with a clustering-driven alignment technique, ensuring a finer granularity of the conceptual space.
***(iii)* Fault Diagnosis.** Delving deeper into the outcomes from the second component, we employ statistical methods on the aligned concept index matrices and their respective distance matrices. This analytical approach aids in elucidating the DNN's response to the probing samples.
***(iv)* Mitigation.** Given diagnostic findings, we advocate for mitigation strategies, with an emphasis on identifying anomalous or malicious samples rooted in latent concept patterns.

2.1 Probing Samples

We use three fault settings to obtain "probing samples", including *adversarial attacks* for both white-box (e.g., Fast Gradient Sign Method (FGSM) [20], Projected Gradient Descent (PGD) [39], DeepFool [42], JSMA [45], Carlini & Wagner C&W [14] and Pixel Attack [29]) and black-box (e.g., Square Attack [5]), *semantic attacks* (e.g. contrast change [19], rotation [17], color-shift [25]) and *data drifts* (e.g., MNIST-C [43] and CIFAR-C [24]). By analyzing probing samples, we can gain a deeper understanding of patterns resulting in faults, and develop strategies to mitigate vulnerabilities. Detailed settings of probing samples are in Appendix A.

2.2 Conceptual Space Mapping

2.2.1 Construction of Concept Codebook

Vector Quantized Variational AutoEncoders (VQ-VAE) [47] are used to learn discrete conceptual representations of data and a global conceptual dictionary or codebook. In general, a VQ-VAE consists of three components, the encoder $\mathrm{En}(\cdot)$, decoder $\mathrm{De}(\cdot)$, and codebook $C = \{\boldsymbol{c}_1, \cdots, \boldsymbol{c}_K\}$. The codebook C defines the commonly-shared latent embedding space $C \in \mathbb{R}^{K \times d}$, consisting of K categorical embedding items with d dimensions, which we call *concept* item, i.e., $\boldsymbol{c}_i \in \mathbb{R}^d,\ i \in \{1, 2, \ldots, K\}$. The encoder is a non-linear mapping from the input instance $\boldsymbol{x}$ in the pixel space to the latent representation $\boldsymbol{z}_e(\boldsymbol{x}) \in \mathbb{R}^{W \times H \times d}$. Specifically, $W \times H$ latent embedding vectors with d dimension ($\boldsymbol{z}_e^{(i,j)} \in \mathbb{R}^d,\ i \in \{1, 2, \ldots, W\},\ j \in \{1, 2, \ldots, H\}$). Next, $H * W$ embedding vector of latent representation $\boldsymbol{z}_e(\boldsymbol{x})$ is further mapped to a discrete latent matrix $\boldsymbol{z} \in \mathbb{R}^{H*W}$. Here, each $z^{(i,j)} \in \boldsymbol{z}$ is the index of the nearest concept $\boldsymbol{c}_{\mathrm{nrs}}$ in the codebook for each $z_e^{(i,j)}$ via nearest neighbor searching $\arg\min_m \left\| z_e^{(i,j)}(\boldsymbol{x}) - \boldsymbol{c}_m \right\|$, i.e., the Vector Quantization. The decoder reconstructs the concepts in the pixel space by using the quantized embedding items $z_q(\boldsymbol{z})$ corresponding to the discrete latent concept index matrix via another non-linear function. Trainable components are the

encoder, decoder, and codebook. The loss function is:

$$\mathcal{L}_{\text{VQ-VAE}} = \text{Dist}(\boldsymbol{x} - \text{De}(\boldsymbol{z}_q(\boldsymbol{z}))) + \|\text{sg}[\text{En}(\boldsymbol{x})] - \boldsymbol{c}_{\text{nrs}}\|_2^2 + \beta\|\text{sg}[\boldsymbol{c}_{\text{nrs}}] - \text{En}(\boldsymbol{x})\|_2^2, \quad (1)$$

where $\text{sg}[\cdot]$ is a stop-gradient operation that blocks gradients from flowing into its argument, β is a hyperparameter, and $\text{Dist}(\boldsymbol{x} - \text{De}(\boldsymbol{z_q}(\boldsymbol{z})))$ reveals the reconstruction error. The procedures of training the encoder and decoder, updating the codebook and configuration of the exponential moving average follows two works [55] and [47].

2.2.2 Concept Alignment

To boost the utilization of concept codebook, we apply two enhancement strategies: clustering-based alignment and distance-based similarity to find the nearest vector.

Clustering-based Alignment. Given a pre-trained encoder and a learned codebook, the high-dimensional input can be transformed into an index matrix of concepts within the codebook. However, evaluations (demonstrated in Appendix B) showed that not all K concepts of the codebook were utilized, limiting its effectiveness for subsequent diagnostic procedures. A clustering-based alignment for the codebook mitigates this under-utilization. After the first round of training, all image embeddings $\boldsymbol{z}_e$ are extracted from the training set using the current version of the encoder $\text{En}(\cdot)$ and codebook $C = \{\boldsymbol{c}_1, \cdots, \boldsymbol{c}_K\}$. Next, cluster centers are computed with k-means ($k = K$) for the set of $\boldsymbol{z}_e$. These new centers replace the existing concepts in the codebook. Finally, we fine-tune the VQ-VAE on the training data as the second round training. This ensures a reversible mapping between the updated codebook and images, enhancing the effectiveness of the diagnostic processes (improvements displayed in Appendix B).

Distance-based Similarity. To assist the selection of the nearest quantized concept for each embedding $\boldsymbol{z}_e(x)$, we incorporate the similarity between $\boldsymbol{z}_e(x)$ and its nearest concept as an additional feature for the index. Intuitively, the Euclidean distance between the pair serves as a metric for evaluating similarity. However, the Wasserstein distance, also known as the Earth Mover's distance, has proven to be effective in the context of generative models and continuous representation learning [6,22,53]. The advantage of the Wasserstein distance is that it can still reflect the closeness of two distributions even if the support sets of the two distributions do not overlap or have very little overlap. Therefore, we employ the Wasserstein distance as a similarity metric to align the embedding $z_e(x)$ to concepts in the codebook. Smaller Wasserstein distances indicate higher similarity between two vectors.

2.3 Diagnosis of DNNs' Faults

For diagnosing a DNN fault within a given sample, we rely on the **Index Matrix** $\boldsymbol{Z}$ and the **Distance Matrix** $\boldsymbol{Z_d}$. The index matrix captures the indices of the closest concepts from the codebook for each embedding vector in the input's latent representation, denoted as $\boldsymbol{z}_e(x)$. Concurrently, the distance matrix chronicles the alignment distances between these embedding vectors and their matched concepts. Utilizing both $\boldsymbol{Z}$ and $\boldsymbol{Z}_d$, we derive a composite feature vector for each sample by amalgamating the two matrices and integrating essential statistics (such as mean, variance, maximum, minimum, etc.) from the distance matrix. Subsequently, the final *basic feature* vector is generated through a Principal Component Analysis (PCA) [1] applied to this composite feature vector.

$$\boldsymbol{Z} = \begin{bmatrix} i_{11} & \dots & i_{1\text{H}} \\ \vdots & \ddots & \vdots \\ i_{\text{W}1} & \dots & i_{\text{WH}} \end{bmatrix}, \boldsymbol{Z_d} = \begin{bmatrix} d_{11} & \dots & d_{1\text{H}} \\ \vdots & \ddots & \vdots \\ d_{\text{W}1} & \dots & d_{\text{WH}} \end{bmatrix} \quad (2)$$

Pipeline. Our diagnostic investigation centers on the hypothesis: *"The alignment index matrix and alignment distance matrix can effectively differentiate attack samples from the original ones?"* If true, the subsequent question becomes: *"What malicious patterns emerge from this differentiation?"* Diagnostic exploration is structured into three processes:

***(i)* Kolmogorov-Smirnov (KS) Test.** We first evaluate the *Null Hypothesis $\mathcal{H}_0$: the samples of the original and attack samples are drawn from the same distribution* (Section 2.3.1).

***(ii)* Distance Matrix Diagnosis.** Next, we scrutinize discerning patterns or discrepancies from the sample-wise and position-wise distance distributions of the raw alignment matrix $\boldsymbol{Z}_d$ between original and attack. If the discrepancies remain elusive using raw $\boldsymbol{Z}_d$, we transition to the spectral domain of $\boldsymbol{Z}_d$, aiming to amplify underlying patterns (Section 2.3.2). The rationale behind spectral analysis is its efficacy in revealing structures and patterns which may not be immediately evident in the spatial domain.

***(iii)* Concept Index Diagnosis.** We subsequently examine the aligned concept index matrices of both the original and attack samples. Through a thorough assessment of the distribution and prominence of latent concepts, our objective is to pinpoint specific concept patterns that consistently correlate with faulty samples (Section 2.3.3).

***(iv)* Transition Patterns Diagnosis via Reconstruction.** We compare the investigating samples to their reconstructed counterparts in the pixel space. This diagnostic approach permits visual comparison to transfer nonstructural perturbation to malicious structural patterns, as depicted in Figure 1(c).

2.3.1 Kolmogorov-Smirnov (KS) Test

The KS test [40] is a non-parametric hypothesis test to determine if two sample distributions are different. The KS test operates under the *null hypothesis $\mathcal{H}_0$: the samples are drawn from the same distribution*. Given two empirical cumulative distribution functions (ECDFs), $F_n(x)$ and $G_m(x)$, the KS statistic D is defined as $D = \max_x |F_n(x) - G_m(x)|$. Intuitively, this statistic quantifies the greatest vertical distance

between the two ECDFs. Two values are calculated for the hypothesis testing, statistic D and p-value. The test statistic D is the maximum difference between the two cumulative distributions. The p-value is the probability of observing the test statistic as extreme as, or more extreme than, the statistic computed from the sample under the null hypothesis. Small p-values (typically $p < 0.05$) reject the null hypothesis.

2.3.2 Distance Matrix Diagnosis

We utilize three metrics for evaluating the distance matrix: sample-, position-wise distances, and spectral properties.

Sample-aware Distance Metrics. Given the distance matrix for a sample, we calculate the average distance across all position of the matrix: $d_s = \frac{\sum_i^W \sum_j^H d_{ij}}{H*W}$. Then, we calculate statistics like the mean and variance for all d_s of the dataset.

Position-aware Distance Metrics. We aggregate each position value of the distance matrix $\boldsymbol{Z}_d$ over all samples in the dataset: $d_p^{(i,j)} = \frac{\sum_x d_{ij}}{|\boldsymbol{X}|}$, where $|\boldsymbol{X}|$ is the size of the dataset. We also calculate the statistics of distance distribution on each position, like mean and variance. The variance provides insights into which specific areas of the latent representation deviate more than others.

Spectral Characteristic Metrics. Further, by applying the Fourier Transform [10] to the distance matrix, we can analyze the spectral properties (frequency components and energy intensity) of the distance values. With a quantification of energy across frequency components, we can discern potential anomalies in data between original and attack. We apply 2D Fourier Transform to transform the 2D distance matrix $\boldsymbol{Z}$ to the frequency domain: $F(u,v) = \sum_{i=1}^{W} \sum_{j=1}^{H} f(i,j) e^{-2\pi\left(\frac{u_i}{W} + \frac{v_j}{H}\right)}$, where $f(i,j)$ is an element of the distance matrix $\boldsymbol{Z}_d$. u and v represent spatial frequencies in the horizontal (along the x-axis) and vertical (along the y-axis) directions, respectively. To better visualize frequency components, the zero-frequency component is shifted to the center. When capturing spectral information, low frequencies typically represent principal information, while higher frequencies typically pertain to noise or finer details. Filters are used to isolate specific frequencies. The intensity of a frequency (and thus the information component) is proportional to its energy $E = \sum |F(u,v)|^2$.

2.3.3 Index Matrix Diagnosis

To emphasize the indices undergoing the most frequent changes or increased usage, we compare pairs of concept index metrics between original and attack data.

Concept Distribution. The usage of indices may reveal specific patterns unique to the original or attack samples.

Frequently Changed Position. Given a paired index matrix for an original sample x and its attack or faulty counterpart x', we compute a Boolean difference matrix, $\boldsymbol{BD}$, to discern discrepancies across the positions of both index matrices. Specifically, $BD^{(i,j)}$ is set to 0 if $\boldsymbol{Z}_x^{(i,j)} = \boldsymbol{Z}_{x'}^{(i,j)}$, otherwise 1. Accumulating these differences across all samples pinpoints positions undergoing concept changes most frequently. We spotlight the top-20 positions with the most recurrent shifts from the original to the adversarial samples, referred to as 'hotspots'. This offers insights into potential vulnerabilities or areas particularly prone to perturbation.

Transition Patterns. We examine the transition patterns between original and adversarial samples for individual positions. This analysis captures the most prevalent transition pairs $(\boldsymbol{Z}_x^{(i,j)}, \boldsymbol{Z}_{x'}^{(i,j)})$ and computes the entropy for each transition originating from a particular original index. The entropy for a concept index s is given by: $H(s) = -\sum_t p(s,t) \log_2 p(s,t)$, where $p(s,t)$ represents the probability of the transition pair $(\boldsymbol{Z}_x^{(s,t)}, \boldsymbol{Z}_{x'}^{(s,t)})$ among all possible transitions from s. Indices characterized by high entropy indicate diverse transitions, suggesting unpredictability. In contrast, those with low entropy signal consistent transitions to specific adversarial indices, offering potential insights into predictable adversarial strategies.

2.4 Mitigation by Detection

Beyond diagnosis, we construct detection approaches to distinguish between the class of malicious/abnormal samples and the original samples. Our primary objective in mitigation is to "Assess the richness of latent conceptual representations for the downstream tasks". To this end, we employ a simple end-to-end machine learning model for detection, leveraging our *basic features* (see Section 2.3) as a baseline. Only features from the original dataset is used to train an unsupervised detector, which is tested against our multiple fault settings with different attacks. We shall apply the unsupervised method of One-Class SVM [49] later in Section 6. We acknowledge other unsupervised models exist, including Local Outlier Factor (LOF) [9] and Elliptic Envelope [48], however One-Class SVM was sufficient to achieve state of the art results, and used as the lower bound of the effectiveness.

One-Class SVM finds a hyperplane that optimizes the separation between data points considered normal, with points outside this hyperplane as anomalies. One-Class SVM does not make strong assumptions about the requirement of the clean (or "normal") data. Given a set of training data, the objective of a one-class SVM is to find a function f such that: $f(x) = \mathbf{w} \cdot \phi(\mathbf{x}) - \rho$, where $\mathbf{w}$ is the weight vector, ϕ is a function mapping data to a higher-dimensional space (if a kernel trick is used), and ρ is a threshold. Samples with $f(\mathbf{x}) \leq 0$ are considered anomalies.

Metrics used to measure model performance include: Accuracy for a model's ability to correctly identify both faulty and original samples, and False Positive Rate (FPR) captures the ratio of mislabeled faulty samples as original samples.

3 Evaluation Settings

Our analysis compares diagnoses from an *Original Set* and an *Attack Set*. The Original Set is randomly sampled from the original validation set and serves as a point of reference. The Attack Set contains samples that are expected to exhibit notable change in the output of target models after perturbation, transformation or data drift. The following evaluation seeks to answer the following questions: *"Do the index and distance matrices contain enough distinguishing information to distinguish between original and attack (adversarial, semantic, or drifted) samples?"* and *"Do attack samples exhibit unique behavioral patterns within the index and distance matrices?"*

Datasets. Noting the increased difficulty of concept extraction from images compared to tabular data, in our experiments, we employ three benchmark datasets found in image classification tasks, including MNIST [31], CIFAR-10 [30] and CelebA [34]. Dataset specifics are expanded in Appendix C.

Models. We utilize Convolutional Neural Networks (CNNs), e.g., ordinary CNN with different layers, and standard models of ResNet-18 [23] and DenseNet-121 [26] as target models of evaluation. Detailed configurations are in Appendix C.

Attacks. We study adversarial attacks of FGSM, PGD, JSMA, DeepFool, CW attacks, and Pixel Attack. For semantic attacks, we investigate rotation and color shift attacks. The detailed description of such attacks can be found in Appendix A.

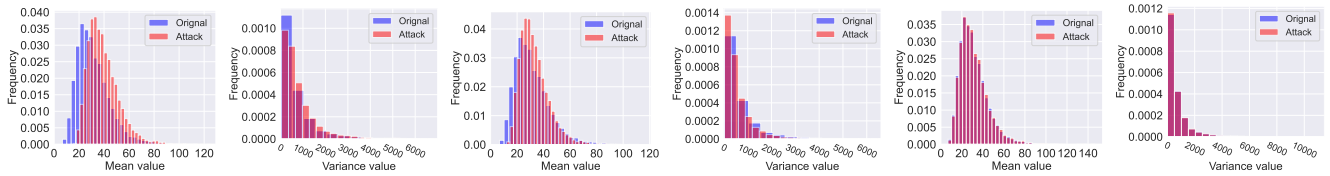
Detection Benchmarks. We use existing detection benchmarks for comparison, including unsupervised {Z-Score [52], NIC [37], MagNet [41](reconstruction error-based), and supervised LID [38]. Default settings are same with [4].

Difference. We reiterate that DNN-GP's detection approach delineates itself from other benchmarks through several key attributes. DNN-GP operates unsupervised and requires no white-box information of a model. Furthermore, it is lightweight and relies exclusively on the original data. Notably, its design is both fault-agnostic and model-independent.

For evaluating adversarial attacks, given the limited efficacy of current methodologies, we offer an extensive evaluation of the CIFAR-10 results in the main text, framing it as a worst-case scenario. While we provide brief summaries for the MNIST and CelebA datasets within the main body, their detailed results are presented in Appendix D. For semantic attack evaluation, we consider rotation for MNIST, CIFAR-10 and CelebA, contrast for MNIST, and Color shift for CIFAR-10 and CelebA. Our subsequent evaluation is separated by the type of fault, with Section 4 diagnosing Adversarial Examples, Section 5 diagnosing Semantic Attacks, and Section 6 evaluating downstream tasks of detection for attacks and data drift. Appendix D.2 presents auxiliary diagnosis of Data drift with similar conclusions to semantic attacks. Default (K,d,H,W) values for the VQ-VAE are given as: $(512,40,7,7)$ for MNIST, $(512,64,8,8)$ for CIFAR-10, and $(512,64,64,64)$ for CelebA. Default values for the One-Class SVM are: nu $= 0.04$, kernel = "rbf", gamma $= 0.01$.

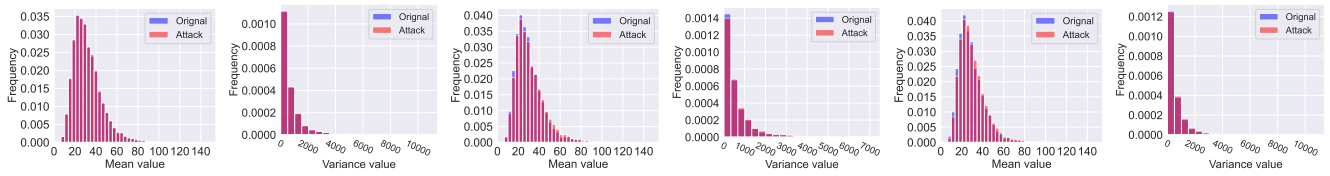
4 Diagnosis of Adversarial Examples

In this section, we perform a detailed diagnosis of perturbations that induce adversarial attacks. Our objective is to decipher the mechanics underpinning these perturbations and comprehend their conceptual implications. With foresight from our reconstruction error-driven detection results later in Section 6, we categorize the perturbations by stealthiness: ***(i)* Obvious Perturbations:** These are typically associated with attacks like FGSM or PGD that leverage larger perturbation factors (e.g., $\varepsilon \geq 32/255$). ***(ii)* Minimal Perturbations:** Bounded perturbations like CW, or those utilizing smaller scales (e.g., $\varepsilon < 32/255$). ***(iii)* Pixel Attack Perturbations:** Attacks whereby perturbations change fewer than three pixels.



4.1 Kolmogorov-Smirnov (KS) Test

To demonstrate the insights from the KS test, we first use FGSM with noise magnitude $32/255$ (obvious perturbation), CW-inf (minimal perturbation), Pixel (a challenging case), these tree form the basis of our evaluation moving forwards. We additionally include PDG, Deepfool and JSMA for additional comparisons. Table 1 presents the results of the KS test comparing basic feature distributions between the original and attack CIFAR-10 datasets. A key observation is that every adversarial attack type produces a p-value substantially below 0.05 across all noise levels. This outcome rejects the null hypothesis $\mathcal{H}_0$, suggesting that the original and perturbed data do not share the same distribution. Furthermore, as the magnitude of adversarial noise intensifies, there is a notable escalation in the D-statistic, leading to an even more diminished p-value. For example, as the noise magnitude in FGSM varies from $8/255$ to $32/255$, the D-statistic surges from 0.002 to 0.036. In each instance, the p-values remain below the 0.05 threshold. This suggests that higher adversarial noise magnitudes result in a distribution increasingly distinct from the original. Importantly, these significant distributional disparities arise regardless of the subtlety of the adversarial perturbations. The results on MNIST and CelebA also confirm these findings, with p-values substantially below 0.05 across all attack types and noise levels. We shall now delve into the patterns contributing to discrimination from the alignment distance matrix and index matrix.



4.2 Distance Matrix Diagnosis

Our diagnostic method for the distance matrix adopts two perspectives: one focuses on individual samples, while the other emphasizes particular positions within the matrix.

Sample-aware Metrics. The mean and variance of sample-aware distance between original and attack datasets is depicted in Figure 3. Seen from Figure 3a, we observe attacks with obvious perturbations (e.g., FGSM-32/255) demonstrate a distinct histogram pattern, with clearly separable peaks. We

(a) Mean (FGSM-32) (b) Var. (FGSM-32) (c) Mean (PGD-32) (d) Var. (PGD-32) (e) Mean (JSMA, inf) (f) Var. (JSMA, inf)

(g) Mean (DF, inf) (h) Var. (DF, inf) (i) Mean (CW, inf) (j) Var. (CW, inf) (k) Mean (Pixel, 3) (l) Var. (Pixel, 3)

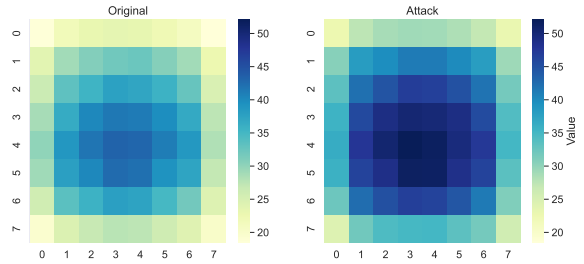


Figure 3: Sample-wise distance distributions of original and adversarial samples for different adversarial attack methods.

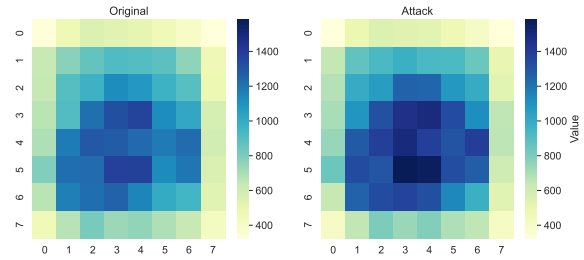
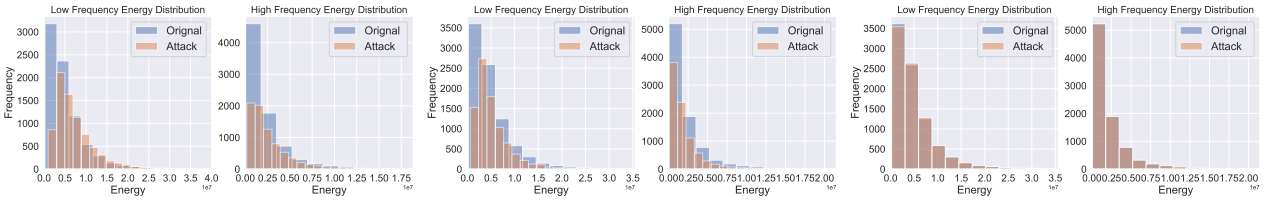
Table 1: KS test results between different attacks and the original CIFAR-10 distribution.



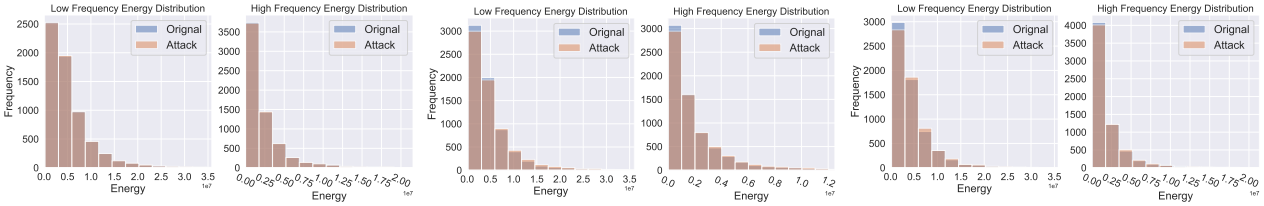
Attack Setting		D-value	p-value
Attack Method	Noise Parameter		
FGSM	8/255	0.002	0.048
	16/255	0.036	4.45×10^{-5}
	32/255	0.036	1.84×10^{-23}
PGD-Linf	8/255	0.008	2.49×10^{-17}
	16/255	0.029	1.30×10^{-219}
	32/255	0.089	≈ 0
CW-Linf	-	0.030	0.008
Pixel	3	0.003	0.030
DeepFool	-	0.002	0.022
JSMA	-	0.008	7.00×10^{-18}

also observe the variance of the informed datasets exceeds that of the original, signaling a broader distribution around the mean. When it comes to minimal perturbations (Figure 3i, CW) or pixel perturbations (Figure 3k, pixel attack with 3 pixels change), the distance distributions overlap. When the perturbation is small, attack samples are difficult to separate from the original samples with only the mean or variance of sample-wise distance.

Position-aware Metrics. Delving into the position-wise mean and variance metrics in the latent concept distance matrix visualized in Figure 4, the heatmaps provide a spatial sense of changes among the positions in a sample. We generally see larger perturbations yield relatively increased means, echoing our earlier observation in the sample-aware distributions. For the minimal perturbation scenario, the proportion of positions with pronounced distance values is less than the obvious perturbation. Nevertheless, examining the position-wise variation serves as an effective method to identify which positions are more susceptible or resilient.



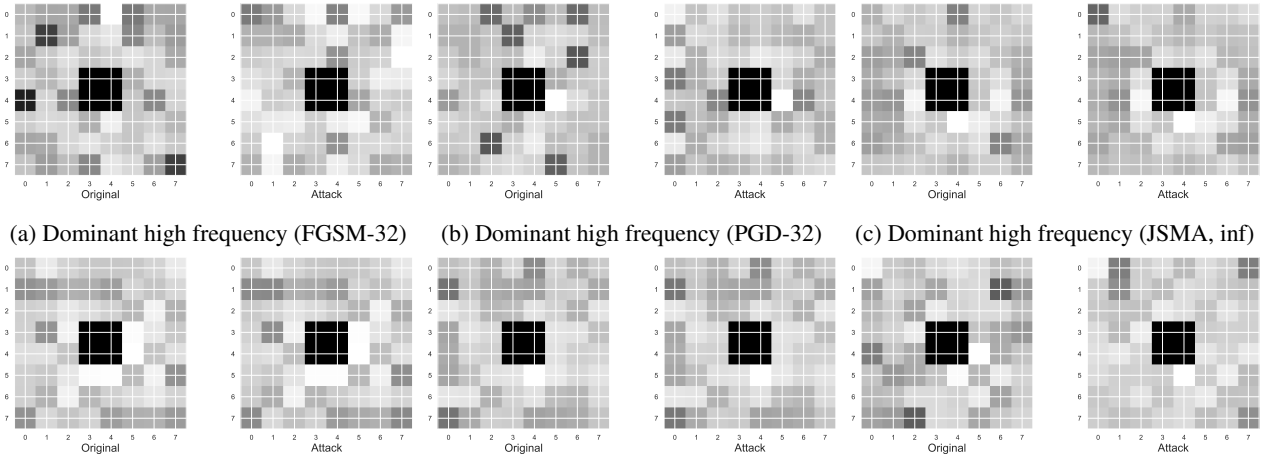
(a) Mean (FGSM-32)



(b) Variance (FGSM-32)

Figure 4: Position-wise distance distributions of original and adversarial samples with the FGSM attack.

Spectral Characteristic Metrics. Comparing the energy distribution of the low and high-frequency components between the original and attack data in Figure 5 observes differences in both low and high-frequency energy distributions between the original. The obvious perturbations have significant impacts on both overall structure (high-frequency) and detailed information (low-frequency), while minimal and pixel attacks mainly affect the detailed information and have no impact on the overall structure of the object. The high-frequency components can also capture some features of the affected areas. We also find that the influence of the perturbation is mainly reflected in the high-frequency components. Figure 6 confirms the spatial patterns in the respective high frequency



(a) Low/High energy dist. (FGSM-32) (b) Low/High energy dist. (PGD-32) (c) Low/High energy dist. (JSMA, inf)

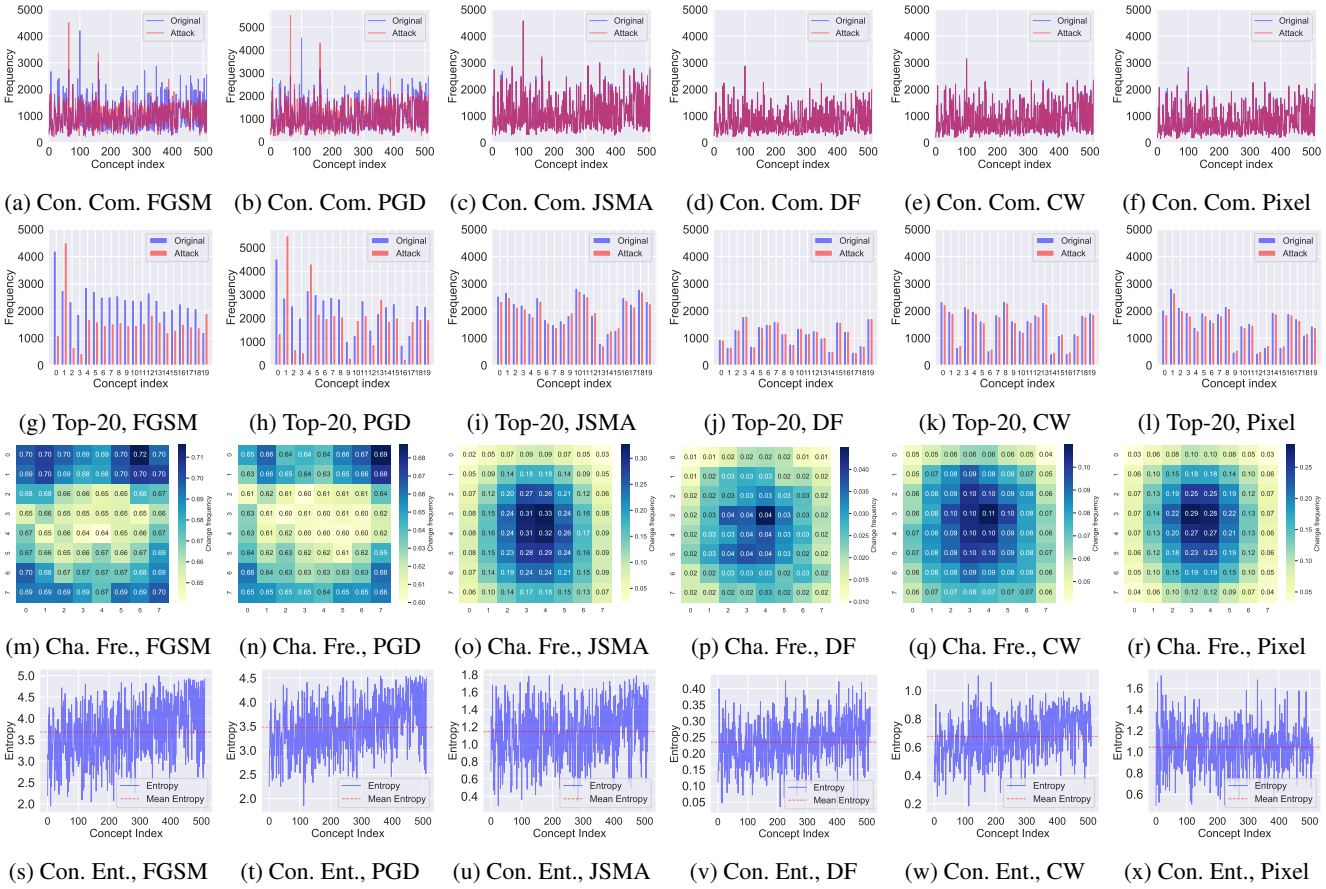
Figure 6: Dominant high frequency plots of original and adversarial samples for different adversarial attack methods.

components. The high frequency components magnify the discrepancy compared to the raw distance matrix domain.



These results provide a compelling visual representation of the differences in the distributions of distance. It is evident that the adversarial perturbation exhibits a distinct distribution pattern when compared to their original counterparts. Additionally, prominent perturbations exert a widespread influence across the data. In contrast, minimal and pixel-specific attacks are meticulously crafted to minimize their impact on the low-frequency components, focusing their perturbations predominantly on the high-frequency components.

We additionally present the efficacy of DNN-GP for DenseNet-121 and ResNet-18 architectures on CelebA-10, with comparable conclusions drawn from results shown in Appendix Figure 12 and 13. In conclusion, for obvious perturbations, differentiation can be accomplished by solely relying on alignment distance. Conversely, reliance on alignment distance alone presents challenges when differentiating minimized perturbations. This necessitates in-depth exploration of the features within the alignment index.

4.3 Index Matrix Diagnosis

The overall frequency and alterations of latent concepts occurring between the original and attack samples in addition to the spatial distribution of changes and the entropy of concepts are visualized in Figure 7.

Concept Distribution Analysis. We fist show the frequency distribution of specific concept indices. The first row of Figure 7 delineates the usage and prevalence of certain indices for both the original and adversarial sets. Identifying the most recurrent indices in both the original and attack sets offer

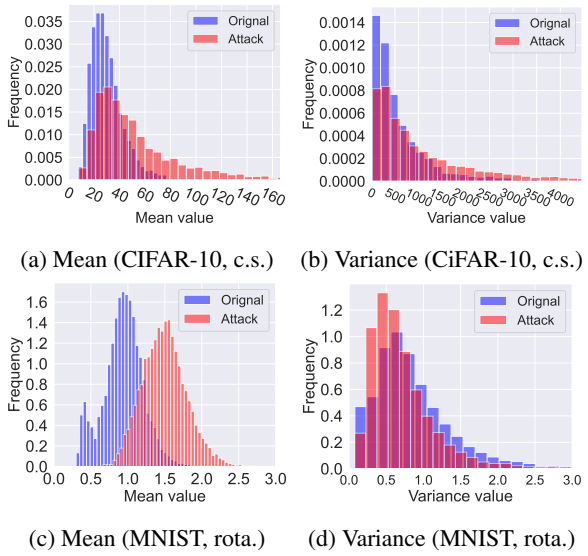
Figure 7: Latent concept index matrix metrics, *Con. Com.* represents 'concept comparison', *Top-20* refers to the top-20 indices exhibiting the largest discrepancies between the original and adversarial samples, *Cha. Fre.* refers to 'change frequency', and *Con. Ent.* refers to 'concept entropy'. The attacks are configured as follows, FGSM as (FGSM, 32/255), PGD as (PGD, 32), JSMA as (JSMA, inf), DF as (DeepFool, inf), CW as (CW, inf), and Pixel as (Pixel, 3).

insight into specific attack patterns or abnormalities. For example, Index 498, which corresponds to a "black background" upon reconstruction in the original dataset, emerges as a favored target for adversarial manipulation. In the second row of Figure 7, we emphasize the top-20 indices that exhibit the greatest discrepancy between the original and adversarial samples, highlighting instances where certain indices are notably more prevalent in one set over the other. For obvious perturbations, a strong contrast is evident in the frequently used indices between the original and adversarial samples. Both minimal and pixel perturbations exhibit a frequency distribution more akin to the original than the obvious perturbations do, with only slight differences in index usage between the original and the minimal/pixel perturbations. This underscores that obvious perturbations might introduce more distinct conceptual patterns than minimal perturbations.

Frequent Change Positions. We now investigate how faults induce changes to the latent concepts with regards to the relative positions of the latent concepts. Darker spots on the third row heatmaps of Figure 7 indicate positions with larger difference exist, implying that these positions are more frequently changed under an adversarial attack. The obvious perturbations indicate high amounts of conceptual change in across all positions (over 82% in all datasets). For the minimal and pixel perturbations, the greatest values of changes are lower, and are found towards the center of the concept heatmap. All of these perturbations a high frequently of changed positions, indicating that these positions are the vulnerable positions to be targeted. As certain positions within the grid exhibited more pronounced changes than other, recognizing these regions can be crucial for understanding and locating vulnerabilities or areas most affected by the attack.

Transition Patterns. We further calculate the entropy for each latent concept from the frequency of change in the sample sets. Low entropy reflects consistency in concepts between original and attack samples, with high entropy indicating greater transition between concepts. Consequently, concepts with high entropy values are more susceptible to being changed during the attack. The fourth row of Figure 7 shows pronounced perturbations yield a higher average entropy than minimal

and pixel perturbations. This can be attributed to the tighter constraints imposed on the design of the latter perturbations. Furthermore, it is feasible to identify a collection of recurring transition patterns at positions that garner significant interest.



4.4 Pixel-space Diagnosis

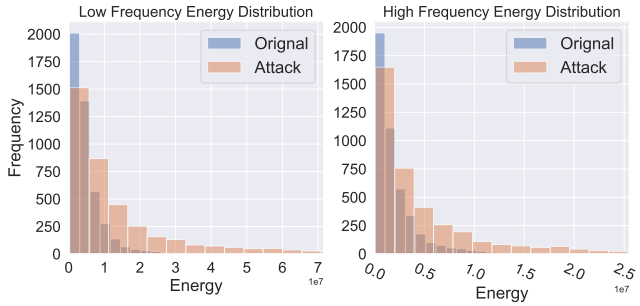
We also analyze adversarial perturbations based on reconstruction. Understanding the nature of the visual perturbations can provide insights into the conceptual vulnerabilities of the model and potential strategy of the attacker. In scenarios where the perturbation is evident to the human eye, the reconstructed versions of the attacked images can shed light on the meaning of latent concept the attacker attempts to exploit. For example, the absence of a small stroke or strike of the digit in Figure 1, with more examples in Appendix D.3. Such structural patterns may not be revealed in the attacked image only becoming evident after reconstruction. This suggests that the adversarial attack introduces features that sufficiently changes key latent concepts that alter the target class. Further, the adversarial output and reconstruction indicate this latent concept contains a vulnerability linking it to image regions beyond the visible stroke. On the other hand, vector quantization plays a pivotal defensive role by representing the original data with fewer bits, with similar data points mapped to the same concepts in the latent space. In the context of adversarial attacks, this means that the subtle, malicious changes introduced by an attacker can be"averaged out" or reduced during the quantization process. Thus, when the attacked image undergoes vector quantization and subsequently reconstructed, the impact of the adversarial perturbation is diminished, akin to a "purification" process. Despite these reconstructions mitigating perturbations, they retain and emphasize the essential structural and content influences of the original image. This dual characteristic ensures that while the adversarial noise is filtered out, the salient features of the image, which may have been the target of the adversary, remain discernible. Such a process offers valuable insights into both the robustness of the reconstruction mechanism and the specific targets or vulnerabilities that adversaries seek to exploit in a given model.

5 Diagnosis of Semantic Attacks

Recall that our objective remains to understand influence a semantic attack has on latent concept. Specifically, we investigate semantic attacks including rotation, contrast change on MNIST and the color shift attack with CIFAR-10.

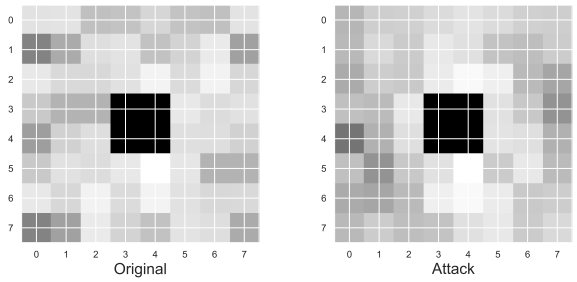
KS Test. The KS test for rotation, contrast and color shift yields a D statistic less than 0.05 with a p-value less than 0.05. As such we can confidently reject the null hypothesis that the samples of original and semantic attack are drawn from the same distribution.

(a) Mean (CIFAR-10, c.s.) (b) Variance (CiFAR-10, c.s.)



(c) Mean (MNIST, rota.) (d) Variance (MNIST, rota.)

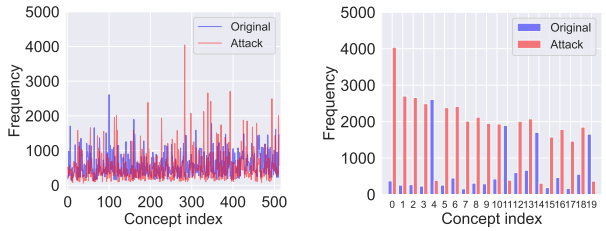
Figure 8: Sample-aware distance distributions of original samples and semantic attack samples. Here, *c.s.* indicates color shift attacks, and *rota.* indicates rotation attacks.



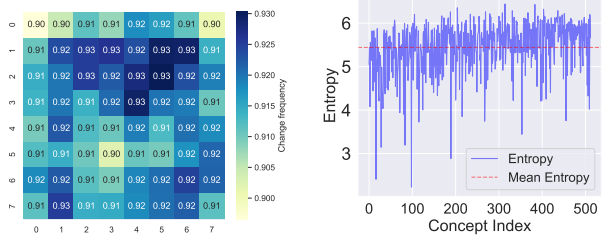
5.1 Distance Matrix Diagnosis

Sample-aware Distance Metrics. Recall the position-aware distance metrics are derived from the difference between the sample embedding vector and our codebook concepts. The mean and variance of these deviations are computed across the samples of the original (blue) and attack (red) data in Figure 8. There is an observable difference between the mean peaks, albeit, with overlap. Specifically, average sample-wise distance values show differences that separate the original and attack distribution. Their variance is also spread across a broader range for rotation and contrast change, emphasizing its increased variability. Smaller scales of the transformation in smaller distributions of distances are yielded by spatial rotation; however notably, the peaks of the distribution are clearly separable. In all attacks, the attack distributions skew to the larger side, presenting concepts that are unlike naturally aligned codebook concepts.

Spectral Characteristic Metrics. From the low and high frequencies components shown in Figure 9a, the low-frequency component can capture the overall structure of the object, with color shift having no significant impacts on the overall structure of the object. The high-frequency components of Figure 9b also capture contextual features of the color shift with similar observations for rotation and contrast in Appendix D. By comparing the energy distribution of the low and high-frequency components between the original and semantic attack data, we can see that there are significant differences in high-frequency energy distributions between them while the low-frequency parts remain the same for all three semantic attacks.



(a) Low/High energy dist.



(b) Dominant high frequency

(a) Concept comparison

(b) Top-20 comparison

(c) Change frequency

(d) Concept entropy

Figure 10: Latent concept index matrix metrics for the color shift semantic attack.

5.2 Index Matrix Diagnosis

Concept Distribution Analysis. With the histogram of frequency of latent concepts between our original and semantic attack samples displayed in Figure 10a, we can identify if particular concepts are more commonly to attack than others. We observed more unique index values that only appeared in either original or semantic attack samples, albeit in even lower quantities (in contrast to adversarial attacks). It is possible to observe the clear difference in the top-20 latent concepts with the largest differences after the semantic attack in Figure 10b.

Frequent Change Positions. Figure 10c's heatmap illustrates the position-wise spatial patterns between the original and attack concept index matrices. Brighter spots imply that these positions are more frequently altered during attacks.

We observe semantic attacks cause general changes of the aligned index for most positions in contrast to adversarial attacks. The widespread changes are a result of the transformation incorporating structural pattern changes that affect many pixels. Even with the color shift attack's global shift, there are still specific positions of the index matrix that retain low change frequencies. As such it is possible to design robust defenses or detection using these positions.

Transition Patterns. We finally calculate the entropy of transitions for each original index based on the original to attack sample transition matrix in Figure 10d. Indices with high entropy suggest that there is much variability in how they transition to attack indices, while those with low entropy tend to transition in a more consistent and predictable manner to specific attack indices. Additionally, some transition pairs have higher intensities, indicating certain transitions that occurred more frequently. This suggests that there are specific latent values are more susceptible to being changed during an attack, useful for both detection and mitigation efforts.

5.3 Pixel-space Diagnosis

Our final diagnosis delves into the transformations achieved through a decoder-based reconstruction for semantic attacks. We briefly describe our findings, with visual demonstrations of these transformations shown in Appendix D.3. Across all transformations, the reconstructed versions of the compromised images illuminate the intrinsic patterns targeted by the attacker. This reconstruction-based analysis is particularly beneficial as it demystifies the subtle adversarial alterations of each specific transformation, revealing the regions and features of the image that attackers deem critical for successful adversarial manipulation. By comprehensively examining these reconstructed images, researchers and practitioners alike can gain insights into potential areas of improvement for model robustness against semantic attacks.

6 Mitigation Countermeasures: Use Cases

We first benchmark DNN-GP's performance against standard detectors, followed by DNN-GP evaluated under adaptive attacks and data drift.

Table 2: Adversarial attack detection performance on CIFAR-10. DR and FPR is respectively the Detection Rate and False Positive Rate of a given detection method.

Attack Setting		Detection Baseline								**DNN-GP (Ours)**	
Attack type	Noise parameter	MagNet [41]		Z-score [52]		NIC [37]		LID [38]		One-Class SVM [49]

6.1 Detection Performance

We employ the detector detailed in Section 2.4 as a mitigation countermeasure, the detection results for CIFAR-10 are consolidated in Table 2. Notably, our proposed detector surpasses all pre-existing methodologies. Test samples consist of 500 successful attack samples based on 500 randomly selected testing original samples (100 from 100 for CelebA). Across all adversarial perturbations, from obvious (FGSM), minimal (CW), Deepfool, JSMA, pixel attacks, and black-box attacks (e.g., Square Attack) on CIFAR-10, our detector, leverages basic feature vectors in tandem with a One-Class SVM to achieve a detection rate of 100% and a false positive rate of 4%. This places DNN-GP significantly ahead of the current state-of-the-art methods, including NIC.

The detected 4% false positive rate within the original dataset indicates that a small subset of genuine data points was mistakenly classified as adversarial, as the cost of one-class classification. This rate can be further improved through sample reconstruction techniques, presented in Table 4 of Appendix D.3. Through reconstruction, the original samples observe a minimal accuracy reduction of 2% when transitioning to their reconstructed versions within the same classifier framework. Remarkably, for adversarial samples, over 87% are rectified to their correct labels, effectively neutralizing the malicious perturbations.

6.2 Analysis of Adaptive Attacks

In light of emerging threats from adaptive adversaries, devising a robust defense strategy necessitates a deep understanding of potential attack avenues. We examine two potent cases:

A1: Leveraging DNN-GP diagnosis for Adversarial Guidance. Attackers may employ the diagnostic insights from DNN-GP to identify and target specific regions that are either robust or susceptible. By pinpointing these regions, they can strategically craft perturbations to trigger misclassifications. Attackers consistently exploit the identified vulnerable regions, such as those positions with larger mean alignment distance values or those with high index change frequency. The detection accuracy would remain high, around 100%. The converse is also true, attempting to craft successful adversarial examples solely within the robust regions – those with smaller mean alignment distance values or low index change frequency – poses significant challenges. The inherent tug-of-war between vulnerability and detection accuracy arises from the foundational property of consistent conceptual alignment. Given that these concepts encapsulate the quintessential patterns and nuances of the dataset, any misalignment due to perturbations will inevitably disrupt this harmony.

A2: Detector as a Discriminator. Another conceivable attack strategy would involve using the detector itself as a discriminator to guide adversarial perturbation crafting, a setting akin to Generative Adversarial Networks (GANs). This approach proved to be extremely challenging in successfully generating adversarial samples that could deceive both the classifier and the detector simultaneously; the success rate was below 1% (e.g., 8 out of 10,000), with substantial computational resources consumed. Secondly, adaptive samples that did bypass the system were those that are generally difficult to recognize in nature from the testing dataset, as illustrated in Figure 16 of the Appendix.

To counteract detector-adaptive attacks, a multi-pronged strategy can be implemented. By training a series of detectors and a set threshold for adversarial scores (for example, detector confidence). If an input's computed adversarial score overshoots this threshold, the final prediction for that input should be derived from a weighted majority voting mechanism. The ensemble can be diversified in multiple ways: using

autoencoder models derived from various checkpoints during DNN-GP training, combining autoencoders from differing architectures, or combining detection techniques.

6.3 Data Drift Detection

We expanded our evaluation to encompass both the MNIST-C and CIFAR-10-C datasets, renowned for their corrupted and perturbed samples. These samples undergo various alterations including noise, blur, and changes in brightness, leading to a systematic decline in the performance of the model. We interpret these samples as data drifts deviating from the original dataset. To detect these drift samples, we trained a One-Class SVM model using the original samples alone. Our detection accuracy reached 100% for both MNIST-C and CIFAR-10-C, maintaining a false positive rate below 5%.

7 Takeaways and Limitations

We revisit and summarize the key takeaways from DNN-GP and present possible limitations.

• **Latent Concept Understanding.** The aligned latent concept distance and index matrices effectively capture the essence of the original dataset and malicious patterns introduced by faults, enabling clear differentiation.

• **Specific Concept Patterns.** Distinct concepts were observed in each of original, adversarial, and semantic data. Recognizing these offers a deeper understanding of attack techniques.

• **Spatial Pattern Abstraction.** The position-aware metrics of the index matrix, successfully discerns high-level abstraction of spatial patterns in the pixel space. This provides a more intuitive understanding of how faulty samples are perceived and the image is spatially processed.

• **Impact of Positions.** The position-aware distance and spectral metrics reveal that specific positions in the latent concept matrix exhibit greater deviations when faults were present.

• **Spectral Feature Insights.** The spectral perspective of concept distances distinguishes between structural (low-frequency components) and intricate (high-frequency components) attributes. Perturbations primarily influence high-frequency components, whose subtle discrepancies present in the raw distance domain are amplified by spectral analysis.

• **Pixel Space Structural Patterns.** DNN-GP's reconstruction forcefully aligns non-structural pixel perturbations to expressed structural patterns, offering a window into the model's conceptual faults.

• **Limitations.** While most diagnostic results are based on the entire testing set, class-specific patterns are not distinctly evident. Although hypothesis testing validates the distinction between malicious and benign entities through alignment distance matrix metrics, the specific patterns contributing to this differentiation remain insufficiently explored. For instance, simple statistical measures such as the mean and variance of sample-wise distances prove inadequate. There is a clear need to employ more sophisticated statistical methodologies to achieve a deeper understanding. Nonetheless, DNN-GP is a versatile open tool, and with more refined settings, such as class-wise, or sample-wise analysis, additional patterns potentially with causality could possibly emerge. We have shown basic sample investigations.

8 Conclusion and Future Work

By proposing DNN-GP, we have addressed research gaps within abstraction and integration when interpreting DNN faults. By eclipsing traditional instance-level interpretations and delving deeper into the conceptual realm, our research paves the way for more resilient, transparent, and trustworthy deep learning systems. This study highlights the importance of the latent concept space in understanding and diagnosing the vulnerabilities found within DNNs. Our contributions include providing a comprehensive dataset for evaluating model vulnerability, creating an integrated diagnostic tool, establishing a new research direction by mapping probing samples into a conceptual space, and providing a valuable step in enhancing model resilience.

Moving forward, the latent concept space can be used for improved adversarial training to develop DNNs more robust to adversarial attacks and less prone to errors induced by data drifts. Further, one can incorporate larger models like transformers into the codebook training to potentially unlock richer conceptual spaces to enhance the quality of the conceptual fault diagnosis, detection and mitigation. Our evaluation of DNN-GP has been performed on image classification, but DNN-GP not confined to this domain. There are promising avenues to expand the application of DNN-GP to malware detection or large language models.

Finally, we publicly release datasets, code, diagnostic results, and detection results at https://github.com/TASI-LAB/DNN-GP.

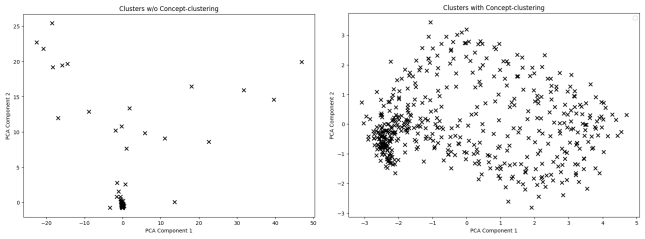
Appendix

In this section, we provide additional background for adversarial attacks and defenses. We also present a evaluation on the importance of cluster-based alignment, details on datasets and models, and additional results. Unfortunately, due to space limitations, additional details are available in the full version of the Appendix presented in the GitHub repository https://github.com/TASI-LAB/DNN-GP.



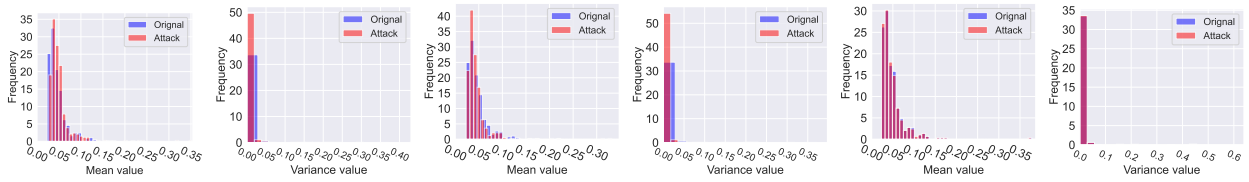
A Probing Approaches and Settings

Vulnerabilities derived from adversarial and semantic attacks involves the manipulation of input data intended for machine learning models, that induce errors [33]. One common example is the realm of image classification, where small, carefully crafted changes to an image can cause a state-of-the-art model to misclassify [20]. This phenomenon raises serious concerns about the robustness and reliability of machine learning models, particularly in critical applications such as autonomous driving or cybersecurity [2].

Adversarial Attacks. Full description of adversarial attacks of FGSM, PGD, JSMA, DeepFool, CW, and the Pixel Attack are available in the full version of the Appendix in GitHub.

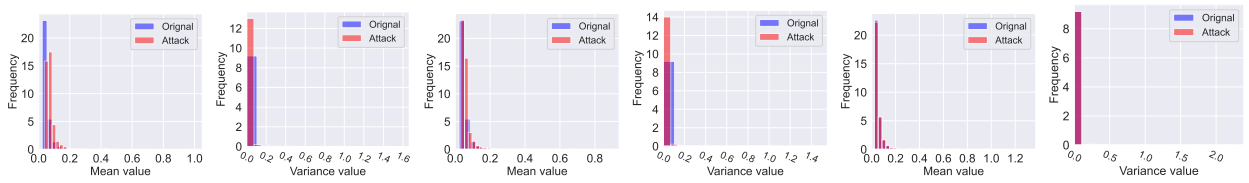
Semantic Attacks. Semantic attacks [27] on DNNs are a relatively new area of research. These attacks exploit the model's inability to understand the semantic meaning of the input data. In the context of image recognition, a semantic attack might involve manipulating transformation $T(\cdot)$, such as the rotation or lighting of an image, to fool the model into misclassification, i.e., $f(T(\boldsymbol{x})) \neq f(\boldsymbol{x})$ [11, 17]. Unlike traditional adversarial attacks that add imperceptible noise to the input, semantic attacks modify the image in a way that is perceptible but semantically plausible to humans. The detailed description of semantic attacks contrast change, rotation, and color-shift against image classification are provided in the full version of the Appendix in the GitHub repository.

Data Drift: Instance Corruptions. Another typical semantic attack against DNNs in the image domain is the introduction of corruptions that preserve the semantic content of the image but significantly degrade the performance of state-of-the-art computer vision models. This approach is demonstrated in MNIST-C dataset, a comprehensive suite of 15 corruptions applied to the MNIST test set, for benchmarking out-of-distribution robustness in computer vision [43]. The corruptions are model-agnostic and do not seek worst-case performance. Instead, they are designed to be broad and diverse, capturing multiple failure modes of modern models.



(a) W/o clustering alignment. (b) With clustering alignment.

Figure 11: Visualization of concept items in the codebook with and without clustering-based alignment.



B Clustering-based Alignment

We underscore the importance of employing a clustering-based alignment strategy, with the MNIST dataset as an illustrative example as its latent space is more straightforward to interpret. Figure 11 demonstrates that without the clustering-based alignment, a majority of codebook concept items will cluster closely, rendering them unused in the alignment for both original and adversarial samples. Only the remaining sparse concepts are actively utilized in alignment. This results in original and adversarial samples index matrices being highly similar, complicating the task of concept-based diagnosis. In contrast, after implementing cluster alignment, the concept items are more evenly distributed. Moreover, there is a pronounced difference in the concepts used in the alignment for original and adversarial samples, both in terms of index and alignment distance. This enhances the identification of unique concepts that are specifically employed during adversarial sample alignment, as compared to the original.

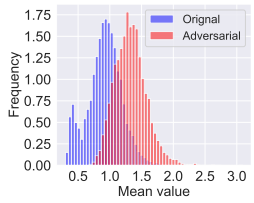
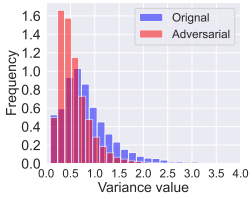
C Datasets and Models

In the experiments, we use benchmark image datasets of MNIST [31], CIFAR-10 [30], and CelebA [34]. We use a 7-layer ordinary CNN model for MNIST, a 9-layer ordinary CNN model for CIFAR-10, and a 5-layer ordinary CNN model for CelebA. Due to page limits, we provide detailed description of datasets and model architecture in the GitHub repository at https://github.com/TASI-LAB/DNN-GP.



D Extended Diagnosis Results

D.1 Additional Results on MNIST and CelebA



In this section, we provide typical diagnostic results on MNIST, including KS test results in Table 3 and a diagnose case of FGSM when the target model is a 9-layer ordinary CNN model in Figure 15. In addition, to show DNN-GP's model-agnostic property, we provide additional diagnostic results on CelebA when the target model is ResNet-18 or DenseNet-121 attacked by three adversarial attacks of FGSM, PGD, and CW in Figure 13 and Figure 12. All these results confirm the findings in CIFAR-10 in the main text. Complete results for all datasets across various faulty settings can be accessed within our repository at GitHub.

Table 3: KS test diagnosis results under multiple adversarial attacks for the MNIST

Attack Setting		*D*-value	*p*-value
Attack Method	Noise Parameter		
FGSM	8/255	0.017	0.028
	16/255	0.014	1.712×10^{-4}
	32/255	0.009	1.489×10^{-4}
	64/255	0.020	1.213×10^{-6}
	80/255	0.048	5.858×10^{-19}
PGD-Linf	8/255	0.013	1.329×10^{-33}

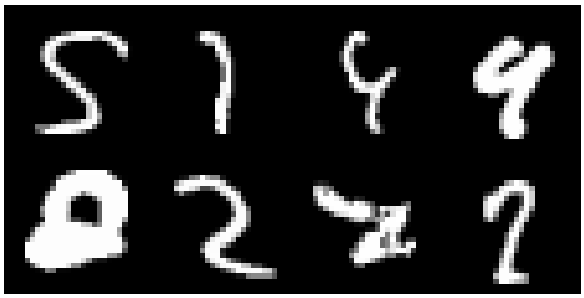

Figure 16: Hard samples recovered from false positive set.

D.2 Diagnosis on Data Drift

In this section, we present the diagnostic results for MNIST-C and CIFAR10-C, as shown in Figure 14. These results align with our findings from the semantic attacks, as they are similar in transformations but without verifying if each sample results in a misclassification for MNIST-C and CIFAR10-C. Complete results for all datasets across various faulty settings are provided in GitHub.

D.3 Reconstruction of Samples

In this section, we provide reconstruction visualizations of original and adversarial samples in Figure 17 to understand how the reconstructed versions of the attacked images can shed light on the meaning of latent concept the attacker attempts to exploit. The complete reconstruction visualizations for MNIST-C and semantic attack samples in CIFAR-10 and CelebA are provided in the GitHub link. We also report the classification performance after reconstructions in Table 4.

D.4 Additional Detection Results

We also study the detection performances of DNN-GP on MNIST and CelebA. We find that DNN-GP works well on detecting faulty samples on MNIST and CelebA, aligning with our findings on CIFAR-10 in Table 2. Detailed tables are provided in the GitHub.

Table 4: Prediction accuracy on faulty MNIST samples before and after reconstruction by DNN-GP. As we can see, DNN-GP has a certain ability to purify faulty samples.

Attack Setting		Before	After	Original	Ori. Reconstruct

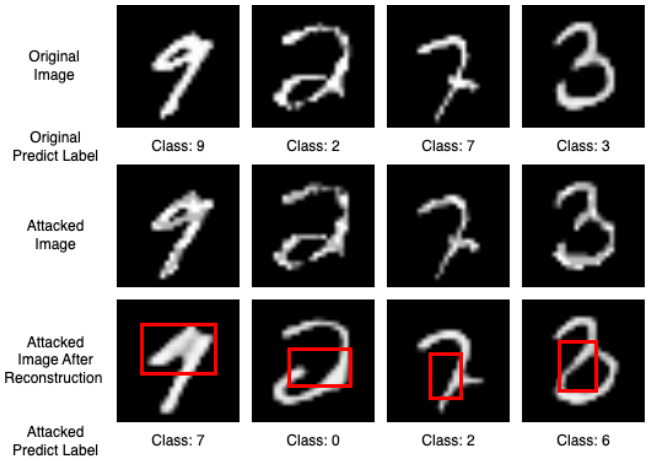

Figure 17: Reconstruction of Adversarial Examples from MNIST using FGSM-32/255. The attack on the first image fills in blank spaces of the number 9 to forge a 7. The tail of number 2 in the 2nd image is weakened, leading to its reconstruction as a 0. The third attack shifts the upper stroke of the number 7 to the right, connecting it at the tail, resulting in a 2 classification. The fourth merges the bottom half of the number 3, into a circular shape resembling the number 6. The adversarial samples show no damage the original image's structure and content, with noise spread across the entire number, the reconstruction revealing the basic attack patterns (i.e. in our MNIST examples, by altering small strokes, a transition to another number with a similar structure), and also within remaining stroke areas, reconstruction removes impacts of adversarial noise.

Yes, One-Bit-Flip Matters! Universal DNN Model Inference Depletion with Runtime Code Fault Injection

Abstract

We propose, FrameFlip, a novel attack for depleting DNN model inference with runtime code fault injections. Notably, FrameFlip operates independently of the DNN models deployed and succeeds with only a single bit-flip injection. This fundamentally distinguishes it from the existing DNN inference depletion paradigm that requires injecting tens of deterministic faults concurrently. Since our attack performs at the universal code or library level, the mandatory code snippet can be perversely called by all mainstream machine learning frameworks, such as PyTorch and TensorFlow, dependent on the library code. Using DRAM Rowhammer to facilitate end-to-end fault injection, we implement FrameFlip across diverse model architectures (LeNet, VGG-16, ResNet-34 and ResNet-50) with different datasets (FMNIST, CIFAR-10, GTSRB, and ImageNet). With a single bit flipping, FrameFlip achieves high depletion efficacy that consistently renders the model inference utility as no better than guessing. We also experimentally verify that identified vulnerable bits are almost equally effective at depleting different deployed models. In contrast, transferability is unattainable for all existing state-of-the-art model inference depletion attacks. FrameFlip is shown to be evasive against all known defenses, generally due to the nature of current defenses operating at the model level (which is model-dependent) in lieu of the underlying code level.

1 Introduction

Deep neural networks (DNNs) have demonstrated impressive performance on various tasks [18, 25, 69, 70]. However, their security and safety usage is threatened by adversarial attacks that are generally introduced either during the model training phase or the model inference phase [30]. Training phase attacks conventionally include data poisoning attacks, which tamper with the model prior to deployment such that it deviates from its benign behavior on either all inputs [31] (i.e., model utility depletion) or specific inputs with triggers [20] (i.e., backdoor attacks). A notable attack at the model inference phase is the adversarial example attack [58].

Conventional attacks attempt to breach either model integrity (i.e., training phase attack) or data integrity (i.e., inference phase attack). However, they do not target the integrity of the hardware on which DNN models deploy and execute. Recent work has looked at a new type of fault injection attack [11, 28, 43, 52, 59, 67], where model integrity is violated by compromising the underlying hardware. It tampers the model in a manner similar to the conventional training phase attack *but occurs after the model deployment.* Consequently, all countermeasures applied prior to deployment are inapplicable. In contrast to the conventional inference phase attack (i.e., adversarial examples), which only manipulates each incoming input, the fault injection attack completely contaminates the underlying model to compromise all upcoming inputs.

These studies demonstrate the feasibility of launching fault injection attacks to compromise DNN model integrity after deployment. However, there are still some challenges that need to be overcome. Firstly, these works are all model dependent. A DNN model has some tolerance on its weight value change unless specific positional weights are delicately changed. The positions of those critical weights are unique to each victim model, and cannot be transferred to a different model. Secondly, they all require injecting multiple bits of fault deterministically and simultaneously, which is extremely challenging in practice. This is because flippable memory cells in the DRAM are sparse and it is hard to find a physical memory page that contains more than one flippable bit [28, 59]. In addition, injected faults may need to be increased as the model size increases. Thirdly, to be efficient, these attacks all assume to have full knowledge of the victim model – that is, white box access – which may not always be available. This is problematic when the deployed model, and its weight values, are updated through online learning, which renders the previously identified vulnerable bits futile. To this end, we are interested in the following research question:

Is it practical to universally breach the post-deployment DNN model integrity with a single-bit fault injection given black-box victim models?

General Challenges. This work provides an affirmative an-

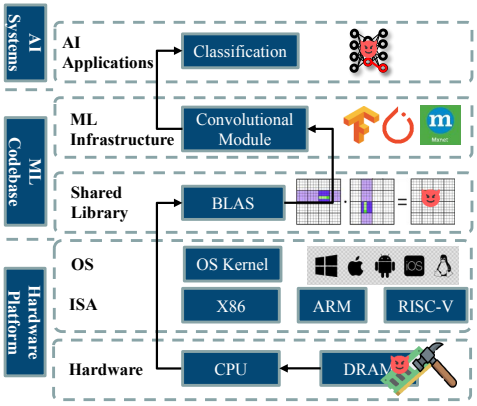

Figure 1: Attack flow of FrameFlip.

swer to the above research question. However, given the extremely stringent constraints, there are three crucial general challenges (GCs):

- **GC1: Model-independence.** The exact bits of the model weights that ultimately affect the inference result vary from model to model, and even vary for the same model between updates, e.g., through fine-tuning. In this context, identifying a subset of bits that can be universally applied to every model is challenging.
- **GC2: Black-box knowledge.** As for a DNN model already deployed on a server, in a typical application of machine learning as a service, the model provider normally only offers an API interface to provision inference results. Therefore, accessing the underlying model is infeasible. In addition to **GC1**, this black-box condition (no knowledge of model weights, or even model architecture) makes faulty bit identification seemingly unattainable.
- **GC3: Practical single-bit injection.** While it is possible to inject multiple faults into the hardware, primarily in the main memory of the server, inducing a single-bit fault deterministically is realistic. However, constrained by **GC1** and **GC2**, reducing a set of faulty bits to a single bit that is able to universally affect any unknown models seems almost impossible.

Our Solutions. If we follow the existing paradigm of fault injection attacks on model inference, where the attack is conducted from the model level, it is almost impossible to resolve the research question when constrained by the above three general challenges. We overcome this hurdle by looking at the fundamentally different paradigm of the underlying *code level*. At a high level, we inject faults into the compiled running code library to consequently corrupt all model inferences that are supported by the library for high-performance computation (see an overview of the attack flow in Fig. 1). More specifically,

- To **address GC1**, the target runtime codebase supporting the model inference is independent of the specific upper-layer models.
- To **address GC2**, the libraries that are widely adopted across mainstream machine learning frameworks are identified. Faults induced into these libraries affect any model that must require these libraries' support.
- To **address GC3**, the branch condition of the code is targeted to alter the control flow with a single bit flip to amplify the fault adverse effect with a single-bit flip.

For **GC1** and **GC2**, we identify libraries that provide fundamental functionalities across prominant machine learning frameworks such as PyTorch [49], Tensorflow [3], Caffe [32], and Apache MXNet [1]). The linear algebra backend is a basic module of these Machine Learning (ML) frameworks, which has critical effects on the DNN's performance. To date, these ML frameworks rely on high-performance Basic Linear Algebra Subprograms (BLAS) to implement their linear algebra backend. BLAS is a de facto standard for low-level linear algebra routines, such as vector addition and dot product. Popular BLAS implementations include OpenBLAS [63], Eigen [24] and Intel MKL [60]. These implementations have been widely applied to mainstream ML frameworks. Therefore, the linear algebra backend is chosen as the targeted library.

To address **GC3**, the combined restrictions of single-bit fault determination and practicality present three technical challenges. The first technical challenge is to determine salient vulnerable bits within the identified library—ultimately, a single salient bit. We solve this by traversing the `cblas_dgemm` function of the OpenBLAS library and choosing all conditional branch instructions as vulnerable bit candidates. The reason is that a branch instruction has a significant effect on the final computation result due to control flow change. More specifically, for each vulnerable candidate, we manipulate its condition and switch it to the other traversed path. Then by evaluating the inference accuracy on the flipped instruction, we can determine the most vulnerable code point that exhibits the worst utility deterioration. We have designed an automatic and efficient vulnerable bit search scheme fulfilling the above goal by leveraging LLVM tools.

The second technical challenge towards practical single-bit injection is to retain stealthiness. The injected fault tampers with the control flow of the inference routine. In addition to the desired degradation of inference accuracy, the fault injection can lead to system warning notifications or result in program crash [28]. Our extensive experiments confirm that the compromised control flow of the inference routine does throw warning notifications, including *i)* error and warning messages from the DNN runtime process, *ii)* abnormal fluctuation in the memory usage statistics, and *iii)* a denial-of-service incident at the inference service. Obviously, the occurrence of either one of the listed warning signs notifies

the victim of a possible DNN fault injection exploitation, reducing the feasibility of the attack. To circumvent this technical challenge, we introduce a more controlled fault injection primitive, *opflip*, to flip the opcode of an instruction to its adjacent instruction as, in most cases, the bit flips in opcodes will yield other valid instructions [23]. In this context, we identify that there is a type of instruction, conditional jump instruction, whose one-bit adjacent instruction is a valid instruction with the exact opposite semantics. By compromising this type of instruction with a single bit fault, the control flow of the DNN inference computation can be corrupted while avoiding exceptions. Thus, the fault injection is stealthy.

The third technical challenge of a practical single-bit injection is the viable means of injecting the fault. To be practical, the attacker has to be an unprivileged user who accesses the victim model on a deployed server machine, e.g., co-resident tenants in the MLaaS cloud. Therefore, fault injection requiring physical/local access to the machine (i.e., radiation-induced bit flip in main/DRAM memory [8]) is prohibited. In this work, we leverage the Rowhammer attack to manipulate a code page that resides in the address space of another process. As Rowhammer is capable of flipping bits in DRAM, flipped code segmentations of the compiled ML codebase are located in the page cache. The OS does not detect this change as it is directly made in the hardware by a completely isolated process and it keeps providing the page cached modified copy to the victim on subsequent accesses.

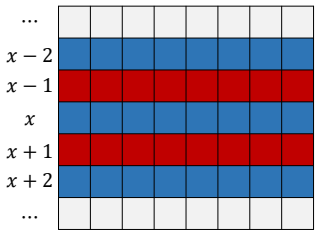
By systematically resolving three general challenges and their associated technical challenges, we are able to demonstrate an end-to-end universal DNN model inference depletion attack with a single bit flip. Notably, our attack debunks all existing defenses because they only consider model level fault injection attacks and not the lower code level fault injection attack. We analyze existing prominent countermeasures in terms of effectiveness and performance overhead. The results are summarized in Tab. 1.

In summary, we make the following key contributions:

- We reveal a new paradigm of universally depleting DNN model inference by generally injecting fault into the running compiled code, requiring only a single-bit flip to stealthily and completely alter the program control flow. The FrameFlip is the first end-to-end demonstrated attack under the practical constraints of black-box knowledge and model-independence.
- We devise a new automatic algorithm AutoVIS to identify vulnerable instructions in commonly-used machine learning code libraries. Our critical instruction search scheme can quantify the influence of each instruction on the DNN model's inference utility when those instructions are flipped with a single bit fault.
- We evaluate the effectiveness of FrameFlip on 10 groups of DNN benchmarks. FrameFlip outperforms the state-of-the-art DNN prediction degradation attacks implemented by tampering with the DNN weight parameters. Significantly, FrameFlip, for the first time, exhibits high attack transferability across different DNN models.
- We investigate several state-of-the-art mitigation techniques to prevent DNNs from fault injection attacks. Experiments show that our proposed attack can successfully circumvent state-of-the-art countermeasures.

Ethical Considerations. FrameFlip exploits a publicly known Rowhammer bug [34], and thus there is no need to report it.

2 Background



This section provides the required background knowledge, including ML codebases and the Rowhammer bug.

2.1 Machine Learning Codebases

Implementing a fully functional DNN from scratch is an extremely demanding task since it requires proficient coding skills and cross-domain expertise, e.g., algorithm optimization and hardware acceleration. Therefore, the conventional DNN development pipeline depends on industrial ML codebases (e.g., PyTorch [49], Caffe [32], and TensorFlow [3]). Those ML codebases are comprised of open-source repositories and off-the-shelf modules provided and maintained by commercial vendors and thousands of contributors. ML codebases' functions (e.g., training and inference) rely heavily on tiled GEMM (Generalized Matrix Multiply) which is implemented by high-performance BLAS (Basic Linear Algebra Subprograms) libraries. BLAS is a de facto standard for low-level linear algebra routines, which has extensively optimized blocked matrix multiply.

2.2 The Rowhammer Bug

DRAM (Dynamic Random Access Memory) is organized in multiple memory channels. Each channel serves as a link between the DRAM module (DIMM) and its corresponding

(a) Demonstration of Double-sided Rowhammer.

```
loop:
    mov (x-1), %r10
    mov (x+1), %r10
    clflush (x-1)
    clflush (x+1)
    jmp loop
```

(b) Code Snippet of Double-sided Rowhammer.

Figure 2: Double-sided Rowhammer

memory controller which is usually integrated into processors. A Dual Inline Memory Module (DIMM) is a physical memory module attached to the motherboard, with one or two ranks (on the front-side and back-side of the module). Each rank usually has 8 banks for DDR3 chips and 16 banks for DDR4 chips. A bank is a minimal unit the memory controller can control and is a grid of memory cells arranged in rows (word-lines) and columns (bit-lines). Each memory cell has a capacity which can be charged and discharged. A transistor controls access to the content of the capacity. When reading a row, the memory controller activates the word-line. The transistors in the activated row are opened and the content of all capacitors on that row are discharged to the bit-lines. Sense amplifier circuitry on each bit-line captures and amplifies the signal and stores the result in the row buffer, and also refreshes the charge in the activated row.

The Rowhammer bug refers to a hardware vulnerability validated on various DRAM chips [34]. As demonstrated in Fig. 2, if an attacker rapidly accesses two DRAM rows (aggressor rows) with row index $x-1$ and $x+1$ (i.e., *double-sided Rowhammer*), this will result in electromagnetic interference in row x, making its stored values flipped. This means that if a memory cell in row x originally stores 0, then it will be flipped to 1, or vice versa. To mitigate the Rowhammer bug, DRAM vendors have implemented hardware solutions in recent DRAM modules (e.g., DDR4), such as Target Row Refresh (TRR) [47]. However, the TRR solution has been bypassed by TRRespass [19] via the so-called *many-sided Rowhammer*. To date, the Rowhammer bug still remains a threat to commodity DRAMs.

3 Threat Model

In this section, we break down the victim's capability and the attacker's goal and capability.

3.1 Victim's Capability

Trustworthy Model Training. The models are benign in the sense that the training process is not tampered with by any malicious party. The models are free from algorithm-based adversaries, e.g., model poisoning [31] and Trojan attacks [40, 44]. This is a practical assumption for well-trained models. The models can be either trained on a secure training device or downloaded from a trusted source. In both cases, the training process is not tampered with. This is in contrast to existing algorithm-based attacks that inject stealthy payloads to the DNN model and re-distribute it to victim users (e.g., model poisoning and Trojan attacks).

Resource-Sharing Platforms. Following prior bit-flip-based attacks [28, 53, 67], we assume that a trained deep learning model is deployed on a resource-sharing platform that provides an inference-phase service. This assumption is feasible, as current MLaaS jobs are deployed on clouds [16, 54, 65].

Online Learning. During inference, the trained DNN model is loaded into the system's (shared) memory and applied to the real world. However, in most inference practices, a DNN that achieves high evaluation results in training does not perform as effectively for real-world samples. This is mostly caused by the distribution discrepancy between the real-world data and the training data [56]. To tackle this issue, a simple but effective approach is to continually fine-tune the trained DNN model with more real-world samples after it goes online. Therefore, the model weights may or may not get updates, and the attacker is unaware of either circumstance. This deployment paradigm is becoming a typical scenario due to the prevalence of MLaaS platforms [56, 68]. Note that, for those online learning cases, existing weight-based fault injection attacks [11, 28, 52, 53, 59, 67] are invalid because of their strong dependency on the DNN's weight parameters. Once the model weights are updated, the vulnerable bits that need to be flipped may also change.

Deployment of Defenses. We assume the victim can apply any SOTA defense against inference depletion attacks.

3.2 Attacker's Capability

Attacker's Goal. The attacker aims to deplete the DNN's inference utility by injecting a single-bit error into the runtime ML codebase while maintaining maximal stealthiness. The injected error tampers with the normal control flow of the inference routine, causing a degradation of inference accuracy. Meanwhile, the attacker aims to induce as few warnings as possible, to make the attack imperceptible as well as to extend the living time of the injected error. When a fault is injected, its adverse effect remains effective until a system reboots.

System Side. We assume that the attacker process can co-locate with the target DNN service, sharing computation resources with the victim's process. Specifically, the attacker is an unprivileged user who shares the same physical memory as the victim. This is a common assumption adopted by previous works [23, 28, 67]. In this paper, we leverage double-sided Rowhammer and many-sided Rowhammer for DDR3 and DDR4 chips, respectively, as the primitive of software-induced DRAM fault injection. Both hammering techniques need to know the DRAM memory address mapping function.

We assume the adversary can obtain the DRAM addressing scheme by applying reverse engineering techniques [50, 62]. We assume that the OS of the resource-sharing platform is secure. Particularly, the system has installed an up-to-date administrative program, which implements necessary software-level confinement policies such as process isolation.

Model Side. The threat models of existing works [11, 28, 52, 53, 67] are conventional white-box attack approaches, that is, an adversary is assumed to have access to the network architecture, weight parameters and one batch of test data. Note that it is feasible to steal the model architecture [21] and model weights [51] through the side-channel information in the MLaaS setting. In contrast to them, we void such assumptions by adopting a black-box setting where no prior knowledge of a target network architecture (including weights at deployment and online weight updates) is required, as the transferability of our attack applies to various network architectures (refer to Fig. 7 in the experimental results).

ML Codebase Side. Different to existing works that require the attacker to know model parameters, this work requires the attacker to know which ML frameworks are utilized by the model. Following Yan et al. [66], we believe the knowledge of open-source ML frameworks is publicly available (e.g., Tensorflow, Pytorch, Caffe, and MXNet), while the victim's DNN weight parameters are valuable intellectual property and are private. In our investigation, we found that mainstream ML frameworks (e.g., TensorFlow, PyTorch, Caffe, and MXNet) are supported by the OpenBLAS library. For the model inference frameworks that are not within the set of the mainstream ML frameworks mentioned above, their BLAS backends may still be the reputable, efficient, and standard linear algebra libraries, e.g., OpenBLAS. As implementing these libraries requires advanced expert knowledge of both algorithms and hardware to achieve optimal performance, it is unnecessary and difficult to implement the BLAS backend from scratch.

Options for Linking. Static linking links related library functions directly into a victim's binary, and thus the linked functions cannot be called by other binaries. Consequently, FrameFlip cannot find the exact physical locations of vulnerable bits of library functions in the victim process and instead might cause the victim to crash. However, static linking generates large-size binaries and dynamic linking produces small-size binaries. Thus, developers are likely to use dynamic linking in practice to distribute their models. Therefore, in this work, we assume the victim adopts dynamic linking to link object files into an executable output file.

4 FrameFlip Design

In this section, we present FrameFlip in detail. FrameFlip is comprised of three steps: the vulnerable bit search in ML codebases, memory massage, and single-bit fault injection. To clarify the notations, we call bit flips found in the victim's physical memory "flippable bits", and bit flips found in ML codebase search "vulnerable bits". Fig. 3 demonstrates the overview of the proposed FrameFlip.

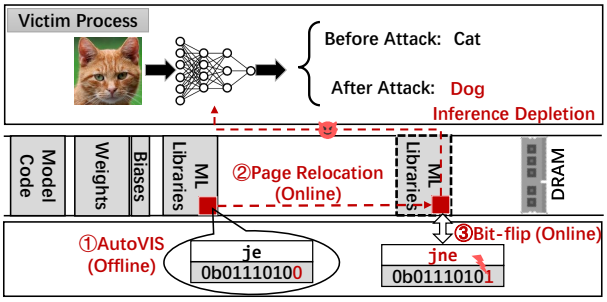


Figure 3: An overview of FrameFlip.

The attack is comprised of offline and online phases. In the offline phase, the attacker scans the ML codebase via an automatic vulnerable bit identification algorithm (detailed in Section 4.2) to select the instruction to be flipped. In the online phase, the attacker scans the target memory to identify a suitable bit flip, and exploits the memory waylaying to relocate the vulnerable instruction into the matched memory page (i.e., the flippable page has the same page offset and flipping direction). At last, the attacker employs a hammering technique to flip the bit in the specific memory cell.

4.1 Vulnerable Bit Search in ML Codebase

In this step, the adversary identifies the bit to be flipped in the ML codebase. Note that in our threat model, the attacker is only required to perform vulnerability analysis on the codebase offline and does not need to manipulate the codebase repository and redistribute it.

4.1.1 Linear Algebra Backend

ML codebases invoke miscellaneous shared libraries (`ELF` files) to support its foundational functions. In practice, a function called GEMM, a part of the BLAS (Basic Linear Algebra Subprograms) library is invoked to make deep neural networks perform faster and more power efficient. Note that these shared libraries are optimized for algorithms and hardware, and thus possess high performance on time and space complexity. We choose the shared library of the linear algebra backend as the attack module because of its indispensability and wide adoption. Implementations of the linear algebra backend used by ML codebases are compiled into linkable object files with file extensions such as `.so` (Shared libraries) for Unix-based systems. A shared library is comprised of several sections specified in a section header table. The most important section is the `.text` section which holds the executable instructions of the library. For a shared library, its `.text` section is a list of independent functions that can be invoked by external `ELF` files.

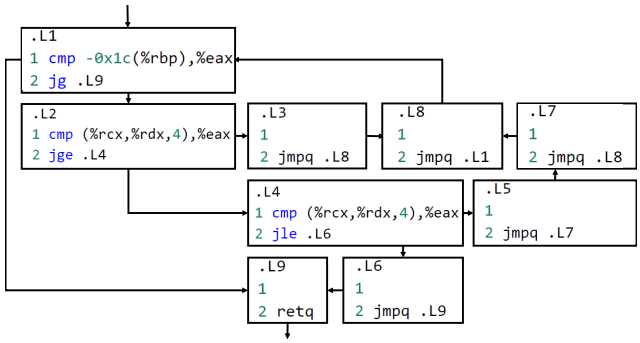

Figure 4: Demonstration of CFG.

The shared library that contains the linear algebra backend implements a set of APIs defined in the Basic Linear Algebra Subprograms (BLAS) standard. For instance, scalar and vector operations are defined in level 1 BLAS, including the dot product (DOT: $\boldsymbol{x}^T\boldsymbol{y}$) and vector scaling (SCAL: $\alpha\boldsymbol{x}$). Vector-matrix operations are defined in level 2 BLAS. The operations include general matrix-vector multiplication (GEMV: $\alpha A\boldsymbol{x}+\beta\boldsymbol{y}$) and general rank 1 operation (GER: $\alpha\boldsymbol{x}\boldsymbol{y}^T+A$). Matrix-matrix operations are defined in level 3 BLAS and include general matrix multiply (GEMM: $\alpha AB+\beta C$).

In the next subsection, we present a method for identifying a vulnerable bit in ML codebases that can be exploited by an attacker. Our approach involves a meticulous code analysis of the linear algebra backend.

4.1.2 Vulnerable Code Statements: Branch Statements

In code analysis, a *control-flow graph (CFG)* is a graph representation of all paths that might be traversed through a program during its execution. In a CFG, each node represents a *basic block*, which is a straight-line piece of code sequence that the processor must execute the entire basic block from the beginning to the end. The only instructions that can exit this basic block are at the entry and exit points. This restricted form makes a basic block highly amenable to program analysis. Directed edges in the CFG represent the relationships among blocks, i.e., jumps in the control flow. By definition, there is an edge from block b_1 to block b_2 if and only if the code in b_2 can be executed immediately after the code in b_1. Fig. 4 demonstrates the CFG of a demo binary search program. In the assembly code, we can find conditional and unconditional branch instructions that comprise the global control logic of the program, as represented by the CFG.

Compared with the basic blocks, most of which are not invoked by the control logic of the program, the *control flow statements* (edges in CFG) are critical to controlling the execution logic of the whole program. More specifically, the control flow statements can alter the contents of the CPU's Program Counter (PC). The PC maintains the memory address of the next machine instruction to be fetched and executed. Therefore a control instruction, if executed, causes the CPU

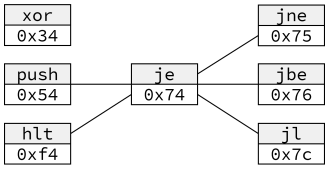

Figure 5: Demonstration of the adjacent instruction.

to execute code from a new memory address, changing the program logic. Control flow statements mainly contain three types of control instructions, listed as follows:

Jump instructions directly modify the value of the PC with another basic block's entry point other than being incremented past the current instruction to its next instruction. Typical jump instructions in assembly language include `je`, `jne`, `jg`, and `jle`. Jumps typically have unconditional and conditional forms where the latter may be taken or not taken (the PC is modified or not) depending on some conditions.

Call instructions are used to implement subroutines. In assembly language, it is presented as the `call` instruction. The `call` instruction pushes the current value of the PC to a stack data structure in memory, and leaves this value as the return address. Upon completion of the subroutine, this return address is restored to the PC, and program execution resumes with the instruction following the call instruction.

Return instructions pop a return address off the stack and load it into the PC register, thus returning control to the calling routine, i.e., a `ret` instruction.

Among those control flow statements, the jump instruction possesses semantic similarity, in which its adjacent instruction is still a valid instruction but with the opposite semantic. This property can minimize the risk of program crashes introduced by control flow tampering. Fig. 5 illustrates the semantic similarity property of jump instructions. Each node in Fig. 5 presents an instruction (denoted by an opcode of x86-64 ISA), and the adjacent node presents its adjacent instructions in which the Hamming distance is 1. In particular, there is only 1 bit of difference in their opcodes and the format of their operands must be the same. Note that even if two instructions only have 1 bit of difference in their opcode, they may not be thought of as adjacent. Since, if we exchange their opcodes, it will result in invalid semantics due to a mismatch in the format of the operand, such as `je` (jump if equal) with 1 operand and `xor` (exclusive or) with 3 operands.

As demonstrated in Fig. 5, the adjacent instructions of the jump instruction `je` (jump if equal) contain its semantic opposite instruction `jne` (jump if not equal). The semantic opposite instruction of `jg` (jump if greater than) also appears in its adjacent instructions (i.e., `jle`), as well as `jc` (jump if carry) and `jnc` (jump if no carry). This observation indicates that a single bit flip in the opcode of branch instructions can switch the semantic of the control flow into the opposite branch. Based on this observation, we selected the conditional

jump instructions as the target instruction to compromise the global control logic of the program.

4.1.3 Vulnerable Bit in Opcode

In this subsection, we introduce the process of how the attacker selects the specific bit to be flipped in chosen branch instructions. On the processing architecture, a given machine instruction may specify: i) the opcode (the instruction to be performed) e.g., add, copy, test; or ii) any explicit operands (registers, literal/constant values, addressing modes used to access memory). For readability for programmers, assembly language was designed to use a mnemonic to represent each low-level machine instruction. For each machine instruction, assembly language usually has one corresponding statement. For instance, the instruction `cmp $0x65, %edi` (AT&T format) corresponds to the machine code `83 ff 65`, where `0x83` is the opcode with the corresponding format `CMP r/m32, imm8` (Intel format) under the x86-64 ISA. The machine code `0xff` tells the processor to fetch the first operand from the `EDI` register. `0x65` is an immediate operand.

Flipping any bit in the instructions can dramatically affect the operation results of the instructions. Notably, when the bit flip appears in the opcode, the semantics of the instructions are manipulated. Since the potentially flippable memory cells in the DRAM are sparse, it is hard to find a physical memory page that can flip more than one bit [28, 59]. To minimize the cost of attacking time and the requirement of the hardware constraints, we select the bit in the opcodes as the vulnerable bit to be flipped.

Takeaway 1: In summary, given an ML codebase, we have selected the shared library of the linear algebra backend as the attack module because of its indispensability and wide adoption. We have selected the conditional jump instructions from a shared library (i.e., OpenBLAS), to manipulate the control flow within the program and minimize the risk of program crashes. Finally, we have identified the vulnerable bit to be flipped within the opcode.

The vulnerability of a branch statement, or candidate bit, is measured by two properties: the degree of degradation induced in the DNN model and whether the change generates warnings or crashes. There are 65913 over 843724 (8%) branch instructions within the shared library (i.e., `openblas-0.3.20.so`) that need to be verified and compared according to this measure. To avoid manually analyzing each branch statement, we introduce an automatic and efficient algorithm to identify the most vulnerable code point.

4.2 Automatic Vulnerable Instruction Search

In this subsection, we introduce an LLVM-based **Auto**matic **V**ulnerable **I**nstruction **S**earch algorithm (AutoVIS) that automatically identifies the most vulnerable bit in the linear algebra library of the ML codebase.

LLVM is a set of compiler and toolchain technologies used to turn source code (e.g., C programs) into a language-independent intermediate representation (IR) that serves as a high-level assembly language that can be optimized by LLVM Passes. Then the LLVM backend turns the IR into the final machine code. In this work, we implement a LLVM Pass to analyze the linear algebra library (i.e., `cblas_dgemm` function of OpenBLAS). In particular, the LLVM compiler decomposes the program into different levels of granularity according to hierarchical relationships (function units, basic blocks, and instructions) within the code. In AutoVIS, we traverse each instruction and assign a branch instruction an index (Branch Index). For each branch instruction (i.e., `br`, `switch` and `select` in LLVM IR), we employ the opcode flipping primitive to compromise the control logic of the program.

Specifically, the AutoVIS algorithm was defined by overriding the `llvm::ModulePass::runOnModule` method and registering it as a standard LLVM Pass. The AutoVIS algorithm was written in the required format of an LLVM Pass and then compiled using `CMake`, resulting in a shared object file (`.so` in Linux). Next, we utilized the optimization tool provided by LLVM, namely `opt`, to dynamically load the shared objective file generated above and modify the IR of the `cblas_dgemm` function according to the AutoVIS algorithm. Finally, the LLVM backend converted the modified IR into the binary code for different ISAs. In this way, for each branch instruction, we generate a re-compiled corrupted version of the `cblas_dgemm` function by invoking our AutoVIS Pass. The details of the AutoVIS are shown in Algorithm 1.

In Algorithm 1, *parseOpcode* translates an instruction into its opcode. The *instrument* function in line 9 queries all adjacent instructions for a given branch instruction, then returns the instruction with the opposite semantic. After the traversal, the algorithm outputs the vulnerable bit location in the shared library's code section that can be used to inject fault. We then evaluate the prediction accuracy of the DNN inference infrastructure that invokes the modified linear algebra library. By evaluating all of these branch instructions, we can find the most vulnerable branch instruction that has the best attack performance (most utility degradation, neither warnings nor crashes). All these actions are performed automatically by LLVM and only take tens of minutes. In contrast, as reported by Hong et al. [28], a weight-based fault injection would take approximately 942 days to identify a single bit corruption in a 138M VGG model on a 488 node high-performance computing cluster.

In AutoVIS, the LLVM compiler plays a critical role, as it enables us to inspect and manipulate instructions. LLVM compilation process can be briefly decomposed into three phases, namely, programming code, intermediate representation (IR), and machine-level instructions. Our LLVM plugin is embedded in the process of translating from IR to instructions.

Algorithm 1: LLVM-based automatic vulnerable bit search algorithm

Input: IR files of compiled ML codebase *Code*, DNN infer infrastructure *network*
Data: Validation dataset *dataset*
Output: Vulnearble code points in code section that can be used to inject fault

```
Vulnerable set V ← {};
// Random guess accuracy
acc_random ← 1/numOfClasses(dataset);
foreach functional unit F in Code do
    foreach basic block BB in F do
        foreach instruction Inst in BB do
            if Inst ∈ {br, switch, select} then
                opcode ← parseOpcode(Inst);
                instrument(Inst, opcode);
                lib ← generateLibrary();
                model ←
                  buildDeepLearningApp(lib, network);
                acc ← inference(model, dataset);
                if acc ≤ acc_random then
                    V ← V ∪ {V};
                end
                recover(Inst, opcode);
            end
        end
    end
end
return V;
```

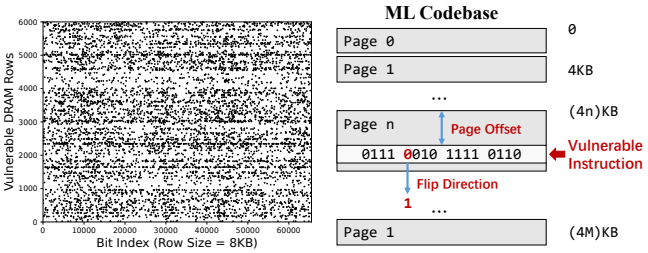
The plugin inspects every incoming IR, filters the conditional branching instructions (a subset of IR opcodes), and modifies the branch by changing the branching condition. The plugin helps us produce modified BLAS libraries in which exactly one branching condition is maliciously modified. The modified library acts as the candidate and is linked to the DNN model. If this modified library achieves the best attack performance (most utility degradation, neither warnings nor crashes), the corresponding branch instruction is chosen as the target conditional branch.

Takeaway 2:
***(i)* Executed Offline.** Note that our algorithm is executed offline because the targeted ML codebases are open-sourced. This avoids the time overhead concern arising from the brute-force strategy.
***(ii)* Scalability.** AutoVIS is designed to improve the efficiency of the complete analysis of ML Codebases as they scale up. It is also easily extended to other libraries.

5 End-to-End Attack via Rowhammer

By employing the automatic vulnerable instruction search algorithm, the attacker can identify the most effective instruction in the target ML codebase, as measured by utility degradation and the requirement that the change does not induce warnings or crashes. The attacker now needs to locate the corresponding vulnerable bit at the flippable physical location in the DRAM, and precisely induce the desired bit flip in real hardware systems. Specifically, the attacker first identifies the physical pages that contain flippable memory cells that match the virtual page containing the found vulnerable instruction (i.e., has the same bit offset and flip direction). Then, the attacker employs the memory waylaying technique [23] to relocate the page containing the vulnerable instruction to one of the matched physical locations mentioned above. Finally, the attacker prepares the pattern for the aggressor rows of Rowhammer and frequently accesses these rows to successfully obtain the desired bit flip.

5.1 Offline Memory Profiling



Memory profiling is a process utilized to profile the addresses of flippable bits in the DRAM. This procedure can be executed offline before the victim starts to operate. In particular, we perform double-sided Rowhammer or many-sided Rowhammer on randomly allocated memory and document all the identified bit flips. To enable the hammering technique, the attacker configures its virtual pages in physically consecutive rows in the same bank (sandwich layout) of DRAM chips. Thus, the attacker should crack the virtual-to-physical address translation and decode the DRAM addressing mechanism.

Cracking Virtual-to-Physical Address Translation. The attacker exploits the deterministic behavior of the *buddy allocator* by coercing the kernel to provide physically consecutive memory [13, 36]. Specifically, the attacker keeps requesting small free memory blocks using the `mmap` system call with the `MAP_POPULATE` flag, until there are less than 2 MiB of free space left in blocks with an order smaller than 10.

If the free space in blocks of order below 10 is less than 2MiB, the attacker sends two 2MiB requests. The kernel satisfies the first request by splitting one of the 10th order blocks (4 MiB in size). Therefore, the second request is fulfilled by a consecutive physical space. The second request's allocated memory has an identical lowest 21 bits in the virtual and physical addresses. Consequently, this block can have the equivalent offset in both virtual and physical address spaces.

Decoding Physical-to-DRAM Address Mapping. Note that the physical address space organizes memory as a continuous large array, which hides the components of the actual physical memory architecture, such as channel, DIMM, rank, bank, row, and column. We are required to identify three physical addresses that are located in three consecutive rows within the same bank of DRAM chips. We exploit a DRAM row buffer timing side channel [50] to identify the pages belonging to the same bank.

When two physical addresses (presented as A and B) are located in the same bank, if we alternatively access them, the time for accessing B is the sum of the row buffer update time (switch from A to B) and the time for reading the row

(a) Offline Memory Profiling. **(b) Page Offset Alignment.**

Figure 6: Demonstration of offline memory profiling and page offset alignment.

buffer (read B from row buffer). Conversely, when A and B are in different banks, and we alternatively access them, the accessing time for B is only the row buffer reading time, because it is recently accessed. Employing this row buffer timing channel, we can know whether two physical addresses are located in the same bank of DRAM.

Based on the primitives mentioned above, we have adopted the Rowhammer-test tool [2] to profile our DDR3 chips and TRRespass [19] for DDR4 chips. The result of memory profiling is a list of bit positions that are flippable in the physical memory (i.e., candidate flippable pages). Each entry records the partial physical address of the byte that contains the flippable bits (because we can only partially translate virtual to physical addresses in a consecutive 2MB block), the bit index within the memory cell and the flipping direction. Fig. 6a demonstrates the bit flip locations in a bank of our DDR3 chip. From the physical address, we can infer the offset of the flippable bits within a page. In a 4KB page, the offset refers to the index of the byte that contains the flippable bits. The offset is used to rule out bit flips that are inconsistent with our attack. As demonstrated in Fig. 6b, the vulnerable page must have the same page offset and flip direction as the flippable page. The offset of the vulnerable page from the starting address of the `cblas_dgemm` function can be gained in the compiling process, where we know to which instruction the target is translated. The Rowhammer attack handles the rest of the attack, mainly including a page relocation and triggering an accurate bit flip.

5.2 Rowhammer Exploitation

Memory Massage. We exploit the *memory waylaying* [23] technique to relocate the vulnerable virtual page to the matched physical page found in the previous step. Memory waylaying performs on pages in the page cache. Since these cache pages can be evicted at any time, they are not shown in the system's memory utilization and are treated as available memory. After being removed from DRAM, page cache pages are randomly relocated when accessed. Continuous eviction eventually places the vulnerable page on the physical location desired by the attacker. Memory waylaying leverages the prefetch side channel to identify when a virtual page is loaded to predetermined physical locations. Once the data is in the desired location, the intended bit flip can be induced.

Rowhammer Exploitation. Once the vulnerable bit is populated to the flippable bits in DRAM, the attacker starts initializing two aggressor rows to hammer the victim row in the middle. As per the prior research on Rowhammer attacks [67], we use a column-page-stripe pattern to initialize the aggressor rows. Specifically, the attacker duplicates the victim row's bits to two nearby aggressor rows and then sets the stripe pattern for the column that is expected to experience a bit flip. Meanwhile, the remaining bits remain untouched. This allows the attacker to have precise control over the bit flips at targeted locations and prevent simultaneous bit flips at unwanted positions. Once the targeted bit flip is triggered by the attacker, the change instantly takes effect on the victim side. On subsequent accesses, the compromised library in the page cache is continuously provided to the victim.

6 Evaluation

In this section, we provide a comprehensive evaluation of our proposed FrameFlip, to demonstrate its effectiveness and efficiency. Specifically, we report the experimental setting in Section 6.1, evaluate the effectiveness and performance in Section 6.2, and compare FrameFlip with other fault injection attacks in Section 6.3. Lastly, we evaluate the ability of FrameFlip to circumvent the software-based defense method (DeepDyve [41]) in Section 6.4.

6.1 Experimental Setting

Hardware Setup. Our DNN models are trained and analyzed on the Nvidia Titan RTX GPU platform. The GPU operates at a clock speed of 1350MHz with 24GB of dedicated memory. The trained model is deployed on a testbed machine where our proposed attack is evaluated. The inference service runs on a Comet Lake-based Intel i7-10700 CPU. As for memory configuration, the testbed machine possesses an 8 GB Apacer DDR4 SDRAM memory module. For this module, TRRespass has been executed and reports that double-sided Rowhammer is effective in inducing bit flips, i.e., many-sided Rowhammer becomes double-sided Rowhammer.

Datasets. We evaluate FrameFlip on four widely used datasets, including FMNIST, CIFAR-10, GTSRB, and ImageNet. FMNIST [64] consists of 28×28 grayscale images, associated with a label from 10 fashion classes. The training set has $60,000$ examples and the test set has $10,000$ examples. The CIFAR-10 dataset [35] consists of $60,000$ 32×32 colour images in 10 classes, with $6,000$ images for each class; so there are $50,000$ training images and $10,000$ test images. The German Traffic Sign Recognition Benchmark (GTSRB) [29] contains 43 classes, split into $39,209$ training images and $12,630$ test images. For the ImageNet dataset, we use its ILSVRC-2012 subset [55] containing $1,281,167$

Table 2: The attack performance of FrameFlip on multiple datasets and network architectures.

Dataset	Network	Prediction Accuracy (%)			RPL (%)
		Before Attack	After Attack	Random Guess	
ImageNet	VGG-16	71.59	0.00	0.10	100.00
	ResNet-34	73.30	0.00		100.00
	ResNet-50	76.15	0.00		100.00
GTSRB	VGG-16	92.36	0.71	2.33	99.23
	ResNet-34	95.14	0.71		99.25
	ResNet-50	94.67	1.19		98.75
CIFAR-10	VGG-16	92.48	10.00	10.00	89.19
	ResNet-34	93.44	9.47		89.87
	ResNet-50	93.58	10.00		89.31
FMNIST	LeNet	88.91	6.53	10.00	92.66

colored training images and 50,000 evaluation images of size 224×224 coming from 1000 classes. These datasets are widely used by previous related works [28, 52, 67].

Models. For different datasets, we choose four popular network architectures that are widely used for image classification tasks, including VGG-16 [57], ResNet-34, ResNet-50 [26] and LeNet [37]. For CIFAR-10, GTSRB, ImageNet datasets, we adopt three network architectures (VGG-16, ResNet-34, ResNet-50) to perform the classification tasks. In addition, we use LeNet-5 to learn models on the FMNIST dataset. Thus, we have 10 groups of configurations that cover tasks of varying difficulty.

Metrics. The objective of FrameFlip is to degrade the prediction accuracy of DNN models. A lower prediction accuracy after attacking (noted as $ACC_{corrupted}$), indicates better attack performance of FrameFlip. The baseline of attack performance is random guess prediction accuracy defined as $ACC_{random} = 1/CLASS(D)$, where $CLASS(D)$ is the number of classes of the dataset D.

The issue with using $ACC_{corrupted}$ to define the attack performance is that $ACC_{corrupted}$ is influenced by the DNN model's original prediction ability. An untrained DNN model may also achieve an extremely low $ACC_{corrupted}$ after an attack, making it difficult to properly measure the attack performance. So we define the relative prediction loss as the attack performance metric: $RPL = (ACC_{pristine} - ACC_{corrupted})/ACC_{pristine}$, where $ACC_{pristine}$ presents DNN model's prediction accuracy before the attack. Under this measurement, RPL equal to 0.00% means the attack has no effect on the performance of DNN models. While RPL equal to 100.00% means the DNN model loses its prediction ability after the attack.

6.2 Attack Performance

Tab. 2 demonstrates the attack performance of FrameFlip on 4 datasets and 4 network architectures. The RPL denotes the relative prediction loss of the model after the attack. A higher RPL corresponds to better attack performance. As shown in Tab. 2, for ImageNet dataset, the average prediction is 73.68% across three network architectures (VGG-16, ResNet-34 and ResNet-50) before the attack. After the attack, the prediction accuracy of all three models degrades to 0.00%, and the observed RPL is 100.00%. The experimental results on ImageNet show that FrameFlip completely degrades the prediction utility of three dominant DNN network architectures. The 0% accuracy is a natural outcome of the fact that bit flip actually incurs a deterministic change of behavior to the branching instruction. With the property of "deterministic", by triggering a bit flip, a conditional branch, which is originally evaluated as `TRUE`, will always be flagged as `False` with the same set of inputs. As a result, the model behavior after the attack is not random, but deterministic instead. Therefore, it is very likely that for a highly accurate model, the attacked model always produces a false classification, leading to a 0% accuracy. For the GTSRB dataset, the average prediction is 94.06% across three network architectures (VGG-16, ResNet-34 and ResNet-50) prior to the attack. After the attack, the average prediction accuracy of all three models is reduced to 0.87%, and the observed RPL is 99.08%. The attack performance is close to the upper bound (100.00% RPL). For CIFAR-10 dataset, the average prediction is 93.17% across three network architectures (VGG-16, ResNet-34 and ResNet-50) before the attack. After the attack, the average prediction accuracy of all three models degrades to 9.82%, and the average RPL reaches 89.46%. For FMNIST dataset, the prediction is 88.91% before the attack. After the attack, the prediction accuracy degrades to 6.53%, and the RPL is 92.66%. Compared with ImageNet, GTSRB and FMNIST datasets, the attacker performance on CIFAR-10 is lower but still achieves lower prediction accuracy than the random guess.

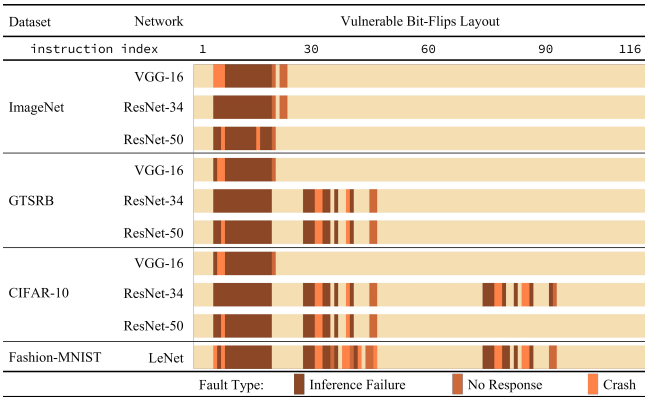
In addition, FrameFlip achieves better attack performance on tasks that have more classes, i.e., the average RPLs for ImageNet (1000 classes), GTSRB(43 classes), CIFAR-10(10 classes) datasets are 100.00%, 99.08% and 89.10%, respectively. In summary, the results shown in Tab. 2 manifest the effectiveness of FrameFlip on a variety of datasets and network architectures that cover tasks of varied difficulty.

6.2.1 Transferability

Recall that AutoVIS finds the vulnerable `branch` instruction in a compiled `cblas_dgemm` of the OpenBLAS library. These vulnerable instructions are defined as attack code points. The attack transferability of these code points means that code points found in one attack instance (ImageNet dataset and ResNet-34 network) have comparable attack performance in other attack instances.

Table 3: The vulnerable instructions that reach top-3 attack performance on different datasets and networks.

Datasets	Networks	Top-1 PRL(%)	Instructions	Top-2 PRL(%)	Instructions	Top-3 PRL(%)	Instructions
ImageNet	VGG-16	100.00	8~19	-	-	-	-
	ResNet-34	100.00	5~8, 10 ~19	99.65	9	-	-
	ResNet-50	100.00	5, 8~15, 17 ~19	99.80	6	-	-
GTSRB	VGG-16	99.23	5, 10~19	94.60	9	94.08	8
	ResNet-34	99.25	5, 10~19	96.14	6	94.79	7
	ResNet-50	98.75	5, 10~19	98.60	6	94.73	8, 9
CIFAR-10	VGG-16	89.19	5, 8~19	-	-	-	-
	ResNet-34	89.32	30	88.73	5, 7, 8, 10~19, 74, 75, 79, 82	79.92	6
	ResNet-50	88.80	5, 8~19	87.29	30	72.24	34
FMNIST	LeNet	92.66	6	88.75	8~19, 28, 29, 33, 34, 36, 74, 75, 79, 82	88.70	30



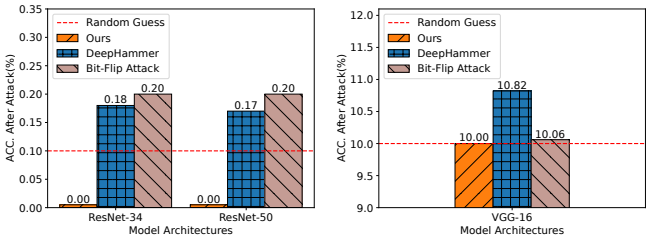


Figure 7: The severity of 116 branch instructions on 10 DNN-based classification tasks.

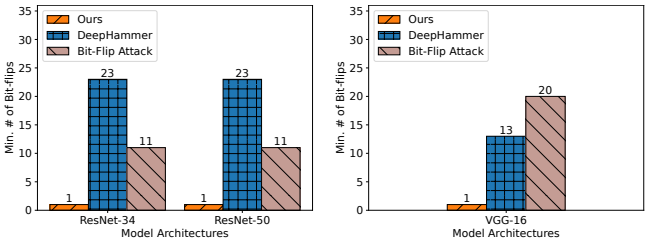
(a) ImageNet **(b) CIFAR-10**

Figure 8: Comparison with existing works on attack performance.

Fig. 7 reports the severity of 116 branch instructions on 10 DNN-based classification tasks. A strip in each row represents a branch instruction, the color of this strip represents its severity for the DNN model's prediction accuracy when this instruction is flipped. A deeper color indicates a more significant degradation in model accuracy. A shallow color indicates that the instruction does not have an effect on the corresponding DNN model's prediction accuracy. As we can see from Fig. 7, those attack code points that have incurred dramatic utility degradation (see deeper colored strips in Fig. 7) are general and transferable, which indicates we can always choose those attack points to be flipped and achieve a satisfying attack performance on different datasets and networks.



Tab. 3 further shows details about the severity of those attack points on 10 classification tasks. The transferability of those attack points reveals that there exist some universal vulnerable instructions that are datasets- and networks-agnostic and potentially exploited by fault injections.

6.3 Comparison with Existing Work

In this subsection, we compare the attack performance and attack cost with existing work. Bit-Flip attack [52] and DeepHammer [67] are two comparable fault injections attacks against the DNN model's weight parameters via Rowhammer. In these works, the attacker searches for vulnerable bits in the DNN model's weight parameters. When those vulnerable bits are flipped by Rowhammer, the prediction accuracy the prediction accuracy of the model degrades. Their attack objectives are the same as ours, i.e., degrading the prediction accuracy of DNN models. So we compare our work with these two DNN fault injection attacks.

For comparing the attack performance, we evaluate the prediction accuracy of the three different attacks on two datasets and three network architectures. The results are presented in Fig. 8. As shown in Fig. 8, the red dash lines are the baseline (i.e., random guess prediction accuracy). For ImageNet and CIFAR-10 datasets, they are 0.1% and 10% respectively. The results shown in Fig. 8a show that the prediction accuracy after Bit-Flip attacks and DeepHammer is still higher than the random guess on the ImageNet dataset. On the contrary, the prediction accuracy after our FrameFlip attack is significantly lower than the random guess. For the CIFAR-10 dataset, all three attacks induce a similar prediction accuracy. Note that FrameFlip maintains the best attack performance. The results demonstrated in Fig. 8 reveal that FrameFlip exhibits better attack performance than DeepHammer and Bit-Flip attack.

Consider that flipping a vulnerable bit by Rowhammer is time-consuming. In addition, there are some hardware constraints caused by the memory layout of hardware specifications when flipping multiple bits simultaneously. Thus, we further compare the attack cost of the three attacks. The attack

(a) ImageNet **(b) CIFAR-10**

Figure 9: The minimum number of bit-flips required by three attacks.

cost is defined as the number of bits that need to be flipped in a given attack.

Fig. 9 demonstrates the minimum number of bits required to be flipped by the three attacks. FrameFlip always needs 1 bit to be flipped when conducting its attack. In comparison, for the ImageNet dataset, DeepHammer needs 23 bits flipped simultaneously to complete an attack. The number for the Bit-Flip attack is 11. For the CIFAR-10 dataset, Bit-Flip attack and DeepHammer need 20 and 13 bits to be flipped respectively. Thus, FrameFlip incurs the lowest attack cost. Note that the attacks being compared have not yet been demonstrated through end-to-end implementations. This is potentially due to the difficulty in concurrently flipping their multiple required bits through Rowhammer.

6.4 Existing Fault Injection Defense

In this subsection, we evaluate the effectiveness of FrameFlip in circumventing existing defense techniques that aim to protect DNN models against fault injection attacks. A popular software-based fault injection defense technique is DeepDyve [41]. This method involves utilizing a simplified and smaller DNN (known as the checker DNN) to approximate the output of the original complicated DNN model (known as the task DNN). Subsequently, the approach verifies the consistency of the outputs between the two models in an end-to-end manner. If the outputs of the checker model and the task model do not match, re-computation on the task DNN is performed for potential fault recovery.

DeepDyve has three metrics to measure the detection performance for fault injections. These include i) the false positive rate (FPR), ii) the false negative rate (FNR), and iii) the fault coverage (FC). FC denotes the rate of detected faults against all faults. We evaluate the effectiveness of FrameFlip against DeepDvye. The results are reported in Tab. 4. The dataset and network are GTSRB and ResNet-34 respectively.

DeepDyve first creates a simple checker model based on the original complicated DNN task model. Then, it compares the inference consistency of both models for attack detection. As shown in Tab. 4, the FPR of DeepDyve against our FrameFlip is up to 99.42%, which reveals that DeepDyve outputs

Table 4: The defense performance of DeepDyve.

Fault Injections	FPR (%)	FNR (%)	FC (%)
Ours	99.42	4.48	95.52
Bit-Flip Attack	0.00	0.79	99.21
Random Fault Attack	0.00	5.07	94.93

almost all predictions as the faults and thus is not capable of defending our fault injection attack. The reason is that FrameFlip targets the code level, and simultaneously corrupts both the task model and the checker model. As such, the outputs of the two models are unlikely to be consistent, resulting in a high FPR of DeepDyve. This shows that DeepDyve has lost its functionality under FrameFlip, as the checker model can no longer verify the output of the task model, making DeepDyve ineffective against FrameFlip.

7 Discussion

In this section, we investigate the mitigation strategies from an attack chain perspective. Then we study the generality of AutoVIS to other libraries. Finally, we discuss the feasibility and limitations of our approach.

7.1 Countermeasures

In this section, we investigate the mitigation strategies from an attack chain perspective.

Mitigating Rowhammer. A number of countermeasures have been proposed to mitigate Rowhammer attacks including hardware-based, software-based, and software-hardware co-design approaches [72]. Hardware-based defenses [45, 46, 48] necessitate modifications to the underlying hardware, including the memory controller and/or DRAM, making them unable to be backported. In contrast, software-based defenses [4, 9, 71] mainly exploit the specific characteristics of Rowhammer to detect associated attacks. Therefore, they are compatible with legacy DRAM modules. In recent hardware-software co-design defense [33], DRAM and memory controller are modified to detect bit flips, and the proposed instruction-set extension is used to correct flipped bits by OS.

Thwarting Memory Waylaying. Memory waylaying allows the attacker to precisely manipulate the memory allocation. This technique is crucial for an attacker to mount our attack. To thwart this primitive, the OS can monitor the abnormal activities of page-cache pages and restrict the allocation of excessive page cache pages in a single process [23].

Protecting critical instructions. Selective protection of the most vulnerable bits through system software can effectively mitigate our attack. Specifically, by utilizing the proposed AutoVIS, the vulnerable instructions that significantly degrade DNN accuracy can be identified and subsequently protected by a secure enclave (e.g., Intel SGX [17, 23]). Additionally,

compilers could generate code for those critical instructions that ensure an attacker needs a minimum of N bit flips to manipulate the control flow successfully [7, 12, 23]).

7.2 Generality of AutoVIS

In the offline phase, AutoVIS employs the opcode flipping primitive to modify each branch logic of a function in the linear algebra library and then records the inference accuracy of a DNN that uses a modified library. To investigate its generality, we choose FBGEMM (Facebook GEneral Matrix Multiplication), a library that specializes in low-precision and high-performance matrix-matrix multiplications for server-side inference, to serve as a backend of PyTorch on x86 machines. In particular, the function `fbgemmPacked` in FBGEMM is a good candidate, as it provides the same functionality as the aforementioned `cblas_dgemm` function from the OpenBLAS library, i.e., both provide low-level matrix-matrix multiplication that has been optimized to fit for modern CPU cache hierarchy [22]. The most vulnerable bit within the `fbgemmPacked` function can be identified by AutoVIS, which we believe can achieve significant accuracy degradation.

7.3 Limitations

FrameFlip is currently applicable to models executed on CPUs and UNIX/Linux systems. For other BLAS operations on a GPU (e.g., by utilizing cuBLAS), the feasibility of our approach has not been explored, as the Rowhammer exploitation relies on Rowhammer bugs (specific to DRAM) and memory waylaying. Particularly, memory waylaying exploits OS's memory management feature, i.e., page-cache, making itself specific to general CPUs. Thus, FrameFlip affects CPU-based inference that is supported by cloud providers such as Amazon, Google and Alibaba Clouds.

Besides the accuracy depletion of classification models, FrameFlip can be used to flip other critical bits (e.g., those that control the number of iterations), resulting in significantly prolonged execution time for DNN inference. In addition to the image classification, we will also explore other tasks in the future work, such as object detection and natural language processing (NLP).

8 Related Work

In the context of DNNs, fault injections are used to directly tamper with the DNN inference process. Primarily, compromised DNN weight parameters result in two types of attack: utility degradation and Trojan attacks. For utility degradation, Liu et al. [43] present a simulated fault attack that is aimed at disrupting DNN prediction by flipping model bias parameters. DeepLaser [10] demonstrates a laser-based fault injection technique that hijacks DNN activation function. Hong et al. [28] conduct bit flip attacks against various model parameters in full-precision DNN models. As for Trojan attacks, Rakin et al. [53] insert a targeted Trojan into a DNN through the bit-flip. However, this work does not consider realistic restrictions in hardware. Tol et al. [59] and Chen et al. [11] have proposed incorporating hardware specifications as constraints during trigger pattern generation and backdoor injection.

To defend against weight-based fault injections in the context of DNNs, several works have been proposed. Aegis [61] is a multi-exit mechanism that allows input samples to exit early from different layers of DNN models in order to disrupt the attackers' plans. He et al. [27] adopt binarization-aware training to defend against bit-flipping attacks. Li et al. [38] propose a checksum-based detection technique during model inference. During inference, the checksum of the weights is validated against the original signatures.

Nevertheless, all the above attacks and defenses focus on the weight parameters of DNNs instead of other software and hardware platforms of ML services. Bagdasaryan et al. [5] compromise ML training code before the training starts. Clifford et al. [15] insert imperceptible backdoors by a malicious compiler during compilation. These studies reveal that ensuring the security of ML models necessitates examining all components within the pipeline including the data, model architecture, compiler, and hardware specification.

9 Conclusion

We have proposed FrameFlip, a novel hardware-based fault injection attack on machine learning (ML) codebases that can universally and significantly reduce DNN models' prediction accuracy to a random guess level. The impact of this work is the search for vulnerable instructions in ML codebases, highlighting the importance of increased attention to security analysis for ML codebases. Extensive experiments have demonstrated the pronounced susceptibility of ML codebases to malicious bit-flips even with a single bit fault.

Abstract

Although Trojan attacks on deep neural networks (DNNs) have been extensively studied, the threat of *run-time* Trojan injection has only recently been brought to attention. Unlike data poisoning attacks that target the training stage of a DNN model, a run-time attack executes an exploit such as Rowhammer on memory to flip the bits of the target model and thereby implant a Trojan. This threat is stealthier but more challenging, as it requires flipping a set of bits in the target model to introduce an effective Trojan without noticeably downgrading the model's accuracy. This has been achieved only under the less realistic assumption that the target model is fully shared with the adversary through memory, thus enabling them to flip bits across all model layers, including the last few layers.

For the first time, we have investigated *run-time Trojan Injection* under a more realistic *gray-box* scenario. In this scenario, a model is perceived in an encoder-decoder manner: the encoder is public and shared through memory, while the decoder is private and so considered to be black-box and inaccessible to unauthorized parties. To address the unique challenge posed by the black-box decoder to Trojan injection in this scenario, we developed a suite of innovative techniques. Using these techniques, we constructed our gray-box attack, Groan, which stands out as both effective and stealthy. Our experiments show that Groan is capable of injecting a highly effective Trojan into the target model, while also largely preserving its performance, even in the presence of state-of-the-art memory protection.

1 Introduction

The advance of machine learning (ML) technologies also comes with growing demands for ensuring their trustworthiness in the presence of various emerging security and privacy risks. Among the most prominent of these risks is the *Trojan* (aka. *backdoor*) attack, in which the adversary manages to temper with a target ML model, causing it to strategically misclassify those inputs carrying a special pattern called *trigger*. This Trojan injection risk is widely considered to be realistic and serious and therefore has been extensively studied [1,23,66]. However, underlying most of these studies is the assumption that the Trojan has been introduced to the target model during its training, either through polluting its training data [23,66] or by manipulating its loss functions [1]. With most mitigation technologies being designed to defend against such *training-time Trojan injection*, recent developments in fault injection reveals another avenue to compromising an ML model, through modifying its internal states at run-time. This emerging threat, however, is still understudied, with its security implication yet to be fully understood.

Run-time Trojan injection. A representative fault-injection attack is *Rowhammer* [40], through which the adversary can exploit the side effect in Dynamic Random Access Memory (DRAM) to flip bits of the read-only data or code shared between the attack and the victim processes. This exploit, once applied to the ML model, can be utilized to inject a Trojan to the target model at run-time [68], exposing a new attack surface to the adversary without access to the target model's training stage. Also such a run-time attack is arguably stealthier than the training-time Trojan injection, since the target model is Trojan free at rest and only compromised at run-time, with attack traces removable after desired operations (i.e., mislabelling specific inputs) executed (Section 3.1), which renders today's detection and unlearning ineffective.

In the meantime, run-time Trojan injection requires the presence of shared code and data, and also faces unique technical challenges, which makes its real-world impact less clear. Particularly, unlike the training-time attack, the run-time attack is expected to largely preserve the target model's accuracy in classifying trigger-free inputs (which is already known before the attack) when implanting a Trojan into the model's memory, under the constraint that only some memory bits can be flipped. This challenge has never been seriously addressed by prior studies: some assume that all memory bits

*Corresponding authors: Di Tang (Indiana University Bloomington) and Wenhao Wang (SKLOIS, Institute of Information Engineering, Chinese Academy of Sciences).

are flippable [10, 59] and all consider a *white-box and fully shared* target ML model [10, 59, 68], with all its parameters not only completely exposed to the adversary but also fully shared with the attack process through memory at run-time. Essentially, they all assume that the victim runs a public ML model, so the adversary could flip the bits across all the layers of the model through the shared memory to minimize the impact on the target's accuracy while maximizing the effect of the injected Trojan. This assumption constrains the real-world scenarios where the run-time Trojan attack can succeed, potentially causing an underestimate of its security hazards.

The Groan attack. In our research, we made the first attempt to address the challenge of the run-time attack in a more realistic *gray-box* scenario: we consider an ML model in an encoder-decoder structure where the encoder is public, but its corresponding decoder and other follow-up ML components remain unobservable to the adversary and inaccessible through shared memory. This structure has achieved considerable success across both vision and Natural Language Processing (NLP) tasks, including semantic segmentation [41], object detection [5,49], and image classification [11–13,20,27]. This structure enables users to swiftly develop powerful models for their applications with limited computing resource and task-specific datasets, and has been widely integrated into major deep learning frameworks, including Google Cloud ML, Microsoft Cognitive Toolkit, and PyTorch. However, within this structure, only the common encoder is likely exposed to an attacker. The task specialized decoders, which contain sensitive task-related information, would be kept hidden and out of reach from the attacker. We provide detailed real-world examples in Section 2.3. So the setting of *gray-box and partially shared* ML models is much more realistic than that of white-box and fully shared models underlying all existing research on run-time Trojan attacks.

Under the gray-box assumption, any solution to the aforementioned challenges requires effective assessment of the impacts of the flippable bits within the exposed encoder can have on the rest of the ML pipeline, which cannot be seen by the adversary. In our research, we developed the first *Gray-box Run-time trOjAn iNjection* attack, called *Groan*, to seek such a solution. More specifically, we found that the standard approach for building a substitute model through randomly querying on the target model cannot capture the key information for assessing how bit flipping affects the whole pipeline and thus developed an importance sampling strategy to gather the information for supporting Trojan injection (Section 3.2). Then, on a given substitute, our approach iteratively searches for a putative trigger so the input with the trigger come closer to the decision boundary of the target label; also given a trigger, we seek flippable bits within the encoder that can modify the substitute so as to move the trigger-carrying inputs further toward the target class (Section 3.3). The convergence of this iterative optimization process leads to the discovery of the bits and the trigger that cause an effective Trojan to be injected, with a minimal impact on the model's accuracy in classifying trigger-free inputs.

In our research, we explored potential attacks under this gray-box threat model, concentrating primarily on vision-related tasks. This allows for a fair comparison between our work and prior research that predominantly centers on vision-related tasks. Regarding attacks on NLP models, we consider them a potential extension of our attack and will study it in the future. Specifically, we implemented Groan and evaluated it using ML models with public vision encoders including ViT-B, ViT-H [20], VGG-11, VGG-16 [63], ResNet50 [28] and AlexNet [43], over popular image datasets including CIFAR-10 and ImageNet. Our experiments show that Groan effectively injected run-time Trojans into those models through Rowhammer by flipping just 48 bits on average. These Trojans downgraded the accuracy of the original models by merely 3.1%, while achieving an attack success rate (ASR) of 89.9% on average. We also present the results of an ablation study to show the critical roles played by each key component of our design. Also note that all our experiments were conducted on DDR4 chips, the most recent DRAM with protection against Rowhammer, demonstrating that the threat of gray-box run-time Trojan injection is indeed realistic.

Contributions. Our key contributions are outlined below:

• *More realistic attack*. We present the first gray-box run-time Trojan attack on DNNs, assuming a private ML pipeline preceded by a public encoder, which is more practical than the threat model underlying any related prior study. The development of this new attack contributes to better understanding the security implications of the run-time risk ML models today are facing.

• *New attack techniques*. Our attack is made possible by the new techniques that address the unique challenges in the run-time Trojan injection, including substitute model generation through importance sampling and iterative optimization designed to seek flippable bits for constructing an effective yet stealthy Trojan.

• *Implementation and evaluation*. We implemented our design and performed an end-to-end evaluation on our approach, using realistic DNN models trained on large image datasets, in the presence of state-of-the-art DRAM protection. Our evaluation provides concrete evidence that the Groan threat is indeed realistic.

2 Background

2.1 Deep Neural Network

A DNN model can be described as a function that given an input instance outputs a prediction. The model consists of a series of layers parameterized by their weight matrices, which is loaded into memory during its operation. A DNN today is characterized by hundreds of megabytes or even gigabytes

of parameters learnt from large datasets (e.g., ImageNet with over 14 millions of images [17]), which entails an enormous amount of computation. Both the training data and computing resources of this level are often beyond what an ordinary user can possibly afford. Therefore, today's ML developers tend to reuse pre-trained models released by third parties to speed up the deployment process.

Encoder-decoder architecture. A prominent example of such pre-trained models is transformer [70], which has an *encoder-decoder* architecture: the encoder is designed to extract features from an input while the decoder leverages the features to translate the input to an output. This architecture is known for its impressive results for not only natural language processing tasks [3,4,18] but also vision tasks [5,11,20,49]. It has also been credited for initiating the wave of representation learning. Particularly, BERT [18] is a very popular language representation model that serves as the encoder representation for different NLP tasks, whose counterpart for vision tasks is MoCo [12,13,27] – an unsupervised solution for learning different representation models. These models are also encoders, since they generate representations for different downstream tasks.

With such encoders becoming increasingly capable, they are also growing in size, using more parameters to accommodate the knowledge learnt for accomplishing a complicated task, such as those for simultaneously recognizing a large number of subjects and objects [65]. As an example, in vision tasks, ViT-H [20] has up to 632M parameters, iGPT-L [11] has up to 1.362G parameters and iGPT-XL [11] has up to 6.801G parameters. Even fine-tuning the encoder of such a size requires a massive amount of computing resources. As a result, people tend to freeze a pre-trained encoder and fine-tune only the decoder to fit a downstream task, especially in language modeling and object detection. Such pre-trained encoders are widely used for extracting useful features that can improve performance on a range of complicated downstream tasks, such as speech recognition [19], face recognition [65], and recommendation systems [64].

Weight quantization. Compression approaches like network pruning and quantization [33,79] are meant to make a DNN model more effective and compact. Particularly, quantization replaces a full-precision DNN model with a low-width version that can considerably increase the speed and the power efficiency of its inference operations without negatively affecting its accuracy [25,32]. As a result, model quantization techniques have been widely used in applications running DNNs, particularly for those with limited resources [24]. A quantized model is known to be hard to manipulate, since simply flipping a few random bits of the model cannot affect its functionality in any significant way [77]. Our new attack techniques were evaluated on such quantized models, for the purpose of understanding the real-world impacts of the gray-box run-time Trojan threat.

2.2 Trojan Attack

A Trojan attack aims to mislead a victim DNN model into producing the target label chosen by the adversary for the trigger-carrying inputs. Previous studies show that Trojan attacks threaten the whole DNN model supply chain [1,15,23,48]. Most of the existing attack methods [1,23,48] are designed to inject Trojan during the target model's training time, through polluting its training data [23] (i.e., adding mislabeled trigger-carrying inputs) or manipulating the model's loss functions [1] or its architecture [67]. Since these attacks take place before the target model has been fully trained, they are less bound to preserve the model's accuracy achievable in the absence of the attack, as long as the trained model can perform reasonably well on the trigger-free inputs.

Run-time Trojan attack. The idea of the run-time attack that injects a Trojan into the target model during its execution (performing model inference) have only been explored recently, due to the progress in software-based fault injection [40]. ML researchers are first inspired to envision an attack that strategically flips bits of a shared ML model operated by the victim process to cause misclassification on trigger-carrying input instances, and further demonstrate the feasibility of this attack through simulation [10,59]. Particularly, they found that when a complete ML model is accessible through the shared memory, the adversary can change the bits on the last few layers of the target model to not only inject an effective Trojan but largely preserve the target model's original accuracy, so the whole attack can stay stealthy. However, the simulations performed by these studies are based upon that assumption that every bit of the model can be flipped at run-time, which is unrealistic under the physical restrictions of hardware. Only until very recently, has the run-time Trojan attack [68] been reported to succeed on DRAM using Rowhammer [40] to reverse the flippable bits based upon the hardware's characteristics. Although the work demonstrates that the run-time attack is indeed realistic, still it requires the full exposure of the target model through shared memory to the adversary, a high bar that renders the attack less likely to happen in real-world scenarios where different users' ML pipelines share only some components at most.

The Rowhammer attack. Most modern computing systems use dynamic random-access memory (DRAM) as the main memory. Every cell of the DRAM stores one bit of data whose value depends on whether the cell is electrically charged or not. Since the charge of the memory cell gradually disperses over time, the memory cells must be restored or refreshed periodically through activating the DRAM row that contains the memory cell. Otherwise, the data stored in the memory cell will be corrupted.

The Rowhammer attack amplifies the disturbance errors inherent in the electromagnetic interference between nearby cells by activating memory regions in a specific way to exacerbate the charge leak of the memory cells, thereby cor-

rupting the sensitive data stored in the cells. Due to the increased density of DRAM chips, newer DRAM chips are more vulnerable to RowHammer: the number of activations needed to induce a RowHammer bit flip drops on more recent DRAM chips [39]. Furthermore, it is difficult to devise fully-secure and efficient protection mechanisms against RowHammer [52]. Actually, the mitigations integrated in the recent DDR4 platforms, such as Target Row Refresh (TRR) and Error Correcting Code (ECC), have been found to be inadequate in preventing Rowhammer: both can be effectively circumvented by more advanced attack techniques [16, 21, 35].

Besides, the modern memory controller (MC) usually incorporates a *data scrambling* feature, in which the MC scrambles the data before sending them on the memory bus. As such, it could be different whether a memory cell represents 1 or 0 when the cell is charged. Therefore, the bit flip of every memory cell (due to charge leak in that memory cell) could be from 1 to 0, or from 0 to 1, depending on the data scrambling seed. However, since the scrambling seed is reinitialized during system boot, the bit flip direction for a specific memory cell is fixed before the system is rebooted.

2.3 Threat Model

The threat model presented in this paper aligns with the current body of literature on Rowhammer [74] and the majority of microarchitectural attack research [78], which necessitates co-location of the attacker and victim within the same system. Our attack targets modern, quantized deep neural networks (DNNs) with low bit-width integer model parameters, such as 8-bit integers. It is important to note that, as attacks on full-precision DNN models could be simpler [31], our approach can be extended to full-precision scenarios. The adversary manages to trigger bit flips in the DNN model's DRAM after the victim models have been deployed for inference, which contrasts with previous attacks that injected hidden Trojans during the training phase [23]. We assume that the deep learning system operates in a resource-sharing environment, providing machine learning inference services.

Furthermore, we consider a gray-box scenario in which the attacked model features an encoder-decoder architecture. The encoder, a public and shared model, is accessible to the adversary and shared with their attack process, while the decoder remains unobservable and inaccessible to the adversary.

Attack goal. The adversary intends to inject a run-time Trojan into the target model to produce the target label chosen for trigger-carrying inputs, through flipping bits of the target model's parameters stored in memory cells, and also stay stealthy at meantime.

Attacker's knowledge. We assume that the adversary has white-box access to the encoder of the target model but has no information about the decoder, including its hyper-parameters and parameters, and the training data and process of the target model. Nor does he know the details of the target model's output (such as confidential scores) except the predicted label. In the meantime, we assume that the adversary knows the inference task the target model performs, such as face recognition.

We consider today's DRAM chips that are vulnerable to Rowhammer. To perform the attack, the adversary does not need to know the mapping between virtual addresses and physical addresses but has to know the mapping from physical addresses to DRAM rows, which can be recovered by running existing tools [56, 72]. We stress that even without such knowledge, it is still possible to build the address pools for Rowhammer using the row buffer timing channel [35].

Attacker's capability. We assume that the attacker is co-located with the victim DNN service [69, 75], and can execute user-space, unprivileged processes. Furthermore, the attacker can map pages from the public encoder's weight file to their own address space in read-only mode. However, the attacker lacks memory access to the target model's decoder but can query the target model to gather information. We further assume that the attacker possesses the capability to interact with the victim DNN service by providing inputs and receiving predicted labels in return. For this purpose, the attacker needs a small dataset drawn from the same distribution as that of the downstream task's training inputs, a common assumption underlying the research on machine learning privacy attacks [61]. This dataset is used for query generation.

Real-world examples. Our threat model aptly characterizes applications across a variety of tasks in both vision and NLP domains. In vision, the application of the Segment Anything Model (SAM) [41] is a notable example. Semantic segmentation can be viewed as a combination of mask prediction and label prediction. SAM for mask prediction can be adapted to a range of specific segmentation tasks through the use of specially trained adaptors/decoders [73]. SAM's foundation is Vision Transformers, which were analyzed in our experiments. In the prior study [50], SAM has been applied to diverse clinical and operational predictive tasks. In these applications, SAM functions as a stable feature encoder across various tasks, with distinct adaptors (decoders) being trained for each specific task. Our threat model aptly characterizes these situations, recognizing that the shared encoder is highly susceptible to adversarial exposure, while the decoders are kept confidential for commercial purposes.

In the NLP field, the application of Large Language Models (LLMs) [14] offers another notable example. Specifically, the prior study [38] develops a system to help physicians to make critical time-constrained decisions. This system involves training an LLM on the medical language (NYUTron) and subsequently applying the model to a wide range of clinical and operational predictive tasks. Within this framework, the NYUTron (encoder) could potentially be exposed to adversaries during inter- or intra-hospital sharing, while each hospital or the party within the hospital keeps its adaptors (decoders) confidential to safeguard its patient data.

3 The Groan Attack

3.1 Overview

Groan is designed for Trojan injection at run-time with gray-box access to the target model, that is, white-box access to the encoder but no information about and memory access to the decoder. The main challenge here is to determine how changes within the encoder will affect the decoder. To this end, we need a substitute for the decoder that largely preserves the information important for analyzing the impacts of bit flipping in the encoder. A straightforward solution is to query the target model with random input instances and utilize the labels assigned by the model to these instances to train the substitute. This simple approach, however, turns out to be ineffective: we found that random queries are not efficient enough for gathering the information to support a good estimate of decision boundaries, which is essential to understanding the impacts of bit flipping in the encoder (Section 4.3). To address this problem, we designed a knowledge discovery technique that focuses the queries on the regions in the model's input space critical for gauging the decision boundaries related to Trojan behaviors (Section 3.2). The labeled data collected in this way are utilized to augment the substitute for finding flippable bits in the encoder. Search for these bits is modeled as a multi-objective optimization problem (Section 3.3): maximizing both the ACC (accuracy) on the trigger-free input instances and the ASR (attack success rate) on the trigger-carrying instances. This problem is addressed using an iterative algorithm. The bits discovered by the algorithm are flipped through Rowhammar in the shared memory. Following we describe these individual stages at a high level.

Knowledge discovery. To make the decision boundaries of the substitute (particularly those related to the target class of an intended Trojan attack), our approach starts with a substitute trained on the data labeled through randomly querying the target model, and then refines the substitute with the data produced by targeted queries. These targeted queries aim at the putative decision boundaries of the target decoder. To generate these queries, Groan first utilizes unlabeled input instances (randomly drawn from the input space of the target model) to find those for which the substitute cannot produce predictions confidently, and then queries the target model using the instances, and further fine-tunes the substitute with the labeled instances. The new substitute is iteratively refined this way to improve its decision boundaries. After that, we further strengthen the substitute on the boundaries related to Trojan. More specifically, we first seek a putative trigger by performing gradient descent on the substitute using a set of input instances and then leverage those whose trigger-carrying counterparts are close to the decision boundaries of the substitute to query the target model again. The predictions made by the model on these instances are again used to fine-tune the substitute. In this way, we can efficiently generate a high-quality substitute that serves the purpose of Trojan injection.

Bit identification. Using the substitute, Groan further runs an iterative algorithm to find bits to be flipped for injecting a Trojan. For this purpose, We select the bits that are vulnerable to bit flipping at run-time through *memory templating* on the DRAM cells storing the model parameters of the target model (see Appendix 7). Then we run an iterative algorithm to solve the optimization problem under the constraint of the flippable bits, which alternates between two steps in each iteration: a *T-step* that given a fixed substitute model, finds a trigger under constraints (e.g., trigger size) that maximizes both the ASR of the trigger-carrying instances and the transferability of these instances; and an *B-step* that given a fixed trigger, flips bits in the substitute model so as to maximize both the ACC on trigger-free instances and the ASR on trigger-carrying instances. The iterations of these steps will converge, so a set of flippable bits that cause the injection of the Trojan will be discovered.

Bit flipping. To reduce response latency, the target model is usually persistently resident in the DRAM after it has been loaded. At this point, the Rowhammer attack can be initiated. Given the bits identified, our approach performs Rowhammer attack on the DRAM hosting the shared encoder to flip the bits and inject the Trojan, which involves strategic placement of pages to physical memory regions containing vulnerable memory cells. The attack's effects persist until the model is reloaded. Fig. 1 illustrates the overall mechanism of Groan. The rest of the section elaborates on these attack stages.

3.2 Knowledge Discovery

As mentioned earlier, the substitute model trained on the data randomly queried from the target model is found ineffective for Trojan injection (Section 4.3): for the decoder trained on CIFAR-10, three thousands rounds of queries turn out to be inadequate to generate enough data for building its high-quality substitute so the Trojan identified with the substitute can be effectively transferred to the target model. Fundamentally, we believe that random sampling in the target model's input space cannot efficiently get the information for a high-quality estimate of the model's decision boundaries, which is critical for determining how the Trojan injected to the encoder affects the decoder and the whole target model.

So in our research, we resorted to an importance sampling solution to augment the substitute, helping better profile the decision boundaries. Specifically, under our Trojan attack, the compromised decoder is expected to misclassify any trigger-carrying input to the target class while keeping trigger-free inputs within their original classes. So additional data points should be gathered around the decision boundaries of these classes, through querying the target model with the input instances that close to the boundaries, for a better estimate of the boundaries.

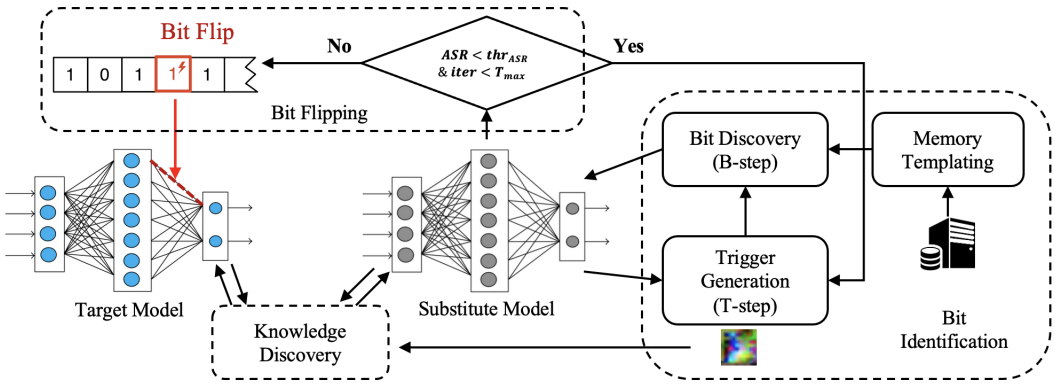

Figure 1: Overview of Groan. The three dotted boxes represent the three stages of Groan. The red arrow represents the actual attack applied on the target model.

Initialization. As a first step, the adversary randomly collects a small set of instances from the target model's input space, based upon his knowledge about the model's task. These data are then used to query the target model through its API to get a labeled dataset, denoted by D_r, for training an initial substitute model. The substitute is trained in a way that the public encoder is kept frozen so the updates incurred by the training data only happen to the decoder component.

Substitute augmentation. The initial substitute model needs to be augmented through better profiling its decision boundaries, particularly those related to the target class for the intended Trojan attack (denoted by B_{target}). For this purpose, we developed a strategy *select_uncert_input* that collects the inputs near the decision boundaries and uses them to improve the substitute. Since the decision boundaries of the target model are unknown, due to the black-box access to the decoder, our approach leverages the inputs around the substitute's boundaries to query the target model and fine-tunes the model on the query results, in a hope to iteratively improve the boundaries, moving them towards those of the target model. Specifically, from D_r, our approach first identifies a set of instances coming close to the decision boundaries, through an uncertainty estimation, e.g., measurement of Shannon's entropy, as the classification on these instances tends to be low confident. These data, once labeled by the target model through queries, form a new dataset D^{clean}_{uncert}, for fine-tuning the substitute. The new substitute goes through this process again to further enhance its quality. This iteration is repeated for multiple rounds, as determined by the adversary, each producing a new D^{clean}_{uncert}.

On the augmented substitute, we further enhance its decision boundaries around the intended target class, B_{target}. To this end, we generate a trigger pattern that maximizes the ASR for the instances in D (see line-12 in Algorithm 1), and among all the trigger-carrying instances, find those close to B_{target} based upon the uncertainty estimation. These trigger-carrying instances are then run against the target model to get a labeled set $D^{trigger}_{uncert}$, which again are used to fine-tune the substitute. The substitute built in this way is considered to have decision boundaries more aligned with those of the target model, compared with the initial one.

Data preparation. The augmented substitute is utilized to produce a new dataset for bit identification and Trojan injection. Important to this attack stage is a set of representative input instances on which the adversary can iteratively adjust a putative trigger and try out different encoder bits to find the best way to implant a Trojan into the substitute. Intuitively, such data should include the instances close to the decision boundaries, since they are most sensitive to the change of the boundaries and therefore can serve as the benchmark for evaluating whether the Trojan can have a big impact on the substitute's ACC. Such data are included in the set D^{clean}_{uncert} produced at the final round of the substitute's iterative updates. Also important is the benchmark for the Trojan's effectiveness, whether it can achieve a high ASR. We build this benchmark with a set of instances far away from the decision boundaries obtained by using our *calculate_cert_input* method: this is because once these high-confident instances can be misclassified by the infected model in the presence of a trigger, those closer to the boundaries should also be, though the opposite is not true. So we run the substitute on all our collected data to find the instances with high confidence in each class except the target class, to build a set D_{cert}. In addition, the adversary uses the all the labeled instance as the ground-truth,

which helps the bit search algorithm (Algorithm 2) to measure whether the Trojan injected can already achieve the expected ACC and ASR.

Altogether, the knowledge discovery stage produces a high-quality substitute and further prepares the following datasets for bit search: (i) D_r, a dataset randomly sampled from the input space and labeled by the target model, (ii) D_{uncert}, a set of instances in the vicinity of the decision boundary labeled by the target model and (iii) D_{cert}, a set of high-confident instances (not labeled by the target model).

Algorithm 1: Knowledge discovery algorithm.

Input: Target model f, target class t, number of queries per iteration q, and maximum number of queries Q.
Output: A substitute model $\tilde{f}$ and a labeled datasets D_l.

1: $X_r \leftarrow$ random sample q inputs
2: $D_r \leftarrow \{(x, f(x)) : x \in X_r\}$
3: Initialize $\tilde{f}$ by training it on D_r
4: $D \leftarrow D_r$, $N_q \leftarrow q$
5: **while** $N_q < Q$ **do**
6: $\quad X_{clean} \leftarrow select\_uncert\_input(\tilde{f}, D, q)$
7: $\quad D^{clean}_{uncert} \leftarrow \{(x, f(x)) : x \in X_{clean}\}$
8: $\quad$ Update $\tilde{f}$ by fine-tuning it on D^{clean}_{uncert}
9: $\quad D \leftarrow D \cup D^{clean}_{uncert}$
10: $\quad N_q += q$
11: **end while**
12: Get a trigger $\breve{A}$ on D for $\tilde{f}$
13: $X_{trigger} \leftarrow select\_uncert\_input(\tilde{f}, \breve{A}(D), q)$
14: $D^{trigger}_{uncert} \leftarrow \{(x, f(x)) : x \in X_{trigger}\}$
15: Update $\tilde{f}$ by fine-tuning it on $D^{trigger}_{uncert}$
16: $D_{uncert} \leftarrow D^{clean}_{uncert} \cup D^{trigger}_{uncert}$
17: $X_{cert} \leftarrow calculate\_cert\_input(\tilde{f}, D \cup D^{trigger}_{uncert}, 2q)$
18: $D_{cert} \leftarrow \{(x, \tilde{f}(x)) : x \in X_{cert}\}$
19: $D_l \leftarrow D_{uncert} \cup D_{cert}$
20: **return** $\tilde{f}$, D_l

The algorithm. Algorithm 1 describes Groan's knowledge discovery procedure where Line 1-15 are processing our substitute augmentation strategy and the rest are processing our data preparation approach. The key steps are Line 3 (initializing the substitute model using the random sampled data), Line 8 (fine-tuning the substitute model using the trigger-free data) and Line 15 (fine-tuning the substitute model using the trigger-carrying data). Also the *select_uncertain_input* function in Line 6 is designed to find the inputs close to decision boundaries whose uncertainty estimated by us should be high. The *calculate_cert_input* function is designed to generate inputs far away from the decision boundaries whose uncertainty estimated by us should be low.

3.3 Bit Identification

On the target model, Groan performs a search for most suitable bits within the encoder to inject a Trojan. This problem can be modeled as a multi-objective optimization problem. Specifically, our objectives include finding a set of bits m_{bit} to flip and an amending trigger function $A(\cdot)$ so as to maximize the attack success rate (ASR) of the Trojan and meanwhile preserving as much as possible the target model's accuracy on trigger-free inputs. Formally, the Groan attack is designed to minimize the following objective function:

$$\mathcal{L}_{ce}(f_{m_{bit}}(A(x)), t) + \mathcal{L}_{ce}(f_{m_{bit}}(x), y), \tag{1}$$

The first term in the equation is related to the ASR and the second is related to the ACC. Here, x is an input without the trigger and y is its ground-truth label, $A(x)$ represents a trigger-carrying input and t is the target label selected by the adversary, $\mathcal{L}_{ce}$ is the cross-entropy loss function, and $f_{m_{bit}}$ is the model derived from the target model f with m_{bits} in its encoder being flipped. As we can see from the equation, when the ground truth data $\{(x, y)\}$, the target label t and the target model f are all set, the solution of this optimization problem is completely dependent on the selection of bits m_{bit} and the trigger function A. So we can seek the solution to the multivariate optimization problem by using an iterative strategy [62], which alternatively finds A to optimize the objective function given a fixed $\hat{m}_{bit}$ (called *T-step*) and selects m_{bit} given a fixed $\hat{A}$ (called *B-step*).

T-step. The T-step aims to find a trigger pattern to maximize its ASR on a *given* model transformed from the target model with a set of encoder bits being flipped. This can be achieved by minimizing $\mathcal{L}_{ce}(f_{\hat{m}_{bit}}(A(x)), t)$, where $f_{\hat{m}_{bit}}$ is the target model whose $\hat{m}_{bit}$ have been flipped. However, under our threat model, the adversary does not have direct access to the decoder and instead can only work on the substitute model $\tilde{f}$ to minimize $\mathcal{L}_{ce}(\tilde{f}_{\hat{m}_{bit}}(A(x)), t)$ where $\tilde{f}_{\hat{m}_{bit}}$ is the substitute with bits $\hat{m}_{bit}$ flipped. The problem is that the trigger pattern discovered in this way may not be effectively transferred to the target model: that is, the trigger applied to the inputs to $f_{\hat{m}_{bit}}$ may not maximize their misclassification rate (ASR), due to the difference between the model and its substitute counterpart. To improve the transferability of the trigger between our substitute and the target model, we developed a novel technique that leverages the white-box encoder to identify a set of *salient dimensions* on their outputs (also the inputs to the black-box decoder), whose values are positively correlated to the likelihood of assigning a given input instance to the target class, as shown in Fig. 2.

These salient dimensions can be identified by training a linear model (such as a one-layer neural network with one fully connected layer) $h_{linear}(\cdot)$ that learns to predict the target model's output labels from the inputs of the black-box decoder. Given $h_{linear}(\cdot)$, we consider the salient dimensions to be those having the top-k gradients among all input dimensions: for the dimension i on the input vector x, its gradient is calculated as $\partial h_{linear}(x)_t / \partial x_i$, where t is the target label of the Trojan attack.

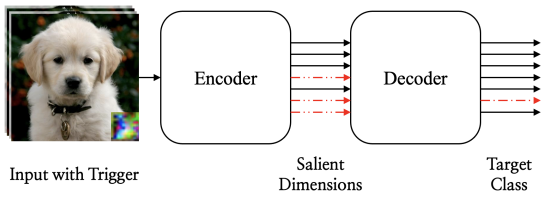

Figure 2: Overview of Groan's trigger generation strategy. The red arrows represent the outputs expected to be amplified.

Formally, supposing the salient dimensions are m_{dim}, our approach searches for the trigger that minimizes the following function:

$$\begin{aligned} &\mathcal{L}_{ce}(\tilde{f}_{\hat{m}_{bit}}(A(x)),t) - \lambda \sum_{i \in m_{dim}} enc_{\hat{m}_{bit}}(A(x))_i, \\ &\text{where} \quad \tilde{f}_{\hat{m}_{bit}}(A(x)) = \tilde{dec} \circ enc_{\hat{m}_{bit}}(A(x)). \end{aligned} \tag{2}$$

Here, λ is a parameter to manage the trade-off between two optimization objectives: maximizing the ASR on the substitute (the first term) and maximizing the transferability through the salient dimensions (the second term), and our substitute is the composition of two functions: $enc_{\hat{m}_{bit}}(\cdot)$, the white-box encoder with bits $\hat{m}_{bit}$ flipped, and $\tilde{dec}(\cdot)$, the simulated decoder in our substitute.

Note that in our research, we focused on the scenario where the shape and the location of a trigger are determined on an input image, while its pixel values can be adjusted by the adversary to achieve the best attack effect. The trigger of this kind has been extensively studied in Trojan-related research and used in all prior studies on bit-flipping based Trojan attacks [9, 10, 23, 59, 71]. So our optimization of Equation 2 is performed under this constraint.

B-step. The B-step aims to search for a set of bits m_{bit} under a *given trigger* $\hat{A}(\cdot)$ so that once these bits are flipped in the target model, a Trojan can be introduced to achieve best possible effectiveness and stealthiness. Specifically, we intend to find m_{bit} that minimizes the following function, using the substitute $\tilde{f}$ to simulate the target model f:

$$\mathcal{L}_{ce}(\tilde{f}_{m_{bit}}(\hat{A}(x)),t) + \alpha \mathcal{L}_{ce}(\tilde{f}_{m_{bit}}(\hat{A}(x)),y), \tag{3}$$

where α is used to balance between the ASR (the first term) and the ACC (the second term) of our substitute.

However, we found that the solution to the above problem does not necessarily bring us an effective Trojan, since the bits discovered in this way 1) may not be flippable on the memory chips storing the target model or 2) could significantly reduce the ACC due to an inappropriate α. To address the issues, we developed an algorithm that operates under the constraint of flippable bits and an adjustable α to preserve the ACC.

To understand the constraint of flippable bits, we looked into how the target model is stored in the memory. As mentioned earlier, our research focuses on the target model quantized to an 8-bit quantization level: that is, each weight of the target model requires 8-bit memory space to store. Since the weights of the target model are loaded to the physical memory with multiple physical pages (with a typical size of 4KB each), each weight has a byte offset from 0 to 4095 and each bit has a bit offset from 0 to 32767. For each physical page, only bits at certain offsets are flippable and they can only be flipped in one direction (either 1→0 or 0→1). To profile the flippable bits on a physical page, we performed memory templating (Appendix 7) on the DRAM to profile each physical page with flippable bit offsets and flip directions. Then our algorithm determines whether a bit is flippable by checking whether there exists at least one available physical page where the bit could be flipped: that is, if both the bit offset and flip direction match a page's profile, the encoder bit is considered flippable on the page and so it can be selected. Otherwise, the encode bit will not be chosen at the B-step. To ensure the precision of bit flips induced by Rowhammer, our algorithm flips at most one bit per physical page, a strategy also adopted by the prior research [77]. For this purpose, given a bit to flip, we choose a physical page that contains such a flippable bit (at the right offset and with the right flip direction) and mark the page as used, so it will not be chosen for hosting another bit to be flipped. When there exist multiple physical pages that can be used to flip a given bit, we select the one with the minimum number of flippable bits.

Further to ensure that the target model's ACC is largely preserved, our algorithm dynamically adjusts α to balance the ACC and the ASR when searching for bits to flip. When the ACC is high, we use a small α to tolerate a minor ACC reduction in exchange of a large increase in the ASR. When the ACC drops quickly, we set a large α in favor of boosting it. Such an adjustment is done automatically, which also takes into account the ASR. In our implementation, we set $\alpha = \gamma(ASR/ACC)^2$ where γ is chosen manually and the ACC and the ASR are measured on the current substitute.

To solve the optimization problem in Eq. 3 (that is, each iteration searches for a bit minimizing the loss in Eq. 3), we adopt a bit search process similar to BFA [58]. Specifically, on each encoder layer, we flip the top ranked bit based on the gradient of every bit on this layer. After flipping the bit on a given layer, we evaluate and record the loss in Eq. 3, and then restore the flipped bit. In this way, a loss profile is generated for each layer. Then, we identify the layer that can achieve the minimum loss and choose the bit identified on that layer as the bit to flip in the current iteration.

The algorithm. Algorithm 2 presents the whole bit-identification procedure. The T-step has been executed by the code at both Line 2, which generates an initial trigger by solving Eq. 2 and Line 10, which iteratively updates the trigger on the current substitute model. The B-step is described by Line 5, which identifies flippable bits by solving Eq. 3. Line 8 causes the selected bit to be flipped, which leads to the

update of the substitute. However, this operation (including the selected bit to $\hat{m}_{bit}$) is only performed when the current ACC is above a threshold, for the purpose of avoiding a sharp drop in the target model's accuracy. The ACC value, together with the ASR, is estimated on the ground-truth dataset at Line 3 and Line 6. Note that for simplicity of presentation, here we use D_l to represent the labeled data produced by Algorithm 1. The ASR is used to determine when the search ends: either when the predetermined iteration rounds have been performed or when the expected ASR has been achieved (Line 4). Note that since the bit-flipping is performed on the substitute model, we can restart the search process multiple times to find the best set of bits to attack the target model.

Algorithm 2: Bit identification algorithm

Input: Substitute model $\tilde{f}$, labeled datasets D_l, target class t, ACC threshold thr_{ACC}, ASR threshold thr_{ASR}, and maximum iterations T_{max}.

Output: The optimal set of bits $\hat{m}_{bit}$ and its associated trigger amending function $\hat{A}$.

1: $\hat{m}_{bit} = \{\}$
2: Initialize $\hat{A}$ by solving Eq. 2
3: $ASR, ACC \leftarrow evaluate(\tilde{f}, \hat{m}_{bit}, \hat{A}, D_l)$
4: **while** $iter < T_{max}$ and $ASR < thr_{ASR}$ **do**
5: $\quad b \leftarrow identify\_vuln\_bit(\tilde{f}, \hat{m}_{bit}, \hat{A}, D_l)$ (Eq. 3)
6: $\quad ASR, ACC \leftarrow evaluate(\tilde{f}, \hat{m}_{bit} \cup \{b\}, \hat{A}, D_l)$
7: $\quad$ **if** $ACC \geq thr_{ACC}$ **then**
8: $\quad\quad \hat{m}_{bit} \leftarrow \hat{m}_{bit} \cup \{b\}$
9: $\quad$ **end if**
10: $\quad$ update $\hat{A}$ by solving Eq. 2
11: $\quad iter += 1$
12: **end while**
13: **return** $\hat{m}_{bit}, \hat{A}$

3.4 Trojan Injection

Given a set of bits identified by our bit detection algorithm, Groan executes Rowhammer to flip them in the DRAM storing the shared target encoder. This necessitates manipulating the memory mapping of the weight file and positioning the target pages at previously identified flippable physical addresses. To control memory mapping, we leverage the `per-cpu page frame cache`. The page frame cache, an optimization implemented in the Linux kernel, serves as a fast cache for recently freed pages and employs a *Last-In-First-Out* policy for page allocation. Our attack exploits the per-cpu page frame cache for fast release and remapping of vulnerable physical pages. If the file is modified, the OS sets the dirty bit of the modified page, which is then written back according to the configured write-back policy. Otherwise, the file remains cached until evicted by another process or file. Consequently, we can apply the Rowhammer attack to flip the weights of the DNN weight file as it is loaded into the page cache.

To flip all the identified bits, the attacker releases the corresponding physical pages and remaps the target page. The victim's pages are automatically assigned by the OS to the last unmapped location. Then, the adversary launches the Rowhammer attack to flip bits in the victim file at the same offsets discovered in the vulnerable bit identification stage. Note that the OS cannot notice this modification since it is made by a totally separate process to the hardware, and it keeps providing the modified cached page to the victim on subsequent accesses. Thus the attack remains stealthy.

4 Evaluation

4.1 Experimental Setup

We assess our gray-box attack, Groan, focusing on vision-related tasks. This is to ensure a fair comparison with previous studies, which mainly concentrates on vision-related tasks. Extending Groan to NLP tasks is part of our future work. Our evaluation not only demonstrates Groan's efficacy but also highlights the real risks our attack poses to vital vision-based applications, including healthcare and autonomous vehicles.

Datasets. We conducted our experiments on CIFAR-10 [42] and ImageNet [17] datasets. CIFAR-10 has 50K training images and 10K test images covering 10 classes, with input dimensions of $32 \times 32 \times 3$. ImageNet is a large dataset with 1.2M training images and 50K test images covering 1000 classes. Its input dimensions are $224 \times 224 \times 3$. For all experiments on CIFAR-10, we selected a random set of 2K images from the test dataset as the original unlabeled images that the attacker owns, and the remaining 8K of the test dataset to evaluate the ACC and ASR achieved by the attacker. For all experiments on ImageNet, we randomly chose 10K images from the test dataset as the original unlabeled images that the attacker owns, and measured the ACC and ASR on the remaining 40K test images. We further augmented these selected image sets (2K images from CIFAR-10 and 10K images from ImageNet) by applying image corruption techniques [30]. Following the data preparation methodology described in Section 3.2, we selected 3K images for CIFAR-10 and 15K images for ImageNet. These images were then used to query the target models.

Software settings. Our deep learning platform is Pytorch 1.6.0, which supports CUDA 10.2. On CIFAR-10, we evaluated VGG-11, VGG-16 [63] and AlexNet [43]. To perform a classification task on ImageNet, we deployed ResNet-50 [28], ViT-B [20], and ViT-H [20]. In all these experiments, we quantized the DNNs involved to the 8-bit quantization level. Note that we regard the architecture comprising a CNN embedder followed by an MLP classifier as an encoder-decoder structure, which encompasses cases such as employing the first 13 CNN layers of VGG16 as the encoder and the final three fully-connected layers as the decoder. This setting has become increasingly popular due to the success of MoCo [12, 13, 27],

which trains the encoder/embedder using unsupervised visual representation learning without simultaneously training a decoder/classifier. Consequently, we evaluated these CNN models as well. Additionally, we also evaluated ViT-B and ViT-H, which are of classic encoder-decoder architecture for image classification.

Hardware settings. Our DNN models were trained and analyzed on a NVIDIA Tesla V100 32GB GPU and an Intel Xeon Gold 6248 CPU. The Rowhammer experiments were conducted on 8GB DDR4 DRAM (Kingston 99P5701-005.A00G).

Groan configuration. For the knowledge discovery stage, we set the default parameters to t =2, q =1K, Q =2K for the CIFAR-10 experiments, t =2, q =5K, Q =10K for the ImageNet experiments: that is, $D_{uncert}^{trigger}$, D_{uncert}^{clean} and D_r each contains 1K images for the CIFAR-10 experiments and 5K images for the ImageNet experiments. For the gray-box bit search (Algorithm 2), we set the default parameters to t =2, T =1k in all the experiments. thr_{ACC} is set to 0.8 for CIFAR-10 and 0.7 for ImageNet. thr_{ASR} is set to ACC, which is determined by the substitute model's ACC measured on D_r. For the *T-step*, the trigger mask is initialized as a black square on the right bottom corner of a clean image with the size of 10x10 (TAP = 9.76%) and 73x73 (10.62%) on CIFAR-10 and ImageNet respectively. The hyper-parameter λ in Eq. 2 is set to 1 and the optimization problem was solved through back-propagation. For the *B-step*, α (in Eq. 3) is set to $(ASR/ACC)^2$ with an upper bound 1 and a lower bound 0.01, where the ASR and the ACC are estimated by the substitute model $\tilde{f}$ upon the queried data D_l. In the memory templating phase (Appendix 7), we observed an average of 3.5 bit flips per second using 3-sided Rowhammering. We identified a total of 80,048 flippable bits, which served as constraints for the subsequent bit search.

4.2 Effectiveness and Performance

In this section, we report our evaluation of the achievable ASR of Groan without significantly affecting the ACC of the original tasks. Table 1 presents our experimental results. In the experiment, we ran Groan to inject Trojans into models spanning 6 distinct architectures and trained on the CIFAR-10 and ImageNet datasets. From the table, we observe that Groan successfully injects the Trojan to all these architectures by flipping no more than 136 bits, achieving a high ASR ($\geq$ 84.67%) while preserving the accuracy (ACC drop $\leq$ 4.64%) across all models. Particularly, the Trojan introduced to the ViT-H model (with 632M parameters) trained on ImageNet has an ASR of 91.60% and in the meantime, only causes the ACC of the target model to drop by 3.89%. This demonstrates that our approach indeed generalizes well to large data sets and models.

From the Table, we also observe that the larger the model, the more bits needed to be flipped by Groan. Specifically, for ImageNet dataset, Groan requires flipping 85 bits to inject a Trojan into a ViT-B model with 86M parameters. This is about three times the 27 bits required to embed a Trojan into a ResNet-50 model which contains 23M parameters, indicating a nearly linear relationship with model size. However, this linearity does not hold for even larger models. Specifically, ViT-H is more than seven times larger than ViT-B, yet the number of bits required to be flipped is less than twice that of ViT-B. This suggests that the rate at which Groan needs to flip bits does not go up as rapidly as the growth in model size, and further demonstrates the efficacy of Groan against large models.

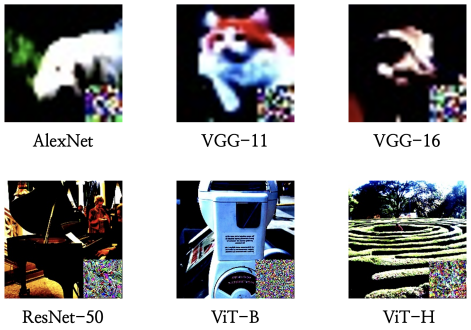

Figure 3: Demonstration of the trigger patterns. The top three are trigger-stamped images on CIFAR-10. The below two are trigger-stamped images on ImageNet.

4.3 Ablation Study

In addition to the end-to-end evaluation on Groan, we further studied the role played by its individual components, both in the knowledge discovery stage (Section 3.2) and the bit identification stage (Section 3.3). Specifically, we analyzed the effects of the three components – knowledge discovery, and the T-step and the B-step of bit identification, by running experiments on the models in three different architectures trained on CIFAR-10. In each of these experiments, we kept the total number of queries to 3K for fairness of comparison. Our experimental results are presented in Table 2 where the fourth and fifth columns show the ACC and the ASR of the substitute model and the sixth and seventh columns show the ACC and the ASR of the target model after the Groan attack.

Effect of knowledge discovery. Our knowledge discovery algorithm strategically queries the target model and trains a substitute based on the querying results. To understand the impact of our discovery algorithm on Groan's performance, we compare the substitute it produces with that trained over the outcomes of random queries on the target model (called *Groan-Random* model). The experimental results are presented in the - *Random* rows of Table 2. As we can see

Table 1: Summary of Groan's performance.

Dataset	Architecture	Network Parameters	ACC. before Attack (%)	ACC. after Attack (%)	Attack Success Rate (%)	# of Bit Flips
CIFAR-10	AlexNet	61M	87.70	86.74	89.27	11
	VGG-11	132M	88.14	83.50	93.13	20
	VGG-16	138M	88.35	84.51	91.44	14
ImageNet	ResNet-50	23M	76.03	72.53	84.67	27
	ViT-B	86M	78.89	76.63	89.37	85
	ViT-H	632M	79.93	76.04	91.60	136

from the table, the Trojan injected using the Groan-Random model vastly underperform its counterpart supported by the enhanced substitute model: the target model infected by the former is found to have much lower ASR ($\leq 66.68\%$) than the model infected by the latter ($\geq 89.27\%$); also the Groan-Random model reduces the ACC of the target model significantly (from $\geq 87.70\%$ to $\leq 77.10\%$) while the enhanced substitute helps largely preserve its accuracy (ACC reduction is less than 5%).

Further the advantage of our enhanced substitute over the Groan-Random model can also be observed from the Trojan's transferability to the target model. To measure the Trojan's transferability across all model structures used in our research, we introduce the following two metrics:

$$Trans(ACC) = \frac{\sum_{arch} ACC(target)}{\sum_{arch} ACC(sub)}, \text{ and } \quad Trans(ASR) = \frac{\sum_{arch} ASR(target)}{\sum_{arch} ASR(sub)}$$

$Trans(ACC)$ measures how much the ACC of the substitute can be transferred to the target model and the $Trans(ASR)$ measures the transferability of the ASR. Using the metrics, we found that Groan with the knowledge discovery achieves $Trans(ACC) = 1.02$ and $Trans(ASR) = 0.98$, much higher than those attainable with the Groan-Random model: $Trans(ACC) = 0.84$ and $Trans(ASR) = 0.65$. This indicates that our effort to improve the quality of the substitute model is indeed necessary.

Effect of the T-step. Our *T-step* is designed to seek the trigger that maximizes the ASR on input instances given a substitute model, and can also be effectively transferred to the target model. To study the effect of the T-step, we replace the step with TBT [59], a state-of-the-art technique to find the trigger from the substitute, and compare the effectiveness of the new attack (Groan-TBT) with Groan. Our experimental results are presented in the - *TBT* rows of Table 2. Groan-TBT also largely keeps the ACC of the target model but only gets a 50.34% ASR, significantly lower than 89.27% achieved by Groan. This difference is mainly caused by the former's lack of transferability: its $Trans(ASR) = 0.51$, much lower than $Trans(ASR) = 0.98$ of Groan. This finding demonstrates that the T-step, particularly the effort to maximize the salient output dimensions of the encoder to ensure transferability, is indeed important to the success of the Groan attack.

Effect of the B-step. In the *B-step*, to achieve a high ASR while preserving ACC of the target model, our algorithm automatically adjusts the parameter α (in Eq. 3) to balance these two optimization objectives. To understand how this search strategy (Section 3.3) contributes to the success of the attack, we set $\alpha = 1$, which is widely-used in prior studies [10, 59, 68], and then compare this Groan version with our original attack. The results of the experiments are presented in the - *Fix.* rows of Table 2. As we can see from the table, the attack with the fixed α results in an exceedingly low ASR. This is because the bits identified with a fixed α always leads to a lower ACC than the threshold so the search cannot make progress due to the ACC check at Line 6 in Algorithm 2. As a result, the approach with the fixed α can only raise the ASR up to 2.23% across all the architectures. Note that if we remove the ACC check in Algorithm 2, the ASR could go up but the ACC will drop significantly.

Fundamentally, the balance between ACC and ASR cannot be achieved statically. At the beginning of the optimization process, a few bits being flipped will quickly raise the ASR but also significantly degrade the ACC. At this stage, a small α should be chosen to preserve the ACC. With the ASR going up, it becomes increasingly hard to improve further. In this case, we will prefer a larger α to move the focus of optimization to the ASR.

Note that this balance can be easily achieved in white-box run-time Trojan injection by seeking the flippable bits mainly on the last layer [10, 59]: (i) flipping the bits on the last layer has the most direct impact on the output, which helps get a high ASR; (ii) the impact of such modification will not spread over to other layers, which helps preserve the ACC. However, in the gray-box attack, since the adversary only has black-box access to the decoder and therefore cannot temper with the weights of the last layer, changes to the model can only take place in the encoder, which will propagate from the flipped bits to other layers. As a result, to preserve the ACC in the gray-box attack, we need a more delicate balance between the ACC and the ASR, which is achieved in our attack through dynamically adjusting α.

Table 2: The results of ablation study of Groan on CIFAR-10

Architecture	ACC. before Attack (%)	Method	ACC. on Sub. (%)	ASR on Sub. (%)	ACC. on Target (%)	ASR on Target (%)	# of Bit Flips
AlexNet	87.70	**Groan**	85.1	89.0	**86.74**	**89.27**	11
		- Random	86.5	95.7	77.10	62.14	7
		- TBT	86.7	94.2	86.55	50.34	3
		- Fix	84.8	2.1	85.85	0.03	1
VGG-11	88.14	**Groan**	81.8	93.2	**83.50**	**93.13**	20
		- Random	82.7	93.1	60.68	54.49	23
		- TBT	82.1	85.3	82.04	47.72	6
		- Fix	81.8	0.1	83.46	0.08	1
VGG-16	88.35	**Groan**	81.5	94.6	**84.51**	**91.44**	14
		- Random	84.0	91.5	74.89	66.68	8
		- TBT	84.4	91.1	86.02	41.06	5
		- Fix	81.6	1.4	87.36	2.23	2

5 Discussion

Limitations. Groan needs to trigger bit flips in the DRAM chips storing the target model at run-time. Since the charge leaks in the memory cell is uni-directional, those flipped bits are hard to be flipped back and could only be refreshed by triggering a reload to the memory from the model file. Thus, there is a chance to detect Trojan injected by Groan through checking the DRAM's integrity. However, since the model is usually large, checking the integrity of DRAM at run-time will produce additional overhead.

Besides, Groan requires a little more bits to be flipped in target model for Trojan injection compared with those alternatives evaluated in Section 4.3. For instance, on AlexNet models, Groan requires flipping 11 bits while alternatives require flipping ≤ 7 bits. However, we argue that this minor overhead is acceptable, since this will neither increase the difficulty to flip those bits nor reduce the stealthiness of Trojan injected by Groan (Groan has preserved the ACC much better than those alternatives as shown in Table 2).

Future works. Groan is designed for working in the gray-box scenarios. It could be improved to be adaptive to the black-box scenarios, through cooperating with a more powerful knowledge discovery strategy that can not only reveal the decision boundaries but also some weights of the target model, and an improved method to place the target model bits to the flippable DRAM locations without sharing anything with the victim process hosting the target model. One potential way is to cooperate with the model extraction attack and the access-free Rowhammer attack. Model extraction attack enables an adversary to gain model parameters [7, 34, 57] in the black-box scenarios. Access-free Rowhammer attack [6] gives an solution to flip the target bits in memory without the need of access permission to the target model. More possible approaches deserve future studies.

Moreover, the stealthiness of the Trojan injected by Groan through flipping bits could be improved by cooperating with a method to revoke those flipped bits. Revoking the flipped bits enables the adversary to activate the Trojan only when necessary and "turn off" it after using it. This is possible if the adversary can force the victim pages (storing the target model) to be evicted from the page cache. Once the page is evicted, the follow-up references to the data (model weights) will be loaded from the local file again, restoring those flipped bits to their original values. For this purpose, the adversary can leverage the existing techniques for page cache eviction whose effectiveness has been demonstrated in the page cache attacks [22]. We will also expand our Groan to NLP related tasks in future research.

5.1 Mitigation

Detection. A natural idea to detect Trojan at run-time is to apply Trojan detection approaches very frequently. e.g., applying them every minute. By doing so, methods [8,48,71] for detecting Trojans at training time could be adapted to work at run-time. However, detecting in this manner has a very high overhead, rendering it impractical in reality. There are several methods that have been proposed to detect Trojan at run-time. Liu et al. [47] proposed to check whether the encoded weights are different from the stored values that have been calculated before the model's run. This approach will add extra overhead, especially for large networks, and could be bypassed by adding the weights encoding constraint to the bit searching step. Li et al. [44] proposed RADAR, a checksum-based detection method during the inference time. It divides the weight parameters into several groups and gets the checksum of the most significant bits within the parameters of each group. Similarly, the detection could be bypassed if the adversary added a new constraint when doing bit search to avoid flipping the most significant bits. Li et al. [46] proposed DeepDyve, a dynamic verification method to detect run-time Trojan attacks.

DeepDyve first generates a compressed version of the target model as the benchmark model. Then, it checks whether the outputs of the current target model are the same as the outputs of the benchmark model for some inputs. However, this method brings not only computation but also memory overhead.

Prevention. A number of methods have been proposed to mitigate the Rowhammer vulnerability at the DRAM level [51,54,76]. However, the most recent attacks [26,36,55] demonstrate that the threat from Rowhammer will still exist in the near future [52, 53]. Preventing Trojan injection through Rowhammer could be achieved by compressing model weights into low-bits representation. In the extreme case, we could compress the target model into a binarized model. However, compressing the model brings the cost of its performance on benign inputs [29]. How to trade-off between the security and the effectiveness of the model are left to be studied in the future.

6 Related Works

Run-time attacks. Groan injects Trojan at run-time. The possibility of doing that is demonstrated by Hong et al. [31] who have shown that deep neural networks are vulnerable to run-time attacks such as the Rowhammer attack. This is due to the fact that bit flipping can cause a significant change in the model's outputs if the model weights are represented by floating variables with high precision, resulting in a significant drop in the ACC and possibly even the ASR. Later on, Yao et al. [77] and Rakin et al. [58] showed that even a quantized DNN is vulnerable to run-time Trojan attacks. The ACC of quantized DNN can also be reduced by flipping a set of bits. After that, Rakin et al. proposed Targeted Bit-Flip Attack (T-BFA), which forces the quantized DNNs misclassify the inputs as belonging to the target class. However, all these attacks damage the DNNs in a permanent way, and thus could be detected afterwards. Recently, Rakin et al. [59] and Chen et al. [10] show that run-time Trojan attacks could be induced by flipping only a small number of bits in quantized DNNs. Both attacks assume that all the bits in the DNNs are flippable, which is unrealistic in the real hardware. On the other hand, Tol et al. [68] achieved the run-time Trojan attack in DDR3 DRAM chips using Rowhammer attack. However, all the previous attacks assume the adversary has white-box access to the whole DNN model, unlike Groan which injects Trojan under gray-box settings.

Trojan attacks on encoder-decoder architecture. Groan injects Trojan into the target model with encoder-decoder architecture. For achieving this, Jia et al. [37] proposed BadEncoder attack that injects Trojan into the encoder during the training period. They aim to make all the downstream classifiers built on the Trojan infected encoder for different downstream tasks simultaneously contain the Trojan. They showed that BadEncoder can achieve high ASR while preserving the ACC for the downstream tasks. Comparing with BadEncoder, our Groan achieved similar attack performance, but, under more strict constraints brought by the hardware. Specifically, our Groan is constrained by that only a small set of bits that are flippable in the real hardware could be modified to inject the Trojan, while BadEncoder could modify all the bits to do that. Moreover, the decoder of the target model cannot be changed by the Groan (in the gray-box setting), which brings much more difficulties in keeping the ACC of the target model and obtaining a high ASR, while BadEncoder can fine-tune the decoder after injecting the Trojan into the encoder for better ACC and ASR. Finally, the Groan, a run-time Trojan attack, is stealthier than the BadEncoder, since the Groan infected model might only be detected at run-time, while the BadEncoder infected model could be detected both during the training period and at run-time.

Hardware Attacks. Groan could be seen as a hardware attack. One example of this kind of attacks is Adversarial Weight Duplication (AWD) attack. AWD is a fault injection attack on FPGA that takes advantage of the co-tenancy when multiple tenants are on the FPGA [60]. It aims to destroy the functionality of the target model and could thus be easily detected by performance checking. Breier et al. [2] proposed a laser-based fault injection attack that hijacks the activation function of neurons within the target model by using laser injection technique on embedded systems. Clements et al. [15] and Li et al. [45] inject Trojan into DNN by changing the circuit functionality. In general, these hardware attacks all require physical access to the target hardware to induce faults into it, unlike our Groan which could be launched remotely.

7 Conclusion

In this paper, we proposed Groan, a gray-box run-time Trojan attack that achieved a high attack success rate on trigger-carrying inputs while preserving the prediction accuracy of the target model on clean inputs. Multiple techniques were devised to achieve the attack goal. We designed a knowledge discovery strategy for efficiently generating a high-quality substitute model. We further designed a novel gray-box bit identification technique that seeks a set of bits for Trojan injection together with a transferable trigger. We implemented Groan with a Rowhammer-based fault injection method on the real system and systematically evaluated its effectiveness on a range of models, including those of a large scale. Our evaluation shows that Groan can successfully inject Trojan into various models by flipping only a small number of bits, at the cost of only a slight drop in accuracy. Our work highlights the need to protect the deep neural networks at run-time, which is originally thought to be the safest stage in the DNN supply chain.

Appendix

A Memory templating

Memory templating aims to scan the memory for bit locations that are vulnerable to bit flips in order to deterministically induce bit flips in the target model. The attacker should first comprehend the physical address to row mapping scheme in order to perform the rowhammer. We reverse-engineer the DRAM addressing schemes with a specific hardware configuration using techniques proposed in [56]. To profile on the DDR4 memory which are protected from DDR3 double-sided Rowhammer attacks, we basically follow the techniques in the TRRespass tool [21], where multiple rows of DRAM are accessed sequentially resulting in flips on the memory. In detail, a victim is produced above the attacker row, and an attacker is formed above the new victim a variable number of times rather than just one row above and below the victim row being read. The normal operation of the underlying system will not be unaffected because the profiling is done in the attacker's own memory space. A list of physical pages with their page frame numbers, vulnerable bit offsets and flip directions are generated during the memory templating phase.

Forget and Rewire: Enhancing the Resilience of Transformer-based Models against Bit-Flip Attacks

Abstract

Bit-Flip Attacks (BFAs) involve adversaries manipulating a model's parameter bits to undermine its accuracy significantly. They typically target the most vulnerable parameters, causing maximal damage with minimal bit-flips. While BFAs' impact on Deep Neural Networks (DNNs) is well-studied, their effects on Large Language Models (LLMs) and Vision Transformers (ViTs) have not received the same attention. Inspired by "brain rewiring," we explore enhancing Transformers' resilience against such attacks. This potential lies in the unique architecture of transformer-based models, particularly their Linear layers. Our novel approach, called *Forget and Rewire* (FaR), strategically applies rewiring to Linear layers to obfuscate neuron connections. By redistributing tasks from critical to non-essential neurons, we reduce the model's sensitivity to specific parameters while preserving its core functionality. This strategy thwarts adversaries' attempts to identify and target crucial parameters using gradient-based algorithms. Our approach conceals pivotal parameters and enhances robustness against random attacks. Comprehensive evaluations across widely used datasets and Transformer frameworks show that the FaR mechanism significantly reduces BFA success rates by 1.4 to 4.2 times with minimal accuracy loss (less than 2%).

1 Introduction

LLMs [33] and ViTs [10] have transformed tasks in natural language processing and computer vision, demonstrating impressive capabilities in text understanding and generation, and image classification [4, 9, 11, 15]. However, these models are vulnerable to hardware-induced adversaries, such as Bit-Flip Attacks (BFAs) [7, 18]. BFAs exploit the hardware layer to introduce errors in the memory regions storing a model's weight parameters, compromising the model's integrity and performance. Techniques like DeepHammer [49] target specific bits within a DRAM page, altering sensitive weights and degrading model performance.

Despite advances in memory technology, new methods can still remotely influence memory content without direct physical access [26]. Defending against BFAs is complex due to the gradient-based Progressive Bit Search algorithm, which identifies the most sensitive bits within the model's weights. Therefore, understanding and mitigating these attacks is crucial for ensuring the robustness and reliability of these advanced models in real-world applications.

Although modern memory technologies have enhanced resilience to BFAs, researchers continue to uncover novel methodologies capable of influencing the content of memory remotely, without the necessity of direct physical access [26]. Mounting a defense against BFAs is inherently a complex task. This complexity arises from the BFA's utilization of a gradient-based Progressive Bit Search algorithm, which meticulously identifies and modifies bits within the model's most sensitive weights.

Inspired by the renowned neuropsychologist Donald Hebb, who coined the well-known phrase "Neurons that fire together, wire together" [29], we discover parallels in the adaptability and resilience of the human brain in the face of challenges. This popular statement underscores the brain's capacity for ongoing reorganization and rewiring, adapting to our activities, thoughts, and emotions in a dynamic process. Similarly, if certain thought patterns no longer serve our best interests, our brains have the ability to rewire to adopt alternative thoughts, showcasing a remarkable capacity for change.

In this study, we draw inspiration from the brain's adaptive mechanisms to address analogous vulnerabilities in transformer-based architectures [42]. Our proposition centers on the reallocation of redundant parameters in transformer-based models such as LLM and ViT, redirecting them to augment more crucial parameters. This strategy ensures the collective operation of lesser-used parameters with pivotal ones, enhancing the model's resilience against hardware-induced adversaries such as BFAs [35, 36], while maintaining accuracy with negligible loss.

Taking cues from the tactics employed by attackers, this work introduces a novel defense mechanism aiming to obfus-

cate the transformer-based models' most sensitive weights. The proposed methodology identifies the most and least sensitive parameters within the model, subsequently rewiring the least sensitive parameters to those deemed most crucial. This redistribution of task responsibility across the parameters effectively diminishes the sensitivity gradient, rendering gradient-based search algorithms less effective in identifying key parameters. Essentially, this approach aims to cloak these important parameters, ensuring that any bit-flip injections target less pivotal parameters.

We present a thorough exploration of the theoretical and practical aspects of BFAs, specifically, considering the real-world constraints of LLMs and ViTs. Building on these insights, we introduce a framework (*Forget and Rewire: FaR*) dedicated to pinpointing sensitive parameters and bolstering their resilience against adaptive attacks.

Our comprehensive evaluations reveal that our proposed approach, while minimally affecting model accuracy (-1.97% on ImageNet without the need for retraining), significantly obfuscates critical weights by up to 84% and 91% from potential expert and basic attackers, respectively. Concurrently, FaR compels Oracle and basic attackers to execute 1.6x up to 4x more bit-flips to achieve the same level of disruption (over 10% accuracy degradation) as they would in the absence of FaR enhancement. To achieve acceptable robustness against BFAs by obfuscating 15% of parameters per layer, FaR incurs up to 4.5% and 9.3% overhead in inference time and model storage, respectively.

It is worth noting that our proposed defense mechanism exhibits considerable compatibility, allowing it to synergize with other defensive strategies, such as NeuroPots [25] and Aegis [43]. This compatibility is attributed to FaR's primary focus on enhancing the overall robustness of models rather than solely on attack detection and recovery.

To the best of our knowledge, this is the first work that adopts a rewiring method to conceal important parameters of transformer-based models, improving their resilience against the challenging model-centric bit-flip attacks. These attacks pose a significant challenge with an attack surface potentially too extensive for existing solutions to comprehensively cover. Last but not least, the FaR library is open-sourced and publicly available to the community for development and evaluation[1]. We hope that our results could provide a new perspective for defending against emerging attacks in deep learning, fostering further in-depth research in this direction.

2 Background

In this section, we present a concise overview of the essential preliminary knowledge, especially on Transformers, floating points representation in modern hardware, and bit-flip attacks.

[1]Access at: http://tinyurl.com/farusenixsecurity

2.1 Transformer-based Models

The Transformer architecture forms the backbone of Large Language Models and Vision Transformers, playing a pivotal role in contemporary, cutting-edge pipelines for natural language processing and image classification [1]. In this section, we provide details of the Transformer architecture, underscoring the compatibility and effectiveness of our approach when applied to this class of models.

The Transformer model has two main parts [42]: the encoder and the decoder, as shown in Figure 1. The encoder takes an input and turns it into a representation (features). This helps the model understand the input. On the other hand, the decoder uses the representation from the encoder and some other information to create an output sequence. Either of these two blocks can be employed independently based on the nature of the task at hand:

- Encoder-only: Suitable for tasks that require an understanding of the input, such as text classification and named entity recognition (NER).
- Decoder-only: Suitable for generative tasks.
- Encoder-decoder: Suitable for generative tasks that require input, such as summarization or translation.

A key characteristic of Transformer models lies in their incorporation of specialized layers known as attention layers. These layers instruct the model to give particular emphasis to specific words within a sentence, effectively prioritizing them while de-emphasizing others when constructing the representation of each word. The attention mask can also be used in the encoder/decoder to prevent the model from paying attention to some special words.

Delving into the multi-head attention layer, It is comprised of several Linear modules, each with its own set of weights [42]. Within the attention layer, there are three essential parameters: Query, Key, and Value. These three distinct Linear layers, which share a similar structure, treat each word in the sequence as a vector. The encoded input representation is passed through all three parameters. This process results in an updated encoded representation that includes attention scores for each word.

Within the Transformer architecture, the Attention module carries out its computations in parallel multiple times. Each of these parallel computations is referred to as an Attention Head. The Attention module divides its Query, Key, and Value parameters into N separate parts, processing each of these splits independently through its own dedicated Head. After these individual Attention calculations, which share a similar structure, are completed, their results are combined to generate a final Attention score. This approach is known as Multihead attention, and it empowers the Transformer to capture a broader range of relationships and subtleties associated with each word, enhancing its overall capacity.

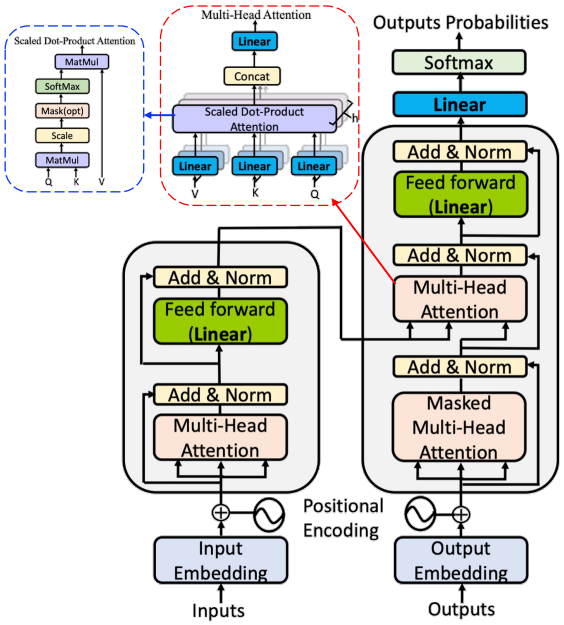

Figure 1: Architecture of Transformers.

2.2 IEEE 754 Floating Point Arithmetic

Weight parameters are typically represented using IEEE-754 32-bit single-precision floating-point numbers. This format exploits exponential notation but sacrifices precision for a broader range of possible values. For example, the value 0.34375 in exponential notation is expressed as 1.375×2^{-2}, where 1.375 is the mantissa, and -2 is the exponent. The IEEE754 single-precision floating-point format allocates 23 bits for the mantissa, 8 bits for the exponent, and one bit for the value's sign. What makes this format intriguing from an adversarial standpoint is the varying impact of different bits on the represented value. For instance, consider flipping the 20th bit in the mantissa, which results in a slight increase from 0.34375 to 0.359375, constituting a typically inconsequential perturbation. Conversely, flipping the highest exponent bit transforms the value into 1.375×2^{126}. Although both scenarios involve a single-bit manipulation, they produce two different outcomes.

2.3 Bit-Flip Attacks

The robustness, security, and safety of a modern computing system depend on the memory isolation enforced at the software and hardware level [12]. However, even in modern DRAM chips, memory isolation can be compromised by read disturbance. A notable instance of this is RowHammer [30], an extensively researched read-disturbance phenomenon. In RowHammer, the act of repetitively accessing and closing (hammering) a DRAM row numerous times results in bitflips

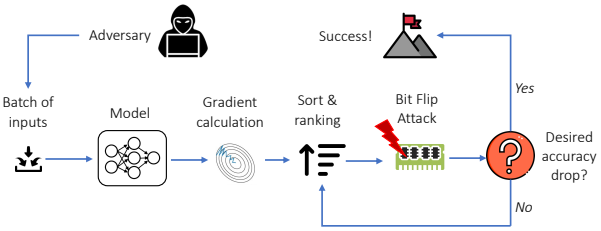

Figure 2: Bit-Flip Attack overview.

occurring in rows that are physically close by. Another example is RowPress [26], the most recent memory fault injection attack targeting DDR4-based systems that are hardened by RowHammer protection hardware. RowPress showed that even a user-level program can still breach memory isolation by maintaining an open state in a DRAM row for an extended duration, leading to disruptions in physically adjacent rows significant enough to induce bitflips.

The primary objective of bit-flip attacks is to use any practical memory fault injection attack to reduce the accuracy of a model while minimizing the number of bit-flips performed. A stealthy attacker's aim is to reclassify inputs originally belonging to source category p into a different target category q (where q is not equal to p) while ensuring that the remaining inputs maintain their original categories, thereby preserving their accuracy and ensuring the attack remains stealthy.

One of the most successful BFAs is the DeepHammer attack [49] which enhances BFAs by refining the algorithm used to search for vulnerable bits. DeepHammer also uses gradient-based Progressive Bit Search (PBS) to find vulnerable bits, as shown in Figure 2. In this attack, during the k^{th} iteration, DeepHammer first selects n vulnerable bits based on a gradient ranking of the model's parameters. Subsequently, DeepHammer individually flips each of these bits, generating a loss set denoted as L. This process is repeated for each layer, resulting in a total of $n \times l$ candidate bits and their corresponding loss set. DeepHammer identifies the most vulnerable bit as the one with the highest loss. Bit-flip is repetitively done until the desired outcome is achieved. While DeepHammer is limited to flipping just one bit per page, we are assuming that the adversary has the capability to flip any number of bits per DRAM page.

3 Motivation

3.1 Unveiling Security Challenges and Threats on LLMs and ViTs

The prevalence of transformer-based models such as LLMs and ViTs has surged dramatically, marking a significant shift in the landscape of machine learning. These sophisticated models, exemplified by transformer architectures, have found

extensive application across numerous domains, from machine translation [44] and content generation [50] to virtual assistants [21] and data analysis [13]. However, this proliferation has brought to the forefront a range of security concerns [5, 54]. The immense power of LLMs to generate coherent and contextually appropriate text can be harnessed by malicious actors for purposes such as misinformation dissemination, automated phishing, and even the creation of convincing fake content [53]. Additionally, LLMs and ViTs are not immune to adversarial attacks, where subtle input modifications can manipulate their output or compromise their decision-making processes [45]. As LLMs and ViTs become more deeply integrated into critical systems, the potential impact of these security vulnerabilities becomes more pronounced. Addressing these concerns is crucial to ensure that the benefits of transformer-based models are harnessed without undermining data integrity, and privacy in the digital landscape.

Security attacks on machine learning models can be categorized as follows: 1) evasion attacks [8], which involve perturbing inputs during testing to deceive the classification model; 2) poisoning attacks [47], aimed at manipulating training datasets to yield poorly-trained ML models; and 3) fault injection attacks [6], which modify ML parameters to alter the classifications of specific inputs towards target labels. Irrespective of the attack category, the overarching objective of adversarial attacks is to induce misclassifications in certain inputs, while maintaining a high model accuracy for others to remain stealthy.

3.2 Addressing the Research Gap

While numerous studies have explored the vulnerabilities of DNNs to fault attacks [32] or the susceptibility of LLMs and ViTs to evasion attacks [27], a significant gap in research remains unaddressed: the investigation of fault injection attacks specifically targeting transformer-based models. Fault attacks on DNNs have focused on exploiting vulnerabilities in their hardware implementations or manipulating their parameters to induce misclassifications. Similarly, evasion attacks on LLMs and ViTs have delved into generating adversarial inputs to deceive the models' decision-making processes. However, the distinct realm of fault injection attacks on LLMs [7] and ViTs [52], which involves introducing controlled memory corruptions or parameter perturbations to manipulate their output, has remained less explored. This uncharted territory presents a unique challenge, given the complex nature of transformer-based architecture and its diverse applications. Fault injection attacks on LLMs and ViTs could potentially result in unintended or biased text generation, or misclassification, undermine their coherence, or even enable subtle manipulations that are difficult to detect.

With the aim of uncovering the susceptibility of LLMs and ViTs to fault attacks, we embarked on an investigation. Our primary objective was to evaluate the resilience of these

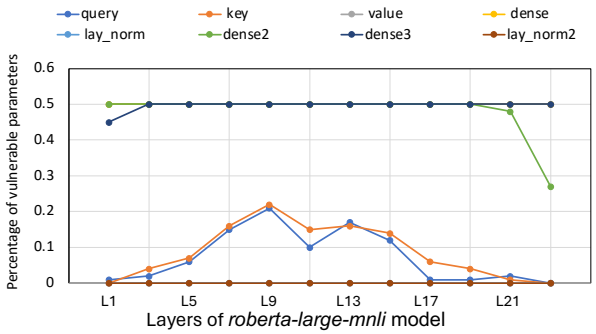

Figure 3: Vulnerability analysis of transformer layers and modules to single-BFA.

models by analyzing the manipulating individual model components and parameters through the introduction of bit-flips. We sought to understand how these induced faults could potentially compromise classification outputs, remaining imperceptible to human observers. In pursuit of this goal, we exposed transformer parameters to the latest BFAs.

Our analysis unveiled a critical observation: within LLMs and ViTs, certain parameters emerged as Achilles' heels. These select parameters represented singular points of failure within the model, where even a single bit-flip (SBF) could inflict severe performance degradation. This observation is supported by findings from Reference [7], which noted that single-bit-flips in certain *non-Wquery* and *Wkey* parameters could severely disrupt translation output, reducing BLEU scores to near zero. Single-bit-flip attacks, if successful, would lead to a complete model failure (e.g., accuracy drops to 0), often indicated by *"NaN"* values in PyTorch tensors. Since this behavior is easily detectable, it is not a favorite approach for attackers. It is important to emphasize that BFAs are more stealthy adversaries capable of flipping multiple bits per DRAM page to degrade the performance without being detected. Figure 3 shows an example of our analysis of SBF on *roberta-large-mnli* model from the hugging-face library. We randomly selected 100 parameters per layer of the transformer encoder and investigated if SBF can change the text classification output. The observation illustrates that dense3 and dense2 are the most vulnerable modules while normalization modules do not show any vulnerability.

Conversely, we also observed the existence of numerous neurons and parameters within the model that remained dormant, generating negligible activations without impacting model sensitivity. This observation led us to contemplate an innovative approach aimed at leveraging these non-essential parameters to enhance the model's robustness against BFAs.

3.3 Design Intuition

Consider a pre-trained ML model with parameter set P. In the presence of any input x, adversaries aim to find a universal set of weight bit-flips that result in misclassification, changing the correct label y to an incorrect label. In practice, adversaries

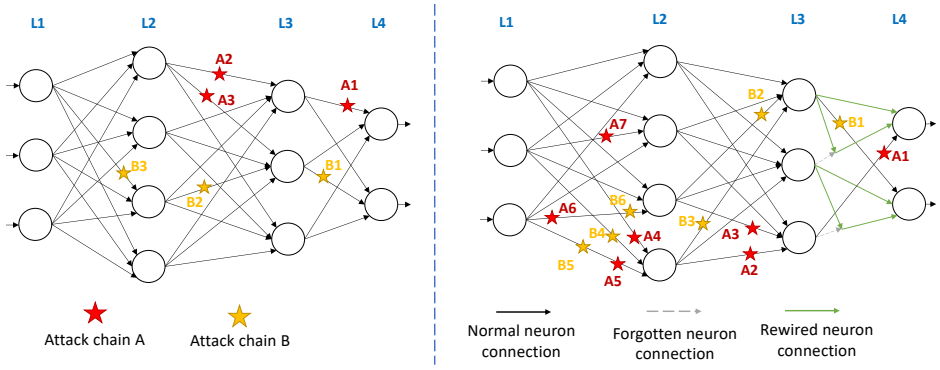

Figure 4: Comparison of the normal model and hardened model under BFAs. (a) The left diagram shows the position of bit-flips of 2 attack chains in a normal model. (b) The right diagram shows the position of bit-flips of 2 attack chains in a hardened model with FaR that demonstrates the increase in BFAs to achieve the same results.

are searching for a systematic misclassification of any valid input x by altering the fewest number of bits in the model parameter set P.

Drawing inspiration from concepts such as brain rewiring and guided by gradient-based search algorithms, we are driven to propose a methodology to reconfigure linear layer parameters. Our motivation is to diminish the model's sensitivity to a few critical parameters by redistributing their responsibilities to less crucial counterparts. In essence, our objective is to increase the model's resilience against BFAs by strategically rewiring its neural connections and optimizing its parameter utilization.

Figures 4 (a) and (b) illustrate the distribution of bit-flips in an attack chain within a linear model, both before and after rewiring. In the absence of rewiring (Figure 4(a)), the bit-flips within the attack chains can affect important weights across all layers. In Figure 4(b), we introduce a rewiring technique, where non-important parameters are interconnected with important ones in each layer. This serves to reduce the sensitivity of important parameters and conceal their significance. Consequently, if an attacker attempts to identify crucial parameters using gradient search, they will primarily discover less significant parameters that have minimal impact on the model's outputs. As a result, the attacker would need to flip a larger number of bits, rendering their efforts impractical.

The compatibility between our methodology and other detection and recovery techniques such as NeuroPots further enhances the overall resilience of the system, creating a more robust and comprehensive defense against a broader spectrum of potential threats and adversarial scenarios. NeuroPots operates by designating certain non-critical parameters as *bait* to detect attacks, and it checks them for any alteration to restore the original weights. In contrast, FaR is designed to enhance the robustness of the model against BFA. By redistributing critical parameter influence, FaR increases the number of bit-flips an attacker must execute to significantly degrade model performance. FaR focuses on preventing effective attacks by diluting parameter sensitivity.

Figure 5 illustrates our *Forget and Rewire* scheme. In Figure 5(a), we have a standard linear model where three neurons in layer $l-1$ are connected to one neuron in layer l. Suppose we perform sensitivity analysis on three parameters of W using a batch of input data. In this analysis, we find that X_2, the activation from neuron m_2, is predominantly close to 0, making W_2 the least important. Similarly, because X_1 is larger than X_3, the gradient of the output with respect to W_1 surpasses that of W_3. Furthermore, the output of neuron Y depends solely on $X_1W_1 + X_3W_3$.

In Figure 5(b), we showcase the layer following the application of our Forget and Rewire scheme. Since m_2 is considered a dead neuron, its connection to n_1 becomes a candidate for the "Forget" operation. Recognizing that W_1 holds the utmost importance in the network, we opt to hide it from potential attackers. Conversely, we select W_2 for the "Rewiring" operation and replace its value with that of W_1 as W_2 no longer affects the output of neuron n_1. To achieve this, we divide the activation from neuron m_1 by 2 (the division factor). Half of this division is passed to the same parameter W_1, and the other half replaces the activation of the dead neuron, going to W_2 (which now holds the value of W_1). This way, when attackers employ gradient search and loss backpropagation, they discover that the weight ranking has changed. With X_1 now reduced by half, it is smaller than X_3 making W_3 the most important parameter in the layer. It's worth noting that despite modifying a weight's value and rewiring activations, the output of neuron n_1 remains consistent, and the layer's functionality undergoes minimal change.

If an attacker arbitrarily targets a critical parameter (known to the developer, such as W_1), the attack is not as effective as in the non-FaR model. This is because W_2, to which the importance of W_1 has been redistributed, also needs to be targeted. Consequently, the model's resilience against random attacks is enhanced as well. We provide a comprehensive evaluation of the impact of our proposed strategy on Bit-Flip Attacks in the section 6.

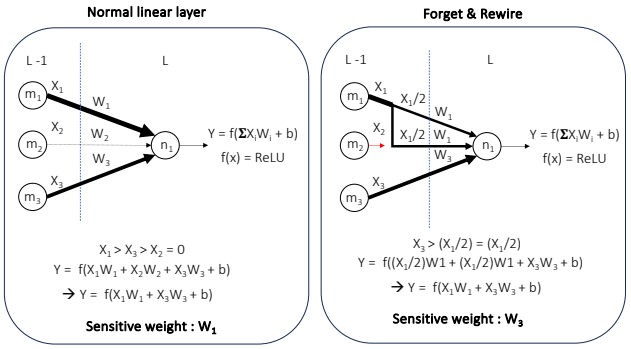

Figure 5: Forget and rewire example on a simple linear model.

4 Threat Model

In this work, our goal is tailored for defense against BFAs. BFA involves direct manipulation of the model's parameters at the deployment stage. This type of attack assumes that the attacker has the capability to alter the model directly, such as inducing bit-flips in the model's memory, which changes its behavior without needing to modify the input. Unlike BFAs, Adversarial Example Attacks primarily manipulate the input to the model without altering the model's parameters directly. The attackers' goal is to deceive the model into incorrect predictions while they may have complete knowledge of the model's architecture (white-box scenario). However, the model itself remains unaltered. Hence, the proposed FaR technique is specifically designed to mitigate the risks posed by BFAs, where the model's parameters are directly vulnerable to manipulation.

4.1 Assumptions

We assume the adversary possesses the capability to execute Bit-Flip Attacks against the models after their deployment. This involves the precise manipulation of multiple bits of multiple parameters to influence the prediction results of the model, not just single-bit-flips. This threat model represents a significantly stronger attack scenario. The feasibility and practicality of such threats have been previously validated and assessed in prior research [6, 25, 34, 37]. Additionally, the adversary has the potential to run their malicious program on the same machine as the victim model (on resource-sharing platforms such as ML-as-a-service) and employs methods such as DeepHammer to carry out BFAs.

Aligned with prior research [25, 43] focusing on DNNs, we adopt the white-box assumption, assuming that the adversary possesses the knowledge and capabilities necessary to execute a potent attack. More precisely, the adversary is presumed to have in-depth knowledge of the victim model, its parameters, and relevant details. Moreover, we extend this assumption to encompass the adversary's familiarity with every facet of any conceivable defense mechanism implemented within the system. This understanding involves the mechanism's operation, algorithms, parameters, and other relevant aspects. This knowledge can be acquired through methods like side-channel attacks [48].

We categorize attackers into three types based on their knowledge levels:

1. Basic Adversary: This attacker has no knowledge about the FaR defense strategy, and has no access to obtain the gradient values on the deployed model. However, the attacker has access to an equivalent model without FaR capability to evaluate its BFA on its local station.

2. Expert Adversary: This attacker is aware of FaR and is able to obtain the gradient values on the deployed model. However, the FaR configuration is not available to the attacker.

3. Oracle Adversary: This attacker is aware of FaR and not only is able to obtain the gradient values on the deployed model, the attacker has access to the FaR configuration.

While the Oracle attack is a very rare scenario, it is the strongest type of attack. It is important to note that the FaR configuration is not publicly available and will be stored securely, only to be applied during deployment. Obtaining such configurations would require an attacker to have an exceptionally high level of access, such as that of a malicious cloud provider [28]. Conversely, a model's architecture and parameters are often easily accessible to the public, as seen with models available on platforms like Hugging Face. Our objective is to enhance the model's robustness against more prevalent threats, such as RowPress and Deephammer, which attackers with varying levels of expertise (basic/expert) may exploit.

4.2 Defence Requirements

As mentioned before, in this work we seek to establish a defensive strategy to harden Transformers against a range of BFAs and potential adaptive threats. It's important to emphasize that our objective is not to completely eliminate BFAs but rather to increase the difficulty and cost associated with these attacks. Even with a robust defense in place, adversaries may still attempt to manipulate more parameter bits. Therefore, our aim is to significantly raise the number of bit-flips needed for adversaries to achieve their malicious goals, making the attack less practical and inconspicuous. The specific criteria for our defense strategy are as follows:

1. Our defense solution should have a minimal impact on the model's inference process. It must maintain the usability of the original model, ensuring that it retains its prediction accuracy to a significant extent without significant degradation.

2. Our defense approach should be easily applicable to standard, off-the-shelf Transformers. It should not require significant alterations to the original model's parameters, such as retraining the model from scratch, which can be computationally expensive.

3. Our goal is to implement a solution at the application level that is effective across various hardware architectures, operating systems, and deep learning libraries. In contrast to previous works that have proposed hardware or system-level measures to counteract fault injection attacks, our solution should not be limited to specific platforms.

5 Forget and Rewire

In this section, we introduce both the theoretical principles and practical implementation guidelines for our rewiring strategy. These principles ensure the effectiveness of our proposed approach in countering adversarial bit-flips and establish a robust foundation for the detailed defense implementation covered in the subsequent section.

5.1 Theoretical Basis

To thwart an attacker attempting to flip weight bits on important parameters, we analyze the attacker's strategy, which often involves a greedy approach to identify the most vulnerable weight bits in the model. While the attacker's choice of bit-flip sequence may be influenced by the input, the initial crucial step is to identify a bit with the highest gradient based on the loss function, on a batch of input data, for each layer. Subsequently, the attacker assesses the impact of individual bit-flips on the loss function and iteratively selects the most influential bit to flip in each iteration.

In essence, if we deliberately distribute the importance of critical weights among others, we can enhance the likelihood of preventing bit-flips to those crucial weights, rendering the attacker's bit-flip sequence ineffective. Therefore, we delve into the backpropagation rule for computing the gradient of the loss/cost function C with respect to weight W_{mn}. This weight connects neuron m at layer $l-1$ to neuron n at layer l. The training is the process of minimizing error/cost (which originates from the difference between the output of the model and the desired output). The model's output is determined by the activation produced by the last layer neuron, which is a function of the neuron's parameters (weights): $a = f(W)$. The relationship between activation and weight is linear, computed as a weighted sum of inputs plus a constant bias. In the context of gradient descent training, the goal is to minimize the error by moving along the cost function, in the direction of the slope of C (the derivative of the cost function). Since the formula for the cost function is typically available (with the simplest form being Mean Squared Error), we can readily calculate $\frac{\partial C}{\partial a}$. However, during the attack, the attacker is interested in the weights W. Therefore, we require an expression for the rate of change of the cost function concerning W, which necessitates the application of the chain rule of differentiation: $\frac{\partial}{\partial x} f(g(x)) = g'(x)f'(g(x))$

The attackers' objective is to determine the extent to which they can maximize the error by corrupting the weights W. To achieve this, we need to realize how changes in W impact the output activation, and subsequently, how alterations in the output activation influence the cost function. This can be elucidated as follows: $\frac{\partial C}{\partial W} = \frac{\partial a}{\partial W} \frac{\partial C}{\partial a}$

Building upon the preceding discussion, $\frac{\partial C}{\partial a}$ is readily accessible, and the derivative of activation w.r.t. W is simply the input to the parameter. This approach remains consistent for the hidden layers, as illustrated in Figure 6. $\frac{\partial C}{\partial W}$ likewise signifies how responsive (sensitive) the output is to the parameter W. Through this method, we can discern the degree of influence each parameter in the model has on the output.

Now, we can put it all together in the following equation:

$$\frac{\partial C}{\partial W^l_{mn}} = x_{mn} f'(a^l_n) \Sigma_{i=1}^{k^{l+1}} W^{l+1}_{ni} \frac{\partial C}{\partial a^{l+1}_i}$$

where x_{mn} is the input to the parameter connected to neuron n from neuron m at layer $l-1$. a^l_n is the neuron n's output before passing to its activation function f (such as ReLU). Σ term is the weighted summation of loss of all neurons at layer $l+1$.

The derivative $\frac{\partial C}{\partial W^l_{mn}}$ indicates how sensitive the output is to the weight parameter W. A higher value suggests that this parameter can induce more significant changes in the output (resulting in model loss), which makes it an attractive target for attackers. The goal is to diminish this sensitivity while preserving the layer's functionality. To achieve this, we need to identify which term plays a crucial role in determining the magnitude of this derivative. Typically, $f'(a^l_n)$ remains a constant value (0 or 1), especially with widely used ReLU functions. The summation term (Σ) doesn't necessarily decrease the absolute value because weight values and loss terms can be either negative or positive. However, the activation value from neuron m to neuron n can have the most significant impact. Simply put, by reducing x_{mn}, we can decrease the gradient magnitude of all weights originating from source neuron m to any destination neuron n. This principle also applies to the output layer.

In this section, we detailed our method for identifying critical parameters within a model, emphasizing that the activation from the preceding layer influences neuron activation more than the weight of the parameters themselves. This approach leads us to rank parameters based on their gradients, as illustrated in the simple example in Figure 6. The type of activation function, whether ReLU or GELU, does not affect this process. It is notable that our analysis does not imply linearity in neural networks; rather, it highlights how Transformer models' linear layers facilitate the FaR operation.

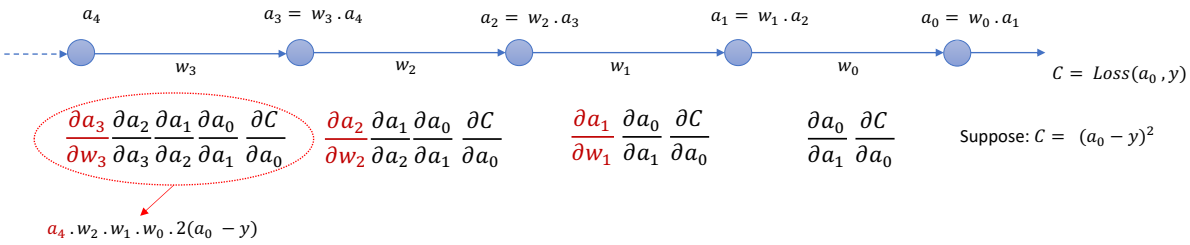

Figure 6: Calculating the sensitivity of output to weights.

5.2 Strategy Principles

Our proposed approach revolves around two key actions: *Forget* and *Rewire*. Additionally, we introduce a hyperparameter known as the *division factor*. The Forget operation involves disengaging an activation generated by a *dead* neuron, meaning it will not be transmitted to other neurons, and its weight parameter will be replaced with a new value. A dead neuron, in this context, is one whose activation hovers around zero or is very close to it when assessed using a batch of input data. Such neurons have minimal impact on the model's functionality. This concept aligns with the well-established "Pruning technique" which typically disregards around 10 to 15% of neurons in a linear layer without compromising model accuracy.

On the other hand, the Rewire action redirects an activation that contributes to a parameter's importance to another parameter. During this process, the magnitude of the activation is divided by the division factor. The division factor plays an important role in determining the complexity and effectiveness of our strategy. An increase in this factor may lead to the utilization of multiple neurons for redundancy, potentially diminishing the model's generalizability and risking a reduction in accuracy. Conversely, a smaller division factor may not adequately achieve the concealing objective, thus lacking sufficient robustness. We will assess the impact of this factor in detail in the Evaluation Section.

To implement our strategy, as shown in Figure 7, we first need to identify the crucial weight parameters within the linear layers of the model and devise a plan to conceal them from potential attackers. To achieve this, we utilize a batch of input data and perform loss backpropagation to compute gradients, subsequently sorting them to rank the parameters. Once an important parameter is identified in a layer, our next step is to locate one or more dead neurons (based on a division factor) within that same layer. When a dead neuron is pinpointed, we subject its activation to the Forget operation, effectively disconnecting it from the neural network. Simultaneously, we select its connection to the neuron containing the important parameter for the Rewiring operation. In this process, the activation directed toward the important parameter is divided by the division factor before being rerouted to the forgotten parameter. Consequently, the value of the forgotten parameter is overwritten by that of the important parameter. This process can be iterated until a sufficient number of parameters are obfuscated, consequently raising the number of bit-flips required to significantly degrade the model's accuracy. It's important to emphasize that after each forgetting and rewiring step, the entire gradient calculation process must be repeated.

5.3 Algorithm for Application

Algorithm 1 outlines a systematic procedure aimed at augmenting the resilience of Transformer-based models against Bit-Flip Attacks. Initially, the model iterates through a predefined number of steps, each representing a single FaR operation. In each iteration, the algorithm first identifies the most crucial parameter within the model by computing and analyzing gradients with respect to the input data. This parameter, deemed significant due to its gradient value, is marked for protection against potential attacks.

Subsequently, the algorithm seeks out dead neurons that contribute minimally to the model's output due to their negligible activation levels. These neurons are pinpointed by inversely sorting the computed gradients, thereby revealing the least impactful parameters in the model's architecture.

Once the critical and dead parameters are identified, the algorithm devises a Forget and Rewire (FaR) configuration. This configuration essentially outlines a strategy for each layer of the model, determining how the activations of dead neurons should be rerouted and their associated weights adjusted to shield the important parameters. Since this configuration is small and does not include all parameters, it can be stored securely on-chip and not be available to public users.

The final step involves applying this FaR configuration to the model during the deployment. This is achieved by locating the specific neurons and layers as per the configuration, and then overloading its customized linear layer with the FaR configuration and weigh replacement. During runtime, the custom linear layer itself adjusts the neural connections accordingly. Notably, the activation directed towards a crucial parameter is rerouted to a previously inactive (dead) neuron, and its magnitude is moderated by a predefined division factor. This step not only camouflages the important parameters but also ensures the model's functional integrity by redistributing activations.

The entire process is iterative, with each cycle further fortifying the model's defense by obfuscating additional parame-

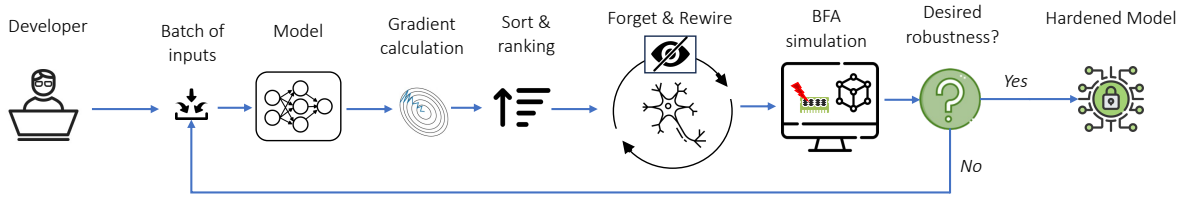

Figure 7: Forget and Rewire hardening framework.

Algorithm 1: Forget and Rewire Pseudo Code

Input: model, sample_data, labels, max_far
Output: Enhanced model

for i = *1 to max_far* **do**

Step 1: Identify Important Parameter

$important\_param\_d \leftarrow compute\_gradient\_wrt\_input(model, sample\_data, labels)$

Step 2: Locate Dead Neurons

$dead\_param\_d \leftarrow get\_dead\_params(model, sample\_data, labels, important\_param\_d)$

Step 3: Generate Forget and Rewire Configuration

$far\_cfg\_d \leftarrow get\_forget\_rewire\_cfg(important\_param\_d, dead\_param\_d, model)$

Step 4: Apply Forget and Rewire Configuration

$model \leftarrow apply\_far\_cfg\_to\_model(model, far\_cfg\_d)$

ters. Post each FaR operation, the model undergoes a reassessment of accuracy and BFA resistance. As soon as the accuracy is dropped or BFA resilience is achieved, the operation can be stopped.

In a network comprising millions of parameters, the division of activations assigned to weights has a substantial impact on the weights ranking within the model. Consequently, an attacker will only identify less important parameters as critical. As a result, they must perform a greater number of bit-flips to achieve the same level of accuracy reduction compared to a network lacking the forget and rewire defense strategy.

5.4 Security Analysis

To enhance the efficiency and efficacy of our strategy, we must explore several key aspects:

1. FaR Placement: It is required to investigate where to position the *Forget and Rewire* neurons, including determining the appropriate layer and specific neuron within a layer.

2. Activation Ranking Strategy: It is essential to develop a robust activation ranking strategy, which may involve ranking at different levels or stages within the model architecture.

3. Hyperparameter Tuning: Fine-tuning the hyperparameters is crucial, including selecting the optimal number of important parameters and determining the *division factor*.

Optimizing these elements will contribute to the overall performance of our strategy in mitigating Bit-Flip Attacks.

6 Evaluation

In this section, we provide overarching recommendations for the selection of pivotal hyperparameters within the Forget and Rewire defense strategy. Specifically, we explore the effects of these parameters, namely the choice of layer, the number of parameters, and the division factor, on our model's performance. We analyze the inference time, accuracy, size overhead, and BFA efforts.

6.1 Experimental setup

Our BFA analysis framework systematically flips individual bits within a model and quantifies the resulting impact using predefined metrics. The implementation of this framework is conducted in Python 3.11 and Torch 2.0.1, which supports CUDA 11.7 for GPU acceleration of computations. The experiments are conducted on an AMD EPYC 7302 CPU (16 physical cores), running at 3.0 GHz. This platform is equipped with four NVIDIA GeForce RTX 3070 GPUs.

We utilize the Yelp Open Dataset, which is available in JSON format for LLM analysis. Specifically, we focus on the *review.json* file, which contains comprehensive review text data.We also evaluate the effectiveness of our FaR-enabled defense framework with MNIST, CIFAR-10, CIFAR-100, and a subset of ImageNet (50 samples per class from validation set) for image classification [2].

For this study, we utilize the *transformers* package from *Hugging Face* [1] and its pre-trained models. We selected two machine learning models suitable for image and text classification tasks. Our selection is based on the most commonly used models ($google/vit-base-patch16-224$ on ImageNet with 86.56M parameters, and $dbmdz/bert-large-cased-finetuned-conll03-english$ on Yelp with 334M parameters). It should be noted that the *dbmdz* model is only

used for the token classification task. Three more custom ViT structures were also developed and trained on MNIST, CIFAR-10, and CIFAR-100 datasets. A comparison of custom models is presented in Table 1.

6.2 Model Integrity Evaluation

A paramount criterion for any effective hardening method is preserving the model's original functionality, ensuring minimal deviation from its trained objectives, and safeguarding against significant accuracy loss. The redistribution of critical weights to *dead neurons* is critical to maintaining accuracy. FaR ensures that essential information still traverses through both original and newly established detour pathways to the output layer, preserving critical data. Hence careful selection of dead neurons via gradient search to avoid data loss is an important step in FaR. Moreover, FaR is a one-shot process that does not necessitate retraining.

Table 2 presents a comparative analysis of the impact of FaR on various models and datasets. It's noteworthy that the amount of degradation is comparable with Aegis, incurring a reduction of 2% [43] on CIFAR-10/100. In contrast, alternative approaches like BIN [16] and RA-BN [38] exhibit more pronounced accuracy degradations, approximately ranging between 2 to 4%. It's also observed that the NeuroPots method demonstrates an accuracy comparable to our FaR approach, reinforcing the notion that the FaR mechanism maintains model integrity without substantially compromising its accuracy.

Our proposed mitigation strategy stands apart from retraining-based methodologies that necessitate complex and resource-intensive fine-tuning processes. Such fine-tuning is typically accessible to defenders with ample resources and access to large training datasets, especially for LLMs and ViTs. In contrast, our strategy offers a one-shot model modification approach that effectively addresses these challenges through straightforward computations, incurring minimal cost. Notably, it is observed that this approach has only a marginal impact on model accuracy, particularly when it involves rewiring critical parameters.

6.3 Model Size Evaluation

While the FaR configuration is securely stored separately from the model's parameters, applying its configuration can lead to an increment in the model's size during deployment. This increase has been systematically assessed across various datasets and model architectures utilized in our study, as shown in Table 3. Notably, this augmentation in size is predominantly influenced by the model's architecture and the quantity of parameters designated for the FaR operation, rather than by the datasets themselves. In particular, FaR's memory usage increases linearly with the number of FaR-enabled parameters.

It is important to underscore that such increments in size

Table 1: Custom ViTs for evaluation on selected Datasets

ViT Params	MNIST	CIFAR-10	CIFAR-100
image size	28	32	32
channel size	1	3	3
patch size	7	8	8
embed size	512	512	512
num heads	8	8	8
classes	10	10	100
num layers	1	3	6
hidden size	256	256	256
Model size	3.19M	9.57M	19.07M

Table 2: The accuracy (%) of models (w/o and w/ FaR) on various validation datasets and transformer structures

Dataset	w/o FaR	w FaR	Ageis	NeuroPots
MNIST	98.3	-0.1	—	—
CIFAR-10	96.1	-1.14	-1.26	-1.0
CIFAR-100	92.8	-1.35	-1.96	—
ImaegNet	88.4	-1.97	—	-1.3
Yelp review	Base	-1.82	—	—

generally are not a bottleneck for the practical deployment of models even on embedded devices. Common embedded devices, such as the Nvidia Jetson Nano, are typically equipped with memory capacities at the GB scale, amply sufficient to accommodate the FaR enhancement. Moreover, the FaR technique significantly bolsters robustness while maintaining accuracy levels, rendering the trade-off of a modest size increase highly beneficial, especially for edge-based inference applications.

To corroborate these assertions, we deployed our FaR-enhanced ViT model on a widely utilized edge device, the Nvidia Jetson Nano, equipped with 4GB of memory. The model's size increment proved manageable for this device since the average inference time increased only 4 to 6%. This underlines the practical viability and efficiency of the FaR approach on embedded devices.

6.4 Performance and Time Overhead

One of the key objectives of our design is to guarantee that the implementation of the FaR mechanism introduces minimal overhead to the operational framework of the model. Table 3 presents the timing metrics associated with model inference, both with and without the integration of FaR. It is evident that the time increment attributable to our approach remains marginal, primarily due to the incorporation of forget and rewire operations within the inference process. This additional time demonstrates a linear correlation with the volume of parameters earmarked for the FaR process.

The process of parameter selection for FaR is conducted offline, post-training. The duration of this process varies depending on several factors, including model size, computing resources (CPU/GPU), FaR configuration, and the desired

Table 3: Storage and Time overhead of FaR-based hardening on different Transformer architectures and datasets.

	MNIST ViT1	CIFAR-10 ViT2	CIFAR-100 ViT3	Yelp dbmdz	ImageNet google

Model Size (%)	+2.7	+3.3	+5.1	+8.9	+9.3
Offline FaR Calculation Time (H)	9	22	65	237	184

level of robustness against BFA. For instance, the time required to find FaR settings for a ViT trained on ImageNet can range from a few hours to several days as shown in Table 3.

Currently, the most significant contributor to the inference time overhead is the fact that our customized linear layer, infused with FaR configurations, lacks optimization with binary libraries and operates solely within a Python environment. This contrasts with the conventional linear layers in PyTorch, which benefit from optimized matrix multiplication operations. Addressing this, we aim to explore Python bindings in C++ for FaR, aspiring to expedite the FaR operations within the linear layer in future endeavors. While principles underlying FaR suggest its theoretical scalability to larger models, including LLMs with multi-billion parameter configurations, in practice, as the results show in Figure 13, an optimized FaR library is a must to achieve acceptable inference overhead for such enormous models.

6.5 Concealing Efficiency

The attack chain refers to the set of parameters targeted in a BFA, indicating which parameters were considered highly important from the attacker's perspective. *Concealing Efficiency* is the rate at which these parameters are concealed (rewired) within the attack chain.

Table 4 demonstrates the proficiency of our hardening technique in obfuscating pivotal parameters that are typically targeted in bit-flip chains orchestrated by BFA strategies. For instance, our fortified model successfully identifies and conceals 92%, 83%, and 77% of parameters in the basic, expert, and oracle attack chains, averaging a concealing rate of 84% in total. While it's acknowledged that our defense mechanism may not obscure every parameter from potential attackers, the FaR-enabled model retains its core functionality and resilience against attacks. This resilience is underpinned by our method's strategic focus on shielding the most critical parameters along the attack's critical path—parameters whose alteration could lead to significant compromise if included in a bit-flip attack chain.

Figure 8 further explores the influence of hyperparameters (elaborated upon in Section 6.9) on the concealing rate. The observations from increasing the number of layers in our experiments show a diminished effect on the concealing rate,

Table 4: Example of BFA chains generated on the model w and w/o FaR and conceal rate

Dataset	Attack	FaR	# of bit-flips	Coverage (%)	Accuracy drop (%)
MNIST	Basic	No	75	—	-32.3
		Yes	282	97	-31.4
	Expert	No	38	–	-31.7

		Yes	371	89	-35.8
	Expert	No	86	—	-36.4
		Yes	210	82	-36.0
CIFAR-100	Basic	No	108	—	-27.1
		Yes	562	89	-27.7
	Expert	No	89	—	-28.3
		Yes	370	78	-28.4

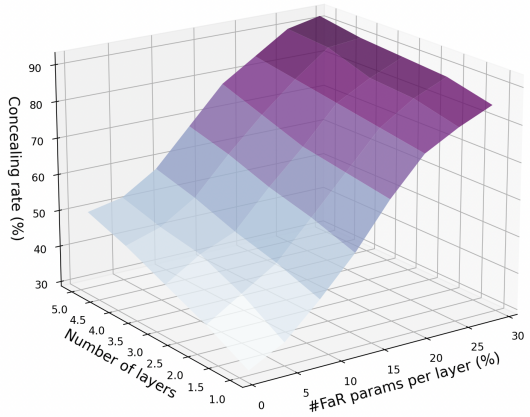

Figure 8: The impact of the number of FaR parameters per layer, and the number of selected layers on the concealing rate of important parameters in basic BFA's critical path.

contrasting with the effect observed when altering the number of FaR parameters per layer. This pattern implies that the majority of critical parameters, which affect the concealing rate, are located within the last few layers of the model.

6.6 Mitigation Effectiveness

Another notable advantage of our proposed strategy is its resilience even against an Oracle attacker with knowledge about the hardened model.

Figure 9 shows our analysis of the number of bit-flips required to degrade the accuracy of the FaR model by more than 10% when the decision factor is changed. The normalization is grounded on the bit-flips required for Oracle attacks on non-FaR models. A division factor of 1 indicates that each critical parameter is rewired with one dead neuron. Figure 9 depicts that even Oracle attackers require 1.68 times more bit-flips (division factor 5). Under the same configuration, the model's accuracy decreases by 1.83% when 10% of parameters per layer are selected for rewiring (Figure 10).

In contrast to NeuroPots, where an attacker aware of the honey neurons can bypass them by avoiding highly sensi-

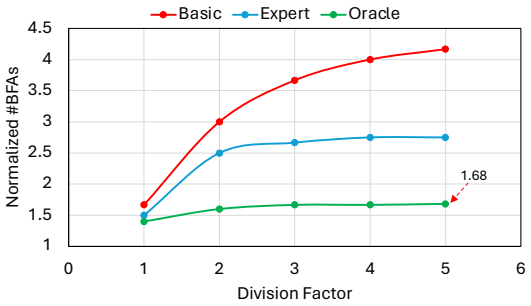

Figure 9: The impact of the division factor on the normalized number of bit-flips required to degrade the accuracy by 10% when 15% of parameters per layer are selected for FaR .

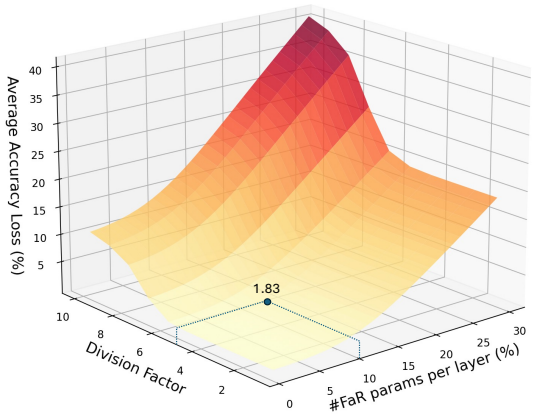

Figure 10: The impact of the number of FaR parameters and division factor per layer on the accuracy loss.

Table 5: Number of bit-flips (Mean and SD) required to degrade 10% of the accuracy of clean models and FaR models (10% per layer) under 20% Dropout (DO) during training and 20% Pruning (PR) post-training

FaR	Regularization	MNIST	CIFAR-10	CIFAR-100
w/o FaR	No DO - No PR	13 ±4	15 ±7	19 ±5
	DO - No PR	13 ±5	16 ±5	20 ±4
	DO - PR	11 ±2	14 ±4	17 ±3
w FaR	No DO - No PR	46 ±11	51 ±8	58 ±6
	DO - No PR	47 ±10	53 ±13	61 ±9
	DO - PR	39 ±6	48 ±9	56 ±8

tive parameters, our approach presents a more robust defense. Even if the attacker is informed about the obfuscation of critical parameters through the forget and rewiring schemes, they cannot exploit this knowledge effectively. This is because the critical parameter is no longer the single point of failure, and the model's critical path has been diversified, with tasks distributed among other neurons. This redistribution creates alternative pathways or *spare paths* via rewired neurons, allowing crucial information to continue propagating through the model even if the original vital parameters are compromised. Consequently, the attacker is still compelled to execute additional bit-flips to degrade the model's accuracy, making the attack considerably more challenging, resource-intensive, and exposed to detection.

Our hardening strategy can seamlessly integrate with various online fault detection and model recovery techniques. One straightforward detection mechanism involves checksum-based detection, applied selectively to a subset of parameters within each model. Following the implementation of the forget and rewire technique on the model, the parameter rankings shift compared to the original model. Less important parameters now assume higher ranks, rendering them more vulnerable to potential attacks by adversaries. Consequently, within each critical layer of the modified model, we can designate a subset of the highest-ranked parameters for checksum calculation, saving the results in a secure zone. During runtime, if the sum of the selected weights deviates from the original sum, it signals potential tampering with the model. Once faults are detected, we can promptly replace the weights of the affected layer with a clean copy in real-time. This integrated approach enhances the model's robustness against both attacks and faults.

6.7 Regularization and Pruning

Dropout [46] is a regularization technique used during the training phase, and randomly deactivates a subset of neurons to prevent the network from becoming overly dependent on specific neurons, thus enhancing generalization. However, during the inference phase, dropout is not active, and all neurons contribute to the output. Pruning [17] involves removing less significant neurons or connections either during or post-training. This process streamlines the network for inference, making it leaner and potentially faster but does not inherently protect against adversarial threats such as bit-flip attacks.

Table 5 presents a detailed comparison of pruning, dropout, and FaR on robustness against BFAs. Neither dropout nor pruning is designed to obscure or protect critical parameters from adversarial discovery and attacks. Pruning inadvertently makes critical parameters more discernible by simplifying the network, easing BFA by 11% on average. Dropout aims to prevent overfitting and does not offer specific protections against gradient-based adversarial attacks during inference. However, it could slightly enhance and increase the number of bit-flips by 4% on average.

6.8 Adversarial Examples

Although adversarial example attacks are not within the scope of our threat model [31], examining the impact of the FaR strategy on model robustness against such attacks offers valuable insights. To this end, we evaluated the resilience of FaR-hardened models against a well-known adversarial example attack, iterative FGSM (epsilon is set to 0.01) [20]. We analyzed

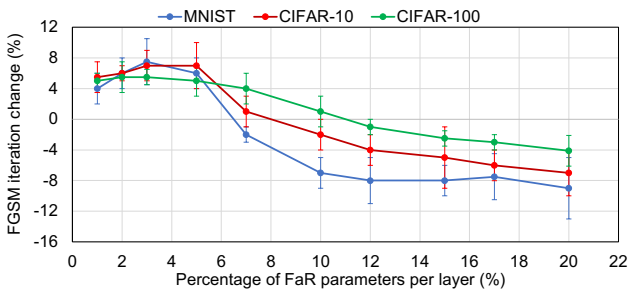

Figure 11: The impact of the number of FaR parameters per layer on the number of iterations required to generate an adversarial example to fool the model.

how reconfiguring model parameters through FaR influences the generation and effectiveness of adversarial examples on ViT models trained on MNIST, CIFAR-10, and CIFAR-100. We randomly selected 100 images from the validation dataset and applied the attack on FaR models. The results, presented in Figure 11, show that limited FaR operations can slightly increase robustness against adversarial perturbations. However, as the number of FaR operations per layer increases, we observed a reduction in the number of iterations required to fool the model. This finding indicates a delicate trade-off between resilience to BFA and susceptibility to adversarial examples. While a higher number of FaR operations enhances resilience against BFA, it can also increase vulnerability to adversarial examples, likely because rewiring parameters may exacerbate the propagation of perturbations within the model. Another observation is that by increasing the model size (from MNIST to CIFAR-100), the impact of FaR on adversarial examples' strength is reduced.

6.9 Ablation Study

In this section, we examine the effects of FaR's hyperparameters (particularly the number of parameters selected for FaR per layer and the division factor) on the performance of Transformer models, specifically focusing on our custom ViT trained on the CIFAR-100 dataset.

Figure 10 illustrates the effect of FaR hyperparameters on the accuracy degradation of our custom ViT. In this study, we varied the percentage of parameters considered for FaR operations per layer from 1% to 30% of the total parameters in a layer. We also incrementally adjusted the division factor from 1 to 10.

The findings reveal that an increase in both the number of parameters involved in FaR operations and the division factor leads to a reduction in accuracy. This outcome is attributed to the fact that rewiring a larger number of parameters compromises the model's generalizability. Essentially, the model becomes overly optimized for resisting BFAs specific to the classes of inputs used in gradient calculation, at the expense of its broader applicability.

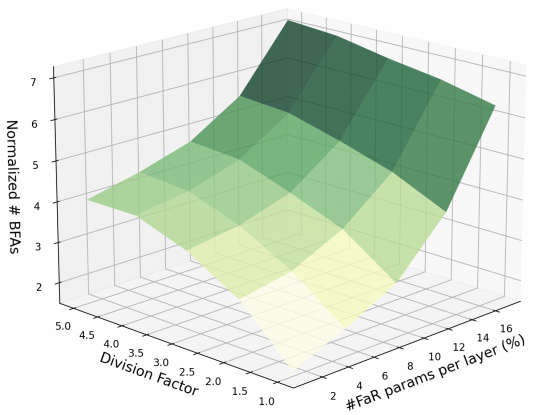

Figure 12: The impact of the number of FaR parameters and division factor per layer on the normalized number of bit-flips (using basic attack) required to degrade the accuracy by 10%.

The accuracy also proves to be highly dependent on the selection of input batches for gradient computation to identify critical parameters. Varying the classes of input samples used in this process would likely alter the parameters deemed most important, thereby affecting the model's validation set accuracy. Our experiments show that diversifying the input batches used to determine significant parameters mitigates the adverse effect on accuracy. However, this strategy may not necessarily enhance the model's overall resilience to generic BFAs but could reduce its defense against targeted BFAs aimed at specific output classes.

Initially, an increase in the division factor does not adversely affect accuracy due to the strategic selection of dead neurons for rewiring. Nonetheless, a notable decrease in accuracy is observed when expanding the scope of parameters classified as dead neurons, particularly when such expansion causes the FaR mechanism to contradict its intended function. This analysis shows that there is a delicate trade-off between FaR parameters and the accuracy of the model.

Figure 12 illustrates the role of FaR hyperparameters in strengthening models against basic BFAs. The findings reveal that an increase in the number of parameters involved in the FaR process leads to a quadratic rise in the number of bit-flips necessary to reduce the model's accuracy to the level of random guesses (representing a 10% loss, with the baseline being the count of BFAs in scenarios not employing FaR).

Furthermore, Figure 13 depicts the influence of the number of FaR parameters and division factor per layer on the inference time overhead. It reveals an anticipated trend: a rise in inference time correlating with an increase in the number of FaR parameters and division factors. It is notable that this additional time overhead is potentially reducible through the implementation of an improved and optimized linear layer. Such a layer would facilitate FaR operations via quicker C/C++ bindings within PyTorch, a modification we aim to explore in our forthcoming research efforts.

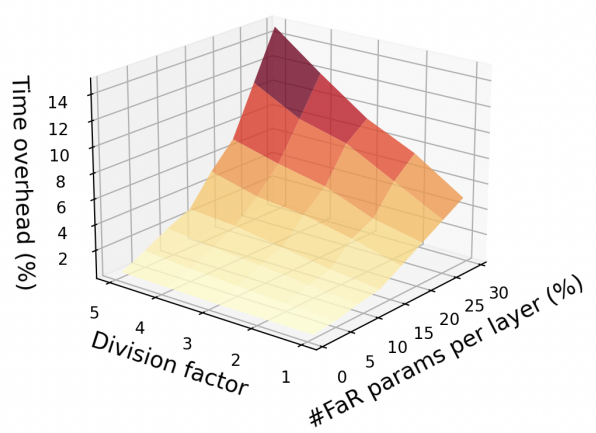

Figure 13: The impact of the number of FaR parameters and division factor per layer on the inference time overhead.

7 Discussion

7.1 Efficacy Against Sophisticated Attacks

Attacks Adapted against Gradient-based Defense: BFA aims to minimize the number of bit-flips required to degrade model accuracy, by targeting the most influential parameters that invariably exhibit high activation levels, making them detectable by gradient-based search. Consequently, our defense mechanism's effectiveness remains intact across different strategies for targeting critical parameters.

Attacks Adapted against Redistribution Strategy: Our defensive strategy, by design, increases the computational and operational cost for an attacker by necessitating a higher number of bit-flips. Should an attacker become aware of our rewiring scheme and attempt to target the original critical parameters, they would face the challenge of having to compromise all or most of the parameters that have been redistributed to a particular neuron. This is because attacking only the originally important parameter would not result in the expected performance degradation, as the activation is now also being propagated through other rewired parameters. This scenario forces the attacker to commit more bit-flips to effectively disrupt the model, aligning with our primary objective of enhancing resilience.

7.2 Using encryption to enhance security

Use of Authenticated Encryption: By applying authenticated encryption techniques to LLM memory, any tampering or bit-flips, such as those caused by row hammer attacks, become immediately apparent upon decryption. This ensures that any unauthorized alteration of the encrypted data can be detected, thus adding a robust layer of security.

Integration of ECC with Encryption: Extending the security measures, the incorporation of Error Correcting Code (ECC) alongside encryption can correct multiple-bit-flips. This is particularly beneficial in environments where data integrity and accuracy are critical. Although ECC can effectively manage multi-bit corrections, the scalability of this approach in the context of LLMs, which utilize billions of parameters, presents substantial challenges.

Resource Intensity and Feasibility: While the combined use of authenticated encryption and ECC offers a high level of security, the resource demands of implementing such comprehensive protection for billions of parameters are immense. Given the current technological and economic landscape, this solution might not be the preferred choice due to its significant resource consumption and associated costs that require further investigation.

7.3 Limitation and Future Research Directions

The current research has focused primarily on the application of our Forget and Rewire technique to linear layers within transformer-based models. However, there remain several promising avenues for future exploration and expansion of this work.

Potential Impact on Model Interpretability: The FaR technique, by design, involves redistributing critical weights across a broader spectrum of neurons, which inherently involves more parts of the network in performing similar tasks. This redistribution could potentially obscure the clarity with which specific network decisions can be attributed to particular neurons or layers. As a result, the effectiveness of techniques like Grad-CAM [40] and Saliency Maps [3], which rely on clear, localized activation patterns to interpret model decisions, might be diminished. While the potential impact on interpretability is valuable, it is important to note that the current scope of our evaluation does not include a comprehensive analysis of interpretability changes due to the implementation of FaR. Investigating the trade-offs between enhanced security and interpretability could provide valuable insights into the design and optimization of secure machine learning systems further studies could explore this dimension.

Extension to Convolutional and Recurrent Layers: One notable direction for future research involves adapting our Forget and Rewire strategy to convolutional layers (CNNs) and recurrent layers. While our current study centered on transformers, the applicability and potential benefits of our techniques in conventional deep neural networks (DNNs) like ResNet and AlexNet warrant investigation. Exploring how Forget and Rewire can enhance the robustness and security of these widely-used architectures is an important next step.

Integration with Other Defensive Techniques: Another intriguing avenue is the integration of Forget and Rewire with existing defensive techniques such as NeuroPots and Aegis. Combining these methods could lead to synergistic effects, bolstering the model's resilience against a broader spectrum of attacks. NeuroPots, serving as a detection mechanism, could

complement Forget and Rewire's protective capabilities, while Aegis, with its randomization approach, could add an extra layer of hardening to the model. Evaluating the effectiveness of these integrated defenses would be an insightful research direction.

Exploration of Non-Gradient-Based Attacks: While our work has primarily focused on gradient-based attacks, future research could explore the development of new fault injection attack methods that do not rely on gradient information. Investigating how Forget and Rewire stands up against such non-gradient-based attacks would provide a more comprehensive assessment of its security benefits.

Transferability and Prompt Tuning: Additionally, it would be valuable to analyze the transferability of our Forget and Rewire approach in the context of large language models (LLMs). Prompt tuning techniques have gained prominence in fine-tuning LLMs for specific tasks. Evaluating how Forget and Rewire can be adapted and integrated into prompt-based fine-tuning processes to enhance LLM security would be an intriguing research avenue.

8 Related Work

Machine learning models are susceptible to various types of attacks, including those focused on manipulating the data or the model itself [7,39,41,52]. Defenses against these attacks have been extensively studied for Convolutional Neural Networks (CNNs) and Recurrent Neural Networks (RNNs), including evasion, poisoning, backdoor/trojan attacks, and hardware-based fault injection techniques. However, the same level of attention and research for defense has not been devoted to transformer-based models. In the case of BFAs, which are a specific type of model-centric attack, studies proposing mitigation strategies in DNNs can be divided into two categories:

1. Hardening the Model: These approaches aim to make the model more robust and resistant to BFAs. They often involve architectural modifications or training techniques to fortify the model against potential attacks.

2. Detecting the Attack: These strategies focus on identifying when a BFA is occurring. They seek to create mechanisms or algorithms that can detect and alert when the model is under attack, allowing for a timely response to mitigate the damage.

In the first category of defenses, we can highlight the work of Li et al. [23], which employs a weight reconstruction method. This method helps neutralize the altered values in several model parameters, thereby reducing the impact of BFAs. Another notable contribution is from Zhan et al. [51], who modified the rectified linear unit (ReLU), a commonly used activation function in DNNs, to make it more resilient to faults caused by bit-flipping in weights. Additionally, there are binarization strategies such as BIN [16] and RA-BNN [38], which have been shown to be more effective than the aforementioned methods. These strategies involve retraining a binarization model from scratch to mitigate the effects of BFAs. However, it's important to note that these methods still require retraining the model, incurring substantial computational costs. Moreover, aggressive quantization, as seen in these approaches, can impact the model's accuracy.

The most recent work falling within the model hardening category is Aegis [43]. Aegis addresses targeted attacks, which aim to flip crucial bits in specific model layers. To thwart this, the authors introduce a dynamic exit mechanism with additional internal classifiers (ICs) in hidden layers. This disrupts attackers by allowing input samples to exit layers prematurely. The dynamic exit mechanism randomly selects ICs for predictions during each inference, making adaptive attacks more costly. They also propose robustness training for ICs, increasing model resilience by BFAs during IC training.

The second category operates independently of model improvement and offers an additional layer of protection. This category for defending against BFAs involves integrity verification [14,19,22,24]. In this approach, the defender generates a reference signature from the model before it is deployed. After deployment, new signatures are generated during inference and compared to the reference signature to detect any discrepancies.

The latest work that proposed a checksum-based BFA detection is NeuroPots [25]. NeuroPots introduces *honey neurons* as intentional vulnerabilities in DNN models, strategically placed to lure attackers into injecting faults by increasing the sensitivity of the model to less important parameters. This forms the basis for a defense framework with trapdoor capabilities. To efficiently detect faults, a checksum-based approach is used, focusing on the trapdoors where most bit-flips occur. Model accuracy is restored by *refreshing* these faulty trapdoors. A potential weakness of this approach arises when the attacker is aware of its implementation. In such cases, the attacker could circumvent trapdoors by disregarding sensitive parameters with sensitivity exceeding a predefined threshold.

The challenge at hand was to create robust defenses and detection methods uniquely suited to transformer-based models, which have distinctive architecture and traits. Our work distinguishes itself from previous research in three key aspects: 1) We introduce the concept of rewiring in a novel manner that eliminates the need for retraining. 2) Instead of exposing less crucial parameters as bait for attackers, we not only conceal important parameters but also enhance the model's resilience against BFAs by rewiring them to other parameters. 3) Our approach complements existing methods and can be employed alongside them, offering an additional layer of protection.

9 Conclusion

In addressing the imperative challenge of Bit-Flip Attacks (BFAs), this study illuminates a critical gap in research about the impact of BFAs on Large Language Models (LLMs) and Vision Transformers (ViTs). Inspired by the concept of "brain rewiring", we have proposed an innovative defense mechanism, *Forget and Rewire (FaR)*, specialized to enhance the resilience of Transformers against bit-flip attacks. FaR entails redistributing tasks from critical to non-essential neurons, effectively diminishing the model's sensitivity to specific parameters while preserving its core functionality. Despite BFAs' complexity, our proposed defense effectively shields sensitive weights, with minimal time and storage overhead while maintaining the model accuracy. The experimental results indicate the efficacy of our proposed approach, greatly decreasing the success rate of BFA attacks and obtaining a reduction factor ranging between 1.4 and 4.2 times, with minimal accuracy loss below 2%. Our novel FaR defense stands as a promising direction in confronting evolving digital threats, potentially steering the future of deep learning security solutions.

Abstract

Null pointer dereference (NPD) errors pose the risk of unexpected behavior and system instability, potentially leading to abrupt program termination due to exceptions or segmentation faults. When generating NPD fixes, all existing solutions are confined to the function level fixes and ignore the valuable intraprocedural and interprocedural contextual information, potentially resulting in incorrect patches. In this paper, we introduce CONCH, a novel approach that addresses the challenges of generating correct fixes for NPD issues by incorporating contextual checks. Our method first constructs an NPD context graph to maintain the semantics related to patch generation. Then we summarize distinct fixing position selection policies based on the distribution of the error positions, ensuring the resolution of bugs without introducing duplicate code. Next, the intraprocedural state retrogression builds the if condition, retrogresses the local resources, and constructs return statements as an initial patch. Finally, we conduct interprocedural state propagation to assess the correctness of the initial patch in the entire call chain. We evaluate the effectiveness of CONCH over two real-world datasets. The experimental results demonstrate that CONCH outperforms the SOTA methods and yields over 85% accurate patches.

1 Introduction

Null Pointer Dereference (NPD) occurs when a program attempts to access memory at a null pointer, and dereferencing a null pointer always causes the program to collapse. If an NPD occurs in a crucial system component, e.g., a kernel module or device driver, it can lead to a system-wide crash [11, 39]. Additionally, NPDs can be exploited by attackers to carry out malicious actions, such as executing unauthorized code or launching a denial-of-service attack [3, 4]. Therefore, NPDs are among the top prevailing security issues in the production environment [8, 9].

Several efforts have been made to patch NPD vulnerabilities [6, 12, 14, 15, 46–48]. Most of them follow the conventional generate-and-validate repair steps. They first traverse the search space using classic search algorithms like genetic programming or random search and then validate the generated patches using test cases. As the SOTA solution for fixing NPDs, VFix [48] localizes suspicious statements by using static value-flow analysis and dynamic test case driven triggering. Then VFix reduces the search space using the predefined fixing patterns, i.e., reallocating a new memory space or adding an if check, to improve the efficiency of the patch process and increase the chances of finding correct patches.

However, all existing solutions are confined to the function level fixes and ignore valuable intraprocedural and interprocedural contextual information when generating NPD fixes. First, the overlook of intraprocedural contextual information may cause overdue occupation of system resources such as memory and locks, denying access to those critical system resources as intended. Second, there is no interprocedural analysis for fixing NPD bugs, disregarding global variable resetting, function argument resetting, and patch validation in the call chain. For instance, it is crucial to reset some global variables and function arguments; otherwise, the program's state could be misidentified [25]. It remains a challenge to correctly fix NPD errors with contextual information.

In this paper, we propose an NPD contextual check mechanism named CONCH for fixing NPD errors with contextual information. By assessing the specific context in which the errors occur, CONCH can effectively generate the NPD fixes for scenarios that insert if checks, which are the most popular cases in real-world vulnerability fixing [44]. To construct accurate NPD patches that work within the function and among the entire call chain, we address three challenges.

The first challenge lies in selecting the appropriate repair position that ensures the correct and efficient repair without redundant patching. VFix [48] uses path congestion to select the repair position; however, its vulnerability path selection relies on test case selection and the dynamic triggering of test cases. We propose a vulnerability fix tailored graph named NPD Context Graph, which only maintains the semantics related to patch generation. In the NPD context graph, we identify the null and error positions and their corresponding paths. Then

we summarize four fixing position selection policies based on the distribution of the null and error positions, ensuring the resolution of bugs without duplicate fixes.

The second challenge involves constructing an initial patch via intraprocedural state retrogression to guarantee the correctness of the generated patch within the local function. This includes building the if condition, retrogressing the local resources, and constructing the return statement. When generating the if condition, we focus on the callee function at the null position. We analyze the implementation of the callee function to determine the exception value it returns when it encounters a failure. This exception value is crucial to constructing the condition for the if check in the current erroneous function. To retrogress the local resources, we have to deal with the diverse naming conventions of memory allocation/deallocation and locking/unlocking functions. To the best of our knowledge, there is no existing research that specifically addresses freeing the allocated memory and releasing the occupied lock during NPD fixing. To retrogress the local resources, we initiate by extracting keywords such as "alloc" and "lock" from the kernel and general libraries. This extraction helps create a dictionary of paired functions. Subsequently, we identify any missing pairs for allocated memory and occupied locks within the buggy function. When constructing a correct return statement, we consider the return type and other return statements in the current function. If the error occurs within a loop, we ensure the function can continue or break the loop without exiting the entire program.

The third challenge entails conducting the interprocedural state propagation, including resetting the global variables/-function arguments and assessing the patch correctness in the call chain. To reset the global variables and function arguments, we first identify which variables should be reset. The search scope is from the function entry to the error position, and we exclude the local variables. Then we determine the value to be reset by referring to the existing error-handling statement within the current function and conducting data flow analysis to infer the condition in the caller that represents a failure state. To assess the NPD fixing handled in the entire call chain, we analyze the return type of the callee function. If the return type is `void`, it returns no value to its caller function. In such a case, if the caller function executes normally after the buggy function returns when detecting a null pointer, we recursively analyze the call chain from the buggy function to the function that handles the error and update the intermediate functions according to the error-handling semantics. If the return type is not `void`, it has a return value to its caller function. Then, we check if the caller handles the return value correctly. If not, we update the caller.

We implement a prototype of CONCH and evaluate its contextual correctness for NPD fixes using two real-world datasets. The first dataset includes 80 NPD vulnerabilities from MITRE [30] and CONCH can generate 68, with an accuracy of 85%, semantic equivalent patches as submitted by the developer, outperforming an accuracy of 26.25% compared to the SOTA approach. The second dataset comes from a well-known benchmark suite [42], containing 18 NPD programs. CONCH can generate 16 correct patches, while the SOTA approach can only generate 12 correct patches.

In summary, we make the following contributions:

- We propose to fix NPD errors with contextual checks, ensuring a more effective and complete vulnerability control throughout the entire call chain.
- We are the first to address local resource retrogression (including freeing the allocated memory and releasing the occupied lock) and reset global variable and function argument in NPD fixing.
- We implement a prototype of CONCH and conduct experiments to evaluate its effectiveness and accuracy. The experimental results show that CONCH outperforms the SOTA approach.

We will open-source our tool and release the tested vulnerability code and benchmark.

2 Background

2.1 Separation Logic

Separation Logic (SL) [38] is grounded in a set of inference rules and techniques that enable effective reasoning about memory allocation, deallocation, and relationships among different memory segments in program analysis. It provides a precise framework for examining the ownership and sharing of heap-allocated data structures and resources. Derived from Hoare Logic [43], SL inherits the fundamental notions of pre- and post-conditions, which define the required conditions before and after program execution, respectively. These concepts are unified in Hoare triples of the form $\{P\}C\{Q\}$, where P and Q represent pre- and post-conditions and C denotes an operation. The logic encompasses a collection of inference rules to facilitate reasoning about program statements, including assignments, conditionals, and loops. Additionally, SL introduces Frame Rule [38] for modular reasoning about program components. By incorporating these elements, SL is able to verify program correctness, detect bugs related to memory access, and reason about heap-related behaviors.

2.2 Incorrectness Separation Logic

Based on separation logic, several approaches were proposed to prove the absence of memory-related bugs [1,2,13], but not reasoning for bug presence. In 2020, Incorrectness Separation Logic (ISL) [37] is proposed to extend SL and catch heap-related errors. Due to the ISL principle, there are no false positives in error detection [37]. The key contribution of ISL is to provide inference rules to define memory safety violations

when accessing deallocated locations. Equation 1 shows the extended rules on NPD issues.

$$\begin{aligned}
&\textsc{LoadErr}: \{y \nrightarrow\}\ x := [y]\ \{err: y \nrightarrow\}\\
&\textsc{LoadNull}: \{y = null\}\ x := [y]\ \{err: y = null\}\\
&\textsc{StoreErr}: \{x \nrightarrow\}\ [x] := y\ \{err: x \nrightarrow\}\\
&\textsc{StoreNull}: \{x = null\}\ [x] := y\ \{err: x = null\}
\end{aligned} \tag{1}$$

The LoadErr rule specifies that an error occurs when attempting to dereference y that has already been deallocated. Similarly, the LoadNull rule states that an error arises when attempting to dereference a null pointer y. The StoreErr rule indicates that an error occurs when trying to assign a value to x that has already been deallocated. Lastly, the StoreNull rule states that an error arises when attempting to assign a value to a null pointer x.

When reasoning on heap-related data structures, an NPD error is identified if a statement satisfies any of the ISL rules in Equation 1. These rules serve as the foundation for detecting NPD vulnerabilities in this paper and we select fault localization using ISL as our initial step to identify the null and error positions in an NPD program. Since SL and ISL mutually reinforce each other in detecting NPD vulnerabilities, we use SL to encompass both SL and ISL collectively.

3 Motivation Examples

Our work is motivated by the NPD fix cases where existing solutions yield incorrect security checks due to the neglect of intraprocedural/interprocedural context, leading to unreleased locks, unreset variables, or even new errors in the call chain. We illustrate three examples to demonstrate the root cause of the inappropriate NPD fixes and show how Conch can overcome the existing limitations in intraprocedural state retrogression and interprocedural state propagation. For simplicity, we focus on error-related statements and their corresponding fixes, normalizing the function names and parameters without changing their execution logic.

3.1 Intraprocedural State Retrogression

We first show an example in which the intraprocedural state retrogresses, e.g., releasing locks, should be considered when generating NPD patches. A simplified code segment of CVE-2022-41858 is shown in Figure 1, with an NPD error due to the possible null pointer of `sl->tty` at Line 7. When constructing the repair statement, existing solutions only check if `sl->tty` is null and generate a return statement according to the `void` function type.

Fixed by Conch. Apart from generating the if condition and return statements, we ensure resource retrogression of unlocking the occupied lock. First, we construct lock/unlock function pairs to record the locking state. Then, when analyzing the CFG from the function entry to the error position,

```
1 void buggy(param1, param2){
2     spin_lock(&sl->lock);
3 +   if(sl->tty == NULL){
4 +
5 +       return;
6 +   }
7     function(sl->tty, … );
8 }
```

(a) Fixed by SOTA work

```
1 void buggy(param1, param2){
2     spin_lock(&sl->lock);
3 +   if(sl->tty == NULL){
4 +       spin_unlock(&sl->lock);
5 +       return;
6 +   }
7     function(sl->tty, … );
8 }
```

(b) Fixed by Conch

Figure 1: An example of the necessity of unlocking an occupied lock (CVE-2022-41858).

we match the functions in the pairs to check if further unlock operation is required. If so, we extract the paired unlock function and insert it before the return statement, as shown in the shadow rectangle of Figure 1(b).

3.2 Interprocedural State Propagation

We use two examples to show that the interprocedural state propagation (e.g., global variable resetting, function argument resetting, and entire call chain assessment) has been overly neglected by existing approaches. We also explain how our solution can correctly generate the fixes.

3.2.1 Function Argument Resetting

Figure 2 depicts an example where the patch generation is affected by the restriction of only returning a single value. In the C programming language, when a function necessitates multiple return values, since only one value can be conveyed through the return statement, the remaining values are transmitted via function arguments. However, in existing solutions, the return values passed through the arguments are often neglected and need to be reset.

The simplified code segment of CVE-2022-2153 is shown in Figure 2(a), where the function argument `*r` in function `buggy` needs to be reset before returning since `*r` value will be passed to the `caller` function as its return value. The resetting operation of `*r` value can rectify the function state. However, no existing fixing methods address this issue.

Fixed by Conch. To fix this issue, the key is to obtain the expected `*r` value before returning. By constructing the call graph of the function `buggy` and analyzing the data flow of function argument `*r`, we can determine that the `*r` value is further returned by `caller` function as an if condition in the function `caller_caller`. Specifically, if `*r` is equal to 0 that signifies a failure state, the function `schedule_work` will not be called. Conversely, if `*r` has a non-zero value, the `schedule_work` function will be invoked to conduct a scheduling task. To generate a correct patch, it is essential to reset the value of `*r` to 0 before leaving the security check, as depicted by the shadow rectangle in Figure 2(b). This resetting step ensures the program behaves as intended with the NPD vulnerability mitigated.

```
bool buggy(int *r, … ){
    *r = -1;
    if(condition1){
+       if (src == NULL){
+
+           return true;
+       }
        // return 0 if discarded
        *r = func(src->vcpu, …);
        return true;
    }
}
int caller( … ){
    int r = -1;
    if(buggy(&r, … ))
        return r;
}
int caller_caller( … ){
    if(caller( … ))
        schedule_work();
}
```

(a) Fixed by SOTA work

```
bool buggy(int *r, … ){
    *r = -1;
    if(condition1){
+       if (src == NULL){
+           *r = 0;
+           return true;
+       }
        // return 0 if discarded
        *r = func(src->vcpu, …);
        return true;
    }
}
int caller( … ){
    int r = -1;
    if(buggy(&r, … ))
        return r;
}
int caller_caller( … ){
    if(caller( … ))
        schedule_work();
}
```

(b) Fixed by CONCH

Figure 2: An example of the necessity of resetting an argument in a function (CVE-2022-2153).

3.2.2 Call Chain Assessment

Figure 3 shows an example of how an NPD error should be handled in the call chain. The simplified code segment of CVE-2022-3112 has an NPD error at Line 7. Since the failure of `kzalloc` returns null to the pointer `new_ts`, dereferencing the null pointer triggers the NPD error. However, the function `caller` is unaware of this error as the `buggy` function of type `void` does not return any value to the `caller`. It leads to the uninterrupted execution of the `caller`, failing to handle this error appropriately. A correct patch requires analyzing the code implementation of `caller_caller` since it encompasses the value scope when `caller` encounters a failure. However, existing approaches can only construct fixing within the current function by checking if `new_ts` is null and returning directly, considering the `void` return type.

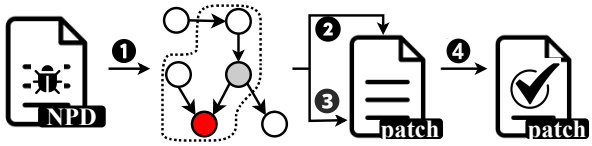
```
void buggy(param1, param2,… ){

    struct *new_ts;
    new_ts = kzalloc(sizeof());
+   if(new_ts == NULL)
+       return;
    new_ts->ts = ts;
}
int caller(param1, param2){
    int ret;
    if(error)
        return -EAGAIN;
    buggy( … );

    …
    return 0;
}
void caller_caller(param) {
    if(caller( … ) < 0)
        break;
}
```

(a) Fixed by SOTA work

```
- void buggy(param1, param2,… ){
+ int buggy(param1, param2, … ){
    struct *new_ts;
    new_ts = kzalloc(sizeof());
+   if(new_ts == NULL)
+       return -ENOMEM;
    new_ts->ts = ts;
}
int caller(param1, param2){
    int ret;
    if(error)
        return -EAGAIN;
-   buggy( … );
+   ret = buggy( … );
+   if(ret)
+       return ret;
    …
    return 0;
}
void caller_caller(param) {
    if(caller( … ) < 0)
        break;
}
```



(b) Fixed by CONCH

Figure 3: An example of the necessity of handling an NPD error in the call chain (CVE-2022-3112).

Fixed by CONCH. To fix this NPD error, we first conduct intraprocedural analysis to generate an initial patch as shown in Figure 3(a). Here, the `caller` does not have error-handling statements, and the `caller_caller` handles the error when `caller` returns a negative value. To fix the NPD error in the call chain, the `caller` needs to return a negative value, while the `buggy` should have an explicit return value for the `caller`. Thus, we generate the patch in three steps. First, we modify the return type of function `buggy` from `void` to `int`, facilitating the `caller` to handle the error. Second, we add a security check so that the `buggy` returns a negative integer once the `new_ts` is null. Third, when the `caller` receives the negative integer, it returns the negative integer to the `caller_caller`. The generated patch is shown in Figure 3(b).

4 CONCH Design

CONCH consists of four steps to fix NPD errors with contextual checks, as shown in Figure 4. Note that CONCH focuses on the scenarios where the NPD errors can be fixed by adding if statement checks.

NPD Program | Context Graph | Initial Patch | Final Patch

Figure 4: The CONCH overview: ❶ NPD context graph construction; ❷ path-sensitive fixing position selection; ❸ intraprocedural state retrogression, and ❹ interprocedural state propagation.

Given an NPD program, we first generate an NPD Context Graph to preserve the semantics related to patch generation by including the simplified control flow graph (CFG) of the vulnerable function and the calling pattern of the caller and callee functions. The context graph serves as a prerequisite for the subsequent components. Second, we define four policies to select the fixing position based on the distribution of the null position and the error positions. Given the policies, we overcome the challenge of selecting the appropriate repair point and we ensure the correct repair of vulnerabilities without introducing redundancy patches. Third, the intraprocedural state retrogression aims to generate an initial patch, ensuring that the NPD error is correctly handled in the current function. This step performs the if condition construction, local resource retrogression, and return statement construction. Fourth, we adopt the interprocedural state propagation to obtain the final patch, ensuring that the generated patch handles the NPD errors appropriately in the entire call chain. This step addresses global variable resetting, function argument resetting, and the entire call chain assessment.

4.1 NPD Context Graph Construction

For a given NPD program, we can generate an NPD context graph in three steps, as shown in Figure 5.

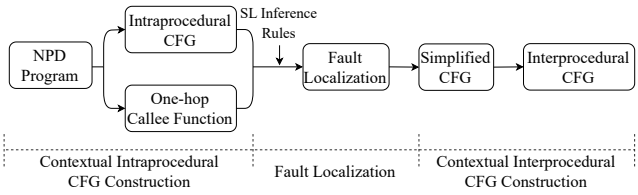


Figure 5: Context graph construction for NPD program.

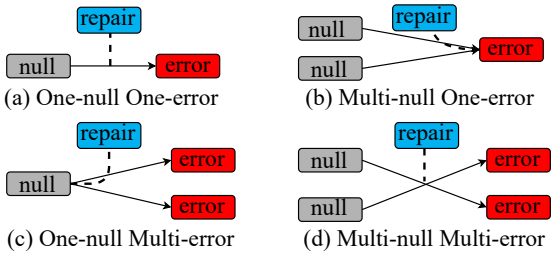

Figure 6: 4 policies of path-sensitive fixing position selection.

Contextual Intraprocedural CFG Construction. We construct intraprocedural CFGs for all functions in the NPD program, as well as the one-hop callee functions. The reasons that we only use one-hop of callee information are two-fold. First, if we consider all callee functions, the recursive tracing can lead to path explosion, while most of them are not necessary after processing. Second, according to real-world vulnerability analysis, the one-hop callee function can cover most cases in inferring the error positions. In some cases where one-hop callee function analysis is insufficient to obtain the required context, we conduct incremental analysis to analyze more hops until the error position is obtained. Additionally, the indirect control flow may hinder the connection of the callee function, and we adopt the SOTA approach MLTA [20] to refine the indirect targets. The generated contextual intraprocedural CFGs extend the contextual information, providing a prerequisite of call relations and path constraints for localizing error positions.

Fault Localization. We rely on the separation logic and its inference rules in Equation 1 to locate the NPD errors. We obtain the null positions where the pointers are set to null and the error positions where the null pointers are dereferenced to trigger errors. Separation logic is utilized to analyze different execution paths, which are identified explicitly by the intraprocedural CFG within the function. When a statement dereferences a null or invalid pointer, an NPD error is detected. In such cases, the null positions, the error positions, and their involved execution paths are identified and recorded, enabling precise error localization within the function and facilitating the subsequent NPD mitigation.

Contextual Interprocedural CFG Construction. After obtaining the contextual intraprocedural CFGs of all functions, along with the null and error positions and their corresponding paths, we construct the interprocedural CFG by streamlining the intraprocedural CFGs. We first prune the intraprocedural CFG of the buggy function and only retain the nodes of the path from the function entry to the error position. Then, for the callee function containing the null position, we preserve the error-handling statements and their return values in their nodes. Next, we analyze the caller function of the buggy function and maintain the statements from the function entry to the calling position of the buggy function. For special cases where the direct caller cannot cover the error handling, we conduct an incremental analysis to recursively trace deeper callers. Finally, we connect these pruned CFGs together to generate an interprocedural CFG, containing all the states related to the error handling while removing irrelevant statements.

4.2 Path-sensitive Fixing Position Selection

Based on the distribution of the null and error positions, we define four different policies to select path-sensitive fixing positions. As the SOTA approach, VFix [48] proposes a congestion calculation to select a fixing position; however, it has two limitations. First, the dynamic test case based localization limits its scalability. Second, this congestion calculation method may lead to ambiguity since all sequential statements in the key path have the same congestion result. Therefore, to select a proper fixing position, we analyze all the NPD records containing commit information in MITRE [33] and summarize four fixing position selection policies according to different control flows, i.e., one null and one error positions, multiple null and one error positions, one null and multiple error positions, and multiple null and multiple error positions, as shown in Figure 6. Our key principle of fixing position selection is that the fixing position should be between the null position and the error position, and repeated fixing should be avoided.

The first type (i.e., one null position and one error position) of fixing position selection is straightforward and widely occurs. When the null position and error position are on the same path without any branches, the typical fixing position is closely behind the null position. This approach ensures that the fix is placed between the null position and the error position, diminishing potential derivative bugs. This fixing pattern can be found in addressing the real-world vulnerabilities in CVE-2022-3112 [26] and CVE-2022-41858 [28].

The second type (i.e., multiple null positions and one error position) of fixing position selection arises when the null positions are located within multiple if branches, as shown in CVE-2023-1355 [32]. Instead of selecting an individual fixing position for each branch, we select the fixing position just prior to the error position to avoid repeated fixes. This strategy allows us to check errors for both branches without introducing redundant code.

The third type (i.e., one null position and multiple error positions) of fixing position selection is similar to the second type except that there is only one null position but multiple

error positions within the if branches. This fixing pattern appears in CVE-2022-3153 [27]. Though it is possible to select an individual fixing position for each error position, it may result in redundant fixing since the fixing statements are identical. To avoid redundancy, we select the fixing position immediately after the null position. This approach allows us to address both error positions while avoiding unnecessary duplication of the fixing process.

The last type (i.e., multiple null and error positions) of fixing position selection is the most complex. A real fixing example can be found in the `JFreeChart` project [48]. To determine the fixing position in such cases, we can consider the null positions as one node and the error positions as another node. The fixing position can be identified as the node through which the flow from all null positions intersects with the flow toward all error positions. This approach ensures that the fixing position captures the necessary context and effectively addresses both the null and error positions.

In general, the first type is the most general and popular case and the other types have more constraints compared to the first type, thus, we select different fixing position selection policies.

4.3 Intraprocedural State Retrogression

We use the intraprocedural state retrogression to generate an initial patch, which includes if condition construction, local resource retrogression, and return statement construction.

4.3.1 If Condition Construction

The if check is an effective and widely used manner in NPD fixes. When constructing the if conditions, a general format would be *if* a checked variable is equal to null or an exception value, *then* the function or loop is terminated. An alternative format is to determine *if* the checked variable is not equal to the exception value, *then* the existing code will be executed. Here, the challenges are how to select the checked variable and how to determine the exception value. Also, after obtaining the variable and value to be checked, we need to choose either the null checking to terminate the code or the non-null checking to execute the existing code.

To solve this issue, we first analyze the existing patches for previous CVEs and summarize three representative patch templates. In Figure 7(a), the variable `pcpu_sum` would be null once the allocation fails in the function `kvmalloc_array`; in this case, dereferencing `pcpu_sum` triggers an NPD error. To fix this issue, null checking is conducted for `pcpu_sum`, and the function terminates if it is null. In Figure 7(b), function `amvdec_add_ts` returns a negative exception value when it fails, and the returned value makes the received variable an invalid pointer. To address this vulnerability, the return value of `amvdec_add_ts` needs to be assigned to a state variable `ret` and check if `ret` is a non-zero value. While in Figure 7(c), variable `info->st_info_list` does not represent a return

```
1     pcpu_sum = kvmalloc_array(param1, param2, param3)
2  +  if(pcpu_sum == null)
3  +      return;
4     this_sum = &pcpu_sum[cpu];
```

(a) CVE-2022-3107

```
1  -  amvdev_add_ts( … );  // return neg when fails
2  +  int ret = amvdec_add_ts( … );
3  +  if(ret)
4  +      return ret;
```

(b) CVE-2022-3112

```
1  +  if(info->st_info_list != NULL){
2         clist_foreach(info->st_info_list, NULL);
3         clist_free(info->st_info_list);
4  +  }
5     free(info);
```

(c) CVE-2022-4121

Figure 7: If condition construction in typical NPD fixes.

value, and the following code has a data flow dependency on this variable. If we check whether the variable is null and return when it is null, the other statements of this function, i.e., freeing a function argument, cannot be completed. Therefore, the generated patch executes the original statements when `info->st_info_list` is not null.

Thus, to select the checked variable, we trace the CFG of the current function and select the variable at the null position since it is the root cause of the NPD errors. To determine the exception value, we analyze the statements of the callee function at the null position and extract the return value when the callee function fails. The failure return value can be determined by analyzing the function specification and enumerating the existing return values of callee failure. For instance, if the specification defines a return value of 0 for success and 1 for failure, we can use 1 as the exception value. When the function specification is unavailable, we determine the exception value by analyzing the existing return patterns, e.g., null is an exception value if all error handling involves returning null; a negative integer can be an exception value when each failure state corresponds to a negative return value.

To construct the if condition, there are two scenarios for the relationship between the checked variable and the exception value. The most typical case is to check if the variable is equal to the exception value when the checked variable receives the failure return value of the callee function at the null position. However, if statements between the null position and the error position have a data flow dependency with the checked variable (usually a free operation), a non-null check should be conducted in the if condition, and the following code executes when the non-null check holds.

4.3.2 Local Resource Retrogression

If the buggy function terminates due to an NPD error, the local resources, e.g., allocated memory and occupied locks, should be retrogressed to the initial states before continuing the execution. Neglecting to perform these retrogressive operations could lead to unreleased memory in the process or

```
1     rcu_read_lock();
2     slave = rcu_dereference(bond->curr_active_slave);
3 +   if(!slave){
4 +       rcu_read_unlock();
5 +       return -ENODEV;
6 +   }
7     xs->xso.real_dev = slave->dev;
```

(a) lock releasing in CVE-2022-0286

```
1     not_checked = kmalloc(sizeof(*not_checked) * 2);
2     checked = kmalloc(sizeof(*checked) * 2);
3 +   if(!not_checked || !checked){
4 +       kfree(not_checked);
5 +       kfree(checked);
6 +       return;
7 +   }
8     checked->data[] = …
9     not_checked->data[] = …
```

(b) memory deallocation in CVE-2022-3104

Figure 8: Local resource retrogression in typical NPD fixes.

invisible locks to other processes.

Figure 8 illustrates two typical cases where retrogression is needed before the function termination. In Figure 8(a), the lock `rcu_read_lock` is invoked before the variable `slave` receives the return value of function `rcu_dereference`. If the function fails, `slave` obtains the exception value and the program terminates. However, before the program termination, the occupied lock should be released; otherwise, other processes may not request the lock successfully. In Figure 8(b), variables `not_checked` and `checked` request a piece of memory space using `malloc`; however, if any of the allocations fails, we need to free both memory spaces using `kfree` and exit the current function. Note that `kfree` does nothing when freeing an empty heap; thus, detecting a failed allocation and freeing both memory spaces will not introduce an error.

To retrogress the local resources, we refine the process into two phases. First, it is straightforward to free allocated memory when an NPD error occurs. However, there are diverse pairs of allocation and free functions, e.g., `malloc`/`free`, `kmalloc`/`kfree`, and `g_malloc0`/`g_free`, while developers can customize their own allocation/free functions. Thus, we traverse all the CVE records [30] until April 21, 2023, including 200,759 items, and the official documents of the Linux kernel and the GNU C Library (glibc), and retrieve the keyword pairs with "alloc" and "free". After manual verification, we generate a memory allocation/free dictionary. When analyzing an NPD program, we search the keywords "alloc" and "free" before the error position of the buggy function. We compare keywords with the generated allocation/free dictionary to determine if further free operations are needed. For the user-defined allocation/free functions, the function names usually contain the listed keywords; thus, we analyze the one-hop call chain from the user-defined allocation/free functions to the functions in the allocation/free dictionary to determine the free operations.

Second, to release the occupied locks, the key challenge is to find the lock/unlock function pairs. Intuitively, we search the keywords with "lock" and "unlock" in the kernel functions to generate a dictionary. Also, we analyze the CVE records [30] to extract the lock/unlock pair information, such as write_lock/write_unlock, write_lock_bh/write_unlock_bh, and rcu_read_lock/rcu_read_unlock. During NPD program analysis, we retrieve the key information "lock" and "unlock" before the error position of the buggy function, and compare them with the extracted lock/unlock pairs to determine the further unlock operations.

In addition, CONCH handles other functions beyond standard C functions by analyzing callee functions along each execution path. When a callee function belongs to the preceding parts of paired functions, CONCH seeks the subsequent part using name similarity and passed arguments.

4.3.3 Return Statement Construction

The repair process involves constructing a return statement, which heavily relies on both the function's return type and the existing return statements within the current function. For a `void`-type function, only a `return` statement is required without any return value. However, for a `bool`-type function, returning `true` or `false` represents a totally different result. In addition, the function can return a null, a predefined macro, or a negative integer. In some cases, the function executes the `continue` statement to enter the next iteration or the `break` statement to terminate the loop. The selection of return values depends on the context statements and an incorrect return value may lead to the chaotic logic of the program.

Figure 9 shows four different return types for handling NPD cases. In Figure 9(a), `input_node` receives the return value of `GetNode` and then the value of `input_node` is passed for further operation. Thus, a null-pointer checking is required, i.e., if `input_node` is null, the function returns to its caller function. Since the return type of current function is `bool` and similar return patterns for error handling (e.g., Line 2) can be referred to, the return value for this null pointer handling should be `false`. In Figure 9(b), function `kcalloc` returns null when fails, so the variable `imx_keep_uart_clocks` requires a null-pointer checking. Due to the `void` function type, the `return` statement is added without any value. In Figure 9(c), if `cl` is a null pointer, the function returns a predefined macro `FAIL`, according to the adjacency error handling code (i.e., Line 2 and 7). In Figure 9(d), if `val` is null, the `strcmp` operation cannot be completed. Because the operation is in a loop and a single iteration failure does not mean the whole loop failure, a `continue` statement is required when `val` is null.

Therefore, to construct the return value, we first analyze the return type of the current function. If the return type is `void`, a `return` statement is required as the initial attempt. However, for the example in Figure 3, a simple `return` is not correct in context and we talk about this scenario in § 4.4. Second, we transfer the existing error-handling statements to the added if check in the same function. For example, in Figure 9, three

```
    if(IstensorIdControlling(tensor_id))
        return false;
    input_node = graph.GetNode(tensor_id.node());
+   if(input_node == nullptr)
+       return false;
    return IsSwitch(*input_node);
```

(a) CVE-2022-23589

```
    if(imx_keep_uart_clocks){
        imx_uart_clocks = kcalloc(clk_count, … );
+       if(!imx_uart_clocks)
+           return;
        if(!of_stdout)
            return;
    }
```

(b) CVE-2022-3114

```
    if(rettv->vval.v_object == NULL)
        return FAIL;
    cl = rettv->vvval.v_object->obj->class;
+   if(cl == NULL)
+       return FAIL;
    if(get_func_argument(…) == FAIL)
        return FAIL;
```

(c) CVE-2023-1355

```
    while(scanindent(s)){
        var = scanname(s);
+       if(!val)
+           continue;
        if(strcmp(var, "command") == 0)
    }
```

(d) CVE-2021-30219

Figure 9: Four typical return types in the NPD fixes.

cases are learned from the existing fixing patterns. Third, we can learn the error-handling statements from the caller function, since the caller function may have the corresponding statements to handle different return values of the callee function. For example, in Figure 3, the function `caller_caller` handles a negative integer when the `caller` fails, so the patch of `caller` needs to return a negative integer for failure. In some cases, we only know the scope of the return value, such as an integer or a negative integer, not the exact value; however, we can match them with the official error macros [5] to obtain the exact return value, such as `ENOMEM` for *Out of Memory* and `EINVAL` for *Invalid Argument*. After constructing if condition, retrogressing local resources, and constructing return statements, an initial patch is generated, guaranteeing its correctness in the current function.

4.4 Interprocedural State Propagation

After obtaining the initial patch, the NPD error is handled in the current function; however, the fix cannot guarantee its correctness in the whole call chain. Thus, we introduce the interprocedural state propagation to obtain the final patch by resetting the global variables and function arguments and handling the NPD errors in the entire call chain.

4.4.1 Global Variable and Function Argument Resetting

To reset the global variables and function arguments, we can update the initial patch as illustrated in Algorithm 1. First,

Algorithm 1 Global Variable and Argument Resetting

Input: initial patch generated by intraprocedural analysis.
Output: updated patch with variable resetting.

```
1:  procedure VARIABLE_RESETTING(DFG)
2:      globals[ ] ← null
3:      arguments[ ] ← null
4:      while stmt ∈ (function_entry, error_position) do
5:          if var ∉ local_vars then
6:              if var ∈ func_arguments then
7:                  arguments.append() ← var
8:              if var ∈ global_vars then
9:                  globals.append() ← var
10:     while funcs ∈ (buggy, err_handled) do
11:         if var ∈ (globals[ ] || arguments[ ]) then
12:             if resetting ∈ other error stmt then
13:                 var ← resetting
14:             else
15:                 var ← data flow analysis
16:     return updated patch with resetting inserted
```

we need to identify the global variables and function arguments. In a buggy function, our analysis scope is from the function entry to the last error position, since the subsequent variables will not affect the error handling. We do not even consider local variables in this scope because our purpose is to reset the global variables and function arguments that affect the function (Line 5). If the variables are passed from the argument list, they are appended to the array *arguments* (Line 7). However, identifying the global variables is complex since their definitions are out of analysis scope; hence, we extend the search space to the global statements prior to the buggy function. Once the global variable definitions are out of the current file, we traverse the included header files. After identifying the global variables, we append them to the array *globals* (Line 9). The identification process is shown in Algorithm 1 of lines 2 to 9.

Then, we obtain the expected values of global variables and function arguments. Our overall strategy is to infer the values from either the existing error-handling code in the buggy function or the data flow in the caller function. In the first case, our observation is that if a global variable or a function argument needs to be reset in a code snippet, it may be reset in other statements of the current function (Line 12). For example, Figure 2 shows the function argument `*r` requires a reset operation while we can obtain its value from call chain analysis in the context. The value can also be obtained from the current function, since the `func` returns 0 to `*r` at Line 9 if the operation in the function is discarded. If no reset statement can be referred to in the current function, we gather information from its caller function via data flow analysis. The second case usually occurs when requiring more return values; however, only one value is directly returned while others are passed via global variables or function arguments.

Hence, we analyze the data flow of the target variable in the call chain from the buggy function to the caller of the function that returns the target variable in its return statement. By inferring the failure state in the caller, the target variable value can be determined (Line 15). The resetting process is shown in Algorithm 1 from Line 10 to Line 15.

4.4.2 Call Chain Assessment

In this step, we further update the patch to generate the final patch. Our goal is to keep the generated patches correct in the whole call chain; in other words, an NPD error should be addressed over all the caller functions. We first analyze the return statement in the updated patch to obtain the return type, e.g., `void`, `bool`, and `int`. If the return type is `void`, the current function does not return any value to its caller function, thus the caller function will not be notified when the current function fails. Hence, we need to check if the caller function can execute without interruption when the buggy function triggers the NPD return because an incorrect return value may propagate errors to the caller functions silently. If the caller function is also buggy, we recursively analyze the predecessor caller function of the buggy function until reaching the function in which there is a statement to handle the error (we call it the *error-handled function*). Then, for all functions between the buggy function to the error-handled function, we update them by adding error-handling statements according to the semantics in the error-handled function. Finally, we update the return type of the buggy function from `void` to `int` and return a value to its caller. Several real-world vulnerabilities, e.g., CVE-2022-3112 [26], follow this fixing pattern. If the return type is not `void`, it already returns specific exception values to its caller. Here, we can check if the caller handles the return value correctly. If not, we update the caller function according to the semantics in the updated patch. The process to generate the final patch is shown in Algorithm 2. After patching into the buggy program, we can obtain a correct program where the NPD errors are handled in the entire call chain.

Algorithm 2 NPD Fixing Assessment in Whole Call Chain

Input: updated patch with variable resetting.
Output: final patch with error handled in the call chain.

```
1:  procedure ENTIRE_CHAIN_ASSESSING(CFG)
2:      returns ← ReturnStmtInPatch()
3:      if returns ∈ void type then
4:          if caller has normal return value then
5:              while funcs ∈ (buggy, error_handled) do
6:                  UpdateFunc(funcs)
7:                  returns ← ReturnUpdate()
8:      else
9:          if caller handles incorrectly then
10:             UpdateFunc(caller)
11:     return final patch
```

5 Implementation

We implement CONCH with about 1,000 lines of Python code, which includes null and error position identifications, NPD context graph construction, fixing position selection, and patch generation.

Null and Error Positions Identification. We build our system on top of Facebook infer (FBinfer) [7]. Given an NPD program, FBinfer takes the source code as input and outputs the null and error positions and their corresponding paths according to the separation logic and its reference rule in Equation 1.

NPD Context Graph Construction. After obtaining the null and error positions and their related paths, we locate the callee functions at the null positions and analyze their implementation. Since we focus on the exception return values of the callee functions to construct the if condition, we only preserve the error-handling statements and their return statements of the callee functions. Then, we traverse the files to obtain the caller functions that call the buggy function and keep the calling statements along with the calling conditions and their return values. Finally, we generate the NPD context graph by connecting the CFG of the buggy function (from the function entry to the last error position) with the pruned CFG of the caller and callee functions.

Fixing Position Selection. We obtain a subgraph from the NPD context graph by only retaining the slice from the first null position to the last error position, along with their corresponding paths. In the subgraph, we mark each null position and each error position. The fixing positions are selected by calculating the distribution of the null and error positions according to the predefined patterns in § 4.2.

Patch Generation. In the intraprocedural state retrogression, the checked variable is obtained from the null position and the checked value comes from the exception value of the callee function. Then the relation between the checked variable and the checked value is determined by the data dependency of the subsequent code. For the local resource retrogression, we create a function pair dictionary by retrieving the keywords in the kernel and generic libraries. Then we match the functions before the error position to determine the release operations. CONCH extends its analysis beyond just standard C functions by examining the functions called within each execution path. If it detects that a called function is the first in a pair of related functions, CONCH identifies the matching second function based on the similarity in their names and the arguments passed to them. The return statement construction relies on the function type and existing error-handling statements in the current function. When conducting interprocedural state propagation, we rely on data flow analysis on the NPD context graph to reset the global variables and arguments and assess the initial patch in the entire call chain.

6 Evaluation

Our objective is to show that CONCH can significantly outperform the SOTA approaches (e.g., VFix) for repairing NPD errors in terms of contextual correctness. By comparing CONCH with SOTA approaches in fixing NPD vulnerabilities reported in CVE, we find that CONCH can correctly repair 85% vulnerabilities while the SOTA approaches can fix up to 58.75%, outperforming accuracy of 26.25 percentage points. In addition, we also evaluate the effectiveness of CONCH using the dataset of 18 NPD errors in `Defects4j`. CONCH can successfully fix 16 NPD errors by generating patches that are as correct as the developers' manual fixes, while the SOTA solutions can only generate up to 12 correct patches.

6.1 Experimental Setup

Datasets. To evaluate the accuracy of our method, we use two real-world datasets. The first dataset comes from real-world vulnerabilities, i.e., CVE records. We search in MITRE with the keywords "Null Pointer Dereference" and get 2,188 records by April 2023. Among them, 177 records have the commit information. We exclude the misclassified records (i.e., not NPD errors), and race conditions are also beyond our consideration. We obtain 81 CVE records and most of them are from the Linux kernel. Regarding patches submitted by developers, 80 vulnerabilities can be fixed by adding if conditions, and only one vulnerability (CVE-2023-1095 [31]) is fixed by initializing the pointer. In this paper, we focus on the case of adding the if check, i.e., 80 CVE records. The second dataset consists of 18 NPD errors, coming from a well-known benchmark, `Defects4j`, with 7 in `Chart`, 6 in `Closure`, 2 in `Lang`, 2 in `Math`, and 1 in `time`.

Other Program Repair Methods. VFix [48] represents the SOTA approach to addressing NPD issues with the best patch accuracy. One of its distinguishing features is its utilization of value-flow information within programs, enabling precise localization of suspicious statements and effectively reducing the search space for potential patches. By narrowing down the patch space, VFix significantly enhances the efficiency of the generate-and-validate process while increasing the likelihood of discovering the correct patches. In comparative evaluations focused on NPDs, VFix has demonstrated superior performance to other SOTA Automatic Program Repair (APR) techniques such as GenProg [15], ACS [47], CapGen [46], SimFix [12], and NPEfix [6]. In this paper, besides the VFix, we also select one NPD-related method (i.e., NFEfix) and one general-purpose APR solution (i.e., SimFix) as the baselines for measuring the accuracy of NPD fixing, since both of them represent the best patch generation accuracy evaluated in VFix.

System Runtime. Our experiments are conducted on a machine with an Intel Core i7 1.8GHz CPU and 16GB memory, running Ubuntu 22.04 with FBinfer 1.1.0.

6.2 Performance on CVE Dataset

There are 80 records in the CVE dataset. CONCH can generate 68 correct patches and 12 incorrect patches, with an accuracy rate of 85%. Among 68 correct patches, 36 fixings are consistent with the developers' patches, and 32 patches have semantic equivalence to the developers' patches. We also apply SOTA approaches to generate NPD fixes for the first dataset; however, they only achieve an accuracy rate of up to 58.75%. Thus CONCH outperforms SOTA approaches with an accuracy of 26.25%.

Same Fixes as Developers' Patches. Among 36 patches that are exactly the same as the developers' fixes, there are 23 null checkings, 12 not-null checkings, and 1 other value checking. For return statements, 11 fixings do not require return statements, 5 fixes return without value, 4 patches return bool values, 3 patches use `break` statement to exit the loop, and the other 13 patches return predefined values or goto labeled code segment. Additionally, there are 3 patches requiring extra operations to free allocated memory (CVE-2022-3104), release the occupied lock (CVE-2022-41858), and reset the function argument (CVE-2022-2153) before return. We list such cases in § A.

Semantic-Equivalent Fixes. The 32 patches that have semantic equivalence to the developers' fixes can be divided into three categories. First, the constructed fix identifies the attribute of the return value (e.g., positive/negative, zero/non-zero) but does not have the exact value compared to the developers' fixes. There are 15 patches for such cases. For instance, when fixing CVE-2022-47021 [29], a negative return value of function `op_get_data` represents the failure state, and the developer uses the macro `OP_EFAULT` (-129); however, we cannot obtain this macro in context and hence return another macro `OP_EINVAL` (-131).

Listing 2: Fix of CVE-2022-3153 generated by CONCH.

Second, seven patches provided by the developers jump to

existing error-handling statements using the `goto` statement. However, there could be hundreds of lines of code between the fixing position and the label position, which makes further analysis complex and confusing. Therefore, we try to avoid the `goto` statement and then simplify the generated patches. For instance, List 1 shows the patch for CVE-2022-3153 generated by the developer. The fix reuses the existing error-handling statements. When the pointer `expected` is null, the program will jump into the label to conduct very complex processing. Since there are one hundred lines of code between the if check position and the label, the difficulty of further analysis increases. As a comparison, when we generate the patch, we first verify that there is no allocated memory, no lock, and no modified global variable, before the fixing position. According to the `void` return type, we return directly when determining that `expected` is null, as shown in List 2.

Third, for the other 10 patches, the developers' patches and the patches generated by CONCH have the same results but are represented in different ways, which include two aspects. The first one is that the developers may use a range to indicate a specific value, but we assess that value directly. For example, when dealing with non-negative integers, a developer may use a check for a value less than 1 to signify an empty state, shown in List 3; however, we simply check whether the value is equal to 0. The second one is that the developer may check the member of a pointer for its empty state, while we cannot obtain the detailed member information and hence check the null pointer directly.

Listing 3: Fix of CVE-2016-2188 generated by developer.

Incorrect Fixes. CONCH cannot generate correct patches for 12 vulnerabilities, as listed in Table 1. The key reason is that we cannot obtain the checked variables or functions in context when constructing the if conditions. First, some class/struct object members cannot be obtained in context. For example, we can get the definition and usage of an object pointer in a function and add null pointer checks; however, the member of this pointer may require further checks. Due to no specific information to determine which member to check, we can only generate a partially correct patch to check the object pointer. Second, the relation between the variables and the specific values may not be inferred in context. Additionally, some complex execution logic can only be obtained from experts' in-depth analysis, such as $uaddr == uaddr2$ in CVE-2021-6647, which breaks the rule of different addresses [24]. In such cases, CONCH can generate patches; however, the patches cannot fix the vulnerabilities. Third, high-customized functions are required in some special scenarios, such as the sanity check functions, validation check functions, and vCPU initializing functions. Even if we can locate the error positions; however, we cannot find the appropriate functions to fix the vulnerabilities, thus CONCH cannot generate patches in this case.

Comparison with SOTA Approaches. For those 80 NPD errors, we also apply SOTA approaches to generate patches. The comparison results between CONCH and SOTA approaches for repairing real-world vulnerabilities are shown in Table 2. We can generate 36 patches that are the same as the developers' patches. Specifically, three patches implement the `break` statement to leave a loop, one uses `spin_unlock` to relinquish a lock, another employs `kfree` to release memory, and another resets a function argument. Additionally, one patch checks a unique function available in the context. These listed cases are beyond the scope of SOTA approaches: VFix has the capacity to generate 29 patches in total, NPEfix generates 15 correct patches, and SimFix has 18 correct patches. We can also generate 32 semantic equivalence patches, among which 11 need contextual information to frame if statements, two are for unlocking designated locks, and one addresses memory release. Based on these results, VFix can formulate 18 patches, while NPEfix and SimFix can muster 4 and 8 patches respectively. Concerning the 12 vulnerabilities for which we couldn't create precise patches, four of them have no patches proposed, three of them cannot catch the error, and five of them generate patches but does not handle resource properly. All of the SOTA approaches cannot yield any results for these 12 vulnerabilities, with an accuracy of less than 58.75%.

The Necessity of Contextual Checks. To demonstrate the necessity of introducing intraprocedural state retrogression and interprocedural state propagation, we evaluate the impact of the local resource retrogression, global variable and function argument resetting, and entire call chain assessment. The results show that six patches require the unlocking or memory-freeing operation, one fixing needs the function argument resetting, and three patches require multiple layers of caller functions to handle the NPD error. These cases occupy a proportion of 14.7% in the correctly generated patches.

We also analyze the number of layers of the call relation from the NPD context graph between the first caller function and the error position. We focus on the programs that have been correctly handled by CONCH. The result is shown in Figure 10. 55 programs have only one caller function, while eight vulnerable programs have two caller functions. There is one buggy program with four caller functions, one with five caller functions, two buggy programs with eight caller functions, and one buggy program with 15 caller functions. Among them, 65 programs can be handled in one layer, while the other three buggy programs require two layers (i.e., the caller of the caller function handles the error case).

Performance Overhead. The performance overhead of

Table 1: The reasons that CONCH cannot generate correct patches and we provide some partially correct patches.

Category	CVE ID	If Condition	Generated Patches	Why CONCH Cannot Generate Correct Patches
Unobtainable Member	CVE-2022-1674	rmp->regprog != NULL	rmp != NULL	member *regprog* cannot be obtained in context
	CVE-2022-1620	rmp->regprog != NULL	rmp != NULL	member *regprog* cannot be obtained in context
	CVE-2016-2782	serial->num_bulk_in < 2	serial != NULL	member *num_bulk_in* cannot be obtained in context
	CVE-2014-0101	!net->sctp.auth_enable	net == NULL	member *sctp.auth_enable* cannot be obtained in context
	CVE-2013-0313	inode->i_op->removexattr != NULL	inode->i_op != NULL	`removexattr` is not a function in context
Unobtainable Relation	CVE-2022-2874	cctx->ctx_skip != SKIP_YES	cctx != NULL	relation with SKIP_YES cannot be obtained in context
	CVE-2018-1092	ino == EXT4_ROOT_INO	ino == 0	relation with EXT4_ROOT_INO cannot be obtained in context
	CVE-2012-6647	uaddr == uaddr2	uaddr && uaddr2	relation that *uaddr* is equal to *uaddr2* cannot be obtained in context
Special Function	CVE-2022-3621	nilfs_is_metadata_file_inode(inode)	-	special function for sanity check
	CVE-2022-2302	JFS_IP(ipimap)->i_imap	-	special function for validation check
	CVE-2013-5634	!kvm_vcpu_initialized(vcpu)	-	special function for initializing vCPU
	CVE-2013-4119	!SecIsValidHandle(handle)	-	special function for validation check

Table 2: Comparison between CONCH and SOTA approaches for repairing real-world vulnerabilities.

	Same Fixing	Semantic Equivalence	Incorrect Patches	Proportion
VFix	29	18	33	58.75%
NPEfix	15	4	61	23.75%
SimFix	18	8	54	32.5%
CONCH	**36**	**32**	**12**	**85%**

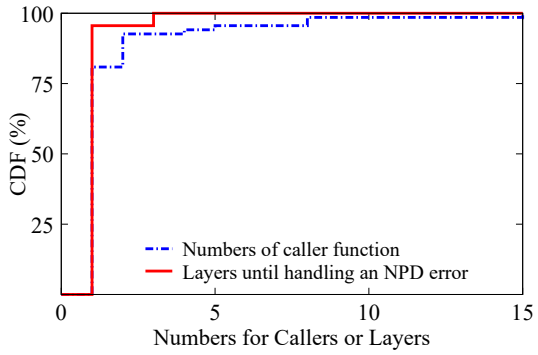

Figure 10: Numbers of callers and layers for CVE Dataset.

CONCH is mainly from locating the null pointer and the error positions using FBinfer [7], constructing the contextual graph for each vulnerable function, obtaining the required information, and generating patches. Specifically, for each NPD error, identifying vulnerable positions and outputting the error information cost 16.17 seconds on average. Constructing the contextual graph by combining the intraprocedural and interprocedural graphs takes about 10 seconds, in which the cost of constructing an intraprocedural graph is negligible (about 0.006 seconds), and querying and connecting each caller or callee function takes about six seconds. Finally, the cost of traversing the paths and obtaining the function pair according to the predefined patterns can be negligible, about 0.006 seconds.

6.3 Performance on Benchmark Dataset

The second dataset contains 18 NPD errors collected from `Defects4j`, which is a well-known benchmark suite used for evaluating APR tools. To be consistent, we select the same version 1.0.1 as tested by VFix, and the detailed information about the collected dataset is shown in Table 4 in § B. Since the accuracy of patch generation for NPEfix and SimFix in fixing this dataset has been tested in VFix and VFix outperforms both of them, we only compare CONCH with VFix. The comparison result is shown in Table 3. We can generate 16 correct patches and 2 incorrect patches, resulting in an accuracy of 88.89%. As a comparison, VFix can generate 12 correct patches and 6 incorrect patches, resulting in an accuracy of 66.67%. Our result outperforms VFix with an accuracy of 22.22%.

Same Fixes as Developers' Patches. Among these correct patches, VFix has the ability to generate 10 patches that are identical to the fixes made by developers. These 10 patches contain 6 null checks and 4 non-null checks. In the case of null checks, the patches simply return an existing variable, a bool value, or null without processing any intermediate states. The non-null checks execute the existing code. CONCH can address all of the vulnerabilities that VFix can fix, as well as an additional vulnerability that requires the use of a `continue` statement to skip a single iteration. Such a vulnerability is beyond the scope of VFix.

Semantic-Equivalent Fixes. Besides generating the 10 correct patches, VFix can also generate two semantic-equivalent patches. For the first patch, the developer checks the existence of the next node by calling `hasNext`, while VFix directly performs a null check for the next node. The second case pertains to the developer checking the invalid value (`NaN`), whereas VFix can produce a similar outcome. In contrast, CONCH can handle these two scenarios as well as three other cases that involve error message logging.

Incorrect Fixes. CONCH is capable of generating partially correct patches for two bugs. The first bug occurs when a variable is null in an if branch, and the developer replaces it

with a customized function. In such cases, we skip the branch, resulting in an inability to reproduce the same customized function. The second case involves resetting a special variable within a branch, which cannot be accomplished in the relevant context. As a consequence, CONCH is incapable of generating precise fixes for these two bugs. Apart from these cases, VFix is unable to address the remaining four bugs, which include throwing the error message and exiting the loop.

The Necessity of Contextual Checks. In the second dataset, 16 programs have only one caller function, while the remaining two have two caller functions. Furthermore, all of them only require a single layer of handling until the errors are resolved.

Performance Overhead. When reasoning about this benchmark, we extract the buggy codes and modify them to the format that FBinfer can compile without changing the previous logic. Then FBinfer does not require compiling the whole project, instead of running the functions in the tested dataset, with the performance overhead for creating the dictionaries and generating correct patches within 10 seconds.

Table 3: NPD errors in `Defects4j` and comparison between CONCH and VFix for repairing NPD errors in `Defects4j`.

Project	#NPD	Fixed by VFix			Fixed by CONCH

Total	18	10	2	6	11	5	2

7 Discussion

Scope and Limitations. Our tool is on top of FBinfer, which is capable of analyzing Java, C, and Objective-C. In this paper, we evaluated C for the first dataset and Java for the second dataset. We will test more different supported languages in further research. The limitations of CONCH are two-fold. First, CONCH may not precisely fix NPD bugs when indirect calls halt the connection of different CFGs. Though the SOTA approach MLTA [20] has been adopted to refine indirect-call targets, the unidentified indirect targets (due to the limitations of MLTA) may still affect accuracy. Second, CONCH may not generate correct patches when essential information is unavailable in context. Specifically, when inferring the relation between the variables and values in the if statement, we cannot get the correct results if the relation is unreachable in context. For example, in List 4, the relationship between the variable `ino` and macro `EXT4_ROOT_INO` cannot be obtained in context, leading to a failed patch. Also, when we infer the previous states for the global variables and return value, we rely on the information provided by the current function and the caller function. Therefore, failing to obtain this information affects the correct patch generation.

```
1  diff --git a/fs/ext4/inode.c b/fs/ext4/inode.c
2  @@ -4732,6 +4732,12 @@ struct inode *ext4_iget(struct
       super_block *sb, unsigned long ino)
3  +    if((ino == EXT4_ROOT_INO)&&(!raw_inode->i_links_count)){
4  +        EXT4_ERROR_INODE(inode, "root inode unallocated");
5  +        ret = -EFSCORRUPTED;
6  +        goto bad_inode;
7  +    }
```

Listing 4: Fixing for CVE-2018-1092 generated by developer.

Race conditions are beyond our scope. The reasons come at three folds. First, race conditions can be timing-dependent, which means that they may only occur under specific timing conditions, making it difficult to detect and reproduce the bug in a controlled environment. Second, race conditions are often non-deterministic, meaning that the outcome of a program can vary depending on the order in which threads execute. Third, fixing a race condition may introduce new bugs, especially when the fix involves changing the order of execution or adding synchronization.

Patch Quality. The quality of proposed patches relies on ISL accuracy, the coverage of fixing position selection, patch generation, and patch verification. As illustrated in ISL, there are no false positives in error detection if the code meets the proposed error patterns [37]. Also, the proposed four fixing position selection policies can cover all cases in our tested dataset. When generating the patches, the return value can be extracted from the function return type, existing error-handling statements in the current function, and error-handling statements in the caller function. We also conduct the intraprocedural and interprocedural analysis to evaluate it in the call chain to further verify the correctness of the obtained return value. After obtaining the generated patches, their quality can be guaranteed for the scenarios in which a simple pointer receives the return value of a failed function. However, for the struct pointer, the patches require further manual verification, since the relation with the member and special function of the struct pointer may not be obtained. In addition, after generating patches, we check the patch equivalence with the patches developed by the developers manually. We will automate the checking process in future work.

Scalability and Usability. In this paper, we generate patches for NPD errors with contextual checks, and it is promising to extend this method to a broader scenario where contextual checks are required to make the program consistent after adding if checks. Specifically, for all vulnerabilities that can be fixed by adding an if check, we can conduct path-sensitive fixing position selection, perform intraprocedural state retrogression to build if condition, retrogress the local resources including freeing the allocated memory and releasing the occupied lock, and construct return statements to obtain an initial patch. Finally, we can conduct the interprocedural state propagation to reset the global variable and function argument

and assess the initial patch in the call chain to generate the final patch.

We also input all the tested buggy programs into ChatGPT [35] to evaluate the performance on NPD fixing. Our test method is divided into two ways: only inputting the vulnerable code, and inputting the vulnerable code with labeled error position. Unfortunately, if we just input the vulnerable code, the result of fault localization in ChatGPT is much worse than FBinfer. If we input both the vulnerable code and the error position, the generated results fail to consider the contextual information, with a fixed format as "$if(p! = null)$ *return*;". The reasons that ChatGPT cannot generate correct patches come at two folds: i) when conducting intraprocedural analysis, there is no existing pattern to be learned; ii) for interprocedural analysis, the sequence-based method always ignores the call relation, failing to analyze the large code base projects.

8 Related Work

1) Automatic Program Repair. The search-based and constraint-based repairs are two popular automatic program repair techniques. Search-based repair techniques, such as GenProg [15], RSRepair [36], and HDRepair [14], utilize predefined templates and search algorithms to explore search spaces and generate potential bug-fixing patches. Another set of techniques, including AE [45], SPR [18], and Prophet [19], employ predefined transformation schemas and probabilistic models to identify and apply syntactic fragments, aiming to indirectly achieve the desired semantic effect for bug fixing based on a given test suite.

Constraint-based repair techniques, such as DirectFix [22], Angelix [23], and SemFix [34], utilize a set of constraints to guide the search for a solution and traditionally rely on test cases for patch validation, which can lead to overfitting problems [41]. SemGraft [21] references a correct program to generate input-output constraints for a semantic-equivalent buggy program, achieving higher-quality patches with partial correctness guarantees.

CONCH combines search-based and constraint-based repair techniques to conduct NPD error fixing. We first use separation logic to reason about the program errors and then limit the search space by utilizing the contextual information and with the assistance of caller functions.

2) Null Pointer Dereference Fixing. NPEfix [6] proposes runtime strategies, Sinha et al. [40] identify fault sources, and VFix [48] localizes statements using static and dynamic analysis. However, their approaches may produce incomplete or function-specific patches [17]. As a comparison, our approach contains contextual checking, guaranteeing one NPD error is handled successfully in all paths. Also, our approach takes the memory freeing and lock resetting operation into consideration, enhancing the usability of NPD fixing.

3) Separation Logic to Fix Memory-related Bugs. MemFix [16] simplifies the call graph and solves double-free and use-after-free issues using separation logic and a cover problem. SAVER [10] builds on MemFix by introducing an object flow graph to analyze memory-related object flow and generate patches within if branches. Compared to them, we rely on separation logic to generate patches for NPD issues. We first generate CFG and call graphs to locate the buggy positions and record the null position and error position of the buggy program. Then we select the fixing positions and construct repair statements combined with contextual checks, ensuring that NPD errors are handled in the entire call chain.

9 Conclusion

To address the challenges of generating accurate fixes for NPD errors, we propose CONCH to generate correct patches with contextual checks. We first generate an NPD context graph to preserve the semantics related to patch generation. Then we define four fixing position selection policies based on the distribution of the null and error positions, ensuring all errors can be resolved without introducing redundancy fixing. Next, we propose the intraprocedural state retrogression to generate an initial patch that includes building if condition, retrogressing local resources, and constructing return statements. Finally, we conduct interprocedural state propagation to reset some global variables and arguments and assess the initial patch in the whole call chain to obtain the final patch. We evaluate the effectiveness of CONCH with two real-world datasets. The experimental results show CONCH outperforms the SOTA approach over an accuracy of 22%.

Unleashing the Power of Type-Based Call Graph Construction by Using Regional Pointer Information

Yuandao Cai Yibo Jin Charles Zhang
The Hong Kong University of Science and Technology
{*ycaibb, yjinbd, charlesz*}*@cse.ust.hk*

Abstract

When dealing with millions of lines of C code, we still cannot have the cake and eat it: type analysis for call graph construction is scalable yet highly imprecise. We address this precision issue through a practical observation: many function pointers are simple; they are not referenced by other pointers, nor do they derive their values by dereferencing other pointers. As a result, simple function pointers can be resolved with precise and affordable pointer aliasing information. In this work, we advocate KELP with two concerted stages. First, instead of directly using type analysis, KELP performs regional pointer analysis along def-use chains to early and precisely resolve the indirect calls through simple function pointers. Second, KELP then leverages type analysis to handle the remaining indirect calls. The first stage is efficient as KELP selectively reasons about simple function pointers, thereby avoiding prohibitive performance penalties. The second stage is precise as the candidate address-taken functions for checking type compatibility are largely reduced thanks to the first stage. Our experiments on twenty large-scale and popular software programs show that, on average, KELP can reduce spurious callees by 54.2% with only a negligible additional time cost of 8.5% (equivalent to 6.3 seconds) compared to the previous approach. More excitingly, when evaluating the call graphs through the lens of three various downstream clients (i.e., thread-sharing analysis, value-flow bug detection, and directed grey-box fuzzing), KELP can significantly enhance their effectiveness for better vulnerability understanding, hunting, and reproduction.

1 Introduction

Call graph (CG) construction is a fundamental and essential problem, underpinning a myriad of downstream security applications (e.g., heap error detection [14, 27, 51, 52, 68], taint analysis [5, 93], fuzzing testing [11, 18, 34], and control-flow integrity [40, 41, 57, 91]). In low-level C programs, function pointers are often employed as a powerful mechanism for producing compact and flexible code. However, by their dynamic nature, function pointers pose a critical challenge to statically resolve indirect calls for feasible targets. Even worse, despite the tremendous progress over decades, the previous approaches [4, 26, 29, 46, 50, 75, 77, 80] for CG construction are either imprecise or inefficient when scaling up to the ever-growing complexity of modern software systems.

Previous Approaches. In general, there are two basic ways to construct CGs: pointer analysis and type analysis. First, pointer analysis computes the possible values of each memory location, thereby using the function-pointer values to resolve each indirect call [29, 69, 77]. Unfortunately, due to the sophisticated memory operations, existing highly precise pointer analysis has faced difficulty in scaling up to million-line software [28, 40, 50]. For example, the recent study [28] shows that a field-sensitive and flow-insensitive Andersen's pointer analysis [29, 60] fails to construct a CG for Bind (680 KLoC) within eight hours. Moreover, another recent work [40] shows that SUPA [77, 78, 80], a state-of-the-art field-, flow-, and context-sensitive demand-driven Andersen's pointer analysis, cannot construct a CG for GCC (135 KLoC) with a twelve-hour time budget.

In contrast, type analysis has shown its promise to readily handle millions of lines of code in minutes [50, 94]. Specifically, function signature analysis (FSA) [6] identifies indirect-call targets by matching the types of function pointers with the ones of address-taken functions. On the downside, FSA is highly imprecise. For instance, the recent work [94] shows that FSA for the Linux kernel spent a few minutes constructing a highly imprecise CG with 81K callees per indirect call. The main reason for imprecision is that indirect calls with a few general parameter types (e.g., void* or char*) can potentially match a large number of infeasible callees [50]. To mitigate the precision issue,

most recently, multi-layer type analysis (MLTA) [50] additionally considers types of memory objects that hold the function pointers. However, much work [28, 29, 40] shows that type-based CG construction remains imprecise for adoption in industrial settings because pure type analysis is unaware of any pointer aliasing information.

Our Contributions. In this work, we advocate a staged and concerted approach, namely KELP, to alleviate the tricky precision-scalability dilemma. Our practical observation is that many function pointers are used simply without being referenced by other pointers or deriving their values by dereferencing other pointers. Consequently, these simple function pointers can be effectively resolved by using "low-hanging" regional pointer aliasing information. Interestingly, early capturing of the unique callees invoked through these simple function pointers can help reduce the number of candidate address-taken functions for checking type compatibility.

We use the buggy program shown in Figure 1 to illustrate KELP, where the simple variable `b1` defined at Line 17 contains the address of `checked_print`, while the complex variable `b2` derives its value, the address of `unchecked_print`, by dereferencing pointer `p` at Line 18. By merely checking type compatibility, MLTA [50] can imprecisely compute two callees for both the indirect calls at Lines 13 and 14. In contrast, by using regional (not whole-program) pointer analysis to compute the def-use relations of the variable `b1` at Line 13, KELP can infer that only the function `checked_print` is invoked. Furthermore, `checked_print`, whose address is assigned only to `b1`, cannot be invoked by accessing another variable `b2` at Line 14. As a result, the type analysis can only match `unchecked_print` to the indirect call at Line 14. More illustrations are presented in § 2.

To validate our observation, we empirically studied the Linux kernel (§ 3). We revealed two major findings that 34.5% of indirect calls use simple function pointers (often as stack variables or global variables), and those indirect calls uniquely invoke 23.9% of address-taken functions, which strongly imply KELP's effectiveness.

As depicted in Figure 2, KELP has two concerted stages, arming with several customized techniques (§ 4).

- First, KELP resolves the callees of those indirect calls through simple function pointers. To this end, we present a def-use analysis, computing the regional pointer aliasing information related to the simple pointers. For each indirect call of interest, our analysis tracks the transitive def-use relations across functions in a forward and backward manner, thereby reaching the sites of address-taken functions and precisely capturing the feasible callees.
- Second, KELP resolves the callees of the remaining indirect calls through complex function pointers (i.e., relative to simple ones), resorting to checking type compatibility. Specifically, our analysis recognizes and safely removes those address-taken functions that only those indirect calls computed at the first stage can invoke. As a result, the number of the candidate functions that can be matched in the type analysis is significantly reduced.

```
1  typedef void (*fptr_t)(int*);
2  struct A {fptr_t printer;};
3  struct B {struct A a;};
4  void checked_print(int* val){
5     if(val) printf("%d\n", *val);
6  }
7  void unchecked_print(int* val){
8     printf("%d\n", *val);
9  }
10 void process_input(struct B b1, struct B b2){
11    // return NULL for invalid inputs
12    int* ret = examine_input(user_input);
13    (*b1.a.printer)(ret); // safe
14    (*b2.a.printer)(ret); // NPD
15 }
16 void get_printers(struct B* p){
17    struct B b1={.a = {.printer = &checked_print}};
18    struct B b2 = *p; // dereferencing p
19    process_input(b1, b2);
20 }
21 int main(void) {
22     struct B* p = (struct B*) malloc(...);
23     struct B b ={.a={.printer= &unchecked_print}};
24     *p = b;
25     get_printers(p);
26     ...; // e.g., clearing the allocated memory
27 }
```

Figure 1: MLTA calculates two possible callees for each of the indirect calls, which is less precise than KELP.

Notably, KELP has three eminent merits, thereby establishing a new sweet spot between precision and efficiency in the realm of type-based CG construction.

1. Given the same indirect call, KELP can always precisely compute a subset of the callees concluded by the existing type analysis [6,26,46,50]. Specifically, our two core stages work in concert: the preceding def-use tracking precisely resolves the indirect calls through simple function pointers, thereby considerably "squeezing" the address-taken functions that can be matched in the incoming type analysis.
2. KELP remains lightweight without inducing many time overheads. Our regional def-use analysis automatically distinguishes the simple function pointers from the complex ones on-the-fly, computing the affordable pointer information in an elastic manner.
3. KELP does not induce *additional* false negatives to type-based call graph construction. Specifically, our analysis conservatively handles a few corner cases (e.g., the unknown def-use chains of simple function pointers) and safely uses type-analysis results as a fallback to refrain from any new false negatives.

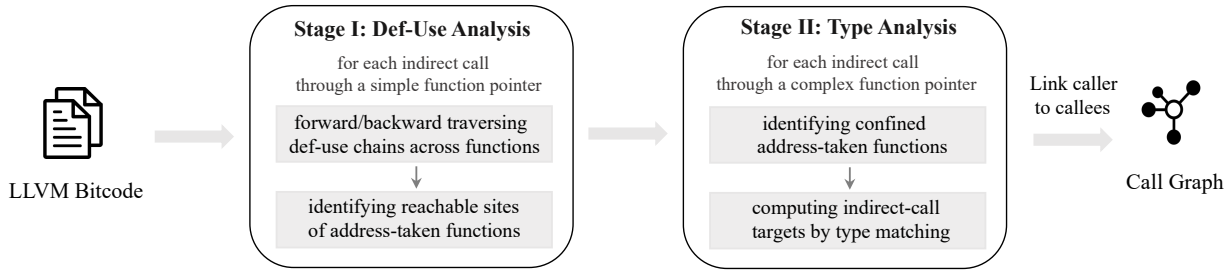

Figure 2: The workflow of KELP: a staged and concerted approach to type-based call graph construction.

To sum up, our new scheme is orthogonal to the type-analysis formulation and can serve as a pre-processing step to existing type analysis for refining indirect-call targets in a precise, efficient, and safe manner.

Experiment Highlights. We have implemented our design of KELP and performed extensive experiments on twenty software programs to demonstrate its effectiveness (§ 5 and § 6). Excitingly, even though CG construction has been studied for over forty years, KELP still can significantly advance the state-of-the-art type analysis [50] in terms of effectiveness in most programs. Furthermore, it is quite inspiring that KELP's ability to provide more precise CGs, as opposed to MLTA's, can significantly enhance three various downstream applications. Our promising results are highlighted below.

1. Compared to MLTA, on average, KELP can precisely identify 396 more uniquely-resolved indirect calls, reduce the average callee size by 54.2%, and remove 94 bogus callees from the indirect call with the largest callee size. KELP can reduce the average callee size by more than 20% for 18 programs.
2. Compared to MLTA, KELP remains lightweight and, on average, incurs only an additional 8.5% time overhead (accounting for 6.3 seconds). KELP can construct a precise CG for six million-line systems (e.g., Firefox) in around four minutes per system and for the Linux kernel in around 11 minutes.
3. KELP can help thread-sharing analysis [35, 76] to precisely reduce 25.3% more spurious thread-shared load/store memory accesses for better understanding and debugging concurrent programs.
4. KELP can help value-flow analysis, SABER [81], precisely validate three source-sink properties (i.e., memory leak, double free, and file description leak) by reducing 17.1% more false warnings on average.
5. KELP can help directed grey-box fuzzing, BEACON [34], to reproduce existing ten CVE-ID vulnerabilities by largely reducing total time costs by 51.9% and irrelevant program executions by 46.9%.

We stress that the three downstream clients broadly involve static and dynamic program analyses, as well as reasoning about sequential and concurrent programs, which can benefit various phases and tasks throughout software development. Given the importance of CGs, we believe that KELP can beef up more downstream clients. To sum up, this paper makes four main contributions:

- We advocate type analysis with regional pointer information, a big stride forward towards refining indirect-call targets in a precise and efficient way.
- We present a novel way to resolve simple and complex indirect calls in a staged and concerted manner.
- We empirically demonstrate that KELP can achieve the best precision with negligible extra time costs compared to the most recent type-based solution.
- We use the CGs produced by KELP to help improve the effectiveness of three existing clients. KELP will soon be open-sourced to foster future research.

2 KELP in a Nutshell

In this section, we first give an overview of basic pointer manipulations (§ 2.1) and then reuse the example shown in Figure 1 to show how the previous work impairs the precision of the downstream bug finding (§ 2.2). We then orchestrate the essence of KELP (§ 2.3).

2.1 Basic Concepts of Pointer Operations

We first clarify some basic terminology of pointer manipulations [30, 47, 77]. The $\&p$ denotes the address-of operation, retrieving and exposing the memory address of pointer p. In addition, we say that p is referenced by (or pointed to by) q if q contains the address of p. Particularly, when a function exposes its address (assigned to a pointer) via an address-of operation, we call the function *an address-taken function* [50]. Correspondingly, address-taken sites refer to the statements (or the initializers of global variables) where the functions expose their addresses via the address-of operations.

Besides, for the load statement $p = *q$, we say p derives the value by dereferencing q or the value of p is loaded from the memory object referenced by q. Sim-

ilarly, for the store statement $*q = p$, the value of p is stored in the memory object referenced by q.

2.2 Previous Type-Based Approaches

Much recent work [50,94] shows that the type-based call graph construction is scalable to millions of lines of code in minutes. However, existing type analysis is still highly imprecise, creating a significant obstacle to adoption in practice. We reuse the buggy code shown in Figure 1 to illustrate further that the spurious callees computed by the previous type-based approaches [6, 26, 46, 50] compromise the precision of a downstream bug checker.

Recall that the code in Figure 1 defines two structures, `A` at Line 2 and `B` at Line 3, where `A` contains a field, `printer`, with a function-pointer type, `fptr_t`, and `B` has an instance of `A`. Also, the variable `b1` is defined at Line 17, holding `checked_print`'s address. Comparatively, `b2` contains `unchecked_print`'s address, which is derived by dereferencing `p` at Line 18. Both `b1` and `b2` are passed into the function `process_input` as parameters. At Line 12, `process_input` processes the untrusted `user_input` by running the function `examine_input`. When `ret` is NULL due to the invalid `user_input`, the code can invoke `unchecked_print` at Line 14, dereferencing a NULL pointer at Line 8.

Previous Type Analysis. All the previous type analyses [6, 26, 46, 50] can imprecisely identify two callees for the two indirect calls at Lines 13 and 14. First, function signature analysis [6] (FSA) identifies indirect-call targets by matching the types of function pointers with the ones of address-taken functions. In particular, the indirect call at Line 14 uses the function pointer `b2.a.printer` with the type `fptr_t`. Since both functions, `checked_print` and `unchecked_print`, have the matched types, and their addresses are exposed (via the address-of operation) during the initialization of variables `b` and `b1`, FSA can regard both as feasible callees for Line 14. Similarly, FSA can match both functions to the indirect call at Line 13 as callees imprecisely.

To improve the precision of FSA, multi-layer type analysis [50] (MLTA) refines indirect-call targets by additionally considering the types of memory objects holding function pointers. For instance, the function pointer `b2.a.fptr_t` at Line 14 has the type `fptr_t`, and the pointer's value is loaded from the type-`A` object `a`, which is then loaded from the type-`B` object `b`. MLTA considers that the callees at Line 14 should have their addresses taken to some pointers with the three-layer type `B.A.fptr_t` rather than merely the one-layer type `fptr_t` in FSA. However, by examining Line 17, the function `checked_print` is still type-compatible to be invoked at Line 14, which is still imprecise as FSA.

Incurring False Warnings. The imprecision of CGs can compromise the effectiveness of downstream applications. Consider that a static Null pointer dereference checker uses the indirect-call results of either FSA or MLTA. The checker first finds that the `ret` at Line 12 could be NULL and proceeds to track whether the `ret` could be dereferenced somewhere without NULL checking. Along the control flows, the checker reaches the indirect call at Line 13, enters both callees, and reports an NPD warning at Line 8. However, the warning is bogus, as the indirect call at Line 13 never invokes the function `unchecked_print`. In § 2.3, we show how KELP can help the NPD checker suppress the false warning.

2.3 A Staged and Concerted Approach

We first define the basic notions, which enable KELP to improve the precision of type-based CG construction.

Definition 1. A function pointer is called *simple* when it is not referenced by other pointers and does not derive its values by dereferencing other pointers.

In essence, simple function pointers do not have the complexity introduced by referencing or dereferencing operations involving other pointers. In contrast, complex function pointers could be referenced by other pointers or obtain their values with pointer dereferencing. Correspondingly, we define an indirect call as simple (complex) when the call site uses simple (complex) function pointers to perform indirect invocation. Next, we characterize the functions that are only invoked by simple indirect calls, thus limiting the scope of address-taken functions that can be matched to complex indirect calls.

Definition 2. We refer to a function as *confined* when it can only be invoked in simple indirect calls.

That is, the address of a confined function is only propagated to simple indirect calls along def-use chains.

Back to the example in Figure 1, KELP first performs regional pointer analysis for each indirect call, tracking the def-use chains of the simple function pointer. The analysis is regional as it does not perform an exhaustive analysis of the whole program. Specifically, our analysis ensures the tracked function pointer is not referenced by other pointers and does not propagate its values with pointer dereferencing in both the forward and backward control flow paths. By tracking the def-use chains, KELP can also capture the confined values of the simple function pointer. In the example of Figure 1, since the variable `b1` is defined with the function `checked_print`'s address at Line 17 and then used at Line 13 without being referenced by other pointers or propagating its value with pointer dereferencing, KELP can precisely compute that the indirect call at Line 13 can invoke `checked_print`. In contrast, when tracing the def-use chains of the variable b2 for resolving the indirect call at Line 14, KELP

can recognize the load site at Line 18 and differentiate b2 as a complex variable that derives its value by dereferencing the pointer p. As a result, by design, KELP leaves the complex indirect call to the succeeding efficient type analysis for avoiding prohibitive performance penalties.

Next, KELP then employs the type analysis to resolve the complex indirect call at Line 14. To embrace high precision, we compute the candidate address-taken functions that can be matched due to type compatibility by removing the confined function `checked_print`. Specifically, `checked_print` is uniquely invoked by the simple indirect call at Line 13, because the function's address is taken only once and then propagated to the indirect call without pointer dereferencing. By checking the type compatibility from fewer candidate functions, as a result, KELP can precisely identify the single callee at Line 14. With the precise CG, the NPD checker can precisely identify the control flows of the bug.

Note that the previous type analyses [6, 26, 46, 50] focus on using more type information rather than reducing the candidate address-taken functions; KELP is orthogonal to their formulation and can act as their preprocessing step to further refine indirect-call targets.

Roadmap. We have introduced the essence of our staged approach to type-based call graph construction. In what follows, we orchestrate KELP in a systematic way.

1. In § 3, we perform a characteristic empirical study on the Linux kernel and reveal two major findings that significantly imply the practicality of KELP.
2. In § 4, we present a staged and concerted approach with several tailored techniques to resolve the indirect calls through simple and complex function pointers in a precise and efficient manner.

3 A Characteristic Empirical Study

To understand how prevalent simple function pointers are in practice, we conducted an empirical study on the Linux kernel (v5.15), one of the most popular open-source software. In particular, a plethora of research [22, 37, 44, 87, 88, 90] has focused on the Linux kernel owing to its vital security impacts. To reveal the effectiveness of our staged and concerted strategy, we investigate two critical research questions listed below.

- **Q1**: Is it common to use simple function pointers?
- **Q2**: Is it common for address-taken functions to be only invoked by simple indirect calls?

For Q1, if most function pointers are not simple, the regional def-use tracking at our first stage cannot effectively resolve many indirect calls. For Q2, consider that most functions are address-taken more than once and can be invoked in both simple and complex indirect calls. As

```
1  typedef void (*fptr_t)(struct unix_sock *);
2  void unix_gc(void){
3     list_for_each_entry(u, &gc_candidates, link)
4        scan_children(&u->sk, dec_inflight);
5     ...;
6     while (cursor.next != &gc_candidates){
7        scan_children(..., inc_inflight_move_tail);
8     }
9     ...;
10    list_for_each_entry(u, &gc_candidates, link)
11       scan_children(&u->sk, inc_inflight);
12 }
13 void scan_children(struct sock *x, fptr_t func){
14    if (x->sk_state != TCP_LISTEN) {
15       scan_inflight(x, func);
16    }
17 }
18 void scan_inflight(struct sock *x, fptr_t func){
19    if (test_bit(CANDIDATE, &u->gc_flags)){
20          func(u); // a simple indirect call
21    }
22 }
```

Figure 3: An example in Linux kernel (`af_unix.c`).

a result, the type analysis at our second stage cannot precisely resolve the complex indirect calls because the candidate functions for checking type compatibility cannot be largely reduced by identifying the confined functions. To answer the two questions, we statistically count each address-taken site of functions and each indirect call by analyzing the LLVM bitcode of the Linux kernel.

> **Finding I**: Considerable indirect calls (34.5%) are through simple function pointers.

More specifically, for the 87355 indirect calls being studied, many indirect calls (34.5%) are through simple function pointers. Through our observation, we have noted that simple function pointers are commonly employed as global or stack variables, where their values are directly defined during declaration. Conversely, complex function pointers tend to be implemented as heap objects. Specifically, first, the def-use chains of stack variables are very short, commonly spanning across several functions without complicated control flows. Second, the global variables are often initialized once and remain unchanged for the left execution (also called stationary [16]). To sum up, our Finding I implies that the def-use tracking at our first stage is highly cost-efficient thanks to the characteristics of simple function pointers.

Example 3.1. Figure 3 shows the usage of simple function pointers. In the function `unix_gc`, the three functions `dec_inflight`, `inc_inflight_move_tail`, and `inc_inflight`, are address-taken to the simple variable `func`, which then acts as a parameter passed from `scan_children` to `scan_inflight` and finally used in the indirect call at Line 20. Since the address of `func` is never exposed to other pointers, `func`'s value at Line

20 can be precisely determined by reasoning about direct def-use relations. If using pure type analysis for the indirect call at Line 20, a dozen false callees can be induced.

> **Finding II**: Considerable functions (23.9%) are only invoked by simple indirect calls.

In addition, for the 90127 address-taken functions being studied, most functions (76.3%) are only address-taken once, having only one address-taken site. The result implies that simple and complex indirect calls commonly invoke different groups of functions. To sum up, our Finding II implies that our type analysis at our second stage is highly effective in reducing the candidate address-taken functions for checking type compatibility.

Example 3.2. In `unix_gc` of Figure 3, the three functions, `dec_infligt`, `inc_infligt_move_tail`, and `inc_infligt`, are address-taken to and only once to the simple function pointer `func`. In other words, only the indirect call through accessing `func` at Line 20 can invoke the three functions and any other indirect calls cannot. If directly using pure type analysis [6, 50], the three functions can be matched to other type-compatible indirect calls, which can induce tremendous bogus callees.

Summary. The above two findings on the Linux kernel strongly imply the effectiveness of our two concerted stages to resolve indirect-call targets. To the best of our knowledge, the previous type-based approaches are all oblivious to simple function pointers. On the other hand, precise pointer analysis that computes the possible values of all function pointers is prohibitively expensive for large codebases [28, 41]. In § 4, we detail the key techniques behind KELP for refining indirect-call targets.

4 Algorithm Design

This section first presents the basic notions for program abstraction and states two key challenges (§ 4.1). Then, we present the two core stages in KELP (§ 4.2 and § 4.3).

4.1 Preliminaries

In this part, we describe the program abstraction for formulating our approach and state two key challenges.

Assumption. As with most previous pointer analysis and type analysis [6, 26, 46, 50, 77], we assume that the code being analyzed is closed, meaning that all of the source code for the target program is available and within the scope of our analysis. If the code is open and some functions are passed from outside the program for inner indirect calls to invoke, both the conventional pointer analysis and type analysis may not be able to resolve the corresponding indirect calls.

$$
\begin{aligned}
&\text{Program}\quad \mathbb{P} := \mathbb{F}^{+}\\
&\text{Function}\quad \mathbb{F} := f(v_1,\ldots,v_n)\{\mathbb{S}^{*};\}\\
&\text{Statement}\quad \mathbb{S} :=\\
&\qquad\qquad | \; v_1 = v_2 \mid v = \&o \mid v_1 = *v_2 \mid *v_1 = v_2\\
&\qquad\qquad | \; v_1 = \phi(v_2, v_3) \mid \mathit{return}\ v \mid v = \ v_0(v_1, v_2, \ldots)\\
&\qquad\qquad | \; v_1 = \&v_2 \rightarrow \mathit{fld} \mid s_1; s_2
\end{aligned}
$$

Figure 4: The syntax of the language.

Program Abstraction. Like much work [10, 14, 16, 30, 31, 68, 77], we formalize KELP with a standard LLVM-like language shown in Figure 4. Note that we also use the *mem2reg* [83] optimization to produce and simplify the LLVM IR of an analyzed program, which is further discussed in § 5. Specifically, we have call sites denoted as cs, which may accept a variable. We use $\mathbb{IC}$ to denote all indirect calls. The `Phi` instruction, $v_1 = \phi(v_2, v_3)$, merges the values of v_2 and v_3 from different basic blocks into a single value v_1. Besides, to reach field-sensitivity, we have the instruction that, given a memory address operand, returns a new address by adding a relative offset, corresponding to a field element.

We follow the LLVM convention of separating program variables into two disjoint sets of top-level variables ($v \in \mathbb{V}$) and address-taken objects ($o \in \mathbb{O}$). First, top-level variables may hold some memory addresses, comprising stack virtual registers and global variables. The variables $\mathbb{V}$ are in SSA form, where every variable has only one definition. Second, the objects $\mathbb{O}$ represent abstract memory locations, accessed indirectly via loads and stores by taking the variables $\mathbb{V}$ as arguments.

Points-to Relations. The points-to set of a pointer v at a statement s is denoted as $pt(s,v) = \{o | o \in \mathbb{O}\}$. In Figure 5(a), for example, we can infer $pt(s_2, p) = \{o_1\}$ at s_2. To resolve the indirect calls at s_{20} and s_{21}, KELP needs to compute $pt(s_{20}, b1)$ and $pt(s_{21}, b2)$ by identifying and tracing their def-use chains, as shown in Figure 5(b).

Def-Use Chains. We define the inter-procedural def-use graph that captures the data dependencies of variables and objects, upon which KELP resolves the simple indirect calls by the regional traversal of direct value flows.

Definition 3. A DUG is denoted as $G = (N, E)$, where

- N is a set of nodes, each of which, n, denotes a statement s. Thus, we also use s to denote a node.
- $E \subseteq N \times N$ is a set of directed edges, each of which represents a def-use relation. First, a direct value-flow edge $s_1 \xrightarrow{v} s_2$ ($v \in \mathbb{V}$) from a statement s_1 to a statement s_2 denotes a def-use relation for v with its def at s_1 and use at s_2. Second, an indirect value-flow edge $s_1 \xrightarrow{o} s_2$ ($o \in \mathbb{O}$) from s_1 (a store) to s_2 (a load or a store) denotes an approximate def-use

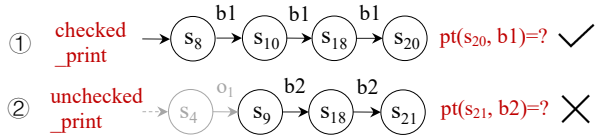
chain for o with its def at s_1 and use (or def) at s_2.

Remark. The direct value flows in DUG (e.g., $s_1 \xrightarrow{v} s_2$) can be readily constructed thanks to its SSA form. In contrast, the indirect value flows $s_1 \xrightarrow{o} s_2$ require additional pointer aliasing information to determine the objects of pointer dereferencing and match the loads and stores precisely. The previous pointer analyses [31, 77, 81, 89] construct the DUG by using an expensive whole-program Andersen's pointer analysis [29], which is difficult to scale up to large-scale million-line software programs (e.g., the Linux kernel) [40, 50]. Instead of tracking all value flows, KELP only precisely monitors the direct value flows to resolve simple indirect calls, which greatly reduces the performance overhead. When realizing that the tracking passes through indirect value flows with pointer dereferencing, KELP categorizes the corresponding indirect calls as complex based on Definition 1.

Example 4.1. Figure 5(b) shows the def-use chains ① from variable $b1$ defined at s_8 to $b1$ used at s_{20} and ② from variable b defined at s_3 to $b2$ used at s_{21}, which would be tracked by KELP in a backward way. For example, the $s_{18} \xrightarrow{b2} s_{21}$ is a direct edge through variable $b2$ while $s_4 \xrightarrow{o_1} s_9$ is an indirect edge through object o_1. The grey part means the corresponding chains are not backward tracked by KELP, as the value of the complex pointer $b2$ is propagated along the indirect value flow.

Problem Statement. We deliberate on two technical challenges for KELP to reach precise and efficient:

1. How to devise the def-use analysis to selectively resolve simple indirect calls and automatically avoid reasoning about complex indirect calls (§ 4.2).
2. How to leverage the regional pointer information of direct value flows to boost the precision of resolving complex indirect calls in type analysis (§ 4.3).



4.2 Resolving Simple Function Pointers through Efficient Def-Use Tracking

At the first stage, we resolve the indirect calls through simple function pointers (denoted as $\mathbb{IC}_1$). Specifically, we devise a regional def-use analysis to capture the values of the simple function pointers and bypass the prohibitive resolution of the complex ones. In what follows, we first investigate the def-use analysis. We then unravel the approach of resolving the indirect-call targets.

Regional Def-Use Tracking. At a high level, KELP carries out regional field-, flow-, and context-sensitive def-use analysis to resolve each simple indirect call. Specifically, the analysis ensures the function pointers being tracked are simple, thereby efficiently computing the confined values of the simple function pointers. To

```
1  int main(void){
2      p=&o1;
3      b=&unchecked_print;
4      *p=b;
5      get_printers(p);
6  }
7  void get_printers(p){
8      b1 =&checked_print;
9      b2= *p;
10     process_input(b1, b2);
11 }
12 void checked_print(int* val){
13     if (val) printf("…", *val);
14 }
15 void unchecked_print(int* val){
16     printf("…", *val);
17 }
18 void process_input(b1, b2){
19     ret = examine_input(…);
20     (*b1)(ret);
21     (*b2)(ret);
22 }
```

(a)

(b)

Figure 5: (a) shows the simplified code of Figure 1 by omitting the type information, e.g., two struct types `A` and `B`. (b) shows the tracked def-use chain (the node s_3 in the chains ② defining b is omitted) to compute the points-to set of simple $b1$ and complex $b2$, respectively.

this end, we combine both forward and backward def-use tracing for direct value flows. When perceiving that the tracked function pointers can propagate their values along the indirect value flows in either the forward or backward control-flow paths, KELP ceases further prohibitive tracking and classifies these pointers as complex.

Backward Phase. At the core, the backward analysis examines whether the function pointer of an indirect call is simple without propagating its value by dereferencing other pointers. By backward tracking the direct def-use chains, the analysis can compute the values of the interesting pointer. In detail, we conduct a backward def-use reachability analysis by computing a reachability relation denoted as $\leftsquigarrow$. Formally, $(s,p) \leftsquigarrow (s_1,q)$ signifies a computed def-use from a definition of q at s_1 to a use of p at s in DUG. Unlike the previous work [31, 77, 80], the top-level variables q and p could not be memory objects o according to the definition of direct value flows.

First, we introduce three basic rules of [FUNC-SITE], [COPY], and [PHI], as shown in Figure 6.

• In rule [FUNC-SITE] to handle $p = \&func$, a function $func$ is address-taken being referenced by pointer p, producing $pt(s,p) = \&func$. In particular, reaching the address-taken of a function means that the value of the function pointer is successfully checked.

• In rule [COPY] to handle $p = q$, a variable q is backward def-use reachable from the variable p.

• In rule [PHI] to handle $p = \phi(q,r)$, both variables q and r are backward def-use reachable from p.

Next, we describe [FIELD] to handle $p = \&q \rightarrow fld$, where a variable q is backward def-use reachable from the variable p, which is similar to [COPY]. Differently,

$$[\text{FUNC-SITE}]\ \frac{s : p = \&func}{pt(s,p) = pt(s,p) \cup \{func\}} \qquad [\text{COPY}]\ \frac{s : p = q \quad s_1 \xrightarrow{q} s}{(s,p) \leftsquigarrow (s_1,q)}$$

$$[\text{PHI}]\ \frac{s : p = \phi(q,r) \quad s_1 \xrightarrow{q} s \quad s_2 \xrightarrow{r} s}{(s,p) \leftsquigarrow (s_1,q), (s,p) \leftsquigarrow (s_2,r)} \qquad [\text{FIELD}]\ \frac{s : p = \&q \rightarrow fld \quad s_1 \xrightarrow{q} s}{(s,p) \leftsquigarrow (s_1,q) \quad p = FLD(q,fld)} \qquad [\text{LOAD}]\ \frac{s : p = *q}{(s,p) \leftsquigarrow \times}$$

$$[\text{CALL}]\ \frac{s_{call} : p = q \quad s_1 \xrightarrow{q} s_{call}}{(s_{call},p) \leftsquigarrow (s_1,q)} \qquad [\text{RET}]\ \frac{s_{ret} : p = q \quad s_1 \xrightarrow{q} s_{ret}}{(s_{ret},p) \leftsquigarrow (s_1,q)}$$

Figure 6: Basic rules for backward def-use tracking for simple indirect calls.

we introduce a new function notation $p = FLD(q, fld)$, which signifies that p represents the field fld of q. This rule is important for achieving field-sensitivity, as it enables the differentiation of various function-pointer fields and the fields' values within a struct variable.

Example 4.2. For the def-use chains ① in Figure 5(b), we can infer $(s_{20}, b1) \leftsquigarrow (s_{18}, b1) \leftsquigarrow (s_{10}, b1) \leftsquigarrow (s_8, b1)$ through the parameter passing by using the rule [COPY].

Importantly, indirect value flows refer to the propagation of values through pointer dereferencing, specifically from stores to loads. Once the tracking of def-use chains encounters these indirect value flows, the backward analysis ceases any further expensive tracking. Specifically, when the analysis reaches a load site where the value of the tracked function pointer is obtained by dereferencing other pointers, KELP employs the below [LOAD] rule.

• In rule [LOAD] to handle $p = *q$, the analysis considers that the value of p is derived by dereferencing pointer q and, thus, recognizes p as complex. Reaching a load site leads to the termination of our backward def-use analysis, indicated by the notation $(s,p) \leftsquigarrow \times$.

Example 4.3. In Figure 5(b), using [LOAD], the value of variable $b2$ at s_9 is loaded from the memory object o_1 referenced by pointer p, denoting $b2$ as a complex function pointer and s_{21} as a complex indirect call.

Moreover, we introduce the inter-procedural analysis rules (i.e., [CALL] and [RET]) for the def-use traversal. To be precise, context-sensitivity is reached by CFL-reachability [63]. Since CFL-reachability is orthogonal to our contributions, we briefly describe the process. Specifically, we maintain a string during the def-use traversal to validate the feasibility of the calling contexts. The traversed def-use path is realizable if strings between calls and returns have matched parentheses.

• In [RET] to handle a $p = q$ at s_{ret}, q is backward reachable from p. When traversing along the return edge, we append a left parenthesis $(_{cs}$ to the string.

• In [CALL] to handle $p = q$ at s_{call}, q is backward reachable from p. When traversing back to the call site, we append a right parenthesis $)_{cs}$ to the string.

Forward Phase. The goal of the forward def-use analysis is to ensure that the values of the function pointer being tracked are not propagated to memory objects referenced by other pointers in the forward control-flow path. Otherwise, the values of the function pointers may propagate to complex indirect calls, implying that the referenced values (i.e., functions' addresses) are not confined. In our second stage (§ 4.3), we would identify the confined functions that are only invoked by simple indirect calls. For the forward def-use tracking, KELP employs rules for handling statements that are similar to those used in the backward tracking. However, differently, the def-use reachability relation is computed in a forward manner.

Handling Global Variables. The tracking of global variables is different from the non-global ones. Specifically, flow-sensitively tracking def-use chains of global variables that can be assigned multiple times (without passing through explicitly as parameters and returns) is challenging, as the control flows are unknown. Thus, simple global variables are handled flow-insensitively. Specifically, when backward analyzing an indirect call and identifying the function pointer as a simple global variable, the def-use analysis also globally collects all possible ever-written values to the global variable in different regions as the potential callees. In our study of § 3, we found that most global variables of function pointers are initialized once, perhaps because multiple writes to global variables in different modules can be error-prone in large systems, thus being commonly avoided.

Resolving Simple Indirect Calls. After identifying the regional def-use relations of simple function pointers, we resolve the indirect calls. Specifically, for each indirect call $s : v = v_0(v_1, \dots)$ that is successfully tracked without termination, we identify the corresponding callees based on the reachable address-taken sites of functions and collect the indirect call in the set $\mathbb{IC}_1$.

We also record each def-use reachable address-taken site of functions after tracking (denoted as a set $DefUseReachingSites$). The address-taken sites of functions can be either the stores or the initializers of global variables. The set $DefUseReachingSites$, as shown in § 4.3, can help identify and reduce the candidate

address-taken functions for checking type compatibility, largely improving the precision of KELP.

Example 4.4. For the def-use chains ① in Figure 5(b), we can compute $pt(s_{20}, b1) = \{\&checked\_print\}$. As a result, the indirect call at s_{20} is resolved. We also collect s_8, the address-taken site of *checked_print*, for the incoming type analysis to identify the candidate functions.

Summary. By courtesy of the first stage, KELP has two salient advantages. First, our def-use tracking enables the early and principled discovery of indirect calls through simple function pointers. As a result, many indirect calls can be resolved precisely without more conservative type matching. Second, our regional def-use tracking actively avoids reasoning about the complex function pointers that could otherwise trigger performance penalties, judiciously leaving the corresponding indirect calls to the succeeding stage to embrace high efficiency.

4.3 Resolving Complex Function Pointers through Precise Type Analysis

Our second stage handles the remaining complex indirect calls (denoted as $\mathbb{IC}_2$) via type analysis, which, notably, cannot be resolved efficiently by the def-use tracking at the first stage. Specifically, instead of using the whole address-taken functions as the candidate functions for checking type compatibility, KELP removes those confined address-taken functions that only those simple indirect calls can invoke. Intuitively, confined functions are characterized by having all their address-taken sites included in the def-use chains of function pointers used in simple indirect calls. Thus, these confined functions cannot be invoked in complex indirect calls.

In what follows, we first investigate how to efficiently identify the confined address-taken functions by leveraging the reachable address-taken sites computed by the preceding def-use tracking. We then orchestrate how to remove the confined address-taken functions from the candidate functions for type checking, thereby precisely resolving the complex indirect calls.

Identifying Confined Function Set. We use *ConFunc* to denote the Confined address-taken Functions and *CandiFunc* to represent Candidate Functions for type checking. At a high level, KELP captures the functions *ConFunc*, which have all address-taken sites reachable by our forward and backward def-use tracking. Intuitively, this case guarantees that the functions' addresses are only propagated to simple indirect calls, thus only invoked by simple indirect calls. Specifically, the method `IdentifyConfinedATFunc()` in Algorithm 1 describes two critical steps to capture the functions *ConFunc*.

- Lines 2 and 7: We first check whether an address-taken function denoted by *func* can be invoked by simple indirect calls. That is, *func* is one of the callees of an indirect call *cs* in $\mathbb{IC}_1$.
- Lines 8 and 10: We next enumerate each address-taken site (denoted as *s*) of the function *func*, checking whether all the sites are def-use reachable ($s \in DefUseReachingSites$). If so, *func* is confined in simple indirect calls and put to *ConFunc*.

Algorithm 1: Precise Type Analysis.

```
1  Function IdentifyConfinedATFunc():
2      𝔽 ↩ retrieveAllFunc();
3      ConFunc ↩ ∅;
4      foreach func ∈ 𝔽 do
5          if ¬isAddressTaken(func) then
6              continue;
7          if ∃cs ∈ 𝕀ℂ1 : func ∈ ICToCalleeMap[cs] then
8              𝕊 ↩ getAllAddressTakenSites(func);
9              if ∀s ∈ 𝕊 : s ∈ DefUseReachingSites then
10                 ConFunc ↩ ConFunc ∪ {func}
11     return ConFunc
12 Function ResolveComplexICall():
13     𝕀ℂ2 ↩ 𝕀ℂ − 𝕀ℂ1;
14     ConFunc ↩ IdentifyConfinedATFunc ();
15     ATFunc ↩ getAllAddressTakenFunc();
16     CandiFunc ↩ ATFunc − ConFunc;
17     foreach cs ∈ 𝕀ℂ2 do
18         Callees ↩ retrieveTypeResult(cs) ;
19         NewCallees ↩ ∅ ;
20         foreach func ∈ Callees ∩ CandiFunc do
21             NewCallees ↩ NewCallees ∪ {func} ;
22         ICToCalleeMap[cs] = NewCallees;
23     return ICToCalleeMap;
```

Thanks to the first stage that captures all reachable address-taken sites, our second stage can efficiently recognize the confined address-taken functions *ConFunc*.

Example 4.5. Back to Figure 5(b), *checked_print* is only address-taken once, and its address-taken site s_8 is def-use reachable from $b1$ used in the indirect call at s_{20}. Thus, *checked_print* can only be invoked at s_{20}. As a result, the complex indirect call at s_{21} cannot invoke *checked_print* through accessing another pointer $b2$.

Resolving Complex Indirect Calls. After capturing the confined functions *ConFunc*, KELP identifies the candidate functions *CandiFunc*, for effectively checking type compatibility. The type analysis here can be either the traditional function signature (one-layer) analysis or the multi-layer type analysis, as identifying fewer candidate address-taken functions *CandiFunc* is orthogonal to their approach formulation. The algorithm to resolve complex indirect calls is shown by

the method `ResolveComplexICall()` in Algorithm 1. More specifically, KELP has two critical steps.

- Lines 13 and 16: We identify *CandiFunc* by finding an address-taken function absent from *ConFunc*.
- Lines 17 and 22: Finally, we retrieve the type-compatible targets for each indirect call in $\mathbb{IC}_2$ and precisely remove the callees not in the *CandiFunc*.

Example 4.6. Back to Figure 5(b), we resolve the remaining complex indirect call at s_{21}. First, we identify the candidate functions $\{unchecked\_print\}$ by removing the confined function *checked_print* from all address-taken functions $\{unchecked\_print, checked\_print\}$. Second, by checking the type compatibility, we can precisely match *unchecked_print* to the indirect call at s_{21}.

Summary. KELP confers two salient privileges over the pure type analysis [6, 50]. First, our type analysis is precise, removing those address-taken functions uniquely invoked by the simple indirect calls. As a result, the type-compatible targets of complex indirect calls are significantly refined. Second, our type analysis remains lightweight, as identifying the confined address-taken functions is efficient thanks to the def-use reachable address-taken sites provided by the preceding stage.

5 Implementation

KELP is built on the LLVM infrastructure, where it serves as the pre-processing step for the state-of-the-art multi-layer type analysis (MLTA) [50]. Figure 2 illustrates the workflow of KELP, where it takes the LLVM bitcode file of the target program as input, resolves indirect calls, and generates the call graph as output. Next, we will delve into two implementation details.

Promoting Memory to Register. LLVM IR can include excessive stack traffic for very simple and common operations, potentially degrading the performance of the def-use analysis. To address this issue, we use the mem2reg optimization pass [83], which transforms memory references into register references and introduces `Phi` nodes when necessary. Specifically, the pass promotes `alloca` instructions that are solely used for loads and stores.

Safe Fallback Strategy. We assume that the analyzed code is self-contained as a standard practice; otherwise, most previous type and pointer analysis techniques could overlook indirect-call targets. In addition, there are two possible causes of producing new false negatives by employing KELP when the def-use chains of simple function pointers cannot be fully collected. First, the def-use traversal may encounter unknown control flows or code, such as dynamically-linked libraries, indirect calls, and assembly code. Note that the case is uncommon in practice since, intuitively, the uses of simple stack variables do not span across complicated control flows. The second source is handling global variables, whose def-use chains are collected in a flow-insensitive and conservative manner. When an initialized global variable is reassigned with the value gained by dereferencing other pointers somewhere, the indirect def-use chains of the global variable are hard to be fully collected by KELP. Note that the case is uncommon because we observed that most global variables are simple and initialized once without modification anymore [16]. To mitigate both the problems, we design an automatic fallback strategy during def-use traversal in KELP. Specifically, for both the corner cases, KELP leaves the indirect calls being computed to the incoming type analysis as a backup. As a result, our approach does not introduce additional false negatives to type analysis.

6 Evaluation

This section investigates the following questions:

- § 6.1: Compared to the pure type analysis, how precise and efficient is KELP?
- § 6.2: How much can KELP improve the effectiveness of the downstream security applications?

Furthermore, we discuss other questions in § 6.3, such as the effectiveness of each stage and potential false negatives. All the experiments were finished on a computer with two 20-core Intel(R) Xeon CPU@2.20GHz and 128GB physical memory running Ubuntu-16.04.

6.1 Advancing Pure Type Analysis

First, we compare KELP to the most recent multi-layer type analysis, MLTA [50]. This experiment aims to show that our two concerted stages can effectively act as a pre-processing step to improve the pure type analysis in terms of precision with negligible extra time overheads.

Experiment Setup. Based on the four principles below, we chose twenty representative real-world C-based software suites as the benchmarks shown in Table 1. First, the software is mature, with a long code history. Second, the award-winning software has significant impacts on both academia and industry. Specifically, much work [14, 24, 50, 68, 89] has evaluated these systems to ensure their security owing to their impacts. Third, these systems represent a broad spectrum of popular applications, such as databases, network protocols, and operating systems. Fourth, the software is large-scale and extensively exploits indirect calls. Importantly, each software program has more than 100 KLoC, and seven million-line software programs are involved in showing KELP's effectiveness in industrial settings.

Table 1: Comparison on time costs (second) and precision in refining indirect-call targets.

ID	Project	Size (KLoC)	Indirect Calls	MLTA				KELP			
				Sing.	Avg.	Max.	Time	Sing.	Avg.	Max.	Time
1	OpenSSH	118	136	6	13.4	58	6.4	7 (1 ↑)	6.2 (53.7% ↓)	18 (40 ↓)	6.7 (+ 0.3)

Sing., Avg., and Max. denote the number of single-callee indirect calls, the average callee size of all indirect calls, and the maximum callee size, resp.

We assess the precision of refining indirect-call targets by using three metrics, i.e., the number of single-callee indirect calls, the average callee size of all indirect calls, and the largest callee size, which are critical for various applications. In particular, uniquely-resolved indirect calls can be transformed into direct calls, subsequently inlined, and optimized further. Intuitively, more precise call graphs lead to more single-callee indirect calls and optimization. In addition, reducing the average and largest callee sizes is critical to many applications, such as CFI [40, 55, 57] and bug finding [24, 27, 52, 68].

Precision. The results are shown in Table 1, where KELP is more precise than MLTA at any metric. Compared to MLTA, on average, KELP can additionally increase 396 uniquely-resolved indirect calls, reduce the average callee size by 54.2%, and remove 94 false callees from the indirect call with the largest callee size. In addition, for 18 projects, KELP can reduce the average callee size largely by more than 20%. At most, KELP can prune away 82.8% of bogus indirect-call targets in PJSIP.

To investigate how our two concerted stages contribute to the precision of KELP, we examine the simple and complex indirect calls (i.e., $\mathbb{IC}_1$ and $\mathbb{IC}_2$), and the confined and candidate address-taken functions (i.e., *ConFunc* and *CandiFunc*). The results are shown in Figure 7. We observed that all programs use simple indirect calls, accounting for 33.0% on average, which suggests the effectiveness of computing the regional pointer information at the first stage. Also, those simple indirect calls uniquely refer to many confined functions (32.0% on average), which suggests that the candidate functions for checking type compatibility can be significantly reduced, thereby improving the precision of pure type analysis.

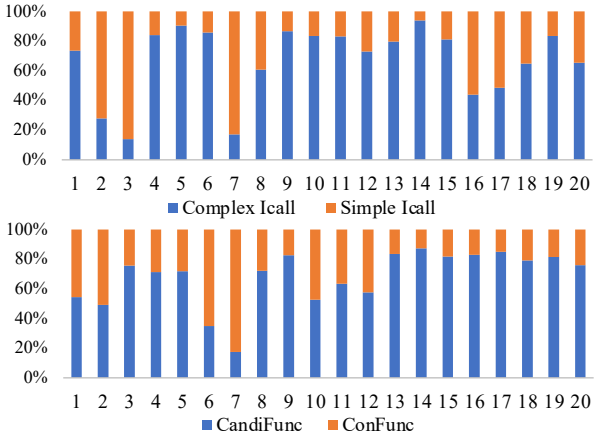

Figure 7: (a) and (b) show the relative proportion of the simple indirect calls (Icall) and the confined functions.

Time Cost. After showing the high precision of KELP, we next assess whether KELP induces negligible time costs. As shown in Table 1, KELP incurs a few extra time costs against MLTA, on average, only increasing by 6.3 seconds and incurring 8.5% time overheads. The negligible time costs are due to the affordable, regional information of simple function pointers, which is efficiently tracked by our def-use tracking. More importantly, KELP remains very scalable and lightweight for the Linux kernel, constructing its precise call graph in around eleven minutes. For each project of the remaining six million-line industrial-strength software programs, KELP can finish its analysis within four minutes. Therefore, considering the average precision improvement of 54.2%, we believe that KELP is promising to serve as an efficient and precise pre-processing step for pure type analysis.

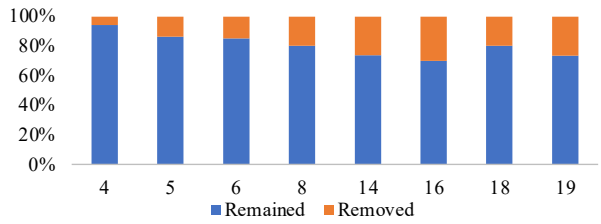

Figure 8: Statements that do not access thread-shared memory in FSAM are removed by using KELP's CGs.

6.2 Enhancing Downstream Clients

In § 6.1, we have shown that KELP advances the state-of-the-art type analysis. Furthermore, we assess the KELP's effectiveness through the lens of three downstream applications: thread-sharing analysis [35, 76, 85], value-flow bug detection [21, 68, 81], and directed grey-box fuzzing [17, 34, 96]. Importantly, these clients' effectiveness strongly relies on the precision of the call graphs being provided (explained in § 6.2.1, § 6.2.2, and § 6.2.3).

Experiment Setup. To select the tools of these downstream clients, first, we chose FSAM [76] in the MTA module of SVF [79] as thread-sharing analysis to identify loads and stores accessing thread-shared memory. Second, we chose SABER [81] in SVF as a bug finding tool for checking source-sink properties. More specifically, we used the three built-in checkers in SABER, the memory leak checker, file leak checker, and double free checker. Note that SVF is a popular tool that underpins many security applications [18–20, 37, 40, 42, 58]. Third, we used the recent work BEACON [34] as our directed fuzzer for the contexts of bug reproduction. In our dedicated evaluation of call graphs produced by KELP and the pure type analysis (the focus of this paper), we constructed call graphs using the two different sets of indirect-call results. Our examination measured the extent of improvement in the effectiveness of each tool when utilizing call graphs of varying precision.

6.2.1 Thread-Sharing Analysis

Thread-sharing analysis (TSA) that determines whether a statement can read or write thread-shared data shores up many popular applications, such as understanding and debugging concurrent programs [36, 53, 73], and concurrency bug detection [7, 18, 37]. By the nature of the inter-procedural analysis, FSAM [76], the TSA tool, requires a precise CG to identify the related statements.

We chose the eight software programs in Table 1 that use Pthread APIs as our benchmarks. To perform TSA for large codebases, we chose Steensgaard's pointer analysis [75] in the WPA module of SVF. We evaluate the reduction in false thread-sharing statements in FSAM by using the CGs generated by KELP and MLTA, respectively. As illustrated in Figure 8, on average, 25.3% of false thread-sharing statements can be additionally removed by using KELP's call graphs. As shown in Table 1, the precision improvement is due to further removing 55.5% of bogus indirect-call targets by KELP, with a few (9.2%) extra time costs in building CGs. To sum up, KELP is effective in helping thread-sharing analysis.

Table 2: Precise call graphs for finding value-flow bugs.

Project	Memory Leak	File Leak	Double Free
(1) OpenSSH	78 (71, -7)	37 (32, -5)	21 (18, -3)
(2) GCC	50 (41, -9)	6 (6, -0)	2 (2, -0)
(3) Curl	6 (6, -0)	14 (11, -3)	5 (5, -0)
(4) redis	124 (94, -30)	64 (58, -6)	42 (39, -3)
(6) zfs	95 (81, -14)	32 (21, -11)	111 (91, -20)
(12) Wrk	281 (223, -58)	74 (61, -13)	250 (211, -39)

6.2.2 Source-Sink Value-Flow Bug Detection

Value-flow analysis [14, 21, 68] is powerful at checking many source-sink properties, such as heap memory errors. SABER [81] detects source-sink value-flow bugs by tracking a global value-flow graph. We used the six software programs from Table 1 that did not run out of memory in our running environment as our benchmarks. Intuitively, more precise CGs for the same tool result in more precise control flows during bug detection, leading to removing false bug warnings.

As shown in Figure 2, KELP can help SABER to further reduce 17.1% of false positives. As shown in Table 1, the precision improvement is due to further removing 54.9% of bogus indirect-call targets by KELP, with only a few (6.2%) extra time costs in building CGs. By examining bug reports, we observed that the less than 20% false-positive reduction is reasonable because many bugs do not span across indirect control flows. In addition, some false warnings in the reports are induced by other factors (e.g., path conditions, imprecise points-to sets of general pointers). A precise and efficient vulnerability hunting tool requires various efforts, and we focus on improving call graphs. To sum up, KELP's CGs are effective in helping value-flow bug detection.

6.2.3 Directed Grey-Box Fuzzing

Directed grey-box fuzzing is a promising technique for bug reproduction, a crucial part of bug understanding and fixing [36, 49]. The recent work, BEACON [34], speeds up the bug reproduction process by pruning away irrelevant paths that cannot reach the target code. To this end, BEACON performs static control-flow reachability and "asserts" irrelevant paths through instrumentation. As a result, the executions irrelevant to the target code are stopped early during fuzzing. At a high level, more

Table 3: Precise CGs for directed grey-box fuzzing (the numbers in parentheses represent the improvement of KELP).

Project	CVE ID	T_{stat} (s)	$T_{fuzzing}$ (h)	T_{all} (h)	#Executions (million)	Avg. Callee Size
Ming-4.7	2016-9827	6.3 (7.0, +0.7)†	0.79 (0.40, 49.2%↓)	0.79 (0.40, 49.2%↓)	1.20 (0.71, 41.0%↓)	5.5 (3.8, 30.9%↓)
	2016-9829	6.3 (7.0, +0.7)	4.09 (1.30, 68.3%↓)	4.10 (1.30, 68.3%↓)	8.88 (1.99, 77.6%↓)

	2018-8962	7.2 (8.1, +0.9)	5.09 (2.44, 52.0%↓)	5.09 (2.44, 52.0%↓)	22.14 (17.19, 22.4%↓)	
libxml	2017-5969	839.0 (846.9, +7.9)	1.05 (0.11, 89.2%↓)	1.28 (0.35, 72.8%↓)	4.02 (0.59, 85.4%↓)	11.9 (3.9, 67.2%↓)
binutils	2017-7209	46.3 (48.1, +1.8)	1.33 (0.57, 57.0%↓)	1.34 (0.58, 56.5%)	6.94 (3.78, 45.5%↓)	2.1(1.8, 14.3%↓)
binutils	2020-16590	83.1 (86.3, +3.2)	4.68 (2.87, 38.7%↓)	4.70 (2.98, 36.5%↓)	42.16 (24.52, 41.8%↓)	4.1 (2.2, 46.4%↓)
binutils	2020-16591	54.2 (57.3, +3.1)	10.55 (6.95, 34.1%↓)	10.57 (6.97, 34.1%↓)	68.11 (58.66, 13.9%↓)	4.1 (2.2, 46.4%↓)

The versions of binutils are 53f7e8ea, f717994, and c98a454 from top to bottom. †: the difference is spent in CG construction.

precise CGs lead to more precise control-flow reachability and, thus, more precise path pruning. Consequently, the fuzzer can explore fewer infeasible program paths, thereby increasing the reproduction efficiency.

We followed the benchmarks [34] and chose ten previous CVE IDs impacted by indirect-call control flows from Libxml, Binutils, and Ming spreading across different historical versions. We assess (i) the time costs (second) of static analyses (e.g., building CGs to perform control flow reachability), denoted as T_{stat}. In addition, we measure (ii) the time costs of reproducing the CVEs through fuzzing $T_{fuzzing}$ and (iii) the number of executions required (million) to reproduce the CVEs #*Executions*. Specifically, more effective CG construction leads to more effective control-flow path pruning, thus resulting in fewer time costs $T_{stat} + T_{fuzzing}$ and fewer executions #*Executions* to reproduce bugs.

Five runs of fuzzing were performed to compute the average results shown in Table 3. On average, KELP can help BEACON further reduce 51.9% of time costs ($T_{stat} + T_{fuzzing}$) and 46.9% of executions (#*Executions*). Specifically, by using our CGs for reproducing the ten CVEs, BEACON only needs to additionally pay a few seconds (fewer than ten seconds for each project) in T_{stat}, thereby reducing 16.618 hours in whole time costs T_{all} and 67.389 millions of executions. Shown in Table 3, the efficiency improvement is due to additionally reducing 49.3% of bogus indirect-call targets by KELP. To sum up, KELP's CGs are effective in helping directed fuzzing.

6.3 Discussion

Constant Propagation. Constant propagation [64] is a technique used in compiler optimization and static analysis to determine and propagate constant values through a program. It could handle single-callee indirect calls by capturing the constant values of function-pointer variables. We perform an experiment that compares KELP to MLTA powered by constant propagation. Our results on the twenty software programs show that KELP is 45.7% more precise than MLTA with constant propagation, with only about 4 seconds of additional overheads. In conclusion, constant-value propagation is ineffective for handling numerous simple indirect calls that can have multiple callees across different calling contexts due to the dynamic nature of function pointers.

Ablation Study. Next, we perform an ablation analysis on each stage of KELP to assess the precision enhancement achieved by characterizing simple function pointers and confined functions. The precision improvement is measured using the average callee size as a metric. Our results show that when only the first stage is used, KELP could only improve MLTA by 32.7%. When only the second stage is used, KELP could only improve MLTA by 23.2%. In conclusion, the combined use of both stages in KELP can result in a significantly higher level of precision compared to MLTA.

False-Negative Analysis. We also investigate whether KELP may incur new false negatives in regional def-use tracking. To reduce subjectivity and collect ground truths, we implemented a trace collection tool using Intel PT-based (Processor Tracing) to dynamically collect indirect-call traces through instrumentation. To alleviate the poor-coverage limitation of dynamic execution, we used AFL++ as our fuzzer to extensively test the three popular software programs (with six different versions shown in Table 3) under various inputs in around one week. Since the traces have debug information (e.g., the line number), we used such information to identify the matched callees. By analyzing the traces, initially, we found a few callees were missed at eight indirect calls, all due to the implicit casting of primitive types in the type analysis (e.g., casting from `long int` to `char *`). The reasons for these false negatives in type analysis are well studied by the previous work [50, 55, 82]. We have fixed these cases by equalizing certain primitive types [55]. Consequently, at the time of writing, we did not find any new false negatives. In another experiment, shown in Table 3, KELP did not remove the real callees in indirect calls leading to the target code and succeeded in reproducing the CVE IDs. In summary, KELP does not induce extra false negatives owing to our safe fallback strategy.

7 Related Work

A long stream of downstream program analysis applications [13–15, 24, 68, 93] require effective CG construction. We discuss two lines of existing CG construction.

Pointer Analysis. Pointer analysis is an essential technique with much seminal work [32, 69]. Particularly, many important dimensions are developed to determine how precisely the pointer information is computed, including field-sensitivity [10, 59], flow-sensitivity [30, 31, 38, 47], context-sensitivity [45, 48, 70], and inclusion-based or unification-based analyses [4, 29, 60, 75]. In principle, more precise pointer analysis can bring more performance overheads and, thus, be less efficient for large programs. Much research may focus on other problems (e.g., bug finding [5, 38, 39, 72], persistent pointer information [67, 86]). We discuss the pointer analysis from the problem of the indirect-call resolution.

The existing pointer analysis could be categorized into exhaustive analysis (function pointers and general pointers are computed simultaneously) and on-demand analysis (function pointers are resolved when needed). On-demand pointer analysis [74, 77, 80] is more efficient for resolving function pointers by reducing redundant computation on general data pointers. However, existing precise demand-driven pointer analysis is still very hard to scale up to hundreds of thousands of lines of code.

More specifically, SUPA [77, 80] is the state-of-the-art field-, flow-, and context-sensitive Andersen-style on-demand pointer analysis. SUPA first performs exhaustive flow-insensitive Andersen's analysis [29] to construct a conservative value-flow graph that captures the def-use relations of variables and objects. Then, for a function pointer of interest, SUPA conducts points-to refinements based on the graph. Despite the advancement, the recent work [40] still shows that SUPA has difficulty in scaling up to GCC (135 KLoC) within twelve hours to resolve function pointers. In contrast to SUPA, KELP differentiates simple function pointers from the complex ones, using the regional pointer information of direct value flows to resolve the simple pointers precisely. In addition, our def-use analysis can make type analysis more precise by reducing the candidate address-taken functions. Therefore, as shown in Table 1, KELP is highly scalable for the twenty programs with more than 100 KLoC.

Lastly, we delve into the differences between KELP and our other concurrently published work, CORAL [16]. Specifically, CORAL defines the concept of stationary function pointers, which can be precisely resolved even with flow-insensitive unification-based or inclusion-based analyses. The results show that CORAL can scale up to millions of lines, analyzing MariaDB (1.8 MLoC) within 2.5 hours. First, it is important to note that stationary function pointers are complex because they can be referenced by other pointers [16]. KELP utilizes scalable type analysis to resolve the indirect calls using stationary and complex function pointers, whereas CORAL adopts a progressive and refinement-based approach, combining multiple pointer analyses to achieve higher precision. Second, CORAL is designed for scenarios where time and memory costs can be tolerated in order to embrace high precision, such as the daily build process [68]. On the other hand, KELP can analyze millions of lines of code in just a few minutes, making it suitable for scenarios that prioritize efficiency, such as the continuous integration process. In summary, KELP and CORAL leverage different characteristics of function pointers, are tailored to different scenarios, and harness different techniques.

Type Analysis. Type analysis can scale up to millions of lines of code in minutes. First, function signature analysis (FSA) [6] identifies indirect-call targets by matching the types of function pointers (used in indirect calls) with those of candidate address-taken functions. Due to the low costs, FSA has been extensively used for control-flow integrity [12, 55, 56, 91, 92, 95]. Some work [26, 46] additionally considers field types of two-layer structs. To improve the precision, multi-layer type analysis [50] considers the field types of multi-layer structures to prune away infeasible indirect-call targets. However, as shown in our experiments and other literature [28, 40, 94, 94], pure type analysis can still induce many false positives. To address the precision problem, KELP uses the regional pointer information of simple pointers for the first time, thereby improving the precision of both complex and simple indirect calls.

Finally, much seminal research shares a different problem scope with us, constructing CGs for binaries [8, 9, 43] or other high-level languages (e.g., Java [1, 2, 62], Python [65], C# [66], JavaScript [54, 71], and Scala [3, 61]), or resorting to dynamic program information [23, 25, 33, 57, 84]. We believe that extending our insights and approaches to other high-level languages is an exciting direction, and we leave it to our future work.

8 Conclusion

We have introduced a staged and concerted approach named KELP to improve the precision of type-based call graph construction with negligible additional time overheads. Our extensive experiments have shown that using regional pointer information for simple function pointers is a big stride forward in the realm of type-based CG construction, significantly improving the effectiveness of refining indirect-call targets. We expect that our work can improve more downstream program analysis clients and also offer intriguing insights for other static analyses.

Practical Data-Only Attack Generation

Brian Johannesmeyer Asia Slowinska Herbert Bos Cristiano Giuffrida

Vrije Universiteit Amsterdam

Abstract

As control-flow hijacking is getting harder due to increasingly sophisticated CFI solutions, recent work has instead focused on automatically building data-only attacks, typically using symbolic execution, simplifying assumptions that do not always match the attacker's goals, manual gadget chaining, or all of the above. As a result, the practical adoption of such methods is minimal. In this work, we abstract away unnecessary complexities and instead use a lightweight approach that targets the vulnerabilities that are both the most tractable for analysis, and the most promising for an attacker.

In particular, we present EINSTEIN, a data-only attack exploitation pipeline that uses dynamic taint analysis policies to: (i) scan for chains of vulnerable system calls (e.g., to execute code or corrupt the filesystem), and (ii) generate exploits for those that take unmodified attacker data as input. EINSTEIN discovers thousands of vulnerable syscalls in common server applications—well beyond the reach of existing approaches. Moreover, using `nginx` as a case study, we use EINSTEIN to generate 944 exploits, and we discuss two such exploits that bypass state-of-the-art mitigations.

1 Introduction

> *"Everything should be made as simple as possible, but not simpler." – attributed to Albert Einstein*

Since control-flow hijacking attacks came to the fore over three decades ago [81], attacks and defenses have battled over "control" of a program's control flow. Such attacks follow the general steps listed in Figure 1a: they overwrite certain *control data* of a program; force it to execute attacker-specified code snippets, i.e., *gadgets*; and may even chain enough of these gadgets together to achieve arbitrary computation, i.e., *Turing completeness* [19, 20, 24, 49, 71, 77]. This escalated into an arms race—between attacks exploiting some control flow, and defenses restricting that control flow—until the wide deployment of control-flow integrity (CFI) [11, 86, 87, 89, 96], which made exploitation of a program's control flow increasingly difficult.

The promise of data-only attacks. In response, attackers turned to data-only attacks, which promised to exploit a program's (massive) set of data flows (i.e., any program data being used in any operation). Yet, although these attacks technically exploited *non-control data*, many of them still relied on exploiting control-*adjacent* data (e.g., branch conditions) to perform "legal" control-flow hijacking. In effect, they were still exploiting the (tiny) residual attack surface of a program's control flow. Hence, to identify data-only attacks from such a small attack surface, these approaches employed heavyweight analyses (e.g., symbolic execution) to reason about numerous complex constraints.

In reality, however, it is extremely difficult, if not impossible, to solve all constraints in bounded time for a sufficiently complex program. The problem space—i.e., overwriting *any* possible data to *any* possible value, using it in *any* potential gadget, from *every* possible program point, to achieve *arbitrary* computation—is too large. Hence, in order to scale, these approaches are forced to make several simplifying assumptions, e.g., that: (1) an attack must only overwrite specific parts of memory, or (2) an attacker must use another exploit to reach the gadget's entrypoint, or (3) an attacker must manually chain together gadgets to build an exploit. While these assumptions make exploit generation a tractable problem, they unfortunately either dramatically limit the scope of the resulting exploits, or leave parts of it to future or manual work. In short, the overarching complexity of these approaches prevents them from achieving all the goals listed in Figure 1b, thereby limiting their practical adoption.

A lightweight approach. In this paper, we investigate a novel lightweight technique to build data-only attacks. Our approach relies on four key insights that dramatically reduce the problem space. First, not unlike Newton's approach in the related domain of control-flow hijacking [88], we observe that dynamic taint analysis simplifies away many complex constraints for data-only attacks. In other words, rather than trying to reason about vast swathes of unknowns, we can simply reason about the concrete data used in a concrete

Step 1:	Exploit a *memory write* vulnerability.
Step 2:	Steer the execution to a gadget's *entry point*.
Step 3:	Execute some payload via a *gadget chain*.

(a) Steps in any non-control (or control) data attack.

Goal 1:	Automatically model an arbitrary *memory write* vulnerability.
Goal 2:	Automatically identify an arbitrary *gadget entry point*.
Goal 3:	Automatically produce a full *gadget chain*.

(b) Goals for automating data-only attacks.

Figure 1: Data-only attacks: steps and goals.

program execution. Second, we observe that expressiveness (and especially Turing completeness) is not necessary. Rather, attackers simply want to achieve specific goals, such as running code via `execve`, or writing to a file via `write`. Third, we observe that manipulating a program's intended path is not necessary. In reality, programs will invoke `execve`, `write` or other interesting system calls all by themselves, without any additional interference from an attacker. Finally, we observe that after initialization, a program treats many types of data as immutable, and hence, that data has few (if any) constraints. By targeting these straightforward "identity" dataflows, we can corrupt data (e.g., a filename) at one program point and expect it to remain unchanged all the way to another program point (e.g., the filename getting passed to `execve`)—all the while without performing any heavyweight constraint solving. Using these insights, we make the problem tractable, even for lightweight analysis.

We present EINSTEIN, a data-only attack exploitation pipeline. EINSTEIN uses custom taint policies (rather than constraint solving) to identify attacker-controllable syscalls (rather than Turing completeness) along a program's (already valid) runtime path, generating exploits for syscall arguments that have an identity dataflow (rather than a complex dataflow) from attacker data. Given a vulnerable target program as input, it instruments the code to model and track each step of an attack, allowing it to identify gadget chains at runtime.

Specifically, we first taint any data that could be overwritten by an attacker with a unique color. Then, we track the flow of taint into security-sensitive system calls [29, 32, 40, 64, 87]. Moreover, we track the flow of taint into certain library state that is shared across system calls. If this state can be controlled by one system call, and used by another, we have evidence that an attacker can exploit it to chain together two otherwise safe system calls in a data-only attack. Finally, we generate exploits that corrupt the identified syscall arguments with attacker data, and confirm the exploits' effectiveness by running them on the target application.

EINSTEIN's low complexity approach allows it to identify thousands of vulnerable gadgets. Taking the popular web server `nginx` as a case study, we use EINSTEIN to generate 944 exploits, including 1 CODE-EXECUTION primitive, 17 WRITE-WHAT-WHERE primitives, and 41 SEND-WHAT-WHERE primitives. Moreover, many of these exploits bypass state-of-the-art mitigations, e.g., syscall filtering [34, 35, 44, 67] and selective DFI [44, 79].

As case studies, we discuss the CODE-EXECUTION exploit, as well as one of the WRITE-WHAT-WHERE exploits. The former demonstrates the rich attack surface that data-only approaches offer, with plenty of low-hanging fruit available to an attacker. It exploits an `execve` syscall that takes its `pathname` and `argv` parameters directly from a global variable, allowing an attacker to trivially execute arbitrary code. The latter demonstrates the power of syscall chaining, which further expands the available attack surface. It exploits the `pathname` parameter of an `open` syscall and the `fd` and `buf` parameters of an unrelated `write` syscall, allowing an attacker to corrupt the server's filesystem.

Contributions. We make the following contributions:

- We present a practical approach to building data-only attacks in complex programs.
- We develop EINSTEIN, an open-source[1] data-only exploitation pipeline.
- We evaluate EINSTEIN on popular server applications to identify thousands of previously unknown vulnerable syscalls and use `nginx` as a case study to generate hundreds of working exploits.

2 Background & Related Work

2.1 Data-Only Attacks & Defenses

Young and McHugh presented one of the first examples of a data-only attack in 1987 [95], and subsequent work suggested their viability in practice [30, 84, 91]. Then, Chen et al. presented the first extensive look of such attacks on real-world programs in 2005 [26].

Running example. Figure 2 outlines one of the classic data-only attacks described in the literature [26]. In this example, the server uses the `sort-script` program to sort numbers specified by a client. In the benign case, a client first sends a `POST /sort-script` request to the server with the unsorted numbers in the request body, which the server feeds to `/sort-script` in the the CGI-BIN directory. Finally, the program returns the sorted numbers to the server, and the server passes them on to the client. However, a memory write vulnerability in the Null HTTPD web server allows attackers to overwrite the CGI-BIN path, for instance by setting it to `/bin`. When the attacker now sends a `POST /sh` request to the server, it will execute the shell commands contained in the request body.

Practical vs. comprehensive defenses. Mitigations for these attacks generally attempt to prevent one of two operations: (1) the *definition* (i.e., *def*) of malicious data, i.e., the memory

[1] EINSTEIN is available at https://github.com/vusec/einstein.

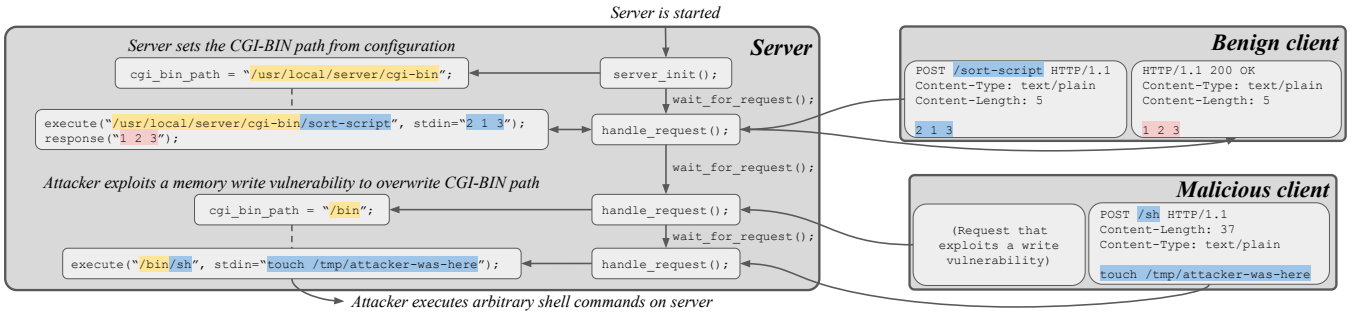

Figure 2: The data-only attack presented by Chen et al. [26] (with minor modifications for clarity). Despite its discovery almost two decades ago, EINSTEIN still identifies similar gadgets that exploit the CGI-BIN path of popular web servers.

write vulnerability; or (2) the *use* of malicious data, e.g., passing malicious data to `execve`. Unfortunately, *comprehensive* solutions to prevent the *def* of malicious data (e.g., memory safety [13, 14, 22, 45, 56, 57, 94], data space randomization (DSR) [16, 17, 21, 68]) or to prevent its *use* (e.g., dataflow integrity (DFI) [23, 51, 80]) either incur poor performance or require onerous changes in the software or hardware, thereby limiting their adoption in practice. On the other hand, *practical* measures against the *def* of malicious data (e.g., memory error scanning [12, 36, 75, 76, 83], selective DSR [62, 63]) or against its *use* (e.g., selective DFI [44, 79], syscall filtering [34, 35, 44, 67]) are non-comprehensive, because they leave a significant portion of the attack surface vulnerable to attacks.[2]

2.2 Automated Data-Only Attacks

Despite the discovery of data-only attacks such as the one in Figure 2 almost two decades ago and the lack of practical, comprehensive mitigations, automatic solutions to building attacks are still limited in a few ways: they are limited in scope, require significant manual effort, or make unrealistic assumptions. These limitations often relate to the inherent complexity and poor scalability of the concolic/symbolic execution that underlies most of these solutions, but sometimes their objectives are also different. For instance, some approaches strive for Turing completeness, which is interesting from an academic viewpoint, but not so relevant for attackers. In the remainder of this section, we break down various ways in which previous approaches fall short (see also Table 1).

Vulnerability-dependent analysis. While preventing the use of malicious data requires a comprehensive attack surface analysis: the identification (and elimination) of *any* dangerous data flow, regardless of its origin, previous approaches [39, 41, 66] have a narrower scope, limiting themselves to specific memory write vulnerabilities rather than generic primitives. In other words, the attacks they generate are *only applicable* to the *specific vulnerability* supplied by the user, including the specific addresses and values it may write. A partial exception is Limbo [73], which models arbitrary stack overflows, although that is still a long way from general memory corruption. In contrast, EINSTEIN starts its analysis from *generic attacker capabilities* (e.g., an arbitrary read/write primitive), regardless of the specific vulnerability.

Predetermined gadget entry point. Next, previous approaches may require the user to predefine the gadget entry point [43, 66]. In other words, in order to build attacks, they need the user to *already know how to exploit the program* in a way that steers its execution to the first gadget. This is the typical model of any "weird compiler" whose goal is to chain together Turing-complete gadget chains (e.g., ROP compilers [72], which assume the user can already exploit one return instruction), and it is also the model for data-only gadget compilers [43, 66]. However, identifying an entry point can be a non-trivial task, because it often requires a user to develop a separate exploit that just forces the program's execution to reach the first gadget (e.g., by "legally" diverting control flow). Previous approaches may *partially* model the entry point by either being incomplete (e.g., due to the poor coverage of concolic execution [39, 73]) or unsound (e.g., by assuming any loop executed after a memory error could be a gadget dispatcher [41]).

Manual gadget chaining. Finally, previous approaches may require the user to manually chain gadgets [41]. However, *chaining is often a non-trivial task*, as CFI limits which gadgets may be chained together and gadgets may be "volatile" (i.e., selecting one gadget in a chain may rule out the selection of other gadgets in that chain [43]). Several previous approaches do not handle chaining at all, while all others do so only partially (e.g., due to concolic execution's poor coverage [39, 73], or the problem being NP-hard [43]).

3 Threat Model

We assume mostly the same threat model as previous work [39, 41, 43, 66, 73]. In particular, we consider a target program that: (1) has a memory corruption vulnerability [1, 3–6]; and (2) is protected with DEP [15], ASLR [65], state-of-the-art control-flow hijacking defenses (e.g., CFI [11, 86, 87, 89, 96]), and strong stack protections (e.g., perfect stack canaries, shadow stacks [31]). This differs slightly from pre-

[2] We refer the interested reader to previous surveys of data-only attacks [27, 28] and memory corruption defenses [85].

Table 1: Overview of approaches to building data-only attacks and how they model the steps in Figure 1a. Specifically, whether they: can model an attack step (●), can *partially* model an attack step (◐), or require an attack step to be defined by the user (○).

Approach		Design		Models this attack step?			Is practical?	
Name	Year	Type of dataflow analysis	Goal	Memory write vulnerability	Gadget entry	Gadget chaining	Models all primitives	Models primitive completely
FlowStitch [39]	2015	Concolic execution	Attacker-centric	○	◐	◐	✗	✗
MinDOP [41]	2016	Static taint analysis	Turing-complete	○	◐	○	✗	✗
BOPC [43]	2018	Symbolic execution	Turing-complete	●	○	◐	✗	✓

EINSTEIN	-	Dynamic taint analysis	Attacker-centric	●	●	●	✓	✓

vious work [39, 41, 43, 66, 73], which do not assume strong stack protections. For simplicity, we focus specifically on popular server programs, similar to much prior work in the area [18, 52, 59, 60, 74, 87–89].

Moreover, we assume that an attacker: (1) has access to a binary equivalent of the one deployed by their prospective victim; (2) can legitimately interact with the target program (e.g., by sending requests to a target web server); (3) can bypass ASLR via an information leak [33, 37, 42, 70, 78]; (4) can exploit the memory corruption vulnerability for an arbitrary write primitive from a quiescent program state, as in previous work [60, 88]; and (5) aims to force the target program to invoke system calls with attacker-controlled parameters [29, 32, 40, 64, 87]. This differs from previous work, which assumes: (1) an attacker can carry out the arbitrary write primitive from an *arbitrary* program state [43], rather than a *quiescent* state; and (2) an attacker that aims for *Turing completeness* [41, 43, 66], rather than an attacker that aims for *security-sensitive controllable system calls* (which we introduce later, see Table 2).

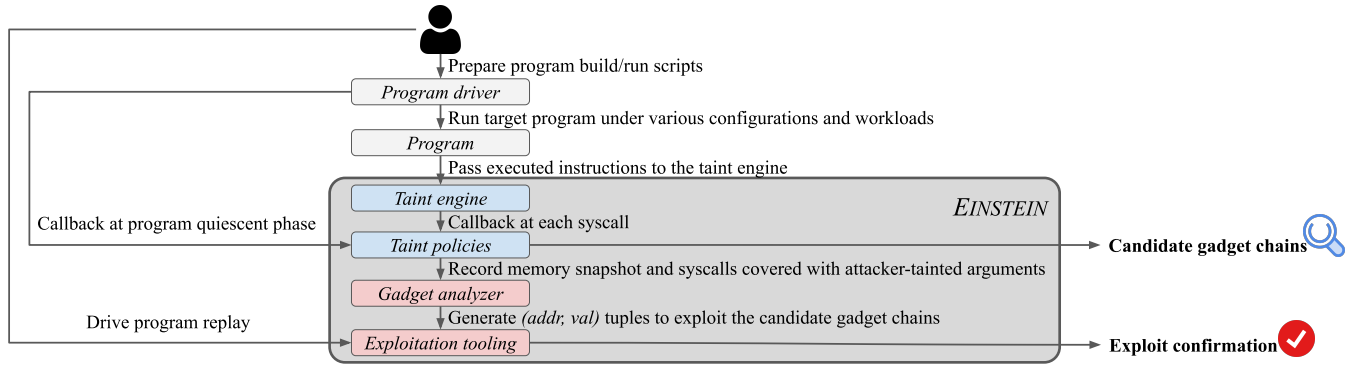
4 Overview of EINSTEIN in Action

Before we discuss our design in detail, we walk through EINSTEIN's operation with our running example. We consider a target program, e.g., the web server, to have three application-dependent phases of execution: (i) an *initialization phase*, where the program starts and initializes long-lived data, e.g., configuration data; (ii) a *quiescent phase*, where the program waits for user interaction, e.g., by idly waiting for new client requests, at which point an attacker may exploit the memory write vulnerability; and (iii) a *processing phase*, where the program handles user interaction, e.g., by invoking `execve`.

To guide our explanation of EINSTEIN's operation, we refer the reader to Figure 3, which shows the main components at the top and the main analysis steps at the bottom. Next, we explain how EINSTEIN identifies (Steps 1–4) and builds (Steps 5–6) the attack of Figure 2. We defer the more complex aspects of EINSTEIN, such as the exact taint policies and chaining, until later.

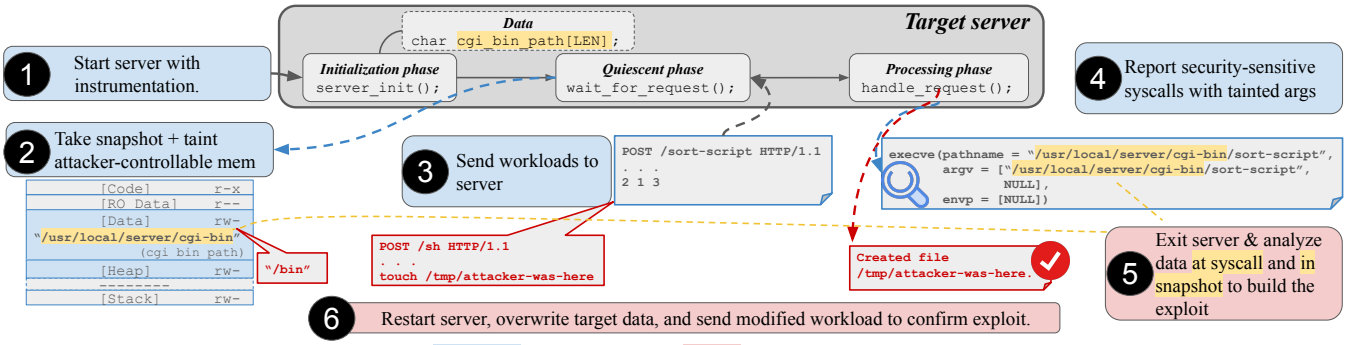
Step 1. We use a *program driver* (e.g., a test suite) to run the victim program with EINSTEIN instrumentation. As in previous work [60, 88], EINSTEIN begins its analysis with the program in a quiescent state, by which time, all initialization (e.g., of `cgi_bin_path`), has completed.

Step 2. EINSTEIN then models an arbitrary memory write vulnerability by tainting all data that could be affected by it (again, including `cgi_bin_path` string), thereby fulfilling **Goal 1** of Figure 1b. This is the first of our *taint policies*. Additionally, it records the tainted data in a memory snapshot.



Step 3. To uncover gadgets, the driver sends standard requests to the server (e.g., the `POST /sort-script` request from the example), while the taint engine propagates the flow of attacker data through the target server's execution.

Step 4. As the server handles the example `POST` request, it invokes `execve` with attacker-tainted arguments. Recognizing the system call as sensitive, EINSTEIN's second *taint policy* identifies it as a *candidate gadget*, fulfilling **Goal 2**. Additionally, it records information about the syscall, such as its arguments and their taintedness.



Step 5. Having identified the candidate gadget, it now tries to build an exploit. First, EINSTEIN's *gadget analyzer* determines that parts of `execve`'s `pathname` and `argv` arguments are tainted with a color that corresponds to `cgi_bin_path`. Upon further inspection, it finds that they are in fact identical to `cgi_bin_path`. We refer to this kind of straightforward dataflow as an *identity dataflow*. EINSTEIN builds a candidate exploit by generating $(addr, val)$ pairs to overwrite the target data from `"/usr/local/server/cgi-bin"` to `"/bin"` (**Goal 3**).

Step 6. To confirm its effectiveness, EINSTEIN's *exploitation tooling* restarts the server, overwrites the target data defined by the $(addr, val)$ pairs, and sends the workload to exploit the gadget—in this case `POST /sh` with a shell command to create a file in the /tmp directory. If the file is created, EINSTEIN confirms the exploit to be successful.

For the running example, a single-blow overwrite of the arguments of a single system call is sufficient for exploitation.

(a) Architecture.

(b) Operation: EINSTEIN identifies (Steps 1–4) and builds (Steps 5–6) the example attack in Figure 2.

Figure 3: Overview of EINSTEIN.

While simple, such cases are still common (Section 7). On the other hand, we will show that EINSTEIN supports system call chaining also when we discuss the complete set of EINSTEIN's taint policies. We demonstrate the usefulness of chaining in our second case study (Section 8).

5 Design

In this section, we discuss EINSTEIN's design by introducing each of the components in Figure 3a in some detail.

5.1 Taint Engine

To track attacker-controllable data at runtime, a dynamic taint analysis (DTA) engine models the flow of data from each executed instruction's inputs to its outputs. To do this, DTA engines make use of the following constructs (which may have different names depending on the engine): (1) a *color* is some kind of program metadata, which in our case, is an address that can be overwritten by the attacker; (2) a *tag* (also called a *tagset*) is the set of colors corresponding to some program data (e.g., a memory location), which in our case, indicates that some data is attacker-controllable; and (3) the *tagmap* contains the tags for all program data. This is a fairly typical design of DTA [25, 46, 58, 69, 82, 88], and indeed our design is inspired by a DTA engine [88] that was used by previous work to identify control data attacks[3].

However, our use case, i.e., non-control data attacks, poses two unique challenges, which existing DTA engines cannot solve. First, because all non-control data is a potential attack vector, we need an approach that can uniquely track an *unbounded* number of taint colors over an *unbounded* amount of data. For instance, in our example attack, we need to know that, out of all the possible data that our exploit could overwrite, it should specifically overwrite the server's CGI-BIN path. Second, because programs typically invoke system calls at complex points (e.g., a time-sensitive network write, or a large file read), we need an approach that can *scale* to complex workloads covering complex features. For instance, in our example attack, we need to indeed be able to cover the code-path that handles the exploit's `POST` request. In contrast, we confirmed previous similar DTA engines cannot easily scale beyond a single default request to a server program, as the excessive slowdowns cause complex requests to time out [88]. Hence, it is around *scalability* and supporting *unbounded colors* for *unbounded data* that we design three fundamental

[3]Their approach, which was the successor to prior work named Galileo [77] (*"space"*), was named Newton [88] (*"absolute space and time"*). Since our approach generalizes the approach of Newton to non-control data attacks, we name it EINSTEIN (*"spacetime"*).

aspects of our DTA engine, in particular: (1) how it accesses the tagmap, (2) how it initializes the tagmap, and (3) how it combines tags.

Accessing the tagmap. Every time a program accesses data (e.g., via a load or store), the DTA engine accesses its tag. The DTA engine typically does this by taking the program data's address and performing some mapping to locate the corresponding tag. Some DTA engines may be *slow but memory-efficient* by navigating through multiple layers of a dynamically managed data structure (e.g., page tables) on every access [9, 10, 47, 88]. Others may be *fast but memory-inefficient* by indexing into a statically managed data structure (e.g., shadow memory) on every access [8, 83].

Our approach takes the best of both worlds by combining a *fast* shadow memory organization with a *memory-efficient* design. Specifically, we instruct the linker to constrain the user address space to the top 4 GB and reserve the lower part for shadow memory. This organization yields (i) fast shadow memory-based mappings between addresses and corresponding tags (only 2 arithmetic and 1 masking operations needed) and (ii) 64-bit user pointers easily compressible to 32 bits, since the top 32 bits are always identical. Since we use pointers as taint colors, such pointer compression strategy [50] also translates to our (32-bit) colors, thereby reducing the overall size of the tagmap by 50%.

Initializing the tagmap. Before accessing a tainted entry in the tagmap, the DTA engine must first initialize the tagmap. Some DTA engines may be *fast but taint limited data* by starting with an untainted (i.e., zero-initialized) tagmap [8–10, 75, 83]. Such approaches take advantage of the fast hardware MMU, because any access to an uninitialized tag page generates a page fault, which then automatically maps a zero-initialized page into the tagmap. Other DTA engines may be *slow but taint unbounded data* by starting with a mostly-tainted tagmap [82, 88]. Such approaches require a slow software-based MMU to check every access, so that when an uninitialized tag page is identified, they can map a custom-initialized page into the tagmap.

Our approach takes the best of both worlds by combining a tagmap that can taint *unbounded data* while enabling *fast* access checks by the hardware MMU. In particular, we use Linux's `userfaultfd` feature to: (1) quickly identify an uninitialized tag page via a hardware page fault, and (2) handle the page fault in software, so our DTA engine can taint the entries of the tagmap that represent attacker-controllable data.

Combining tags. Every time a program combines data (e.g., via arithmetic), the DTA engine combines their tags. The DTA engine does this by performing a set union of the colors in one tag with the colors in another tag. Some DTA engines may aim to be *fast but support few colors* by representing a tag as a size-limited array, with an entry allocated for every possible color—e.g., an array containing either 1 color [10, 47, 83], 8 colors [8, 47], 256 colors [7, 9], etc. Other DTA engines may aim to be *slow but support unbounded colors* by representing a tag as an unbounded set, with an entry for each color added at runtime [82, 88].

Our approach takes the best of both worlds by using a tagset that *supports unbounded colors*, while limiting its runtime capacity in order to stay *fast*. In particular, our array-based tagset contains an entry for each color added at runtime, up to some limit N. If a tagset contains more than N colors at runtime, then we denote the tagset as *overfilled* and do not combine any more colors into it. We rely on the insight that if a tag contains numerous colors, then it likely represents complex data, with multiple sources (e.g., the output of a cryptographic hash), and hence, that data would be very challenging for an attacker to exploit than a tag with few colors. For our experiments, we select $N = 16$ as it produces few tagset overfills while maintaining an acceptable memory overhead.

5.2 Taint Policies

We design taint policies to model the steps of a data-only attack listed in Figure 1a. At a high level, we initially mark attacker-controllable regions as tainted, while EINSTEIN's DTA engine propagates the taint information to syscall callsites, and checks the tags of syscall arguments to identify those that may be exploitable.

5.2.1 Modeling an arbitrary memory write

We model the arbitrary memory write by tainting all memory that an attacker could overwrite. We discuss *which* data is attacker-controllable, and *what* we taint it with.

Because we consider an arbitrary memory write primitive, we taint data in *any writable memory segment*. However, since we focus on long-lived (and exclude short-lived) data corruption effected by the primitive, we *exclude the stack's segment*. (It is not a fundamental limitation, and our approach can easily accommodate tainting the long-lived data on the stack.) Moreover, to model the effect of long-lived data corruption, we taint memory when the program is in a quiescent state, as done in prior work [88].

For EINSTEIN's analysis it is vital to be able to precisely identify the origin of every tainted byte. To track memory dependencies at a byte granularity, we configure our DTA engine with a unique tag for every attacker-controllable byte: specifically, the compressed (32-bit) version of its memory address. To track the specific *value* that it originates from, we also record a memory snapshot tainting all memory. Hence, for any tainted tag, we have its origin: its $(addr, val)$ pair. The source of the taint is later a candidate location for the attacker to corrupt, control a syscall argument, and launch their attack.

5.2.2 Tracking dependencies

Traditional taint implementations [47] model taint strategies that track direct attacker-controlled memory dependencies (i.e., syscall argument X was read at tainted address Y), and ignore indirect ones (i.e., syscall argument X was read at address Y' using a tainted pointer). To support the latter, we

additionally implemented load pointer propagation (i.e., taint every value read via a tainted pointer), allowing us to model attackers corrupting data pointers, array indexes, etc. to indirectly control syscalls arguments.

5.2.3 Modeling syscall exploitation

We model the next part of an attack, the execution of a gadget, with taint sinks that check whether syscall arguments are attacker-controllable. Specifically, we insert hooks before the invocation of the security-sensitive syscalls listed in Table 2. If we identify any attacker-tainted arguments, we generate a syscall report that includes: (1) info about the syscall, such as its name, arguments, arguments' taint, and backtrace; (2) info to distinguish it from other reports, such as the target process's PID and TID, and an incrementing report number; and (3) info to help reproduce the exploit.

5.2.4 Modeling syscall chaining

We model gadget chaining with a combination of taint sources and taint sinks. We note, however, that chaining may not even be required for many end-to-end attacks. Namely, because our gadgets are syscalls—rather than small snippets that e.g., perform arithmetic, or conditional branching. [19, 20, 24, 43, 49, 66, 71, 77]—one gadget may suffice for an entire attack. For instance, the example attack in Figure 2 only exploits *one* syscall, `execve`. However, if such a syscall is unavailable to the attacker (e.g., due to mitigations), syscall chaining greatly expands the set of available gadgets.

Chaining syscalls via file descriptors. Just like any other gadget compiler [43, 66, 72], we chain syscalls by chaining the data output by one gadget into the input of another gadget. The syscall interface may chain together many different types of data: process IDs (from `getpid` to `kill`), semaphore IDs (from `semget` to `semop`), and so on. EINSTEIN chains *file descriptors (FDs)*, as they are used by some of the security-sensitive syscalls that we target. An FD uniquely identities an open *I/O stream*, e.g., a file or a network socket. If an attack controls an I/O stream, then it controls *where* the target program sends and receives data. We focus on output streams as they allow attackers to effect changes, but our approach equally applies to input streams.

Table 2 lists the syscalls that EINSTEIN targets and that are relevant for chaining. In particular, some security-sensitive syscalls only operate on some types of FDs (e.g., `sendto` only takes a socket FD), so they can only be chained to specific FD-creating syscalls (e.g., `socket`). On the other hand, `write` can operate on multiple types of FDs, and hence, can be chained with multiple types of FD-creating syscalls.

I/O streams can be either *directly* or *indirectly* controllable by an attacker. First, an I/O stream is *directly* controllable if the attacker controls how it was created, i.e., the arguments to an FD-creating syscall, e.g., the `filename` argument to `open`. Second, an I/O stream is *indirectly* controllable if the attacker controls an FD argument to a security-sensitive syscall and can redirect it to a directly-controllable I/O stream. For example, by controlling the `fd` argument to `write`, the attacker can redirect it to the aforementioned directly-controllable file. Because an indirectly-controllable stream depends on the existence of a directly-controllable stream, we first explain how we track directly-controllable streams, then we explain how we identify directly- and indirectly-controllable accesses.

Tracking file descriptors. To identify directly-controllable output streams, we add taint sinks to FD-creating syscalls that check their arguments. First, our sinks determine whether the created stream can indeed be an *output* stream. For some syscalls, this is not necessary to check, but for others, this is specified by the arguments (e.g., `open`'s `flag` argument determines whether the file is writable). In such cases, we conclude that the syscall can create an output stream if: (1) the relevant arguments specify to create one, or (2) the relevant arguments are attacker-tainted, and hence, an attacker can coerce it into creating one. Second, our sinks determine whether an attacker can *directly control* "where" the output stream will go by checking if relevant arguments are attacker-tainted, e.g., `open`'s `pathname` or `connect`'s `addr` arguments.

Next, we need a way to track these directly-controllable streams. Namely, the kernel maintains an FD table, which maps FDs to their corresponding I/O streams. If attackers control a created stream, then they control its entry in the FD table. Hence, any future references to an attacker-controllable stream should be treated as tainted—regardless of whether the FD is tainted. To model this, we maintain our own *controllable FD table*, which mirrors the kernel's FD table, but with a few differences. Specifically, our table: (1) only creates entries for controllable output streams, (2) maps FDs to the report number of the syscall that created it, and (3) is consulted to taint any subsequent FD syscall argument that may refer it (whether directly or indirectly).

Identifying accesses to controllable file descriptors. The final question we reach in our design is: How do we identify accesses to attacker-controllable I/O streams? The naive approach would be to use the same taint sinks described in Section 5.2.3 to simply check whether FD arguments to security-sensitive syscalls are tainted. However, this is imprecise because it would: (1) fail to identify many controllable accesses, e.g., if the FD argument is *untainted*, but its I/O stream is *tainted*; and (2) falsely identify many non-controllable accesses as controllable, e.g., if the FD argument is *tainted*, but all open I/O streams are *untainted*. Hence, we modify our taint sinks for FD arguments to instead check our *controllable FD table*. In particular, we determine that a syscall's FD argument is: (1) directly-controllable if it exists in our controllable FD table; or (2) indirectly-controllable if it is tainted and our controllable FD table contains an FD of the same type (e.g., a socket FD, if the syscall requires a socket FD).

Table 2: Syscalls targeted by EINSTEIN. We target a similar set of security-sensitive syscalls as previous work [29, 32, 40, 64, 87] and a set of FD-configuring syscalls that demonstrates their feasibility. As this is not an exhaustive list of syscalls that an attacker can exploit, EINSTEIN is easily extendable to handle more syscalls, and to target different classes of syscalls [48, 61, 90].

Type of syscall	Chaining type	Syscalls
Security-sensitive syscalls	Does not chain	`execve`, `execveat`, `mprotect`, `mremap`, `remap_file_pages`
	Input: File FD	`mmap`
	Input: File or socket FD	`pwrite64`, `pwritev`, `pwritev2`, `sendfile`, `write`, `writev`
	Input: Socket FD	`sendmmsg`, `sendmsg`, `sendto`
FD-configuring syscalls	Output: File FD	`creat`, `open`, `openat`, `openat2`
	Output: File or socket FD	`dup`, `dup2`, `dup3`
	Output: Socket FD	`bind`, `connect`, `setsockopt`, `socket`, `socketpair`

5.3 Gadget Analyzer

To build exploits for the identified gadget chains, one could employ a heavyweight analysis that determines the exact constraints of all attacker dataflows e.g., via symbolic execution. However, as EINSTEIN aims to identify low-effort attacks, our gadget analyzer takes a lightweight approach that targets *identity dataflows*, i.e., dataflows where the value at the sink is identical to the value at the source. As we show in Section 7.1, this already yields a rich attack surface.

In our case, a *sink value* is a tainted syscall argument, and a *source value* is the data it originates from in the memory snapshot. We can map *sink values* to their corresponding *source values* by checking the *sink value*'s taint color, which contains its *source address* in the snapshot. In other words, we use the taint color of each reported syscall argument to identify the value it originates from in the memory snapshot. If these values are equivalent, then the argument has an identity flow.

Then, to exploit the identity flows, we generate $(addr, val)$ pairs to overwrite some *source value*. The specific exploit pairs that we may generate depend on a particular attacker's goals and the particular target program. Hence, for simplicity, we generate generic per-syscall exploits, e.g., with `execve` creating a particular file, or `write` writing a particular string. If the user wishes, the exploits may be modified from our exploitation tooling.

5.4 Exploitation Tooling

Because our gadget analyzer forgoes complex constraint solving, we consider the set of $(addr, val)$ pairs that it generates to only make up a *candidate* exploit. In order to confirm it as a *working* exploit, we must confirm that our exploit indeed stems from an identify data flow not violating any program invariants. Hence, rather than e.g., symbolically verifying all possible constraints that our exploit may effect, we punt the problem to the program itself—i.e., to a real, concrete execution. In particular, our exploitation tooling simply re-runs the target program and confirms whether the exploit is indeed successful. It does this by: (1) rewriting the data specified by the $(addr, val)$ pairs from the arbitrary memory write primitive; then (2) sending some workload to the target program to trigger the gadget chain; and finally (3) checking whether the exploit achieved its desired outcome. If the exploit is successful, then we confirm it to indeed be a *working* exploit.

We observe that some candidate exploits have a better chance of being successfully confirmed than others. Fortunately, because our approach casts such a wide net—e.g., by tracking *any possible* attacker data to *any combination* of security-sensitive syscalls—we have plenty of candidate exploits at our disposal. We prioritize those gadgets that we consider to be more robust and stronger attack primitives, e.g., gadgets that (1) exploit higher-value syscalls (e.g., `execve`), (2) exploit multiple syscall arguments, (3) overwrite deterministic addresses (e.g., global data), and (4) exploit syscall arguments with larger identity flows (for our experiments, we target identity flows that span at least 4 bytes).

6 Implementation

We base the implementation of our DTA engine on libdft [47]. Like other analyses that use libdft, the runtime component of EINSTEIN (which specifies the taint policies) is statically linked with our libdft variant. We invoke the target program with our tool enabled and with ASLR disabled. Although our threat model already assumes an attacker that bypasses ASLR, disabling ASLR for the analysis does provide a couple of implementation-level benefits: (1) it allows us to enforce 32-bit addressing, so that we can compress our tags from 64 bits to 32 bits; and (2) it causes deterministic addresses to stay constant across multiple runs, which, while not important for an attacker armed with an information leak, it does simplify the confirmation of candidate exploits that target such addresses. We expand upon other parts of our implementation in Appendix A.

7 Evaluation

We evaluate EINSTEIN in terms of attack surface and performance on an AMD Ryzen 9 3950X CPU with 128GB of RAM running Ubuntu 22.04.3 LTS (kernel v6.2). To run Newton [88], we use an Intel Xeon Silver 4108 CPU with 32GB of RAM running Ubuntu 16.04.7 LTS (kernel v4.3).

Table 3: Number of gadgets found per syscall and argument type.

Syscall*	Total covered	Total covered where this argument has a dataflow from attacker data and the percentage of those that are identity dataflows.					
		Arg. 1	Arg. 2	Arg. 3	Arg. 4	Arg. 5	Arg. 6
`execve`	11	7 (86%)	7 (86%)	7 (86%)			
`mmap`	787	55 (5%)	441 (8%)	55	16 (100%)	17	73
`mprotect`	144	97 (68%)	98 (27%)	1			
`mremap`	11	11	7	11	-	-	
`pwrite64`	1270	1217 (3%)	741 (47%)	399 (19%)	506 (36%)		
`pwritev`	10	10 (100%)	10 (10%)	-	10 (20%)		
`sendfile`	1	-	-	1	1		
`sendmmsg`	2	2	2	-	-		
`sendmsg`	12	5 (100%)	3 (100%)	-			
`sendto`	431	389 (7%)	410 (38%)	408 (6%)	-	-	-
`write`	3083	768 (74%)	2877 (91%)	1265 (10%)			
`writev`	754	244 (18%)	742 (76%)	-			

* Did not cover `execveat`, `pwritev2`, or `remap_file_pages`.

Table 4: Number of gadgets found and performance per target program.

Target program	*Non-control data* gadgets (% identity dataflow)	*Control data* gadgets* (% identity dataflow)		Runtime (h:mm:ss)		Peak PSS (MB)			Code coverage
		With register operand	With memory operand	Baseline	EINSTEIN	Baseline	EINSTEIN (1 color per tagset)	EINSTEIN (16 colors per tagset)	
`httpd`	1834 (97%)	2082 (42%)	15,179 (94%)	0:04:00	0:35:08	26	1560	3129	27.3%
`lighttpd`	92 (98%)	50 (34%)	155 (94%)	0:00:05	0:01:51	3	176	257	27.8%
`nginx`	1623 (82%)	503 (60%)	564 (99%)	0:08:41	3:27:05	24	479	848	49.1%
`postgres`	2105 (27%)	1382 (11%)	4690 (13%)	0:00:56	1:47:27	175	1568	11,621	46.5%
`redis`	218 (84%)	160 (22%)	53 (100%)	0:04:01	1:01:13	191	3257	32,188	33.6%

* Mitigated by code reuse defenses.

Programs and drivers. We target the web servers `httpd`, `lighttpd`, and `nginx`; and database servers `postgres` and `redis`—all of which have been shown to be at risk of memory write vulnerabilities [1–6]. Although we follow previous work by targeting server applications [18, 52, 59, 60, 74, 87–89], we note that even programs with more limited user-input interaction and few obviously dangerous syscalls (like `execve`), may well be at risk. Because EINSTEIN's approach only builds on a standard write vulnerability, it can indeed generalize to such applications.

We use each server's test suite to drive the analysis, since test suites are designed to test a variety of features and therefore cover a diverse set of code paths. If EINSTEIN is able to craft exploits based on simple test suites, it validates our claim that our approach greatly simplifies data-only attacks. Moreover, because `nginx` is a common target for exploitation case studies [55, 88, 92], we use our exploitation tooling to confirm the candidate exploits that EINSTEIN generates for `nginx`.

Program phase determination. As explained in Section 4, the phases of program execution (i.e., the initialization, quiescent, and processing phases) are application-dependent. Although more sophisticated approaches can determine the different phases of execution for a program (e.g., syscall monitoring [35]), all of our target servers initialize in a couple of seconds. Thus, we simply conservatively wait 10 seconds before establishing post-initialization quiescence.

7.1 Attack Surface Analysis

We investigate the attack surface uncovered by our approach based on: how effectively an attacker can control security-sensitive syscalls, and what an attacker can do with those syscalls. In Appendix B, we also evaluate how this attack surface compares with the attacks surface of control-flow hijacking attacks.

As in previous work [54], we present the number of syscalls in terms of *unique backtraces* since other possible metrics are problematic: presenting the *total executed syscalls* would artificially inflate the numbers (because the longer a program

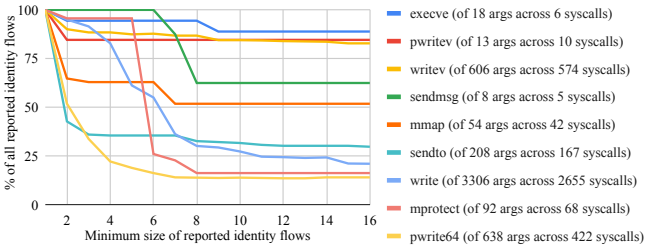


Figure 4: Percentage of all identity flows reported versus the minimum size of reported identity flows.

runs, the more syscalls it executes); while presenting *unique callsites* would artificially deflate the numbers (because a single syscall site may be called from many parts of a program).

Controllability. To evaluate the degree to which an attacker can control syscall arguments, we first refer to Table 3, which presents the number of tainted syscalls arguments, and in particular, the percentage of those with an identity flow. The first observation we make is that *most arguments have an identity flow*. Unsurprisingly, many of the identity flows are for data types that are generally treated as "immutable", e.g., the strings used in: the `pathname` and `argv` arguments to `execve` (86%); and the `buf` argument to `write` (91%) and `writev` (76%). Similarly, FD arguments tend to have a high rate of identity flow (e.g., 100% for `pwritev`, 100% for `sendmsg`, and 74% for `write`); this is also unsurprisingly because these FDs are often configured by syscalls that also take string-based arguments, e.g., the `pathname` to `open` and `creat`, and the `addr` to `connect` (which may be a string depending on its `sa_family`).

The second observation we make is based on Figure 4, which presents the lengths of the identity flows, broken down by syscall. We observe that many of the identity flows span at least 16 bytes, and hence, much of the data that an attacker can corrupt *remains unchanged* all the way to the vulnerable syscall. Given the prevalence of attacker data remaining unchanged to so many syscall arguments, we conclude that our data-only attacks are *low-effort*.

Syscall-based exploitation. To evaluate what an attacker can do with these controllable syscalls, we once again refer to Table 3 and observe that *every argument can be attacker-tainted*. Even for syscall arguments that we do not expect to be attacker-tainted (e.g., `mprotect`'s `prot` and `sendmsg`'s `flags` arguments, which are typically compiled down into a constant), we still encounter cases of tainted arguments. For example, we identify a case where `pthread_create` calls `mprotect` with a `prot` argument that has an identity flow from attacker-controllable data on the heap.

Next, we refer to Table 5, which presents our confirmed exploits for `nginx`, and observe that they offer *many primitives to an attacker*. For example, a vulnerable `execve` gives us a CODE-EXECUTION primitive; vulnerable file-configuring syscalls (e.g., `openat`) combined with vulnerable file-write syscalls (e.g., `write`) give us 17 WRITE-WHAT-WHERE primitives; vulnerable socket-configuring syscalls (e.g., `connect`) combined with vulnerable socket-write syscalls (e.g., `sendmsg`) give us 41 SEND-WHAT-WHERE primitives; and vulnerable syscalls combined with non-vulnerable syscalls give us less powerful, but still more numerous primitives (i.e., 885 total WRITE-WHAT, WRITE-WHERE, SEND-WHAT, and SEND-WHERE primitives). In comparison, FlowStitch [39]—a previous approach that also (i) generates syscall-based exploits, and (ii) assumes an arbitrary memory write primitive in its evaluation of `nginx` [2]—is hampered by concolic execution's poor coverage, and as a result, only generates 2 exploits for `nginx`. Because EINSTEIN identifies such a broad range of tainted arguments, and generates a variety attack primitives, we conclude that our data-only attacks are *diverse*.

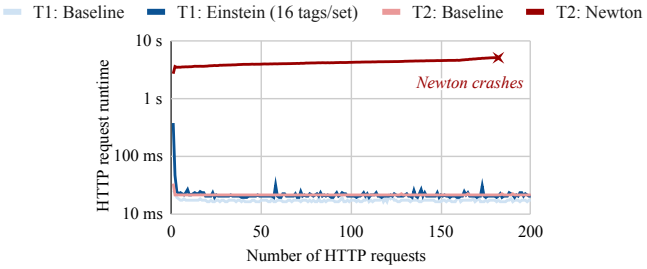
Table 5: Confirmed exploits for `nginx`.

Attack primitive	Count
CODE-EXECUTION	1
WRITE-WHAT-WHERE	17
WRITE-WHAT	375
WRITE-WHERE	79
SEND-WHAT-WHERE	41
SEND-WHAT	372
SEND-WHERE	59
Total	944

7.2 Performance Analysis

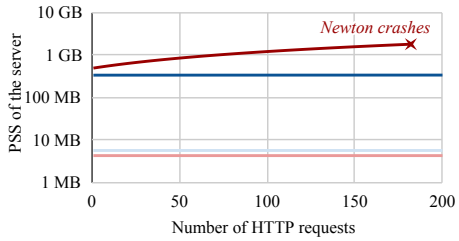
We investigate the performance of EINSTEIN along two dimensions. First, we investigate the overall performance of EINSTEIN per target program, as shown in Table 4. The baseline that we compare to is the vanilla target program, i.e., without any instrumentation.

Second, we investigate the performance of EINSTEIN's DTA engine. To do this, we compare the overhead of EINSTEIN to the overhead of Newton [88], which, in contrast to EINSTEIN, does not have the DTA engine optimizations described in Section 5.1. Specifically, its DTA engine: (1) accesses its tagmap via a *page table walk*, (2) initializes its tagmap via a *software-based MMU check*, and (3) represents tags as *unbounded sets*. Figure 5 presents the overheads of Newton, EINSTEIN, and their baselines from running `nginx` under a minimal configuration and processing multiple HTTP requests. We note two issues that led to this evaluation setup: (1) any moderately complex workload (e.g., running with a configuration that loads more than a few modules, or processing an HTTPS request) caused Newton to immediately crash, so we only run with a minimal configuration and process simple requests; and (2) for a variety of technical reasons (e.g., Newton requiring an older kernel version, full 32-bit support, etc.) we could not evaluate EINSTEIN and Newton on the



same machine, so we present the baseline overheads on both machines; T1 is EINSTEIN's machine, and T2 is Newton's machine.

Runtime overhead. As we see in Table 4, the runtime overhead of EINSTEIN ranges from 8x–26x. Our extensive experiments, including full test suites, confirm that the DTA engine easily scales to a complete testing campaign. Moreover, we see in Figure 5a that EINSTEIN handles `GET` requests at least two orders of magnitude faster than Newton. We attribute EINSTEIN's speedup primarily to the way it accesses the tagmap: on every access, it performs a fast shadow memory lookup, whereas Newton navigates its page table structure. Because our DTA engine optimizations enables a practical analysis platform, we consider the runtime overhead *acceptable*.



Memory overhead. Next, we evaluate the memory overhead of EINSTEIN when using both 1 color per tagset and when using 16 colors per tagset (i.e., the default). With 1 color/tagset, tags are easily prone to overfill, because adding any more than 1 color to a tagset results in it no longer tracking individual colors. Hence, this configuration cannot build candidate exploits for many gadget chains, because many syscall arguments' tags are overfilled. Nonetheless, it still identifies all the candidate gadget chains that the 16 colors/tagset configuration identifies.

We find in Table 4 that the memory overhead of EINSTEIN with 1 color/tagset is 9–60x relative the uninstrumented baseline. This overhead accounts for the internal data structures of EINSTEIN, `libdft64-ng`, etc.—most significant of which is the tagmap, which contains a tagset for every byte of program memory. If we increase the number of colors/tagset from 1 to 16, we would expect the resulting memory overhead to be 16x in the worst case. However, we find that our target databases have a 7.4–9.9x overhead, and our target web servers only have a 1.6–2.0x overhead. We attribute worse overheads to target applications having more spatially fine-grained access patterns, because they need to page in more of the tagmap per page of program memory.

Next, we see in Figure 5b that EINSTEIN has a constant memory overhead, whereas Newton's memory overhead grows for each additional `GET` request, until it eventually crashes from reaching the 2 GB limit for 32-bit processes. We attribute this difference to the way the DTA engines represent tags: whereas EINSTEIN uses *bounded* sets of 16 tags/set, Newton uses *unbounded* sets. As a result, Newton will combine any new colors with a tag until it runs out of memory. In principle, this has a worst case $O(n^2)$ memory overhead (where n is the total program memory), if every byte of program data is combined with every other byte of program data. Hence, an application such as `nginx`, which requires about 16 MB to run normally, would in the worst case, require 256 TB to run with Newton. In reality, however, the 2 GB limit masks this overhead, and it simply crashes well before this limit is reached. We conclude that because of our DTA engine optimizations and because of its configurable number of colors per tagset (i.e., to accommodate the tradeoff between total available memory and number of exploits generated), our memory overhead is *acceptable*.

(a) Runtime of a request versus the number of requests.

(b) PSS of the server versus the number of requests.

Figure 5: Comparison of running `nginx` with EINSTEIN and Newton [88] to running `nginx` as is (i.e., the baseline).

Coverage. As with any dynamic analysis, its efficacy is dependent on program coverage: poor coverage will generally yield poor results, and vice-versa. Yet, even though the test suites only covered 27–49% of the programs' code, EINSTEIN still uncovered many gadgets. Future work to increase code coverage, e.g., by exploiting syscall-guard variables [93], would undoubtedly *yield more gadgets*.

8 Case Studies

We have demonstrated that EINSTEIN builds diverse, low-effort attacks for popular servers. To demonstrate that such attacks pose a serious threat, we present two case studies of attacks against `nginx`. For each case study, we will: (1) explain how EINSTEIN identifies the gadget chain, builds a candidate exploit for it, and confirms the exploit's effectiveness; and (2) discuss how the exploit bypasses state-of-the-art defenses.

Defenses targeted. In considering which defenses to center our discussion around, we recall our explanation in Section 2 about the *practical* and *comprehensive* defenses against vulnerable *defs* and *uses*. Because we assume the existence of a memory write vulnerability, any *def*-centric defenses (e.g., memory safety, DSR, and memory error scanning) are implicitly out of scope. Moreover, because the *comprehensive* defenses (e.g., memory safety, full DSR, and full DFI) are not widely deployed, we also consider them out of scope. Hence, we center our discussion around the *practical use*-centric defenses, i.e., syscall filtering [34, 35, 44, 67] and selective

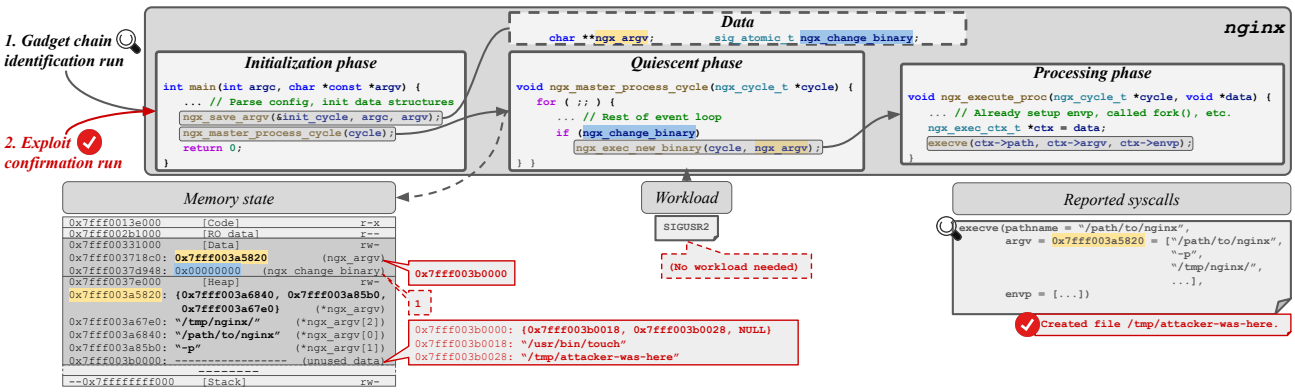


Figure 6: An `execve`-based gadget in `nginx` that EINSTEIN identified and built an attack for.

DFI [44, 79]. As we demonstrate that such *practical* defenses are fundamentally unsecure, we conclude that more *comprehensive* defenses should be deployed.[4]

8.1 Bypassing Syscall Filtering

This case study exploits an `execve` gadget in `nginx`'s live binary upgrade feature, wherein `nginx` replaces its own running binary while maintaining all of its connections. Figure 6 walks through how we identify and exploit the gadget with EINSTEIN.

Identification and exploitation. First, when starting up, `nginx` saves its `argv` to the global variable `ngx_argv`, which is subsequently tainted by EINSTEIN. Next, when sending workloads to `nginx`, EINSTEIN sends the `SIGUSR2` signal to the `nginx` master process, which initiates the live binary upgrade. This raises the `ngx_change_binary` condition, which causes `nginx` to call `ngx_exec_new_binary` with `ngx_argv` as an argument. Eventually, this results in `nginx` calling `execve`, passing to it the same `argv` that it had initially saved during start up. EINSTEIN identifies the attacker-tainted argument to `execve` and reports it.

EINSTEIN builds an exploit for this by first identifying the identity dataflow from `execve`'s `argv` argument to the `ngx_argv` global variable. Then, EINSTEIN builds an "arbitrary code execution" candidate exploit by generating $(addr, val)$ pairs that overwrite `ngx_argv` to point to an array of two strings: `"/usr/bin/touch"`, `"/tmp/attacker-was-here"`, and a `NULL` terminator. After re-running `nginx` to confirm this exploit, it indeed creates the file `/tmp/attacker-was-here`, indicating that our exploit was successful.

Because this gadget is triggered server-side (via `SIGUSR2`) rather than client-side (via a network request), it would appear at first glance that a remote attacker cannot trigger it—rather, the attacker would have to wait until the `nginx` process upgrades itself. However, our exploitation tooling (which parses the gadget's backtrace) makes it immediately clear to us that we can indeed trigger this gadget remotely. In particular, by trivially overwriting the tainted global variable `ngx_change_binary`, we can force `nginx` to take the conditional branch before `ngx_exec_new_binary`, and therefore call `execve`. Hence, with just a bit of manual inspection, an attacker can escalate non-triggerable gadgets such as this into triggerable gadgets. We note that this approach to "legal" control-flow hijacking differs from previous data-only approaches for a couple reasons. First, it is *optional*, because this gadget can also be triggered: (1) by `nginx`, when it upgrades itself, and (2) by the attacker, by hijacking a tainted `kill` syscall. Second, it is considerably *lower effort*, because we simply flip a single branch that precedes our already-identified gadget, whereas other approaches analyze all possible branches in an attempt to identify new gadgets [41, 43, 73].

Discussion. The objective of syscall filter-based defenses [34, 35, 67] is to disable high-value syscalls, e.g., `execve`. However, *syscalls filters are fundamentally imprecise* because they cannot disable legitimate syscalls. In other words, if `nginx` can legitimately invoke `execve`, then a defense cannot disable `execve`—otherwise it would break `nginx`. EINSTEIN exploits this imprecision because it does not divert control flow, and hence, it only covers legitimate syscalls, thereby eliding syscall filter-based defenses.

In principle, if a security-conscious sysadmin designed a configuration for `nginx` that completely disabled all legitimate uses of `execve` (e.g., by disabling CGI, live binary upgrade, etc.), then a syscall filter could indeed disable `execve`, thereby mitigating this gadget. However, in practice, this is nearly impossible because: (1) it is not possible to disable some features from a configuration (e.g., live binary upgrade); and (2) it is non-trivial to determine that no possible program point could invoke `execve` (e.g., due to the presence of dynamically loaded libraries and modules). This observation is confirmed by the evaluation of state-of-the-art syscall filters on `nginx`: none of them are able to completely disable `execve` [34, 35, 67].

[4] Indeed, developers may deploy the comprehensive (but costly) defenses to thwart EINSTEIN's attacks. Moreover, they may use EINSTEIN's reports to harden their program (e.g., by sanitizing particular syscall arguments).

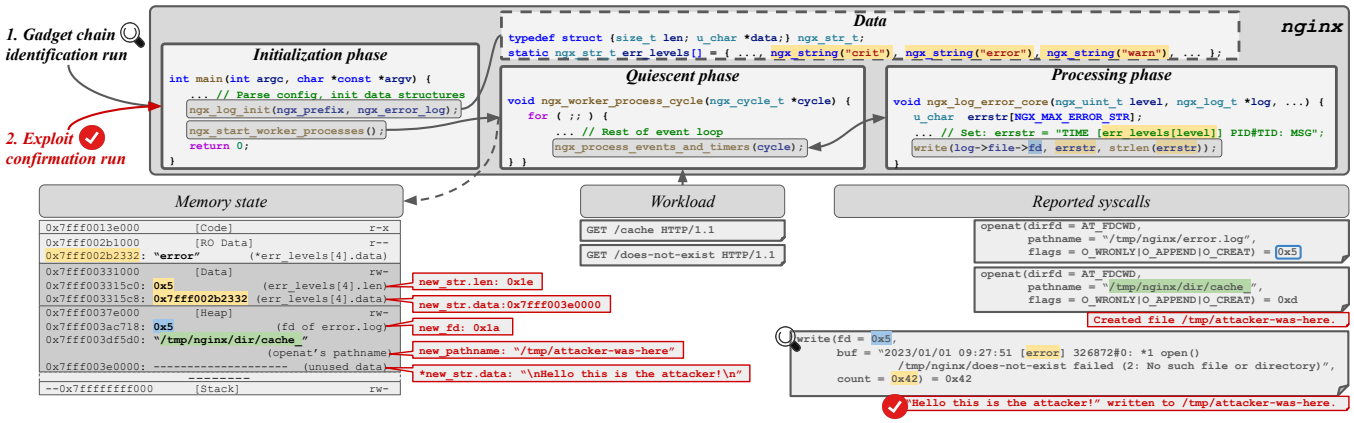

Figure 7: An `openat`-to-`write`-based gadget chain in `nginx` that EINSTEIN identified and built an attack for.

8.2 Bypassing Selective DFI

This case study exploits an `openat` to `write` gadget chain in `nginx`'s error log. Figure 7 walks through how we identify and exploit the gadget with EINSTEIN.

Identification and exploitation. After `nginx` enters its quiescent phase, EINSTEIN taints three `nginx` objects in particular: (1) the `err_levels[]` global array, which contains pointers to logging strings (e.g., `"crit"`, `"error"`, `"warn"`) and their lengths; (2) the pathname of a configuration-defined cache file, which `nginx` opens upon requests for `/cache`; and (3) the FD of `nginx`'s error log. Then, EINSTEIN sends requests to `nginx`, two of which trigger the syscalls of our gadget chain. First, it sends a `GET /cache` request, which causes `nginx` to open the cache file. It opens it via an `openat` with a tainted `pathname`. EINSTEIN then adds the created file to its directly-controllable FD table. Second, EINSTEIN sends a `GET /does-not-exist` request, which causes `nginx` to write an `"error"` message to the error log. It does this via a `write` with a tainted `fd`, `buf`, and `count`. Because the FD argument is tainted, and there is a file in the directly-controllable FD table, EINSTEIN determines that the `write` could be redirected to another file, thereby identifying the chain from the `openat` to the `write`.

EINSTEIN builds an exploit for this by first identifying an identity flow between: (1) `openat`'s `pathname` and the cache pathname on the heap, (2) `write`'s `fd` and the error log's FD on the heap, and (3) `write`'s `buf` and the pointer to the `"error"` string in global data. Then, EINSTEIN builds a "write-what-where on the filesystem" candidate exploit by generating $(addr, val)$ pairs that overwrite: (1) the cache file's pathname to a file `"/tmp/attacker-was-here"`, (2) the error log's FD to the cache file's FD, and (3) the pointer to the `"error"` string to a pointer to a `"Hello this is the attacker"` string. Next, we re-run EINSTEIN to confirm this exploit, but unfortunately, it only writes `"Hello"` to our file. Upon closer inspection as to why, we quickly notice from the tagset of `write`'s `count` argument that it depends on the `"error"` string's length—i.e., `0x5`, thereby explaining why only the first five characters of our target string were written to the file. Our analyzer did not initially target the string length because it does not have an identity dataflow to `write`'s `count`, since their values differ. Hence, we modify our exploit to also overwrite the `err_levels[]` string length to `0x1e`, i.e., the length of our string. As a result, we are able successfully write our entire attacker-specified string to our attacker-specified file.

Discussion. The objective of selective DFI is to only enforce DFI for select *def-use* chains, e.g., for syscall argument *use*s [44]. However, *selective DFI is fundamentally imprecise* because: (1) it leaves many dataflows unsecure (i.e., it is "selective"), and (2) for any complex dataflows it does attempt to secure, it must statically over-approximate the set of legal *def*s for a given *use*, or otherwise risk breaking the target program. EINSTEIN exploits this imprecision because it uses a lightweight dynamic analysis, which encounters no issues with complex dataflows.

Specifically, if the selective DFI's points-to analysis cannot determine all the possible *def*s for some loaded data—e.g., due to notoriously difficult interprocedural analyses, pointer aliasing problems, etc. [38]—then it must assume that *any def* is legal. For example, in our gadget, the dataflow from the *def* of the `"error"` string to the *use* of `write`'s `buf` is difficult to resolve: `err_levels[]` has four address-taken locations that may be passed interprocedurally up to five calls deep (e.g., to a custom implementation of the variadic `sprintf`). Hence, securing every possible *def* for `write`'s `buf` is non-trivial, and over-approximation would likely incur a significant performance overhead. Unsurprisingly, recent work that applies selective DFI to syscall arguments does not attempt to secure `write`s [44]. Finally, we note that this gadget is also resistant to syscall filtering because numerous legitimate program features rely on `openat` and `write`.

9 Limitations

Coverage. The coverage of our analysis is limited for a few reasons. First, like any dynamic analysis, our code coverage is not complete. Nonetheless, we still find many exploits, and

as Section 7.2 explains, further work into improving code coverage would also identify more attacks. Second, like other DTA engines, we do not track implicit flows. However, we consider this acceptable, because implicit flows are less useful to an attacker since they typically only propagate one bit of data. Third, EINSTEIN does not build every kind of data-only attack, e.g., those that aim for Turing-completeness. Instead, EINSTEIN aims for a simpler, but more powerful primitive: controllable syscalls. Identifying and eliminating these will raise the bar for attackers significantly.

Constraints. Like other approaches that use DTA, our analysis is limited as it does not track all possible dataflow constraints in two ways. First, it does not track exactly how arbitrary program operations (e.g., arithmetic) affects attacker data. However, this is not an issue for us, because our identity dataflow analysis filters out these more complex gadgets, and we are still left with plenty of candidate gadgets. Second, it does not track exactly how attacker data affects the program's path. However, this is also not an issue, because our exploit confirmation filters out these more complex candidate exploits, and we are still left with plenty of working exploits.

10 Conclusion

We presented EINSTEIN, a lightweight approach to building practical attacks that are out of reach of prior solutions. We use EINSTEIN to build hundreds of data-only attacks and present two low-effort case studies that bypass state-of-the-art defenses. We conclude that data-only attacks are well within reach of attackers, and hence, vendors should consider stronger defenses such as full DFI and memory safety.

Acknowledgments

We would like to thank the anonymous reviewers for their feedback. We would also like to thank Alyssa Milburn for helping with the initial shadow memory implementation and Mans van Someren for fixing a number of libdft bugs. This work was supported by the Dutch Research Council (NWO) through project "INTERSECT" and "Theseus".

A Implementation Digression

In this appendix, we discuss the features we added and merged into our DTA engine to make it general-purpose and extendable. We base the implementation of our DTA engine on libdft [47], a DTA engine built on top of Intel Pin [53], which was released more than 10 years ago.

Merged features. Since libdft's release, many forks of it have emerged, each adding their own features to suite their own particular analyses [25, 69, 82, 88]. Unfortunately, no single version of libdft exists that supports all of these features, so we merge many of them into one *general-purpose* DTA engine, i.e., our libdft variant. In particular, we merge support for: (1) 64-bit instructions; (2) load pointer propagation, i.e., on a load instruction, propagating not only the tag of the loaded data to the output, but also the tag of the pointer; (3) tagging all data with its own address; (4) an interface to the process's memory map to e.g., check whether some memory segment is writable; and (5) a uniform logging interface, which supports applications that are multi-threaded and applications that redirect standard logging interfaces (e.g., `nginx`).

Added features. We also add several new features to libdft. The first set of features we add provide scalability (as discussed in Section 5.1). In particular, we add: (1) `userfaultfd`-based tagmap initialization, (2) bounded array-based tagsets, and (3) a shadow memory-based tagmap.

Figure 8 describes the layout of our shadow memory implementation. At a high level, the region from `MAIN_START` to `MAIN_END` is the main address space, and the region from `SHADOW_START` to `SHADOW_END` is the corresponding shadow address space. Because the region from `MAIN_START` to `MAIN_START+RESERVED_BYTES` would map into null shadow memory, we cannot use it for program memory. Hence, we reserve this region to store custom tags. For example, to taint a file read (as Angora does [25]), we can create unique tags in this reserved region for each byte of a file. Hence, by supporting custom, unique tags—e.g., for each byte of a file, network read, etc.—our shadow memory provides an *expressive* interface for other analyses.

```
==== 0x000000000000: SHADOW_START
...
==== 0x000000100000: SHADOW_START+RESERVED_BYTES
...
...
...
==== 0x............: SHADOW_END, MAIN_START
...
==== 0x............: MAIN_START+RESERVED_BYTES
...
...
==== 0x7fff00101000: BIN_START
...
==== 0x800000000000: MAIN_END
```

Figure 8: Shadow memory layout.

The shadow memory layout assumes the target program is an `x86_64` binary built as position-independent (the default for most compilers), so that its stack and `mmap_base` are at the end of the address space. Next, the layout requires us to relink the target program such that its base address is at `BIN_START`. The value of `RESERVED_BYTES` and `SHADOW_END` depend on the tag size—i.e., the number of colors per tagset, and the size of each color (which depends on whether pointer tag compression is enabled).

The second set of features we add provide other various functionalities. First, we add support for recording memory snapshots. We do this by invoking `gcore` when tainting all memory to produce a core dump. Because the shadow memory comprises a significant portion of the address space, we advise the kernel to not dump shadow pages so that the core dumps are not too large. Moreover, to aid our exploitation tooling, we use `lldb` to also log all runtime symbol information when the snapshot is recorded. Second, we add an interface to receive miscellaneous runtime info. We use this interface to receive the most recently executed line of the program driver, so that we can include it in the syscall reports, thereby aiding our exploitation tooling in knowing the workload that covers a particular gadget chain. Third, we fix many instruction-level taint propagation rules, e.g., by: (1) considering the byte-level semantics of masking operations (e.g., `AND`, `OR`); (2) adding support for various vector instructions (e.g., `VZEROUPPER`, `PUNPCKLQDQ`); (3) correctly handling various x86-64 quirks (e.g., zero-extending a 32-bit `MOV`, but not an 8-, 16-, or 64-bit `MOV`); etc. Fourth, we update our libdft variant to use the newest version of Pin and to support newer syscalls (e.g., `execveat`, `openat2`).

B Control Data Attack Surface Comparison

In this appendix, we compare our *non-control data* attack surface to the *control data* attack surface. To do so, we re-implement the taint policies of Newton [88] (with our taint engine) for identifying control-flow hijacking attacks, and re-run our evaluation. We note that our non-control data gadgets are inherently more powerful than control data gadgets, because even if an attacker can divert a branch, the attacker still needs to divert it to some target code that e.g., invokes a syscall with controllable arguments. In contrast, our non-control data gadgets already are syscalls with controllable arguments.

Table 4 presents the number of non-control data gadgets (i.e., syscalls with attacker-tainted arguments) and control data gadgets (i.e., indirect branches with an attacker-tainted branch target) that we identified in each target program, as well as the percentage which have identity flows. Just as previous work does [88], we count indirect branch sites, rather than backtraces; however, counting backtraces give us similar results. We distinguish control data gadgets based on the type of branch target, i.e., whether it is a register or memory operand.

First, we observe that control data gadget with memory operands have higher rates of identity flows than those with register operands. Upon closer inspection, we notice this is because register operands tend be more constrained, as they are typically used for branches with a bounded set of targets (e.g., switch statements), whereas memory operands are typically used for branches with a relatively unbounded set of targets (e.g., indirect calls). Second, we observe that the rates of identity flows for non-control data gadgets and control data gadgets with memory operands are roughly similar. This is unsurprising, because a program treats many types of long-lived data as "immutable", regardless of whether it is control data (e.g., function pointers), or non-control data (e.g., strings). Hence, we conclude that our lightweight identity flow-based analysis is applicable to domains beyond data-only attacks.

Don't Waste My Efforts: Pruning Redundant Sanitizer Checks by Developer-Implemented Type Checks

Abstract

Type confusion occurs when C or C++ code accesses an object after casting it to an incompatible type. The security impacts of type confusion vulnerabilities are significant, potentially leading to system crashes or even arbitrary code execution. To mitigate these security threats, both static and dynamic approaches have been developed to detect type confusion bugs. However, static approaches can suffer from excessive false positives, while existing dynamic approaches track type information for each object to enable safety checking at each cast, introducing a high runtime overhead.

In this paper, we present a novel tool T-PRUNIFY to reduce the overhead of dynamic type confusion sanitizers. We observe that in large complex C++ projects, to prevent type confusion bugs, developers often add their own encoding of runtime type information (RTTI) into classes, to enable efficient runtime type checks before casts. T-PRUNIFY works by first identifying these custom RTTI in classes, automatically determining the relationship between field and method return values and the concrete types of corresponding objects. Based on these custom RTTI, T-PRUNIFY can identify cases where a cast is protected by developer-written type checks that guarantee the safety of the cast. Consequently, it can safely remove sanitizer instrumentation for such casts, reducing performance overhead. We evaluate T-PRUNIFY based on HexType, a state-of-the-art type confusion sanitizer that supports extensive C++ projects such as Google Chrome. Our findings demonstrate that our method significantly lowers HexType's average overhead by 25% to 75% in large C++ programs, marking a substantial enhancement in performance.

1 Introduction

Type confusion [3] is a critical type of vulnerability common in type-unsafe programming languages such as C/C++. It occurs when the program allocates or initializes a resource such as a pointer or object using one type, but later accesses that resource using a type that is incompatible with the original type. When a program experiences type confusion, it can result in undesirable behaviors such as a system crash [10], information leakage [13], and even arbitrary code execution [11].

To mitigate the threats introduced by type confusion vulnerabilities, both static and dynamic analyses have been applied. For example, static type inference and pointer analysis have been developed to determine if a type cast is safe [9]. However, static approaches can generate a large number of false positives because of their inherent imprecision and over-approximation.

Besides static analysis, sanitizer-style runtime checks have also been proposed [19, 22, 24, 26, 30, 31]. The key idea is simple. Instead of checking for type compatibility at compile time, the sanitizer instruments the program and tracks the type of objects at runtime in order to perform precise type checks. Clearly, such approaches are more precise than static approaches, but are also more expensive as they incur runtime overhead. Although these type confusion sanitizers are faster than C++'s built in `dynamic_cast` [22, 24, 26], their runtime overhead is still too high for deployment in production systems.

One promising direction to reduce runtime overhead is to statically recognize safe casts and avoid instrumentation selectively. For example, CaVer [26] and HexType [24] track data flow via pointers from object allocation sites to cast sites; if the cast type is a supertype of the allocation site type, then the corresponding runtime check can be eliminated. However, as discussed in [9], static analyses are in general imprecise and will often make conservative inferences, i.e., treating a safe type cast as potentially unsafe. For example, pointer analysis, relied upon by CaVer [26], is a known hard problem in static analysis. As a result, many unnecessary runtime checks cannot be eliminated.

In this paper, we make the observation that *pointer analysis is not the only way to show a cast is safe*. In particular, we find that developers often encode custom runtime type information (RTTI) directly into a structure or class, especially in complex C++ class hierarchies, to facilitate their own type checks. For example, Chrome defines a class `BasicShape` and many

classes inherit from this class, such as `BasicShapeCircle`, `BasicShapeEllipse` and `BasicShapePolygon`. Those subclasses override a virtual function `GetType()`, which returns enumeration constants `kBasicShapeCircleType`, `kBasicShapeEllipseType`, and `kBasicShapePolygonType`, respectively. In addition, we find that before casting a pointer `BasicShape *basic_shape` to a subclass, developers usually insert a type check using `GetType()`, e.g., checking that `basic_shape->GetType() == kBasicShapeCircle` before casting to `BasicShapeCircle`. Such checks ensure the downcast is safe – and are often voluntarily inserted to avoid type confusion bugs [5, 6, 8].

Our key insight is to leverage these developer-implemented type checks to discover opportunities to remove redundant sanitizer checks for type casts. Achieving this goal requires addressing two key challenges. First, we must *identify* developer-encoded RTTI and the corresponding type checks, and *validate* the correspondence between these checks and the class hierarchy. Developer-written type checks may involve arbitrary logic and can vary from one class hierarchy to another, and the source code does not explicitly identify which logic serves as a type check. To this end, we conduct an exploratory investigation of real-world programming conventions in Chrome, distilling them into several general patterns. The most-common patterns encoded custom RTTI as a set of predefined values (i.e., constants) in class definitions. By performing a class-hierarchy-wide static analysis, we could track the definitions and uses of such values and thereby automatically deduce developer-inserted custom RTTI and type checks. Note that our analysis *verifies* the correspondence between the custom RTTI and the type hierarchy – each class needs to take a unique value, allowing it to be distinguished from others in the same hierarchy.

The second key challenge is to discover where a type cast is correctly guarded by a custom type check, thereby proving the cast cannot fail and enabling the removal of redundant sanitizer checks. We tackle this challenge by using a flow- and field-sensitive intra-procedural analysis to track the refined type suggested by developer-implemented type checks, validating if a downcast is always safe under all execution paths.

Based on the above insights, we implemented our techniques in an automated solution called T-PRUNIFY, that conducts static analyses for C++ programs to (1) extract custom RTTI based on understanding and surveying diverse class hierarchies in popular applications, (2) identify developer-implemented type checks based on the identified type information, and (3) further validate the developer-implemented type checks. In addition, T-PRUNIFY also uses the results to prune unnecessary sanitizer checks. Our analysis is designed to be sound with multiple verifications throughout the process and will conservatively prune sanitizer checks only when the developer-implemented checks are deemed safe. We evaluated our solution on the SPEC CPU 2006 C++ programs, LLVM toolchain and Chromium browser (the open-sourced version of Google Chrome), one of the largest C++ programs, which is also known to be prone to type-confusion vulnerabilities [14–17]. The results showed that T-PRUNIFY can indeed prune a large number of sanitizer checks safely and reduce the runtime performance overhead compared to the state-of-the-art sanitizer-based solution.

In summary, our main contributions of this paper are:

- We identify developer-inserted custom runtime type checks as a previously-overlooked source of opportunity to reduce the performance overhead of type confusion mitigation techniques.
- We develop a custom solution to (1) automatically identify developer-implemented custom runtime type checks and (2) leverage them to prove the safety of type casting in C++ programs.
- We develop T-PRUNIFY that packages the insight into a fully-automated system. To facilitate further research in this direction, we have made the system open source and accessible at `https://github.com/seclab-ucr/TPrunify`.
- We evaluate T-PRUNIFY against a state-of-the-art type sanitizer Hextype [24] against popular open-source projects and showed that the relative runtime overhead reductions range from 25% to 75% for Chromium under standard benchmarks, and 35.19% for the LLVM Clang toolchain.

2 Background and Motivation

In this section, we start with some basic background relevant to type confusion. First, we describe the C++ type hierarchy, casting operations and type confusion vulnerabilities. Then we illustrate, with examples, how previous type confusion checks are performed statically or dynamically (including sanitizer checks executed at runtime), and why they are inefficient. This will then motivate the design and implementation of T-PRUNIFY.

2.1 Type Casting in C++

C++ is an object-oriented programming language, which allows programmers to define new types as classes. A class can inherit from multiple ancestor classes. Descendant classes inherit members (methods and variables) from their ancestor(s) and can optionally define additional members [28]. Generally speaking, upcasts (i.e., casting a pointer of a derived class to a pointer of an ancestor class) are considered safe, because the memory scope an ancestor pointer can access is strictly smaller than the memory scope of a descendent class; however, downcasts (i.e., casting a pointer of an ancestor class to a pointer of a descendent class) may introduce memory corruption vulnerabilities, when the underlying allocated memory object has a smaller memory scope than the destination type

demands. Figure 1 illustrates such an example; the code allocates a pointer of the base class and subsequently casts it to the derived class (which is always at least as big as the base class). In this example, the derived class includes an additional field `y`, and accessing this field on the improperly-casted `Base` pointer leads to an out-of-bounds memory access.

```
struct Base {int x;};
struct Derived : Base {int y;};
Base *base = new Base();
Derived *derived;
derived = static_cast<Derived*>(base);
derived->y; //<-error
```

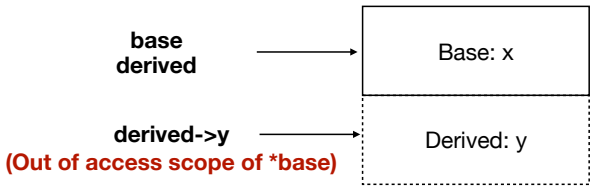

Figure 1: A code example and diagram of a type confusion problem where a base class is incorrectly accessed using a pointer to a derived class. The static_cast results in type confusion and accessing the field y is out of the access scope of type `Base`. In the class definition, the members are public, we ignore it to save space.

C++ provides four built-in type casting operations, including `reinterpret_cast`, `static_cast`, `dynamic_cast`, and `const_cast`, which we describe below:

`reinterpret_cast<dest>(src)` is similar to an explicit cast in C, which allows conversion between any two arbitrary types, regardless of their compatibility. Although this primitive grants flexibility, the lack of safety checks can lead to type confusion bugs.

`static_cast<dest>(src)` casts a pointer/object of `src` type to a pointer/object of the `dst` type. Unlike `reinterpret_cast`, `static_cast` performs lightweight compile-time type checking to avoid bad casting. Specifically, the compiler will verify whether the source class and the destination class are within the same class hierarchy. However, it cannot detect an unsafe downcast and thus, can still result in type confusion bugs.

`dynamic_cast<dest>(src)` can avoid unsafe downcasts because it performs a runtime type check to make sure the allocation type of the source object is actually compatible with the destination type, using C++'s own runtime type information (RTTI). To perform a runtime type check, `dynamic_cast` first locates the RTTI of the source object from a pointer stored in its virtual function table. The RTTI contains a null-terminated byte string of the mangled type name as the type information of the current type, and one or more pointers to its base classes' RTTI. To check for type compatibility, `dynamic_cast` recursively compares the mangled name of all base classes of the source object with the mangled name of the destination type. If a match is found, the casting is valid and `dynamic_cast` returns a valid pointer; otherwise a null pointer is returned. Since the type check involves slow string comparison and possible recursive traversal of the base classes' RTTI, using `dynamic_cast` operators can be 90 times slower than using `static_cast` [26]. Due to its performance overhead, `dynamic_cast` is intentionally avoided in release builds of well-developed applications such as Chrome.

`const_cast<dest>(src)` simply drops the `const` qualifier of the source object. Since it does not actually modify the type itself, it is not of interest to us.

For backward compatibility, C++ compilers also support C-style explicit casts. When encountered, the compiler will try the following sequence of casts one after another until the program can be compiled without an error: (1) `const_cast`, (2) `static_cast`, and (3) `reinterpret_cast`.

2.2 Type Confusion Sanitizers

Type confusion sanitizers [22, 24, 26] aim to overcome two limitations of `dynamic_cast`: (1) its high runtime performance overhead and (2) its limited protection scope (i.e., it only supports classes with virtual function tables). To reduce the runtime overhead, type confusion sanitizers typically employ two optimizations. First, instead of storing the type information as a string, they store a unique hash (guaranteed at link time) of the mangled name, so that a compatibility check can be done using an integer comparison instead of a string comparison. Second, they compact all base classes' type information into a single RTTI, where the hash values are also sorted for faster binary search. To overcome the second limitation, type confusion sanitizers store the RTTI of an object in a disjoint lookup table. To perform runtime type checks, type confusion sanitizers first extract the type hierarchies during compile time and emit RTTI that records all the compatible types of a class (i.e., all ancestor classes, including itself). At runtime, after an object is allocated, type confusion sanitizers associate the object with its RTTI (e.g., by using a hash table where the key is the address of the object and the value is the RTTI entry). At the cast site, the sanitizer retrieves the RTTI and looks for a matching hash value among all compatible types with the destination type.

2.3 C++ Casting with Custom Run Time Type Information (RTTI)

Although designers of type confusion sanitizers have spent lots of effort trying to reduce the runtime overhead, these sanitizers still introduce significant overhead. For example, during our evaluation, a state-of-the-art type confusion sanitizer HexType [24] still introduces a $10.2\% - 65.7\%$ overhead on Chromium benchmarks. A large portion of this overhead comes from its lookup of RTTI. Specifically, to maintain

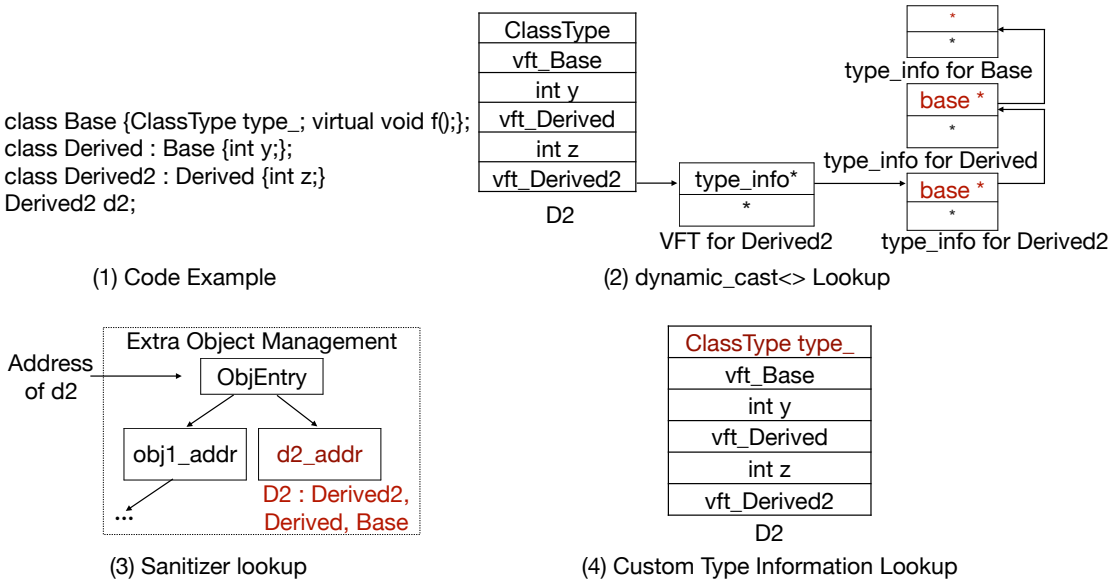

Figure 2: The code example and three different methods for verifying the safety of a type cast. (2) The `dyn_cast` method validates the safety of the cast by utilizing the type information stored in the virtual table. (3) Sanitizer approaches perform type checks by tracking and extracting the type information stored in a disjoint data set. (4) Developers perform the type checks directly through the custom RTTI defined within the class hierarchy.

binary compatibility, type confusion sanitizers use decoupled RTTI (i.e., the RTTI of an object is stored disjointedly at another memory location). As a result, they need extra steps to find the RTTI. In practice, large C++ projects like the Chromium browser and the LLVM compiler frameworks prefer developer-inserted custom RTTI and type checks to prevent type confusion vulnerabilities. Because such RTTI is tightly coupled with an object (e.g., as a member field or a special virtual function), runtime type checking is much more efficient than both `dynamic_cast` and type confusion sanitizers.

Figure 2 visualizes the differences between the three different approaches, i.e., `dynamic_cast`, type confusion sanitizers, and developer-inserted RTTI. In (1), a base class and two derived classes are defined, with one derived class inheriting from `Base` and the other from `Derived`. The `ClassType` is a predefined enumeration variable. An object `d2` of the `Derived2` class is then instantiated. In (2), the memory layout of the `d2` object is depicted. When a `dynamic_cast<dst>(d2)` operation is executed, it first locates the RTTI of the object, which is stored as the first item in the virtual function table (VFT). By following the pointer, the mangled name of the base class is extracted and compared with type name of `dst`. If a match is found, the casting is considered valid. However, this lookup process involves traversing a linked list, making it relatively slow. The sanitizers' lookup is demonstrated in (3). After obtaining the address of `d2`, it refers to an additional data structure specifically designed for efficient lookup. This data structure stores all compatible types of the runtime object, including `D2`. By utilizing caching, the lookup process becomes significantly faster compared to the `dynamic_cast` operation. Finally, in (4), the lookup process is illustrated when the class encodes custom RTTI. In this case, the field `type_` which holds the custom RTTI is directly accessed, and a value comparison is performed, resulting in the fastest lookup method.

In fact, during our investigation, we found that most of the type confusion vulnerabilities in the Chrome browser have been preemptively fixed by means of developer-implemented type checks with custom RTTI [5, 6, 8]. This motivates us to develop T-PRUNIFY. For instance, CVE-2021-30561 [12] is a type confusion vulnerability in Chrome. It allows a remote attacker to potentially exploit heap corruption via a crafted HTML page. Figure 3 shows the vulnerability and the main patch. Inside function `WasmJs::InstallConditionalFeatures()`, the variable `maybe_webassembly` is retrieved as a type of `Object`; it is then directly cast into a `JSObject` and used later. However, the object retrieved could in fact be of types other than `JSObject`, which causes a type confusion vulnerability. The patch fixed the bug by adding a custom type check `webassembly_obj->IsJSObject()` at line 15 to ensure that the type is of `JSObject` before proceeding to the subsequent type cast.

```
/* Main patch for CVE-2021-3056,
 * uninteresting code lines are ommited.
 */
void WasmJs::InstallConditionalFeatures(Isolate* isolate,
                                        Handle<Context>
                                        ↪ context) {
-  Handle<JSObject> webassembly = Handle<JSObject>::cast(
-    maybe_webassembly.ToHandleChecked());
+  Handle<Object> webassembly_obj;
+  if (!maybe_webassembly.ToHandle(&webassembly_obj)) {
+    // There is not {WebAssembly} object.
+    // We just return without adding the
+    // {Exception} constructor.
+    return;
+  }
+  if (!webassembly_obj->IsJSObject()) {
+    // The {WebAssembly} object is invalid.
+    // As we cannot add the {Exception}
+    // constructor, we just return.
+    return;
+  }
+  Handle<JSObject> webassembly =
  ↪  Handle<JSObject>::cast(webassembly_obj);
}
```

Figure 3: The simplified patch for CVE-2021-30561

3 Overview of T-PRUNIFY

In cases where developers have already encoded custom runtime type information (RTTI) into C++ classes and implemented their own type checks, we aim to identify and remove redundant type confusion sanitizer checks, thereby reducing sanitizer overhead. To this end, we design and implement a lightweight static analysis tool named T-PRUNIFY that can achieve this goal.

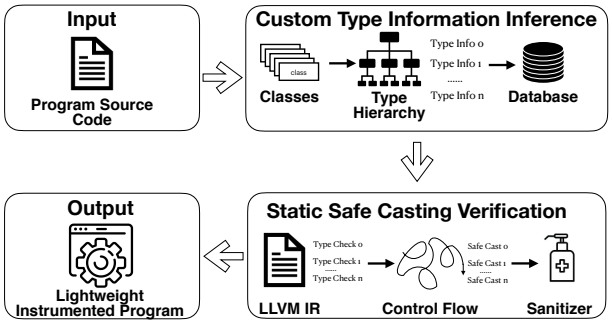

Figure 4: Work flow of T-PRUNIFY.

Figure 4 depicts the workflow of T-PRUNIFY. It consists of two high-level components, which are briefly described below:

1. Custom Type Check Inference. In this step, T-PRUNIFY takes the source code of the target program as input and attempts to recognize all the custom type checks inserted by developers. To do so, we first infer custom runtime type information (RTTI) encoded by developers by analyzing class definitions. The challenge lies in the lack of a unified standard for encoding or annotating such custom type information, which can vary across modules and class hierarchies in the program. Therefore, we need to have a comprehensive understanding of the various patterns developers can choose to encode custom types. In our solution, we perform an offline manual investigation of various class hierarchies in Chrome, and summarize them into three common patterns. With these patterns, T-PRUNIFY performs static analysis to automatically recognize and validate custom RTTI in classes, and then stores them in a database. Based on the identified custom RTTI, we then recognize developer-implemented type checks (e.g., in the form of `if` statements) as operations over the type information.

2. Static Safe Casting Verification. Based on the identified custom type checks, we then try to prove statically whether a downcast is always safe (i.e., the destination class is always compatible with the class indicated by the type check under all execution paths). The challenge is that type casts may not be performed immediately after a type check, and furthermore the type check may not always be correct. To tackle this challenge, T-PRUNIFY employs an intra-procedural flow- and field-sensitive static analysis to track the refined type suggested by developer-implemented type checks, and validate if a downcast will be safe. Once T-PRUNIFY determines a cast is safe, it will instruct a sanitizer to not insert another redundant type check at compile time. In the end, the output is a hardened program that enjoys the same level of security guarantee but with a much lower runtime overhead.

4 Custom Type Check Inference

As mentioned above, T-PRUNIFY uses existing developer-inserted custom type checks to eliminate type confusion sanitizer-induced checks. In this section, we describe how to identify developer-inserted custom type checks.

4.1 Systematic Investigation

Developers can choose to explicitly encode the runtime type information (RTTI) in a class definition directly. However, such encoding can be ad-hoc as it is entirely up to the developers to design a scheme to differentiate types. To understand how custom RTTI are commonly encoded, we conduct a manual investigation of over 100 Chrome hierarchies and identified several common categories as follows.

Category 1: Custom RTTI encoded in a Base Class Field. One way to store type information in C++ is by using a field defined in the base class, which is initialized to a different and unique value in each subclass according to its concrete type. Figure 5 shows part of the type hierarchy that class `CSSValue` belongs to. Class `CSSValue` defines a private member called `class_type_`, which is initialized in the constructor. Three subclasses `CSSImageValue`, `CSSShadowValue`, and `CSSURIValue` initialize this member field through their respec-

```
class CSSValue {
public:
  explicit CSSValue(ClassType class_type)
      : class_type_(class_type) {}
  bool IsImageValue() const {
      return class_type_ == kImageClass; }
  bool IsShadowValue() const {
      return class_type_ == kShadowClass; }
  bool IsURIValue() const {
      return class_type_ == kURIClass; }
private:
  const uint8_t class_type_; // enum ClassType
};
class CSSImageValue : public CSSValue {
public:
  CSSImageValue() : CSSValue(kImageClass) {}
};
class CSSShadowValue : public CSSValue {
public:
  CSSShadowValue() : CSSValue(kShadowClass) {}
};
class CSSURIValue : public CSSValue {
public:
  CSSURIValue() : CSSValue(kURIClass) {}
};
```

Figure 5: An example in Category 1: type information is stored in a member field, which is initialized with a different enumeration constant. Arrow indicates the inheritance relationship.

tive constructors with different values. In this example, the three values, e.g., `kImageClass` are unique enumeration constants. The base class `CSSValue` also defines three utility functions for type checking `IsImageValue()`, `IsShadowValue()`, and `IsURIValue()`.

Category 2: Custom RTTI as a Constant Without Fields. Classes in this category override a virtual method defined in the base class to return different constants to indicate the actual type of the object. Consider the class hierarchy of class `BasicShape` shown in Figure 6, it defines a virtual method `GetType()`. Each subclass overrides this method by returning a different enumeration constant that uniquely identifies its object type. For example, the subclass `BasicShapeCircle` overrides `GetType()` inherited from the base class to return `kBasicShapeCircleType`, which is unique to this subclass.

Category 3: Custom RTTI as a Type Check Function. Classes in this category do not use enumeration constants to indicate custom types; instead, they define custom type check functions. Figure 7 illustrates such an example where a base class `CanvasImageSource` defines a number of virtual methods, like `IsVideoElement()` and `IsCanvasElement()`, which returns `false` by default. The two subclasses: `HTMLVideoElement` and `HTMLCanvasElement` each override the corresponding type check method to return `true`. When the `IsVideoElement()` method is called, it returns `true` only if the object is of class `HTMLVideoElement`. This method, along with its return value `true`, serves as a way to uniquely identify the object type.

```
class BasicShape {
public:
    virtual ShapeType GetType() const = 0;
};
class BasicShapeCircle : public BasicShape {
public:
  ShapeType GetType() const override {
    return kBasicShapeCircleType;
  }
};
class BasicShapeEllipse final : public BasicShape {
public:
   ShapeType GetType() const override {
    return kBasicShapeEllipseType;
   }
};
class BasicShapePolygon final : public BasicShape {
public:
   ShapeType GetType() const override {
        return kBasicShapePolygonType;
   }
};
```

Figure 6: An example in Category 2: the type information returned by a virtual method is overridden in each subclass to return a different enumeration constant.

4.2 Custom RTTI Identification

As the foundation of our solution, we need to construct a precise database that contains custom RTTI for a class hierarchy (i.e., a group of classes that share a base class), referred as *class signatures*, that can uniquely identify a class/type in the hierarchy. In other words, we will construct a map between a class signature and the actual (allocation) type. More specifically, we scan all the source code files (including header files) and look for class hierarchies that match the aforementioned three categories. For the first two categories, we check the following conditions at the syntax level:

1. a unique enumeration constant is either assigned to a member field of each class in the hierarchy, or returned by a virtual method;
2. if a member field is assigned with the constant, the assignment should happen inside the constructor and the field should not be modified once it is initialized.

For the third category, we use the following heuristics:

1. each class in the hierarchy overrides a unique method and changes its return value.
2. each class should have at least one overridden method that returns a unique value not seen in other classes in the hierarchy.

For each class hierarchy (classes that share a base class), we store the unique constant and method (collectively considered as the class signature) and its corresponding class type

```
class CanvasImageSource {
public:
    virtual bool IsVideoElement() const { return false; }
    virtual bool IsCanvasElement() const { return false; }
    virtual bool IsVideoFrame() const { return false; }
};
class HTMLVideoElement : public CanvasImageSource {
public:
    bool IsVideoElement() const override { return true; }
};
class CanvasRenderingContextHost : public
↪ CanvasImageSource {
};
class HTMLCanvasElement : public
↪ CanvasRenderingContextHost {
public:
   bool IsCanvasElement() const override { return true; }
};
class VideoFrame : public CanvasImageSource {
    bool IsVideoFrame() const override { return true;}
}
```

Figure 7: An example in Category 3: type information is encoded as the return value of a custom type checking function that is overridden to return `true` in the corresponding subclass.

```
1  /* Some code snippet for use of custom type information,
2  * uninteresting code lines are ommited.
3  * */
4  std::unique_ptr<Shape> Shape::CreateShape(const
   ↪ BasicShape* basic_shape) {
5    std::unique_ptr<Shape> shape;
6    switch (basic_shape->GetType()) {
7      case BasicShape::kBasicShapeCircleType: {
8        /*To<> is implemented as a static_cast<>*/
9        const BasicShapeCircle* circle =
         ↪ To<BasicShapeCircle>(basic_shape);
10       //...
11     }
12     case BasicShape::kBasicShapeEllipseType: {
13       const BasicShapeEllipse* ellipse =
         ↪ To<BasicShapeEllipse>(basic_shape);
14       //...
15     }
16     case BasicShape::kBasicShapePolygonType: {
17       const BasicShapePolygon* polygon =
         ↪ To<BasicShapePolygon>(basic_shape);
18       //...
19     }
20   }
21 }
```

Figure 8: The simplified code for class `BasicShape`.

in our database. Note that we find that a class hierarchy can sometimes have a subset of classes with signatures while the remaining classes do not have signatures by design. In other words, there may be a "sub-class-hierarchy" within a complete hierarchy that encodes class signatures. To accommodate such cases, we effectively look for such sub-class-hierarchies. As long as the heuristics described above apply to the sub-class-hierarchy, we still infer that it has encoded class signatures.

4.3 Custom Type Check Identification

Given the database, we can perform an analysis to find the type checks in the target program. In general, any statement that uses the custom type information to control the program flow is considered a type check. More specifically, we look for statements that are of the form of `type == c` (including `switch` cases), where the left-hand side can be any expression that evaluates to a previously-recognized type-indicating member variable or type-indicating method, and the right-hand side is a constant. Given that we have mapped each unique constant to a corresponding class type, we can tell exactly which type is checked for in the statement.

Figure 8 shows an example of type checks relating to class `BasicShape`, which is described in Figure 6; the type check compares `basic_shape->GetType()` against enumeration constants that we record in the database (e.g., `kBasicShapeCircleType`), and then jump to different program branches. T-PRUNIFY can identify each switch case as a type check, and determine that the type of object `basic_shape` is `BasicShapeCircle` between line 7 and line 11. We also discuss how Chrome sometimes uses custom C++ template expressions to perform type checks in §6.

Note that we find rare cases where a type check would not look like a straight equality comparison in the form of `type == c`. Instead, it can use inequality comparisons, e.g., `>=` or `<=`. We do not currently recognize such type checks and leave them as future work.

5 Static Safe Casting Verification

After constructing the database of custom type information and identifying the custom type checks in the program, the next step is to determine whether the type casts are actually safe, i.e., sufficiently protected by those checks. At a high level, given a type check, we analyze all the type cast statements that are dominated by the type check. If the destination type in the type cast statement is compatible with the checked type, we consider it a safe type cast.

There are several considerations in performing such an analysis. First, type casts do not always happen immediately after a type check, and the pointer used for the type check may not be the same one that is used for type casts. Therefore, we perform a flow-sensitive and field-sensitive intra-procedural pointer analysis to make sure that the pointer points to the same object at the type check and the type cast. For example, the casting at line 13 in Figure 9 is safe because `case1` and `base` point to the same object.

Second, the pointer analysis needs to consider different execution paths and summarize possible types along all execution paths. Therefore, T-PRUNIFY will only determine a casting as safe if all types are compatible with the destination

```
1  class Base;
2  class Sub : Base;
3  class SubSub: Base;
4  // operator isa<>() is an identified type check
5  void foo(Base *base, Base *other) {
6    Base *case1, *case2, *case3, case4;
7    Sub *sub; SubSub *subsub;
8    case1 = case2 = case3 = case4 = base;
9    if (isa<Sub*>(base)) {
10     // case1: check is done using base
11     // but casting is done using case1
12     // need to know base alias with case1
13     sub = static_cast<Sub*>(case1); // SAFE
14     if (other != nullptr) {
15       case2 = other;
16     }
17     // case2: may point to both 'other' of Base* type
18     // and base of Sub* type (due to the check)
19     // Base* is not compatible with Sub*
20     sub = static_cast<Sub*>(case2); // possibly UNSAFE
21     // case3: the check is insffucient
22     // previous check only indicate base if of Sub* type
23     // not compatible with SubSub*
24     subsub = static_cast<SubSub*>(case3); // possibly
       ↪ UNSAFE
25     if (isa<SubSub*>(base)) {
26       // case4: continuous refinement
27       // after this check, we know base is of
28       // SubSub* type
29       subsub = static_cast<SubSub*>(case4); // SAFE
30     }
31   }
32 }
```

Figure 9: Different corner cases need to be considered when proving when a type cast is safe.

type. For example, T-PRUNIFY cannot prove that the casting at line 20 in Figure 9 is safe. This is because `case2` *may* point to both an object of `Sub` type due to the type check at line 9, and an object of `Base` type due to the pointer reassignment at line 15. As not all aliased objects are compatible with the destination type `Sub*`, the casting is potentially unsafe and needs an additional runtime check.

Third, it is possible that the type check is insufficient in protecting subsequent type casts, e.g., the target of the type cast is not compatible with the type checked. Therefore, T-PRUNIFY does not blindly trust a custom type check; it also performs a type compatibility check to ensure that the refined type suggested by the type check is indeed compatible with the destination type of cast. If T-PRUNIFY cannot determine the casting is safe, it acts conservatively and will not eliminate a sanitizer check. This is because such cases can potentially be real type confusion bugs. For example, T-PRUNIFY cannot prove the casting at line 24 in Figure 9 as safe, because the check at line 9 only indicates `case3`, which is a must-alias with `base`, is of type `Sub*`, which is not compatible with type `SubSub*`.

Fourth, the analysis should consider multiple type checks that gradually narrow down the type to a more specific type (i.e., subclass). This also means the analysis should be flow-sensitive. For example, the casting at line 29 in Figure 9 is safe, because after the check at line 25, the type of `base` is further narrowed down to `SubSub*`. However, without a flow-sensitive analysis, one cannot be sure `base`'s type must be `SubSub*`.

Finally, type casts can be performed in a separate function from the function that performed the type check. For example, the type cast may happen in a callee of a caller that performs the type check. In such cases, we cannot conclude that the type cast is safe simply because one caller has performed a safe type check. Instead, we need to analyze all callers to make sure safe type checks are always present before the type cast. In our current design, we perform only an intra-procedural analysis that makes sure the type cast happens in the same function that performs the type check. We consider this a conservative solution and will extend it to the inter-procedural case in the future.

In the end, once T-PRUNIFY finds a safe casting, it will inform an existing type confusion sanitizer not to emit redundant type checks during the compilation.

6 Implementation

In this section, we describe several key implementation details. Overall, we implement T-PRUNIFY on top of the libclang library and LLVM (v14.0.5). The implementation consists of 9,652 lines of code in total. Specifically, we implement the component "custom runtime type information inference" using libclang by analyzing the source code of the target program (as certain information like the C++ class hierarchies is preserved better at the source code level). We implement the component "static safe casting verification" using LLVM passes as LLVM is more appropriate for pointer analysis. Since our analysis spans source code and LLVM IR, we need to pass intermediate analysis results from source code level to the IR level, which we will describe in this section. In addition, we modified a state-of-the-art type confusion sanitizer, HexType [24], to facilitate the evaluation of T-PRUNIFY.

Class Hierarchy Construction. The C++ compiler front-end like Clang can accurately parse the C++ class hierarchy. However, as the LLVM IR language is generic (i.e., needs to support different source languages) and is relatively low level, the C++ class hierarchies are not explicitly stored at the IR level. Therefore, we implement a Clang plugin to store the C++ class hierarchies (i.e., inheritance relations and type compatibility) and store them for further use.

Class Signature Database Building. This part is done by analyzing the source code of a target program directly (instead of LLVM IR). Specifically, we use libclang's python binding. Besides missing the class hierarchy information at the LLVM

IR level, another reason for source code analysis is that enumeration constants at C/C++ level will be lowered to integer constants thus losing their semantic information and become indistinguishable from other integer constants. libclang allows the user to iterate the abstract syntax tree (AST) to get compilation time information (e.g., the type of the variable, the name of the variable, the type of the functions). Using libclang, we iterate through the AST to (1) extract enumeration constants used to assist identification of custom runtime type information (see §4 for details), and (2) record the use of these constants (e.g., assignment, comparison, return value).

Feeding Source Code Analysis Results to the LLVM Analysis. The class signature database stores variable names, method names, and enumeration constants to assist identification of custom type checks. However, at the LLVM IR level, names of C++ virtual methods are available only in type definitions. At method call sites, virtual methods will be lowered to indirect calls, thus losing the source code level semantics. For example, a simple method call of `basic_shape->GetType()` would look like the following in LLVM IR (simplified for reading):

```
%41 = getelementptr (%"class.blink::BasicShape"*)** %40, 5
%42 = load i32 (%"class.blink::BasicShape"*)** %41
%43 = call noundef i32 %42(%"class.blink::BasicShape"* %0)
  switch i32 %43, label %342 [
  ...
```

To overcome this issue, we modified the Clang++ front-end to annotate LLVM IR with method names. In the above example, our annotation would label `%42` as `GetType()`. The IR snippet is shown as:

```
@.str.2 = "blink::BasicShape::GetType"
%vfn = getelementptr (%"class.blink::BasicShape"*)** %vtable, 5
%10 = load i32 (%"class.blink::BasicShape"*)** %vfn
%call31 = call noundef i32 %10(%basic_shape)
%11 = call i32 @llvm.annotation(i32 %call31, (@.str.2))
 switch i32 %call31, label %sw.default [
 ...
```

The `%vtable` is the equivalent pointer as `%40` before the annotation.

Manually-Summarized Type Checks We find that some subsystems of Chrome choose to use custom C++ templates to implement type checks. For example, we have seen `IsA<T>` frequently which operates as a type check for type `T`. Behind the template, different classes can choose to implement it differently. Since our solution to recognize type checks is by analyzing the source code, we currently recognize these statements specifically through manually-curated domain knowledge. Technically, we could pre-process the source code into a version without templates and then perform our follow-up analysis. However, due to implementation issues, we were not able to succeed at this point. We leave this as our future work.

7 Evaluation

To assess the extent of custom Run-Time Type Information (RTTI) usage and the effectiveness of T-PRUNIFY, we conducted a comprehensive examination of open-source C/C++ software. Subsequently, we carried out a systematic evaluation with the aim of addressing the following research inquiries:

- **RQ1:** How prevalent is custom RTTI?
- **RQ2:** How many casts can be classified by T-PRUNIFY as safe casts out of all the downcast operations?
- **RQ3:** How accurate is T-PRUNIFY in identifying classes with custom RTTI, type checks, and safe casts? In other words, we measure the false negatives and false positives of T-PRUNIFY.
- **RQ4:** How much runtime overhead can T-PRUNIFY improve by pruning unnecessary sanitzier checks?

Experimental Setting. All evaluations are conducted on machines equipped with Intel(R) Xeon(R) Gold 6248 CPU processors and 1024GB RAM, running on a 64-bit Ubuntu 18.04.6 LTS operating system.

Evaluation Target and Experimental Setup. To investigate the prevalence of custom RTTI, we sampled open sourced C/C++ programs with large code bases. Then, we applied T-PRUNIFY to the following programs: the SPEC CPU2006 C++ program, Chromium and the LLVM toolchain. We chose Chromium and the LLVM toolchain as evaluation targets because they are complex, large-scale, and well-engineered pieces of software. If we show that our analysis if effective on them, we argue that it should also work on other targets, as long as the project leverages developer-inserted custom runtime type information (RTTI) to avoid unsafe castings.

In addition, unlike smaller programs that may not have complex class hierarchies (and hence, few developer-implemented type checks), according to our analysis, both Chromium and LLVM source code indeed have many complex class hierarchies and a large number of developer-implemented type checks. Therefore, we believe they represent ideal benchmarks to validate the ideas proposed in this paper. We believe that other large-scale programs would also similarly benefit from our solution.

We design experiments by compiling those programs into three versions: the original program (original) without any instrumentation, the fully HexType-instrumented program (`program-hextype`), and the program with reduced instrumentation after applying T-PRUNIFY (`program- T-Prunify`). For `program-hexytpe` and `program- T-Prunify`, we did not instrument libc++ as the standard C++ library because (1) we consider it as safe and (2) it does not include any custom RTTI.

HexType Configurations. The original HexType [24] was implemented based on llvm-3.9.0, which is no longer compatible with the Chromium version we tested. Therefore, we ported it to llvm-14.0.5, which could be used to compile the target Chromium we evaluated. When assessing the overhead, we considered all the optimizations implemented by HexType, including the elimination of checks for safe casts that can be verified during compilation time. We also apply this HexType version when evaluating SPEC CPU2006 and the LLVM toolchain.

Benchmarks. In order to effectively showcase the performance improvements achieved through the use of T-PRUNIFY, we provide further details on the benchmarks used in our experiments. SPEC CPU is a well-established benchmark, and we use the running time to represent the performance. For Chromium, we chose three different benchmarks, namely Speedometer, JetStream2, and Motion Mark [4] to exercise different parts of a browser. Speedometer is a benchmark that measures the responsiveness of web applications by simulating user interactions with the browser (e.g., DOM manipulation). JetStream2 is a comprehensive benchmark suite that measures the performance of JavaScript and WebAssembly in advanced web applications. It consists of a variety of tests, including latency and throughput tests, that cover a wide range of web application use cases. Finally, Motion Mark is a benchmark designed to thoroughly test the graphics systems of web browsers. This benchmark includes a variety of subtests, including the CSS, image and text rendering, that assess the performance of the browser's rendering capabilities. For LLVM toolchains, we use the Linux kernel v6.5 under `allyesconfig` as the compilation target.

7.1 Prevalence of custom RTTI

We selected seven C/C++ open sourced software projects with large codebases. As shown in Table 1, we observed that 4 out of 7 projects had type confusion CVEs, implying common uses of type casts. In addition, we randomly sampled 10 class hierarchies for each project and found the use of custom RTTI in 6 of the 7 projects. In summary, all six projects demonstrated a substantial utilization of custom RTTI. This result underscores the prevalence of custom RTTI in C/C++ software. For Chromium, we find 8 out of the 10 sampled class hierarchies were found to contain custom RTTI; for Firefox and the LLVM toolchain, 6 out of 10 sampled class hierarchies include custom RTTI. In the case of JavaScriptCore, although only 3 out of 10 sampled classes contain custom RTTI, some are located in important modules, e.g., the DOM module.

7.2 Coverage

In this section, we will first show the overall results of analyzing the three projects, based on the results, we calculate the **coverage**, which measures out of all the downcasts, how many of them are identified as the safe casts.

Table 1: Prevalence of the custom RTTI in large scale C/C++ software.

Software	TypeConfusion CVE	Custom RTTI
Chromium	Y	Y (8/10)
Mozilla Firefox	Y	Y (6/10)
Hermers	Y	Y (7/10)
JavaScriptCore	Y	Y (3/10)
LLVM ToolChain	N	Y (6/10)
QT	N	Y (5/10)
Boost	N	N

The overall result is shown in Table 3, using Chromium as an example; there is a total of 54,617 classes that are part of class hierarchies, out of which 6,671 are base classes, forming class hierarchies. We observe that all downcasts occur within 1,123 of these class hierarchies and a total of 5,160 classes appear as downcast targets.

Among the 1,123 class hierarchies, we identify 719 hierarchies, and 3,585 classes within these hierarchies, that have custom RTTI. Furthermore, we find 827 classes in total that have both RTTI and appear as downcast targets. As we can see, many classes have custom RTTI but are never used as downcast targets. Upon inspecting some such cases, we find that their custom RTTI is used in scenarios like serialization and deserialization [1] or logging [7].

Finally, we find 49,364 downcast operations in Chromium, and 23,721 of them have destination types with custom RTTI. A subset of these downcasts, i.e., 6,704, are determined to be safe casts. In other words, T-PRUNIFY finds these downcasts are protected by developer-inserted type checks. Overall, this represents a significant fraction of downcasts that can be exempt from sanitizer checks.

Since 6,704 out of 49,304 downcasts in Chromium are identified as safe casts by T-PRUNIFY, the coverage is $6,704/49,304 = 13.58\%$. Similarly, the coverages for SPEC CPU xalancbmk and the LLVM toolchain are 9.82% and 9.49%, respectively. Although the static coverage appears low, the dynamic type checking reduction is far more significant, which we will show in §7.4. Since T-PRUNIFY does not find custom RTTI in the other six SPEC CPU C++ programs, we only list the results for xalancbmk here.

7.3 Accuracy

In this section, we selected Chromium as our test subject to evaluate the outcomes at each critical step. These steps include custom RTTI identification, type check identification, and safe casts identification. Then, we manually curated the ground truth of the above steps relating to the top 50 classes (that appeared as destination types of downcasts). Using this dataset, we then analyzed the accuracy of the results produced by our system, specifically looking for any false positives or

false negatives.

Custom RTTI Identification We collected the top 50 downcast targets and list them in the Table 2. We found that 25 of the top 50 classes had custom RTTI encoded, and our approaches correctly identified 20 of the 25, resulting in 5 false negatives. We are unable to infer the custom type info encoded in 5 classes primarily due to the patterns that we currently do not recognize, as described in §4.1. For instance, one of them is the class `v8:Uint32` which has a member function `IsUint32()` that returns `true` if the object is of class `v8::Uint32`. However, this function examines whether the object value is within the range of [0, kMaxUInt32]. Among the 20 classes that are identified to have custom RTTI by T-PRUNIFY, we find no false positives; this is expected as our analysis is conservative.

Type Check Identification. In terms of false negatives in this step, since T-PRUNIFY failed to identify the RTTI of 5 classes, it will therefore automatically miss type checks relating to these 5 classes. To evaluate whether our safe cast identification will miss any additional cases, we sample 54 type checks from the remaining 20 classes with custom RTTI. For most classes, we sampled three checks per class (however, note that there are cases where we can find only one type check). The results show that T-PRUNIFY can identify all 54 type checks, meaning no false negatives. To evaluate false positives, we sample 50 type checks that are reported by T-PRUNIFY, and all of them are true positives.

Safe Cast Identification. We follow a similar approach described above to evaluate the false negatives and false positives of safe cast identification. The same 54 sampled type checks are also in fact safe casts, according to our manual analysis. T-PRUNIFY successfully identifies 51 to be safe casts, missing the remaining 3 because of the lack of an inter-procedural analysis, i.e., the check is performed in a caller function but the cast happened in a callee. So, we have 3 false negatives in this data set. In addition, we sampled some cases to see whether the lack of inter-procedural analysis is the only reason. In particular, we find one false negative even when the check and cast are in the same function. The example is located in the v8 submodule: a base class `BaseSpace` which has two subclasses `NormalPageSpace` and `LargePageSpace`. Before casting an object `space` to type `NormalPageSpace`, the developer performed a type check `!(space.is_large())`. This case constitutes a safe cast. However, T-PRUNIFY failed to identify it because it did not take into account the fact that there are only two possible types, `!is_large()` effectively indicates that `space` is of type `NormalPageSpace`. Finally, we also collect 3 patches that fix type confusion vulnerabilities in Chrome with developer-implemented type checks and they are all identified by T-PRUNIFY, i.e., no false negatives. To evaluate false positives, we sample 50 safe casts reported by T-PRUNIFY from six different submodules and find none of them are false positives. Overall, the results exhibit a high accuracy, with

Table 2: The top 50 downcast classes targets in the Chromium, `# of cast` is the frequency, `Type Info?` is the ground truth whether the class has encoded some form of the custom type information. The last column shows whether T-PRUNIFY captured those information into our database.

downcast ops with type checks (safe casts)	6,704	30,027	55

no false positive and very few false negatives in each steps.

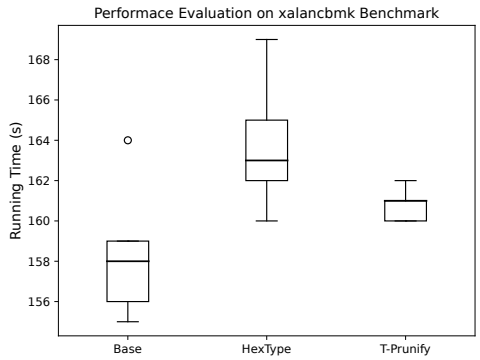
7.4 Runtime Overhead Reduction

So far, we have evaluated the results of T-PRUNIFY statically, e.g., the effectiveness of T-PRUNIFY in terms of the statically-identified safe casts. In this section, we will measure the runtime overhead achieved by T-PRUNIFY compared to the state-of-the-art solution, HexType. As mentioned, we evaluate T-PRUNIFY in three programs: xalancbmk in SPEC CPU 2006, Chromium and LLVM toolchain. When evaluating Chromium, we utilize three widely recognized web browser benchmarks. As for the LLVM toolchain, we assess its performance by compiling the Linux kernel version 6.5 with the `allyesconfig` configuration. We tested each benchmark six times back-to-back, and eliminate the first run as it would be a cold start. Then we use the box plot to visualize the result of the last five run for programs with some deviations. We use the median values as the representative numbers to represent the overhead; the results are depicted in Table 4. Further, we calculate the type checks that instrumented by HexType and T-PRUNIFY when running those benchmarks; the results are shown in Table 6.

Results for xalancbmk. We measured the performance with five runs. As seen in Figure 10a, the median of the baseline running time (without any instrumentation) is 158s. When compiled with HexType, the median running time increases to 163s, which translates into an overhead of 1.03×. When compiled with T-PRUNIFY, the median running time is 161s, resulting in an overhead of 1.02×. Interestingly, we do observe the program compiled with T-PRUNIFY experiences significantly fewer type checks, i.e., from 283 million to 80 million. Yet the end-to-end overhead reduction is not pronounced in this benchmark. This is attributed to the fact that these type checks constitute a relatively minor portion of the total execution time.

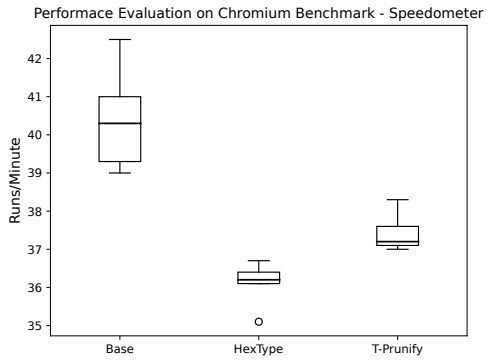
Results for Chromium. To compute the runtime overhead for Chromium, we rely on the "scores" produced by each benchmark for each Chromium, Chromium-hextype, and Chromium- T-PRUNIFY, respectively. Note that these scores from different benchmarks may consist of different metrics,

Table 4: Overhead improvement for three projects relative to their respective benchmarks, the improvement is calculated based on the HexType instrumentation.



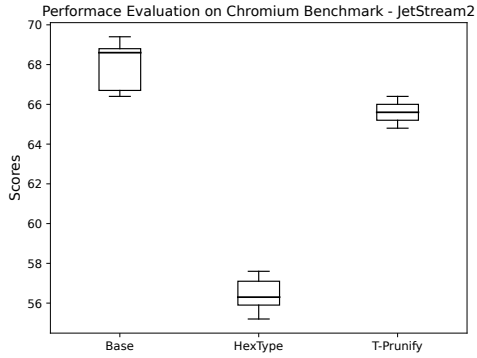
Software	Benchmark	Hextype	T-PRUNIFY
SPEC CPU	xalancbmk	1.03×	1.02×
Chromium	Speedometer	1.11×	1.08×
Chromium	JetStream2	1.22×	1.05×
Chromium	MotionMark	2.92×	1.51×
LLVM	Linux	16.7×	10.5×

e.g., throughput. Nevertheless, we assume these scores captured the most suitable metrics as intended by each benchmark, where high score shows better performance.



For Speedometer, we see that the original Chromium can achieve 40.3 runs/min, while chrome-hextype and chrome-reduced achieved 36.2 runs/min and 37.2 runs/min, respectively. Overall, Chromium-hextype experiences a relatively low overhead on the Speedometer benchmark to begin with, i.e., 10.2%, indicating that the exercised sanitizer-inserted checks have a relatively low proportion. Nevertheless, T-PRUNIFY manages to reduce the overhead from 10.2% (= $1-\frac{36.2}{40.3}$) to 7.7% (= $1-\frac{37.2}{40.3}$), representing a 25% relative reduction. In Table 6, we also report the total number of type checks that are executed at runtime with HexType and T-PRUNIFY. We can see that T-PRUNIFY successfully eliminated a large number of checks that would otherwise be performed by HexType. The box plot for five runs is shown in Figure 10b.

In JetStream2, the overall score of the original Chromium is 68.6, while Chromium-hextype and Chromium-reduced achieved scores of 56.3 and 65.6 respectively. The improvement is significant, from 17.9% (= $1-\frac{56.3}{68.6}$) to 4.4% (= $1-\frac{65.6}{68.6}$), representing a 75% relative reduction in overhead. In fact, the score of Chromium-reduced is very close to that of the uninstrumented Chromium. Looking at Table 6, we can see that the majority of the sanitizer checks are pruned, i.e., 2,800M out of 3,795M. We believe that the observed high ratio can be attributed to the predominant use of the V8 engine in the exercised code paths by JetStream2. The V8 engine has a history of being susceptible to numerous type confusion bugs [14–17]. Consequently, developers have inserted a significant number of type checks as a precautionary measure to mitigate potential vulnerabilities. The box plot for five runs is shown in Figure 10c.



In MotionMark, the overall score of the original Chromium is 72.31, while Chromium-hextype and Chromium-reduced achieved 24.75 and 47.78, respectively. The improvement of results is the most significant out of the three benchmarks, i.e., from 65.8% (= $1-\frac{24.75}{72.31}$) to 33.9% (= $1-\frac{47.78}{72.31}$), representing a 48.5% relative reduction in overhead. The box plot for

(b) The box plot for performance comparison among three configurations in `Speedometer` benchmark. Higher number means better performance.

(c) The box plot for performance comparison among three configurations in `JetStream2` benchmark. Higher score means better performance.

(d) The box plot for performance comparison among three configurations in `MotionMark` benchmark. Higher score means better performance.

Figure 10: Box plots for `xalancbmk` and Chromium benchmarks. Figure (a) is the boxplot for `xalancbmk`, lower running time means higher performance. Figures (b), (c) and (d) shows the benchmarks for Chromium, higher score means better performance.

five runs is shown in Figure 10d.

According to Table 6, T-PRUNIFY results in 327M fewer sanitizer checks at runtime. The significant number of pruned checks in this benchmark is due to the many rendering elements such as SVG node and HTML elements with CSS style. Many of these classes have custom RTTI and safe casts (as some of our examples showed in §2).

Results for LLVM Toolchain. Next, we calculate the runtime overhead for the LLVM toolchain. Specifically, we use it to compile the Linux kernel v6.5 with `allyesconfig` and measure the compilation time to represent the performance. Overall, we find that HexType takes 369 mins to finish the compilation, while T-PRUNIFY takes only 231 mins. We conducted five runs in this experiment and dropped the first run, since four runs yield identical running times measured in minutes, we do not include the box plot here. The compilation speed up is shown in Table 4, we reduced the HexType's 16.2× overhead to 10.5×, representing a 35.19% overhead improvement. This significant improvement can be attributed to the 743B (46.82%) fewer sanitizer checks at runtime.

Compilation overhead Besides the run time overhead, we also log the compile time overheads that T-PRUNIFY brings to compile the Chromium and LLVM Toolchain; the results are shown in Table 5. Compared to HexType, the compilation time is shorter, which means the analysis performed by T-PRUNIFY is relatively lightweight and saves significant instrumentation workload. The difference in compilation time between HexType and T-PRUNIFY can be attributed to two reasons. First, HexType inserts sanitizers' type check functions in the front end. Second, in the optimization phase, HexType analyzes each inserted type check function, extracting the source type and target type to perform the compilation time safe casts validation. T-Prunify can help reduce the overheads from both operations because fewer sanitizer's type check functions are inserted in the first place.

In summary, we demonstrate that in each of the benchmarks, T-PRUNIFY significantly reduces the overhead of redundant sanitizers' type checks at runtime, even though only about 10% of the type-cast checks are pruned statically as described in §7.2. This is likely due to such redundant

Table 5: Compilation time comparison.

Program	original	HexType	T-PRUNIFY
Chromium (-j32)	38min	59min	56min
LLVM Toolchain (-j32)	13min	67min	39min

Table 6: Number of dynamic cast verification performed by HexType versus TPRunify.

Benchmark	Hextype	T-PRUNIFY	Reduced
Chromium-Speedometer	1, 558 M	241 M	1, 317 M (84.53%)
Chromium-JetStream2	3, 795 M	995 M	2, 800 M (73.78%)
Chromium-MotionMark	502 M	175 M	327 M (65.24%)
xalancbmk	283 M	80 M	203 M (71.73%)
LLVM-compile-Linux	1, 587 B	844 B	743 B (46.82%)

checks being frequently executed at runtime, and these checks being expensive to execute.

8 Limitations and Extensions

While our experimental results are quite promising, we did encounter some practical limitations of T-PRUNIFY while manually assessing accuracy. In the custom RTTI identification phase, we discovered cases where a wide range of constants or even structure pointers were used to assist encoding custom RTTI information, patterns not handled by our current approach. These cases could be addressed in future work by doing deeper semantic analysis during the RTTI identification phase. It is also interesting to investigate the encoding patterns of custom RTTI across open-source projects beyond Chrome. Additionally, our safe cast analysis is currently intra-procedural, which means that it may overlook certain safe casts that occur across different function calls. In future work we plan to make this analysis inter-procedural, thereby supporting cases where a type check occurs in a caller while the cast occurs in the callee.

Beyond the aforementioned improvements, there are multiple fruitful ways to broaden and extend this work. First, we believe there are uses for automatic detection of custom RTTI schemes beyond reducing sanitizer overhead. For example, in cases where casts are not protected by a type check, one could automatically insert type checks into the code using the custom RTTI found by our technique. Also, we believe it would be worthwhile to extend our RTTI detection approach could to support `structs` in the C language—there also, custom RTTI has been used to ensure cast safety [2].

9 Related Works

In this section, we compare T-PRUNIFY with closely related work in two areas.

Type Confusion Sanitizers. As mentioned before, type confusion sanitizers aim to detect bad castings that can introduce confusion vulnerabilities, by instrumenting the target program with additional runtime checks. Undefined Behavior sanitizer (UBSan) [31] is one of the earliest available type confusion sanitizers. It relies on the standard C++ RTTI to perform type compatibility check. As a result, it does not support non-polymorphic classes and may introduce crashes [26]. Recently, Clang CFI [30] also added support for detecting type confusing bugs by leveraging the standard C++ RTTI. CaVer [26] aims to address two main issues of the standard C++ RTTI: (1) it improves the speed of type checking by using unique hashes instead of mangled names, and by including all compatible types in a single RTTI entry, instead of requiring traversing the class hierarchy; (2) it supports non-polymorphic classes by using a decoupled lookup table to find RTTI associated with a memory object. TypeSan [22] and HexType [24] further improve the performance and coverage over CaVer by using lower cost data structures, caching, and by expanding the instrumentation targets. EffectiveSan [19] can also detect type confusion vulnerabilities, besides other memory errors like out-of-bound and use-after-free. EffectiveSan uses low-fat pointer [18, 20, 25] to achieve efficient metadata access. It also supports checking casts between primitive types. Bitype [27] further compress the metadata structure into bit stream and speedup the compatibility check via `xor` operations. T-PRUNIFY is orthogonal and complementary to these type confusion sanitizers as our goal is to leverage developer-inserted custom type checks to eliminate redundant checks induced by type sanitizers. Therefore, T-PRUNIFY can be combined with any of these type sanitizers.

Optimizing Sanitizer Checks. There are also some work to reduce the sanitizers' overhead, these work could be divided into two categories. The first is using sanitizer-specific static analysis to remove only semantically redundant checks, for example, RedCard [21] is designed to use static analysis to reduce the redundant instrumentation for dynamic race conditions. Similarly, DataGuard [23] uses a set of sophisticated static analyses to prove the safety of stack objects and migrate them to safe stack, thus reducing the runtime protection overhead. Furthermore, WPBound [29] utilizes value range analysis to effectively minimize the number of out-of-bound memory checks inserted by sanitizers. Besides static analysis, SIMBER [33] incorporates statistical inferences to identify redundant bound checks. Another approach develops the framework and use general heuristics to remove costly sanitizer checks irrespective their semantics, those work includes ASAP [32] and SanRazor [34]. ASAP [32] allows developers to specify the acceptable percentage of runtime overhead based on their resource constraints. Leveraging this information, ASAP automatically instruments the program to maximize the security promise within the given budget. While SanRazor [34] combines runtime profiling and static

analysis to identify and eliminate repeated and redundant checks, thereby optimizing computing resources. T-PRUNIFY falls within the first category, but with a specific focus on type confusion sanitizers.

10 Conclusion

Type confusion vulnerabilities are severe security threats to C/C++ programs. Due to the high performance overhead of the standard C++ runtime type information (RTTI), in large complex C++ projects like the Chrome browser, developers usually introduce custom RTTI and type checks to prevent type confusion bugs. Based on this observation, we implemented T-PRUNIFY, a tool that can automatically identify developer-inserted type checks and leverage these checks to validate the safety of type casts. Applying T-PRUNIFY to the Chrome browser allows us to identify a large number, i.e., 6,704, of safe casts. Leveraging this information, T-PRUNIFY can help remove redundant type casting checks induced by type confusion sanitizers like HexType and reduce the corresponding performance overhead by 25% to 75%.

Two Shuffles Make a RAM: Improved Constant Overhead Zero Knowledge RAM

Yibin Yang
Georgia Institute of Technology

David Heath
University of Illinois Urbana-Champaign

Abstract

We optimize Zero Knowledge (ZK) proofs of statements expressed as RAM programs over arithmetic values. Our arithmetic-circuit-based read/write memory uses only 4 input gates and 6 multiplication gates per memory access. This is an almost 3× total gate improvement over prior state of the art (Delpech de Saint Guilhem et al., SCN'22).

We implemented our memory in the context of ZK proofs based on vector oblivious linear evaluation (VOLE), and we further optimized based on techniques available in the VOLE setting. Our experiments show that (1) our total runtime improves over that of the prior best VOLE-ZK RAM (Franzese et al., CCS'21) by 2-20× and (2) on a typical hardware setup, we can achieve $\approx 600K$ RAM accesses per second.

We also develop improved read-only memory and set ZK data structures. These are used internally in our read/write memory and improve over prior work.

1 Introduction

Zero Knowledge (ZK) proofs [28] allow a prover $\mathcal{P}$ to demonstrate to a verifier $\mathcal{V}$ the truth of some statement while revealing nothing additional. ZK is a powerful technology with a variety of applications, e.g., private blockchain [39], private bug-bounty [32], private software analysis [25, 35], ZKML [45], private network auditability [29], and many more.

General-purpose ZK systems often express proof statements as *circuits* or *constraint systems* over Boolean or arithmetic values. However, the past decade has shown increased interest in expressing statements as random access machine (RAM) programs [6, 8, 10, 11, 13, 14, 20, 26, 30, 31, 33, 37, 41]. The RAM-ZK paradigm is exciting both because some statements are made more efficient by the random access capability and because RAM-ZK opens the door to handling statements written in commodity programming languages (see e.g. [6, 32]). Thus, RAM-ZK promises to allow a broad audience to use widely available tools to build efficient proofs of arbitrary statements. If we hope to deliver on this promise, it is crucial to develop RAM-ZK that is as efficient as possible.

The cost of ZK proofs. General purpose ZK systems incur three primary costs: proof size (communication), $\mathcal{P}$ computation, and $\mathcal{V}$ computation. The literature has generated *many* approaches to ZK, and these approaches achieve varying levels of efficiency with respect to these metrics.

Seeking RAM improvement for a variety of circuit-based ZK systems, we instead focus on the *total circuit size* metric, the improvement of which implies improvement to *all* basic costs. Specifically, we reduce the size of circuit needed to implement ZK RAM, and our results accordingly imply general improvement to ZK RAM.

Constant overhead ZK RAM. Recently, [20] demonstrated a reduction from ZK RAM to arithmetic circuits where the size of the arithmetic circuit scales *linearly* with the number of memory accesses. I.e., the number of gates needed for each RAM access is only a *constant*.

While this asymptotic scaling is ideal, the underlying constants remain relatively high. In most arithmetic ZK systems, we are most interested in reducing the number of *non-linear* gates, which include multiplication gates and input gates (linear gates are typically far cheaper). The [20] construction uses 27 non-linear gates per access.

The full version of this paper is publicly available [48].

1.1 Our Contribution

We construct constant overhead ZK RAM with state-of-the-art circuit size. Given standard arithmetic circuits, our construction uses only 4 input gates and 6 multiplication gates per RAM access (and a constant number of linear gates).

The gates in our RAM are *highly structured*: viewing the circuit globally, five of six multiplication gates are each part of a large product computation (i.e., a high fan-in gate). This structure is important because in some ZK systems, it is possible to exploit such structure to further improve performance.

We implemented our RAM in the context of ZK based on vector oblivious linear evaluation (VOLE) [3–5, 22, 23, 44–

47], a ZK paradigm noted for its fast end-to-end proofs (see discussion of VOLE-based ZK in Section 2.3). We use an idea suggested by [26] to leverage QuickSilver's [47] support for *polynomial evaluation* to take advantage of circuit structure and significantly decrease total cost. Our implementation is publicly available (see the full version).

Prior work [26] developed a ZK RAM specialized for VOLE-based techniques. We compare to their publicly available implementation [43]; our experiments (see Section 6) show that our end-to-end proof runtime performance outperforms that of [26] by 2-20×, depending on the network bandwidth and the RAM size.

We also present related ZK data structures: a read-only memory (ROM) and a set membership structure whose performance substantially improves the state of the art. Our ZK ROM outperforms that of [26] by 3-34×, depending on the network bandwidth and the ROM size. On a standard setup, it can execute each access in under $1\mu s$.

While our constructions leverage novel insights, their designs are conceptually simple and easy to implement. The results are also highly generic, and are suited to any ZK system (even those that use, e.g., R1CS instead of circuits) with support for (1) arithmetic gates over a large field and (2) public-coin random challenges. Indeed, our results are applicable to arithmetic ZK systems in the commit-and-prove paradigm [17] (see Appendix A), including VOLE-based systems, proof systems based on MPC-in-the-head, e.g. [1,19,34], and zkSNARKs, e.g. [2, 15, 18, 36].

1.2 Intuition

A key insight behind ZK RAM is that the ZK prover $\mathcal{P}$ can act as an oracle, providing as input the correct data corresponding to each memory access. However, $\mathcal{P}$ might try to cheat, on each access providing arbitrary values that lead to an erroneous "proof". The challenge is thus to check that malicious $\mathcal{P}$ inputs memory values correctly.

Prior state-of-the-art ZK RAM [20, 26] build such checks from *permutation proofs* (see Section 2.2), which allow $\mathcal{P}$ to convince the verifier $\mathcal{V}$ that one vector of wire values is a permutation of another. Based on this, [20, 26] allow $\mathcal{P}$ to introduce two vectors. One vector is a list of memory access metadata arranged in the order accesses occur in the program; the second vector is the same metadata arranged in order of memory address. The first vector is used to satisfy each memory access; the second is used to prove $\mathcal{P}$ did not cheat. $\mathcal{P}$ proves that the two vectors are related by a permutation, then uses a circuit to scan the second vector, proving global consistency properties of the vector.

While conceptually simple, this global check introduces inefficiency in the form of large numbers of inputs from $\mathcal{P}$ and relatively costly comparisons (see Section 3 for details).

Our construction also leverages permutation proofs, but its permuted vectors are (1) the list of elements written to RAM (with metadata) and (2) the list of elements read from RAM (with metadata). We discard [20, 26]'s global consistency check in favor of a *local* check performed each time an element is accessed:

Check 1. The memory element read from RAM at time t was also written to RAM at some time t', and in particular $t' < t$.

Our key insight is that – with careful design – *locally* performing Check 1 enforces a *global* consistency property sufficient to achieve a sound protocol.

Our approach requires fewer gates than prior work because (1) we can assemble our two vectors with fewer inputs from $\mathcal{P}$ and (2) our local checks can exploit static information available at the time of each access. For instance, [20, 26]'s consistency check must explictly check whether two compared addresses are equal to each other or not; for us, this check is irrelevant, as from our permutation check we *implictly* know that the read value is equal to some past write value to the same address.

In total our entire proof uses:

- A permutation proof (reads are a permutation of writes).
- A per-access set membership proof (the corresponding write was made in the past).
- A per-access multiplication (used to multiplex the effect of `load` versus `store`).

We give a set data structure that implements our membership proofs and that can be achieved from a single permutation proof. Thus, the entire RAM essentially reduces to two permutation proofs (and one auxiliary multiplication). This yields a small circuit that is fast to execute and easy to implement.

2 Preliminaries and Notation

2.1 Universal Composability

We formalize security in the universal composability (UC) framework [16]. Our protocol is proven secure in the presence of a malicious, static adversary. See the full version for a review of the UC framework.

2.2 Checking Permutations via Polynomials

Our approach relies on efficient *permutation proofs*. Namely, given two vectors $\mathbf{x}$ and $\mathbf{y}$ stored on arithmetic circuit wires, we wish for $\mathcal{P}$ to prove to $\mathcal{V}$ that there exists some permutation π such that $\mathbf{x} = \pi(\mathbf{y})$. When $\mathbf{x}$ and $\mathbf{y}$ are indeed related by a permutation, we write $\mathbf{x} \sim \mathbf{y}$:

$$\mathbf{x} \sim \mathbf{y} \quad \Longleftrightarrow \quad \exists \pi, \mathbf{x} = \pi(\mathbf{y})$$

One approach to proving $\mathbf{x} \sim \mathbf{y}$ uses circuit structures called *permutation networks* [9, 42]. Such networks can permute n

wire values using $O(n \cdot \log n)$ gates. Several works use such networks in the context of ZK RAM [6,8,30,31]. The inherent $\log n$ overhead is relatively expensive in practice.

A more efficient approach observes that to prove $\mathbf{x} \sim \mathbf{y}$ it is not necessary to *compute* a permutation π. Instead, $\mathcal{P}$ can prove *non-constructively* that such a permutation exists with high probability. To achieve this, prior work [38] suggested interpreting the two vectors $\mathbf{x}$ and $\mathbf{y}$ as *polynomials*, and then testing those polynomials for equality. Namely, we can view $\mathbf{x}$ (resp. $\mathbf{y}$) as a polynomial p (resp. q) with formal parameter X where each element $\mathbf{x}[i]$ (resp. $\mathbf{y}[i]$) is a polynomial root:

$$p(X) = \prod_i (X - \mathbf{x}[i]) \qquad q(X) = \prod_i (X - \mathbf{y}[i])$$

If the two vectors $\mathbf{x}$ and $\mathbf{y}$ are indeed related, then they contain the same roots, and hence they encode the same polynomial. Thus, to prove that $\mathbf{x}$ and $\mathbf{y}$ are related, it suffices to prove that p and q are the same polynomial:

$$\mathbf{x} \sim \mathbf{y} \quad \Longleftrightarrow \quad p = q$$

Checking equality of two polynomials can be achieved with high probability using the well known *polynomial identity test*. In this test, we uniformly sample a value $r \in \mathbb{F}$, and then check if $p(r) - q(r) = 0$. The well known fact is that if this check passes, then p and q are indeed the same polynomial with very high probability. Specifically, if $p \neq q$, then the check will succeed with probability only $\frac{d}{\mathbb{F}}$, where d is the degree of the polynomial [21,40,51].

In the ZK setting, $\mathcal{V}$ can send r as a random challenge, then $\mathcal{P}$ and $\mathcal{V}$ can evaluate $p(r)$ and $q(r)$ via an arithmetic circuit that grows *linearly with low constants* in the length of $\mathbf{x}$ and $\mathbf{y}$. Indeed, if $\mathbf{x}$ and $\mathbf{y}$ are length n, then the check requires only $2n-2$ multiplications (and $2n+1$ subtractions).

The above definitions of p, q work when $\mathbf{x}$ and $\mathbf{y}$ are vectors of individual field elements. However, we will need to consider vectors of *tuples* of field elements. [20] points out that the above polynomial checks can be extended to vectors of tuples by taking a random linear combination of the content of each tuple. Suppose $\mathbf{x}$ and $\mathbf{y}$ are vectors of ℓ-tuples, and let $\langle \_ \cdot \_ \rangle$ denote the vector inner product operation; we can redefine p and q as follows:

$$p(X, \mathbf{Y}) = \prod_i (X - \langle \mathbf{Y} \cdot \mathbf{x}[i] \rangle) \quad q(X, \mathbf{Y}) = \prod_i (X - \langle \mathbf{Y} \cdot \mathbf{y}[i] \rangle)$$

$\mathbf{Y}$ is a length-ℓ vector. Thus, p and q now denote multivariate polynomials over $\ell + 1$ arguments, but otherwise [20] proves that the reasoning is the same.

In the ZK setting, we can check $p = q$ by (1) allowing $\mathcal{V}$ to choose two random challenges $r \in \mathbb{F}$ and $\mathbf{s} \in \mathbb{F}^\ell$, (2) computing $p(r, \mathbf{s}) - q(r, \mathbf{s})$ inside ZK, and (3) checking that the result is indeed zero. Note, the challenge vector $\mathbf{s}$ is a public value known to both $\mathcal{P}$ and $\mathcal{V}$, so evaluating $p(r, \mathbf{s}) - q(r, \mathbf{s})$ still requires only $2n-2$ private-input multiplication gates.

2.3 VOLE-based Zero Knowledge

The literature has generated many powerful ZK proof systems suited to various settings. Our ZK data structures are highly generic, relying only on typical features of ZK systems for arithmetic circuits. Still, we find it instructive to implement our approach in the context of a particular ZK system, and to demonstrate clear concrete improvement.

We implement our approach in the ZK paradigm based on *vector oblivious linear evaluation* (VOLE) [3–5,22,23,44–47]. VOLE-based ZK is an interactive ZK technique notable for its linear scaling (with low constants) in all cost metrics. This scaling makes VOLE-based ZK useful when the goal is to complete a ZK proof as fast as possible; prior work has shown that VOLE-based ZK can handle ≈ 5 million arithmetic multiplications per second [47].

VOLE-based ZK is particularly interesting for large, complex statements, for instance those that demonstrate the existence or non-existence of software vulnerabilities in a complex code-base (see e.g. [32, 35]). In the context of large, general-purpose statements, RAM becomes a crucial ingredient, as it supports programs with large data and complex branching/looping control flow.

We choose to implement in the VOLE-based ZK paradigm because VOLE-based ZK is well suited to the complex proofs supported by RAM. As an additional convenience, prior work [26] is also based on VOLE, allowing a clean comparison. Our VOLE-based implementation builds on the publicly available EMP Toolkit [43]. See the full version for a standard VOLE functionality.

2.4 Miscellaneous Notation

We consider read-only and read/write memories. We use n to denote the number of memory elements stored and T to denote the number of accesses. In our analysis, we often assume there are a large number of accesses, i.e. that $T = \omega(n)$. We consider memories that store tuples of ℓ field elements. All operations are over a prime field $\mathbb{F} = \mathbb{Z}_p$ for prime p; we require that $|\mathbb{F}| \geq 2T$, sufficient to embed memory-specific values in the field without overflow.

We index a vector $\mathbf{x}$ at index i using bracket notation: $\mathbf{x}[i]$. Indexing starts at zero.

We use $\sim$ to denote an operation that checks its two vector arguments are related by a permutation.

We denote logical memory operations by *load* and *store*, and disambiguate these from *physical* operations *read* and *write*. Each of our logical operations requires one read and one write. Our circuits use constants $\texttt{load} = 0$ and $\texttt{store} = 1$.

We refer to the ZK prover $\mathcal{P}$ by she/her/hers and to the ZK verifier $\mathcal{V}$ by he/him/his.

We refer to ZK operations that multiply two private values or require $\mathcal{P}$ to provide input as *non-linear*. Operations that add two private values, subtract two private values, or

$\texttt{input}_\ell : 1 \to \mathbb{F}^\ell$ | $\_ + \_ : \mathbb{F} \times \mathbb{F} \to \mathbb{F}$

$\_ \sim \_ : (\mathbb{F}^\ell)^n \times (\mathbb{F}^\ell)^n \to 1$ | $\_ - \_ : \mathbb{F} \times \mathbb{F} \to \mathbb{F}$

$0, 1, 2, \ldots : \mathbb{F}$ | $\_ \cdot \_ : \mathbb{F} \times \mathbb{F} \to \mathbb{F}$

Figure 1: Syntax on which we build our RAM. We consider circuits over a field $\mathbb{F}$ with support for permutation checks. We include gates that accept ℓ inputs from $\mathcal{P}$, gates that check two vectors of ℓ-tuples are related by a permutation, gates that add/subtract/multiply wires, and wires that hold constants. Section 2.2 discusses how $\_ \sim \_$ can be implemented.

$\texttt{input}_\ell : 1 \to \mathbb{F}^\ell$ | $\_ + \_ : \mathbb{F} \times \mathbb{F} \to \mathbb{F}$

$0, 1, 2, \ldots : \mathbb{F}$ | $\_ - \_ : \mathbb{F} \times \mathbb{F} \to \mathbb{F}$

$\texttt{make-mem} : (\mathbb{F}^\ell)^n \to \texttt{mem-id}$ | $\_ \cdot \_ : \mathbb{F} \times \mathbb{F} \to \mathbb{F}$

$\texttt{access} : \texttt{mem-id} \times \mathbb{F} \times \mathbb{F} \times \mathbb{F}^\ell \to \mathbb{F}^\ell$

Figure 2: Our target syntax supports arithmetic gates and gates that manipulate random access memories. `make-mem` generates a fresh memory and `access` loads/stores to a memory. Figure 4 specifies semantics.

scale a private value by a public value are *linear*. Typically, non-linear operations are *far* more expensive than linear operations. Accordingly, our cost accounting precisely enumerates only the number of non-linear operations.

2.5 Models

Our goal is to UC-realize the functionality $\mathcal{F}_{ZK}^{ram}$ (Figure 4). This functionality allows arbitrary arithmetic circuits augmented with random access memory. We achieve this functionality given access to circuits with arithmetic gates and support for permutation proofs (Figures 1 and 3). As discussed in Section 2.2, such permutation proofs can be achieved from standard arithmetic circuits with support for public coin random challenges, so our approach can be implemented on top of standard arithmetic ZK techniques.

Our functionality $\mathcal{F}_{ZK}^{ram}$ can serve as the basis for arbitrary ZK CPU architectures, as have been explored by prior work, e.g. [6, 26, 32, 49].

Boolean vs. arithmetic circuits. We develop ZK RAM compatible with arithmetic gates. It is well known that Boolean and arithmetic circuits trade off in efficiency. For instance, arithmetic circuits are better at multiplication; Boolean circuits are better at comparisons.

We believe that in the ZK setting and for large proofs, it is becoming clear that arithmetic circuits are a superior model of computation. Indeed, the introduction of fast arithmetic-

Functionality $\mathcal{F}_{ZK}^{perm}$

Let C be an arithmetic circuit with permutation check gates (i.e., C is written in the syntax of Figure 1). $\mathcal{F}_{ZK}^{perm}$ interacts with $\mathcal{P}$, $\mathcal{V}$, and the adversary $\mathcal{S}$. Upon receiving $(\texttt{prove}, C, \mathbf{w})$ from $\mathcal{P}$ and $(\texttt{verify}, C)$ from $\mathcal{V}$:

- If when running $C(\mathbf{w})$ it holds that (1) the circuit outputs 0 and (2) for each internal call to $\mathbf{x} \sim \mathbf{y}$, $\mathbf{x}$ and $\mathbf{y}$ are indeed related by a permutation, then output $(C, \texttt{true})$ to $\mathcal{S}$ and $\mathcal{V}$; else output $(C, \texttt{false})$ to $\mathcal{S}$ and $\mathcal{V}$.

Figure 3: The functionality for Zero Knowledge proofs over arithmetic circuits with access to a permutation check gate. Figure 1 defines syntax of such circuits.

circuit-based read-only memory (ROM) – such as the state-of-the-art ROM introduced in this work – can significantly mitigate the downside of arithmetic circuits.

As an example, consider the problem of comparing two, say, 16-bit values. This problem can be solved by subtracting the one value from the other and then looking up the difference in a ROM with 2^{17} entries. For negative indices, the ROM stores a 0; for positive indices it stores a 1. To compare larger numbers, we can first break the numbers into chunks, element-wise compare chunks, and combine the results. As long as enough comparisons are performed across the proof, this approach yields comparison operations for only a small constant number of arithmetic gates.

3 Related Work

Approach of Franzese et al. [26]. [26] constructed the first concretely efficient ZK RAM with constant overhead. Their approach works in the VOLE-based ZK setting for mixed circuits containing both arithmetic and Boolean gates[1]. [26] leverages permutation proofs (Section 2.2). We compare our performance to that of [26] in Section 6.

The [26] approach is as follows. On each memory access to address *addr*, $\mathcal{P}$ provides the loaded value *val* as part of her input. Then, the system records a 4-tuple of (1) the address *addr*, (2) the *time* t of the access (according to a monotonically increasing clock), (3) a bit *op* indicating if this access is a `load` or a `store`, and (4) the value *val* that is loaded or stored.

Of course, on any particular load, $\mathcal{P}$ might cheat and provide an incorrect value. Hence, after all T accesses are completed, [26] performs a global consistency check. Note that after T accesses, the system holds a vector of T 4-tuples.

In the first step of the consistency check, $\mathcal{P}$ inputs a new version of this length-T vector, where this second version

[1] [26] targets Boolean computation, but they must pack Boolean values into a larger field to achieve efficient permutation proofs.

Functionality $\mathcal{F}_{ZK}^{ram}$

Let C be an arithmetic circuit with RAMs (i.e., C is written in the syntax of Figure 2). $\mathcal{F}_{ZK}^{ram}$ interacts with $\mathcal{P}$, $\mathcal{V}$, and the adversary $\mathcal{S}$. Upon receiving $(\texttt{prove}, C, \mathbf{w})$ from $\mathcal{P}$ and $(\texttt{verify}, C)$ from $\mathcal{V}$, execute $C(\mathbf{w})$:

- For each arithmetic gate, run the gate normally.
- For each `make-mem` gate with input vector $\mathbf{x}$, store $\mathbf{x}$ as a memory, initialize a fresh memory identifier, associate the identifier with the stored memory, and place the identifier on the gate output wire.
- For each `access` gate with $(id, op, addr, w)$, look up the memory associated with id, read address $addr$, and save the result on the gate output wire. If $op = \texttt{store}$, then write w to memory address $addr$.

If the circuit output wire holds 0, then output $(C, \texttt{true})$ to $\mathcal{S}$ and $\mathcal{V}$; else output $(C, \texttt{false})$ to $\mathcal{S}$ and $\mathcal{V}$.

Figure 4: Our target functionality $\mathcal{F}_{ZK}^{ram}$ supports arithmetic circuits with random access memories. We achieve this functionality in the $\mathcal{F}_{ZK}^{perm}$ (Figure 3) hybrid model.

is sorted first by memory address, then by time. Thus, the accesses are grouped into memory addresses such that one can locally scan from left to right, checking consistency. $\mathcal{P}$ proves that this second vector is indeed a permutation of the first via techniques discussed in Section 2.2.

The consistency check scans the second vector from left to right, ensuring that (1) the vector is indeed sorted correctly and (2) each load operation reads a value consistent with the most recent store to the same memory address. In particular, for each index i, [26] checks:

$$\begin{aligned}&((addr_i < addr_{i+1}) \vee ((addr_i = addr_{i+1}) \wedge (t_i < t_{i+1})))\\ \wedge\ &((addr_i \neq addr_{i+1}) \vee (val_i = val_{i+1}) \vee (op_{i+1} = \texttt{store}))\\ \wedge\ &((addr_i = addr_{i+1}) \vee (op_{i+1} = \texttt{store}))\end{aligned}$$

With this done, $\mathcal{V}$ is confident that values provided by $\mathcal{P}$ are correct, so the approach achieves ZK RAM.

There are several efficiency problems in this approach. First, the above consistency check requires circuits that compare addresses/values. A comparator on length-ℓ values requires $\Theta(\ell)$ gates, and RAM addresses/values have size $\Theta(\log T)$. Hence, the number of gates is super-constant.

While [26] are still able to claim constant ZK communication overhead[2], the super-constant number of gates is problematic. In particular, the technique is a poor fit for arithmetic circuits, because we must simulate each Boolean gate with arithmetic gates, incurring unacceptable cost. Many ZK systems are best suited to arithmetic circuits, so RAM over arithmetic values is arguably preferable.

Moreover, even [26]'s own performance suffers from the large number of gates, not in communication, but in computation. Specifically, each of [26]'s AND gate operations requires only ≈ 1 bit of communication, but it also requires that both $\mathcal{V}$ and $\mathcal{P}$ perform operations over the field $\mathbb{F}_{2^\kappa}$ where κ is a computational security parameter (e.g. 128). Together, these operations are expensive.

In our approach, we construct arithmetic ZK RAM where the total number of gates is a small constant. This allows us to build VOLE-based ZK where *all* costs have constant overhead, allowing us to significantly improve over [26] in terms of total wall-clock time performance. Indeed, while we achieve only a small communication improvement over [26], we improve in wall-clock time by up to $20\times$.

Approach of Delpech de Saint Guilhem et al. [20]. [20] were the first to achieve ZK RAM whose arithmetic circuit size is linear in the number of RAM accesses T. Hence, unlike [26], [20] achieves constant overhead in all costs.

In short, [20] leverages the same approach as [26], except that they carefully optimize the comparison/equality operations. [20]'s key ingredient is an elegant *bounds check*, and this check is used to implement comparison.

The [20]'s bounds check proceeds as follows. Suppose the arithmetic circuit holds a length-T vector $\mathbf{x} \in \mathbb{F}^T$, and $\mathcal{P}$ would like prove in batch that each element of $\mathbf{x}$ is in $1, ..., T$. To achieve this, [20] first constructs the following vector:

$$\mathbf{y} = \mathbf{x}[0], \mathbf{x}[1], ..., \mathbf{x}[T-2], \mathbf{x}[T-1], 1, 2, 3, ..., T-1, T$$

[20] then requires that $\mathcal{P}$ inputs a new vector $\mathbf{z}$ and proves that $\mathbf{z}$ is a permutation of $\mathbf{y}$: $\mathbf{y} \sim \mathbf{z}$. If $\mathcal{P}$ is honest, then she will input $\mathbf{z}$ in sorted order. With this done, $\mathcal{P}$ can prove that all elements $\mathbf{x}[i]$ are in the range $1, ..., T$ by proving that (1) the last element of $\mathbf{z}$ is T and (2) the difference between any two consecutive elements $\mathbf{z}[i+1] - \mathbf{z}[i]$ is either 0 or 1. It is easy to perform this check with a linear-size arithmetic circuit.

[20] uses this linear-sized circuit to handle all comparisons of the [26] consistency check in batch. Equality computations can similarly be handled by a constant overhead circuit. Thus, [20] removes the logarithmically-sized circuit components from [26], achieving true constant overhead in circuit size.

While [20] indeed improves over [26], it retains inefficiencies of [26]'s consistency check, so the approach still requires 27 non-linear gates per access.

[20] specialized their approach for the ZK paradigm based on 'MPC-in-the-head' [19,34], but since it is an arithmetic circuit, it can be used in other paradigms as well. Indeed, we implemented [20]'s approach in the VOLE-based ZK paradigm so that we can compare to it (see Section 6).

Our ZK RAM leverages a fundamentally different approach to consistency, allowing us to achieve RAM from fewer gates.

[2] The [26] notion of 'overhead' is the total communication cost divided by the number of bits read from RAM. Since the number of gates grows linearly in the size of RAM words, [26] can claim constant overhead.

Other related work. A number of other works [7, 8, 30–32, 41] achieved proof system RAM. These works are based on permutation networks [9, 42], requiring polylogarithmic overhead for each access.

[13] was the first to achieve only super-constant prover cost based on shuffle proofs, e.g. [38]. Their approach is not practical, as explicitly stated by the authors.

[14] developed proofs for programs in the Map-Reduce model; they do not achieve general RAM.

We note that our ZK ROM shares some similarities with Plonk's lookup table literature (starting from [27]). Similar intuition to our ZK RAM has been applied in the *memory checking* literature (e.g., [12, 24, 50]), which focuses on providing a correct outsourced memory (*without ZK*). Our work ensures memory-checker-like techniques are efficiently handled in the ZK setting, where we are strictly limited in that all operations must be handled by black-box field arithmetic. Achieving this efficiently requires careful handling of ROM/RAM.

4 Technical Overview

4.1 Read-Only Memory

To begin, let us elide writes, and suppose that we wish to implement read-only memory (ROM). Namely, $\mathcal{P}$ and $\mathcal{V}$ agree on a length-n vector of wires $\mathbf{x}$, and we encode $\mathbf{x}$ as a ROM data structure. Now, given an address wire i, the circuit can query $\texttt{lookup}(i)$, which returns a wire holding $\mathbf{x}[i]$. We present an efficient instantiation of `lookup`.

As a first insight, observe that each call to `lookup` can leverage honest $\mathcal{P}$ as an oracle; honest $\mathcal{P}$ knows the cleartext value of $\mathbf{x}$ and i, and hence she can simply provide $\mathbf{x}[i]$ as input. Of course, $\mathcal{P}$ might be cheating, so we must check that each such input is indeed correct.

Our ROM data structure handles all such checks in batch by maintaining two vectors of tuples, *reads* and *writes*. On each call to `lookup`, we append one element to *reads* and one to *writes*. Our key insight is that with minimal added metadata, we can ensure that each call to `lookup` is correct if and only if *reads* is a permutation of *writes*.

Each element of *reads* (resp. *writes*) is a three-tuple of (1) the element's address, (2) the element's value, and (3) a metadata value called the *version*. Versions act as address-specific counters, and each call to `lookup` increments a version.

To set up our ROM data structure, for each address $i \in [n]$ we append to *writes* the following tuple:

$$(i, \mathbf{x}[i], 0)$$

I.e., we initialize each element with version 0. Then, on each call to $\texttt{lookup}(i)$, $\mathcal{P}$ provides two inputs: (1) the value $\mathbf{x}[i]$ and (2) the *latest* version v associated with address i. We then update both *reads* and *writes* by appending the old version $(i, \mathbf{x}[i], v)$ to *reads* and a fresh version $(i, \mathbf{x}[i], v+1)$ to *writes*.

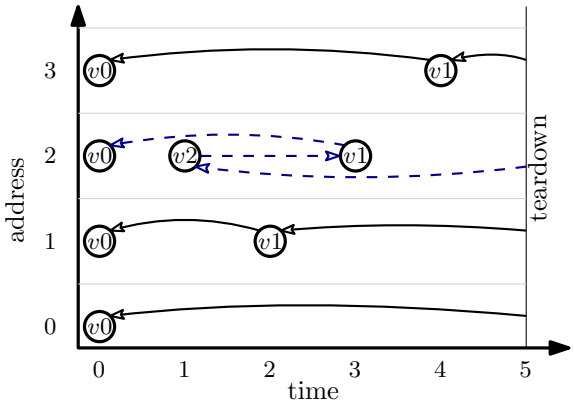

Figure 5: Access pattern for a size-4 ROM with lookup pattern $2, 1, 2, 3$. On each lookup, we read an element and write back a fresh version of that same element. Nodes represent writes; edges represent reads. Because (1) versions monotonically increase and (2) reads must be a permutation of writes, even malicious $\mathcal{P}$ cannot read an element that was not written at setup time. It *is* possible for malicious $\mathcal{P}$ to read elements written "in the future" (e.g., $\mathcal{P}$ can construct the graph for address 2), but it is *not* possible for $\mathcal{P}$ to form a cycle.

When we are finished with ROM, we perform a simple cleanup step that we call a *teardown*. For each address $i \in [n]$, honest $\mathcal{P}$ inputs the latest version v, and we append $(i, \mathbf{x}[i], v)$ to *reads*. Finally, $\mathcal{P}$ demonstrates that the reads and writes are related by a permutation: *reads* $\sim$ *writes*. Perhaps surprisingly, this simple approach is already correct and sound.

Correctness. Correctness of our ROM follows from the following key invariant:

Invariant 1 (ROM Invariant)**.** *On each call to* `lookup` *and for each address i, the vector writes contains (at least) one tuple of the form (i, val, v) that does not appear in reads.*

The setup phase establishes Invariant 1, because it writes version 0 of each element. Then, on each call to `lookup`, honest $\mathcal{P}$ propagates Invariant 1 by reading the latest version v of $\mathbf{x}[i]$, and writing back a fresh version $v+1$. Finally, the teardown phase reads the last version of each element, ensuring that every written version is also read. Hence, if $\mathcal{P}$ is honest, *reads* is indeed a permutation of *writes*.

Soundness. The key insight behind the soundness of our ROM is that even a malicious $\mathcal{P}$ *must* read each version of an element that is written, or else *reads* will not be a permutation of *writes*. Moreover, on each call to `lookup`, the circuit structure ensures that for whatever version v $\mathcal{P}$ chooses to read, a fresh version $v+1$ is written.

The above two facts bind $\mathcal{P}$ into building per-element chains of reads and writes (see Figure 5), where (1) each

read is made to a version written at some different point in time, (2) the initial link of the chain is written at setup, and (3) the final link is read at teardown. Because each element $\mathbf{x}[i]$ written at setup is stored on circuit wires (i.e., is not a prover input), and because on each `lookup` we write back the same element that was read, it must be the case that all reads made to the same address i match the initial value $\mathbf{x}[i]$.

Interestingly, our ROM does allow malicious $\mathcal{P}$ to "read from the future". Namely, on a particular call to $\texttt{lookup}(i)$, malicious $\mathcal{P}$ can read a version of $\mathbf{x}[i]$ that is only written at a *later* call to $\texttt{lookup}(i)$. This remains sound because the value $\mathbf{x}[i]$ does not change over the lifetime of the ROM. The crucial point is that it is *not* possible for $\mathcal{P}$ to form cycles, where two calls to `lookup` each read a version written by the other call. It is impossible to convincingly construct such a cycle because versions monotonically increases on each call to `lookup`, so $\mathcal{P}$ cannot arrange two versions such that each version is greater than the other.

The ability for malicious $\mathcal{P}$ to read from the future is the key distinction between ROM and full-fledged read/write RAM: in full RAM we must ensure that each of $\mathcal{P}$'s read values comes from the past.

Remark 1 (Looking up an illegal address)**.** *If a circuit calls* $\texttt{lookup}(i)$ *where i is not written at setup, then the proof will fail. This is because $\mathcal{P}$ cannot construct a chain, as there is no first link written at setup. This fact will be useful later.*

Generalizing to tuples. So far, the ROM stores individual wire values. It is easy to generalize the ROM such that each address stores an ℓ-tuple of wires for arbitrary ℓ. This simply requires changing the number of inputs provided by $\mathcal{P}$.

Generalizing to read-only key-value stores. So far, our ROM stores elements at addresses $0, 1, ..., n-1$. It is easy to generalize to a key-value store where the key space is an arbitrary set. In particular, at setup we initialize the key-value store from a list of pairs $(i, \mathbf{x}[i])$. So long as each address i is unique, this generalization incurs no extra cost. This is useful when using key-value stores to encode sets (Section 4.2)

Gate cost. Consider a ROM of size n where `lookup` is called T times. For a ROM storing ℓ-tuples, where ℓ is an arbitrary constant, each call to `lookup` requires $\ell+1$ inputs from $\mathcal{P}$ (the ℓ entries of the tuple and the version), for a total of $T \cdot (\ell+1)$ input gates. The teardown phase similarly requires that $\mathcal{P}$ reads each of the n slots, requiring $n \cdot (\ell+1)$ additional input gates. Finally, the permutation proof *reads* $\sim$ *writes* inspects vectors of length $n+T$; this can be implemented using two fan-in $n+T$ multiplication gates (see Section 2.2).

In sum, the full construction requires:

- $(n+T)(\ell+1)$ input gates.
- Two fan-in $n+T$ multiplication gates.
- $O(n+T)$ linear gates.

4.2 Sets with Membership Queries

As mentioned in Section 4.1, the key difference between ROM and full-fledged RAM is that in RAM we must check that each read value was written at some time in the past. As we will see, we achieve this by checking that on each access a particular timing value is in a public set $\{1, ..., T\}$, where T is the total number of RAM accesses.

We observe that our read-only key-value store (RO-KVS, Section 4.1) is well suited to this set membership proof. In particular, consider an RO-KVS where we set the size of tuples to $\ell = 0$. We initialize an RO-KVS with addresses $1, ..., T$. Then, to check that a particular value t is a member of a set, we call $\texttt{lookup}(t)$. This call does not return any data, but if t is not in the set $\{1, ..., T\}$, then the proof will fail, as was observed in Remark 1. Thus this call to `lookup` serves as a proof that t is in the set.

Gate cost. The cost of our set structure is inherited from the cost of ROM. For a set with T values and T membership queries (these parameters are used in our RAM), total cost is:

- $2T$ input gates.
- Two fan-in $2T$ multiplication gates.
- $O(T)$ linear gates.

4.3 Read/Write Memory

Consider a random access memory (RAM) equipped with a single `access` instruction. Each call to `access` accepts as input three arguments:

- $op \in \{0, 1\}$ is 0 on a load and 1 on a store.
- $i \in \mathbb{F}$ is an address.
- w is the value to store, if this operation is indeed a store.

Each RAM access both reads and writes data, whether the operation is a load or a store. On a store, we read the old data and write the new data; on a load, we read the old data and write back a fresh copy of the same data. Just like our ROM, our RAM maintains two vectors *reads* and *writes*, and on each access we update each vector. Also like our ROM, our RAM checks that reads are a permutation of writes: *reads* $\sim$ *writes*.

As mentioned in Section 4.1, the main challenge in RAM as compared to ROM is that we must prevent malicious $\mathcal{P}$ from reading a value written in the future. Our approach here is to maintain a monotonically increasing public value *clock* which is set to 0 at setup and then incremented on each `access`.

When we write a value *val* to address i, we append the following tuple to *writes*:

$$(i, val, clock)$$

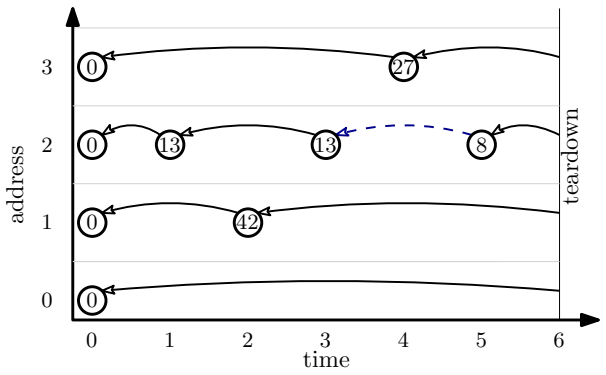

Figure 6: Zero-initialized RAM with history $(\texttt{store}, 2, 13)$, $(\texttt{store}, 1, 42)$, $(\texttt{load}, 2, \_)$, $(\texttt{store}, 3, 27)$, $(\texttt{store}, 2, 8)$. Each node represents a write; each edge represents a read. Our construction forces $\mathcal{P}$ to prove that (1) each node has one incoming edge and (2) each edge points to the left. Point (1) is achieved by checking that reads and writes are related by a permutation; point (2) is achieved by a set membership proof. This forces $\mathcal{P}$ to organize each address's history as a linked list. E.g., on operation $(\texttt{store}, 2, 8)$, $\mathcal{P}$ *must* read from the immediately preceding address 2 write.

I.e., we mark each write with the time it occurred. To read a value and ensure *reads* $\sim$ *writes*, we must also mark each read value with the time at which that value was written. Accordingly, each call to `access` at address i requests that $\mathcal{P}$ inputs two values: (1) the value *val* that was last written to address i and (2) the *time* t when the write occurred.

Of course, $\mathcal{P}$ might be malicious, so we must check that the input (val, t) is consistent with the semantics of read/write RAM. The permutation proof *reads* $\sim$ *writes* ensures that each such triple (i, val, t) is indeed written at *some* point in time. The remaining challenge is to ensure that this point in time is *in the past*, which can be achieved by checking that $clock - t$ is a strictly positive value. Said another way, we can check that $clock - t$ is in the set $\{1, \ldots, T\}$, where T is the total number of RAM accesses. Each such check is achieved by our set data structure (Section 4.2).

This simple set membership proof is sufficient, and we *do not* need to explicitly prove that each read corresponds to the *most recent* write. Indeed, this stronger property (each read comes from the latest write) is *implied* by the local checks combined with the permutation proof *reads* $\sim$ *writes*.

To see that this is true, observe that our RAM maintains the following key invariant:

Invariant 2 (RAM Invariant)**.** *Before each call to* `access` *and for each address i, writes contains exactly one tuple of the form* (i, val, t) *that does not appear in reads. Moreover, the value t is highest amongst all such tuples in writes; i.e., this tuple records the most recent write to address i.*

When we set up RAM with initial content $\mathbf{x}$, we append the following write for each address i: $(i, \mathbf{x}[i], 0)$. Since we write each address once, our setup trivially establishes Invariant 2.

On each call to `access`, $\mathcal{P}$ is forced to input values (val, t) such that $clock - t$ is positive. By Invariant 2 there is only *one* such choice that will pass the permutation proof, and this choice must be the most recent version of address i, so this access is sound. Moreover, this access propagates the invariant because we increment the clock and write a fresh copy of address i; see also Figure 6.

Once all T accesses are complete, note that we have written $n + T$ values, but we have only read T values. We allow $\mathcal{P}$ to complete the read history in a teardown step, where we read (without writing back) each RAM address. In particular, for each address i, $\mathcal{P}$ again inputs a pair (val, t), and we append (i, val, t) to *reads*. Note that on this step and by Invariant 2, we do not need to check that $clock - t$ is positive; it *must* be, or else the permutation proof will fail.

Generalizing to tuples. As in our ROM, it is straightforward to generalize the RAM such that each address stores an ℓ-tuple of wires for arbitrary constant ℓ. This simply requires changing the number of inputs provided by $\mathcal{P}$.

Gate cost. Our RAM has four relevant costs:

- We maintain the set $\{1, \ldots, T\}$ (Section 4.2) and perform one membership proof per access.
- We use a permutation proof (Section 2.2) on two length-$(T + n)$ vectors: *reads* $\sim$ *writes*.
- $\mathcal{P}$ inputs two values (val, t) on each of the T accesses, and for each of n addresses at teardown.
- We include a single multiplexer that disambiguates load operations from store operations. In particular, after reading *old* from RAM, we compute:

$$new \leftarrow old + op \cdot (w - old)$$

  If the operation type is public, this is not needed. For completeness, we assume operation types are private.

In total, the RAM incurs the following gate cost:

- $4T + 2n$ input gates.
- Two fan-in $2T$ multiplications (from the set) and two fan-in $T + n$ multiplications (from the permutation proof). We optimize one of the fan-in $2T$ multiplications to be only fan-in T; see Section 5.2.
- T fan-in two multiplications (from multiplexers).
- $O(n + T)$ miscellaneous linear operations.

When we assume that the number of accesses T is significantly greater than the RAM size n, we obtain the per-access costs listed in our contribution.

5 Approach

5.1 Formal Protocol and Security

We formalize our ZK RAM as a protocol in the $\mathcal{F}_{ZK}^{perm}$-hybrid model. This protocol formalizes ideas explained in Section 4. Our protocol is defined with respect to Figures 7 to 9.

Protocol 1. *$\mathcal{P}$ and $\mathcal{V}$ agree on an arithmetic circuit with RAM access C; i.e., C is written in the syntax of Figure 2. $\mathcal{P}$ holds as input a witness $\mathbf{w}$. $\mathcal{P}$ and $\mathcal{V}$ compile C to an arithmetic circuit with permutations (Figure 1) in the following manner:*

- *For each* `input` *gate, addition gate, subtraction gate, multiplication gate, and constant wire, they trivially compile the circuit element.*
- *For each* `make-mem` *gate, the parties invoke* `setup` *(Figure 9) which produces a circuit-based RAM data structure. $\mathcal{P}$ locally maintains a cleartext copy of this RAM (and its internal set structure), allowing $\mathcal{P}$ to track which value is stored at each address.*
- *For each* `access` *gate, the parties invoke the* `access` *procedure of Figure 9. $\mathcal{P}$ extends her witness $\mathbf{w}$ by using her local copy of the RAM to recall the last time t when the queried address was accessed and what value val was stored there (and to find the set version of clock $-t$) so that these values can be passed to* `input` *gates. $\mathcal{P}$ updates her local copy of RAM.*
- *Once all gates are compiled, the parties invoke* `teardown` *on each RAM data structure created by a call to* `setup`*. $\mathcal{P}$ uses her local copy of RAM (and its internal set) to appropriately extend her witness $\mathbf{w}$.*

$\mathcal{P}$ and $\mathcal{V}$ thus agree on a circuit C' with arithmetic gates and permutation proofs. Next, (1) $\mathcal{P}$ sends $(\texttt{prove}, C', \mathbf{w})$ to $\mathcal{F}_{ZK}^{perm}$, (2) $\mathcal{V}$ sends $(\texttt{verify}, C')$ to $\mathcal{F}_{ZK}^{perm}$, (3) $\mathcal{P}$ outputs $\perp$, and (4) $\mathcal{V}$ outputs whatever he receives from $\mathcal{F}_{ZK}^{perm}$.

Our key security property is that Protocol 1 achieves the Figure 4 functionality, allowing us to securely implement ZK proofs with RAM.

Theorem 1. *Protocol 1 UC-realizes $\mathcal{F}_{ZK}^{ram}$ (Figures 2 and 4) in the $\mathcal{F}_{ZK}^{perm}$-hybrid model (Figures 1 and 3) with no soundness error.*

The full version includes a detailed proof of Theorem 1. For now, we sketch the argument, focusing on soundness.

Proof Sketch. By construction of a simulator $\mathcal{S}$.

Our protocol can be viewed as a circuit compiler that maps arithmetic circuits with RAM (Figures 2 and 4) to arithmetic circuits with permutations (Figures 1 and 3). Accordingly, $\mathcal{S}$'s only task is to tediously convert between RAM circuits and permutation circuits, and to collect $\mathcal{P}$'s witness $\mathbf{w}$ before sending it to the $\mathcal{F}_{ZK}^{ram}$ functionality.

However, we still must demonstrate that $\mathcal{S}$ is a valid simulator, and that the UC environment cannot distinguish the simulation from the real world protocol. The challenge in showing this is that our compilation generates non-trivial `input` gates, allowing $\mathcal{P}$ extra degrees of freedom in choosing a convincing witness. Therefore, we must argue that our construction is sound. All compiled gates in Figure 2 are trivially sound, save for `make-mem` and `access` gates.

In short, these gates are sound because our RAM construction includes a permutation proof on its reads and writes, and because on each access we check that $\mathcal{P}$'s chosen time t is less than *clock* (this latter property is checked by a set membership proof). As per discussion near Invariant 2, these local checks enforce a global ordering of reads/writes on each address, on each access forcing $\mathcal{P}$ to input the most recent value written to the same address.

It remains to show that the underlying set data structure is sound. As discussed in Section 4.1, our set (as inherited from our ROM) on each access forces $\mathcal{P}$ to input a version. Because we monotonically increase versions and because we use a permutation proof on set reads/writes, we force $\mathcal{P}$ to construct a linked list of read/write pairs, connecting each read value to the setup-time write on the same address.

Together, this means that $\mathcal{P}$'s extra inputs must respect the semantics of `access` gates, so the protocol is sound. □

Prior work on VOLE-based ZK gave powerful constant round protocols for proving arithmetic statements. Such prior works, together with the permutation proof method discussed in Section 2.2 and an optimization discussed in Section 5.2, imply the following (see Appendix B.2 for more details):

Lemma 1. *There exists a 5-round protocol in the VOLE-hybrid model that UC-realizes $\mathcal{F}_{ZK}^{perm}$. For each use of* `input` *and of $\llcorner\cdot\lrcorner$, $\mathcal{P}$ and $\mathcal{V}$ use 1 VOLE correlation; for each use of $\llcorner\sim\lrcorner$ on two length-n vectors, $\mathcal{P}$ and $\mathcal{V}$ each evaluate a linear number of field operations and consume $\frac{2n}{\varepsilon-1}+o(1)$ VOLE correlations, for any constant $\varepsilon \geq 2$. The protocol achieves soundness error $O(\frac{n+m}{|\mathbb{F}|})$, where n is the size of the largest vector passed to $\llcorner\sim\lrcorner$ and m is the number of multiplications.*

Together, Theorem 1 and Lemma 1 allow us to instantiate ZK RAM from VOLE-based ZK:

Corollary 1 (RAM from VOLE)**.** *There exists a 5-round protocol in the VOLE-hybrid model that UC-realizes $\mathcal{F}_{ZK}^{ram}$. For each call to* `access` *on a size-n memory that is accessed $T=\omega(n)$ times, $\mathcal{P}$ and $\mathcal{V}$ each evaluate a constant number of field operations and consume $5+\frac{5}{\varepsilon-1}+o(1)$ VOLE correlations, for any constant $\varepsilon \geq 2$. The protocol achieves soundness error $O(\frac{T+m}{|\mathbb{F}|})$, where T is the largest number of accesses used by any memory and m is the number of multiplications.*

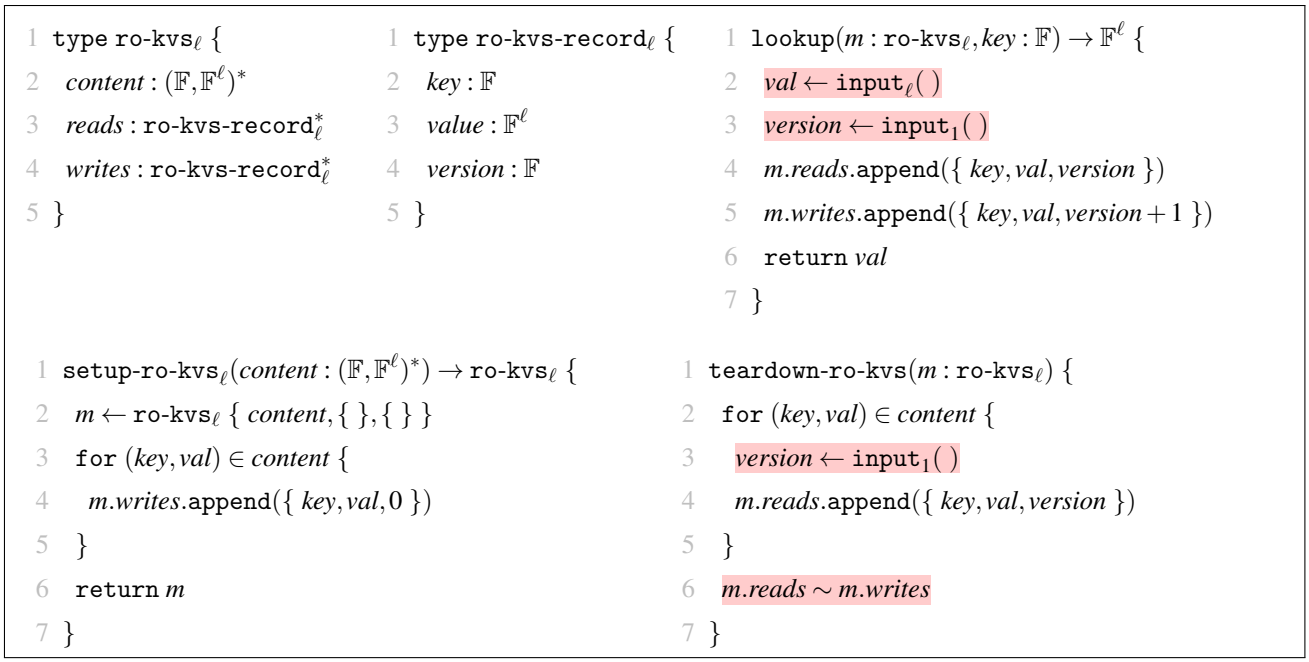

Figure 7: Our ZK read-only key-value store holds ℓ-word values at each key. We highlight uses of non-linear gates.

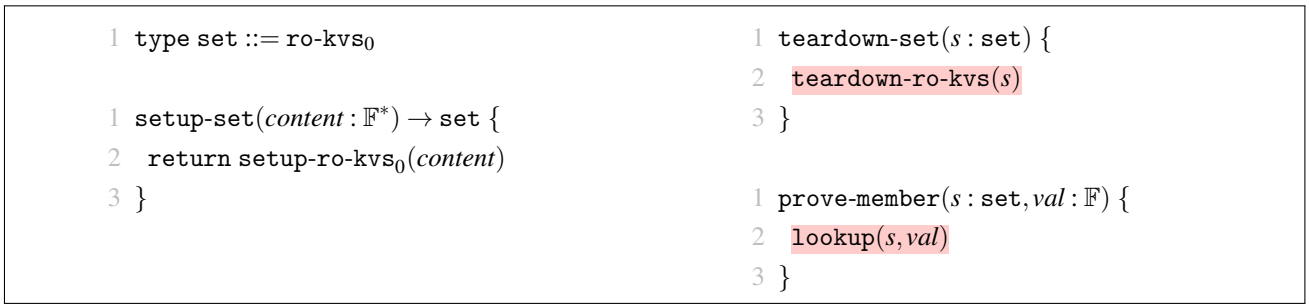

Figure 8: Our ZK set data structure is a specialization of our read-only key-value store (Figure 7) where each key holds 0 words. An element is considered a member of the set if it is a key in the key-value store. We highlight uses of non-linear gates.

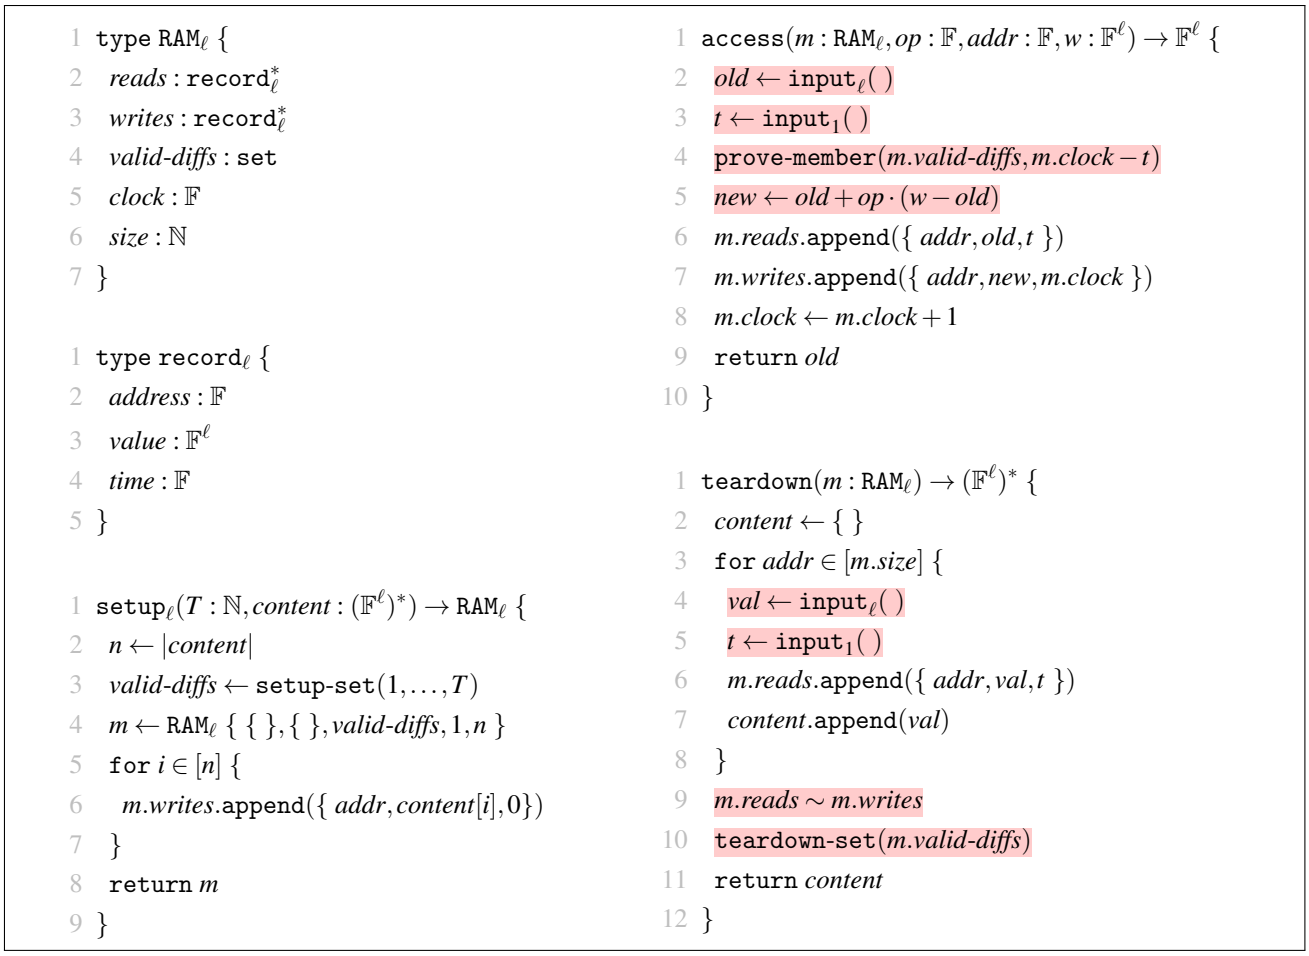
Formalizing ROM (including our set data structure). For simplicity and because RAM is more interesting than ROM, we chose to not formalize ROM as part of our top level functionality (Figure 4). Such a formalism can be derived from our RAM formalism by substituting RAM-related gates to initialize ROM and access ROM, and correspondingly modifying Protocol 1 according to Figure 7. Soundness of ROM gates follows from our proof of Theorem 1. We include security games crucial for the soundness proof of ROM in Appendix B.1.

5.2 Optimizations



Accelerating permutation proofs. The main cost of our protocol comes from permutation proofs, and permutation proofs can be achieved by high fan-in multiplications (Section 2.2). We note two important available optimizations.

The first optimization is generally applicable for any ZK system and saves T multiplications. Consider the permutation proof performed on the publicly known set $\{1,\ldots,T\}$ (Section 4.2). Here, the first T writes are *publicly known* to be $(1,0),(2,0),\ldots,(T-1,0),(T,0)$. Hence, in the permutation proof, once $\mathcal{V}$ chooses a random challenge, $\mathcal{P}$ and $\mathcal{V}$ can *locally* compute the product of the first T components of *writes*. Again, this saves T ZK multiplications.

The second optimization leverages a VOLE-specific trick to reduce cost of high fan-in multiplications. QuickSilver [47] supports *polynomial proofs*. Namely, [47] can efficiently prove a batch sub-statements of the following form:

$$p(\mathbf{x}_0) = 0, \ldots, p(\mathbf{x}_{n-1}) = 0$$

Here, p is a degree-d polynomial over arithmetic wires. The batch of n sub-statements requires only d VOLE correlations (VOLE correlations are the primary cost in VOLE-based ZK). This trick reduces VOLE correlations, but can increase com-

  return content
}
```

Figure 9: Our ZK read/write memory. Each memory slot holds an ℓ-tuple of field elements. The memory is defined in terms of our `set` data structure (Figure 8). We define three procedures: `setup`, `access`, and `teardown`. Valid usage consists of one call to `setup`, an arbitrary (polynomial) number of calls to `access`, and one call to `teardown`. We highlight uses of non-linear gates.

putation, as $\mathcal{P}$'s compute scales with $O(d^2)$.

Polynomial proofs can optimize fan-in-n multiplications as follows. Consider a fan-in-ε multiplication for any constant $\varepsilon \geq 2$. We can implement such a multiplication by allowing $\mathcal{P}$ to input a value *prod*, and then defining a degree-ε polynomial that multiplies the ε values and subtracts *prod*. This is a degree ε polynomial, and we can use [47] to prove it equals zero (if it does, $\mathcal{P}$ input *prod* correctly). It is straightforward to use $\lceil \frac{n}{\varepsilon-1} \rceil$ fan-in-ε multiplications to implement a fan-in-n multiplication, so we can use $\lceil \frac{n}{\varepsilon-1} \rceil$ polynomial proofs to implement a fan-in-n multiplication.

Prior work [26] also used this trick, but their corresponding improvement was limited, as their cost is dominated by comparisons, not by permutation proofs. In our approach, almost all multiplication cost comes from high fan-in multiplications, so we enjoy substantial improvement.

By choosing arbitrary constant $\varepsilon \geq 2$, we reduce the number of VOLE correlations from $\approx 10T$ to $\approx (5 + \frac{5}{\varepsilon-1})T$. This reduces the communication used by $\mathcal{P}$ and $\mathcal{V}$, and it also reduces the amount of computation needed to construct the correlations. However, as stated above, $\mathcal{P}$'s proof computation increases as we increase ε, so we limit ε to constant values to avoid asymptotic problems. In Section 6 we find it is best to set ε between 8 and 32, depending on the network.

To our knowledge, this polynomial proof optimization is currently specific to VOLE-based ZK. It is possible similar optimizations will emerge in other ZK paradigms, particularly because ZK RAM provides compelling motivation.

Other optimizations. We discuss some additional (unimplemented) optimizations in the full version.

6 Evaluation

Our implementation. We implemented our ROM, our set, and our RAM ZK data structures from VOLE in C++. We use the learning-parity-with-noise-based VOLE protocol of [44]

which is implemented as part of the EMP Toolkit [43]. While our VOLE-based approach will extend to any large field, we use the field $\mathbb{F}_{2^{61}-1}$ because this is the only arithmetic field currently implemented by EMP.

[26] and [20] implementation. We compare our RAM to that of [26] and of [20]. We also compare our ROM to that of [26]. [26]'s RAM/ROM implementation is publicly available as part of the EMP Toolkit [43]. [20]'s RAM implementation is not publicly available. We implemented a VOLE-based version of their RAM[3] in C++. Other ZK RAMs do not have constant overhead per access.[4]

As discussed in Section 3, [20]'s RAM leverages permutation proofs. Recall, VOLE-based ZK offer optimizations for permutation proofs (see Section 5.2). We also note that several gates in [20]'s protocol can be further optimized in VOLE-based ZK. In particular, these gates require checking that the product of two wires is some constant; such checks can be done in VOLE-based ZK without communication. For fair comparison, we incorporate all such VOLE-based optimizations in our implementation of [20].

Experimental setup. We ran all three RAMs on a benchmark where we instantiate a RAM of sizes n ranging from 2^{11} to 2^{20} and perform $T = 2^{23}$ accesses. We run our ROM, [26]'s ROM, and our set data structure with the same n and T.

In all cases, $\mathcal{P}$ and $\mathcal{V}$ run single threaded on a separate Amazon EC2 `m5.2xlarge` machine[5]. We measure total (and per-access) communication in bytes and per-access runtime in microseconds. For the latter, we experiment with different network bandwidth settings, varying between a WAN-like 25Mbps connection and a LAN-like 1Gbps connection.

Parameter ε for accelerating permutation proofs. Our RAM, ROM, and set data structures (and our implemented [20]'s RAM) all benefit from VOLE-based polynomial proofs used to optimize to high-fan-in multiplications (see Section 5.2). In particular, recall that parameter ε trades off between number of required VOLE correlations and $\mathcal{P}$ computation. Figure 10 tabulates the impact of ε on performance (we set $n = 2^{20}$ and $T = 2^{23}$).

For simplicity of implementation, we organize our high fan-in-n multiplications as trees of multiplications, and we only use fan-in-ε gates at the widest tree level. The remaining multiplications are achieved with fan-in-two gates. This means our high fan-in gates use $\approx \frac{2n}{\varepsilon}$ VOLES, rather than $\lceil \frac{n}{\varepsilon-1} \rceil$s. In practice, the change in performance is not noticeable.

[3] [20]'s RAM was designed for the MPC-in-the-head paradigm, but, like our RAM, it is a pure arithmetic circuit with random challenges, so it can also be implemented for VOLE-ZK.

[4] [26] reported clear concrete improvements over earlier ZK RAMs.

[5] Intel Xeon Platinum 8175 CPU @ 3.10GHz, 8 vCPUs, 32GiB Memory, 10Gbps Network

$n = 2^{20}$	Bandwidth	ε

Figure 10: Per-access runtime (μs) and communication (bytes) of our data structures as a function of ε, the degree of polynomials used in our handling of high fan-in multiplications; see Section 5.2. As ε increases, we use fewer VOLE correlations, but $\mathcal{P}$ computes more field operations.

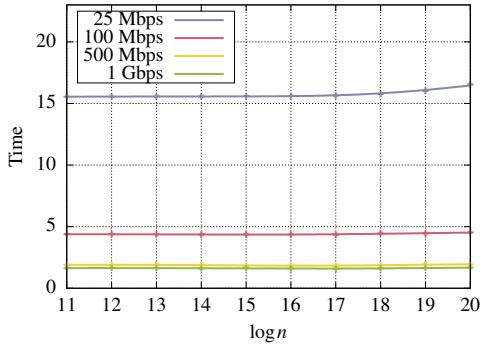

Figure 11: Per-access runtime of our RAM (μs).

In subsequent experiments, we set $\varepsilon = 16$. Increasing ε beyond this point yields greatly diminished communication improvement, as input gates dominate cost and are not improved by increasing ε.

Our RAM performance. Figure 11 plots per-access runtime of our RAM in microseconds. On a slow 25Mbps WAN-like connection, our RAM requires $\sim 15\mu s$ per access; On a faster 100Mbps WAN-like connection, our RAM requires $< 5\mu s$ per access; On a 1Gbps LAN-like connection, our RAM requires only $\sim 1.5\mu s$ per access, achieving access at ≈ 600 KHz. As n ranges from 2^{11} to 2^{20}, the per-access communication increases only from 47 to 50 bytes; runtime remains essentially unchanged (caching begins to impact performance at high n). The full version includes detailed data.

Our ROM and set performance. On a 25Mbps WAN-like connection, our ROM (resp. set) requires $< 8\mu s$ (resp. $< 4\mu s$) per access; on a 1Gbps LAN-like connection, our ROM (resp. set) requires $\sim 1\mu s$ (resp. $< 1\mu s$) per access. As n ranges

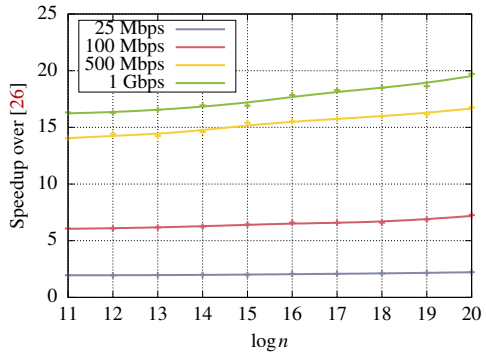

Figure 12: Speedup of our RAM over [26]'s RAM.

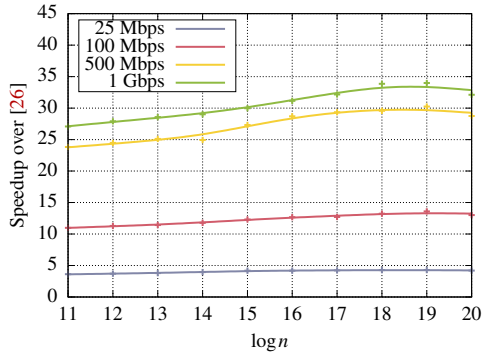

Figure 13: Our ROM's speedup over [26]'s ROM.

from 2^{11} to 2^{20}, the per-access communication is 19-22 (resp. 10-12) bytes; runtime remains essentially unchanged (caching effects begin to impact performance at high n). We defer plots and detailed data to the full version.

Our RAM/ROM vs. [26]'s RAM/ROM. Figures 12 and 13 plot our RAM/ROM's speedup over [26]'s RAM/ROM. Speedup is defined by per-access $t_{baseline}/t_{ours}$. [26]'s implementation is over Boolean circuits with $\mathbb{Z}_{2^{32}}$ ring algebraic structure. Our ROM improves over [26]'s ROM by 3-34×, depending on bandwidth. Our RAM improves over [26]'s RAM by 2-20×. Figure 14 tabulates communication required by our RAM/ROM as compared to [26].

Our speedup comes primarily from improved computation, resulting from a greatly reduced number of gates. Note the significant communication reduction from $\mathcal{V}$ to $\mathcal{P}$, reflecting our reduction in the number of required VOLE correlations.

Our RAM vs. [20]'s RAM. Figure 15 plots our RAM speedup over our optimized implementation of [20]'s RAM.

Even though we heavily optimize [20]'s RAM, our RAM still improves per-access runtime by 2.2-2.9×. As n ranges from 2^{11} to 2^{20}, [20]'s per-access communication goes from 129 to 145 bytes, which is $\approx 3\times$ more than our RAM.

	Direction	Benchmark	log n				
			12	14	16	18	20
ROM	$\mathcal{P} \to \mathcal{V}$	[26]	28.4	29.2	30.1	31.5	34.7
		Ours	18.4	18.5	18.6	19.2	21.8
	$\mathcal{V} \to \mathcal{P}$	[26]	12.6	12.9	13.4	14.0	15.3
		Ours	0.7	0.7	0.7	0.7	0.9
	Total	[26]	41.0	42.1	43.5	45.6	50.1
		Ours	19.1	19.2	19.3	19.9	22.7
RAM	$\mathcal{P} \to \mathcal{V}$	[26]	32.3	33.1	34.1	35.5	39.2
		Ours	45.7	45.8	45.9	46.5	49.0
	$\mathcal{V} \to \mathcal{P}$	[26]	14.5	14.8	15.2	15.9	17.5
		Ours	1.3	1.3	1.3	1.3	1.3
	Total	[26]	46.9	48.0	49.3	51.4	56.8
		Ours	47.1	47.1	47.3	47.9	50.3

Figure 14: Per-access communication (bytes) used by our ROM (resp. RAM) versus [26]'s ROM (resp. RAM).

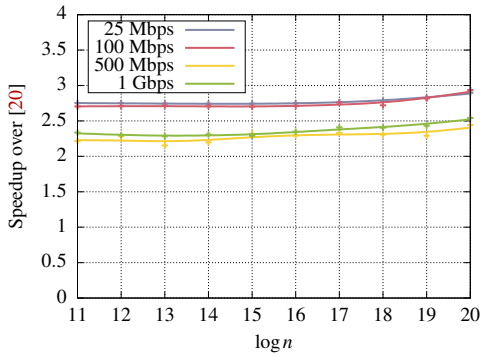

Figure 15: Our RAM's speedup over [20]'s RAM (we optimize [20]'s RAM).

As one additional data-point, we disabled all VOLE-based optimizations for both our RAM and our implementation of [20], then ran with $n = 2^{20}$. Here, our RAM requires 88 bytes per access while [20] requires 242 bytes. These numbers reflect our raw advantage in total number of non-linear gates.

$n = 2^{20}$	ROM			RAM		
Bandwidth (Mbps)	25	100	500	25	100	500
Setup	0.66	0.26	0.19	0.76	0.38	0.32
Access	5.30	1.38	0.47	10.56	2.73	0.87
Teardown	1.53	0.45	0.29	5.23	1.42	0.74
Total	7.49	2.09	0.95	16.55	4.53	1.93

Figure 16: Runtime cost breakdown of our ROM/RAM (μs).

Microbenchmarks. Figure 16 breaks down the per-access runtime of our RAM and ROM. The main components include setup, access, and teardown (see Figures 7 and 9). Access clearly dominates cost, and setup is by far the cheapest step.

Appendix A Commit-and-Prove ZK

For completeness, Figure 17 lists the standard commit-and-prove ZK functionality, as formalized by [17].

Functionality $\mathcal{F}_{ZK}^{cp}$

$\mathcal{F}_{ZK}^{cp}$ considers a prover $\mathcal{P}$, a verifier $\mathcal{V}$, and an adversary $\mathcal{S}$, and it is parameterized by a field $\mathbb{F}$:

Commits: Upon receiving $(\texttt{commit}, cid, x)$ from $\mathcal{P}$ where (a) there is no recorded tuple $(cid, \cdot)$, and (b) $x \in \mathbb{F}$: Record the tuple (cid, x) and send $(\texttt{commit}, cid)$ to $\mathcal{S}$ and $\mathcal{V}$.

Proof: Upon receiving $(\texttt{prove}, C, cid_1, \ldots, cid_n)$ from $\mathcal{P}$ where (1) C is a circuit $C : \mathbb{F}^{(n)} \mapsto \mathbb{F}$, and (b) each $cid_{i\in[n]}$ was recorded:

- Fetch recorded $(cid_1, x_1), \ldots, (cid_n, x_n)$, compute $y := C(x_1, \ldots, x_n)$. If $y = 0$, send $(\texttt{prove}, C, \textbf{cid}, \texttt{true})$ to $\mathcal{S}$ and $\mathcal{V}$; else send $(\texttt{prove}, C, \textbf{cid}, \texttt{false})$ to $\mathcal{S}$ and $\mathcal{V}$.

Appendix B Proof of Security

B.1 Soundness Lemmas

Protocol 1 requires that $\mathcal{P}$ input extra field elements. The soundness of our protocol is based on the fact that even a malicious $\mathcal{P}$ cannot input values that disagree with the semantics of ROM/RAM. This section formalizes $\mathcal{P}$'s inability to cheat as security games and lemmas. Our main proof of security relies on these lemmas.

Lemma 2. *Let $\mathbb{F}$ be a prime field, and let m a positive integer s.t. $m < |\mathbb{F}|$. Let $P \triangleq \{t_1, \ldots, t_m\}$ be an ordered set of any m field elements. Let $Q \triangleq \{t_1+1, \ldots, t_m+1\}$ be an ordered set. P and Q cannot form a permutation: $P \not\sim Q$.*

Proof. By induction on the entries of P and Q. Consider t_1 in P. By construction, we ensure t_1+1 is in Q. If $P \sim Q$, then t_1+1 is also in P. By repeating this argument, P must have $t_1, t_1+1, t_1+2, \ldots, t_1+m-1$. Accordingly, Q must have $t_1+1, t_1+2, t_1+3, \ldots, t_1+m$. However, since $m < |\mathbb{F}|, t_1 \notin Q$, contradicting $P \sim Q$. □

Game 1 (Single Element ROM)**.** Let $\mathbb{F}$ be a prime field, and let $T \in \mathbb{N}$ s.t. $T < |\mathbb{F}|$. Consider lists R and W, both initialized as empty. Let $c_{begin}, t_{begin} \in \mathbb{F}$ be arbitrary values. The T-round game with $\mathcal{A}$ proceeds as follows:

1. Append (c_{begin}, t_{begin}) to W.
2. In each round $i \in [T]$: $\mathcal{A}$ chooses $c_i, t_i \in \mathbb{F}$. Append (c_i, t_i) to R; append (c_i, t_i+1) to W.
3. After T rounds: $\mathcal{A}$ chooses $c_{end}, t_{end} \in \mathbb{F}$. Append (c_{end}, t_{end}) to R.

We say that $\mathcal{A}$ wins i.f.f. W $\sim$ R at the end of the game.

Lemma 3. *If $\mathcal{A}$ wins Game 1, then the following must hold:*

$$c_{begin} = c_1 = \cdots = c_T = c_{end}$$

Namely, each $c_{i\in[T]}$ and c_{end} provided by $\mathcal{A}$ are equal to c_{begin}.

Proof. By induction on T.

Base case: When $T = 0$, W (resp. R) only has a single element (c_{begin}, t_{begin}) (resp. (c_{end}, t_{end})). If W $\sim$ R, then the single element in R must be (c_{begin}, t_{begin}). This implies $c_{begin} = c_{end}$, so the lemma holds.

Induction: By the inductive hypothesis, the lemma holds when $T = n$. Consider $T = n+1$. Suppose $\mathcal{A}$ wins the game when $T = n+1$, and thus R $\sim$ W. Consider (c_{begin}, t_{begin}) in W. The value (c_{begin}, t_{begin}) must be in R, and there are two possible placements of this value:

1. (c_{begin}, t_{begin}) is the last element of R:

   $$(c_{end}, t_{end}) = (c_{begin}, t_{begin})$$

   If we ignore (c_{end}, t_{end}) in R and (c_{begin}, t_{begin}) in W, then the remaining $n+1$ elements in R and W must still form a permutation:

   $$\{(c_1, t_1), \ldots, (c_T, t_T)\} \sim \{(c_1, t_1+1), \ldots, (c_T, t_T+1)\}$$

   But this is impossible by Lemma 2.

2. (c_{begin}, t_{begin}) is *not* the last element of R. I.e., there exists some $j \in [n+1]$ such that:

   $$(c_j, t_j) = (c_{begin}, t_{begin})$$

   In this case, the corresponding tuple appended to W in round j (c_j, t_j+1) can be understood as a tuple (c'_{begin}, t'_{begin}) in a new game with $T' = T-1 = n$. By the inductive hypothesis, we know all $c_{i\neq j}$ and c_{end} are equal to c_j, and c_j is equal to c_{begin}. Thus, the lemma holds for $T = n+1$.

Note, the inductive argument only holds when $T < |\mathbb{F}|$. □

Game 2 (ROM)**.** Let $\mathbb{F}$ be a prime field, and let $n, T \in \mathbb{N}$ s.t. $n, T < |\mathbb{F}|$. Consider lists R and W, both initialized as empty. Consider a size-n set of field elements $\{\ell_1, \ldots, \ell_n\}$ called the address set. For each $\ell_{k\in[n]}$, let $c_{k,begin}, t_{k,begin} \in \mathbb{F}$ be arbitrary values. The T-round game with $\mathcal{A}$ proceeds as follows:

1. For each $k \in [n]$, append $(\ell_k, c_{k,begin}, t_{k,begin})$ to W.
2. In each round $i \in [T]$: $\mathcal{A}$ chooses $c_i, t_i \in \mathbb{F}$ and $r_i \in [n]$. Append (ℓ_{r_i}, c_i, t_i) to R; append (ℓ_{r_i}, c_i, t_i+1) to W.
3. After T rounds: for each $\ell_{k\in[n]}$, $\mathcal{A}$ chooses $c_{k,end}, t_{k,end} \in \mathbb{F}$. Append $(\ell_k, c_{k,end}, t_{k,end})$ to R.

We say that $\mathcal{A}$ wins i.f.f. W $\sim$ R at the end of the game.

Lemma 4. *If $\mathcal{A}$ wins Game 2, then the following must hold:*

$$\forall k \in [n], \forall (\ell_k, c, t) \in \mathsf{R}, c = c_{k,begin}$$

Namely, once $\mathcal{A}$ selects r_i in each round, c_i must be equal to $c_{r_i,begin}$. Also, $c_{k,end} = c_{k,begin}$ for each $k \in [n]$.

Proof. By partitioning W and R into address-specific permutations, then applying Lemma 3.

In more detail, recall that in each round $i \in [T]$, $\mathcal{A}$ selects $r_i \in [n]$. We denote by T_k the number of rounds where $\mathcal{A}$ selects $r_i = k$. For each $k \in [n]$, we define address-specific reads and writes:

$$\mathsf{W}_k \triangleq \{(c,t) \mid (\ell_k, c, t) \in \mathsf{W}\}$$
$$\mathsf{R}_k \triangleq \{(c,t) \mid (\ell_k, c, t) \in \mathsf{R}\}$$

Note, $|\mathsf{W}_k| = |\mathsf{R}_k| = T_k + 1$. Since W $\sim$ R, and since each tuple is explicitly tagged with its address ℓ_k, it must be that $\mathsf{W}_k \sim \mathsf{R}_k$. For each k, we can now apply a T_k-round Game 1 to W_k and R_k, where (c_{begin}, t_{begin}) is set to $(c_{k,begin}, t_{k,begin})$. Since $T_k \leq T < |\mathbb{F}|$, applying Lemma 3 n times completes the proof. □

Game 3 (Single Element RAM)**.** Let $\mathbb{F}$ be a prime field, and let $T \in \mathbb{N}$ s.t. $T > 1$ and $|\mathbb{F}| \geq 2T$. Consider lists R and W, both initialized as empty. Let $c_{begin} \in \mathbb{F}$ be an arbitrary value. Consider a non-empty size-m set $S \triangleq \{s_1, \ldots, s_m\}$ called the timestamp set where:

$$1 \leq s_1 < s_2 < \cdots < s_m \leq T$$

The m-round game with $\mathcal{A}$ proceeds as follows:

1. Append $(c_{begin}, 0)$ to W.
2. For each round $i \in [m]$: $\mathcal{A}$ chooses $d_i, t_i, c_i \in \mathbb{F}$. Append (d_i, t_i) to R; append $(c_i, \mathsf{embed}(s_i))$ to W where $\mathsf{embed}(\cdot)$ denotes the trivial embedding from $[T]$ to $\mathbb{F}$ (henceforth, we omit calls to embed).
3. After m rounds: $\mathcal{A}$ chooses $d_{end}, t_{end} \in \mathbb{F}$. Append (d_{end}, t_{end}) to R.

We say that $\mathcal{A}$ wins i.f.f. at the end of the game:

$$\mathsf{W} \sim \mathsf{R} \qquad \text{and} \qquad \forall i \in [m], (s_i - t_i) \in \{1, 2, \ldots, T\}$$

Lemma 5. *If $\mathcal{A}$ wins Game 3, it must be that* $\mathsf{W} = \mathsf{R}$.

Proof. In short, we argue that at each round $\mathcal{A}$ has exactly one value it can "read" (similar to Invariant 2).

In more detail, note:

$$\mathsf{W} = \{(c_{begin}, 0), (c_1, s_1), \ldots, (c_m, s_m)\}$$

If $\mathsf{W} \sim \mathsf{R}$, then it must be that the following holds:

$$\{t_1, \ldots, t_m, t_{end}\} \sim \{0, s_1, \ldots, s_m\} \tag{1}$$

Consider t_1. By Equation (1), we know $t_1 \in \{0, s_1, \ldots, s_m\}$, and because $\mathcal{A}$ won the game, we know $(s_1 - t_1) \in \{1, \ldots, T\}$. Now, we argue it must be that $t_1 = 0$. Indeed, any other choice $t_1 \in \{s_1, \ldots, s_m\}$ will yield a difference $s_1 - t_1$ that outside the allowed range $\{1, \ldots, T\}$. This is because $s_1 - s_1$ is 0, and all other choices s_m are even greater than s_1:

$$s_1 - s_m + |\mathbb{F}| \geq 1 - T + |\mathbb{F}| > T$$

Similarly, consider t_2. By Equation (1), we know $t_2 \in \{0, s_1, \ldots, s_m\}$, and because $\mathcal{A}$ won the game, we know $(s_2 - t_2) \in \{1, \ldots, T\}$. It must be that $t_2 = s_1$. Indeed:

$$s_2 - s_m + |\mathbb{F}| \geq 1 - T + |\mathbb{F}| > T$$

Thus, t_2 must be in the set $\{0, s_1\}$. Moreover, $t_1 = 0$, so to satisfy the permutation requirement, t_2 can only be s_1.

We can inductively repeat the above analysis for each t_*. I.e., $t_i = s_{i-1}$ (assume $s_0 = 0$) for all $i \in [m]$ and $t_{end} = s_m$.

To sum up, $\{t_1, \ldots, t_m, t_{end}\} = \{0, s_1, \ldots, s_m\}$, where we interpret these as ordered sets. Note that each s is distinct and non-zero. Since $W \sim R$, it must be that $W = R$. □

Game 4 (RAM)**.** Let $\mathbb{F}$ be a prime field, and let $T \in \mathbb{N}$ s.t. $T > 1$ and $|\mathbb{F}| > 2T - 1$. Consider lists R and W, both initialized as empty. Consider a set of field elements $\{\ell_1, \ldots, \ell_n\}$ called the address set. For each $\ell_{k \in [n]}$, let $c_{k,begin} \in \mathbb{F}$ be an arbitrary field element. The T-round game with $\mathcal{A}$ proceeds as follows:

1. For each $k \in [n]$, append $(\ell_k, c_{k,begin}, 0)$ to W.
2. For each round $i \in [T]$: $\mathcal{A}$ chooses $d_i, t_i, c_i \in \mathbb{F}$ and $r_i \in [n]$. Append (ℓ_{r_i}, d_i, t_i) to R; append (ℓ_{r_i}, c_i, i) to W.
3. After T rounds: for each $\ell_{k \in [n]}$, $\mathcal{A}$ chooses $d_{k,end}, t_{k,end} \in \mathbb{F}$. Append $(\ell_k, d_{k,end}, t_{k,end})$ to R.

We say that $\mathcal{A}$ wins i.f.f. at the end of the game:

$$\mathsf{W} \sim \mathsf{R} \qquad \text{and} \qquad \forall i \in [T], (i - t_i) \in \{1, 2, \ldots, T\}$$

Lemma 6. *If $\mathcal{A}$ wins Game 4, then the following must hold: For each $k \in [n]$, define lists W_k and R_k as follows:*

$$\mathsf{W}_k \triangleq \{(c, t) \mid (\ell_k, c, t) \in \mathsf{W}\}$$
$$\mathsf{R}_k \triangleq \{(d, t) \mid (\ell_k, d, t) \in \mathsf{R}\}$$

I.e., fetch (in order) the tuples in W *and* R *with ℓ_k as the address. For each k, it holds that* $\mathsf{W}_k = \mathsf{R}_k$.[6]

Proof. Immediate, by partitioning W and R into address-specific permutations, then applying Lemma 5 n times. □

B.2 Proof of Lemma 1

We instantiate our protocols as a VOLE-based ZK system. Lemma 1 shows that $\mathcal{F}_{ZK}^{perm}$ can be UC-realized in the VOLE-hybrid model. This is achieved by prior work, e.g., [26, 47]. For completeness, we state facts supported by prior work.

Lemma 7. *There exists a 3-round protocol in the VOLE-hybrid model that UC-realizes $\mathcal{F}_{ZK}^{perm}$* without permutation gates*. For each use of* `input` *and of $\llcorner \cdot \lrcorner$, $\mathcal{P}$ and $\mathcal{V}$ use 1 VOLE correlation. The protocol achieves soundness error $O(\frac{m}{|\mathbb{F}|})$, where m is the number of multiplications.*

Proof. See [47]. □

Lemma 8. *There exists a 3-round protocol in the VOLE-hybrid model that UC-realizes $\mathcal{F}_{ZK}^{perm}$* with only permutation and input gates*. For each use of* `input`*, $\mathcal{P}$ and $\mathcal{V}$ use 1 VOLE correlation; for each use of $\llcorner \sim \lrcorner$ on two length-n vectors, $\mathcal{P}$ and $\mathcal{V}$ each evaluate $O(n)$ field operations and consume $\frac{2n}{\varepsilon - 1} + o(1)$ VOLE correlations, for any constant $\varepsilon \geq 2$. The protocol achieves soundness error $O(\frac{n}{|\mathbb{F}|})$, where n is the size of the largest vector passed to $\llcorner \sim \lrcorner$.*

Proof. See [26]. □

The proof of Theorem 1 is included in the full version.

[6] This does *not* imply that W and R will be identical.

Notus: Dynamic Proofs of Liabilities from Zero-knowledge RSA Accumulators

Jiajun Xin Arman Haghighi Xiangan Tian Dimitrios Papadopoulos

The Hong Kong University of Science and Technology

Abstract

Proofs of Liabilities (PoL) allow an untrusted prover to commit to its liabilities towards a set of users and then prove independent users' amounts or the total sum of liabilities, upon queries by users or third-party auditors. This application setting is highly dynamic. User liabilities may increase/decrease arbitrarily and the prover needs to update proofs in *epoch* increments (e.g., once a day for a crypto-asset exchange platform). However, prior works mostly focus on the static case and trivial extensions to the dynamic setting open the system to windows of opportunity for the prover to under-report its liabilities and rectify its books in time for the next check, *unless all users check their liabilities at all epochs*. In this work, we develop Notus, the first *dynamic PoL* system for general liability updates that avoids this issue. Moreover, it achieves $O(1)$ query proof size, verification time, and auditor overhead-per-epoch. The core building blocks underlying Notus are a novel zero-knowledge (and SNARK-friendly) RSA accumulator and a corresponding zero-knowledge MultiSwap protocol, which may be of independent interest. We then propose optimizations to reduce the prover's update overhead and make Notus scale to large numbers of users (10^6 in our experiments). Our results are very encouraging, e.g., it takes less than 2ms to verify a user's liability and the proof size is 256 Bytes. On the prover side, deploying Notus on a cloud-based testbed with eight 32-core machines and exploiting parallelism, it takes ∼3 minutes to perform the complete epoch update, after which all proofs have already been computed.

1 Introduction

The emergence of the decentralized finance (DeFi) ecosystem and cryptocurrency assets has led to increased demand for auditing and regulation of involved markets [22,24,27,41,63]. For instance, cryptocurrency holders may store their assets in exchange platforms lacking "traditional" financial regulation and policies [1,5,28,50], which leaves them open to incidents such as the recent collapse of the very popular exchange of FTX due to malpractice [1]. This has led researchers and industry to explore the design of mechanisms that can provide strong security guarantees, regarding the availability and liquidity of funds in such systems. One particular such mechanism is *proofs of liabilities (PoL)*, a cryptographic primitive that allows a party to prove the amounts of funds it "owes" to its customers to a third-party auditor—e.g., as part of proving its financial solvency during an audit process.

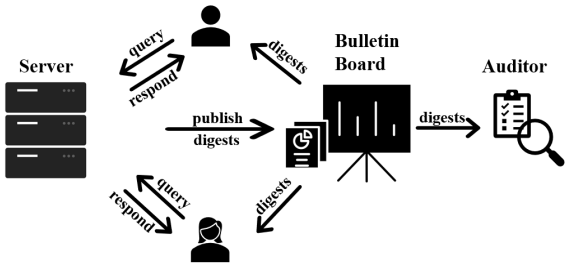

Figure 1: Model of a dynamic proof-of-liabilities system.

In more detail, a PoL system (see Figure 1) consists of one *server* that stores liability (or transaction) records associated with its *users* and publishes a succinct *digest* of this dataset (e.g., a short, binding, cryptographic representation) on a public bulletin board, e.g., a blockchain platform. Users can query the server to get their latest record and check it is up-to-date and accurate with respect to the latest digest. The model also includes a third-party *auditor* who can periodically request the server to prove its total sum of liabilities with respect to the public digest or ask for the liabilities of individual users. From a security point of view, a dishonest server is clearly motivated to *under-report* these values [41], but not the other way around—artificially increasing liabilities offers no benefit as it makes it appear to "owe more" (see also our threat model discussion in Section 3.1). We also stress that a malicious server operates in a very favorable setting as it can readily tamper user records or even introduce artificial transactions and the only entities that can "catch" such behavior are the affected users themselves (we are not assuming any public-key or certificate infrastructure for authenticating records).

PoL has been the focus of a growing line of works and

various systems have been proposed in the academic literature [22–24, 27, 30, 36, 39, 41, 56] and adopted in practice, e.g., by Binance [6] and OKX [52]. Focusing on academic proposals, the state-of-the-art constructions include the DAPOL+ system [41], and the TAP system [56]. DAPOL+ proposed a scheme based on a Merkle tree of Pedersen commitments [54], with user liabilities stored at the leaves and the root published as the digest. The homomorphic property of Pedersen combined with efficient range proofs [13] makes it easy to prove individual liabilities (as well as sums of liabilities) in a secure and privacy-preserving manner (i.e., no "sibling" node information is revealed when proving membership). TAP takes a different approach, relying on *append-only dictionaries* [59] based on Merkle sum trees [40] for proving sums of liabilities; this is similar to DAPOL+'s Merkle tree with the additional requirement of sorting all tree leaves in ascending order.

Focusing on PoLs that have been deployed in practice, two highly-visible approaches come from exchange platforms Binance [6] and OKX [52]. Besides *third-party auditability*, they aim for a comprehensive set of features to accommodate their business model, including the ability to prove global sums across *multiple assets* while considering varying exchange rates. Binance [6] commits users' liabilities in a Merkle tree where each leaf is a hash digest of one user's liability information. It then uses succinct non-interactive arguments (SNARKs) to prove the sum of all users' liabilities committed in the Merkle tree across multiple assets. Because of the large number of users (45 million) they have, it is infeasible to generate a single SNARK proof that checks all users in the Merkle tree. Instead, Binance separates users into multiple batches, with each batch containing several hundreds of users, and constructs proofs for the entire set of users incrementally. Starting from an empty tree, it builds the entire Merkle tree with all users' liability information gradually. OKX [52] also commits users' liability information with Merkle trees. However, it employs scalable transparent arguments of knowledge (STARK) [3] as the proving system to achieve a faster prover and a transparent setup. Unfortunately, this comes at the cost of a much larger proof size. For ∼25 million users, the proof that needs to be checked (either by a trusted auditor, or by *each user* independently) is of size 1.2GB!

Challenges of Designing PoL in the Dynamic Setting. The applications PoL target clearly operate in a *dynamic* setting that can be expressed via a series of *epochs* during which users can perform transactions (deposits, withdrawals, and transfers) that will alter their liabilities. Correspondingly, the server should be able to provide proofs that are "fresh" with respect to the latest epoch (and the latest corresponding digest). For instance, a cryptocurrency exchange could be required by regulatory authorities to publish a new digest corresponding to its state regularly, e.g., Binance and OKX currently publish new digests and prove liabilities *every month*. This epoch duration may vary greatly for different applications from a few minutes (e.g., the time it takes to publish a new blockchain block) to once a year (e.g., for financial tax auditing). Despite this, most prior PoL works focus their security analysis and their system design on the *static* case. While this yields conceptually "simpler" schemes, one can argue it does not provide the comprehensive auditing capabilities that would be necessary to guarantee accountability. For instance, the monthly digests provided by Binance and OKX provide monthly independent *snapshots* to the auditor that are not "linkable", e.g., the auditing authority has no information about what transactions took place from one month to the next, in order to reach the new liabilities. Ideally, in a dynamic PoL, the auditing process should "link" the prior epoch's digest to the new in a way that guarantees certain properties. As we discuss next, such an extension of PoLs to the dynamic case introduces subtle challenges.

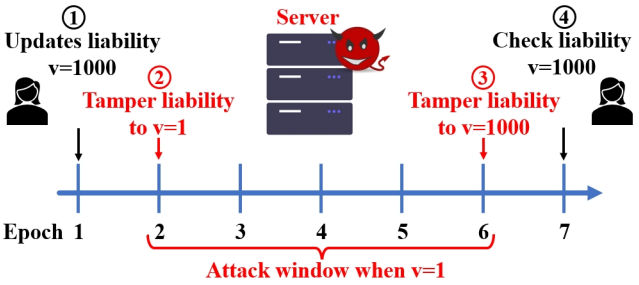

Figure 2: This figure illustrates a window-of-opportunity attack between the times a user checks her record. The user updates her liability in Step 1 and checks again in epoch 7. The malicious server reduces the user's liabilities to 1 in Step 2, and restores to 1000 in epoch 6, leading to a temporary decrease in its liability sum, without being caught.

Window-of-Opportunity for Attacks. In PoL systems, users check and verify their corresponding records to avoid foul play by the server. In the dynamic setting, this means that to guarantee security *all users must query for their records at all epochs*. If this does not happen, this gives a "window of opportunity" for the server to perform an attack by first lowering a user's liabilities, producing a decreased sum to the auditor that passes verification, and then increasing it again—all this within the time interval between two checks by the affected user (see Figure 2). To the best of our knowledge, existing PoL works suffer from this "catastrophic" attack. Indeed, [41] discussed the effect of users not verifying their records. Therefore, trivially extending static PoL schemes from the literature [6, 23, 24, 41, 52] would impose a very stringent condition for users to remain largely online and would incur massive communication cost to the system.

One exception to the above limitation is the recent TAP system [56] which is also the only work that is explicitly focused and designed for the dynamic case. However, by design, TAP can only support positive *monotonically increasing liabilities*. In practice, this is a limiting condition for several applications. E.g., in the Binance PoL [6], currency exchanges (say,

	Dynamic	Negative Updates	Update Pattern Privacy	Trusted Setup	Prover Overhead	Verifier Overhead for m epochs	Auditor Overhead	Proof of Sum size	Cryptographic Techniques
DAPOL+ [41]	No	N/A	N/A	No	$O(n\log n)$	N/A	N/A	$O(1)$	PedersenTree+RangeProof
TAP [56]	Yes	No	No	No	$O(n'\log n')$	$O(m\log n')$	$O(n')$	$O(m)$	PedersenTree+RangeProof
OKX [52]	No	Yes	N/A	No	$O(n\log^2 n)$	$O(m\log n)$	$O(\log^2 n)$	$O(1)$	STARK+Mekle Tree
Binance [6]	No	Yes	N/A	Yes	$O(n\log n)$	$O(m\log n)$	$O(1)$	$O(1)$	SNARK+Mekle Tree
Notus (Ours)	Yes	Yes	Yes	Yes	$O(n\log n)$	$O(1)$	$O(1)$	$O(1)$	SNARK+zkRSA Acc.

Table 1: Comparison of Notus with prior state-of-the-art PoL schemes. DAPOL+ is designed for the static case. TAP can only support monotonically increasing liabilities. Notation: n is the number of users in the system, n' the number of users whose records changed in one epoch, m is the number of consecutive epochs for which a user did not check its record.

from ETH to BTC) are encoded as increases *and decreases* in the respective currency accounts of the user, following the specified exchange rate. As another example of an application that requires both liability increases and decreases, consider decentralized loans [63]. When a user gets a loan, she needs to show her liabilities are less than her lending capacity. When the loan is issued, her liabilities increase, but after the loan is repaid, her liabilities should again decrease. Finally, with TAP, if a user delays checking by m epochs, eventually, she needs to perform an amount of work that is *linear* to m to "catch up", effectively checking her status for all intermediate epochs. Ideally, we would like to make this process efficient, e.g., it should only take a single check to catch up.

This Work. In this paper, we propose Notus, the first *dynamic proof-of-liabilities (**DPoL**)* system that supports general liability updates and achieves provable security and privacy guarantees in the dynamic setting. In particular, Notus overcomes the need for all users to check their records at all epochs. Instead, users can verify their records at arbitrary times while: (i) verification overhead and proof size is $O(1)$, and (ii) they have the guarantee that any (prior or ongoing) tampering of their record by the server will be identified. Compared to TAP [56], our system supports arbitrary (positive and negative) liability updates, m times faster verification after m unchecked epochs, and much lower overhead for the auditor's check in every epoch—$O(1)$ for Notus vs. linear in the number of transactions that took place in TAP. A side-effect of the last property is that making the auditor so lightweight makes it possible to instantiate it in a "trustless" manner, e.g., via a smart contract [15,48,57]. Finally, compared to commercially deployed systems [6, 52], our system supports dynamic updates, shorter proof size, and concretely faster prover. Table 1 asymptotically compares Notus with prior works.

At a technical level, Notus combines a novel hidden-order-group *zero-knowledge accumulator* [34] for individual user queries, with an "accompanying" new *zero-knowledge MultiSwap* [53] protocol based on SNARKs for efficiently proving and verifying the execution of updates between consecutive epochs. To allow users to check their records at arbitrary times, within the accumulator we encode and connect the liability information of each user via a hash chain. Notably, updating a *private* dataset while enforcing certain checks via SNARKs is challenging from an efficiency perspective. To propose a system with good practical performance, we designed our accumulator to be "SNARK-friendly" to keep the prover overhead low. At the same time, to keep the "online" overhead for the server minimal, we adopt a massive pre-computation strategy for the accumulator proofs. To scale this approach to numerous users (as we expect to be the case for PoL applications) we introduce a series of important optimizations.

Our overall contributions can be summarized as follows:

1. We propose security and privacy definitions for **DPoL** and the first scheme that satisfies them for general liabilities called Notus. It achieves $O(1)$ proof size, verification cost, and auditor overhead (Section 3).
2. We propose the first zero-knowledge RSA accumulator, which supports precomputing all zero-knowledge membership proofs in $O(n\log n)$ time. We also propose the first zero-knowledge MultiSwap (ZK-MultiSwap) protocol based on our accumulator. Its overhead is similar to that of prior (non-zero-knowledge) MultiSwaps [16]. (Section 4). Finally, we propose optimization techniques for our RSA accumulator and Notus. (Section 5).
3. We experimentally evaluate the performance of our constructions. Notus achieves the fastest update speed among current PoL schemes (e.g., 3 mins to update 1 million users) and achieves extremely fast verification cost (2ms for user liabilities) and proof size 256Bytes (Section 6).
4. Our zero-knowledge RSA accumulator also works as a zero-knowledge lookup system. Compared to the state-of-the-art Caulk [67] system for zero-knowledge lookups, our accumulator achieves up to *three orders of magnitude faster* online prover time with similar offline time.

2 Preliminaries

Notation. Let λ denote a security parameter. A function $\text{negl}(\lambda)$: $\mathbb{N} \to \mathbb{R}^+$ is negligible if for every positive polynomial $poly(\lambda)$ there exists a $\lambda_0 \in \mathbb{N}$, such that for all $\lambda > \lambda_0$: $\varepsilon(\lambda) < 1/poly(\lambda)$. Let $[i,j] = \{i, i+1, \ldots, j-1, j\}$. We denote by $x \xleftarrow{\$} F$ sampling uniformly at random from domain F. $\mathcal{H}_\lambda$ is a public function family, where every $H \in \mathcal{H}_\lambda$ is modeled as a random oracle that maps an arbitrary string to a random number with λ bits. Formally, $H : \{0,1\}^* \to \{0,1\}^\lambda$.

Proof of Exponentiation. Given a hidden order group $\mathbb{G}$, one integer x and two group elements g, y, a Proof of Exponentiation (PoE) protocol proves exponentiation relation $g^x = y \in \mathbb{G}$. We follow the approach of Wesolowski [62],

generalized in [9]. It allows the verifier to check the exponentiation in constant calculations, where the verifier first sends a prime challenge l, the prover calculates q, r s.t. $x = ql + r, r \in [0, l)$, and sends $\pi = g^q \in \mathbb{G}$ to the verifier. The verifier computes $r = x \mod l$ and checks $\pi^l g^r \stackrel{?}{=} y$. Boneh *et al.* extended the above idea and provided a non-interactive zero-knowledge proof of knowledge of exponentiation (NI-ZKPoKE) in [9]. We refer to their protocol as (1) a prove function $\pi \leftarrow$ **NI-ZKPoKE.Prove** $(G, g; x)$ where π is the proof, x is the witness and $G = g^x$, and (2) a verification function $1/0 \leftarrow$ **NI-ZKPoKE.Verify**(G, g, π).

RSA Accumulators. An RSA accumulator [4, 9, 45] is a cryptographic commitment to a set $S = \{e_1, \ldots, e_n\}$. It has pros/cons compared to Merkle tree-based accumulators and bilinear accumulators as discussed in [59, 60]. Its main advantage is constant-sized membership proof for any set size.

Setup. An RSA accumulator can be set up by picking two random large prime p', q', calculating $N = p'q'$, and finding one large group $\mathbb{G} \subseteq \mathbb{Z}_N^*$ and its generator g such that strong RSA assumption [2] and adaptive root assumption [62] holds in $\mathbb{G}$. We additionally require that p', q' are two primes, i.e., $p' = 2p + 1$ and $q' = 2q + 1$, and that the group order is odd (pq). The most commonly used such group is the quadratic residue group of N ($QR(N)$). This setup process can either be performed by a trusted party, or via a multi-party protocol [10, 14] to generate the group $\mathbb{G}$. Alternatively, one can also rely on class groups [12] which do not need a trusted setup but are slower in performance and less studied.

Membership proofs. Let $S = \{e_1, e_2, \ldots, e_n\}$ denote a set of elements that are either prime numbers or output of Division Intractable (DI) hashes [33]. $acc(S)$ denotes the digest of committing set S using accumulator $acc(S) = g^{\prod_{e_i \in S} e_i}$. To prove one element $e' \in S$, the prover calculates $\pi = g^{\prod_{e_i \in S \setminus \{e'\}} e_i}$. Verifier checks if $\pi^{e'} \stackrel{?}{=} acc(S)$. All such membership proofs can be generated in batch (e.g., in pre-computation) in time $n \log n$ using divide-and-conquer (e.g., see [60]).

MultiSwap. MultiSwap is a cryptographic primitive for proving the update state of an accumulator C after removing a set X and adding a set Y is C'. It was introduced by Ozdemir et al. [53] and improved by Campanelli et al. [16]. Both schemes rely on SNARKs for this check, which we introduce next.

SNARKs. A **S**uccinct **N**on-interactive **AR**gument of **K**nowledge (SNARK) for a relation $\mathcal{R}$ comprises of three algorithms as follows:

- Π.**Setup**$(1^\lambda, \mathcal{R}) \rightarrow$ crs. crs is a common reference string.
- Π.**Prove**$(\text{crs}, x; w) \rightarrow \pi$. x is a statement and w is the witness such that $\mathcal{R}(x, w)$ holds. It outputs π as proof.
- Π.**Verify**$(\text{crs}, x, \pi) \rightarrow \{0, 1\}$. It inputs the crs, statement x and proof π. If the proof checks correctly, it outputs 1; otherwise, it outputs 0.

A SNARK is *complete, knowledge-sound, and succinct*. Completeness means that if $\mathcal{R}(x, w)$ holds, an honest prover fails to generate the proof π with probability less than $\text{negl}(\lambda)$. Knowledge soundness means that given a valid proof, there exists an extractor to extract the witness for that statement. Finally, a SNARK is succinct if the proof and verification time are poly-logarithmic in the witness size. This property allows the verifier to check any statement in $\mathcal{R}$ faster than checking the statement and witness (if given) directly. If a SNARK is also zero-knowledge, it leaks no information of the witness and is called zkSNARK [8]. For our implementation, we use a Groth16-type SNARK [38], which requires a trusted setup.

In this paper, we use a Commit-and-Prove SNARK (CP-SNARK) [17] for the security and composition of different SNARK proofs. Informally, the prover can commit the inputs and witnesses of a SNARK through some commitment scheme, e.g., extended Pedersen commitments which are perfect hiding and computationally binding. We denote $\boxed{c_{w1}}$ the committed witness $w1$ for a CP-SNARK proof $\pi \leftarrow \Pi$.**Prove**$(\text{crs}, \boxed{c_{w1}}, x; w2)$ where $w2$ is the non-committed part of the witness. As discussed in [17], CP-SNARK allows the modular composition of SNARKs through the committed witness. For example, given two relations $\mathcal{R}_1$ and $\mathcal{R}_2$, the prover can prove $\mathcal{R}_1(\boxed{c_{w1}}; w_2)$ and $\mathcal{R}_2(\boxed{c_{w1}}; w_3)$ hold with two CP-SNARKs for the same committed witness $\boxed{c_{w1}}$.

Definitions of range proofs, universal accumulators, and division intractable hashes can be found in Appendix A. Definitions of cryptographic assumptions and the generic group model can be found in the extended version of our paper [65].

3 Definition of Dynamic Proofs of Liabilities

Here we propose our new definition for dynamic PoL. Looking ahead, in our dynamic PoL, the server demonstrates the "correct update" between successive epochs and their respective digests. This is in contrast to relying on a static PoL and simply publishing a series of unrelated digests, computed from scratch each time. Note that, during consecutive epochs, some users' liabilities may remain unchanged. Any modifications should be accurately captured in the updated digest while also updating the total sum of liabilities. Next, we first provide an overview of the **DPoL** system and explain its data structures and threat model. Then we present function definitions along with formal security and privacy definitions for the **DPoL**. Finally, we discuss the limitations of current works and why they do not satisfy such security requirements.

3.1 System overview and data structures

A **DPoL** system is a versioned ledger system, where time is split into epochs, and each epoch bounds a unique ledger digest. It involves three entities: users, a server, and an auditor (Figure 1). We also assume a public bulletin board where digests are published (e.g., a public blockchain). We denote $\mathcal{U} = \{u_1, \ldots, u_t\}$ as the set of t users.

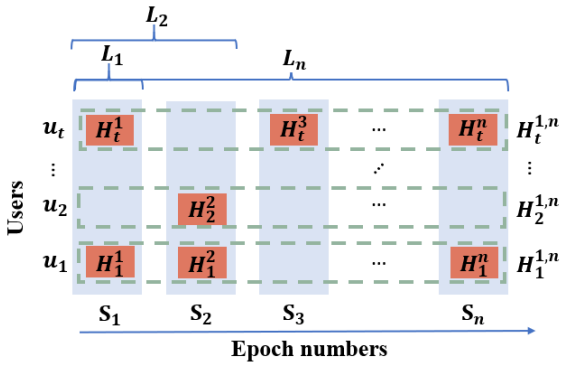

Figure 3: The ledger can be examined both vertically and horizontally. Each row represents the transaction history of an individual user, whereas each column represents the updated users within a single epoch. As the epoch number increases, the ledger naturally expands column-wise.

Users update their liabilities through transactions, which are subsequently stored on the server. The server, denoted by $\mathcal{S}$, maintains the versioned ledger in an append-only way for all transaction histories. It provides a digest of the whole ledger, the sum of all liabilities, and the lookup proof for each user's transaction history. The server provides an updated digest and corresponding proofs in each new epoch to show the ledger is append-only. It publishes the digest and the append-only proof on the bulletin board. Users retrieve the latest digest from the public bulletin board and can check the correctness of their records (full transaction histories) in the ledger versus this digest. The auditor checks the correctness of the updated digest in every epoch and the correctness of the sum of liabilities and user histories when delegated.

Data structures. The ledger is a set of transactions (txs) where each tx is a tuple of user ID, this user's final liability after the update, and the timestamp of the updated epoch. We use $tx.id$, $tx.lia$ and $tx.upd$ to denote these values respectively. Without loss of generality, we assume these have a fixed bit length, and user IDs are unique. Within a single epoch, users may perform multiple operations on their liabilities, but only one transaction is needed to summarize the liability updates. A user's liability can increase or decrease across different epochs but must always remain non-negative.

The ledger operates on an append-only basis, maintaining a complete history of every transaction. Let L_i represent the state of the ledger at epoch i. Since each transaction includes a timestamp indicating when it was added, it is easy to deduce all previous versions of the ledger, denoted as L_j, for all $j < i$, given the current ledger state L_i. For a user denoted by u, $H_u^{i,j}$ represents the history of transactions (i.e., the complete set of all transactions) occurring between epochs i and j. It is evident that $H_u^{1,i} \subseteq H_u^{1,j}$, for all instances where $i \leq j$. We use H_u^j to denote the transactions of user u in epoch j and $H_u^j.lia$ to represent her final liability in epoch j. In cases where a user does not update during epoch j, her final liability value $H_u^j.lia$ will remain the same as her previous liability, $H_u^{j-1}.lia$.

We denote S_i as the set of transactions in epoch i. The notation $u \in S_i$ refers to a user who performed an update in epoch i. Clearly, $S_i = L_i \setminus L_{i-1} = \bigcup_{\forall u \in S_i} H_u^i$ and $L_j = \bigcup_{i=1}^{j} S_i = \bigcup_{\forall u \in \mathcal{U}} H_u^{1,j}$. We illustrate one example of such data structure in Figure 3. The sum of liabilities for ledger L_i is the sum of all users' final liabilities in epoch i. For example, let's consider epoch 3 in Figure 3. In this epoch, one update happened for user u_t. The sum of liabilities at epoch 3 equals to $H_1^2.lia + H_2^2.lia + H_t^3.lia$.

Threat Model. In the **DPoL** system, a malicious server tries to opportunistically *decrease* the sum of all liabilities even for brief periods [41]. We stress that artificially increasing the amount of liabilities is not a valid attack vector as it would make the adversary appear to have more debt (in practice when used to prove the financial solvency of a party, a PoL will typically be combined with a, conceptually simpler, proof of reserves [6, 41, 52] that complements it by stopping the adversary from over-reporting).

To achieve its goal, a malicious server may employ various tactics, such as deleting transactions, modifying transactions' values or their order, intentionally delaying transaction updates, and introducing counterfeit transactions (e.g., with negative liabilities), including the possibility to *fabricate and manipulate* any number of "virtual users" to further its objectives. Honest users update their own transactions as they occur and need to check their state "*only occasionally*" (as opposed to mandatorily checking at every epoch) through membership queries. Our auditor is assumed honest. For every epoch, it receives the updated public digest and proof from the server that allows it to check if the server has correctly updated the system, according to the following properties: (1) the update is append-only; (2) the update only appends transactions with a timestamp of the current epoch number; (3) the update does not cause any user's liability to become negative; (4) the sum of all liabilities is updated consistently with the transactions. Finally, regarding the privacy of the ledger, we consider both users and the auditor to be curious, i.e., they may try to infer additional information about the data, besides what they know (from their specific transactions and the sum of liabilities), e.g., transactions of other users, update patterns of users, etc.

Users colluding with the server & fake accounts. We stress that our threat model already considers the possibility of users colluding with the server, to help under-report liabilities, trivially since the latter can always "spawn" fake users anyway. Looking ahead to our solution, as long as we ensure that the liabilities of all user accounts in the system remain "positive", creating fake accounts or colluding with users can only *increase* the server's liability, and does not benefit the adversary.

Window-of-opportunity attacks & fake transactions. Since we do not assume a public-key or certificate infrastructure for authenticating records, neither do we require all users to check their history at every epoch, "window-of-opportunity"

(Figure 2) attacks are always possible. Recall that this entails the server issuing fake transactions to artificially lower liabilities, pass the audit, and rectify the liabilities in time before affected users perform their checks. Our threat model addresses this by ensuring the ledger is append-only. If the server artificially lowers liabilities by fake transactions, evidence will remain "in perpetuity" (captured by subsequent digests). Thus, affected users can *eventually* catch the cheating server and have evidence of this malpractice.

3.2 DPoL API

In **DPoL**, the prover implements the following algorithms:

- $(ek, vk) \leftarrow \textbf{Setup}(1^\lambda)$. Randomized algorithm that returns evaluation key ek used by the prover and a verification key vk used by users. Here, λ is the security parameter.
- $d_i \leftarrow \textbf{Digest}(ek, L_i, aux_i)$. Randomized algorithm that generates digest d_i. aux_i is the auxiliary information (e.g., randomness) needed to generate the digest up to epoch i.
- $\pi_{\text{mem}} \leftarrow \textbf{LookupProof}(ek, L_i, u, aux_i)$. This algorithm provides a lookup proof for user u's full history in epoch i with a membership proof π_{mem}.
- $\pi_{\text{sum}} \leftarrow \textbf{ProveSum}(ek, L_i, aux_i)$. This algorithm proves the sum of all liabilities with a sum proof π_{sum}.
- $\pi_i \leftarrow \textbf{ProveConsistent}(ek, L_i, aux_i)$. Randomized algorithm that proves the ledger committed in d_i is append-only and consistent, resulting from the application of changes in epoch i to the ledger committed in d_{i-1}.

The auditor implements the following algorithms:

- $\{1/0\} \leftarrow \textbf{VerConsistent}(vk, i, d_{i-1}, d_i, \pi_i)$. This algorithm ensures the transactions are append-only and consistent after the changes in epoch i.

The auditor and users implement the following algorithms:

- $\{1/0\} \leftarrow \textbf{VerLookup}(vk, d_i, H_u^{1,i}, \pi_{\text{mem}})$. This algorithm verifies proofs returned by $\textbf{LookupProof}(\cdot)$ against the digest d_i for user u. It verifies the full history of user u is in the set via the membership proof π_{mem}.
- $\{1/0\} \leftarrow \textbf{VerSum}(vk, d_i, \text{sum}, \pi_{\text{sum}})$. This algorithm verifies proofs returned by $\textbf{ProveSum}(\cdot)$ against the digest d_i. It verifies sum is the total final liabilities committed in d_i.

3.3 Correctness and Security of DPoL

We require that a Dynamic Proof of Liabilities (DPoL) system satisfies the following properties: Completeness, Undeniability, Update Soundness, Sum Soundness, and Privacy. We provide their intuitive explanations here and defer their formal definitions to Appendix B.

Completeness ensures that when all participating entities act honestly and adhere to the established protocol, verification will always succeed. Note that this definition handles all possible orders of appending elements.

Undeniability ensures the non-equivocation of the committed ledger and the sum: for any digest d_i, it bounds a unique sum and a unique ledger. It also implies *collision-resistance*: i.e., different ledgers and sums cannot have the same digest.

Update Soundness ensures that: 1) the update is append-only, the ledger L_i is a superset of ledger L_{i-1}; 2) all transactions updated in this epoch ($tx \in S_i$) have the update epoch number the same as the current epoch number i; 3) all updated users' final liabilities are still positive; 4) the sum of all liabilities is also updated accordingly and consistently. One special case of this definition is inserting new users. For a new user u in S_i, H_u^{i-1} does not exists, we set $H_u^{i-1}.lia = 0$ as a special case.

Sum Soundness ensures that the sum of all liabilities of the ledger is not smaller than the total sum of liabilities of those honest users who have checked their own entries.

Privacy ensures the proofs do not reveal any additional information about the **DPoL** system except for what is explicitly provided by the server. We formulate this by a real/ideal simulation paradigm for an adversary that corrupts users and the auditor, chooses the ledger, and makes lookup/sum queries. We require that the view of this adversary throughout multiple epochs can be simulated without access to the ledger.

Having defined these security properties, we now examine why existing schemes fail to meet them, setting aside any functional constraints they may have and the fact that some of them are only set on the static setting. A common issue impacting Soundness in static PoL systems is the necessity for users to examine all intermediate states across every epoch to ascertain their full history. DAPOL+ [41] does not satisfy **DPoL**'s Update Soundness definition: for any epoch, the sum of total liabilities is only "correct" when all users verify their membership proofs. In other words, DAPOL+'s soundness hinges on all transactions being verified by some "entities" one by one, either by the union of all honest users cooperatively, or by a "powerful" auditor with access to all users' information. TAP [56] does not satisfy **DPoL**'s Privacy definition. In each epoch, the TAP system's server generates a tree consisting of sorted leaves. The number of these leaves discloses the number of updated users. When a user's transaction is present in the leaves, she can identify her transaction value's position within the sorted set, thereby obtaining additional information about the distribution of other users' transaction values. This presents a privacy issue, as multiple colluding users could merge their insights to deduce statistical information about other participants in the system. Binance [6] does not satisfy **DPoL**'s Update Soundness definition. In their system, the auditor's role is limited to ensuring that the sum is accurately calculated based on all liabilities committed to the Merkle tree without guaranteeing the ledger is strictly append-only. It also does not satisfy **DPoL**'s Privacy definition. Binance employs fixed user IDs to denote users' positions within the Merkle tree and relies on the Merkle path for membership proof, inadvertently exposing information about each user's neighbors.

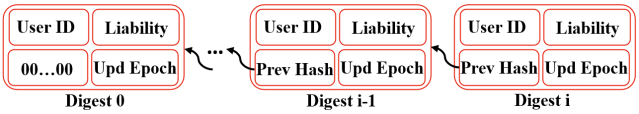

Figure 4: HashChain used in Notus system. Each hash combines the user ID, user's liability, update epoch, and the previous hash as its input. The first hash in the chain uses all "0"s as a special mark.

Likewise, OKX [52] does not satisfy **DPoL**'s Update Soundness definition similar to Binance as it has no append-only guarantees.

4 Notus Design

In this section, we present our instantiation of a **DPoL** system, named Notus. Our objectives, in addition to the security and privacy requirements of the **DPoL** system, include ensuring constant-sized digests, membership proofs, and proof-of-consistency. Moreover, we aim to improve server efficiency by allowing membership proofs to be pre-computed in-batch.

To achieve these goals, Notus encodes each user's history using a HashChain, which results in a succinct representation that makes it easier to verify the append-only property. Notus stores the HashChain digests of all users in a zero-knowledge RSA accumulator and employs zero-knowledge MultiSwaps to confirm two consecutive epochs are updated correctly. The remainder of this section is organized as follows. We first introduce three building blocks of Notus, namely the HashChain, zero-knowledge RSA accumulators, and zero-knowledge MultiSwaps. Next, we provide an in-depth explanation of the Notus system, using the three building blocks as black boxes.

4.1 HashChain

HashChain is a fundamental data structure in the design of secure and tamper-evident systems. It operates by incorporating a series of hash values and linking them in a sequential manner to form a chain. Its key property is immutability, as any attempt to alter the data or its sequence would result in a different digest. This feature allows for the demonstration and verification of the append-only nature of the HashChain. Notus utilizes the HashChain data structure to encode users' transaction histories to achieve the following goals:

1. Ensure the server can unambiguously demonstrate that updates to users' histories are strictly append-only, thus maintaining the integrity of the transaction records.
2. Enable users and the auditor to inspect the most recent HashChain outcome, which in turn facilitates the validation of all intermediate states in the transaction history.
3. Grant users and the auditor the capability to initiate subsequent examinations from a checkpoint once they have verified the transaction histories up until that specific point.

Notus commits each user's transaction history into a HashChain digest k_u^i where u denotes the user and i denotes the epoch number. Notus builds the HashChain with hash functions $\mathbf{Hash}(\cdot)$ that are collision resistant and preimage hard. More specifically, $k_u^i = \text{HashChain}(H_u^{1,i}) = \mathbf{Hash}(tx.id||tx.lia||tx.upd||\text{previous Hash})$ where tx denotes the latest transaction H_u^i, $||$ denotes the string concatenation and previous Hash denotes k_u^{i-1}. For the initial Hash where the previous Hash does not exist, we use all "0" as a special mark. We illustrate one example in Figure 4.

Because the hash function is collision resistant and $tx.id$, $tx.lia$, $tx.upd$ have fixed bit length, we summarize HashChain's properties as follow:

- Transitive. For $H_u^{1,i+1} = H_u^{1,i} \bigcup tx(u, lia, i+1)$, $k_u^{i+1} = \mathbf{Hash}(u||lia||i+1||k_u^i) = \text{HashChain}(H_u^{1,i+1})$.
- Collision resistant. For any two different transactions histories $H_u^{1,i}$, $\hat{H}_u^{1,i}$, $\Pr\left[\text{HashChain}(H_u^{1,i}) = \text{HashChain}(\hat{H}_u^{1,i})\right]$ is negligible in λ.

We denote the digest of the server for epoch i as d_i. For one user u, a valid membership proof should convince her that k_u^i is summarized in d_i. Based on the transitive and collision resistant property of HashChain, once user u checks her membership proof in epoch i, to check her membership proof in epoch $j > i$, she only needs to hold her HashChain digest k_u^i and the transactions history since epoch i, which is $H_u^{i+1,j}$. In other words, once a user checks her membership proof in epoch i, epoch i becomes a checkpoint for her.

4.2 Zero-knowledge RSA accumulator

Zero-knowledge accumulators enable a prover to efficiently commit to a set of values while preserving binding (undeniability) and hiding (zero-knowledge) properties. Adversaries cannot obtain any information from the digest and (non)membership proofs, apart from the information explicitly provided by the prover. The functional definitions of zero-knowledge accumulators resemble those of Universal accumulators in Appendix A. The primary distinction between the two lies in the use of "blinding" random values while generating digests in zero-knowledge RSA accumulators, which is essential for privacy, as demonstrated in [34].

Zero-knowledge RSA accumulator construction. To achieve undeniability and zero-knowledge properties in RSA accumulators, a straightforward strategy is to employ two distinct generators, labeled g and h. Specifically, the generator g is dedicated to committing the product of elements, represented by x, while h is designated for committing random numbers, denoted by t, e.g., $g^x h^t \mod N$. This method is similar to the classical Fujisaki-Okamoto integer commitments [31]. However, the two-generator structure necessitates additional overheads for membership-proof precomputation (and, looking ahead, for the incorporation of the accumulator checks into a SNARK). To avoid this, we choose to employ

RSA.KeyGen(1^λ) — **return:** (ek, vk)

RSA.Acc(ek, X, t) — **return:** C

RSA.Witness(X, x, C, ek) — **return:** (b, w_x)

RSA.Verify(C, x, w_x, b, vk) — **return:** $0/1$

(a) Zero-knowledge RSA accumulator functionalities. **Acc**$(\cdot)$ function accumulates the set X and at least one random number t, and outputs the digest C. **Witness**$(\cdot)$ function generates a (non)membership proof, while its output b denotes it is a membership (when $b = 1$) or a non-membership (when $b = 0$) proof.

Π.**Setup**$(1^\lambda, \mathcal{R}^{tent})$ — **return:** crs

Π.**Prove**$(\text{crs}, C, C', C_{mid}, \boxed{c_{\vec{u}0}}, \boxed{c_{\vec{u}1}}; \tau_0, \tau_1, X, Y)$ — **return:** π

Π.**Verify**$(\text{crs}, C, C', C_{mid}, \boxed{c_{\vec{u}0}}, \boxed{c_{\vec{u}1}}, \pi)$ — **return:** $0/1$

(b) ZK-MultiSwap functionalities. Proof of knowledge of set X, Y s.t. removing X and inserting Y for C gets C', and a tentative relation $\mathcal{R}^{tent}$ holds for (X, Y). crs is the common reference string, C, C', C_{mid} are zero-knowledge RSA accumulators. Hash values of set X and τ_0 are committed in $\boxed{c_{\vec{u}0}}$, and hash values of set Y and τ_1 are committed in $\boxed{c_{\vec{u}1}}$. Hash of τ_0 and τ_1 are used as randomizers.

Figure 5: Zero-knowledge RSA accumulators and ZK-MultiSwaps functions we use to build Notus. We use RSA and Π as prefixes to denote them, respectively.

a single generator to commit the product x of all elements and at least one randomizer t to maintain privacy, e.g., g^{xt} mod N. This RSA accumulator configuration allows for easy precomputation of all membership proofs and can be input into SNARKs with a simple PoKE proof (as we will show later). To further optimize our RSA accumulator for SNARK compatibility, we construct it directly with DI hashes. For ease of presentation, we defer the details of our construction in Appendix C and prove its security and privacy in the extended version of our paper [65]. Here, we only provide the API of zero-knowledge RSA accumulators in Figure 5.

Zero-knowledge Subset. Given two zero-knowledge RSA accumulators, where one is a subset of the other, we can provide a zero-knowledge subset proof of constant size. This subset proof enables efficient updates to zero-knowledge RSA accumulators and serves as a building block for the ZK-MultiSwap protocol, which will be discussed later. Boneh et al. [9] introduced both PoKE and ZK-PoKE protocols for RSA accumulators. It is possible to integrate a ZK-PoKE protocol into our accumulator to prove zero-knowledge subsets. However, the ZK-PoKE necessitates additional elements and incurs increased proving/verifying overhead compared to a PoKE, particularly when combined with SNARKs. Instead, we next design an new zero-knowledge subset protocol for our accumulator based on PoKE protocol and SNARKs.

The high-level idea of our zero-knowledge subset is putting redundant randomizers into the zero-knowledge RSA accumulator beforehand, and utilizing the randomizer to "hide" the subset (exponent). In this way, the group elements and integers in the PoKE transcript become simulatable and therefore the whole protocol achieves zero-knowledge. Due to space limitations, we defer construction and proofs to Appendix D. We also show that our zero-knowledge subset protocol implies an efficient zero-knowledge set insertion protocol for the relation $\mathcal{R}^{Ins}(C, \boxed{c_{\vec{u}}}; \tau, X) = C'$ where the witness vector $\vec{u}$ are hash outputs of τ and X, i.e., $H_K(\cdot)$ is a secure DI hash that can be modeled as a random oracle, $H_K(\tau) = t$ and t is the randomizer for accumulator C'.

4.3 ZK-MultiSwap

ZK-MultiSwap proves that removing a subset X from a zero-knowledge RSA accumulator C and inserting a new set Y leads to the new zero-knowledge RSA accumulator C'. Tentative relations between (X, Y) can be checked by SNARKs and the transcript of the protocol needs to be zero-knowledge. Based on the same analysis in [53], given two zero-knowledge accumulators C, C', a ZK-MultiSwap relation $\mathcal{R}^{MSwap}$ is equivalent to proving an intermediate accumulator C_{mid}, and two set insertion proofs for inserting sets (X, Y) s.t. $\mathcal{R}^{Ins}(C_{mid}, \boxed{c_{\vec{u}0}}; \tau_0, X) = C \wedge \mathcal{R}^{Ins}(C_{mid}, \boxed{c_{\vec{u}1}}; \tau_1, Y) = C'$, while maintaining zero-knowledge. Based on our zero-knowledge RSA accumulator and zero-knowledge subset protocol, we construct a protocol for ZK-MultiSwap. The detailed construction and proofs are in the extended version of our paper [65], and we provide here its function interfaces in Figure 5. Compared with Harisa [16], our ZK-MultiSwap achieves zero-knowledge with the cost of verifying two $H_K(\cdot)$ inside a SNARK, instantiated with two SNARK-friendly sponge hashes like [37].

Dynamic ZK-MultiSwap. We further prove in the dynamic setting of ZK-MultiSwap, the above scheme is still complete, sound, and zero-knowledge. In the dynamic setting, the prover is required to demonstrate a series of chained MultiSwaps where the updated accumulator becomes the original accumulator in the subsequent epoch. Let's represent the series of accumulators as $C_0, C_1, C_2, \ldots, C_n$ and the sequence of acc_{mid} as $C_{0,1}, C_{1,2}, \ldots, C_{n-1,n}$. We employ a "zig-zag" approach to randomize the accumulators. This method ensures that at least one random number is assigned to each accumulator. We denote these random numbers as t_i. Specifically, C_0 is randomized using t_0 and t_1, C_1 is randomized using t_1 and t_2, and so on. Similarly, $C_{0,1}$ is randomized using t_1, $C_{1,2}$ is randomized using t_2, and so forth. In the dynamic setting, the

Detailed relation for $\mathcal{R}^{\mathbf{DPoL}}$

Input: $d_{i-1}, d_i, C_{mid}, i, \boxed{c_{\vec{u}0}}, \boxed{c_{\vec{u}1}}$.

Witness: $\tau_0, \tau_1, \bar{S}_i, S_i, \text{sum}_{i-1}, \text{sum}_i, r_{i-1}, r_i$.

1. Check the ZK-MultiSwap relation $\mathcal{R}^{MSwap}$ holds for $(d_{i-1}.\text{RSA}, d_i.\text{RSA}, C_{mid}, \boxed{c_{\vec{u}0}}, \boxed{c_{\vec{u}1}}; \tau_0, \tau_1, \bar{S}_i, S_i)$
2. Check $|\bar{S}_i| \stackrel{?}{=} |S_i|$, $\forall \bar{s}_j \in \bar{S}_i, \forall s_j \in S_i, \bar{s}_i.id \stackrel{?}{=} s_i.id$
3. Check HashChain is valid: $\forall s_j \in S_i$, $s_j.\text{PrevHash} \stackrel{?}{=} H_{DI}(\bar{s}_j.id, \bar{s}_j.lia, \bar{s}_j.upd, \bar{s}_j.\text{PrevHash})$
4. Check $\forall s_j \in S_i, s_j.upd \stackrel{?}{=} i, s_j.lia \geq 0$
5. Check $\sum \bar{s}_j.lia - \sum s_j.lia \stackrel{?}{=} \text{sum}_{i-1} - \text{sum}_i$
6. Check $d_{i-1}.\text{Ped} \stackrel{?}{=} Com(\text{sum}_{i-1}, r_{i-1})$
7. Check $d_i.\text{Ped} \stackrel{?}{=} Com(\text{sum}_i, r_i)$

Figure 6: Detailed relation for **DPoL**. We denote transactions in $\bar{S}_i$ as $\bar{s}_1, \ldots, \bar{s}_j$ and transactions in S_i as $s_1, \ldots, s_j$.

relation $\mathcal{R}^{MSwap}$ holds for all consecutive pairs, i.e., (C_0, C_1), (C_1, C_2), ..., and (C_{n-1}, C_n). The proof is in the extended version of our paper [65].

4.4 Notus construction

Finally, we can provide details about the construction of Notus. We construct the HashChain using a DI hash H_{DI}, which is collision resistant, and division intractable. The data structure we input into the DI hash is the concatenation of $(tx.id||tx.lia||tx.upd||\text{previous Hash})$. For user u updated in epoch i, her HashChain digest $k_u^i = \text{HashChain}(H_u^{1,i}) = H_{DI}(tx.id||tx_t^i.lia||i||k_u^{i^-})$ where $k_u^{i^-}$ is the hash digest when previous updated in epoch i^-. Given a ledger L_i, we denote D_i as the collection of all users' latest HashChain digest. We use $D_i \leftarrow \textbf{LedgerDigest}(L_i)$ as a helper function. Recall that we denote S_i the set of transactions accumulated in the accumulator for epoch i. We denote $\bar{S}_i$ as the set containing the previous states of transactions that are updated in epoch i. Transactions in $\bar{S}_i$ and S_i are pairwise, i.e. $\forall u \in S_i$, $u \in \bar{S}_i$ and $\bar{S}_i \in L_{i-1}$. During an update, updated users' old digests are removed, and corresponding new digests based on $\bar{S}_i$ and S_i are generated and inserted. $L_i \setminus S_i$ is the set of transactions not updated in epoch i. We use D_{mid} to denote the *un-updated set of users'* latest HashChain digest in epoch i.

We use the helper function $\text{sum} \leftarrow \textbf{GetSum}(L_i)$ to calculate the sum based on the ledger L_i for epoch i, denoted as sum_i. Additionally, we require a prime order group for Pedersen commitments, which offers hiding, binding, and compatibility with CP-SNARKs to commit the sum of all liabilities. As our focus lies on the hidden order group, we do not explicitly describe operations within the prime order group. Instead, we consider the prime order group parameters are included in the *crs* of the SNARKs, thus reducing ambiguity. We represent a Pedersen commitment of value s randomized by r (a uniform random number within the prime field) as $Com(s, r)$. The digest d_i for epoch i consists of two parts: d_i.RSA represents the digest of the RSA accumulator; d_i.Ped denotes the digest of the Pedersen commitment.

We construct the Notus system based on the ZK-MultiSwap with the following relation:

$$\mathcal{R}^{\mathbf{DPoL}}(d_{i-1}, d_i, C_{mid}, i, \boxed{c_{\vec{u}0}}, \boxed{c_{\vec{u}1}}; \tau_0, \tau_1, \bar{S}_i, S_i, \text{sum}_{i-1}, \text{sum}_i, r_{i-1}, r_i).$$

The relation $\mathcal{R}^{\mathbf{DPoL}}$ needs to check that *(i)* the number of deleted users is the same as the inserted users and all deleted users are re-inserted in the HashChain; *(ii)* the update only appends transactions with a timestamp of the current epoch number i; *(iii)* the updated users' liabilities are positive; *(iv)* the sum of liabilities is correctly updated; *(v)* the Pedersen commitments commit the sums. Figure 6 includes the details of relation $\mathcal{R}^{\mathbf{DPoL}}$. Our construction for Notus based on the above components is shown in Figure 7. We refer to the formal theorem statement and proof of its security in the extended version of our paper [65] and details for membership proof precomputation in Appendix E.

5 Performance Optimizations

In this section, we present optimizations aimed at improving the performance of both the RSA accumulator and Notus. During every epoch, the server must perform membership proof precomputation, which has been identified as a bottleneck in this system and other similar systems based on RSA groups [59, 61]. Our goal is to enhance its efficiency.

5.1 User Grouping Strategy

Dividing users into different groups is a common approach when dealing with a large number of users in PoL, e.g., OKX [52]. In our system, we partition users into smaller groups, or subsystems, and provide a single proof of total liabilities as in the original system. Users only need to query their membership proof within their own subsystem, while the auditor is responsible for verifying the correctness of all subsystems. This approach does not negatively impact users' performance, as each user only queries their membership within their respective subsystem (but the auditor must check all subsystems). For subsystems without updates, the server still randomizes each RSA accumulator and provides SNARK proofs. Thus, the server overhead is fully parallelizable; given m groups, it can potentially become m times faster.

Note that, information about users' subgroup participation is potentially revealed in this way. However, we considered this "benign" leakage since this partitioning may be based on a random allocation or even on public information (e.g., user names or user ids). Furthermore, each RSA accumulator remains zero-knowledge, preventing the parties from learning

Setup:(1^λ):
$(\text{RSA}.ek, \text{RSA}.vk) \leftarrow$ **RSA.KeyGen**(1^λ)
$\text{crs} \leftarrow \Pi.\textbf{Setup}(1^\lambda, \mathcal{R}^{DPoL})$
return: $ek = (\text{RSA}.ek, \text{crs}), vk = (\text{RSA}.vk, \text{crs})$
Digest:(ek, L_i, aux_i):
$D_i \leftarrow$ **LedgerDigest**(L_i)
$acc_i \leftarrow$ **RSA.Acc**$(\text{RSA}.ek, D_i, t_i, t_{i+1})$
$\text{sum} \leftarrow$ **GetSum**(L_i)
return: $(d_i.\text{RSA} = acc_i,\ d_i.\text{Ped} = Com(\text{sum}, r_i))$
LookupProof:(ek, L_i, u, aux_i):
$k_u^i = \text{HashChain}(H_u^{1,i})$
$(b, w_x) \leftarrow$ **RSA.Witness**$(D_i, k_u^i, acc_i, \text{RSA}.ek)$
If $b = 0$, **return:** $\perp$
If $b = 1$, **return:** π_{mem}
ProveSum:(ek, L_i, aux_i):
$\text{sum} \leftarrow$ **GetSum**(L_i), $\pi_{\text{sum}} = r_i$
return: $(\text{sum}, \pi_{\text{sum}})$
ProveConsistency:(ek, L_i, aux_i):
$D_{mid} \leftarrow$ **LedgerDigest**$(L_i \setminus S_i)$
$C_{mid} \leftarrow$ **RSA.Acc**$(\text{RSA}.ek, D_{mid}, t_{i-1})$
$\pi_i \leftarrow \Pi.\textbf{Prove}(\text{crs}, d_{i-1}, d_i, C_{mid}, i, \boxed{c_{u\vec{0}}}, \boxed{c_{u\vec{1}}}; \tau_0, \tau_1, \bar{S}_i, S_i, \text{sum}_{i-1}, \text{sum}_i, r_{i-1}, r_i)$
return: π_i
VerConsistency:$(vk, i, d_{i-1}, d_i, \pi_i)$:
Check $\Pi.\textbf{Verify}(\text{crs}, d_{i-1}, d_i, C_{mid}, i, \boxed{c_{u\vec{0}}}, \boxed{c_{u\vec{1}}}, \pi_i)$
return: 0 if rejected and 1 otherwise
VerLookup:$(vk, d_i, H_u^{1,i}, \pi_{\text{mem}})$:
$k_u^i = \text{HashChain}(H_u^{1,i})$
Check $\pi_{\text{mem}}^{k_u^i} \stackrel{?}{=} d_i.\text{RSA}$
return: 0 if rejected and 1 otherwise
VerSum:$(vk, d_i, \text{sum}, \pi_{\text{sum}})$:
Check $d_i.\text{Ped} \stackrel{?}{=} Com(\text{sum}, \pi_{\text{sum}})$
return: 0 if rejected and 1 otherwise

Figure 7: Description of Notus. For each epoch, the server samples two random values, (τ_i, r_i), where $t_i = H_K(\tau_i)$, t_i is used for zero-knowledge RSA accumulators and r_i is used for Pedersen commitment. aux_i is the collection of all random numbers used till epoch i.

any useful information within a given group. In practice, we utilize Groth16 [38] with a public upper bound on the number of updates that can be checked. To accommodate groups with more active users or a surge of transactions, we raise the upper bound as a safeguard, effectively concealing the actual quantity of updates. It should be noted that raising the upper bound could lead to increased overhead for the prover. Nevertheless, the SNARK proving process accounts for only a small fraction of the total runtime and does not introduce a bottleneck in the overall system performance.

	# of bits=200,000		# of bits=2,000,000	
	Time(ms)	Rate	Time(ms)	Rate
2×NaiveExponent	911.9	1	9443.7	1

Table 2: Multi-output exponentiation function completion time and performance gain rate (rate= $\frac{\text{optimized algorithm time}}{\text{naive algorithm time}}$).

5.2 Multi-output Exponentiations

When precomputing membership proofs using the divide-and-conquer trick, at every layer, we calculate the following: $g^x \mod N$ and $g^y \mod N$ where g is a new group element in every layer except for the first layer, and x, y are two large integers with similar bitlengths. The most advanced method to calculate the modular exponent is Montgomery modular multiplication [49] with a binary expression of exponents. Informally, calculating $g^x \mod N$ using left-to-right binary exponentiation keeps squaring g, and based on the bit of x to decide if the squared values should be multiplied into the final result. We observe that to calculate $g^x \mod N$ and $g^y \mod N$, we can combine them using the same squaring of g. Furthermore, we can extract the common "1" bits of x and y as z and have $x' = x - z$, $y' = y - z$ to save common multiplications during the process.

Based on the same idea, we can further combine the process of $g^{x_1} \mod N$, $g^{x_2} \mod N$, $g^{x_3} \mod N$, $g^{x_4} \mod N$ by extracting all combinations of their common bits. We first extract common bits for $\{x_1, x_2, x_3, x_4\}$ and update the original values; then we extract common bits of $\{x_1, x_2, x_3\}$, $\{x_1, x_2, x_4\}$, $\{x_1, x_3, x_4\}$ and $\{x_2, x_3, x_4\}$ respectively and update the original values; finally, we extract $\binom{4}{2}$ combinations for each pair of values and update. In this way, we get four updated values $\{x_1', x_2', x_3', x_4'\}$ that are sparse in terms of "1" bit, and their original common "1" bits that can be calculated at once. This is optimal for calculating the four exponents via two layers of divide-and-conquer for membership precomputing. We show in our experiments that this significantly improves efficiency with 2 and 4 multi-output exponentiations. Besides, this works with precomputation tables for even better speed-up.

In our implementation, we optimize multi-output exponentiations till 4 numbers. For larger values, combining more exponents becomes harder. For example, for the common bits of k integers, the sum of all the combinations is $O(2^k)$, which makes implementation much more complicated.

6 Experimental Evaluation

In this section, we evaluate the performance of Notus. We implemented our scheme and optimizations discussed in Section 5 and our code is available[1] online. Our implementation is in Golang and we used gnark [11] for Groth16-type SNARKs [38], optimized with DIZK [64]. The elliptic curve

[1] https://github.com/notus-project/rsa_accumulator

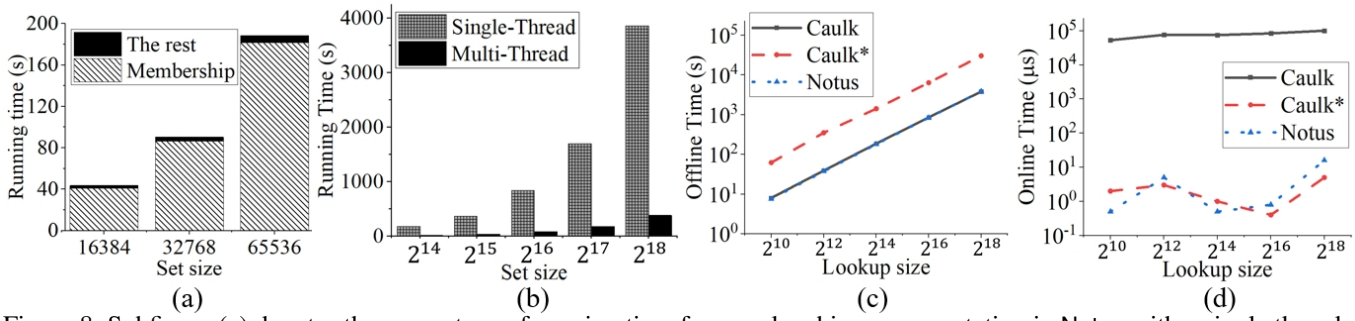

Figure 8: Subfigure (a) denotes the percentage of running time for membership precomputation in Notus with a single thread; Subfigure (b) indicates the membership proof precomputation time under different set sizes with both single-thread and multi-thread; Subfigure (c) and (d) compare our RSA accumulator with Caulk as a lookup argument for both the offline (precomputation) time and online time. Caulk* denotes generating all membership proofs in the offline phase.

we use is bn254. Our experiments were conducted on an Amazon EC2 M6a instance with 32 vCPUs and 128GB of memory. We use DI-Hash with 1024 bits (achieving 80 bits of security) based on Ozdemir et al. [53] as the representatives into RSA accumulators. We use Poseidon hash [37] to make our DI-Hash more SNARK-friendly. First, we evaluate our general optimization applied to multiple output exponentiations. Second, we evaluate our zero-knowledge RSA accumulator, especially the performance of precomputation of membership with different optimizations and parallelization. We also run Caulk as a comparison for efficient lookup proofs for single-element memberships. Finally, we evaluate Notus with different optimizations and compare it with TAP and Binance.

6.1 Effect of Multi-output Exponentiations

Based on Golang's official implementation for Montgomery modular multiplication, we implement the Multi-output exponentiation optimization. We generate a random base g and an odd modulus N with 2048 bits. For consistency, we use the same g and N in each run with randomly selected exponents ranging from 200K to 2M bits. We report the average results across 10 runs. Our findings are summarized in Table 2, which presents the function completion time and the percentage performance gain of our "optimized" execution over the "naive" one. We examine specific functions as follows: 1) 2×NaiveExponent vs. DoubleExponent: We calculate $g^{x_1} \bmod N$ and $g^{x_2} \bmod N$ "naively" by determining each exponent separately and refer to this as the 2×NaiveExponent function. We compare it against our optimized version, DoubleExponent. 2) 4×NaiveExponent vs. FourfoldExponent: For random values x_1, x_2, x_3, x_4, we "naively" calculate $g^{x_1} \bmod N$, $g^{x_2} \bmod N$, $g^{x_3} \bmod N$, and $g^{x_4} \bmod N$. We refer to this function as 4×NaiveExponent and compare it against our optimized FourfoldExponent function. Our optimizations result in DoubleExponent being approximately 30% faster and FourfoldExponent being approximately 60% faster than their original counterparts. Furthermore, we evaluate the performance of FourfoldExponent when combined with a precomputation table containing every single bit precomputed, referred to as the precomFourfoldExponent function. More elaborate precomputation table settings (e.g., including four combinations of every two precomputed bits) lead to faster calculations and larger table sizes. It is important to note that the precomFourfoldExponent optimization is only effective for fixed generators, allowing the exponents to be precomputed. When applying precomFourfoldExponent to membership precomputations, we use it only for the first layer of the divide-and-conquer algorithm, which is the most time-consuming layer. For the remaining layers, we employ FourfoldExponent.

6.2 RSA Accumulator Performance

Next, we evaluate the performance of our zero-knowledge RSA accumulator. A membership proof consists of one RSA group element, which is 256 bytes in size, and verifying a membership proof takes approximately 1 ms. A non-membership proof contains 10 RSA group elements and 18 integers of varying lengths, resulting in a total length of 8960 bytes. The proof generation time depends on the set size. Subsequently, we executed the Notus system with RSA precomputation for lookup proofs implemented using Fourfold Exponent optimizations. We recorded the time taken for each part of the system and the results are shown in Figure 8 (a). The precomputation of membership proofs accounts for the majority of the running time, while the remaining tasks (generating accumulators, ZKPoKE proofs, and SNARK proofs) contribute to no more than 5% of the total running time. Next, we focus more on membership precomputation.

Membership precomputations. In Figure 8 (b), we illustrate the membership precomputations under different set sizes with a single thread and with 32 threads. Note that, due to the divide-and-conquer nature of our membership precomputation, it is not perfectly parallelizable; however, it is still around 9-10× faster than the single-thread version. E.g., for set size 2^{18}, the single-thread precomputation takes 3857 seconds, whereas a multi-thread takes only 384 seconds.

Lookup arguments. We also assess the performance of Notus when used as a lookup argument [67]. We use the single-threaded version of our implementation to directly compare

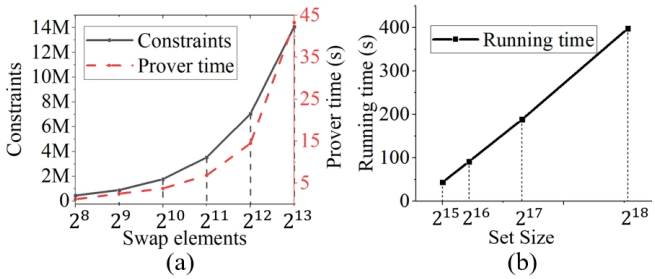

Figure 9: Subfigure (a) illustrates the number of constraints and the prover's time for the Notus SNARK circuit; Subfigure (b) illustrates the running time required to execute Notus under different set sizes with 32 cores and 128GB memory.

with the prior state-of-the-art Caulk [67]. We observe that the offline time for Notus is similar to Caulk. However, unlike Notus, Caulk requires an online phase to "complete" the lookup proof even after precomputation has taken place. In contrast, with Notus, after precomputation, one simply needs to retrieve proofs, which is almost instantaneous (e.g., $< 20\mu sec$). This results in much faster performance, as shown in Figure 8 (c) and (d). We also explore an alternative version of Caulk which generates all membership proofs in an offline phase (similar to Notus) with no additional online overhead, to guarantee full fairness in our comparison; we call this version Caulk*. As shown, the offline time of Caulk* (calculated as offline time of Caulk + (Lookup size $\times$ online time)) is nearly 3 orders of magnitude slower than Caulk and Notus.

6.3 Notus Performance

Finally, we evaluate the performance of Notus and compare it with other PoL approaches. We begin with a comparison of the time it takes for the server to complete an update between epochs. Proving correct updates between consecutive epochs can be a bottleneck for PoL systems when updates are frequent and users are highly active. We compare the proving time, proof size, and verification of Notus with TAP and Binance, as shown in Table 3. Among prior research in PoL, we compare performance with TAP because it is the only solution designed and implemented for the dynamic setting. We also compare with the PoL deployed by Binance as it uses the same gnark libary [11] implementation for SNARK as Notus, facilitating direct comparison of the two system designs. Moreover, as explained in our introduction, the approach of OKX produces a proof of size more than 1GB, making comparisons unrealistic. Recall that TAP is based on Merkle Sum trees, combined with Pedersen commitments and range proofs. For fairness, we run TAP ignoring its increasing proving overhead as epochs progress, and although its code does not support parallelism, we assume it achieves "ideal" perfect parallelization for comparison purposes. As shown, TAP has a fast prover but its proof size grows linearly with the number of updates, resulting in very large proofs.

Binance combines Merkle trees with SNARKs, considering a SNARK-friendly hash [37]. Its code is developed for production and currently considers a PoL for 350 different cryptocurrencies, with all datasets stored in a Merkle tree of depth 28. As we do not have access to the sample data required to run Binance, we first report their own benchmark, also tested on a system with 32 cores and 128GB memory [7], and normalize their results for 2^{10} updates. To conduct a fair comparison, we also ran SNARKed MerkleTree (MT). This is a "simplified" version of the technique behind Binance where we eliminated business-specific details, and built a Merkle tree of depth 28 incrementally within the SNARK by verifying the Merkle path for each newly inserted leaf.

	Prover time (sec)	Proof size (Byte)	Verify time (sec)
TAP [56]	3.8	610K	2.0
Binance* [6]	124.4	256	0.001
SNARKed MT	15.0	256	0.001
Notus	3.7	256	0.001

Table 3: Comparison of proving correct update between TAP, Binance, Merkle Insert, and Notus for 2^{10} updates. Results of Binance* come from its own benchmark with similar settings.

Finally, our results show that Notus achieves the fastest prover time, around $3\times$ faster than SNARKed MT, and even marginally outperforms the range-proof-based system while maintaining succinct proof sizes and verification times.

Next, we turn our attention to the performance of Notus. Having already discussed the zero-knowledge accumulator part in section 6.2, we provide an evaluation for the SNARK part of Notus in terms of its circuit size (number of constraints) and prover time, for a variable number of updated transactions S_i (swap elements) in Figure 9 (a). Then, Figure 9 (b) provides the total prover overhead for Notus run on an AWS server with 32 cores and 128GB memory under different user sizes. Clearly, the running time increases almost linearly with the set size. On the verifier side, the auditor needs to spend 1ms and the proof size is 256 bytes for SNARK and 1024 bytes for MultiSwap, regardless of the set size. For users, membership proofs are one RSA element (256 bytes). Verifying the transaction history from the last checkpoint requires generating a hash chain and one membership proof in less than 2ms.

Super-efficient Auditing. Our auditor overhead per epoch is $O(1)$ and concretely so low that we can actually run it on a smart contract, which no prior PoL system could achieve. This is important as it makes auditing transparent and *eliminates the need to trust the auditor* blindly [15, 55, 57]. We wrote a Solidity smart contract for the auditor check, and the Gas cost per epoch is only 750K (270K for verifying a Groth16 proof and 480K for verifying two PoKEs).

Scaling to Larger User Sets. Increasing the user set size becomes challenging according to Figure 8 (d) as the prover time grows. Moreover, the precomputation table we maintain for exponentiations will quickly cause memory issues as the size increases. However, based on our user-grouping strategy from Section 5, we can naturally scale the Notus prover assuming a setting with multiple machines handling separate

subgroups. E.g., let's aim for 2^{20} users (assuming probability $1/2^6$ for users to update in an epoch), splitting them into just 8 groups, each one has 2^{17} users, $\sim 2^{11}$ of them update within the epoch. (For comparison, OKX currently splits users into $\sim 2K$ groups [52]). We can use eight cloud servers, each with 32 cores, to run this in parallel in approximately *3 minutes* according to Figure 8 (d). The extremely favorable side-effect of our design of Notus is that this approach *only increases the auditor's overhead and not the users'* as each user only verifies with respect to her own subgroup. Hence, if we split the 2^{20} users into 32 groups of 2^{15} users, and we utilize 32 servers to run in parallel, the prover time would become merely $\sim$43 seconds, while the auditor's overhead would still be in the order of milliseconds and the proof a few hundred KB!

These results show the practicality of Notus and indicate its potential as a good candidate for real-world applications. Binance currently operates a static PoL system with 45 million users, proving its solvency every month. Assuming one server with 32 cores and 64G memory, for 45 million users, it takes 68 *days* for Binance to generate the proof. Even with 100 servers, it would still take 16 *hours* [7]. If we extrapolate our results, Notus could build a **DPoL** system for 45 million users for the same configuration, proving its solvency every $43 \times 45 = 1935$ seconds! This is an over-simplified estimation but it clearly shows the potential qualitative difference.

7 Related Work

As discussed in Section 1, prior works on PoL mostly focus on the static case and cannot be readily extended to updates. The authors of [41] briefly mention the possibility of extending their construction to handle updates of liabilities. Identifying the privacy issues that arise from proofs across different epochs, they theoretically discuss relying on oblivious RAM [35] to hide update patterns. However, this introduces the problem of proving statements involving this ORAM [21], either via expensive zero-knowledge proofs, or via relying on trusted hardware, such as Intel SGX, which we consider too strong a security assumption for PoL applications (e.g., due to known attacks such as [43,47]). One could consider extending TAP [56] to handle general liability modifications, e.g., by maintaining one data structure for increasing liabilities and a "dual" one solely for decreasing modifications. Queries would then involve requesting proofs from both instances and computing the joint result. However, this hypothetical approach would require some sort of consistency checking between the two instances during updates, most likely via a SNARK, which would significantly blow up the overhead. Considering DAPOL+, Buterin suggested in a blogpost [15] replacing the Merkle tree with KZG polynomial commitments [42] combined with a "large" SNARK to prove all values are positive. Again, moving to the dynamic case, it is not clear how much this would blow up the overhead. In very recent independent work, Falzon et al. [32] designed a *static* PoL system that improved DAPOL+ by offering a shorter membership proof size at the cost of increased computation overhead for the prover. However, it still operates in *static* setting and compared to Notus, its proof size grows logarithmically with the number of users (concretely, it appears to be larger than ours, which is constant 256 bytes).

Finally, besides proving financial solvency, PoL has also been considered for other applications, e.g., disapproval voting, decentralized lending, taxing, reports of public data, and dynamic pricing based on public data [22,41,56].

Relation to Append-only Authenticated Dictionaries (AADs). A relevant research area to PoL is that of AADs [25, 40, 51, 56, 59, 61] that have found use cases in Certificate and Key Transparency [44]. Like PoLs, these schemes consider an untrusted server maintaining a dataset, however, in that setting, the server only resolves key-lookup queries (e.g., a user's public certificate). Due to this, prior AADs cannot be directly converted to a PoL. TAP [56] extends this line of work and it essentially provides an AAD with added functionalities beyond lookups, which it then uses to build a PoL. Another line of work uses this approach to build append-only relational databases [66]. While supporting more general queries, existing works for verifiable database queries either do not consider privacy [68] (which is crucial for PoLs) or require the auditor to essentially replicate the server's workload [66].

Zero-knowledge Accumulators and Vector Commitments. Zero-knowledge accumulators allow a prover to succinctly commit to a set of values with hiding and binding properties. Zero-knowledge (commonly referred to as *hiding*) vector commitments (VCs) further require commitments to be position-binding. There are limited zero-knowledge accumulators in the literature [18,34,69]. Ours is the first such scheme that is SNARK-friendly, supports efficient membership precomputations, and has constant-sized membership proofs. On the other hand, there are a number of choices for several zero-knowledge VCs [17, 19, 20, 42] and zero-knowledge sets [26, 69]. When designing Notus, we also considered a VC approach. However, there are limited candidates that are simultaneously zero-knowledge, SNARK-friendly, and support efficient lookups. The state-of-the-art candidate for such a VC approach is Caulk [67]. In our experimental evaluation for lookups, we show that our lookup can significantly outperform Caulk by more than 1000 times depending on the set size. To make Caulk support instant online responses like ours, we mimic Caulk* by precomputing all the membership proof offline. Caulk*'s offline line time becomes extremely heavy, almost 3 orders of magnitude slower than Caulk and our zero-knowledge RSA accumulator.

Zero-knowledge Membership Proofs. Zero-knowledge membership proofs allow a party to convince a verifier that it "knows" (e.g., as a commitment pre-image) an element or set of elements belonging to a committed set, without necessarily revealing the element(s). This primitive has been

built as an additional feature for RSA [9, 16] and bilinear accumulators [58], and Merkle trees combined with verifiable random functions [25]. This is different than the privacy property of our zero-knowledge accumulator whose goal is to also hide the committed set. For instance, zero-knowledge membership proofs are also meaningful when the set itself is public, e.g., when designing anonymous credentials and decentralized identities, and they can usually be adapted to hide the element itself (e.g., as the pre-image of a separate commitment). Boneh et al. [9] gave the state-of-the-art RSA accumulator with zero-knowledge membership proofs for a public set. Campanelli et al. [16] extends [9] by providing zero-knowledge subset proofs also for a publicly committed set. Our zero-knowledge RSA accumulator shares a similar basis with [16] but has orthogonal aims. We focus on protecting the privacy of the whole set while providing zero-knowledge membership/subset proofs. Besides, our subset proof is statistically zero-knowledge while subset proof in [16] is computationally zero-knowledge.

MultiSwap. First proposed in [53] for efficient batch "off-chain" verification of blockchain transaction, MultiSwap allows proving the correct updated status of a set after removals and insertions, usually by relying on a SNARK to check the validity of the removed and added subsets. More recently, Harisa [16] improved [53] in efficiency. We improve MultiSwap by making it zero-knowledge with minimal overhead.

8 Conclusion

We presented Notus, the first PoL system that supports general liability updates without requiring users to check their transactions at every epoch. Our system achieves $O(1)$ proof size, and verification and auditing overhead. Contrary to prior attempts, users in Notus can verify their status by checking just one proof, despite how many epochs they were absent. Notus utilizes as building blocks our novel zero-knowledge RSA accumulator and the first zero-knowledge MultiSwap protocol that may find other applications. Our experimental evaluation shows that Notus can scale to large numbers of users while maintaining good overall performance. One future direction in this line of work is to potentially reduce the prover's overhead to linear in the number of transactions in an epoch (as in [56] but for arbitrary updates).

A Extended Preliminaries

A.1 Range proof

Range proofs are zero-knowledge proofs where the prover convinces the verifier that the committed values are in specific ranges. For hidden order group-based commitments, range proofs are usually [29, 46] composed by zero-knowledge argument of positivity (ZKAoP): in order to prove $x \in [a,b]$, the prover proves $x-a>0$ and $b-x>0$. In this work, we use the ZKAoP provided in [29], based on the RSA assumption. In their protocol, the statement is the integer commitment [31] in the format $g^x h^r$ where x is the committed value, and r is a randomness. We modify the statement to the format g^x. We can consider the statement as a special case where $r=0$. We denote the non-interactive version as NI-ZKAoP. We denote the protocol as (1) $\pi \leftarrow$ **NI-ZKAoP.Prove**$(G,g;x)$ where π is the proof, x is the witness such that $x>0$ and $G=g^x$; (2) $1/0 \leftarrow$ **NI-ZKAoP.Verify**(G,g,π). Besides, the authors in [29] also proved its knowledge extractability.

A.2 Universal Accumulators

We follow the universal accumulator definitions provided by [34].

Definition 1. *Given security parameter λ, a universal accumulator is a tuple of four PPT algorithms* **(KeyGen, Acc, Witness, Verify)***:*

- $(ek, vk) \leftarrow$ **KeyGen**(1^λ). *This algorithm takes as input the security parameter and outputs a public evaluation key ek that will be used to generate witnesses and a public verification key vk that will be used to verify witness.*
- $C \leftarrow$ **Acc**(ek, X). *This algorithm takes as input a set $X \subset \mathcal{X}_\lambda$ where $\mathcal{X}_\lambda$ is the input domain for the elements to be accumulated and the evaluation key ek and outputs one accumulation of the set $C \in \mathcal{G}_\lambda$ where $\mathcal{G}_\lambda$ is the output domain for* **Acc***.*
- $(b, w_x) \leftarrow$ **Witness**(X, x, C, ek). *This algorithm takes as input a set $X \subset \mathcal{X}_\lambda$, one element $x \in \mathcal{X}_\lambda$, the evaluation key ek and the accumulation of the set C. It outputs a boolean value b indicating whether the element is in the set and a witness w_x for the answer. $b=1$ indicates the element is in the set and this witness is a membership witness. Otherwise, $b=0$ and this witness is a non-membership witness.*
- $0/1 \leftarrow$ **Verify**(C, x, w_x, b, vk). *This algorithm takes as input the accumulation value $C \in \mathcal{G}_\lambda$, one element $x \in \mathcal{X}_\lambda$, the witness w_x, a bit b and the public verification key vk. It outputs 1 if it accepts the proof and 0 otherwise.*

A.3 Division Intractable Hash

Division Intractable (DI) hash is a special kind of hash function where it is hard to find any set of distinct preimages such that one hash result divides the product of the remaining hash results. It can be formally defined as follows.

Definition 2. *Division intractable. A function family $\mathcal{H}$ is called division intractable (DI) if given security parameter λ, finding $H \in \mathcal{H}$ and distinct inputs $X_1, \ldots, X_m, Y$, $m < poly(\lambda)$ such that*

$$\Pr[H(Y) | H(X_1) \ldots H(X_m)] < \text{negl}(\lambda).$$

Clearly, all Hash-to-prime hash functions are DI. However, most Hash-to-prime functions are time-consuming. According to Lemma 6 in [33], a random oracle with λ^2-bit output is also DI. Informally, random numbers with large bit-length tend to have large prime factors. A large prime factor makes the random number hard to divide from other random numbers with different large prime factors.

In particular, Ozdemir *et al.* [53] conjectured that the density of integers in $[1,\alpha]$ with small factors also holds for a large interval around α, more specifically, $[\alpha, \alpha+\alpha^{1/8}]$. Based on this conjecture, we can construct a DI-hash more efficiently in computation. Let Δ be a large integer with λ^2-bit, and $H(x)$ be a collision resistant and preimage-hard hash function with $\alpha^{1/8}$ bits output. $H_\Delta(x) = \Delta + H(x)$, $H_\Delta(x)$ is also DI.

B Correctness and Security Definitions of DPoL

Definition 3 (**DPoL** Completeness)**.** *$\forall$ ordered sequences of appends S_i, for all users $u \in \mathcal{U}$ and $1 \le i \le m$ epochs,*

$$\Pr\left[\begin{array}{c}(ek,vk) \leftarrow \textbf{Setup}(1^\lambda),\\ d_i \leftarrow \textbf{Digest}(ek, L_i, aux_i)^+,\\ \forall u \in \mathcal{U}, \pi_{\text{mem}} \leftarrow \textbf{LookupProof}(ek, L_i, u, aux_i),\\ \pi_{\text{sum}} \leftarrow \textbf{ProveSum}(ek, L_i, aux_i),\\ \forall i \in [1,m], \pi_i \leftarrow \textbf{ProveConsistent}(ek, L_i, aux_i):\\ \forall u \in \mathcal{U}, \textbf{VerLookup}(vk, d_i, H_u^{1,i}, \pi_{\text{mem}}) = 1,\\ \textbf{VerSum}(vk, d_i, \text{sum}, \pi_{\text{sum}}) = 1,\\ \forall i \in [1,m], \textbf{VerConsistent}(vk, i, d_{i-1}, d_i, \pi_i) = 1\end{array}\right] \ge 1 - \text{negl}(\lambda)$$

Definition 4 (**DPoL** Undeniability)**.** *$\forall$ adversaries $\mathcal{A}$ running in time $poly(\lambda)$, for any user $u \in \mathcal{U}$ and any epoch $i \in [1,m]$,*

$$\Pr\left[\begin{array}{c}(ek,vk) \leftarrow \textbf{Setup}(1^\lambda),\\ (d_i, \text{sum}, \text{sum}', \pi_{\text{sum}}, \pi'_{\text{sum}}, L_i, L'_i,\\ aux_i, aux'_i) \leftarrow \mathcal{A}(1^\lambda, ek, vk) : (\text{sum} \neq \text{sum}'\\ \wedge \textbf{VerSum}(vk, d_i, \text{sum}, \pi_{\text{sum}}) = 1\\ \wedge \textbf{VerSum}(vk, d_i, \text{sum}', \pi'_{\text{sum}}) = 1) \vee\\ (L_i \neq L'_i \wedge d_i \leftarrow \textbf{Digest}(ek, L_i, aux_i) \wedge\\ d_i \leftarrow \textbf{Digest}(ek, L'_i, aux'_i))\end{array}\right] \le \text{negl}(\lambda)$$

Definition 5 (**DPoL** Update Soundness)**.** $\forall$ *adversaries* $\mathcal{A}$ *running in time poly*(λ)*,*

$$\Pr\left[\begin{array}{c}(ek,vk)\leftarrow\textbf{Setup}(1^\lambda),\\ (L_{i-1},L_i,d_{i-1},d_i,\pi_i,aux_i,aux_{i-1},\text{sum}_{i-1},\\ \text{sum}_i,\pi^{i-1}_{\text{sum}},\pi^{i}_{\text{sum}})\leftarrow\mathcal{A}(1^\lambda,ek,vk):\\ d_i\leftarrow\textbf{Digest}(ek,L_i,aux_i),\\ d_{i-1}\leftarrow\textbf{Digest}(ek,L_{i-1},aux_{i-1}),\\ L_{i-1}\subset L_i,\ S_i=L_i\setminus L_{i-1},\\ \textbf{VerConsistency}(vk,i,d_{i-1},d_i,\pi_i)=1,\\ \textbf{VerSum}(vk,d_{i-1},\text{sum}_{i-1},\pi^{i-1}_{\text{sum}})=1,\\ \textbf{VerSum}(vk,d_i,\text{sum}_i,\pi^{i}_{\text{sum}})=1,\\ (\exists tx\in S_i: tx.upd\neq i\vee tx.lia<0)\vee\\ \text{sum}_i-\text{sum}_{i-1}\neq\sum\limits_{u\in S_i}(H^i_u.lia-H^{i-1}_u.lia)\end{array}\right]\leq\text{negl}(\lambda)$$

Definition 6 (**DPoL** Sum Soundness)**.** $\forall$ *adversaries* $\mathcal{A}$ *running in time poly*(λ)*,*

$$\Pr\left[\begin{array}{c}(ek,vk)\leftarrow\textbf{Setup}(1^\lambda),\\ (d_i,\text{sum}_i,\pi^i_{\text{sum}},H^{1,i}_{u_0},\ldots,H^{1,i}_{u_j},\\ \pi_{\text{mem}_0},\ldots,\pi_{\text{mem}_j})\leftarrow\mathcal{A}(1^\lambda,ek,vk):\\ \textbf{VerSum}(vk,d_i,\text{sum}_i,\pi^i_{\text{sum}})=1\wedge\\ \forall j,\textbf{VerLookup}(vk,d_i,H^{1,i}_{u_j},\pi_{\text{mem}_j})=1\wedge\\ \text{sum}_i<\sum\limits_{\forall u}H^{1,i}_{u_j}.lia\wedge\forall H^{1,i}_{u_j}.lia>0\end{array}\right]\leq\text{negl}(\lambda)$$

Additional discussions for these definitions can be found in the extended version of our paper [65].

Definition 7 (**DPoL** Privacy)**.** *Let* F_1 *be a function checking user u's history for a given ledger* L_i*,* $H^{1,i}_u\leftarrow F_1(L_i,u)$*. Let* F_2 *be a function checking the sum of liabilities for a given ledger* L_i*,* $sum\leftarrow F_2(L_i)$*. Let* $\textbf{Real}_{\textbf{Adv}}(1^\lambda)$*,* $\textbf{Ideal}_{\textbf{Adv,Sim}}(1^\lambda)$ *be games between a challenger, an adversary* $\mathcal{A}$ *and a simulator* $\textbf{Sim}=(\textbf{Sim}_1,\textbf{Sim}_2)$*, defined as follows:*

$\underline{\textbf{Real}_{\textbf{Adv}}(1^\lambda)}$*:*

- ***Setup.*** *The challenger runs* $(ek,vk)\leftarrow\textbf{Setup}(1^\lambda)$ *and forwards* (ek,vk) *to* $\mathcal{A}$*,* $\mathcal{A}$ *chooses* S_1 *with* $|S_1|\leq poly(\lambda)$ *and sends to the challenger. The challenger runs* $d_1\leftarrow\textbf{Digest}(ek,L_1=S_1,aux_1)$ *and sends* d_1 *to* $\mathcal{A}$*.*
- ***Query.*** *For* $i=1,\ldots,\zeta$ *where* $\zeta\leq poly(\lambda)$*, the* $\mathcal{A}$ *outputs* $op=(lookup,u)$*,* op*=sum or* $op=(update,S_{i+1})$*.*

  – If $op=(lookup,u)$*, the challenger runs* $\pi_{\text{mem}}\leftarrow\textbf{LookupProof}(ek,L_i,u,aux_i)$ *if user u has transaction history in the ledger in epoch i and returns* π_{mem} *to* $\mathcal{A}$*.*

  – If $op=sum$*, the challenger runs* $\pi_{\text{sum}}\leftarrow\textbf{ProveSum}(ek,L_i,aux_i)$*, returns* $(\text{sum},\pi_{\text{sum}})$ *to* $\mathcal{A}$*.*

  – If $op=(update,S_{i+1})$*, the challenger runs* $L_{i+1}=L_i\bigcup S_{i+1}$*,* $d_{i+1}\leftarrow\textbf{Digest}(ek,L_{i+1},aux_{i+1})$*,* $\pi_{i+1}\leftarrow\textbf{ProveConsistency}(ek,L_{i+1},aux_{i+1})$ *and returns* (d_{i+1},π_{i+1}) *to* $\mathcal{A}$*.*
- ***Respond.*** $\mathcal{A}$ *outputs a bit* $b=0/1$*.*

$\underline{\textbf{Ideal}_{\textbf{Adv,Sim}}(1^\lambda)}$*:*

- ***Setup.*** *The simulator* $\textbf{Sim}_1$ *inputs* (1^λ) *and forwards vk to* $\mathcal{A}$*,* $\mathcal{A}$ *chooses* S_1 *with* $|S_1|\leq poly(\lambda)$*. The simulator (without seeing* S_1*) responds with* d_1 *to* $\mathcal{A}$ *and maintains state* $\textbf{State}_S$*.*
- ***Query.*** *For* $i=1,\ldots,\zeta$ *where* $\zeta\leq poly(\lambda)$*,* $\mathcal{A}$ *outputs* $op=(lookup,u)$*,* op*=sum or* $op=(update,S_{i+1})$*.*

  – If $op=sum$*, the simulator runs* $\pi_{\text{sum}}\leftarrow\textbf{Sim}_2(ek,\textbf{State}_S,F_2(L_i))$ *and returns* $(\text{sum},\pi_{\text{sum}})$ *to* $\mathcal{A}$*.*

  – If $op=(update,S_{i+1})$*, the simulator runs* $(d_{i+1},\pi_{i+1})\leftarrow\textbf{Sim}_2(ek,\textbf{State}_S,d_i)$ *and returns* (d_{i+1},π_{i+1}) *to* $\mathcal{A}$*.*
- ***Respond.*** $\mathcal{A}$ *outputs a bit* $b=0/1$*.*

A ***DPoL*** *scheme is zero-knowledge if there exists a probabilistic polynomial time (PPT) simulator* $\textbf{Sim}=(\textbf{Sim}_1,\textbf{Sim}_2)$ *such that for all* **Adv***,*

$$|\Pr[\textbf{Real}_{\textbf{Adv}}(1^\lambda)=1]-\Pr[\textbf{Ideal}_{\textbf{Adv,Sim}}(1^\lambda)=1]|\leq\text{negl}(\lambda).$$

If the above probabilities are equivalent, the ***DPoL*** *scheme is perfect zero-knowledge. If the inequality only holds for PPT* **Adv***, the* ***DPoL*** *scheme is computational zero-knowledge.*

C Zero-knowledge RSA accumulator

Let λ be the security parameter. We set $\mathcal{X}_\lambda=\mathbb{Z}_{2^{\lambda^2}}$. $\mathcal{X}_\lambda$ is the input domain for the elements to be accumulated. Denote by $X=\{x_1,\ldots,x_m\}$ the set of m elements to be accumulated. $\mathcal{H}_{DI}$ is a DI-hash family.

We use QR_N to denote the subgroup of $\mathbb{Z}^*_N$ of squares (quadratic residues modulo N). In order to let adaptive root assumption hold in $\mathbb{Z}^*_N$, we usually eliminate elements with trivial roots, $\{1,-1\}$. We use $\mathbb{G}=QR_N\setminus\{1,-1\}$ to denote excluding the use of $\{1,-1\}$ in challenges and proofs so that strong RSA assumption, adaptive root assumption hold in $\mathbb{G}$. Denote $K>\max\{\text{maxord}(\mathbb{G})2^{\lambda+2},2^{\lambda^2}\}$ where $\text{maxord}(\mathbb{G})$ is the upper bound for the group order and 2^{λ^2} is the lower bound to make random numbers DI as discussed in Appendix A.

We use $(a,b)\leftarrow\textbf{EEA}(x,y)$ to denote the extended Euclidean algorithm that calculates Bézout coefficients (a,b) s.t. $ax+by=\gcd(x,y)=z$. We present our construction in Figure 10. In the **KeyGen**, we generate two generators g,h. h is not explicitly used in the construction and is only used for the **NI-ZKAoP** for the non-membership proof. For the function **Acc**, it inputs at least one random number $t\xleftarrow{\$}[1,K]$. As shown in our security proofs, one random number uniform in $[1,K]$ is enough to achieve statistically zero knowledge, and random numbers in $[1,K]$ also satisfy the DI property. We generalize to multiple random numbers for dynamic cases, which are used in the dynamic MultiSwap.

KeyGen(1^λ):

$p,q \xleftarrow{\$} \text{Primes}(\lambda)$, $p' = 2p+1$, $q' = 2q+1$, s.t. p',q' are prime, $N = p'q'$, $\mathbb{G} = QR_N \setminus \{1,-1\}$

$g,h \xleftarrow{\$} \mathbb{G}$

return: $ek = vk = (N,g,h)$

Acc(ek,X,t):

Reject if $0 \leftarrow \textbf{NI-ZKAoP.Verify}(A \times B^{\xi},g,\pi_3)$

return: 0 if rejected and 1 otherwise

Figure 10: Our zero-knowledge RSA accumulator. **Acc** inputs at least one random number $t \xleftarrow{\$} [1,K]$. If **Acc** inputs more than one random, then accumulate all of them. For example, if the inputs include t_1, t_2, then $C = g^{ut_1t_2} \mod N$.

D Zero-knowledge Subset

We construct our zero-knowledge subset protocol using two basic CP-SNARKs: $\mathcal{R}^{Hash}$ and $\mathcal{R}^{mod}$.

$\mathcal{R}^{Hash}(\boxed{c_{\vec{u}}};\tau,S) = 1 \Leftrightarrow \forall s_i \in S, u_i = H_{DI}(s_i), u_{i+1} = H_K(\tau)$, which proves the committed values are perspective hash outputs of S and τ, i.e., H_{DI} for each s_i and H_K for τ.

$\mathcal{R}^{mod}(\boxed{c_{\vec{u}}},l,r) = 1 \Leftrightarrow \prod_{\forall i} u_i = r \mod l$, which proves the product of committed values modulo l equals r.

We describe the construction of our zero-knowledge subset accumulator in Figure 11.

Protocol zero-knowledge subset

Setup(1^λ): $N,\mathbb{G} = QR_N \setminus \{1,-1\}$, $g \xleftarrow{\$} \mathbb{G}$;
$\text{crs}_1 \leftarrow \Pi.\textbf{Setup}(1^\lambda,\mathcal{R}^{Hash})$;
$\text{crs}_2 \leftarrow \Pi.\textbf{Setup}(1^\lambda,\mathcal{R}^{mod})$.
Input: $C,C' \in \mathbb{G}$, $\boxed{c_{\vec{u}}}$.

Witness: (τ,S) s.t. $x = \prod_{s_i \in S} H_{DI}(s_i)$, $\tau \xleftarrow{\$} [K]$, $t = H_K(\tau)$, $C' = C^{xt}$.
Claim: Proof of knowledge of set S s.t. accumulating S into C and randomized with t gets C', and hash values of set S and τ are committed in $c_{\vec{u}}$.

1. Verifier sends $l \xleftarrow{\$} \text{Primes}(\lambda)$ to the prover.
2. Prover computes the quotient $q = \lfloor xt/l \rfloor \in \mathbb{Z}$ and residue $r = xt \mod l$ s.t. $xt = ql + r$. $Q = g^q \mod N$.
3. $\pi_1 \leftarrow \Pi.\textbf{Prove}(\text{crs}_1, \boxed{c_{\vec{u}}}; \tau, S)$.
4. $\pi_2 \leftarrow \Pi.\textbf{Prove}(\text{crs}_2, \boxed{c_{\vec{u}}}, l, r)$.
5. Prover sends $\pi = (\boxed{c_{\vec{u}}}, Q, r, \pi_1, \pi_2)$ to the verifier.
6. Verifier accepts if $r \in [l]$ and $Q^l C^r = C'$ holds in $\mathbb{G}$, $\Pi.\textbf{Verify}(\text{crs}_1, \boxed{c_{\vec{u}}}, \pi_1) = 1$ and $\Pi.\textbf{Verify}(\text{crs}_2, \boxed{c_{\vec{u}}}, l, r, \pi_2) = 1$.

Figure 11: Our protocol for zero-knowledge subset accumulator while the complementary set is committed.

E Membership proof precomputation

Our zero-knowledge RSA accumulator, similar to general RSA accumulators, supports precomputing all membership proofs in $O(n \log n)$ time using the divide-and-conquer method [60] with minor modifications. Consider an accumulator $g^{x_1x_2x_3x_4t_1t_2} \mod N$ containing four elements (x_1,x_2,x_3,x_4) and two randomizers (t_1,t_2). The membership for x_1 is represented by the element $g^{x_2x_3x_4t_1t_2} \mod N$, which includes all elements and randomizers except x_1.

In the first round of the divide-and-conquer approach, our method diverges slightly from the general method by computing $g^{x_1x_2t_1t_2} \mod N$ and $g^{x_3x_4t_1t_2} \mod N$. For subsequent rounds, the membership precomputation remains the same, with each branch accumulating half of the remaining elements to generate membership proofs. For instance, in the second round, we compute $(g^{x_1x_2t_1t_2})^{x_3}, (g^{x_1x_2t_1t_2})^{x_4} \mod N$ to obtain the membership proofs for x_3 and x_4, respectively.

Abstract

As privacy-sensitive applications based on zero-knowledge proofs (ZKPs) gain increasing traction, there is a pressing need to detect vulnerabilities in ZKP circuits. This paper studies common vulnerabilities in Circom (the most popular domain-specific language for ZKP circuits) and describes a static analysis framework for detecting these vulnerabilities. Our technique operates over an abstraction called the *circuit dependence graph (CDG)* that captures key properties of the circuit and allows expressing *semantic vulnerability patterns* as queries over the CDG abstraction. We have implemented 9 different detectors using this framework and performed an experimental evaluation on over 258 circuits from popular Circom projects on GitHub. According to our evaluation, these detectors can identify vulnerabilities, including previously unknown ones, with high precision and recall.

1 Introduction

Zero-knowledge protocols (ZKP) have gained traction as a mechanism for proving that a statement is true without providing any other information beyond the correctness of the statement itself. Since their inception, ZKPs have found numerous applications in authentication systems [19, 38], online voting [14], privacy-preserving cryptocurrencies [12], and scaling solutions for blockchains [35].

A particularly attractive zero-knowledge proof protocol is a so-called zkSNARK (Zero-Knowledge Succinct Non-Interactive ARgument of Knowledge), which allows one party (the *prover*) to generate a *succinct* proof that allows the other party (the *verifier*) to *efficiently* check the correctness of the proof. What makes zkSNARKs particularly appealing is that the prover and the verifier can be automatically generated from a so-called *arithmetic circuit* describing a set of polynomial equations over a finite field. Hence, given some computation f on input x, developers of ZK applications only need to construct an arithmetic circuit C such that $y = f(x)$ if and only if $C(x,y)$ is true. Then, given such a circuit C, a zkSNARK proof generator can be used to generate a prover and verifier, thereby allowing the prover to establish that $y = f(x)$ without revealing any information about x to the verifier.

Given the importance of arithmetic circuits in the ZKP domain, several domain-specific languages, such as Circom [10] and Leo [18], have emerged to facilitate the construction of arithmetic circuits. However, despite language and compiler support, building *correct* arithmetic circuits remains a challenge. In particular, given some computation f on input x, the developer still needs to generate a set of constraints C such that $C(x,y)$ is true if $y = f(x)$. If the constraints crafted by the developer do not possess this property, then the resulting ZKP can allow the verifier to accept a *bogus* proof that $y = P(x)$ even though this is actually not the case. Indeed, bugs in arithmetic circuits can result in catastrophic consequences, such as allowing attackers to forge signatures [6] or mint counterfeit cryptocoins [23]. Even worse, attacks on ZK applications are extremely hard to detect, even once they occur, because the only information provided by the attacker, namely the proof, is already accepted as being valid by the application. Hence, there is a pressing need for developing *static* (i.e., compile-time) techniques for ensuring that arithmetic circuits do not contain subtle vulnerabilities.

Motivated by this problem, this paper describes a static analysis framework for automatically detecting common vulnerabilities in arithmetic circuits written in Circom, which is currently the most popular domain-specific language for zkSNARKs. Based on our manual inspection of real-world vulnerabilities in Circom programs, we identify several semantic patterns that underlie common vulnerabilities and propose a static analysis framework for detecting such patterns. Our framework allows describing semantic vulnerability patterns using a domain-specific language, at the heart of which lies an abstraction of Circom programs called a *circuit dependence graph*. Given a semantic vulnerability pattern expressed in this DSL, our framework can statically check whether a Circom program exhibits that vulnerability.

We have implemented a library of several vulnerability checkers on top of this framework and used them to detect vulnerabilities in 258 arithmetic circuits taken from popular

Circom projects on GitHub. Our detectors have high precision and recall and have collectively uncovered 32 unique previously unknown vulnerabilities.

To summarize, this paper makes the following key contributions:

- We present a taxonomy of common vulnerabilities in Circom arithmetic circuits.
- We introduce a program abstraction called *circuit dependence graph (CDG)*, which is useful for expressing and detecting vulnerabilities.
- We present a *vulnerability description language (VDL)* for expressing semantic vulnerability patterns in arithmetic circuits.
- We implemented the proposed ideas in ZKAP, a static analyzer for ZKP circuits, and evaluated it on 258 arithmetic circuits. Our evaluation shows that our checkers have a low false positive rate (16.4%) and collectively detect over 98.6% of vulnerabilities in these circuits. We also show that our approach can detect previously unknown vulnerabilities. The dataset and ZKAP itself have been published on GitHub.[1]

2 Background

In this section, we provide some necessary background on zero-knowledge protocols and give an overview of the syntax and semantics of Circom programs.

2.1 Zero-Knowledge Protocols

A zero-knowledge protocol allows one party, the *prover* $\mathcal{P}$, to convince another party, *the verifier* $\mathcal{V}$, that they know some secret information without revealing what it actually is. In more detail, given some computation f that operates over public inputs x and secret information y, the prover needs to convince the verifier that some output z corresponds to the result of $f(x,y)$ without revealing any information whatsoever about y. What makes such a system *zero-knowledge* is that the prover does not reveal anything about y beyond proving that they have access to it.

While there are several different types of zero-knowledge protocols, *zkSNARK* (*Zero-Knowledge Succinct Non-interactive ARgument of Knowledge*) protocols have become increasingly popular due to their succinct proof size and sublinear verification time. An appealing property of zkSNARKs is that a suitable prover and verifier can be automatically generated from an *arithmetic circuit* representation of the computation. Hence, several domain-specific languages, such as Circom and Leo, have been designed to facilitate the construction of arithmetic circuits.

Language	#Projects	#Circuits
Circom	**518**	**6.4k**
Leo	96	396
Zinc	31	944
Halo2	83	187
Plonky2	17	1.5k
Noir	66	544
Gnark	43	3.6k
ZoKrates	301	5.9k

Table 1: Statistics of different ZK domain-specific languages for constructing arithmetic circuits, collected from GitHub publicly available GitHub codebases.

```
pragma circom 2.0.0;

template Multiplier2(){
  //Declaration of signals
  signal input in1;
  signal input in2;
  signal output out;
  out <== in1 * in2;
}

component main {public [in1,in2]} = Multiplier2();
```

Figure 1: A simple example written in Circom.

An arithmetic circuit is essentially a set of polynomial equations over a finite field. In particular, an arithmetic circuit takes some input signals that are valued in the range $[0,p)$ and performs additions and multiplications modulo a prime number p. The output of every addition and multiplication produces a signal, which is characterized as either an *intermediate* signal or an *output* signal, which denotes the final public output.

2.2 The Circom Language

Because this work primarily targets arithmetic circuits expressed in Circom, we provide some background on the Circom DSL. Circom is one of the most popular and widely used ZK domain-specific languages for constructing arithmetic circuits, since more than 6k circuits and over 500 projects are built with it, which makes it the top choice among all other languages, as shown by Table 1.

At a high level, Circom allows expressing computations in a manner that is low-level enough to be amenable to the generation of a zero-knowledge proof system. Given a program written in Circom, the compiler generates two artifacts, namely:

- **Witness generator program**, which computes the values of all other signals (both intermediate and output) given some input. We refer to the witness generator as the computation expressed by the Circom program and denote it by f.
- **Rank-1 constraint system (R1CS)**, which zkSNARK pro-

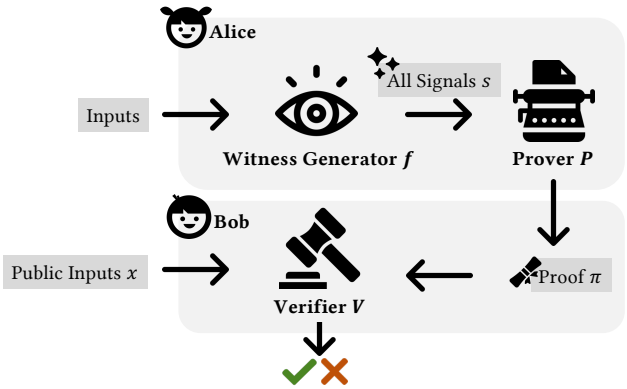

Figure 2: Usage of zero-knowledge circuit: Alice generates a proof using witness generator and prover, and Bob verifies the proof using public inputs.

tocols operate over to produce the prover and verifier. We refer to the R1CS representation as the arithmetic circuit expressed by the Circom program and denote it by C_f.

Hence, one typically uses a ZK circuit in the following way: One party, say Alice, uses the witness generator program f and the prover P to generate a proof π that they have correctly computed $f(x,y) = z$ for some public input x, secret information y, and output z. Then, another party, say Bob, can use π along with the public input x to check whether $z = f(x,y)$ without having access to y. This usage scenario is illustrated in Figure 2.

The crucial point here is that the proof π should only be accepted by the verifier *iff* the output z is indeed equal to $f(x,y)$. However, if there is a bug in the original Circom program, i.e., the arithmetic circuit C_f does not correspond to the computation f, then the verifier may end up accepting bogus proofs. In particular, a malicious party can exploit bugs in the Circom program to produce a *bogus* witness i.e., one which cannot be generated by f, and then use the prover to generate a "proof" that is accepted by the verifier.

Since understanding how bugs can arise in this context requires some background about Circom syntax and semantics, we provide a brief Circom tutorial that is needed for understanding the rest of the paper.

Circom signals. Circuits operate over *signals*, which are finite field elements (or arrays thereof) and are declared using the keyword `signal`. Signals can be qualified as input or output, and any signals without input or output annotations are considered to be intermediate signals. Given an input signal, the witness generator produced by the Circom compiler computes the values of all intermediate and output signals.

Circom operators. Because the Circom compiler is used to generate both the witness calculator program as well as the R1CS constraints, it provides operators that can be used to express both computation (for witness calculation) as well as constraint generation. In particular, the Circom operators `<--` and `-->` are used for signal assignment and are crucial for witness generation. In contrast, the `===` operator is used for *constraint generation*; for example, the statement `x === y` tells the Circom compiler to generate a circuit that only accepts signals where the value of `x` is equal to that of `y`. In practice, however, there is a close correspondence between witness computation and constraint generation: Typically, one needs to add a constraint whenever they use the assignment operator. For this reason, Circom also provides two additional operators, namely `<==`, `==>`, to perform both assignment and constraint generation simultaneously. But there is one key complication: the operands of `===` must obey certain restrictions (e.g., involving only quadratic expressions) in order to facilitate the generation of a Rank-1 constraint system. Hence, it is not always possible to emulate every assignment in Circom directly using the `<==` operator. This introduces one of the challenges of expressing computation in Circom.

Templates. Generic circuits in Circom are referred to as *templates*, and their parametric values must be instantiated when the template is used. Templates can be instantiated using the keyword *component* and by providing the necessary parameters like so:

```
component c = templateId(v1,...,vn);
```

As an example, consider the Circom program shown in Figure 1. First, we use the reserved keyword `template` to define a generic circuit `Multiplier2`. This circuit contains two input signals `in1` and `in2` and a public output signal called `out`. In line 8, we use `<==` to set the value of `out` to be the result of multiplying the values of `in1` and `in2`. Equivalently, we could have also used the operator `==>`, e.g., `in1 * in2 ==> out`. Finally, the values of `in1` and `in2` are public through the instantiation of the component in line 11.

How bugs can arise. Use of ZKP requires a Circom program that expresses both the computation part (via witness generation) and its corresponding arithmetic circuit (via R1CS) part. As the automatic transformation from computation to arithmetic circuit is infeasible from existing compilers, users are the ones that write the constraints from computation, which turns out to be error-prone and the major cause of vulnerabilities. For example, in Figure 1 the output signal `out` is computed, and constrained by two input signals `in1` and `in2`:

```
out <== in1 * in2;
```

which generates the following R1CS constraint via the Circom compiler:

```
out = in1 * in2
```

A common mistake from the users is the misuse between <== and <--, where the latter only states the computation, not the constraints. Hence, the following Circom statement is alarming and could be causing potential vulnerabilities:

```
out <-- in1 * in2;
```

since its corresponding arithmetic circuit part could be missing, which then allows its generated verifier to accept bogus proofs that are not valid for its computation.

2.3 Threat Model

Since we focus on vulnerabilities in the design and implementation of ZK circuits, we make no assumptions about the quality and robustness of their underlying codebase. For attacks on ZK circuits, we consider a trustless set-up where an attacker can access all public information, including but not limited to (a) on-chain blockchain states such as blocks, transactions, accounts, and balances; (b) deployed smart contract bytecode that interacts with ZK circuits; (c) source code of ZK circuits. Furthermore, beyond directly interacting with the victim ZK applications themselves, we assume attackers can deploy their own contract and ZK application on the blockchain, which can in turn invoke public transactions of the target victim contract and circuits.

3 Taxonomy of Circom Vulnerabilities

Since our goal in this work is to understand common Circom vulnerabilities and develop effective techniques to address them, we started out by studying dozens of existing vulnerabilities in Circom programs. Our investigation consists of three stages: data collection, issue validation, and vulnerability categorization. We show each step in detail below:

- **Data collection.** We first collected a set of known vulnerabilities from various sources: open-source issue trackers for ZK circuits[2], public technical reports[3] and GitHub repositories of projects built with Circom[4].
- **Issue validation.** We then filtered the set of vulnerabilities to only keep those directly caused by circuits and removed duplication. For issues with description only, we created their manual proof-of-concept circuits.
- **Vulnerability categorization.** We then categorized all the vulnerabilities by their root causes into major categories.

[2]For example, ZK Bug Tracker from 0xPARC: https://github.com/0xPARC/zk-bug-tracker.

[3]For example, Analysis Passes from CIRCOMSPECT: https://github.com/trailofbits/circomspect/blob/main/doc/analysis_passes.md.

[4]For example, issues from circomlib (https://github.com/iden3/circomlib/pull/81), maci (https://github.com/privacy-scaling-explorations/maci/issues/377) and circom-pairing (https://github.com/yi-sun/circom-pairing/commit/eebee8c68469625a2d662aeb330caf8c35ef3eaa).

Table 2 shows 12 representative ZK vulnerabilities used in the manual inspection with four categories found, which are identified from the curated set of vulnerabilities composed from 489 circuits across more than 15 open-source projects built with Circom[5]. As a result of the manual inspection, we were able to come up with a taxonomy of different vulnerability patterns, which we classify into three main classes:

- **Nondeterministic signals**, where the input or output signals of a circuit are not properly constrained,
- **Unsafe component usage**, where signals of a component are not used correctly,
- **Constraint-computation discrepancies**, where there is a divergence between the witness generation code and the generated constraints.

Circuit	Source	Category
UnconstrainedOutput	Issue Tracker	Nondeterministic Signals
ProcessMessages	Issue Tracker	
BinSum	Technical Report	
SingleAssignment0	Technical Report	Constraint-Computation Discrepancies
DivZero	Technical Report	
Decoder	GitHub Issues	
RangeProofs	Issue Tracker	
BigModOld	GitHub Issues	
SingleAssignment1	Technical Report	
UnusedCompOutput	Technical Report	Unsafe Component Usage
UnusedPubInput	Issue Tracker	
Modulo	Issue Tracker	Integer Overflow

Table 2: Vulnerabilities collected and used for manual inspection and their corresponding sources and categories.

3.1 Nondeterministic Signals

We found that many bugs in Circom programs are caused by *non-deterministic signals*. We say that a signal x is nondeterministic if it can take multiple values for a given assignment to the input signals. Intuitively, if a signal is nondeterministic, the Rank-1 constraint system generated by the compiler will not properly constrain its value, often causing it to accept bogus proofs.

A common source of non-determinism is due to signals that are *unconstrained*, meaning that the signal is not even mentioned in the generated Rank-1 constraint system. If such an unconstrained signal corresponds to an output, this is guaranteed to be a bug.

[5]These projects are: circomlib, circom-pairing, aes-circom, circom-matrix, circom-ml, darkforest-eth, ed25519-circom, hermez-network, hydra-s1-zkps, iden3-core, keccak256-circom, maci, semaphore, zk-group-sigs, zk-SQL, as well as projects mentioned in ZK bug tracker and CIRCOMSPECT.

```
template ArrayXOR(n) {
    signal input a[n];
    signal input b[n];
    signal output out[n];
    for (var i = 0; i < n; i++) {
        out[i] <-- a[i] ^ b[i];
    }
}
component main = ArrayXOR(2);
```

Figure 3: A code snippet demonstrating an underconstrained circuit caused by nondeterministic signals in array `out`.

For example, Figure 3 shows an example from the `circom-pairing`[6] library which implements core cryptographic pairing algorithms and their corresponding computational infrastructure to support signature verification. The `ArrayXOR` template can be instantiated to compute the exclusive disjunction of pairs of signals from the two input arrays, `a` and `b`. However, the circuit does not generate a constraint for `out[i]` in line 6: In particular, because the operator `<--` only performs signal assignment, the circuit ends up *not* constraining the value of the output signal, thereby allowing attackers to forge signatures for potentially malicious behavior.

In addition to output signals, input and intermediate signals that are declared but never used in the constraints are often also problematic. For example, Figure 4 shows a code snippet from Hermez Network[7] with unused input signals, where an array `bjj` is declared in line 2 but one of its elements, namely `bjj[254]`, is not used. Such unused input signals could indicate functional correctness issues but can also result in vulnerabilities in the application that verifies the proof. This is the case because, to verify a circuit, one must provide the set of outputs and public input signals that were used to generate the proof. But, in cases where a public input is completely unused, any input could be used to verify the proof regardless of the value provided to the prover. For the code in Figure 4, this means that a user can generate a proof where `bjj[254]` is 0 and still verify the resulting proof with a non-zero value for `bjj[254]`.

3.2 Unsafe Component Use

Recall that a component is an instantiated template that can be used like a function. In practice, many templates are written in such a way that they expect callers to constrain their inputs and outputs. Hence, if a component is invoked without any constraints on its inputs or outputs, this usage pattern is highly suspicious.

For instance, Figure 5 shows an unsafe component use where the template *input* is unconstrained. Here, `hash` is instantiated from the template `HashMsg` from the MACI[8] project

[6] https://github.com/yi-sun/circom-pairing
[7] https://github.com/hermeznetwork/circuits
[8] https://github.com/privacy-scaling-explorations/maci

```
template BitsCompressed2AySign(){
    signal input bjj[256];
    signal output ay;
    signal output sign;
    component b2nAy = Bits2Num(254);
    var i;
    for (i = 0; i < 254; i++) {
        b2nAy.in[i] <== bjj[i];
    }
    ay <== b2nAy.out;
    sign <== bjj[255];
}
component main {public bjj}
    = BitsCompressed2AySign();
```

Figure 4: A code snippet demonstrating a circuit that violates functional correctness due to an unused circuit signal `bjj[254]`.

```
template ProcessMessages(msgBits) {
    signal input msg;
    signal input secretKey;
    signal output msgHash;
    component msgChecker = Num2Bits(msgBits);
    msgChecker.in <== msg;
    component hash = HashMsg(msgBits);
    hash.in <-- msg;
    hash.secretKey <== secretKey;
    msgHash <== hash.out;
}
component main = ProcessMessages(64);
```

Figure 5: A code snippet showing a bug caused by an unconstrained component input `hash.in`, which causes acceptance of arbitrary `msg`.

at line 7. In order to correctly verify the hash of the current message `msg`, the call to the `hash` component requires its input signal `in` to be properly constrained. However, as discussed earlier in Section 2, the assignment operator `<--` used at line 8 only performs assignment without introducing a constraint. Thus, the input to the hash computation is completely unconstrained, resulting in an underconstrained output signal `msgHash`, which can in turn cause the acceptance of an arbitrary message.

Just as unconstrained inputs often correlate with bugs, unconstrained component *outputs* are also very suspicious, as most templates are written in a way that expects their users to constrain the output signal at the call site. For instance, Figure 6 shows an example of an unused component output vulnerability in `circom-pairing`, a Circom implementation of elliptic curve pairings for the widely-adopted BLS12–381 curve. This bug is caused by using the `BigLessThan` template incorrectly. In particular, note that each `lt[i]` in this example is a component instantiating `BigLessThan` at line 5. Because the `BigLessThan` template requires the caller to explicitly constrain its output signal `lt[i].out` in order to properly compare its two inputs `lt[i].a` and `lt[i].b`, `lt[i].out` is unconstrained at the call site. As a result, `lt[i].a` and `lt[i].b` can take arbitrary values, causing the whole circuit to be under-

```
template CoreVerifyPubkeyG1(n, k){
    // ...
    component lt[10];
    for(var i=0; i<10; i++){
        lt[i] = BigLessThan(n, k);
        for(var idx=0; idx<k; idx++)
            lt[i].b[idx] <== q[idx];
    }
    for(var idx=0; idx<k; idx++){
        lt[0].a[idx] <== pub[0][idx];
        // ...
    }
    // ...: lt.out is not used
}
component main = CoreVerifyPubkeyG1(55, 7);
```

Figure 6: A code snippet that contains unused component output signals `lt[i].out`, which causes the absence of constraint for restricting inputs `lt[i].a` and `lt[i].b`, thus making the circuit underconstrained.

constrained.

3.3 Constraint-Computation Discrepancies

Recall that Circom programs are simultaneously used for generating witness calculation programs as well as a Rank-1 constraint system. However, even though these two aspects are intermingled in Circom code, there could nonetheless be unintended discrepancies between the two aspects. For example, certain operators that are valid for witness generation are actually often invalid for constraint generation. Similarly, recall that *not* every computation can be directly expressed as a constraint; hence, two expressions that are intended to express the same value in two syntactically different ways may actually end up being semantically different, causing discrepancies between witness computation and constraint generation.

To gain more insight about such vulnerabilities, consider the `Edwards2Montgomery` circuit in Figure 7, which is taken from `circomlib`[9], one of the most popular libraries for constructing zero-knowledge protocols. This circuit is intended to convert a point in an Edwards curve to one in a Montgomery curve. Observe that lines 4 and 5 use the multiplicative inverse operator in the right hand side of the assignment, while lines 6 and 7 try to introduce a constraint that "emulates" this computation. Note that the code cannot combine the assignment and constraint generation via the use of the `<==` operator because R1CS constraints cannot contain multiplicative inverse operations. Hence, lines 6 and 7 try to introduce constraints that mimic the computation. However, there is a subtle bug: the constraints generated allow the inverted signal `in[0]` to be `0` and still satisfy the constraints. While the witness generator will never generate witness with `in[0] == 0`, since the multiplicative inverse is undefined in those cases, the constraints introduced at lines 6 and 7 actually accept those undefined

```
template Reward() {
    signal input inp;
    signal output out;
    var gwei = 10 ** 6;
    out <-- inp \ gwei;
    out * gwei === inp;
}

component main = Reward();
```

Figure 8: A code snippet showing a witness assignment (line 5) that has different semantic meaning than its counterpart in constraint generation (line 6). Such a discrepancy leads to a violation of function correctness in the circuit.

values. This makes the overall circuit underconstrained since any assignment to `out[1]` will satisfy the constraints when when `in[0] == 0` and `out[0] == 0`.

As another example of constraint-computation discrepancies, consider the buggy circuit in Figure 8. As in the previous example, line 6 tries to introduce a constraint that emulates the computation from line 5 since the R1CS representation does not permit the integer division operation $\backslash$ in the constraints. However, because the assignment at line 5 ignores the possible remainder of the division, there is a discrepancy between lines 5 and 6. In this case, the circuit is more constrained than the computation as the computation will accept arbitrary `inp` values, while the constraint will only be satisfied when `inp` is a multiple of `gwei`.

3.4 Key Lessons

Because the goal of our manual inspection is to make it possible to automatically detect common vulnerabilities, we conclude this section by summarizing some key take-away lessons that motivate the design of our static checking framework.

The role of semantic analysis. One of the key lessons from our manual inspection is that detecting many real-world vulnerabilities requires reasoning about the semantics of Circom code. For example, to detect discrepancies between the computation and the generated constraints, we need to understand

the semantics of the code, at least to some extent.

Wide variety of different bugs. While our taxonomy identifies three main root causes of vulnerabilities, there are significant variations in how these vulnerabilities manifest themselves in code. Thus, from the perspective of statically finding vulnerabilities, we may need to write many different detectors to get a high coverage of all vulnerabilities.

Useful abstractions. Even though different bugs exhibit different syntactic patterns, there are nonetheless common *semantic abstractions* that underlie all of these patterns. For example, several bugs we have encountered can be understood by considering the discrepancies between variable dependencies at the computational vs. constraint level.

In

4 Static Analysis Framework

Drawing inspirations from the key lessons discussed in Section 3.4, we describe a static analysis framework we have developed for practical security analysis of Circom programs. At the heart of our framework lies a graph representation that we refer to as *Circuit Dependence Graph (CDG)*. In the remainder of this section, we describe our CDG abstraction, present a domain-specific language for describing semantic vulnerability patterns based on this abstraction, and explain our static analysis for constructing the CDG.

4.1 Circuit Dependence Graphs

As mentioned in Section 3.4, many vulnerabilities arise due to discrepancies in signal dependencies at the computational vs. constraint level. Thus, our proposed *circuit dependence graph (CDG)* abstraction is designed to encode such dependencies. Specifically, a CDG is a graph $G = (V, E_d, E_c)$ where V denotes the set of vertices, E_d denotes a set of arcs (i.e., directed edges) encoding dependencies at the computational level, and E_c is a set of *undirected* edges encoding dependencies at the constraint level.

In more detail, we differentiate between two types of nodes in the CDG:

- **Signal nodes $V_s \in V$:** represent signals in the program.
- **Constant nodes $V_c \in V$:** denote fixed literal value in the program (such as a concrete field element).

As mentioned previously, we also differentiate between two types of edges:

- **Data flow edges E_d:** A data flow edge $(u,v) \in E_d$ is a *directed* edge indicating direct data flow from u to v, which can be derived from the assignment operators (e.g., <-- and <==).

Predicate	Indication
`sig(v)`	`v` is declared as a signal of the circuit.
`in(v)`	`v` is declared as an input signal of the circuit.
`out(v)`	`v` is declared as an output signal of the circuit.
`const(v)`	`v` is a constant value.
`expr(e)`	`e` is an expression.
`quad(e)`	`e` is a quadratic expression.
`contains(e,v)`	`e` is an expression that contains signal `v`.
`is(x1,x2)`	`x1` is identical to `x2` in source code.
`assignedTo(e,v)`	`e` is assigned to `v`.
`equivTo(e1,e2)`	`e1` and `e2` are in the same constraint.
`sigOf(v,c)`	`v` is a signal declared in component `c`.
`inOf(v,c)`	`v` is an input signal declared in component `c`.
`outOf(v,c)`	`v` is an output signal declared in component `c`.
`exprDiv(e1,e2,e3)`	`e1` is a division expression with `e2` as dividend and `e3` as divisor.
`exprIte(e1,e2, e3,e4)`	`e1` is an if-then-else expression with `e2` as condition, `e3` as then branch and `e4` as else branch.

Table 3: Some of the predicates used for representing the syntax of Circom programs.

- **Constraint edges $E_c \in E$:** A constraint edge $(u,v) \in E_c$ is an *undirected* edge indicating that u and v appear in the same constraint, which can be derived from the constraint operators (e.g., === and <==).

At a high level, a data flow edge from u to v labeled by s indicates that the value of u directly depends on v due to an assignment to u of an expression s containing v. Similarly, a constraint edge between u and v labeled s indicates that there is an equation s directly relating u and v.

In essence, a CDG is an extended version of data flow graph, which models the arithmetic circuit part in addition to the computation part. Besides the regular data flow edges, constraint edges are added for modeling equivalence between signals and constants in arithmetic circuits.

4.2 CDG Construction

Given a Circom program, our method constructs the CDG by first representing the syntax of the program using the predicates shown in Table 3 and then adding new nodes and edges to the CDG using the (Datalog-style) inference rules shown in Figure 9. As standard, a rule of the form:

$$P(\overline{x}) \Leftarrow P_1(\overline{x_1}), \ldots, P_n(\overline{x_n})$$

indicates that predicate $P(\overline{x})$ is inferred to be true if all the other predicates $P_1, \ldots, P_n$ are also true. We now briefly explain our CDG construction rules.

$$\mathsf{sNode}(v) \Leftarrow \mathsf{sig}(v) \quad (1)$$
$$\mathsf{cNode}(v) \Leftarrow \mathsf{const}(v) \quad (2)$$
$$\mathsf{dEdge}(u,v) \Leftarrow \mathsf{assignedTo}(e,v), \mathsf{contains}(e,u) \quad (3)$$
$$\mathsf{dEdge}(u,v) \Leftarrow \mathsf{inOf}(u,c), \mathsf{outOf}(v,c), \mathsf{dEdge}^{+}(u,v) \quad (4)$$
$$\mathsf{dLabel}(u,v,e) \Leftarrow \mathsf{assignedTo}(e,v), \mathsf{contains}(e,u) \quad (5)$$
$$\mathsf{dLabel}(u,v,\cdot) \Leftarrow \mathsf{inOf}(u,c), \mathsf{outOf}(v,c), \mathsf{dEdge}^{+}(u,v) \quad (6)$$
$$\mathsf{cEdge}(u,v) \Leftarrow \mathsf{contains}(e_1,u), \mathsf{contains}(e_2,v), \mathsf{equivTo}(e_1,e_2) \quad (7)$$
$$\mathsf{cEdge}(u,v) \Leftarrow \mathsf{inOf}(u,c), \mathsf{outOf}(v,c), \mathsf{cEdge}^{+}(u,v) \quad (8)$$
$$\mathsf{cEdge}(u,v) \Leftarrow \mathsf{cEdge}(v,u) \quad (9)$$
$$\mathsf{cLabel}(u,v,e_1 \equiv e_2) \Leftarrow \mathsf{contains}(e_1,u), \mathsf{contains}(e_2,v), \mathsf{equivTo}(e_1,e_2) \quad (10)$$
$$\mathsf{cLabel}(u,v,\cdot) \Leftarrow \mathsf{inOf}(u,c), \mathsf{outOf}(v,c), \mathsf{cEdge}^{+}(u,v) \quad (11)$$
$$\mathsf{cLabel}(u,v,s) \Leftarrow \mathsf{cLabel}(v,u,s) \quad (12)$$

Figure 9: Datalog style inference rules describing CDG construction, where c is a component, u, v correspond to signals and constants e corresponds to an expression, and s correspond to a statement. Given relation R, R^{+} denotes its transitive closure.

Nodes. The first two rules (1) and (2) in Figure 9 create nodes of the CDG abstraction. In particular, a signal (resp. constant) `v` in the Circom program is mapped to a signal node $\mathsf{sNode}(v)$ (resp. constant node $\mathsf{cNode}(v)$).

Data flow edges. The next four rules (3)–(6) describe how data flow edges are constructed. Rule (3) adds data flow edges to model direct assignments in the Circom program. That is, given a statement that assigns to v an expression e containing signal u, we add a data flow edge from u to v and record its label e using the dLabel predicate, as shown in rule (5). Rule (4) summarizes the data flow relations between the input and output of a component. To do so, it constructs the CDG for this component and checks whether there is a data flow dependency between the input and output. Note that, in this rule, the notation R^{+} denotes the transitive closure of relation R. Since data flow edges for components only *summarize* data flow inside components, we label their edges using a special symbol $\cdot$, as shown in rule (6).

Constraint edges. Rules (7)–(12) describe the construction of constraint edges E_c. According to rules (7) and (10), if there is a constraint of the form $e_1 === e_2$ where e_1 and e_2 contain expressions u and v respectively, we add a constraint edge between these two signals and label this edge as $e_1 \equiv e_2$. Rules (8) and (11) are the counterpart of rules (4) and (6) for components, but handling constraint edges rather than data flow. In particular, these rules again conceptually construct

```
ϕ  ::= node(v1) | sig(v1) | const(v1) | in(v1) | out(v1)
     | dEdge(v1, v2) | cEdge(v1, v2)
     | dLabel(v1, v2, e1) | cLabel(v1, v2, s1)
     | sigOf(v1, c1) | inOf(v1, c1) | outOf(v1, c1)
     | matchExp(e, pattern)
     | ϕ, ϕ | !ϕ | ϕ ∨ ϕ
r  ::= ϕ :- ϕ

        vi ∈ nodes,  ci ∈ components
        si ∈ statements,  ei ∈ expressions
```

Figure 10: Vulnerability Description Language

the CDG for the relevant component and adds a constraint edge between the input and output variables if there is any constraint relating to them. As before, such "summary" edges are labeled using the special symbol $\cdot$. Finally, rules (9) and (12) express that constraint edges are symmetric and add an edge (u,v) with the same label for each edge (v,u).

4.3 Vulnerability Description Language

As mentioned in Section 3.4, vulnerabilities in Circom programs take a variety of different forms despite having a few underlying root causes. Hence, in order to build a practical tool that does not suffer from many false positives, it is imperative to build detectors that can accurately identify key semantic vulnerability patterns. To this end, we have designed an extensible vulnerability description language (VDL) for expressing semantic patterns over the proposed CDG representation.

Figure 10 shows the syntax of our vulnerability description language. At a high level, the vulnerability description language has Datalog-like syntax and provides a number of built-in predicates for describing the syntax of the input Circom program as well as properties of the CDG. For example, the predicate `dEdge(`v_1`,`v_2`)` (resp. `cEdge(`v_1`,`v_2`)`) denotes a dataflow (resp. constraint) edge from v_1 to v_2, and $R^{+}(v_1,v_2)$ denotes the transitive closure of binary relation R.

The VDL also provides a number of additional predicates for checking signal types and which signals are declared in which components. For example, `sig`(v) checks whether v is a signal and `sigOf`(v, c) evaluates to true if signal v is declared in circuit c. Finally, the construct `matchExp` allows performing syntactic pattern matching on expressions labeling the edges of the circuit dependence graph. As a rule in VDL is usually a customized predicate composed of finite number of atomic formulas, it is essentially a Constrained Horn Clause [29].

Checking Circom programs against VDL specifications. We refer to programs in our DSL as *anti-patterns* or *semantic vulnerability patterns*. Given a library $\mathcal{L}$ of such anti-patterns and a Circom program P, our static analysis framework first constructs the CDG of the program and checks whether P is an instance of some $\alpha \in \mathcal{L}$. To do so, we first evaluate the truth

value of all ground predicates in the VDL and them as facts to a Datalog program which also includes the code describing the anti-patterns. Finally, to check if the program matches anti-pattern α, we simply issue a Datalog query $\alpha(x)$?, which returns all instances of anti-pattern α for program P.

4.4 Detectors based on VDL

Drawing insights from our manual inspection described in Section 3, we have implemented a library of ZKP anti-patterns based on our VDL from Section 4.3. In what follows, we describe our detectors in more detail.

Unconstrained circuit output (UCO) As discussed in Section 3.1, unconstrained outputs of a circuit indicate a serious vulnerability. In particular, if an output signal is neither constrained to be a constant nor depends (transitively) on an input signal, this means it is unconstrained. This can be described in our VDL using the following anti-pattern:

```
 sigDep(v) :- sig(u), cEdge+(u,v)
isConst(v) :- cEdge+(u,v), const(u), !sigDep(v)
  inDep(v) :- in(u), cEdge+(u,v)
    UCO(v) :- out(v), !isConst(v), !inDep(v)
```

Observe that this anti-pattern specification introduces three auxiliary predicates. First, it defines a predicate `sigDep(v)` indicating that v is dependent on some other signal. Second, it defines a predicate called `isConst(v)` that evaluates to true if v is *only* dependent on a constant (and hence, it must be constrained to be a constant). Finally, `inDep(v)` checks whether v is dependent on an input signal. Using these predicates, an output signal is considered unconstrained if it is neither (a) constrained to be a constant, nor (b) dependent on an input signal.

Unconstrained sub-circuit input (USCI) Recall from Section 3.2 that many templates expect callers to constrain their inputs when instantiated. A component used without any constraints on its inputs is then considered to be suspicious. This can be described in our VDL using the following anti-pattern:

```
exDep(v,c) :- sigOf(v, c), cEdge+(u,v),
              !sigOf(u,c)
   USCI(v) :- sig(v), inOf(v,c),
              !isConst(v), !exDep(v,c)
```

Here the anti-pattern introduces an extra predicate, `exDep(v,c)`, which indicates that signal v of component c has a constraint dependency on a signal outside of c. Using this predicate, we define the input signal v of component c to be unconstrained if it is neither constrained to be a constant nor satisfied the `exDep` predicate. Observe that the definition of `USCI` utilizes the same `isConst` predicate defined earlier in the Unconstrained Circuit Output pattern.

Figure 11 shows the CDG for the `ProcessMessage` example in Figure 5. Here, solid edges represent data dependencies,

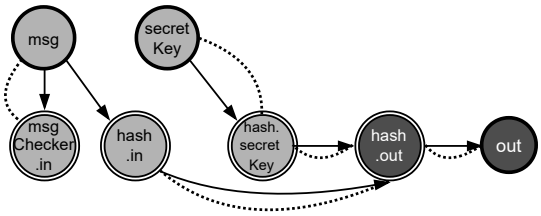

Figure 11: CDG for `ProcessMessage` example shown in Figure 5, which has an unconstrained component input `hash.in`.

```
template SingleAssignment0() {
   signal input a;
   signal input b;
   signal output out;
   out <-- a + 1;
   out === b + 1;
}
component main = SingleAssignment0();
```

Figure 12: A code snippet showing a bug caused by dataflow-constraint discrepancy. In particular, the semantics of computing and constraining `out` are different.

and dashed edges represent constraints. As we can see from the CDG, the input of component `hash` is not constrained because there is no incoming constraint edge to `hash.in`. Hence, our USCI detector will flag this circuit as being potentially vulnerable.

Dataflow-constraint discrepancy (DCD) As discussed in Section 3.3, one of the root causes of vulnerabilities is due to semantic discrepancies between witness calculation and constraint generation. Some of these discrepancies manifest themselves as inconsistencies between the data flow and constraint edges in the CDG. Thus, one of our static checkers looks for the following anti-pattern:

```
 nodeDepOn(v,u) :- sig(u), sig(v), dEdge+(u,v)
nodeCnstBy(v,u) :- sig(u), sig(v), cEdge+(u,v)
        DCD(v) :- nodeDepOn(v,u), !nodeCnstBy(v,u)
```

Here, two additional predicates are introduced to model the data flow and constraint relations between two signals explicitly. `nodeDepOn(v,u)` returns true if there exists a (recursive) data dependence from v to u; `nodeCnstBy(v,u)` returns true if there exists a (recursive) constraint dependence between v and u. Thus, we identify a discrepancy on a signal v by checking whether there exists another signal u such that v (recursively) depends on u via data flow but is not constrained by u.

Figure 13 shows the CDG for the `SingleAssignment0` example from Figure 12. Here, signal `out` depends on `a` during witness generation, but it is only constrained by `b` for constraint generation. Hence, there is a discrepancy between the dataflow and constraint dependencies of v at the CDG level, causing this example to be flagged as potentially vulnerable.

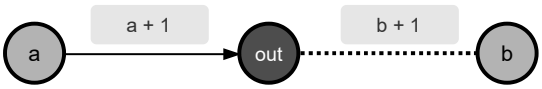

Figure 13: CDG for `SingleAssignment0` example shown in Figure 12.

Type mismatch (TM) There may be semantic discrepancies between witness calculation and constraint generation even when the program does not exhibit the DCD anti-pattern. This is because the CDG is only a coarse abstraction, and identifying a vulnerability may require reasoning more deeply about the underlying semantics of the code. Unfortunately, reasoning precisely about Circom semantics is very challenging because Circom constraints involve non-linear equations over finite fields. This poses a problem because more sophisticated static reasoning often requires querying an SMT solver but solving non-linear equations over large prime fields is intractable for current SMT solvers. Hence, rather than using SMT-based techniques for *precise* reasoning about program semantics, our approach is pragmatic and looks for certain *common* issues that cause a divergence between witness calculation and constraint generation. Our so-called *Type Mismatch (TM)* detector aims to identify one of these patterns.

The key idea behind the Type Mismatch detector is that some of the generated constraints enforce that a signal has a certain type but the witness computation does not, thereby causing a divergence in their semantics. For example, given an array of signals representing an integer in base-k representation, many circuits enforce that the integer representation of x is in the range $[0,N]$ for some N. However, if there is a computation that causes x to fall out of this range, it creates discrepancies between witness calculation and constraint generation. We can detect this divergence using the following anti-pattern:

```
checked(v) :- cLabel(v, _, c), rangeCheck(c).
     TM(v) :-  dEdge+(v, u),  checked(u), !checked(v)
```

Here, the first line line says that a variable is type-checked, denoted `checked`, if it is involved in a constraint that performs a range check. (We omit the definition of `rangeCheck`, as it performs syntactic pattern matching on expressions). According to the TM rule, there is a type mismatch error if there is a dataflow dependence from v to u where u is type checked but v is not.

Other detectors. In addition to the four detectors explained in detail, ZKAP also implements five other checkers that we briefly summarize:

- **Unconstrained signal (US):** This detector checks for *any* unconstrained signals in the circuit. While unconstrained intermediate signals are not necessarily a bug, they can nonetheless be problematic, so we found it useful to generate warnings for unconstrained signals.
- **Unconstrained sub-circuit output (USCO):** This detector checks for unused component outputs. However, we found that naively checking unused component outputs results in too many false alarms, as some components are only used to constrain their input. Hence, our detector first identifies components whose output is *intended* to be checked, using the following observation: Let φ denote the logical encoding of the circuit in terms of the input and output signals. If $\exists o.\varphi$ is vacuously true, then the output o must be constrained at the call site in order for the component to have any effect on the main circuit. However, since it is intractable to perform an actual logical validity query, our detector uses CDG dependencies to over-approximate the set of relevant outputs.
- **Assignment misuse (AM):** This detector checks for misuses of the assignment operator. In particular, if an expression e is allowed as part of the constraint, developers should use `<==` instead of the assignment operator (`<--`).
- **Non-deterministic dataflow (NDD):** The key observation behind this detector is that it is extremely difficult to correctly constrain signals that are conditionally assigned based on a signal. Most conditionals in Circom are over template variables that are resolved at compile time and require no special handling. Conditionals that involve signals, however, can only be expressed in the computation and must be properly emulated as constraints, which we have found to be error-prone. Hence, this detector looks for conditional assignments that are dependent on a signal.
- **Division-by-zero (DBZ):** We found that one of the causes of computation-constraint divergence is due to a potential division-by-zero issue in assignments. Since assignments involving division are modeled using non-linear multiplication in the constraints, division-by-zero issues also introduce discrepancies between witness calculation and constraint generation. Hence, if the denominator of a division expression used in an assignment is dataflow-dependent on an input signal, our DBZ detector flags the circuit as potentially vulnerable.

5 Evaluation

In this section, we describe the results of the experimental evaluation of ZKAP, which refers collectively to the detectors described in Section 4. Our evaluation is designed to answer the following key research questions:

- **RQ1**: How does ZKAP compare against CIRCOMSPECT (the only other tool for finding bugs in Circom) in terms of precision, recall, F1 score, and running time?
- **RQ2**: Is ZKAP effective at finding previously unknown bugs in Circom programs?

Table 4: Statistics of ZKAP's collected benchmark set. Here, #LOC means lines of codes, #Sig means declared signals in the whole project, #Node indicates the total number of CDG nodes across all benchmarks in the project.

- **RQ3:** What is the relative importance of the different detectors in terms of finding bugs in real-world ZK circuits?
- **RQ4:** How do the different detectors compare in terms of false positive rate?

All experiments are conducted on a Macbook Pro® computer with an M1 Pro CPU and 32G of memory running on macOS 12.5.1.

5.1 Dataset Collection and Statistics

Since there is no available dataset for ZK circuits, we collected our own dataset obtained from 17 different Circom projects found on GitHub. We chose these projects based on popularity (i.e., number of stars on GitHub) and the availability of documentation and test cases. Our dataset covers a wide range of applications such as computational libraries, curve pairing, machine learning, gaming, and matrix computation. These projects contain 258 arithmetic circuits, and every benchmark has at least one test case to instantiate the circuit templates. We emphasize that these circuits were *not* used as part of our initial study. As such, neither our taxonomy nor our anti-patterns were influenced by these circuits. Table 4 provides statistics about the projects and circuits used in our evaluation.

5.2 Comparison Against CIRCOMSPECT

In order to answer our first research question (**RQ1**), we perform a comparison against CIRCOMSPECT[10], an open-source static analyzer developed by TrailOfBits, a leading company in blockchain security. CIRCOMSPECT looks for certain syntactic patterns in the abstract syntax tree and, for example, flags *every* use of the <-- and --> operators as a potential bug.

[10] https://github.com/trailofbits/circomspect

	ZKAP	CIRCOMSPECT
FP rate	16.4% (8.6%)	41.4%
FN rate	1.4%	2.1%
Precision	70.9% (82.4%)	48.7%
Recall	96.6%	94.8%
F1 Score	0.82 (0.89)	0.64
Time (s)	7.2	0.2

Table 5: Comparison between ZKAP and CIRCOMSPECT. FP and FN rate indicates the false positive and false negative rates respectively. The data in parentheses is the value computed when excluding two specific circuits in circomlib.

Table 5 shows the result of our comparison between ZKAP and CIRCOMSPECT in terms of precision, recall, F1 score, and running time. Since calculating recall and precision is difficult without having access to the ground truth labels, we estimate these metrics by manually inspecting 140 of the 258 circuits in our benchmark set. In particular, for each of these 140 circuits, we do a manual security audit to identify as many potential vulnerabilities as we can, and we compute precision and recall with respect to these manually-curated labels.

As we can see from Table 5, ZKAP outperforms CIRCOMSPECT in terms of all metrics except for running time. Notably, ZKAP has an F1 score of 0.82 compared to 0.64 for CIRCOMSPECT, and ZKAP's false positive rate is significantly lower (16.4% vs 41.4%). The only metric where CIRCOMSPECT performs better on is with respect to running time: On average, ZKAP takes a median of 7.2 seconds to analyze a benchmark, whereas the median running time of CIRCOMSPECT is 0.2 seconds. This result is expected because CIRCOMSPECT only performs checks at the syntax level. However, since 7 seconds per benchmark is likely to be quite acceptable in the intended usage scenario of ZKAP, we believe this additional analysis time is more than justified by the huge reduction in the number of false positives.

When investigating the sources of false positives, we found two commonly used circomlib templates, namely `isZero` and `BabyAdd`, which match the non-deterministic dataflow and division-by-zero vulnerability patterns but are nevertheless bug free. These templates are frequently used as components in other templates and, as a result, produce many duplicate false positives. To show a more accurate result, we recomputed the false positive rate while excluding the warnings reported from those two circuits and present the new rate in parentheses in Tables 5 and 6. As we can see in Table 5, the false positive rate of ZKAP is only around 9% if we exclude those circuits, making precision 82% and increasing the F1 score to 0.89.

5.3 Detecting Unknown Vulnerabilities

To answer **RQ2**, we inspected all vulnerabilities reported by ZKAP. In our evaluation on 258 circuits, ZKAP reported a total of 405 warnings. However, many of these warnings have the same root cause because multiple circuits in one project invoke the same buggy component. Hence, ZKAP identifies a total of 34 unique problems. Among these, 32 of them are previously unknown vulnerabilities.

To give readers some intuition about the severity of the vulnerabilities uncovered by ZKAP, we briefly describe two vulnerabilities and explain their consequence.

Vulnerability 1: One of the vulnerabilities found by ZKAP is in the ed25519-circom[11] project, which is used to perform curve operations and signature verification for the Ed25519 digital signature scheme. Since this project serves as infrastructure for other Circom circuits, it is quite security-critical. ZKAP detected a previously unknown unconstrained output signal in one of the key circuits used in this project.

Figure 14 shows the template of the `PointCompress` circuit, which implements a compression algorithm to reduce the size of the public key. The public key is represented as the input signal `P[4][3]`, which is a point on the Ed25519 curve. The output signal is declared as an array of size 256 and represents the compressed public key.

ZKAP detected a previously unknown bug located at lines `16-17`. The intention of the developer here is to constrain `out[255]` to be the parity of signal `mod_x.out[0]`. However, line `17` only constrains `out[255]` to be binary, but it remains unconstrained by `mod_x.out[0]`. Therefore, a malicious user can convince the verifier that signal `mod_x.out[0]` is odd when it is even (and vice versa). According to the project's documentation, this template implements a crucial optimization that is directly applied to two inputs of the overall algorithm. Thus, the vulnerability found by ZKAP exposes a substantial attack surface for the whole system. To fix this problem, the developer must first obtain the binary representation of `mod_x.out[0]` (via circomlib's `Num2Bits` for instance) and then constrain `out[255]` to be the least significant bit.

Vulnerability 2: ZKAP's Type Mismatch (TM) detector also detected a bug in a core circuit of the `iden3` protocol[12]. The `iden3` protocol is a ZK-based access control system. Hence, vulnerabilities in the core circuits can potentially lead to privacy leaks in the protocol.

The vulnerability detected by ZKAP originates in template `verifyExpirationTime`, which is shown in Figure 15. The `verifyExpirationTime` template is responsible for validating that a claim (line `2`) was submitted prior to its expiration date. The expiration of the claim is inferred from the `claim`

[11] https://github.com/Electron-Labs/ed25519-circom
[12] https://github.com/iden3/circuits

```
1  template PointCompress(){
2      signal input P[4][3];
3      signal output out[256];
4      ...
5      component modinv_z = BigModInv51();
6      component mod_x = ModulusWith25519Chunked51(6);
7      component mod_y = ModulusWith25519Chunked51(6);
8
9      for(i=0;i<3;i++){
10         modinv_z.in[i] <== P[2][i];
11     }
12     ...
13     component bits_x = Num2Bits(85);
14     bits_x.in <== mod_x.out[0];
15     ...
16     out[255] <-- mod_x.out[0] & 1;
17     out[255] * (out[255] - 1) === 0;
18 }
```

Figure 14: An unconstrained output signal found in ed25519-circom project.

input signal (lines `9-11`), whereas the submission time is represented by input signal `timestamp` (line `3`). To validate that a claim was submitted on time, `verifyExpirationTime` adds adequate constraints to check that `timestamp` is less than or equal to the claim's expiration (lines `9-15`).

ZKAP reported line `14` as vulnerable because of a missing range check on input signal `timestamp`. To see why this is vulnerable, we first need to dive into template `LessEqThan`, circom-lib's circuit that implements the $\leq$ operator for two signals. Specifically, for template `LessEqThan` to work correctly, both of its inputs must be represented using at most N bits, where N is the template's parameter provided during instantiation. For the instantiation of `LessEqThan` on line `14`, the `verifyExpirationTime` template must ensure that both `timestamp` and `expirationComp.expiration` fit in `252` bits. However, only the latter constraint is enforced (via `getClaimExpiration`'s implementation), but the `timestamp` signal is left completely unconstrained. Moreover, we have already identified instantiations of `verifyExpirationTime` in `iden3` that also omit the range check on signal `timestamp`. Therefore, malicious users can easily bypass this check by providing signals that fall out of the expected range. To fix this, the developer must either perform data validation within the `verifyExpirationTime` template or ensure that all users of `verifyExpirationTime` pass inputs in the expected range.

To understand the impact of this bug, we construct an attack scenario where a fake proof can leverage the vulnerability to bypass the verifier: Assume we have a normal timestamp `TIME` around current blockchain timestamp and the verifier is given a public input `claim[8] = [1 « 131, 0, 0, 0, TIME « 64, 0, 0, 0]`. This public input is expected to assert a given private input `timestamp` MUST be less or equal than the `TIME`. Figure 16 shows the expected behavior of this circuit: a proof made by `timestamp = 1` will be accepted, while the proof made by `timestamp = TIME + 1` will be rejected. However, if the attacker carefully constructs the `timestamp` according to this formula: `timestamp = p - (1 «`

```
template verifyExpirationTime() {
    signal input claim[8];
    signal input timestamp;

    component header = getClaimHeader();
    for (var i=0; i<8; i++) {
        header.claim[i] <== claim[i]; }

    component expirationComp = getClaimExpiration();
    for (var i=0; i<8; i++) {
        expirationComp.claim[i] <== claim[i]; }

    component lt = LessEqThan(252);
    lt.in[0] <== timestamp;
    lt.in[1] <== expirationComp.expiration;
    ...
}
component main {public [claim]} =
    verifyExpirationTime();
```

Figure 15: A type mismatch issue found in Circom core library.

`252) + TIME + 1`, the component `LessEqThan(252)` will work beyond its expectation. Here, p is the default prime of Circom, which is larger than 2^{253}, and the `timestamp` now is larger than 2^{252}. In this scenario, the component `LessEqThan(252)` will output `timestamp` is **less than** `TIME` even though it is not, and the verifier will accept this proof.

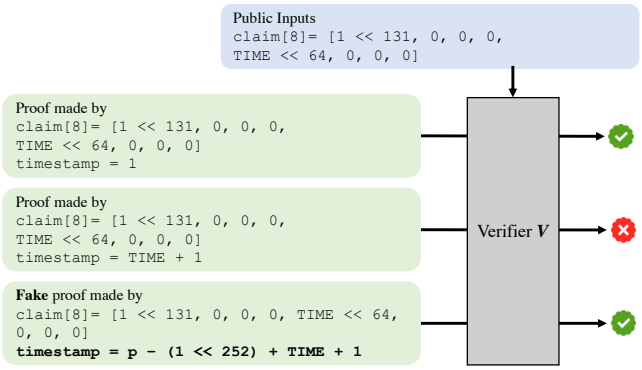

Figure 16: Fake proof could be accepted by the verifier.

If the `verifyExpirationTime` circuit is utilized to regulate business logic within smart contracts, accepting fake proofs with an unexpectedly large timestamp can enable attackers to make fraudulent reward claims, bypass time controls, or other activities with profounding damage.

Responsible disclosure Having uncovered several previously unknown vulnerabilities in public projects, we conducted responsible research to enhance their security. For each project in which vulnerabilities were identified, we adhered to the following procedure:

- Got in touch with the developers/owners through a Telegram channel and GitHub Security Feature privately.
- Notified them we were working on a research paper and shared the vulnerabilities we found in their projects.
- Waited for them to confirm and patch the circuits.

As a consequence of our disclosure to the developers, the following outcomes were confirmed:

- All vulnerabilities were confirmed, except 3 circuits in 2 projects which are not frequently maintained, and were patched by the developers before this submission.
- For vulnerabilities in the core libraries, the developers also notified their upstream applications that depend on the libraries.

5.4 Effectiveness of Different Detectors

To answer **RQ3** and **RQ4**, we present a more detailed breakdown of the results for each individual detector. The results of this evaluation are shown in Table 6. Here, the first column shows the abbreviated name of the detector, and the next column shows the percentage of real bugs uncovered by each detector.[13] The next two columns, TP and FP, report the true positive and false positive rate respectively, and the last column show the number of vulnerabilities uncovered by each checker. In what follows, we summarize some key observations.

Interestingly, around 40% of the vulnerabilities are detected by the Division-by-Zero (DBZ) checker. The other checkers that uncover more than 10% of the vulnerabilities include Dataflow-Constraint Discrepancy (DCD) checker, Unconstrained Circuit Output (UCO) detector, unconstrained signal (US) checker, assignment misuse (AM) analysis, and the type mismatch (TM) detector. While the remaining checkers also find bugs in our benchmarks, they each contribute to less than 5% of the uncovered vulnerabilities.

As we can see from Table 6, after excluding the warnings reported from two specific circuits mentioned in Section 5.2, the USCO detector has a surprisingly high false positive rate. Recall from Section 4.4 that the USCO detector needs to identify circuits whose output is intended to be constrained at the call site. However, doing this precisely requires logical reasoning about a quantified formula, which is very expensive and even intractable for existing solvers. Instead, our analysis uses heuristics to identify circuits whose output should be checked at call sites. This strategy results in a large number of false positives but is still meaningful to exhaustively expose potential vulnerabilities.

6 Related Work

In this section, we survey the closest related works that are relevant to our proposed approach.

[13] Note that these numbers do not add up to 100%, as some bugs are flagged by multiple detectors.

Detector	Contribution	FP	#Vul
UCO	16%	0%	9
USCI	4%	0%	2
DCD	12%	0%	7
TM	21%	37%	12
US	24 %	26%	14
USCO	4%	93%	2
AM	14%	27%	8
NDD	5%	90% (25%)	3
DBZ	41%	25% (11%)	24

Table 6: Performance of ZKAP across different detectors. Contribution shows the percentage of real bugs uncovered by each checker. Here, #Vul means how many benchmarks are detected and their vulnerable patterns are confirmed leading to an issue by our manual review. The data in parentheses is the refined data after excluding two specific circuits in circomlib.

ZK programming languages and compilers. Due to the growing demand for zero-knowledge proofs in many application domains, there have been several proposals for new domain-specific languages for ZKPs. While our proposed approach is primarily intended for Circom, there are other DSLs, such as Leo [18], Zokrates [21], Zinc [30], Snarky [31], and CirC [32], for facilitating the construction of zk-SNARK proofs [13]. Since most of these languages operate over arithmetic circuits, similar approaches to the one proposed here could be applied to other zkSNARK languages.

As mentioned earlier, zkSNARKs are one of several zero-knowledge protocols, and a popular alternative is the so-called zk-STARK proof system [11], which stands for Scalable Transparent ARgument of Knowledge. There are also other programming languages targeting zkSTARKs, the most popular of which is Cairo [27], a Turing complete language that allows general computation. Cairo is quite different than zkSNARK languages and is based on Algebraic Intermediate Representation (AIR) rather than R1CS. Hence, the techniques proposed in this paper are not intended for DSLs targeting zkSTARK proof systems.

Bug detection for cryptography There is a large body of work on finding bugs in cryptographic APIs and protocols. For example, the technique [22], proposed by Manuel, David, Yanick, and Christopher, aims to find bugs in cryptography libraries for Android applications. Later works, such as CryptoGuard [36], Crylogger [34], and CryptoAPIChanges [33] propose more sophisticated and higher-precision techniques aimed at finding cryptography API misuses in Java and Android applications. Recent work [4] systematically evaluates cryptographic misuse detection tools and provides some insights on improving the state-of-the-art in this domain.

There is also a substantial body of work that tries to *formally verify* cryptographic protocols and APIs [3, 5, 9, 16]. In particular, EasyCrypt [3], is developed as a tool to specify and check functional correctness of cryptographic protocols, and used to write machine checked proof of RSA-OESP. Likewise, Appel and Andrew's work [5] generated a machine checkable proof of the correctness of OpenSSL's SHA-256 implementation.

Despite an extensive body of work on verifying and finding bugs in cryptographic applications [8], there is relatively little work on finding bugs in domain-specific languages for ZKPs. To the best of our knowledge, the only existing tool for finding bugs in arithmetic circuits is the CIRCOMSPECT tool [20], which is an open-source tool developed by a leading security auditor. As mentioned earlier, CIRCOMSPECT flags all uses of the assignment operator (<--) as a potential bug and therefore has a high false positive rate. Our approach is guided by a manual study of existing bugs in Circom programs and aims for a pragmatic and extensible framework to catch common vulnerabilities with high precision and recall. However, our approach is neither sound nor complete, and more sophisticated techniques for precise reasoning about Circom would likely require advances in SMT solvers for reasoning about non-linear equations over finite fields.

Program abstractions for bug detection There is a rich body of work on using graph abstractions of programs to catch bugs. Some of these graph abstractions are quite general and domain-agnostic, such as program dependence graphs [25], callgraphs [1], data flow graphs [2] etc. These graph abstractions have found numerous applications for finding security vulnerabilities. As one example, SSLINT [28] uses program dependence graphs to detect SSL/TLS vulnerabilities in Ubuntu applications. However, many other techniques aimed at finding security vulnerabilities use domain-specific program abstractions. For example, [43] is proposed as a weighted contextual API dependency graph to detect Android malware instances. Similarly, Apposcopy [24] utilizes an Android-specific graph abstraction called an *inter-component call graph (ICCG)* to detect Android applications that match semantic malware signatures. Similarly, our proposed circuit dependence graph abstraction is fairly specific to Circom programs, but it is effective for expressing and detecting semantic vulnerability patterns.

Extensible bug detection frameworks. In this paper, we use a Datalog-like domain-specific language for expressing common vulnerability patterns. The key advantage of this approach is to make the framework extensible by building different detectors on top of a common abstraction. Other static analyses leverage Datalog for analyzing different applications and abstractions such as bytecode [26], C/C++ [7], and Java [39], LLVM IR [37], smart contracts [15,40], etc. Beyond, there is a rich history of using declarative languages for writing extensible bug detectors in the program analysis literature. For example, systems like bddbddb [41], Saturn [42], Doop [17] etc. all provide declarative Datalog-like interfaces for writing extensible static checkers. There are also prior

security analysis frameworks that are based on Datalog-style domain-specific languages. For example, PQL is a program query language for expressing several classes of security vulnerabilities, such as SQL injections, leaked file handlers, etc. In the same vein, Apposcopy [24] provides a Datalog-like language for writing semantic malware signatures. Similar to this prior body of work, we propose an extensible framework for building static checkers by writing semantic vulnerability patterns. Compared to previous work, we make the first attempt to establish the semantic abstraction and its checkers for common vulnerabilities in ZKP circuits.

7 Discussion

While designing ZKAP, we strived to achieve a good trade-off between expressiveness and scalability. For complex arithmetic semantics that are hard to express precisely, our current static analysis leverages data- and constraint-dependencies to over-approximate the actual semantics, which in theory, can lead to false alarms. However, as discussed in Section 5, our tool achieves a low false positive rate despite our abstraction.

Our study in this paper focuses on Circom, the most prevalent language for writing ZK circuits. While ZKAP was designed based on common vulnerabilities in Circom, many DSLs for zkSNARKS are quite similar in that they provide mechanisms for witness computation and constraint generation. Hence, we believe that similar insights could be used for designing and building static checkers for other zkSNARK languages.

8 Conclusion

We presented ZKAP, the first semantics-based tool for detecting common vulnerabilities in Circom, which is the most popular DSL for constructing ZKP circuits. The design of ZKAP was guided by a manual study of existing Circom vulnerabilities, which allowed us to categorize root causes of Circom bugs into three main classes. Based on the results of this study, we proposed the *circuit dependence graph (CDG)* abstraction of Circom programs for expressing and checking semantic vulnerability patterns. Our proposed framework allows implementing static checkers by writing *anti-patterns* in our Datalog-style vulnerability description language. Using this framework, we implemented a total of nine different detectors and evaluated them on 258 circuits from popular Circom projects on GitHub. Our evaluation shows that these detectors can identify vulnerabilities, including previously-unknown ones, with high precision and recall.

Formalizing Soundness Proofs of Linear PCP SNARKs

Bolton Bailey
University of Illinois at Urbana-Champaign

Andrew Miller
University of Illinois at Urbana-Champaign

Abstract

Succinct Non-interactive Arguments of Knowledge (SNARKs) have seen interest and development from the cryptographic community over recent years, and there are now constructions with very small proof size designed to work well in practice. A SNARK protocol can only be widely accepted as secure, however, if a rigorous proof of its security properties has been vetted by the community. Even then, it is sometimes the case that these security proofs are flawed, and it is then necessary for further research to identify these flaws and correct the record [39, 58].

To increase the rigor of these proofs, we create a formal framework in the Lean theorem prover for representing a widespread subclass of SNARKs based on linear PCPs. We then describe a decision procedure for checking the soundness of SNARKs in this class. We program this procedure and use it to formalize the soundness proof of several different SNARK constructions, including the well-known Groth '16.

1 Introduction

Over the past decade, cryptographic research has produced Succinct Non-interactive Arguments of Knowledge (SNARKs), which allow a prover to demonstrate knowledge of a witness corresponding to a statement in some NP relation. There exist schemes for instantiating SNARKs [42,43,59] that produce proofs consisting of a $O(1)$-sized message. SNARKs promise to have many applications in verifiable computation [16], blockchains [19, 61], and identity management [50].

Since practitioners are applying this new technology to tasks where security is a main concern, it is important for them to have confidence in the cryptographic properties of the protocols they implement. To this end, the academic review process ensures that SNARKs published in the literature come with mathematical proofs of security properties. But in practice, errors arise. Research from Parno [58] and Gabizon [39] has identified flaws in the soundness property of SNARKs in the `libsnark` library originating from [17], which was a modification of the Pinocchio SNARK [59]. Soundness refers to the property of a SNARK protocol that makes it infeasible for a malicious prover to construct proofs of false statements. This type of problem is potentially very serious – Compromising the soundness can lead to a total breakdown of the security assumptions of whatever system uses the SNARK, potentially without an outward sign that anything is wrong.

To prevent errors like this from happening in the future, we look to apply formal methods to guarantee soundness. We focus on the class of "pairing-based" SNARKs which achieve the fully-succinct $O(1)$ proof-message size previously mentioned. In particular, we deal with linear PCP SNARKs that work in the structured reference string (SRS) model: All parties are assumed to have access to a collection of elements of a pairing-friendly cryptographic group, generated by some trusted third party.

1.1 Our Contribution

Our main contribution consists of formalized proofs about the soundness aspect of several SNARK protocols. This formalization effort can be broken down into three parts:

1. We observe that linear PCP SNARK protocols from the literature have a few regularities that make them amenable to formal analysis. We call SNARKs with these properties "Straightforward linear PCP SNARK schemes". Formally, this is a restriction of the class of linear PCP SNARKs, but every linear PCP SNARK scheme that we are aware of belongs to this class.
2. We develop a mathematical structure to represent instantiations of linear PCP SNARKs, and we formalize this structure in the Lean Theorem Prover [31]. This structure is capable of representing any linear PCP SNARK, but is particularly well-suited to instantiations derived from Straightforward schemes. We formalize six SNARK schemes from the literature in Lean with this structure.
3. We automate a procedure to decide the soundness of straightforward linear PCPs SNARK schemes. That is,

our procedure is given a straightforward linear PCP SNARK scheme, and either produces a proof that every instantiation of a SNARK from that scheme will be sound, or fails to do so, in which case it is possible to attack the soundness of some instance. We run this decision procedure on the six SNARK schemes to verify their soundness.

The six protocols we formalize are of some of the most well-cited and widely-deployed in practice. They are:

- **GGPR** [42]: The first SNARK to encode computations using Quadratic Arithmetic Programs (QAPs), which is the main NP-Complete language to which SNARKs are reduced in this line of work.
- **Pinocchio** [59]: A modification of GGPR which improved efficiency.
- **Groth '16** [43]: A widely-cited SNARK which reduced the proof size to only three group elements.
- **Baghery et al.** [6]: A paper which presented a version of Groth '16 for Type-III pairings.
- **Lipmaa** [47]: Another version of Groth '16, redesigned with an eye to a simulation-extractability property.
- **Baby SNARK** [55]: A simplified version of Groth '16 constructed for educational purposes, designed to have an easy-to-follow soundness proof.

Our work puts the soundness of these SNARKs beyond doubt. Additionally, we identified and formalized a variety of techniques for manipulating constructions such as these, in order to make our work more extensible.

1.2 The Lean Theorem Prover

We carry out our formalization in the Lean 4 Theorem Prover [31]. Lean allows a user to write code that encodes mathematical theorems and proofs in the language of dependent type theory. All proofs that the programmer writes in this language are converted into a machine-readable form which is then checked by the Lean kernel.

The soundness proofs we complete involve reasoning about equalities of multivariate polynomials over finite fields. We base our work on `mathlib` [51], the open-source Lean mathematical library that implements structures and lemmas from much of undergraduate-level mathematics, including finite fields and multivariate polynomials.

Lean is built with a metaprogramming facility which allows the user to write "tactic" code which automatically constructs proofs. We use this to implement a recursive tactic to resolve subgoals consisting of systems of equations over a integral domain. Additionally, we make use of the builtin `simp` tactic, which invokes Lean's simplifier – a proof-producing procedure which allows a user to specify lemmas that are then iteratively applied to simplify an expression. We construct a variety of Lean simplification attributes for normalizing statements about polynomials and their coefficients. The end product is a system which is capable of automatically constructing a proof of the knowledge-soundness theorem for a SNARK.

1.3 Related Work

Cryptography in general and proof systems in particular have been of great interest to the formal verification community. In this section, we will go over some of these contributions and their relevance to the problem at hand.

Lean itself is a somewhat rare choice for formalization of cryptographic protocols. We nevertheless considered it appropriate for our work here, for a few reasons: The comprehensive and well-integrated `mathlib` library and its implementation of numerous lemmas about multivariate polynomials makes Lean ideal in the setting of succinct proofs. Avigad et al. [4] also use Lean and `mathlib` and theirs is the only other work of which we are aware that formalizes statements about a general-purpose succinct proof system: Their development provides a full formalization of the Cairo virtual machine in Lean, with a proof of *correctness* for its execution, (rather than soundness). It is encouraging to see another aspect of a proof system formalized, and it suggests that a full proof of completeness and soundness of some system could be within grasp. Extensions to Lean could make it a better basis for cryptography in the future - In the time our project has been underway, `mathlib` has added an implementation of elliptic curves [3], as well as a tactic [18] for solving Gröbner basis problems. This tactic, `polyrith`, works by calling a web interface to a Sage Gröbner-basis solver - while the problems that our code generates are too large to be handled on their own by `polyrith`, it is promising that a more general version of the problem is being worked on, and in the future it could make our system more flexible.

Coq [46] is the theorem proving language perhaps most related to Lean - both languages are based on dependent type theory. The Certicrypt Coq library [11] provides tools for developing formalizations of cryptographic protocols. Highly relevant is Fournet et al.'s work on a certified compiler for the Pinocchio proof system [37]. This work formally verifies a SNARK "front-end" - code that is necessary to compile a high-level language (in this case C) to the QAP. Also relevant are [5], which formalizes the portion of the zero-knowledge stack which compiles relations into the necessary form to be handled by a SNARK, and [12], which uses Certicrypt to formalize Σ-protocols, a class of proof systems involving three rounds of communication. There have also been several applications of Coq to other (non-proof-system) cryptographic protocols, including Proof-of-Stake consensus systems [66],

mix nets [45] and signature schemes [65]. Efforts in Coq to formalize broader classes of cryptographic techniques include SSProve [1], which formalizes a modularization of cryptographic proofs, the formalization [57] of some of the number-theoretic underpinnings of cryptography, and [9], which formalizes the generic model for group-based cryptography and random oracle model. This last is relevant to our own application - the generic group model [63] is related to the algebraic group model that our own work uses, in that both seek to codify an adversary's interaction with a cryptographic group. External to cryptography, Coq also has well developed math libraries, including the [60] tactic for Gröbner bases - the decision to use Lean over Coq for this project comes down to a few matters of convenience, such as Lean's ability to express tactics themselves in Lean.

EasyCrypt is another proof assistant. Like Coq, it is written in OCaml, but EasyCrypt is designed specifically with cryptography in mind. EasyCrypt allows one to reason about probabilistic computation, which is convenient for the formalization of game-based cryptographic proofs. Works in EasyCrypt relevant to proof systems include [2], which formalizes the "MPC-in-the-head" paradigm for zero knowledge and [36], which formalizes a variety of protocols including protocols for proof of knowledge of quadratic residues, discrete logarithms, and Hamiltonian cycles. The first two of the latter are protocols for specific problems not known to be NP-complete, so they cannot be turned into general-purpose proof systems. The Hamiltonian cycle and MPC-in-the-Head approaches are general purpose, but these proof systems are not succinct - they require the verifier to do work linear or more in the problem. EasyCrypt has also been used for many applications beyond proof systems, including verifications of multi-party computation itself [34,44], post-quantum cryptography [8], Pedersen commitments [54], electronic voting [30], and key exchange [10]. The framework has also formalized some more general techniques, including Canetti's Universal Composability framework [24] in [25] and Brzuska et al.'s State separating proofs [20] in [33].

On the other end of the spectrum from strongly-typed languages like Lean and Coq is the Isabelle [56] ecosystem, with its CryptHOL [14] cryptographic framework. Butler et al. [23] have done work to formalize Σ-protocols using this system, and there are also modules for constructive cryptography [13,48], and oblivious transfer [22]. ACL2, a Lisp-based theorem prover, has been used to verify the Ethereum Recursive Length Prefix encoding scheme [29].

It is also worth mentioning that there is some work done in the space of verification for proof systems which does not prove theorems formally, but nevertheless uses automated processes to check the construction of protocols. These often focus on the circuit compilation component of the SNARK toolchain: Ecne [67] is a Julia project which analyzes Rank-1 Constraint Systems to determine if their outputs are uniquely determined. Picus [26] is a symbolic VM for formal verification of Rank-1 Constraint Systems. [28] describes the Leo language, a DSL for writing SNARK programs with a facility for ACL2 verification.

To summarize, formal modelling of cryptography, like cryptography itself, is diverse both in its scope and in its techniques. For more in-depth surveys, the reader can consult the Systematization of Knowledge papers of [7], [53] or [64]

2 Linear PCP SNARKs

2.1 Overview of Elliptic Curve Pairings and the Algebraic Group Model

In the SNARKs we analyze, every message transmitted during the protocol comes in the form of a collection of elliptic curve group elements. These elements come from one of three predefined elliptic curves G_1, G_2, G_T, each of prime order p. The three curves admit a *pairing* operation: That is, there is an efficiently-computable nontrivial operation $e : G_1 \times G_2 \to G_T$ which satisfies the bilinearity property: For any $g \in G_1, h \in G_2, a, b \in \mathbb{F}_p$, we have

$$e(g^a, h^b) = e(g,h)^{a \cdot b}.$$

Fixing some generators g, h of the first two groups G_1, G_2, and fixing $e(g,h)$ as a generator of G_T, any value computed by any algorithm in the protocol can be expressed as a power of one of these generators. In keeping with the literature, we will often express group elements by corresponding power in $\mathbb{F}_p$ used to obtain it from the corresponding generator.

In order to formally check the soundness of a SNARK construction, we must make a cryptographic assumption that limits what the prover is capable of doing in assembling the proof-message, and as is typical with cryptography done using elliptic curves, our assumption is related to the difficulty of evaluating discrete logarithms in the three groups. In particular, we formalize the soundness of our chosen SNARKs with the *Algebraic Group Model* assumption [38], or AGM. The AGM assumes that the prover can only carry out algebraic operations on group elements that come from the above operations. That is, a prover can carry out group operations (multiplication and exponentiation) within any one of the three groups G_1, G_2, G_T and can use the pairing operation to take an element from each of the groups G_1, G_2 and obtain an element of G_T, but can do nothing else in the way of operations on the group elements it holds. A critical consequence of this assumption is that any element of the G_1 or G_2 curves that the prover outputs must necessarily be a linear combination of elements from those curves that the prover has seen before.

Definition 1 (See [6]). *An algorithm $\mathcal{A} : W \times G_b^k \to G_b^n$ is algebraic if there is a polynomial-time $\mathcal{X} : G_i^k \times G_b^n \to \mathbb{F}_p^{k \times n}$ taking the inputs and outputs of $\mathcal{A}$ and returning an $k \times$*

n matrix of field elements such that, except with negligible probability,

$$\mathcal{A}_i(w, g^{n_1}, \cdots, g^{n_k}) = g^{\sum_{j \in n} n_j \mathcal{X}(g^{n_1}, \cdots, g^{n_k}, \mathcal{A}_i(w, g^{n_1}, \cdots, g^{n_k}))_{i,j}}.$$

2.2 SNARKs

As we have mentioned, we focus on soundness proofs for pairing-based SNARKs in the structured reference string model. In particular, we focus on *knowledge soundness*. This refers to a guarantee that a prover who consistently convinces a verifier of a statement can only do so because they possess knowledge of a witness corresponding to that statement.

A typical approach in the field of interactive cryptographic proof systems is to prove this knowledge by defining an *extractor* algorithm. This algorithm has access to the prover algorithm, and can run it (potentially multiple times with different inputs) to extract the witness. This paradigm is challenging for SNARKs, though, because their non-interactive nature limits the information the extractor can access when trying to recover a witness.

To get around this, the SNARKs we formalize construct proofs from a larger piece of data, called a structured reference string (SRS, sometimes also referred to as a common reference string or CRS), the prover's interaction with which is the basis for the extractor. An SRS is produced before the proof phase of the protocol by a trusted third party. This leads us the usual definition for a Non interactive Zero-knowledge argument, (e.g. as found in [43])

Definition 2. *A Non-interactive argument for a relation R is a triple of randomized PPT algorithms* (SRS, P, V) *where:*

- *The SRS algorithm takes no input and generates a structured reference string* $\sigma \leftarrow SRS()$
- *The prover takes a statement x and witness w for it in the relation* $(x, w) \in R$ *as well as the SRS and returns a proof* $\pi \leftarrow P(\sigma, x, w)$
- *The verifier takes an instance of the relation and the SRS and returns a proof* $0/1 \leftarrow V(\sigma, \pi, x)$

Our formal definition is more specialized than this broad one, to better capture the structure of SNARKs we encountered. For example, the values of the field elements corresponding to the SRS elements are represented as polynomial functions of a collection of 1 to 6 field elements that the trusted third party samples uniformly at random. These sample elements are sometimes called *toxic waste* to reflect the fact that if they become known to the prover, the soundness of the proof system can be broken. The trusted third party produces the SRS from the waste samples, which the prover can then use to produce the proof. The verifier will subsequently verify the proof-message by making equality checks on G_T elements produced through the proof elements, the SRS, the statement, and the pairing.

Another way in which our formalization is specialized is that it assumes the witness is a vector of field elements. In order to provide a proof system for any language in NP in the AGM, we must have some way of reducing the problem to a language that involves the field our pairing works over. This is typically done by first encoding the relation into an arithmetic circuit and then reducing the circuit to a language such as the language of Quadratic arithmetic programs (QAPs) or Square Sum Programs (SSPs). The details of these representations are not too important; we simply refer to them collectively as *circuits*. They do work over field elements, though, which informs our choice of witness representation.

Figure 1 shows the Lean data structure which we use to represent the Proof System instantiations. The structure includes:

- A Type of statements
- A variety of Types to index into the set of toxic waste samples, the equality checks made by the verifier, and the pairings the verifier computes, as well as the SRS elements and Proof elements for both the left (G_1) and right (G_2) groups.
- Explicit lists to represent, for both groups, the complete lists of SRS element indices and proof indices. Additionally, there is a family of lists of pairings, one for each equality check.
- Maps from SRS element indices to the multivariable polynomials over the sample elements that the trusted third party uses to compute them.
- Functions that indicate, for a particular pairing input group, statement, pairing, and SRS element (similarly, proof element), the coefficient to which the verifier will include that SRS element (or proof element) in the linear combination which comprises the corresponding input to that pairing.
- A list of identified proof elements, to capture the possibility of non Type III pairings (see Section 2.3.1)

Note that we use the terminology "instantiation" to indicate that a member of this type is a proof system for a specific circuit or problem instance. By contrast, we use the terminology "scheme" or "protocol" to describe systems which, like the six we cover, are general. While these linear PCP SNARK schemes can represent any problem in NP via a circuit crafted, it should be noted that the SRS will depend on the circuit, and that these SNARKs therefore do not have a "universal" trusted setup.

2.3 Formalizing Soundness in the AGM

The only input to an adversarial proof generation procedure, in terms of cryptographic group elements, are the SRS elements that the trusted third party provides. Thus, the AGM

Figure 1: Data structure for SNARK instantiations

guarantees that each curve point in G_1 or G_2 that comprises the proof will be formed as a linear combination of the SRS elements from those respective groups. With this, and the SNARK and AGM definitions in hand, we can define knowledge soundness against algebraic prover adversaries.

Definition 3. *A SNARK (SRS, P, V) is knowledge-sound with respect to a relation R if for any input statement x and adversarial prover consisting of two algebraic algorithms $\mathcal{A} = \mathcal{A}_1 \times \mathcal{A}_2$ to output proof components in either group, there is a PPT extractor which takes the output of the corresponding $\mathcal{X}_1, \mathcal{X}_2$ and recovers a value w such that either $(x, w) \in R$ or $V(\sigma, \pi, x) = 0$, except with negligible probability.*

Again, the formalization of this makes a few structural elaborations for simplicity. All of the operations the algebraic prover and verifier execute are either additions and multiplications on the underlying elements of $\mathbb{F}_p$ coming from the SRS elements and linear combination coefficients of the prover. Since the SRS elements are themselves multivariable polynomials over the toxic waste elements, we can therefore obtain the expressions which the verifier ultimately compares in its equality checks as multivariable polynomials over the toxic waste. Since the toxic waste elements are chosen at random, the Schwartz-Zippel lemma guarantees that the checks almost certainly will only pass (and therefore that the proof is only likely to succeed) if these multivariable polynomials are exactly equal.

Lemma 1 ([62, 68]). *Let $p \neq q$ be n-variable polynomials of total degree d over a finite field $\mathbb{F}$. Let $r_1, \cdots, r_n \leftarrow \mathbb{F}$ be sampled uniformly at random. Then with probability at most $\frac{d}{|\mathbb{F}|}$ over the samples,*

$$\Pr[p(r_1, \ldots, r_n) = q(r_1, \ldots, r_n)] \leq \frac{d}{|F|}$$

We use this fact to do away with the "except with negligible probability" clause, and simply directly check in our formalization that the polynomials are equal. Figure 2 shows how this is captured in terms of a Lean Proposition, which asserts that this equality holds for all the checks in the index.

```

Figure 2: Verification procedure for SNARKs.

This gives us the path to defining soundness (see Figure 3): In order to formally assert the soundness of such a SNARK instantiation, we provide an extractor which gets access to the prover in the form of the coefficients of the linear combinations of SRS elements used to construct the proof, and

a predicate that the witness should satisfy. We say that if the satisfaction of the multivariate polynomial equalities corresponding to the verifier checks implies that the extracted witness satisfies the predicate, then the system is sound with respect to that predicate and extractor.

    relation stmt (extractor prover)
```

Figure 3: Formalization of the soundness predicate.

To summarize, formally specifying and proving the soundness of a pairing-based linear PCP SNARK in the AGM model consists of:

- Identifying the toxic waste elements
- Formally modeling the SRS elements as polynomials over the toxic waste elements
- Formally modeling the proof elements as parameterized linear combinations of SRS elements
- Formalizing the verification equations as equations over the proof elements and SRS elements
- Formalizing the satisfaction condition for the NP-Complete relation which the SNARK certifies instances of.
- Formally proving that the verification equations holding implies that the extractor obtains a valid witness under this relation.

2.3.1 Pairing types

As a short remark on our framework, we note that elliptic curve pairings can actually come in one of three types: Type I, Type II, or Type III, per the classification of [41]. A Type III elliptic curve is one in which there is no efficiently computable homomorphism between G_1 and G_2. Practically, this means that for a SNARK defined using a Type III curve, we may assume that the prover cannot include components from G_1 SRS elements in a G_2 proof element and vice versa. Most of the SNARKs we deal with use Type III groups. Type II and Type I pairings assume, respectively, an efficiently computable one-way map or an efficiently computable bijection between G_1 and G_2. Thus, for SNARKs designed to work with these pairings, we must assume that SRS elements of G_1 are available in G_2 as well, or that elements of both groups are available in either. This means that adversaries for such SNARKs have access to many more variables, and the soundness proofs can therefore be more involved. The Groth '16 SNARK is notably compatible with any kind of pairing, and we found that the proof of this SNARK was the most computationally intensive (see Table 2). While our own formalization most closely reflects the semantics of the Type III pairing, we can also formalize Type I and II SNARKs in it by providing these additional SRS elements, specifying that proof elements are proved in *both* groups, and using the final `Identified_Proof_Elems` field to guarantee that these two proof elements are equal.

3 Automation of the Soundness Proof

Our development uses a variety of techniques and tools from the Lean ecosystem to automate the soundness proofs for the SNARKs we study. In this section, we outline the general structure of the formal proofs by way of a toy example of a SNARK.[1] While this proof is very simple, it constitutes an outline which is analogous in its steps to the process we applied to all the SNARKs we formalized. In Section 4, we explain some of the reasons why this procedure works even for the much more complicated SNARKs we see in the literature.

3.1 Specification of the Toy SNARK

We first describe the relation our Toy SNARK certifies. We assume that there are two witness elements $A, B \in \mathbb{F}_p$ that the SNARK verifier has access to and three statement elements $x, y, z \in \mathbb{F}_p$ that the prover has access to. The relation that the verifier wants to check is the disjunction "either $Ax = z$ or $By = z$".

$$R = \{((x,y,z),(A,B)) | A \cdot y = z \vee B \cdot x = z\}$$

The SNARK operations work as follows:

- The trusted third party's produces the SRS production by sampling two toxic waste sample elements which we denote $\alpha, \beta \leftarrow \mathbb{F}_p$, it then outputs the group elements $\alpha_1 = g_1^{\alpha}, \beta_1 = g_1^{\beta}$ in group G_1 and $\alpha_2 = g_2^{\alpha}, \beta_2 = g_2^{\beta}$ in group G_2.
- The prover outputs a single proof element, in the first group, $\pi = \alpha_1^A \beta_1^B = g_1^{A\alpha + B\beta}$.
- The verifier constructs the group 2 element $\alpha_1^x \beta_1^y = g_1^{x\alpha + y\beta}$ and computes the pairing with π to get

$$e(\pi, \alpha_1^x \beta_1^y) = g_T^{(A\alpha + B\beta)(x\alpha + y\beta)}$$

[1] For completeness, we also provide this SNARK formalized in our repository.

It also computes another pairing using z and the SRS elements:

$$e(\alpha_1^z, \beta_2) = g_T^{z\alpha\beta}.$$

As its only check, the verifier determines if these pairings are equal.

- Finally, to prove the soundness, we construct an extractor which obtains values for the witness elements A, B by assuming that they are exactly the coefficients to α and β used to construct π in the AGM, as they are supposed to be.

3.2 The Steps of the Proof

We now describe the proof of soundness step-by-step. Accompanying this explanation is Table 1, which depicts the sequence of operations in tabular form.

3.2.1 Introducing the equality check equations

Taking stock, our formalization of the soundness requires us to prove that the witness elements given by the extractor, if they lead to a satisfactory proof, are themselves satisfactory of the relation.

The first step in the proof is to unfold this definition: A Lean proof environment consists of a number of hypotheses and a goal that the user must prove from those hypotheses. To make sure we have the equations corresponding to the verifier checks among our hypotheses, we can use the Lean `intro` tactic. For our toy SNARK, this gives us the equation corresponding to our single verifier check:

$$(\tilde{A}\alpha + \tilde{B}\beta)(x\alpha + y\beta) = z\alpha\beta$$

Or, in Lean notation,

$$(\texttt{extA} * \texttt{X}\ \alpha + \texttt{extB} * \texttt{X}\ \beta) * (x * \texttt{X}\ \alpha + y * \texttt{X}\ \beta) = z * \texttt{X}\ \alpha * \texttt{X}\ \beta.$$

Note the `X`s applied to α, β. These indicate that, rather than being instances of the sample type of which α, β are members, the multiplicands here are the multivariate polynomials in α, β over F (`MvPolynomial.X` is a `mathlib` function which takes a variable and returns the `MvPolynomial` corresponding to that variable).

3.2.2 Normalizing polynomial equations

The first nontrivial step is to normalize our equation expression by distributing multiplications over additions, to get

$$\begin{aligned}\texttt{extA} * x * \texttt{X}\ \alpha^2 + \texttt{extA} * y * \texttt{X}\ \alpha * \texttt{X}\ \beta + \texttt{extB} * x * \texttt{X}\ \alpha * \texttt{X}\ \beta \\ + \texttt{extB} * y * \texttt{X}\ \beta^2 = z * \texttt{X}\ \alpha * \texttt{X}\ \beta\end{aligned}$$

This can be accomplished using Lean's simplifier: Lean has a built-in tactic called `simp` which takes in a list of lemmas which have the form of a equivalence and recursively applies them to selected hypotheses or goals until it no longer can. So for example, we could call `simp [mul_add]`, which invokes the simplifier with the `mul_add` lemma which asserts that $a(b+c) = ab + ac$ for a, b, c in a ring. Calling `simp` with this and the symmetrical `add_mul` fully distributes multiplication over addition wherever this can be done.

3.2.3 Isolating coefficients

We now take advantage of the form of this equation as a multivariable polynomial over α and β. Two multivariable polynomials are equal only if each corresponding coefficient is equal. If we apply this principle to each of the three nonzero coefficients on the left hand side $\alpha^2, \alpha\beta$, and β^2, we get the three equations:

$$\begin{aligned}&\texttt{coeff}(\alpha \mapsto 2, \beta \mapsto 0)(\texttt{extA} * x * \texttt{X}\ \alpha^2 + \texttt{extA} * y * \texttt{X}\ \alpha * \texttt{X}\ \beta \\ &\qquad + \texttt{extB} * x * \texttt{X}\ \alpha * \texttt{X}\ \beta + \texttt{extB} * y * \texttt{X}\ \beta^2) \\ &= \texttt{coeff}(\alpha \mapsto 2, \beta \mapsto 0)(z * \texttt{X}\ \alpha * \texttt{X}\ \beta)\end{aligned}$$

$$\begin{aligned}&\texttt{coeff}(\alpha \mapsto 1, \beta \mapsto 1)(\texttt{extA} * x * \texttt{X}\ \alpha^2 + \texttt{extA} * y * \texttt{X}\ \alpha * \texttt{X}\ \beta \\ &\qquad + \texttt{extB} * x * \texttt{X}\ \alpha * \texttt{X}\ \beta + \texttt{extB} * y * \texttt{X}\ \beta^2) \\ &= \texttt{coeff}(\alpha \mapsto 1, \beta \mapsto 1)(z * \texttt{X}\ \alpha * \texttt{X}\ \beta)\end{aligned}$$

$$\begin{aligned}&\texttt{coeff}(\alpha \mapsto 0, \beta \mapsto 2)(\texttt{extA} * x * \texttt{X}\ \alpha^2 + \texttt{extA} * y * \texttt{X}\ \alpha * \texttt{X}\ \beta \\ &\qquad + \texttt{extB} * x * \texttt{X}\ \alpha * \texttt{X}\ \beta + \texttt{extB} * y * \texttt{X}\ \beta^2) \\ &= \texttt{coeff}(\alpha \mapsto 0, \beta \mapsto 2)(z * \texttt{X}\ \alpha * \texttt{X}\ \beta)\end{aligned}$$

Here, `coeff` (more specifically `MvPolynomial.coeff` from `mathlib`) is a function which takes a finitely supported natural-valued function on the space of coefficients of a multivariate polynomial and returns the coefficient of the monomial in that polynomial for which the exponents to variables correspond to the values of the function. Thus, for the function which maps α to 2 and β to 0, (denoted above as $(\alpha \mapsto 2, \beta \mapsto 0)$), it returns the α^2 coefficient of the polynomial.

This can be carried out in Lean by use of the `congr_arg` lemma, a generic lemma that states that given a function f, $x_1 = x_1$ implies $fx_1 = fx_2$.

3.2.4 Distribute coefficient-taking

We now can carry out another simplification step, which invokes the `coeff_add` lemma. This lemma states that a coefficient of an addition of polynomials is the addition of the coefficients. By applying this lemma, we can transform the

Stage	Description	Tactics invoked	Hypotheses in Proof State
Stage 0	Initial state		`(Aα+Bβ) (xα+yβ) =zαβ`
Stage 1a	Polynomial put in normal form	`simp [...] at eqn`	`Axα²+(Ay+Bx)αβ+Byβ² =zαβ`
Stage 1b	Coefficients are isolated	`h := congr_arg (coeff (...)) eqn`	`coeff αβ (Axα²+(Ay+Bx)αβ+Byβ²` `= coeff αβ zαβ` `...`
Stage 1c	Distribute coefficient-taking	`simp [...] at h`	`coeff αβ Axα²` `+ coeff αβ Ay+Bxαβ` `+ coeff αβ Byβ²` `= coeff αβ zαβ` `...`
Stage 1d	Expression broken down into term-by-term coefficient comparisons	`simp [...] at h`	`(if αβ = α² then Ax else 0)` `+ (if αβ = αβ` `then Ay+Bx else 0)` `+ (if αβ = β² then By else 0)` `= if αβ = αβ then z else 0` `...`
Stage 1e	Coefficient comparisons decided, leaving proof state of polynomial equations in the prover coefficients	`simp [...] at h`	`Ax = 0` `Ay + Bx = z` `By = 0`
Stage 2a	Polynomials are simplified algebraically	`integral_domain_tactic`	`A = 0` or `x = 0` `Ay + Bx = z` `B = 0` or `y = 0`
Stage 2b	Proof state consists of simple equations of prover coefficients	`integral_domain_tactic` or `polyrith`	`Bx = z` `or` `Ay = z`

Table 1: Describing the stages of a proof. The left row gives an example for a toy (incomplete) SNARK illustrating the type of the hypotheses at each stage, with trapdoor elements in blue and prover coefficients in red.

hypotheses to consist of additions of coefficient evaluations solely of monomial terms.

$$\begin{aligned}&\texttt{coeff}(\alpha\mapsto 2,\beta\mapsto 0)(\texttt{extA}*x*\texttt{X}\ \alpha^2)\\&+\texttt{coeff}(\alpha\mapsto 2,\beta\mapsto 0)(\texttt{extA}*y*\texttt{X}\ \alpha*\texttt{X}\ \beta)\\&+\texttt{coeff}(\alpha\mapsto 2,\beta\mapsto 0)(\texttt{extB}*x*\texttt{X}\ \alpha*\texttt{X}\ \beta)\\&+\texttt{coeff}(\alpha\mapsto 2,\beta\mapsto 0)(\texttt{extB}*y*\texttt{X}\ \beta^2)\\&=\texttt{coeff}(\alpha\mapsto 2,\beta\mapsto 0)(z*\texttt{X}\ \alpha*\texttt{X}\ \beta)\end{aligned}$$

$$\begin{aligned}&\texttt{coeff}(\alpha\mapsto 1,\beta\mapsto 1)(\texttt{extA}*x*\texttt{X}\ \alpha^2)\\&+\texttt{coeff}(\alpha\mapsto 1,\beta\mapsto 1)(\texttt{extA}*y*\texttt{X}\ \alpha*\texttt{X}\ \beta)\\&+\texttt{coeff}(\alpha\mapsto 1,\beta\mapsto 1)(\texttt{extB}*x*\texttt{X}\ \alpha*\texttt{X}\ \beta)\\&+\texttt{coeff}(\alpha\mapsto 1,\beta\mapsto 1)(\texttt{extB}*y*\texttt{X}\ \beta^2)\\&=\texttt{coeff}(\alpha\mapsto 1,\beta\mapsto 1)(z*\texttt{X}\ \alpha*\texttt{X}\ \beta)\end{aligned}$$

$$\begin{aligned}&\texttt{coeff}(\alpha\mapsto 0,\beta\mapsto 2)(\texttt{extA}*x*\texttt{X}\ \alpha^2)\\&+\texttt{coeff}(\alpha\mapsto 0,\beta\mapsto 2)(\texttt{extA}*y*\texttt{X}\ \alpha*\texttt{X}\ \beta)\\&+\texttt{coeff}(\alpha\mapsto 0,\beta\mapsto 2)(\texttt{extB}*x*\texttt{X}\ \alpha*\texttt{X}\ \beta)\\&+\texttt{coeff}(\alpha\mapsto 0,\beta\mapsto 2)(\texttt{extB}*y*\texttt{X}\ \beta^2)\\&=\texttt{coeff}(\alpha\mapsto 0,\beta\mapsto 2)(z*\texttt{X}\ \alpha*\texttt{X}\ \beta)\end{aligned}$$

3.2.5 Break down into monomial equality conditionals

We can now simplify further: The `X` function is defined as an application of `mathlib`'s `MvPolynomial.monomial` function, which constructs a monomial out of coefficient terms and uses a finitely supported function to represent the exponents of the variables. We can use the lemma `monomial_mul` to collapse the multiplications into single applications of `MvPolynomial.monomial` and the `coeff_monomial` lemma, which asserts that `coeff` applied to `monomial` yields either

the coefficient argument of `monomial` when the function arguments match, or 0 when they do not. We can then apply *function extensionality*, which asserts that functions are equal if they are equal on all of their arguments. Because there are only a finite number of possible arguments to the functions we are comparing, we can convert the comparison of the functions into a conjunction over comparisons of their evaluations. We get:

$$\begin{aligned}
&\texttt{if } (2=2\wedge 0=0) \texttt{ then } (\texttt{extA}*x) \texttt{ else } 0\\
&\quad + \texttt{ if } (2=1\wedge 0=1) \texttt{ then } (\texttt{extA}*y) \texttt{ else } 0\\
&\quad + \texttt{ if } (2=1\wedge 0=1) \texttt{ then } (\texttt{extB}*x) \texttt{ else } 0\\
&\quad + \texttt{ if } (2=0\wedge 0=2) \texttt{ then } (\texttt{extB}*y) \texttt{ else } 0\\
&\quad = \texttt{ if } (2=1\wedge 0=1) \texttt{ then } (z) \texttt{ else } 0
\end{aligned}$$

$$\begin{aligned}
&\texttt{if } (1=2\wedge 1=0) \texttt{ then } (\texttt{extA}*x) \texttt{ else } 0\\
&\quad + \texttt{ if } (1=1\wedge 1=1) \texttt{ then } (\texttt{extA}*y) \texttt{ else } 0\\
&\quad + \texttt{ if } (1=1\wedge 1=1) \texttt{ then } (\texttt{extB}*x) \texttt{ else } 0\\
&\quad + \texttt{ if } (1=0\wedge 1=2) \texttt{ then } (\texttt{extB}*y) \texttt{ else } 0\\
&\quad = \texttt{ if } (1=1\wedge 1=1) \texttt{ then } (z) \texttt{ else } 0
\end{aligned}$$

$$\begin{aligned}
&\texttt{if } (0=2\wedge 2=0) \texttt{ then } (\texttt{extA}*x) \texttt{ else } 0\\
&\quad + \texttt{ if } (0=1\wedge 2=1) \texttt{ then } (\texttt{extA}*y) \texttt{ else } 0\\
&\quad + \texttt{ if } (0=1\wedge 2=1) \texttt{ then } (\texttt{extB}*x) \texttt{ else } 0\\
&\quad + \texttt{ if } (0=0\wedge 2=2) \texttt{ then } (\texttt{extB}*y) \texttt{ else } 0\\
&\quad = \texttt{ if } (0=1\wedge 2=1) \texttt{ then } (z) \texttt{ else } 0
\end{aligned}$$

Here `if ... then ... else ...` is Lean syntax for the function that takes a proposition as its first argument and, according to its truth value, returns either the second or third argument.

3.2.6 Decide monomial equality conditionals

Finally, we leverage the fact that these equalities can be decided to reduce these equations.

$$\begin{aligned}
(\texttt{extA}*x) &= 0\\
(\texttt{extA}*y)+(\texttt{extB}*x) &= z\\
(\texttt{extB}*y) &= 0
\end{aligned}$$

We are left with a simple collection of equations over the base field.

3.2.7 Recursively factor and simplify

The convenience of having our hypotheses in the form of equations over `F` is that our goal is a formula over equations of values having type `F`. All that remains, then, is to use equational reasoning prove our hypotheses imply this goal.

Because the SNARK equations arise through pairings, our hypotheses are all quadratic in the atoms. In fact, many of the equations are of the form `A * B = 0` for atoms `A` and `B`. This is by design, as it is necessary for the proofs to leverage the fact that the product of two values equating to zero implies at least one of the multiplicands is zero. This leads us to formulate the following approach to simplifying the goal: We use the fact (inferred by Lean's typeclass system) that a polynomial ring over a field is an integral domain, and we simplify all equations of the form `A * B = 0` to `A = 0 or B = 0`.

$$\begin{aligned}
\texttt{extA} = 0 \vee x = 0\\
(\texttt{extA}*y)+(\texttt{extB}*x) = z\\
\texttt{extB} = 0 \vee y = 0
\end{aligned}$$

We can then split these hypotheses into two cases and prove the goal for each case, simplifying our hypotheses by rewriting `A` or `B` to 0, and carry on this process until we are left with a collection of goals that cannot be simplified through these rules. This finishes the soundness proof for the toy SNARK, since whichever disjunction we case over, we will eliminate a term from the second equation and be left with an equation which satisfies the goal relation.

To facilitate this, we wrote a tactic `integral_domain_tactic`, which carries out the above simplifications and calls itself recursively until it reaches a point where it can make no more progress. We can then either solve these goals by hand, or by dispatching them with the built-in `mathlib` tactic `polyrith`, which solves problems of this type.

The core of this recursive operation is only around 13 lines of Lean code, as seen in Figure 4 :

4 "Straightforwardness" for SNARKs from the literature

The development outlined in the preceding sections covers a broad design space for the construction of linear PCP SNARKs instantiations. In our experience, though, there are deep-cutting regularities in the way that SNARK schemes in the literature construct these instantiations for particular problem instances. We call SNARK schemes that display these regularities *straightforward*: We now discuss the requisite properties be straightforward and how they allow us to automate the soundness proving process.

One High-Degree Variable One property of the SNARKs we consider is that all only have one toxic waste element that appears to a non-bounded degree in the SRS elements.

```
syntax "integral_domain_tactic" : tactic

macro_rules
| `(tactic| integral_domain_tactic) =>
 `(tactic|
   -- Simplify
   simp_all
    (config := {decide := false, failIfUnchanged :=
     false})
    only [false_or, or_false, true_or, or_true, not_true,
     not_false_iff, add_zero, zero_add, mul_zero,
     zero_mul, mul_one, one_mul, neg_zero, neg_eq_zero,
     add_eq_zero_iff_eq_neg, eq_self_iff_true, Ne.def,
     eq_zero_of_zero_eq, one_ne_zero, mul_ne_zero_iff,
     zero_sub_eq_iff, mul_eq_zero];
   first
    -- If we are done, halt
    | done
    -- If possible, split and recurse
    | cases_or _ ∨ _
     all_goals integral_domain_tactic
    | skip
 )
```

Figure 4: Recursive simplification tactic for systems of equations in an integral domain.

For an example to demonstrate this, consider the Pinocchio protocol. We show the sample elements and SRS elements for Pinocchio in Equation 1. Note how the only variable that appears to a degree greater than 1 is s – all other variables appear only to degree 1 or not at all in each of the SRS elements.

This feature informs how we represent the type of sample elements in our formalization. Since there is just a single element which has this special feature of being raised to large powers in the SRS element, we represent the type of elements as an `Option` type over an inductive type `Vars`, where the unbounded element is represented by the `none` value, and `some` gives values for the bound elements.

```
inductive Vars : Type where
 | r_v : Vars
 | r_w : Vars
 | α_v : Vars
 | α_w : Vars
 | α_y : Vars
 | β : Vars
 | γ : Vars
deriving Repr, BEq

local notation "poly_s" => X (none)
local notation "poly_r_v" => X (some Vars.r_v)
...
```

Figure 5: Pinocchio's sample element type, as it appears in our formalization. We use the `local notation` feature to work with these variables as `MvPolynomials`

The convenience of this is that it allows is to invoke `mathlib`'s `optionEquivRight` just before the "Isolating coefficients" step described in Section 3.2.3. The `optionEquivRight` object is an isomorphism between the type of multivariate polynomials in this option type `MvPolynomial (Option Vars) F` and the type of multivariable polynomials *over single-variable polynomials in* F `MvPolynomial Vars (Polynomial F)`. Rewriting using this equivalence allows us to "hide" the unbound variable polynomials within the `Polynomial F` type, so that we only have to deal with `MvPolynomials` with a bounded total degree. This is important for the coefficient-taking step to go smoothly, since our proof can only extract a fixed number of these coefficients.

Extractor is a projection Another key commonality displayed by all the SNARK schemes in the literature is that the extractor used to prove soundness is extremely simple. In fact, for the six SNARKs we consider, it is always a projection function: Each witness component that the extractor outputs corresponds to exactly one coefficient of one of the components of the proof-message.

The convenience of this is that a projection function is always linear, and can therefore be interpreted as a polynomial function in the prover coefficients which make up its inputs. This means that, when we reach the stage of our proof described in Section 3.2.7 where our hypotheses have been reduced to equations in the prover coefficients over a field, the goal will itself be of the same form as these hypotheses - an equation over the field, where the equated expressions consist solely of additions and multiplications on the prover coefficients and statement and witness values.

This is an important observation. If we subtract off the right hand side of each of these equations, we are left to prove that when the polynomials that remain in the hypotheses are zero, the polynomial in the goal is also zero. This is known as the *ideal membership testing problem*, and has been well-studied for decades – it is known to be decidable by a class of algorithms known as Gröbner basis methods [21], which `polyrith` implements. This is a strong hint that we have the right approach - because of this regularity, we are consistently able to reduce our soundness proofs to problems of this decidable form.

SRS Components regular and fixed over circuits One issue is that Gröbner basis algorithms are superexponential the size of the circuit [32,52]. This frustrates the goal of verifying soundness because many circuits verified by SNARKs are themselves cryptographic in nature, and therefore too large to be handled by brute force.

However, a second regularity in the SNARK systems in the literature allows us to get around this. While a particular SNARK instantiation may have arbitrarily many SRS variables, a particular *scheme* like Pinocchio or Groth '16 consistently organizes these variables into a fixed number

of components. Each component always has either a single element, or is a collection of elements for which the prover or verifier computes an inner product with the statement or part of the witness to produce either a proof or paring input. When there is a collection with multiple elements, the expression of the elements is always uniform - all elements of the component are obtained by a multiplication of some polynomial in the degree-unbound variable with a fixed polynomial in the bound-degree variables.

We leverage these components by abstracting over them to get a soundness proof that works for all circuit instances at once. The uniformity of the SRS collections is important - when we factor out constants from these sums, we are left with sums over free variables. Due to the linearity of the adversary in the AGM, it will be the case that whenever one of these elements appears in the proof, it is always as part of a sum indexed over all members of the collection. Because we have no constraints over the instance-specific polynomials, once we factor out constant-degree factors, these formal sums can be treated as atoms by the soundness proof.

Abstracting over SNARK schemes in this way, the size of the ideal membership testing problem instances we encounter will depend only on the SNARK scheme. Gröbner basis methods therefore now have a chance of working, since the instance sizes will be smaller and will not implicitly encode cryptographically-hard problems.

Straightforwardness and General SNARK Decidability The observations made in this section can be crystallized into a *straightforwardness* predicate on linear SNARK schemes which captures all of the properties we need in order for us to be able to carry out our proof process. We find that an informative theorem can be demonstrated about SNARK schemes of this kind:

Theorem 1. *Let $\mathcal{E}$ be the set of all cryptographically secure elliptic curve pairings (G_1, G_2, G_3, e), and let ι be the set of all circuit instances accepted by the scheme. Let $\mathcal{S} : \mathcal{E} \times \iota \to \Pi$ be a straightforward linear PCP SNARK scheme for relation $\mathcal{R}$ which returns an instantiated SNARK protocol Π, given a pairing and instance. Then the proposition*

$$\forall E \in \mathcal{E}, \forall i \in \iota, \forall \pi \in \mathcal{A}_{\mathsf{AGM}}, \forall s$$

$$\mathcal{S}_{E,i}.\mathsf{Verify}(s, \pi) \implies (s, \mathcal{S}_{E,i}.\mathsf{Extractor}(\pi)) \in \mathcal{R}$$

is decidable.

A proof of this fact roughly follows from the procedural outline given in the above parts of this section. On the level of individual SNARK instantiations with fixed fields, Theorem 1 does not tell us much. If we were to fix the field and circuit instance, there is a brute-force soundness deciding procedure for the resulting linear PCP SNARK: Since every algorithm in play takes an input consisting of a finite number of group or field elements, one can explicitly enumerate the possible inputs at each step and determine exactly how often each potential adversarial prover tricks the verifier.

But this naive decision procedure has the downsides of having exponential running time in both the size of the field and the size of the instance, as well as only ultimately deciding soundness for a single instantiation. Our procedure, on the other hand, works over a scheme as a whole, rather than particular instantiations of one. Thus, the running time depends only on the description of the scheme, and while this running time is still technically super-exponential due to the Gröbner basis procedure, our results show that it terminates in a reasonable amount of time in practice.

5 Design of SNARKs and their proofs

In this section, we discuss some of the SNARKs as they appear in the original references on which our formalizations were based. The process of creating these formalizations was not always smooth, in part because there are a few places in which the arguments presented in the papers are misleading. In the interest of a better understanding of these proofs by the community as a whole, we will explain why we found these proofs confusing, and the impact it had on our proof efforts.

5.1 Pinocchio

First, we discuss Pinocchio. We present the protocol itself in Equation 1 – we match the notation and description from Protocol 2 of [59], but with some of the intermediate definitions made explicit, and the fact that all values are powers of the generator g made implicit.

Pinocchio represents its circuit in terms of various polynomials v_k, w_k, y_k, with k ranging over various index sets: The I_{mid} associated with the prover's knowledge of the witness for the circuit being evaluated and $0 \cup [N]$ associated with the statement the verifier is checking relationship membership for. The $V_{mid}, W_{mid}, Y_{mid}$ proof elements are meant to represent sums over these polynomials with the witness elements as coefficients - so that the extractor can eventually extract them. Pinocchio structures itself so that these polynomials are mostly kept separate from each other except when necessary, with three of the verifier checks being dedicated to validating these three proof elements related to a single group of these polynomials. It is ensured that none of the prover coefficients for $V_{mid}, W_{mid}, Y_{mid}$ can be manipulated to influence these checks by introducing the $\alpha_v, \alpha_w, \alpha_y$ sample elements and the $V'_{mid}, W'_{mid}, Y'_{mid}$ proof elements. These three samples and proof elements appear only in the validation checks corresponding to the v, w, and y polynomials respectively, and they effectively isolate these equations from a malicious prover introducing coefficients to $V_{mid}, W_{mid}, Y_{mid}$ proof elements that should not be there. As the paper puts it, they are to "Check that the linear combinations of $\mathcal{V}$, $\mathcal{W}$, and $\mathcal{Y}$ are in their appropriate spans". Something similar happens

with the Z proof element – Z is intended to be computed as a sum of polynomials from all three sets, so γ is introduced in the corresponding check to ensure only these coefficients can be used in that check. The final check then proves that, when the verifier adds their own statement-related terms to the V, W, and Y polynomial sums, the Y polynomials can be subtracted from the product of the V and W polynomials to get a resulting polynomial which has zeros at a number of critical points corresponding to "gates" from the circuit, so that each zero's presence proves that the corresponding gate was computed correctly. The presence of the zeros are proved by equating the subtraction on the right-hand side of the last check to a pairing on the left-hand side which takes the product of a polynomial t which has the same zeros with an additional h polynomial (which the prover can choose to make the equation work out).

$$
\begin{aligned}
&\texttt{Pinocchio.Sample} := r_v, r_w, s, \alpha_v, \alpha_w, \alpha_y, \beta, \gamma \leftarrow \mathbb{F}_p \\
&\texttt{Pinocchio.SRS} := \\
&\{r_v v_k(s)\}_{k\in I_{mid}}, \{r_w w_k(s)\}_{k\in I_{mid}}, \{r_v r_w y_k(s)\}_{k\in I_{mid}} \\
&\{r_v \alpha_v v_k(s)\}_{k\in I_{mid}}, \{r_w \alpha_w w_k(s)\}_{k\in I_{mid}}, \{r_v r_w \alpha_y y_k(s)\}_{k\in I_{mid}} \\
&\{r_v \alpha_v v_k(s)\}_{i\in[d]}, \{r_v \beta v_k(s) + r_w \beta w_k(s) + r_v r_w \beta y_k(s)\}_{k\in I_{mid}} \\
&g, \alpha_v, \alpha_y, \alpha_w, \gamma, \beta\gamma, r_v r_w t(s), \\
&\{r_v v_k(s)\}_{k\in 0\cup[N]}, \{r_w w_k(s)\}_{k\in 0\cup[N]}, \{r_v r_w y_k(s)\}_{k\in 0\cup[N]} \\
&\texttt{Pinocchio.ProofElements} := \\
&V_{mid} := r_v \sum_{k\in I_{mid}} c_k v_k(x), V'_{mid} := r_v \alpha_v \sum_{k\in I_{mid}} c_k v_k(x) \\
&W_{mid} := r_w \sum_{k\in I_{mid}} c_k w_k(x), W'_{mid} := r_w \alpha_w \sum_{k\in I_{mid}} c_k w_k(x) \\
&Y_{mid} := r_v r_w \sum_{k\in I_{mid}} c_k y_k(x), Y'_{mid} := r_v r_w \alpha_y \sum_{k\in I_{mid}} c_k y_k(x) \\
&H = h(x), Z = \beta \sum_{k\in I_{mid}} r_v c_k v_k(x) + r_w c_k w_k(x) + r_v r_w c_k y_k(x) \\
&\texttt{Pinocchio.Checks} := \\
&e(V'_{mid}, 1) = e(V_{mid}, \alpha_v), \\
&e(W'_{mid}, 1) = e(W_{mid}, \alpha_w), \\
&e(Y'_{mid}, 1) = e(Y_{mid}, \alpha_y), \\
&e(Z, \gamma) = e\left(V_{mid} + W_{mid} + Y_{mid}, \beta\gamma\right) \\
&e\left(\sum_{k\in\{0\}\cup[N]} r_v c_k v_k(s) + V_{mid}, \sum_{k\in\{0\}\cup[N]} r_w c_k w_k(s) + W_{mid}\right) \\
&- e\left(\sum_{k\in\{0\}\cup[N]} r_v r_w c_k y_k(s) + Y_{mid}, 1\right) = e(r_v r_w t(s), H),
\end{aligned}
\tag{1}
$$

In our formalization we surprisingly had the most trouble with the first three checks. The "appropriate spans" in the paper are identified as "the $v_k(x)$'s, $w_k(x)$'s, and $y_k(x)$'s, respectively". Somewhat confusing is whether this is meant to be just the k indices in the witness or in the statement too - if the witness and statement polynomials are not linearly independent, then an AGM adversary can add these linear combinations to their proof coefficients, leading to a verifying set of coefficients for which the coefficients of the witness polynomials in $\mathcal{V}$, $\mathcal{W}$, and $\mathcal{Y}$ do not match the witness itself. This does not actually change the proof elements, but it makes them trickier to reason about formally in the model.

A more glaring issue is that these checks *by themselves* do not guarantee that the proof elements will be in the span of the statement and witness polynomials combined: It is technically possible for a prover to construct proof elements with nonzero coefficients for verifier key elements, and for which these checks pass. Specifically, after constructing a key honestly, the prover can multiply $g_v^{V_{mid}}$ and $g_v^{V'_{mid}}$ by g^1 and g_v^{α} respectively, and similarly with W_{mid} and Y_{mid}. We noticed this by way of our attempt to construct a proof that the only nonzero coefficients for $\mathcal{V}$ are in this set, finding that even after simplifying using the equalities generated by this check, there were still terms that we could not eliminate.

The fifth check turns out to be enough to complete the guarantee: It primarily shows "that the same coefficients were used in each of the linear combinations over $\mathcal{V}$, $\mathcal{W}$ and $\mathcal{Y}$", but it also precludes the construction of proof terms which fall outside the span. This caused us to change our original plan for the proof: Rather than prove $\mathcal{V}$ was exactly equal to $g^{V_{mid}}$, we left the g^1 terms (as well as the statement polynomial terms) in our simplifications of $\mathcal{V}$, $\mathcal{W}$ and $\mathcal{Y}$, then proved that when one plugs these into the fifth check, the extra terms can be ignored and the coefficients of the $g_v^{\beta v_k(s)} g_w^{\beta w_k(s)} g_y^{\beta y_k(s)}$ terms in Z are equal to the supposed coefficients of $\mathcal{V}$, $\mathcal{W}$ and $\mathcal{Y}$, so that *these* coefficients can act as the extracted witness.

5.2 Groth '16

Consider Groth '16, described in Equation 2 (following the notation from Section 3 of [43]). Groth '16 came after Pinocchio chronologically and made several refinements – its proof is more compact, and it requires only four pairing computations and a single verifier check, making it much quicker to verify.

The one Groth '16 check has to do the work of all the checks from Pinocchio, so the proof is more complicated, but some features are roughly analogous. The A, B and C proof elements essentially correspond to the roles of V, W and Y elements from Pinocchio (note that v, w, y from Pinocchio have been renamed to u, v, w here). The main conceptual difference is that the Z and H proof elements have been folded into C, and some additional terms have been moved around or added. Another small difference is the presence of r and s terms – r and s are random values meant to keep the prover from leaking information.

$$\texttt{Groth16.Sample} := x, \alpha, \beta, \gamma, \delta \leftarrow \mathbb{F}_p$$

$$\texttt{Groth16.SRS} :=$$

$$\alpha, \beta, \gamma, \delta, (x^i)_{i=0}^{n-1}, \left(\frac{\beta u_i(x) + \alpha v_i(x) + w_i(x)}{\gamma}\right)_{i=0}^{l}$$
$$\left(\frac{\beta u_i(x) + \alpha v_i(x) + w_i(x)}{\delta}\right)_{i=l+1}^{m}, \left(\frac{x^i t(x)}{\delta}\right)_{i=0}^{n-2}$$

$$\texttt{Groth16.ProofElements} :=$$

$$A := \alpha + \sum_{i=0}^{m} a_i u_i(x) + r\delta, B := \beta + \sum_{i=0}^{m} b_i v_i(x) + r\delta, \tag{2}$$
$$C := \frac{\sum_{i=0}^{m} a_i(\beta u_i(x) + \alpha v_i(x) + w_i(x)) + h(x)t(x)}{\delta}$$
$$+ As + rB - rs\delta,$$

$$\texttt{Groth16.Checks} :=$$

$$e(A,B) - e(\alpha,\beta)$$
$$= e(C,\delta) + e\left(\frac{\sum_{i=0}^{l} a_i(\beta u_i(x) + \alpha v_i(x) + w_i(x))}{\gamma}, \gamma\right)$$

A first obstacle in formalizing the system as described here is that γ and δ appear in the denominator of some expressions. This means that these are not technically polynomials, but rather Laurent polynomials. This poses a slight problem for the formalization, as `mathlib` does not support multivariable Laurent polynomials.

Luckily, we can sidestep this issue by multiplying through all the SRS elements by $\gamma\delta$. This transformation doesn't impact the functioning or the soundness of the SNARK – we create a formal version of a theorem to this effect in our codebase. After we have done the SRS multiplication transformation, we get the new SRS:

$$\texttt{Groth16.SRS}' :=$$

$$\alpha\gamma\delta, \beta\gamma\delta, \gamma^2\delta, \gamma\delta^2, \{x^i\gamma\delta\}_{i=0}^{n-1}, ((\beta u_i(x) + \alpha v_i(x) + w_i(x))\delta)_{i=0}^{l}$$
$$\{(\beta u_i(x) + \alpha v_i(x) + w_i(x))\gamma\}_{i=l+1}^{m}\}, \{x^i t(x)\gamma\}_{i=0}^{n-2} \tag{3}$$

In the written proof of soundness of Groth16, similar to Pinocchio, it is tricky to parse which equalities of terms in the check polynomial guarantee which relationships between coefficients of the SRS elements. The soundness proof given by Theorem 1 of [43] proceeds by first analyzing the $\alpha^2, \alpha\beta$, and β^2 coefficients of the polynomial, which allows one to simplify this polynomial, zeroing out a few of the terms without loss of generality. We are then shown that the terms involving $1/\delta^2$ give us:[2]

$$\sum_{i=l+1}^{m} A_i(\beta u_i(x) + \alpha v_i(x) + w_i(x)) + t(x)A_h(x) = 0$$

[2]Incidentally, there is a typo in the Groth 16 paper here – A_t is written instead of A_h.

We then get the confusing claim that "the terms in" $\alpha\frac{\sum_{i=l+1}^{m} B_i(\beta u_i(x)+\alpha v_i(x)+w_i(x))+B_h(x)t(x)}{\delta} = 0$ show us:

$$\sum_{i=l+1}^{m} B_i(\beta u_i(x) + \alpha v_i(x) + w_i(x)) + B_h(x)t(x) = 0 \tag{4}$$

What is meant by "the terms in" this expression? It seems the paper is saying that the coefficients corresponding to the monomials α^2/δ, $\alpha\beta/\delta$ and α/δ (the only monomials that appear in this expression) imply Equation 4. It is indeed the case that α^2/δ gives us $\sum_{i=l+1}^{m} B_i v_i(x) = 0$, and $\alpha\beta/\delta$ gives us $\sum_{i=l+1}^{m} B_i u_i(x) = 0$, and these reduce the term to

$$\sum_{i=l+1}^{m} B_i w_i(x) + t(x)B_h(x).$$

But notice that the coefficient of α/δ actually includes a term of the form $A(x)\sum_{i=l+1}^{m} B_i\frac{\alpha v_i(x)}{\delta}$, so summing these three coefficients does not give us that this term is zero, it gives us that the term is equal to $-A(x)\sum_{i=l+1}^{m} B_i\frac{\alpha v_i(x)}{\delta}$. Is this expression itself provably equal to 0? Yes, but the justification is not obvious. One finds that the terms with coefficient $1/\delta$ give $\left(\sum_{i=l+1}^{m} B_i w_i(x) + t(x)B_h(x)\right)A(x) = 0$, and after doing casework on whether or not $A(x) = 0$, one sees that either way, the full Equation 4 can indeed be reduced to 0, saving the theorem. Similar reasoning appears immediately after this with "The terms in $\alpha\frac{\sum_{i=l+1}^{m} B_i(\beta u_i(x)+\alpha v_i(x)+w_i(x))+B_h(t)}{\gamma} = 0$", but this can be fixed in the same way.

Helpful in resolving this confusion was Baghery et al. [6] Theorem 2, which carefully lists the equations from each coefficient, and explicitly clarifies that the proof uses cases on $A(x) = 0$. They do this for a version of the Groth '16 SNARK intended for use with type-III pairing friendly curves, but the proof carries over to the non-type-III case.

6 Evaluation of the Proof code

The initial development of the proofs for the six SNARKs was done in Lean 3 over the course of several months from 2021 through mid-2022. Our first proofs were relatively unsystematic, as we had not identified many of the commonalities from Sections 3 and 4. During 2023, the Lean community deprecated Lean 3 and ported `mathlib` to Lean 4. We ported our code as well, and took the opportunity to make our codebase more uniform by defining the `AGMProofSystemInstantiation` structure and recasting our SNARK definitions in terms of it. While this has codified the SNARK security definitions more strongly, it has made the translation effort more difficult – Our approach to the soundness proofs in Lean 3 was more organic, and used intermediate lemmas to shortcut some parts of the proof or to prepare the proof state before using the heavier tactics to make them run more smoothly. Our more automated approach

Name	Samples	Proof elements	SRS Components	Checks	Check Time	Check Time (Lean 4)
GGPR [42]	5	7 (6)	19	5 (4)	140.61 s	-
Pinocchio [59]	8	8	21	5	342.89s	-
Groth '16 [43]	5	3	8	1	13741.86s	-
Baghery et al. [6]	5	3	7 and 4	1	552.67s	162.74s
BabySNARK [55]	3	3	4	2	74.98s	-
Lipmaa [47]	2	3	7 and 4 and 1	1	81.82s	144.30s

Table 2: Data on different SNARK variants, including the number of toxic waste samples, number of proof elements, number of SRS components, number of verifier equality checks, and the time to check the soundness proofs in both Lean 3 and Lean 4. Note that GGPR includes in the paper a proof element and a check which are not strictly necessary for the soundness proof - we write the number used in our code in parentheticals.

in Lean 4 makes it harder to identify bugs when they exist. Currently we have only translated two of our six soundness proofs to Lean 4.

Summarizing our code by line count, we have:

- 150 LOC defining `AGMProofSystemInstantiation` and its soundness property.
- Approximately 3000 LOC of code in total defining and proving soundness across the six SNARK schemes.
- 80 LOC for `integral_domain_tactic` and other simplification tactics.
- 212 LOC for definitions and theorems about the transformations of SNARKs, including:
  - A theorem proving that, given a SNARK, it is possible to multiply through each SRS element by an existing (or new) toxic waste sample without affecting the soundness of the SNARK. This theorem justifies our treatment of the Laurent polynomials in Groth '16.
  - A theorem proving that if a toxic waste σ element appears to maximum degree $< n$ in a check polynomial, and τ is another toxic waste element, then it is possible to replace τ with σ^n is the maximum degree, thus reducing the number of toxic waste samples needed. One can view this transformation as one of the conceptual differences between the Lipmaa SNARK [47] relative to the Baghery et al. presentation.
  - A theorem proving that if the coefficient of a particular SRS element in a particular proof element is the same for any satisfying statement-witness pair, then we can treat that component as a constant and remove the dependence of the proof element linear combination on that SRS element. This could potentially be useful in optimizing SNARK circuits after the trusted setup.
- 419 LOC for supporting lemmas about polynomials and other datatypes intended for upstreaming to `mathlib`, as well as 53 LOC modifying existing `mathlib` definitions to make them more general and compatible with our development.

Our code is available on GitHub and is also listed on Reservoir, the Lean 4 package index.[3]

Table 2 shows data about the sizes of various parameters of the various SNARKs and the time it takes Lean to verify the proofs. In each case, the proof time is dominated by the mutual simplification phase, as one might expect, given that this phase requires recursive casework.

7 Future Work and Conclusion

To bring our discussion to a close, we mention a few topics that could make for good future research directions in the area of formal verification of SNARKs:

Integrating polyrith and independent verifiability The bulk of the work of our proof procedure happens in the recursive calls to `integral_domain_tactic`. While this is necessary in practice to reduce the size of the Gröbner basis computation instances passed to `polyrith`, a version of `polyrith` with unlimited proof size could dispatch this goal all on its own. One good direction for future work would be to integrate the `integral_domain_tactic` heuristic into `polyrith` to make this possible. One could then take advantage of other features of `polyrith`: In particular, `polyrith` by default logs to the user a description of the sequence of equational operations one carries out on the hypotheses to reach the conclusion. One could use this to create external tools, potential faster than our own, that check the certificates of SNARK soundness our code produces. One drawback is that this external verifier would then itself be part of the trusted computing base for our proof (working in Lean all proofs are

[3]The latest version of our code can be found at https://github.com/BoltonBailey/formal-snarks-project

checked by the kernel – vetting the proof only requires checking our formalization of the *theorem statement*).

Practical Application To bring the work further into practical relevance, one could use our framework to produce soundness proofs for real-world SNARK implementations, or modify it to provide explicit attacks if they exist. This would involve precisely replicating these implementations with our `AGMProofSystemInstantiation` structure. One could also try to use our system to search for new sound schemes. An obstacle here is performance: Each of our proof scripts takes at least several seconds to run, and since there a multitude of different values the generic `AGMProofSystemInstantiation` can take, it would take an unreasonable amount of time to search through them while simultaneously checking each of them for soundness. It would therefore be necessary to aggressively prune the search space, and perhaps also find algorithmic optimizations to our code.

Larger Cryptographic Frameworks Section 1.3 discusses a number of cryptographic frameworks in other languages [11, 14, 25]. Future work could create such a framework for Lean, which our work could then fit into. This would involve both replicating the work of these other frameworks, as well as ironing out some of the details, (such as the Schwartz-Zippel lemma applications) that we currently elide.

Other kinds of SNARKs Future work in formalizing SNARKs could move outside the linear PCP paradigm to newer SNARKs such as Sonic, PlonK, Marlin [27, 40, 49]. These "Polynomial IOP" SNARKs use the Fiat-Shamir paradigm [35], which involves the random oracle model [15], so a formalization here would have to cover this idea.

Conclusion We have presented our efforts to formalize the Groth '16 SNARK and similar constructions in Lean. Our work includes a variety of programs that help accomplish this task, and we have described a variety of pitfalls associated with this challenge and our strategies for overcoming them. Our work indicates that there is substantial facility to use automated proof techniques in the formalization of cryptography – going forward, we hope that tools with which security researchers can more easily analyze SNARKs continue to develop.

Abstract

The InterPlanetary File System (IPFS) is one of the largest platforms in the growing "Decentralized Web". The increasing popularity of IPFS has attracted large volumes of users and content. Unfortunately, some of this content could be considered "problematic". Content moderation is always hard. With a completely decentralized infrastructure and administration, content moderation in IPFS is even more difficult. In this paper, we examine this challenge. We identify, characterize, and measure the presence of problematic content in IPFS (*e.g.* subject to takedown notices). Our analysis covers 368,762 files. We analyze the complete content moderation process including how these files are flagged, who hosts and retrieves them. We also measure the efficacy of the process. We analyze content submitted to denylist, showing that notable volumes of problematic content are served, and the lack of a centralized approach facilitates its spread. While we identify fast reactions to takedown requests, we also test the resilience of multiple gateways and show that existing means to filter problematic content can be circumvented. We end by proposing improvements to content moderation that result in 227% increase in the detection of phishing content and reduce the average time to filter such content by 43%.

1 Introduction

The Internet Planetary File System (IPFS) is one of the largest platforms in the Decentralized Web, with $\approx 30,000$ [74] online IPFS nodes, spread across 2,700 Autonomous Systems (ASes), and 152 countries [72]. IPFS supports a whole ecosystem of decentralized applications [9], including social networking [5, 10], data storage [15, 60, 64], content search [12, 62], messaging [70], streaming [6, 13, 79], gaming [8, 16], and e-commerce [7, 11]. IPFS is also widely used as external storage for blockchain-based applications such as NFT platforms [30, 38]. Growing support to facilitate IPFS access (*e.g.* Cloudflare's HTTP gateways, and integration by browsers like Opera and Brave) has further propelled IPFS usage.

However, the popularity of IPFS comes with challenges. Most notably, there has been growing media attention surrounding the need for content moderation in IPFS [14, 19, 20]. This is not a new problem, and many large platforms (*e.g.* Facebook) have long struggled with the complexities of moderation, such as the removal of Child Sexual Abuse Material (CSAM). In some ways, moderation in IPFS is easier, because its addressing scheme allows each content object to be uniquely identified agnostic to where it is hosted (unlike URLs, which depend on the hosting domain). In other ways, moderation in IPFS is harder, as there is no single point of control to make and enforce moderation decisions. The legal problems faced by earlier peer-to-peer services, such as BitTorrent [34, 35, 41] and Kazaa [42], highlight the importance of this problem. Consequently, various IPFS stakeholders implemented content moderation methods.

The content moderation activities in the IPFS ecosystem are currently led by *Protocol Labs*, the largest single contributor to the IPFS open-source effort [72]. In 2021, Protocol Labs started to compile its *badbits list* [50], listing content deemed as "problematic" after receiving a takedown request. Protocol Labs uses this denylist to filter flagged content from the IPFS gateways it manages. However, in a decentralized system, this is just a partial solution: there are many gateways hosted by different operators that do not necessarily share the same denylist. Thus, Protocol Labs makes the badbits list publicly available, so others can use it if they wish to filter certain content. However, to date, we know little about this process.

In this paper, we conduct the first in-depth analysis of problematic content within the IPFS network and the efforts made to moderate it. We provide a nuanced understanding of the content landscape and offer practical insights for reinforcing content moderation mechanisms. To achieve this, we collect a range of datasets (Section 3), covering (*i*) the content takedown requests received by Protocol Labs, alongside the final badbits list they compile; we extend it with datasets from

*These authors contributed equally to this work.

traditional Web2 providers, creating a more comprehensive *denylist* of problematic content; (*ii*) the presence of such content within the IPFS network, and its related infrastructure; (*iii*) the traffic related to such content; and (*iv*) the implementation of content filtering at various IPFS locations.

We start by studying the content moderation process for the `ipfs.io` gateway, from when content is reported to the actions taken and their impact (Section 4). We show that, while Protocol Labs usually acts upon complaints within 24h, problematic content can be present in the network for years before being reported. This leads us to characterize the content listed in the denylist. We investigate the breakdown of 368,762 files flagged for takedown reviews and find a large fraction of copyright-protected content ($\approx 87.97\%$ of files), as well as phishing campaigns ($\approx 5.81\%$). We also observe the presence of terrorist content ($\approx 0.06\%$), and potential CSAM ($< 0.01\%$). Importantly, to minimize risk and to report offending content, we have worked closely alongside the Internet Watch Foundation (IWF) [43].

Next, we identify which providers host the denylist content (Section 5) and which consumers retrieve it (Section 6). We find a substantial skew, with over 60% of unique denylist content items hosted by just two peers. This, however, is misleading as we show that content is often replicated at multiple locations. This replication creates challenges for blocking such material. This inspires us to measure the success of the moderation process. We observe limited filtering within the core IPFS network. Thus, we measure what content is blocked by gateways (Section 7). We find that gateway operators have different levels of blocking compliance. For example, out of all the gateways, only the ones operated by Protocol Labs filter the entire badbits list. The other public gateways, including those operated by large CDNs, filter less than 20% of the content. Critically, we also discover that some gateways are vulnerable to content filtering circumvention. For instance, we can circumvent the filtering by using different hash-based naming functions, even if they follow the denylist.

Finally, in Section 8, we discuss potential improvements to the existing content-moderation approaches. We propose strategies that aim to enhance the efficacy of content moderation within the IPFS network. We show that a tighter collaboration between Protocol Labs and traditional content filtering services can increase the ratio of detected phishing content by 227%. Our approach reduces the average time between the appearance of deceptive websites and their filtering by 43% and with minimal implementation effort. Our work fills a missing gap in the growing number of studies analyzing IPFS performance [72], security [63, 67], and resilience [32, 37]. We hope that it is useful for both developers and operators of IPFS infrastructure.

2 Background

The InterPlanetary File System (IPFS) is a set of protocols that facilitate decentralized content-addressable media object storage and retrieval. IPFS is an open-source effort where Protocol Labs is the largest contributor [72]. At its core, IPFS is a content-based addressing scheme that uses Content Identifiers (CIDs). CIDs are hash-based, immutable, self-certifying names that decouple the name of the content from its storage location. Accordingly, any peer can serve the content requested via a CID, and the receiver can verify that the data served matches the identifier requested via hashing. A distributed index maintains records of which providers host a given CID, allowing consumers to discover where to request content from without needing a central index. Here, we provide a brief overview of key parts; see [72] for full details.

DHT. IPFS uses a Kademlia-based [61] Distributed Hash Table (DHT) to index which node hosts data for a certain CID. The DHT indexes *provider records*, which maintain a mapping between a CID and the physical node(s) that can serve it. Peers then use this DHT to publish their provider records, so consumers can discover where to download the content from.

InterPlanetary Network Indexers. Involved parties in the IPFS ecosystem also operate a small set of InterPlanetary Network Indexers (IPNIs or "Indexers") to accelerate its performance. Indexers are high-performance keystore servers that index provider records. Providers can optionally publish their provider records to both the DHT and the Indexers. This can substantially increase performance, as the Indexers offer much faster lookup times for clients. Notably, data will stay in the Indexer unless actively removed by the provider, which will become relevant later. We emphasize that Indexers are intended to complement the DHT — the DHT remains the ultimate ground truth index of IPFS content.

Bitswap. To exchange content, IPFS relies on Bitswap [39], a simple protocol used to retrieve blocks of data. Bitswap is used by nodes to both retrieve and send data. The protocol allows one to ask a peer (using a WANT message) whether it possesses the content for a CID. The same protocol is then used to transfer the data.

Content Publication & Retrieval. When a provider wishes to publish a content item, it first computes its hash-based CID. It then publishes a *provider record* that contains the CID and its own network information. The record, by default, is pushed to the DHT but can also be pushed to one or more Indexers. Following this process, consumers in the network can retrieve the object. For this, a node first performs a 1-hop optimistic broadcast via Bitswap to all its connected neighbors looking for the target CID (typically a few hundred random peers). Searching via Bitswap is fast, but does not provide reliable content resolution, in particular for less popular content. Thus, if this does not yield any results, the node queries the DHT

or Indexers for the provider record. Once it has retrieved the provider record, it can then connect to an available host and retrieve the object. The download is performed using Bitswap.

HTTP Gateways. Accessing IPFS via the DHT and Bitswap comes with the substantial overhead of installing an IPFS node implementation (*e.g.* kubo [4]). To minimize the barriers to uptake, IPFS also supports access via *gateways*, which can translate Hypertext Transfer Protocol (HTTP) GET requests to content retrievals in IPFS. Gateways enable IPFS-agnostic users to seamlessly access IPFS content. When a gateway receives an HTTP GET for a CID, it launches a query into the IPFS network and retrieves the content on behalf of the web client. The gateway then returns the content to the client over the original HTTP channel. Gateways (built upon Nginx) also enable HTTP caching to accelerate performance and minimize load on the IPFS network. Protocol Labs maintains a list of public gateways [51], some of which are operated by Protocol Labs (`dweb.link`) and other large operators like Cloudflare (`cloudflare-ipfs.com`).

Protocol Labs Badbits List. Moderating content (*e.g.* filtering) in IPFS is inherently challenging, due to its decentralized nature. The most obvious location where such moderation could take place is at gateways or Indexers, as these are points of centralization. With the above challenge in mind, in 2021, Protocol Labs created a public list of content items that they deemed "harmful" for various reasons (*e.g.* copyright violation, phishing) and, therefore, should not be accessible. This list is referred to as the *badbits* list [50]. The badbits list is centrally maintained by Protocol Labs and built primarily on takedown requests received via email at `abuse@ipfs.tech` [55]. Any entity or person can issue a takedown request. This request is reviewed by a content moderation team and approved requests result in the content being added to their *badbits* list.

To date, the list contains over 410,000 entries, with each entry being a hex-encoded result of applying SHA256 to the base32-encoded CIDv1. This hashing of the CID allows parties to check whether a given CID is part of the *badbits* list without revealing the CID itself. Note, no additional metadata is included in the list.

Takedown Email Notices. We got access to the takedown request emails received via `abuse@ipfs.tech` between 2023-10-22 and 2024-01-11 and analyzed them according to Appendix A.2. This allows us to understand the nature of takedown requests and how they are acted upon. This was done with a team of former researchers at Protocol Labs, who received permission to share information with us for research purposes. This data was never transferred or stored outside of Protocol Labs. It was used only for the purposes of this study, and we never had direct access to the mailbox. Further, we do not review information about the email sender (Section 9).

3 Methodology

In this section, we explain the methodology and the datasets employed in this work. Figure 1 provides an overview of our data collection architecture.

3.1 Content Collection

We use the Protocol Labs *badbits* list [53] (see Figure 1 ①) as our starting point. We have gathered a time series of list versions since its creation in 2021. Because each entry on the badbits list is hex-encoded hash of the CID (see Section 2), inferring the CID directly is not possible. To overcome this, it is necessary to get a large set of valid CIDs, calculate their SHA256 hashes, and then match them against the badbits list. For this, we collect all candidate CIDs from Bitswap and DHT logs (see next).

Bitswap Logs. We collect Bitswap traces from mid-2021 to January 2024 [31] (see Figure 1 ②) using a modified IPFS node implementation with unlimited connections with peers. Our crawler logs all incoming 1-hop Bitswap broadcast traffic (*i.e.* each searching for a CID) to disk. From this, we observe $\approx$ 300B requests, covering $\approx$ 1B unique CIDs.

DHT Logs. We also set up a modified version of a DHT server [58] to collect the IPFS DHT traffic. We set up 20 virtual peer IDs and write all the incoming DHT requests to disk. We log the timestamp, the sender's peer ID and network address, the type of request, and the target key which could be a peer ID or CID depending on the message type. We also log the proxy DHT server if the original sender uses NAT traversal mechanisms (Section 2). Apart from collecting the traffic, our software acts as a regular DHT server following the IPFS specification. We collect traffic from September 2022 to January 2024 (see Figure 1 ③). From this, we observe 1.3B requests, covering 120M CIDs.

Badbits CIDs. Using the above two data sources, we extract all CIDs from the logs (see Figure 1 ④). We then convert all CIDs into their hash (SHA256). Using these hashes, we reverse map the entries on the badbits list to their associated CID. We recover 411,522 ($\approx$ 99.98%) of the CIDs in the badbits list. We refer to these as *badbits CIDs*.

Denylist CIDs. To measure the spread of a wider body of problematic content, we supplement the badbits list, using other lists. Specifically, we take information from Web2 Anti-Phishing Services (APS) (see Figure 1 ⑤, in ThreatChase Intelligence Platform [36]). This platform compiles lists of phishing URLs by combining data from OpenPhish [17], PhishTank [18], URLhaus [21], and the AntiPhishing Working Group (APWG) [1]. From these phishing URLs, we extract any CIDs present using regular expressions.[1] We identify 16,128 CIDs associated with phishing attacks (see Figure 1,

[1] From manual inspection, we see that all of these CIDs are embedded in URLs that access a particular gateway.

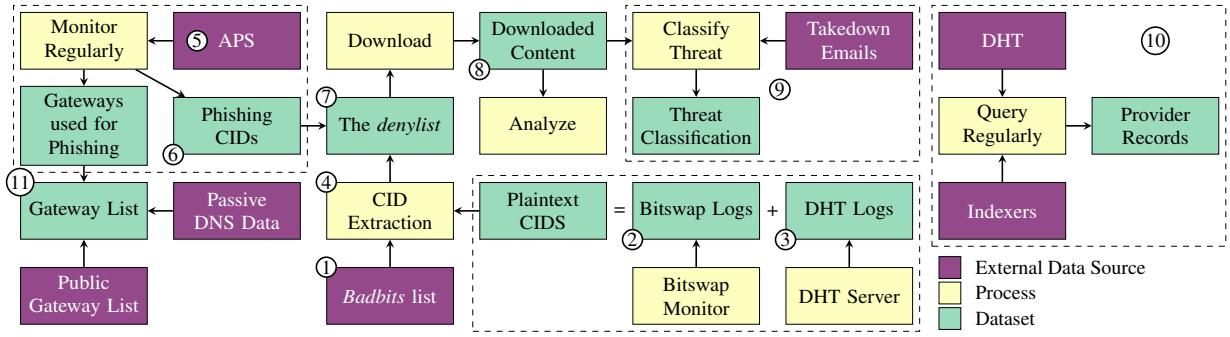

Figure 1: Overview of data collection architecture.

⑥). Our combined dataset, covering both badbits and phishing (*i.e.* Web2-moderated) content, contains 417,912 CIDs. We refer to this combined dataset as the *denylist* (see Figure 1 ⑦).

Content Retrieval. We then attempt to download all the content on the denylist except those reported as CSAM. We configure our IPFS node to not provide the downloaded content to other peers in the IPFS network and delete the content immediately after classifying it (see Figure 1 ⑧, Section 3.2). We successfully download 368,762 content identifiers (CIDs) (≈ 86.60% of all CIDs) in the denylist.

3.2 Content Classification

To gain a more nuanced understanding of the badbits content, we classify the content in the list.

MIME Types. We classify the content based on the MIME type into the following categories: *documents* (*e.g.* pdf, epub), *text* (*e.g.* plaintex, json), *html*, *binary* and *multimedia*.

Text Description. We also generate a text-based description of the material, in cases of text and image content. For documents, (*e.g.* PDFs, epub), we use the open-source GPT Mistral model [47]. This model can extract the language and field/-subject of any given file. For HTML files classified as phishing, we further obtain names or categories of the imitated target website using the *target* field in APS. We submit the remaining unclassified files to Google Bard Large Language Models (LLM) [45] asking it to indicate the target domain. We manually verify the domain detection on 100 files with 100% accuracy.

For images, we use BLIP2 pre-modal pre-training method [57] that combines image encoders and LLMs. We verify our BLIP2 classification on a small sample of 1,000 files manually classified by ProtocolLab/APS with 98% accuracy. We also calculate SHA256 hashes for all the downloaded content and submit them to the IWF [43] for a check against their CSAM database.

From the 368,762 successfully downloaded denylist files, 265,287 (≈ 71.94%) are PDFs, 25,628 (≈ 6.95%) are ePubs, 12,574 (≈ 3.41%) are DjVu files (a type of scanned document), and 7,412 (≈ 2.01%) are HTML files.

Threat Types. We classify all CIDs in the denylist taken from APS as phishing (as those services exclusively list phishing content). To classify the threat type of the remaining content, we first use information from the takedown request emails. We extract the takedown reason from these emails (see Appendix A.2), and classify CIDs into their corresponding category (see Appendix A.2 and A.3): Digital Millennium Copyright Act (DMCA), Phishing, CSAM, Animal Abuse Material (AAM), and Terrorist content. This allows us to label 12,170 of the badbits CIDs.

Partial data about threat types is also hosted in GitHub, containing information about the reason for the inclusion of certain CIDs in the badbits list. We, therefore, use information from GitHub from 2021-02-17 to 2024-01-12, accessed by the same former Protocol Labs researchers (with permission). This enables the classification of 154,465 additional CIDs added to the badbits list before 2023-10-22 (*i.e.* before the email logs are available).

The above data sources allow us to label 45% (166k) of the downloaded files with their threat type. To cover the remaining, we submit them to VirusTotal.[2] This successfully classifies 6,996 (1.9%) files. For the 195k (53%) files that remain unclassified, we employ a local instance of LLAMA2 LLM [71], as detailed in Appendix A.4. We feed it with examples of classified content (classification done by Protocol Labs, VirusTotal, and APS) including the content MIME type and the text description. We then feed it the remaining samples and ask it to perform automatic classification. We classify these files into threat types consistent with those in the badbits list (see Figure 1 ⑨): *DMCA* (*i.e.* copyright-protected content), *phishing*, *malware*, *terrorist content* and *explicit content* (*i.e.* including CSAM and AAM). This gives us labels for 88% of files in the denylist.

3.3 Content Hosting and Consumption

We next gather data on the nodes hosting content in the denylist (*i.e.* providers) and the users requesting it (*i.e.* con-

[2] https://www.virustotal.com

sumers).

IPFS Hosting. We twice-daily collect all provider records from the DHT for each CID in the denylist (see Figure 1 (10)). We do this from 2023-11-01 to 2024-01-13, allowing us to track who hosts the CIDs over time. We crawl the IPFS network to obtain the list of all peer IDs in the DHT and map each CID to the peers responsible for hosting the provider records for that CID, using the techniques from [72]. Then, we directly contact the peers with requests for the provider records of the CIDs. This technique avoids costly DHT queries and limits the impact of the study on the network.

Every three days, we also query the `cid.contact` indexer for provider records of all *badbits* CIDs [54]. We choose this interval to comply with the indexer's policy and its rate limits. During the period of the study, the queried indexer was the only one operational. This data augments the aforementioned DHT data of providers hosting CIDs on the *badbits* list.

Gateway Hosting. We also identify content available via IPFS HTTP gateways. We start with the list of public gateways maintained by Protocol Labs [51] (see Figure 1 (11)). We then expand it with a manual set of additional popular public gateways, and finally add any gateways identified in the URL feeds from the ThreatChase Intelligence Platform.[3] Finally, we add any gateways present in a passive DNS dataset obtained from the Farsight SIE passive DNS channel [40]. This dataset covers all requests made from mid-November 2023 to February 2024. Specifically, from this dataset, we extract any CIDs embedded within the Fully-qualified Domain Name (FQDN). Note that clients can request content from a gateway by embedding the CID as a subdomain [22].

We then implement a gateway checker that verifies the accessibility of all the denylist CIDs from every gateway on the *gateway list*. Our software probed the gateways from 2023-12-27 to 2024-01-31 every three days to avoid rate limits (see Section 7.1).

Consumers. We finally gather data to estimate the demand for each item on the denylist. For this, we extract all the requests for CIDs on the denylist present in the passive DNS, Bitswap and DHT logs. Furthermore, we log the date when each CID is first requested. We observe 7M, 420M, and 63M requests via the DNS, Bitswap and DHT data, respectively. These cover 417,912 unique CIDs.

4 A Badbits Denylist Primer

4.1 Overview of Badbits Compilation

Takedown Request Emails. The takedown email data provides insight into the types of content concerns that third parties flag within IPFS. Figure 2 shows the number of takedown request emails and CIDs received, spanning from 2023-10-22 until 2024-01-11. We break these down into our takedown classification and separately plot the numbers included on the badbits list vs. those discarded by the moderation team. Note, emails, and CIDs marked as "Not Included" could either be discarded items or simply not yet acted upon by the review team.

We observe that over 60% of all email takedown requests are accepted for inclusion in the badbits list. This initially suggests that the quality of takedown notices is relatively high, with fewer examples of miscellaneous submissions. However, Figure 2 also plots the equivalent results based on the number of CIDs (because each email can contain multiple CIDs). In stark contrast, we find that the majority of CID takedown requests are actually *rejected*.

To understand why, we inspect the takedown classification categories, where we see notably different patterns. Closer inspection reveals that these patterns are driven by the tendency for DMCA emails to include up to eight times more CIDs than phishing takedown request emails [19]. Mirroring prior observations [46] in traditional web hosting, it seems that such agencies 'optimistically' send many requests, even though they are not verified. We argue that this strategy creates a significant load, mandating the need for automated tools. Despite the dominance of DMCAs, a minority of emails are also classified as CSAM, terrorist content, or other reasons ($< 1.3\%$ of all emails and $< 1\%$ of all CIDs), confirming that moderation requirements are diverse.

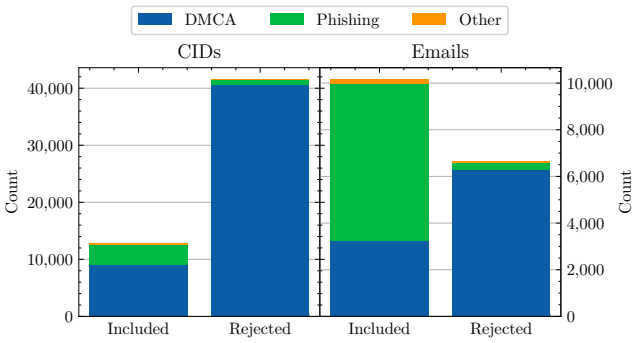

Figure 2: Received takedown emails by category from 2023-10-22 until 2024-01-11. Note that one email may contain multiple CIDs. "Other" includes categories like CSAM, terrorist content, unblock requests, or unspecified reasons.

List Evolution. Figure 3 next shows the growth of the badbits list over time. We plot the absolute number of CIDs received alongside the types. This graph shows that, throughout the existence of the list, the majority of CIDs included are DMCA-related. We also note a recent growth of the list. Almost 90% of the badbits CIDs are added in 2023 alone. We conjecture that this is due to the increasing popularity of the system, which has attracted more users and providers. More

[3] We do this by extracting the domains from URLs that contain a CID and match the correct regular expression.

importantly, it also has attracted the attention of numerous copyright-enforcement agencies [19].

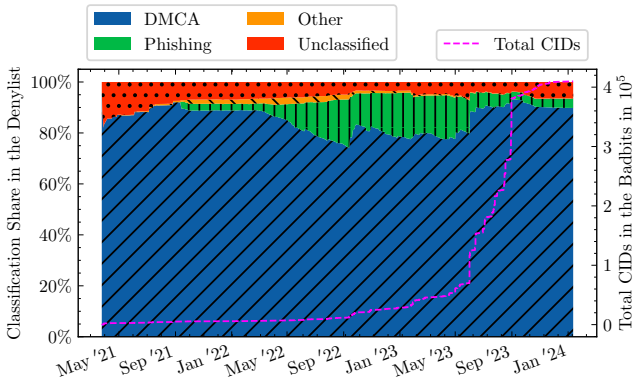

Figure 3: Badbits list evolution by type of threat.

Reaction Time. We are also curious to investigate the time needed to include content on the badbits list. This gives insight into the duration that content can circulate before being identified and moderated. Figure 4 plots the CDF of the number of days from the time we have first seen the content in our Bitswap and DHT logs to the inclusion of its CID on the badbits list. We also include the reaction time after receiving the associated takedown email (from 2023-10-22 until 2024-01-11). For comparison, we use the reaction time of APS in filtering phishing URLs requesting IPFS content through gateways.

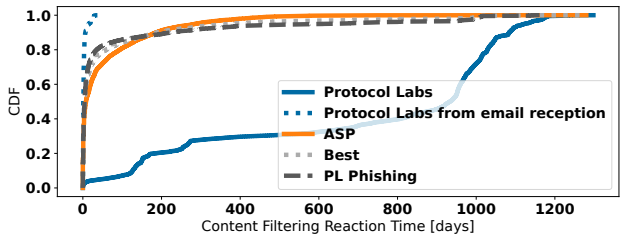

Figure 4: CDF with reaction time distributions for different providers.

For 50% of CIDs flagged for inclusion, the CID is placed on the badbits list within less than 24 hours. This suggests that the list *is* up-to-date and it rapidly reacts to reported content. However, this process naturally relies on the timely submission of takedown notices by third parties. That said, we witness a significant delay between the time content is first requested within IPFS and the time a takedown email is sent to Protocol Labs. This means that, on average, content is available in IPFS for 713 days before being included on the badbits list. In contrast, the reaction time is significantly shorter for APS, adding gateway URLs onto their list in less than a day for most of the CIDs. This indicates that they receive more timely takedown notices than Protocol Labs.

4.2 Overview of Badbits Content

The above has exposed an active and growing list of material in badbits. We next characterize this content.

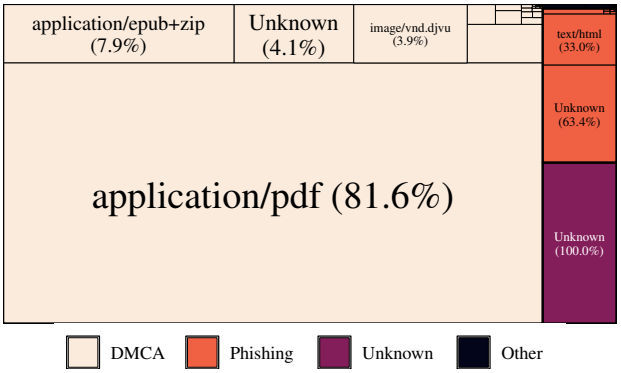

Figure 5: Percentage of content and threat type.

Content Overview. Figure 5 shows the threat and content types associated with denylist content. The "Unknown" file type indicates cases where we did not download the referenced file because of unavailability or it being labeled as CSAM. Reflecting our earlier observations, $\approx$ 87.97% of CIDs are filtered because of copyright violation (*i.e.* DCMA). This threat covers mostly PDF and epub files. The second most common threat is phishing (5.81%) with HTML files and images used as elements of deceptive websites. The remaining threats (*e.g.* malware, terrorist, and explicit content) constitute less than 1% of the CIDs on the denylist.

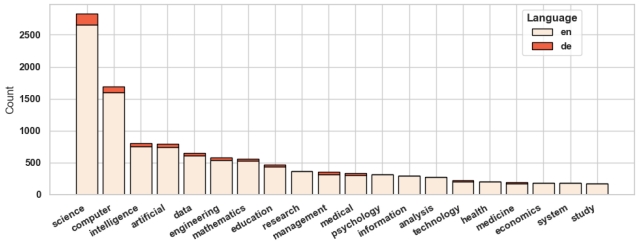

Figure 6: Frequency of subject area keywords for DMCA content.

DMCA. Figure 6 presents the language and subject/area of the DMCA documents. In total, we detect 41 languages. However, the vast majority of documents are in English (84%) and German (12.4%), likely making moderation reviews more straightforward. Interestingly, most of the documents represent academic articles and academic textbooks. We find that this is driven by multiple shadow libraries such as the Free Library, Anna's Archive, and Nexus Search [26, 29, 44] migrating their content to IPFS. This choice perhaps reflects a

perception in such communities that IPFS is an effective tool for hosting censorship-resistant material.

Phishing. Content classified as phishing contains mostly HTML files and images used for creating deceptive websites. In most cases, these appear to be phishing pages that are accessed via gateways using URLs. Specifically, attackers host their pages in IPFS but encourage normal web users to access them by providing HTTP URLs via the gateway services. To explore this further, for the HTML files, we obtain the target domain that the file is trying to imitate. We discover 195 victim services and websites and group them into categories. Figure 10 plots the distribution. 49.4% of these URLs target mail services, 8.8% target file transfer services such as Wetransfer, and 3% hit Microsoft services and websites. To give insight into this content, Figure 7 also presents a word cloud of the phishing image descriptions. Confirming the above victim analysis, we observe logos of multiple companies such as Apple, Yahoo, and Microsoft. Furthermore, the classic elements forming login forms and navigation elements are present (*e.g.* "sign", "envelope", "button"). Beyond the major mail portals, the remaining phishing targets are mainly shipment services such as DHL, financial companies like Visa and Mastercard, and social media networks. This suggests that there is, indeed, an important need for mitigation, as these seem to target high-risk areas, *e.g.* banking.

Terrorist Content. Concerningly, the denylist also contains 255 CIDs marked as terrorist content. This includes documents, videos, images and audio files. To understand the nature of this material, we focus on documents and images, which constitute more than 60% of the content. Figure 8 presents a word cloud of keywords in the content description. Surprisingly, we observe *love* and *poem* being the most repeated words. This results from a collection of literature acting as motivation for terrorist actions [49]. We further spot practical guides on how to blend into society without raising suspicions (*e.g. home*, *marriage*, *job*, *business*). The content relates to multiple groups and geographic locations (*kurdish workers*, *egypt*, *kuwait*). Finally, we observe multiple keywords related to religion and beliefs (*e.g. islam*, *traditional*, *anti-western*). Multiple PDFs contain Twitter screenshots with terrorist propaganda being reflected by the *tweets* keyword.

Explicit Content. Finally, our classification finds a small number of items on the denylist that could be classified as explicit. Figure 9 illustrates the keywords found in the image descriptions classified as explicit content. Multiple intuitive keywords (*e.g.* girl, naked, underwear) indicate the presence of pornography. For added safety, we send the SHA256 hashes of all the images to the IWF [43] that supports online organizations in filtering CSAM. Only three images were present in the IWF database and were classified as *hentai*, a style of Japanese pornographic anime and manga. For the content classified by Protocol Labs as CSAM, we are currently collaborating with the IWF to ethically and legally download and verify those files.

5 A Provider Perspective

Provider Geo-locations. Figure 11 shows the geographical distributions of all 10,668 unique badbits CID hosts that we observe between 2023-11-01 and 2023-11-30. We chose this timeframe because this is the only full month where our DHT and IPNI datasets overlap. Note that we identify unique providers by their peer ID. Figure 11a) shows that we can only geolocate around 30% of providing peers. This is because the provider records either do not contain network addresses and we could not find them in the DHT (20.5%), or the network addresses are private IP ranges (49.7%). The presence of private IPs in the provider records is an interesting phenomenon already reported in previous studies [32]. Potential explanations include misconfiguration (*e.g.* clients using the wrong interface) or outdated software. Only a minority of provider records contain non-private IP addresses that are not found in the Maxmind database ($< 0.1\%$).

Figure 11b) shows again the geographical distributions of all unique badbits CID providers, with each provider now weighted by the number of unique CIDs it hosts. We find 376,201 unique CIDs, with providers in the US and Netherlands sharing most. "Circuit" providers (aka *circuit relay* peers) are special to the IPFS network and exclusively relay control messages to facilitate NAT traversal [65] (*i.e.* they do not exchange traffic of actual content). Their presence hints at a large number of providers operating from residential networks — and therefore requiring NAT traversal. Their geographical location is, therefore, not necessarily representative of the geographical presence of the content providers that exchange actual content traffic. Their presence suggests that some parties may also use circuit relays to mask the hosting of badbits material.

CIDs per Provider. Figure 12 shows the distribution of the number of CIDs hosted per provider for all providers we observe in either the DHT (top) or the Indexer (bottom). The graphs show that, at any point in time, over 99% (DHT) and 70% (Indexer) of the providers host just between 1 and 10 badbits CIDs, respectively. However, about 0.1% (*i.e.* between one and three peers) of providers in the DHT host between 10^4 and 10^5 unique CIDs, which comprises up to 25% of the entire badbits list. In fact, we find single peers in the DHT and Indexers, respectively, that claim to provide more than 19% and 63% of the entire *badbits* list. This suggests that the badbits hosting ecosystem is relatively fragile, and significant volumes of content could be removed with just a small set of targeted takedowns.

Providers per CID. The above fragility may be misleading, as many different nodes could host an individual CID. Thus, Figure 13 shows the distribution of the number of providers

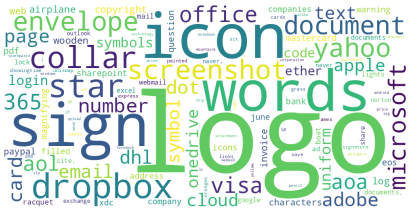

Figure 7: Word cloud of phishing image descriptions.

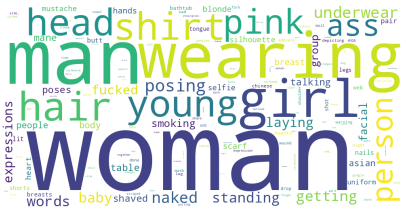

Figure 9: Word cloud of descriptions of explicit images.

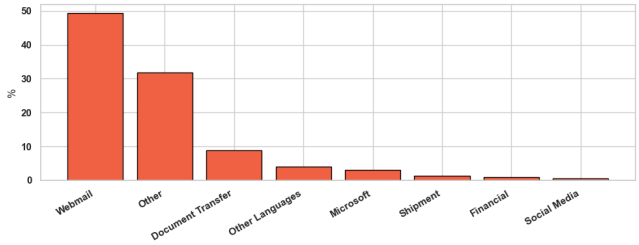

Figure 10: Frequency of services and websites targeted by phishing campaigns.

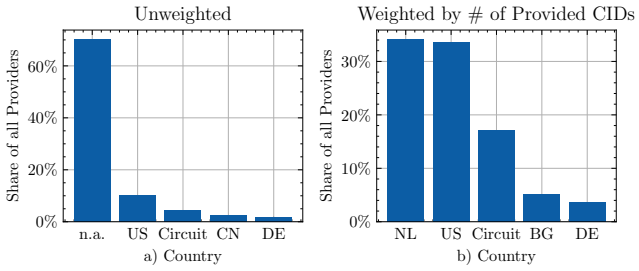

Figure 11: Geolocation distribution of 10,668 unique content providers identified by their peer ID aggregated from 2023-11-01 to 2023-11-30.

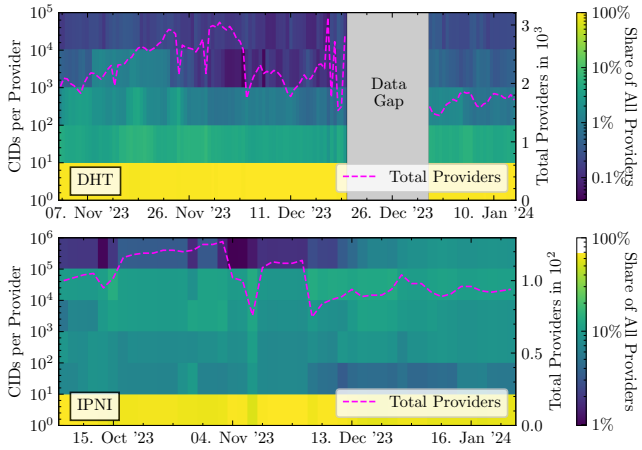

Figure 12: Distribution of the number of unique badbits CIDs hosted per provider and the total number of unique badbits CID providers. CIDs are grouped into bins according to the ticks in the left y-axis. The color indicates the share of all providers that host CIDs in any bin. The right y-axis shows the total number of badbits CID providers that were found in the DHT/IPNI at the time of the measurement.

hosting each CID. Under 0.1% of all provided CIDs were hosted by a single peer over the measurement period. This suggests that the ecosystem is, in fact, far less fragile than the earlier results would suggest: We even find a single CID from the badbits list that is provided by over 91% of all DHT and Indexer peers. Complicating matters, we also witness a growth in replication levels over time. Towards the end of the measurement period, the number of providers per badbits CID seen in the Indexer grows. By the end of our measurement period, the majority of CIDs have five to ten unique providers. We hypothesize that this may be because the Indexer does not automatically remove provider records itself, suggesting that some could be stale (see Section 2). Either way, we argue that this makes takedowns in IPFS more challenging.

CID Churn. Considering the presence of potential takedown attempts, we next measure the underlying churn of DHT providers on the badbits CIDs, depicted in Figure 14. Here, we measure churn by considering CIDs that started and stopped being provided within our total measurement window from 2023-11-01 and 2024-01-12. This means, from the 298,951 CIDs that were provided in the DHT (this excludes CIDs solely indexed in the Indexer), we only consider 60.4% (180,523). The remaining ones were either already present in the network when we started our measurements or were still provided after we stopped.

The graph shows that half of the CIDs added to the badbits are not retrievable after roughly two days. Although this could be because of takedown attempts, we suspect this is through natural churn. The graph also shows that CIDs classified as phishing have a lower churn rate and hence stay longer in the network. Looking at the Indexer, we find that indexed provider records exhibit virtually no churn as only 11 out of 304,495 badbits CIDs are removed during the measurement window from 2023-10-06 and 2024-01-28. We hypothesize that this is

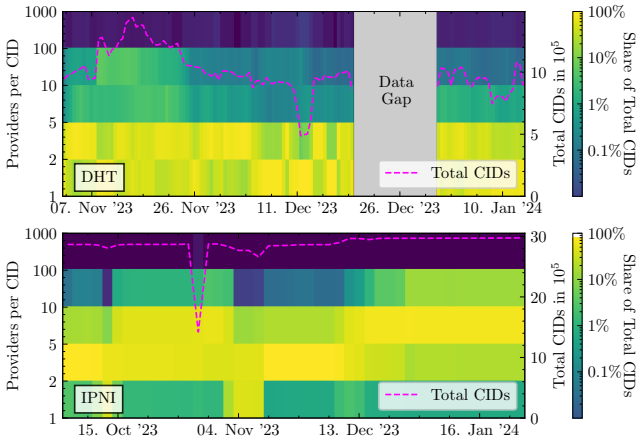

Figure 13: Distribution of the number of providers hosting a single CID and the total number of hosted badbits CIDs. Providers are grouped into bins according to the ticks on the left y-axis. The color indicates the share of all CIDs that providers host in any bucket host. The right y-axis shows the total number of badbits CIDs that were found in the DHT/IPNI at the time of the measurement.

again because Indexer records are not automatically removed.

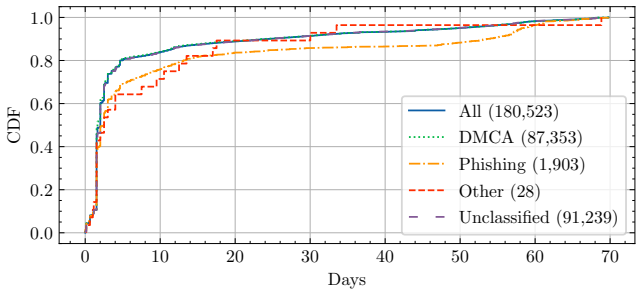

Figure 14: Provider record churn in the DHT. The numbers in parenthesis show the total number of CID uptime measurements for each curve. The measurement resolution is 12h.

6 A Consumer Perspective

We now turn our attention to *consumers*. We explore who requests denylist content through IPFS protocols and gateways, and estimate the popularity of such material.

Injection of new CID Requests. We first analyze when the denylist CIDs were first requested in the network. Figure 15 shows the number of unique, new denylist CIDs requested via Bitswap per month. The labeled dates indicate notable events in the IPFS user community, likely contributing to the reported numbers. At ①, the Free Library project, a shadow library similar to Libgen or Sci-Hub, announced that it was operating on IPFS [44, 75]. At ②, the Nexus project, another shadow library popular using Telegram bots to share content, announced the release of their latest index and dataset on IPFS [23]. At ③, Anna's Archive, an aggregation and indexing project for multiple shadow libraries and knowledge collections, announced they moved the contents of Z-Library, a shadow library recently taken down, to IPFS [28, 29]. Finally, at ④, the Nexus project announced a web frontend on IPFS/IPNS called the Standard Template Construct [26]. The project is particularly vocal about their use of IPFS to combat censorship, with frequent posts about updates and new material accessible via their interfaces as well as encouragements to install IPFS on user machines [24, 25, 27]. Note, the initial spike in 2021 is caused by the start of our data collection, *i.e.* all CIDss are new. Importantly, these bursty patterns create significant challenges for the moderation team, which must handle intense volumes of takedown notices in relatively short periods. Thus, needing to capacity manage for the peak (rather than the average) likely increases cost and complexity.

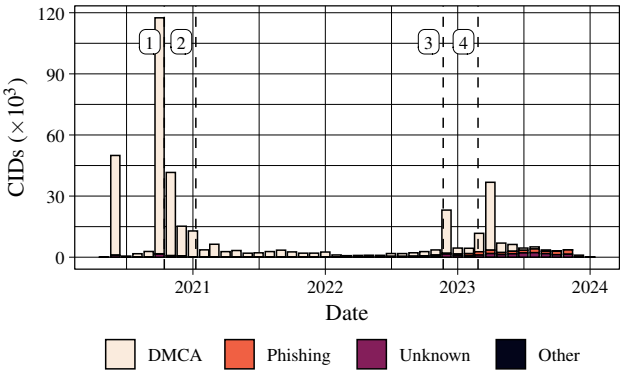

Figure 15: Number of denylisted CIDs seen via Bitswap per month.

Content Popularity. We next investigate the popularity of denylist CIDs. Specifically, we compare the number of denylist CID requests seen against the overall number of requests in our Bitswap traces. Over the entire period, we see an average of 14.23×10^3 denylist vs. 42.00×10^6 other unique CIDs per day. This suggests that only a very small ($\approx 0.034\%$) part of IPFS traffic requests denylist content. Closer inspection of Figure 15 shows that this almost exclusively consists of copyright-protected content. This is in sharp contrast with the HTTP gateway traffic that we analyze in the next section.

Figure 16 plots the number of requests for denylist content over time. For this plot, we first count the number of unique denylist CIDs, as well as the number of unique (CID, PeerID) tuples requesting denylisted CIDs, per month. Counting requests via unique (CID, PeerID) tuples avoids overcounting due to repeated requests, which happen when content is unavailable [31]. We observe a growing number of denylist CID requests, suggesting that demand for such content is expanding. Between January 2021 and November 2023, the number of requests increased 8-fold to almost 2×10^6 requests per

month. Further, we observe a sharp increase in the number of requests for CID classified as phishing starting from November 2022. In January 2024, the phishing queries constituted ≈ 50% of all requests for denylist content. This date correlates with the wider deployment of gateways, which facilitate access to IPFS content (see Section 2) and potentially help spreading IPFS-hosted phishing websites by making them available via HTTP. We suspect that these request patterns could also be exploited by the moderation team to help allocate resources to checking particular types of material.

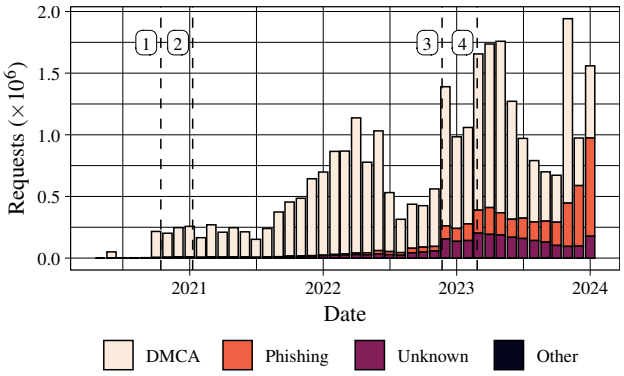

Figure 16: Number of unique peerID/CID combinations requesting denylisted CIDs via Bitswap, by threat type.

Geographical Request Flow. Now that we have a profile of both providers and consumers, we conclude by studying the flow of content between these two parties. Figure 17 shows the request flow from the request initiator to the denylist content provider's Maxmind location for all traced Bitswap requests and unique content providers (DHT and Indexer) from 2023-11-01 until 2023-11-30. Note that we count requests for CIDs hosted by several providers multiple times in the diagram (as we do not know the ultimate provider that the client selects). In total, we observe 5,597,343 requests and 10,668 unique content providers (as identified by their peer ID).

The Sankey diagram reveals a number of interesting trends. We see that the largest share of both requests and providers comes from the US. We see that some countries contribute more proportionate "demand" than "supply". For example, Germany requests 7x more unique badbits items than it serves itself. In contrast, the Netherlands only requests 50% of unique badbits CIDs that they provide.

7 A Gateway Perspective

In this section, we look at the HTTP gateways, as these are a rationale location where content filtering may take place. We investigate to what extent they block denylist content, and test potential filter circumvention techniques.

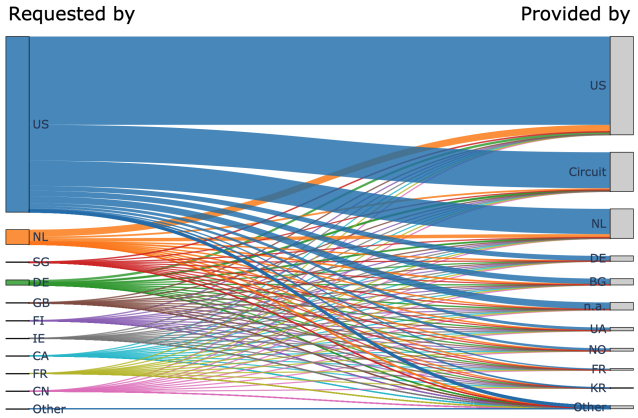

Figure 17: Geographical request flow (2023-11-01 to 2023-11-30). Same CID requests are considered multiple times.

7.1 Access via Gateways

We manually breakdown the 431 gateways in our dataset into four categories: 1. operated by Protocol Labs, 2. operated by a large CDN, 3. public gateways listed on the `ipfs.tech` gateway tracker [51] (excluding the ones in 1 and 2), 4. ephemeral gateways, 5. others. The *ephemeral* and *others* categories consist of unlisted gateways discovered from the ThreatChase Intelligence Platform and the passive DNS dataset. In this set, we identified 105 ephemeral gateways with hostnames belonging to a subdomain of a Web3.0 hosting service named Infura that provides IPFS Gateway-as-a-Service (GaaS) to its clients. The service enables a quick deployment of a custom, HTTP gateway. All the remaining gateways are classified as *others*.

We test the availability of content via these gateways by sending daily requests during the entire month of January 2024. To avoid overloading, we use a daily sample of 10,000 CIDs: 5,000 from badbits and 5,000 blocked by Web2 entities, *i.e.* ones from denylist but are not in badbits. Instead of requesting and downloading the content, an HTTP HEAD request is sent (as opposed to a GET) to which the gateway responds with only the HTTP header containing, among other things, an HTTP status code.

A gateway responds with HTTP status codes 410(Gone) and 451(UnavailableForLegalReasons) for filtered content, according to IPFS standards for public HTTP gateways [52]. We therefore classify responses containing those two codes as *Blocked*. In contrast, we assume the content is *Available* if 200(OK) is returned. We categorize requests that receive other status codes, such as 500(InternalServerError), 504(GatewayTimeout), etc. and those that do not produce a response within 10 seconds as *Failure*. This is mostly caused by the content no longer being available in IPFS.

Figure 18 presents the results of our HTTP requests. We observe significant inconsistent use of the badbits list across operators. The gateways operated by Protocol Labs block

nearly 100% of badbits, but this is not the case for other operators. The list is implemented, to some extent, by the public gateways that are officially listed by Protocol Labs, but not by the others. In particular, the CDN-operated gateways block only around 18% of the requests for badbits CIDs, similar to the gateways in the *others* category. We also observe low adoption of the CIDs moderated by Web2 providers. The gateways operated by Protocol Labs block none of them, while the CDN-operated gateways block up to 7%. At the same time, all the public and other gateways block some Web2-blocked CIDs (average 18%). We suspect that this is caused by the threat of the entire domain being blocked by mechanisms such as Google Safe Browsing (GSB). Such cases were reported in the past [68].

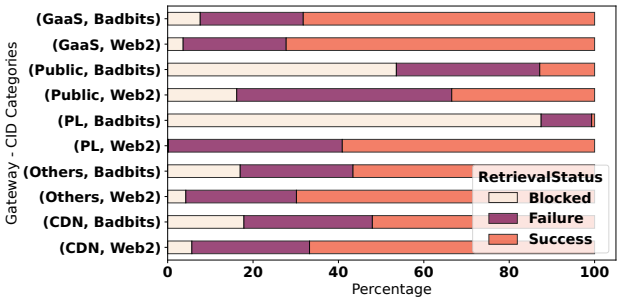

Figure 18: HTTP requests to gateways using a sample of CIDs from badbits and Web2 denylists.

We also use the passive DNS dataset to determine the CIDs requested from each gateway. A CID c can be requested from some gateways either as a part of the FQDN (*e.g.* `http://c.gw.tld/`) or as a part of the path (*e.g.* `http://gw.tld/ipfs/c`). The DNS dataset allows us to observe CIDs expressed in FQDN.[4] It is also a method that we noticed in more than 80% of URLs collected from APS.

Figure 19 shows the percentage of different types of requests for the most popular gateways measured by the overall number of requests. We observe that the gateways have a varied percentage of denylist requests, with one measured gateway showing 99% of requests attributed to phishing. This is in contrast to the DHT results with only $\approx 0.034\%$ denylist traffic share. This suggests that the gateways are frequently used in phishing campaigns to disseminate malicious content to victims without the need to install IPFS software.

7.2 Circumventing Gateway Filters

We conclude this section by testing several potential circumvention attacks on gateways. Specifically, there are multiple ways of requesting content via a gateway — thus, we check if all of these correctly implement filtering.

[4] this is the current recommended way of requesting CIDs from gateways

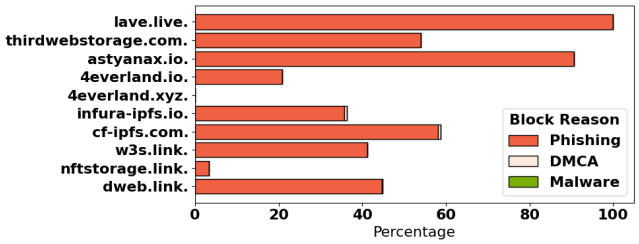

Figure 19: Percentage make-up of types of requests for the top-10 popular gateways. The Y-axis is sorted by the overall number of requests (the bottom is the most popular).

CID Versions. In our first experiment, we test whether gateways correctly hash the CIDs to the correct badbits list format before checking for a match. For that, we request blocked content using the canonical, version 1 CID, as well as the equivalent version 0 CID [2], which is not directly included in the badbits list. We randomly sample 100 CIDs out of those that are in the top 10% blocked by gateways. We request these, as well as their version 0 counterpart, on 2024-02-04, and note whether previously blocked content becomes available if addressed differently. We find no cases of this occurring and thus conclude that all evaluated gateways correctly normalize requested CIDs before checking against the badbits list.

Relative Paths. Next, we investigate how gateways handle requests for blocked data internally. IPFS allows the storage and retrieval of directories. We examine whether it is possible to trick gateways into providing blocked content by creating a wrapping directory around blocked objects. For a blocked CID c, a request would then take the form of `http://gw.tld/ipfs/`d`/foo`, where d is the CID of the directory and `foo` is the *name* of a directory entry referencing c. Upon receiving such a request, a gateway would first fetch d from the network, translate `foo` to the linked CID c, and then proceed with fetching c as usual. Assuming the parent collection CID is not blocked, we thus check whether the gateway correctly checks these internal fetch operations, instead of just the external, user-initiated ones.

We again sample 100 CIDs. We then create a directory collection wrapping these CIDs and provide it using a non-NATed node. Importantly, we *do not* provide any of the malicious content ourselves. Additionally, since the generated CID for this block is only known to us, the chance of it being used to spread malicious content is negligible.

We then attempt to retrieve the blocked content using a path relative to the CID of the generated parent. We find that only one gateway is vulnerable to this type of evasion. This gateway officially blocked 68 CIDs, yet we were able to circumvent the blocking for 67 of them ($\approx 98.5\%$). The failed evasion was not due to the content being blocked, but unavailable. We suspect the one vulnerable gateway is running outdated or custom software, whereas all other gateways use

a correct implementation. Notably, we also ran a preliminary version of this experiment[5] at an earlier date (2023-12-19) and found four additional vulnerable gateways operated by Protocol Labs. We followed responsible disclosure and they have now been fixed.

Alternative Hash Functions. The flexibility of CIDs allows users to generate multiple CIDs for the same content using different hash functions for the embedded digest. It is generally not possible to translate between these without access to the content itself, which would need to be re-hashed using the different functions. At the time of writing, the kubo [4] implementation of IPFS supports 72 hash functions.

We conjecture that attackers could circumvent blocks by generating multiple CIDs using different hash functions. We, therefore, test whether any of the gateways perform advanced, content-based blocking techniques, such as real-time content analysis or generation of alternative CIDs hashes for the requested content. We again sample 100 CIDs, selected from the set of phishing CIDs.[6] For these, we download the referenced content and re-add it to the network using a different CID (using a different hashing function). We then perform the same experiment as outlined earlier, and remove the content from our node immediately afterwards.

This circumvention attack is extremely effective. Out of the 57 gateways blocking any of the requested content, we are able to access the blocked content on 56. For these, evasion was possible for the majority (97.4%) of usually blocked CIDs. The missing evasions stem from unrelated issues, usually because the content is not returned completely within the timeout. The one gateway on which evasion was not possible, blocked *all* attempted evasions. Curiously, this was the one gateway that was vulnerable to our previous relative paths circumvention. We again suspect that they might be running custom software that does not support the alternative hash function. We have contacted them for clarification.

8 Discussion & Recommendations

We now discuss the limitations of the current content moderation approach and propose new improvements.

8.1 Improving the badbits List

We first discuss the quality of the badbits list itself. As shown in Figure 4, Protocol Labs usually processes all takedown requests within a day, suggesting effective decision-making. That said, traditional Web2 services such as APS and VirusTotal seem to get informed faster and thus be able to react quicker. We conjecture that this is caused by specializing in specific types of threats (*e.g.* phishing) and having larger user bases reporting data items. Therefore, we posit that working with established Web2 partners could shorten the time required to identify content. Automatic inclusion of content items into the *badbits* list based on trust could expedite the process. As a preliminary experiment, to simulate the process, we extract CIDs in URLs blocked by APS and compare them against the best detection time between Protocol Labs and APS. If these CIDs were automatically imported, such an enhanced denylist would classify 227% more CIDs and reduce the average reaction time by 43% compared to the current badbits.

We argue that the above process could be a mutually beneficial arrangement. We highlight this using our experiences with VirusTotal. When we initially submitted the SHA256 hashes of all the downloaded denylist files to VirusTotal, 1.2% of them were marked as malicious, and 58% of the files were not present in VirusTotal's knowledgebase. This represents a significant gap in VirusTotal's knowledge base. Indeed, when we checked VirusTotal again two weeks later, they discovered some of the files badbits had already seen. An additional 3618 files were newly labeled as malicious, including phishing (2421 files) and trojans (857 files), bringing the total to 2.2%. Thus, we posit that inputs from the badbits list team could help expand VirusTotal's knowledgebase faster, identifying content worth checking. A good candidate for such verification would be by sharing content requested through gateways. We found that this content has a much higher probability of being harmful (Figure 19). We recognize that operators might be unwilling to provide real-time feeds of content requested through their gateways due to privacy concerns. However, the inclusion of CIDs in the FQDN [3] means such data can be seen through passive DNS monitoring anyway.

Another limitation of the current *badbits* list is that it does not contain any taxonomy of content type or the reason for its inclusion. We hypothesize that gateway operators have different views on which types of threats should be filtered. Indeed, we see that some gateways do not follow the full badbits list (Figure 18). Thus, a concrete recommendation is that the badbits list is augmented with information about the nature of the content to better encourage uptake (*e.g.* allowing gateways to only filter certain types of material). The list should also have separate feeds for different jurisdictions, especially regarding the DMCA content.

8.2 Improving Web2 URL Filtering

Many Web2 filter lists already include URLs for the IPFS gateways, *e.g.* APS and GSB. We argue that their approach, however, stems from a misunderstanding of how IPFS gateways work. For example, we find that most APS blocked IPFS URLs use the gateway URL (*i.e.* gateway + CID combination). However, a CID can simply be requested via another gateway. Thus, once access to a CID is blocked through a gateway, malicious actors could just change the gateway domain to

[5] see Appendix A.1 for details in the difference in methodology
[6] see Section 9 for ethical discussions about this experiment

another one. Gateways-as-a-Service providers simplify the process of deploying short-lived gateways.

We also repeat the same checks for GSB. To test this, we create URLs from every combination of denylist CIDs and gateways in our dataset and submit them to GSB to check. Surprisingly, we find that the GSB blocks *entire* gateways, rather than specific content URLs provided by them. We observe that GSB blocks 56 gateways entirely, yet it allows the downloading of *all* denylist content from the remaining gateways. In practice, this is extremely ineffective, particularly as 95% of blocked gateways are already offline. The remaining 5% does not implement any filtering, suggesting that they could have been serving harmful content (helping to explain why GSB blocks them).

Clearly, both of the above approaches to compiling URL filter lists are ineffective for blocking IPFS gateway material. Instead, we argue that they should maintain a list of blocked CIDs — not gateway URLs. These CIDs can then be used to generate a full set of URLs by combining them with all known gateway domains. We are currently engaging with OpenPhish, the Anti-Phishing Working Group, and Phishtank to advocate for this change.

8.3 Improving IPFS Node Filtering

To date, the badbits list is mainly used by the gateways to implement filtering. However, it still remains possible for nodes to request badbits CIDs via the native IPFS DHT. As of IPFS v0.24.0, there is support for blocklists that filter their local files. However, this has not seen widespread uptake. To improve efficacy, we argue that more comprehensive versions of moderation should be introduced into the native IPFS network. Unfortunately, this raises many philosophical, ethical and technical questions. Our final recommendation is that the IPFS developers explore the development of decentralized moderation schemes that can answer such questions.

9 Ethical Considerations

Our study raises certain ethical queries, which we discuss below. We sought ethical guidance from multiple institutions. We got our methodology, datasets and the submitted version of the manuscript reviewed by Protocol Labs. We further coordinated our work with the IWF and got ethical approval from the IRB of our host institution.

Our overarching goal is to derive general, non-personalized insights about the spread of problematic content on IPFS. We use collected data only for purposes that are permissible with respect to Art. 6(4)GDPR. We operate within the bounds of European data protection law, specifically Art. 5(1)(e)GDPR. We host a user-facing website with our data management policy.[7] We are following data minimization practices: 1) we store the sensitive data for up to 24 months or until we do not need it anymore to complete our research, whichever comes sooner; 2) we are constantly reflecting on our data storage practices; 3) if we conclude that some data fields or whole data sets are no longer needed for our intended purpose, we delete them accordingly. All the acquired content was immediately deleted after analysis.

We emphasize that the badbits dataset is publicly available, and there is no intrinsic way for us to map CIDs to private metadata (*e.g.* the creator of the file). With permission, the takedown request information came from researchers formerly at Protocol Labs. They only accessed the data while still working at Protocol Labs and focused on only the CIDs and the reason for the takedown request contained within the email, which was parsed via script (as shown in Exhibit A.2). Information about the email complainants was not reviewed or used as part of this study.

Due to the sensitivity of the content, we also avoid manual inspection of any material. To circumvent this, we took extensive steps to formulate automatic pipelines capable of classifying the content objects. This does involve downloading each object once. We configure our IPFS node to not provide the downloaded content to other peers. We never inspect the material ourselves and delete the content immediately after classifying it. Importantly, at no point did we download any content recorded as part of a CSAM takedown request. Instead, we shared this information with the IWF and followed their best practice advice at all times.

The files submitted to VirusTotal are publicly available. We only upload those contained on lists curated by Protocol Labs or APS. VirusTotal T&S indicate that the data is stored and shared with authorized parties to "raise global IT security levels". We followed best practices as followed by numerous previous studies that used VirusTotal [56, 59, 69]. Our contribution enabled VirusTotal to detect an additional 3618 malicious files (phishing and trojans) and protect multiple users from online harm.

We note that some of our measurements (the Bitswap, DHT and gateway queries) introduce additional load onto IPFS. As part of this, we rate-limited our queries to reduce the load and, overall, believe that the study had a very minimal impact on operations. This was confirmed by the former Protocol Labs employees themselves, giving us confidence in its safety. Unavoidably, these particular query datasets involved collecting IP addresses. We do not attempt to map these back to personal identities, as such analysis is not within the scope of this study. Furthermore, after performing the geolocation and AS mappings, we make no further use of any IP addresses. Following this step, we perform IP address anonymization using salted hashing The salt is discarded after anonymization to prevent reverting the hash. Finally, we perform no per-user analysis, and focus only on overall system analysis, aggregating behaviors together.

When requesting data from gateways, we used HTTP

[7] https://monitoring.ipfs.trudi.group/privacy_policy.html

HEAD requests without actually downloading the files. This minimizes the overhead and does not expose gateway operators to legal risks. The gateway filtering evasion experiments raise certain ethical concerns because we try to circumvent the blocking of malicious content, and because we ourselves had to provide some data to the network to perform these experiments. For the CID version experiment, we do not provide any data and only check whether gateways correctly implement the specification. For the directory entry evasion experiment, we publish the wrapping directory block, but no malicious content. This experiment also only checks conformance with the suggested blocking methods. The last experiment, for which we provide content using a different hashing function (and thus an entirely new CID) raises limited ethical concerns. The newly-generated CIDs are opaque and known only to us. We stop providing the content after we concluded the experiment. It is thus extremely unlikely the content could spread due to this experiment.

10 Related Work

IPFS. In recent years, numerous studies focus on IPFS. Trautwein et al. [72] present the design of IPFS and evaluate its deployment and performance. Balduf et al. [31] conduct a study monitoring data requests in IPFS. They also examined the viability of running IPFS in restrictive networks, potentially evading censorship [33]. Wu et al. [77] explore the feasibility of using IPFS for decentralized video streaming. Sridhar et al. [67] investigate possible content censorship issues in IPFS. Balduf et al. [32] present a study on the decentralization of IPFS and its implications. They similarly highlighted the importance and high usage of public gateways [30], in particular for NFT-related content. Daniel and Tschorsch [37] propose a method for passively measuring IPFS churn and network size. Prünster et al. [66] discuss the potential eclipse attack on IPFS networks. Trautwein et al. [73] explore techniques for accelerating record storage in IPFS. Wei et al. [76] examine the role of centralization in IPFS and its impact on system dynamics. In contrast to these studies, we focus on content moderation activities in IPFS, and the availability of problematic material. To the best of our knowledge, no prior works have studied this. Our findings can contribute to the design, performance, and security aspects of IPFS.

Moderation in Decentralized Systems. Closest to our work is research on malicious content and moderation in P2P networks, particularly BitTorrent. Cuevas et al. investigate content publishing motivations while proposing TorrentGuard to combat scam and malware distribution [34, 35]. Farahbakhsh et al. examine anti-piracy actions' impact on BitTorrent publishers [41]. Fetscherin analyze movie piracy on KaZaA, highlighting challenges in decentralized file-sharing [42]. Zhou et al. and Kalafut et al. address threats from P2P worms and malware, emphasizing defense strategies [48, 78]. Zuo *et al.* [80, 81] look at moderation in the memo.cash platform. Das *et al.* [38] analyze the NFT ecosystem for security issues. While these studies concentrate on P2P networks, our research delves into similar challenges within IPFS. This is particularly significant considering its evolving role in the Decentralized Web as a storage layer.

11 Conclusion

This paper has studied content moderation in IPFS, one of the largest platforms in the growing "Decentralized Web". We identified, characterized and measured the presence of problematic content in IPFS. We analyzed 368,762 files flagged for inclusion on the Badbits denylist and found copyright material, phishing scams, and even terrorist material.

We also examined whether IPFS gateways filter this content. Gateways play a critical role by facilitating access to IPFS content via HTTP. Although the gateways operated by Protocol Labs blocked all content with accepted takedown requests, there was limited adherence by other operators. For example, gateways operated by CDNs blocked just 19% of such content. We also show that most gateways are vulnerable to simple attacks, *e.g.* using alternative hash functions for naming. We showed that this material was highly available within the IPFS network as there is limited (or no) filtering on IPFS nodes.

We addressed this problem with proposals to improve the speed and quality of the content moderation process. Our solutions increased in 227% the detection of phishing material and reduced the average time to filter such content by 43%. We hope that this work will help developers and operators in addressing the very challenging problem of content moderation in a decentralized ecosystem.

A Additional Methodology

A.1 Initial Gateway Evasion Methodology

For the exploratory directory entry gateway evasion experiment performed in December 2023, we did not create our own directory block wrapper around often-blocked content. Instead, we searched for occurrences of blocked CIDs in *existing* directories. This limits both the directories used as well as the blocked content used for testing, since we needed to find these directory entries.

A.2 Email Classification

The code snippet in Listing 1 shows the methodology to classify the takedown emails.

```
for email in emails:

    sender_domain = email.sender_domain()
    lower_subject = email.subject.lower()
    lower_body = email.body.lower()

    if "Copyright Enforcement Notice" in email.subject:
        email.takedown_type = TakedownType.DMCA
    elif "Notice of DMCA removal from Google Search" in email.body:
        email.takedown_type = TakedownType.DMCA
    elif "Notice of Claimed Infringement" in email.subject:
        email.takedown_type = TakedownType.DMCA
    elif "copyright infringing material" in lower_body:
        email.takedown_type = TakedownType.DMCA
    elif "DMCA Takedown Notice" in email.subject:
        email.takedown_type = TakedownType.DMCA
    elif "alerts@terrorismanalytics.org" in email.from_addresses:
        email.takedown_type = TakedownType.TERRORIST
    elif "Islamic state propaganda" in email.body:
        email.takedown_type = TakedownType.TERRORIST
    elif "child sexual abuse material" in lower_subject:
        email.takedown_type = TakedownType.CSAM
    elif "child sexual abuse material" in lower_body:
        email.takedown_type = TakedownType.CSAM
    elif "cruel animal abuse content" in lower_subject:
        email.takedown_type = TakedownType.AAM
    elif "cruel animal abuse material" in lower_subject:
        email.takedown_type = TakedownType.AAM
    elif "cruel animal abuse material" in lower_body:
        email.takedown_type = TakedownType.AAM
    elif "phising" in lower_subject:  # typo
        email.takedown_type = TakedownType.PHISHING
    elif "phishing" in lower_subject:
        email.takedown_type = TakedownType.PHISHING
    elif "phish" in lower_subject:
        email.takedown_type = TakedownType.PHISHING
    elif "phishing" in lower_body:
        email.takedown_type = TakedownType.PHISHING
    elif "spamcop.net" == sender_domain:
        email.takedown_type = TakedownType.PHISHING
    elif "truelite.it" in email.reply_to_domains:
        email.takedown_type = TakedownType.PHISHING
    elif "scam email" in lower_body:
        email.takedown_type = TakedownType.PHISHING
    elif "restore" in lower_subject:
        email.takedown_type = TakedownType.UNBLOCK
    elif "unblock" in lower_body:
        email.takedown_type = TakedownType.UNBLOCK
    elif "unblock" in lower_subject:
        email.takedown_type = TakedownType.UNBLOCK
    elif "hosting a fake site that contains unauthorized resources" in
       lower_body:
        email.takedown_type = TakedownType.PHISHING
    else:
        unblock_strings = [
            "unable to download pdf",
            "the content is not illegal",
            "the content that i requested has been blocked",
            "contact has been blocked in error",
            "unable to download books",
            "error block",
            "ircorrectly blocked",
            "incorrectly blocked",
            "blocked in error",
            "please unblock"
        ]
        for str in unblock_strings:
            if str in email.subject.lower() or str in email.body.lower():
                email.takedown_type = TakedownType.UNBLOCK
                break
```

Listing 1: Takedown Email Classification

A.3 GitHub Information Classification

The query in Listing 2 shows how we identified any data points that we could not match towards one of our predefined categories. It also indicates which keywords correspond to which takedown type.

```
select *
from github_information gh
where not ( -- dmca
       gh.title like '%DMCA%'
    or lower(gh.title) like '[dmca]%'
    or lower(gh.title) like '%dmca removal%'
    or lower(gh.title) like '%copyright%'
    or lower(gh.title) like '%infringing material%'
    or lower(gh.title) like '%infringing activity%'

    or lower(gh.body) like '%fishing%'
    or lower(gh.title) like '%wetransfer%'
    or lower(gh.title) like '%criminal scam website%'
    or lower(gh.body) like '%domain abuse%'
    or lower(gh.title) like '%domain abuse%'
    )
and not ( -- not possible
    gh.title ~ '\[takedown\] \d+ requests: ''Takedown request \d+'''
)
and not (
    gh.body = ''
);
```

Listing 2: Takedown GitHub Information

A.4 GPT Query Process

To generate summaries and extract information using the GPT model, there are three main components: the *pre-prompt*, the *prompt*, and the *instruction*. Each component serves a specific purpose in guiding the GPT model's response.

Pre-prompt. The *pre-prompt* sets the context and provides any necessary instructions or information before querying the GPT model. It primes the model with relevant details to ensure accurate and coherent responses. For text extraction we use the following:

```
pre_prompt_extraction0 = "In order to extract information, pay attention to the
following file\n"
```

For summaries, we do not provide a pre-prompt. For queries, we use:

```
pre_prompt_query0 = "Pay attention and remember the information below, which
       will help to answer the question or imperative after the context ends.\n"
```

Prompt. The *prompt* is the actual query posed to the GPT model. It directs the model on what information to generate or extract based on the given context. For text extraction, we use:

```
prompt_extraction0 = "Using only the information in the document/file sources
       above, extract: \n"
```

For summaries, we use:

```
prompt_summary0 = "Using only the information in the document/file/ sources
       above, write a condensed and concise summary of key results in a single
       sentence."
```

For queries, we use:

```
    prompt_query0 = "According to only the information in the document/file
       sources provided within the context above, "
```

Instruction. The *instruction* specifies the task or objective to be accomplished by the GPT model. It provides further guidance to ensure that the model's response aligns with our research goals. For PDF summaries, we use:

```
    instruction= "Give a one-line summary of this document"
```

However, we have different prompts for each content type because we observed that mentioning the file type in the prompt enhances the quality of the response we get.

For the subject area we use:

```
    instruction= "Give the subject area of the file or its field please, in
       nothing more than 3 words"
```

Integration. When querying the GPT model, these components are integrated to form a coherent request, structured as follows:

```
"{pre_prompt_query}
{content}
{prompt_query}{instruction}"
```

Note, the ordering might be different depending on whether we are summarizing, extracting or querying the content.

By utilizing the *pre-prompt*, *prompt*, and *instruction* effectively, we facilitate the querying process and enhance the quality of generated summaries, extracted information and labelling.

True Attacks, Attack Attempts, or Benign Triggers? An Empirical Measurement of Network Alerts in a Security Operations Center

Limin Yang[1*], Zhi Chen[1*], Chenkai Wang[1], Zhenning Zhang[1], Sushruth Booma[1], Phuong Cao[2], Constantin Adam[3], Alexander Withers[2], Zbigniew Kalbarczyk[1], Ravishankar K. Iyer[1], Gang Wang[1]

Abstract

Security Operations Centers (SOCs) face the key challenge of handling excessive security alerts. While existing works have studied this problem qualitatively via user studies, there is still a lack of *quantitative understanding* of the impact of excessive alerts and their effectiveness and limitations in capturing true attacks.

In this paper, we fill the gap by working with a real-world SOC and collecting and analyzing their network alert logs over 4 years (115 million alerts, from 2018 to 2022). To further understand how alerts are associated with true attacks, we also obtain the ground truth of 227 successful attacks in the past 20 years (11 during the overlapping period). Through analysis, we observe that SOC analysts are facing excessive alerts (24K–134K per day), but only a small percentage of the alerts (0.01%) are associated with true attacks. While the majority of true attacks can be detected within the same day, the post-attack investigation takes much longer time (53 days on average). Furthermore, we observe a significant portion of the alerts are related to "attack attempts" (attacks that did not lead to true compromises, 27%), and "benign triggers" (correctly matched security events but had business-justified explanations, 49%). Empirically, we show there are opportunities to use rare/abnormal alert patterns to help isolate signals related to true attacks. Given that enterprise SOCs rarely disclose internal data, this paper helps contextualize SOCs' pain points and refine existing problem definitions.

1 Introduction

A Security Operations Center (SOC) is an organization's central unit responsible for detecting, analyzing, and responding to security threats [82]. A key challenge faced by SOCs is to locate signals of *true attacks* from the noisy, unfiltered, and uncorrelated security alerts [4]. Evidenced by a real-world example, during the data breach of Target [26], security alerts were triggered before the attack, but the alerts were unheeded (missed) by the SOC which failed to stop the attack in time.

Recently, researchers have conducted user studies with SOC members to understand what affects the efficiency and effectiveness of SOCs [4, 20, 24, 37, 69, 70]. The results echo that the overwhelming number of alerts generated by security monitoring tools is a common concern [4, 37], which often leads to alert fatigue or burnout of SOC analysts [70, 71]. While such user studies provide a qualitative view of people's perceptions, there is still a lack of *quantitative understanding* of the impact of the excessive alerts, and their effectiveness in capturing true attacks.

A key challenge for quantitative measurements, however, is to obtain real-world data due to its sensitive nature. While a few works have included SOC logs in their study [7, 12, 61, 75], these datasets only cover a short period of time (e.g., weeks). More importantly, the data is only used for "black-box" evaluations of their proposed detectors—often cases, researchers did not (cannot) provide analyses of the data itself. The most related paper is a recent study on a private rule engine from a security company [76] to report statistics of rule changes and false alerts. However, due to privacy concerns, it did not provide detailed analyses of specific (successful) attacks within its client networks (or how these true attacks are detected and investigated).

Research Questions. In this paper, we fill this gap by empirically analyzing the *network logs within a real-world SOC* to explore the answers to the following research questions. *First*, what are the key bottlenecks in the SOC for threat detection, and how do attackers exploit/respond to such bottlenecks? *Second*, how excessive are the security alerts, and what are the common reasons behind the alert triggering? *Third*, how effective are the alerts to correlate or indicate true/successful attacks?

To answer these questions, we obtained a network alert dataset from the SOC of the National Center for Supercomputing Applications (NCSA) via collaboration (approved by IRB). The alert dataset contains 115,617,526 alerts fired by the SOC's network monitoring tool in the past 4 years (2018–

*The authors contribute equally to this paper (co-first authors).

2022). To further correlate network alerts with true attacks, we obtained "ground truth" incident reports from the SOC's forensics analysis. The ground-truth set includes detailed forensics reports of 227 true attacks[1] in the past 20 years (2002–2022), and 11 of them occurred in the overlapping period (2018–2022). We focus on network monitoring tools since they serve a key role in analyzing attackers' reconnaissance, compromise, and data exfiltration activities.

Key Findings. Our analysis returns several key findings. *First*, we observe that *humans* are still the bottleneck, which is reflected in various aspects of the SOC workflow. For instance, the majority of the true attacks (65%) took *more than one analyst* to investigate. While most of the true attacks were detected on the same day (66%), the post-attack investigation (primarily done manually) can take 53 days on average.

Second, our measurement shows that SOC analysts are facing excessive alerts (24K–134K per day), but only a small percentage of the alerts (0.01%) are associated with true attacks. A significant portion of the alerts is related to "attack attempts" (at least 27%) that failed to cause damages. In addition, a large portion of alerts (49%) are benign triggers [37] and can be safely ignored (i.e., correctly matched security events with business-justified explanations[2]). We argue that such "attack attempts" and "benign triggers" are essentially noises in the data labels, and therefore pose a major challenge to learning-based systems that aim to detect true attacks. To the best of our knowledge, no public benchmark datasets are actively measuring and modeling "attack attempts" and "benign triggers" beyond simply classifying network traffic as malicious or benign.

Third, by associating alert logs with true attacks, we find that while the excessive alerts (false positives) are problematic, the *false negative* problem is also concerning. Relying on network monitoring alone has limited capability in capturing the initial host compromise or stealthy post-attack activities. For instance, 4 out of 11 true attacks investigated cannot be detected by the network alerts. In addition, we empirically show there are opportunities to use rare/abnormal alert patterns to help isolate true attacks from other alerts.

Our analysis has positively impacted operational rules at the SOC (e.g., adding new routing policies, §7.3). More importantly, in §8, we discussed key gaps in existing SOC practices (e.g., log linkability, opportunities for automation), and made recommendations to current and future ML-based research that use SOC data to train detectors.

In summary, we present an empirical measurement of network alerts within a SOC based on a dataset of 115 million network alerts over four years. By associating alerts with true attacks, we quantify the impact of excessive alerts and measure the effectiveness of alerts to indicate true attacks. While acknowledging the limitations and biases of the data (i.e., data from a single SOC), we discuss the generalized lessons from our work and provide recommendations for future research on SOC tooling (especially ML-based approaches). To facilitate future research and encourage result reproduction, we release our code and a sample of the alert dataset [78].

[1] We define "true attacks" as successful compromises that lead to damage to the target network. This is different from "attack attempts" which refer to malicious attacks that failed to achieve their goals.

[2] An example can be alerts fired correctly due to a vulnerable Java version, but the SOC chooses to ignore it due to legacy systems [4].

2 Background and Related Work

Security Operations Center (SOC). SOC is an in-house or outsourced unit responsible for monitoring information technology (IT) infrastructures and responding to security incidents [4, 37]. SOCs have three important aspects: people, processes, and technology [4, 82]. First, people: SOCs have a team of security professionals with various duties and roles (e.g., threat hunters, security analysts, and team managers). Second, processes: SOCs involve various workflows in their routine tasks such as vulnerability scanning and handling alerts from Intrusion Detection Systems (IDS) or Security Information and Event Management (SIEM) systems. SOCs typically maintain a *playbook* [69] to document a standard procedure for communicating about and escalating alerts. Third, technology: SOCs may deploy various technical tools to monitor the network and hosts to detect attacks [4, 16, 42, 53, 57, 80].

User Studies with SOC Members. Researchers have studied various challenges faced by SOC analysts by conducting *user studies*. Existing studies have explored SOC analysts' perceptions of IDS usage [24], effectiveness of playbooks [69], system misconfigurations [3], malware detection strategies [1], SOC performance evaluation metrics [1], the "burnout" issues of analysts [70], and how analysts resolve contradictions between people and tools [72].

In particular, Kokulu et al. [37] conducted an interview with 18 SOC members who expressed concerns about the high volume of unfiltered/uncorrelated alerts. However, surprisingly, participants were not concerned about "false positives" (FPs) of the detection tools. Alahmadi et al. [4] further interviewed 20 SOC members to explore the reasons. They revealed that a common perception is that the majority of the "false positives" are caused by *benign triggers*. Benign triggers are correctly fired alerts but can be explained by legitimate behaviors in the organization's context (and thus are safe to ignore).

Our study complements and advances existing literature (which are primarily qualitative user studies) by providing a *quantitative* lens into the problems of security alerts and attack investigation using real-world SOC logs. Also, with empirical data across multiple years, we provide a longitudinal view of how these problems evolve over time.

SOC Tooling. Researchers have proposed technical solutions for threat detection and forensics for SOCs. These solutions broadly include network intrusion detection systems (NIDS) [34, 59, 68, 77, 79], host-based IDS [15, 21, 25,

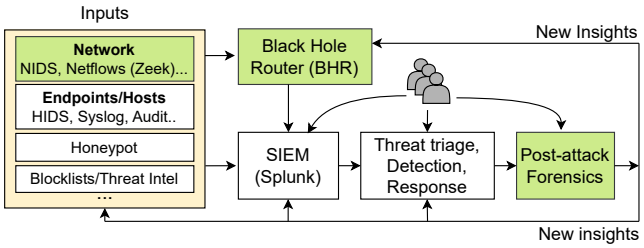

Figure 1: **SOC Workflow**—The highlighted green boxes are the main data sources for our paper. SIEM stands for "Security Information and Event Management."

27, 43, 56], alert triangle [5, 11, 12, 28], verification [38], correlation [61, 63, 66, 75, 80] and prioritization [30, 40] methods, provenance-based threat hunting systems [8, 49], and attack prediction models [7, 67]. The goal of our work is not to develop specific tools but to use real-world data to understand the gaps between existing tools and the needs of SOCs.

A recent paper studied the rule engine used by a Managed-Security-Service-Provider (MSSP) [76] to analyze rule changes and (false) alerts triggered. The key differences are: the prior study [76] was focused more on the relationship between alerts and rule sets, whereas our study was focused on the reasons for alert triggering (distinguishing benign triggers, true attacks, and attack attempts). In addition, [76] did not provide a detailed analysis of successful attacks within the target networks/SOCs, possibly for privacy reasons. Our paper provides a complementary view by diving deeper into one network to analyze its successful attacks and correlate them with alerts.

3 Datasets

We obtained and analyzed the data by partnering with the cybersecurity team at the National Center for Supercomputing Applications (NCSA), located at the University of Illinois Urbana-Champaign. NCSA has been supporting open science research by hosting the first sustained-petascale supercomputer, Blue Waters; and now operates the DeltaAI supercomputer supporting a wide range of workloads for scientific discoveries. The center has thousands of physical nodes, tens of thousands of computing cores, and 10+ petabytes of storage interconnected internationally via a terabit network. The SOC monitors the network/system and user activities leveraging a wide spectrum of internal, open-sourced, and commercial tools to detect and respond to security incidents. Figure 1 shows a simplified view of the process. The SOC analysts use a Splunk dashboard for Security Information and Event Management (SIEM) [41], which provides a real-time view of security events collected by network monitoring tools, system logs, Linux kernel audit logs, and other internal and external data sources (e.g., blocklists, honeypots, threat intelligence).

Network Alert Dataset (2018–2022). Our preliminary dataset contains the *network-level* alerts fired between April 2018 and July 2022 by the SOC's network monitoring tool Zeek (a widely-used open-source tool [81]). As shown in Figure 1, the SOC maintains a customized rule engine that analyzes a variety of network and system logs to detect events that match the pre-defined rules. The network monitoring tool is one of the main sources of alerts. There are other alerts from endpoint/host-IDS, partner sites, and other commercial tools, to which we don't have access. In other words, the dataset represents a lower bound of alerts from this SOC.

Term	Definition
True attacks	The attacker successfully compromised the system and/or caused damages
Attack attempts	The attacker tried but failed to compromise the system or cause damages
False positives	Benign activities that are incorrect determined as security attacks
Benign triggers	Correctly matched security events but have business-justified explanations [4]

Table 1: **Definitions**—Key terms used in the paper.

In total, the dataset contains 115,617,526 network-level alerts. Each alert is characterized by a timestamp, involved IPs, an alert category, and other metadata. Starting from 2020, the SOC implemented a Black Hole Router (BHR) [39] (see Figure 1) to automatically handle a subset of these Zeek alerts without human involvement (e.g., blocking IPs associated with the alert) in real-time. As such, our dataset contains the BHR label from 2020 to 2022.

Ground-Truth: True Attacks. To understand how effective these network alerts are in informing the SOC of true attacks, we also gather data about the ground truth of successful attacks and compromises in the past two decades. This dataset is from "post-attack forensics", as illustrated in Figure 1. The definition of *true attack* (see Table 1) is based on whether the attacks have caused major degradation/interruption to system operation or whether there was evidence of data leakage or system compromise. This dataset contains 227 true attacks from January 2002 to March 2022. Among them, 11 occurred during the overlapping period with the alert dataset (2018–2022). For each attack, SOC analysts collected a set of attack artifacts (e.g., logs, binaries, VM images), conducted a detailed investigation, and produced a report describing their investigation process and conclusions. The reports were written in an unstructured format, describing details about the user accounts, IP addresses, or machines related to and/or responsible for the attacks.

Is the Dataset Biased? We believe the answer is "yes." Given the dataset was collected from a single SOC, we do not expect the result to generalize to all SOCs. Instead, our goal is to present an in-depth case study for a SOC-type that is complementary to (different from) other existing studies. This SOC's network has thousands of servers with 17,000+ active users/researchers, and it represents a typical moderate/large-

sized research facility. The SOC has 9 members, which is among the most common SOC team sizes (2–10) [64]. Note that this SOC is SOC-2-Type-2 [2] certified, which testifies to the legitimacy of its security infrastructure. The SOC's network is *segmented* where certain parts are heavily guarded while other parts are configured as "open networks." The open-network setting allows both users within the research center and researchers outside of the network to access the computation nodes. This presents a unique contrast with enterprise/private networks that usually have a strict firewall to secure the perimeter (i.e., the access to internal resources is usually not openly shared with external parties). In this open network, both malicious and legitimate connections may come from anywhere in the world, making it difficult to flag attacks. Such open-network configuration is common for open research infrastructures. The SOC may not represent those of government agencies or large companies, but one useful context is this research institution not only supports scientific computing but also runs government/military applications. The incidents observed by this SOC are diverse because it not only monitors open networks (recording popular incidents such as volumetric DoS, password guessing, or database ransoms) but also monitors special network segments of closed systems that work with highly regulated industry partners (HIPAA in healthcare) and CUI data with national labs (recording sophisticated incidents such as zero-day exploit privilege escalation and lateral movement to national labs).

To better interpret our results, we note the following limitations of this data. First, the data is from a specific SOC, and thus the result may be biased due to the specific SOC type, size, certification, and network characteristics. These factors should be considered for our result discussion (e.g., in §8). Second, the alert dataset is focused on network alerts which is a lower bound of all alerts in the SOC. The results and observations may not be applicable to host-level alerts or Endpoint Detection and Response (EDR) systems.

What's the Value of Analyzing Private Data? Considering that real-world SOCs rarely share their internal attack details, we believe the data can provide a unique opportunity to quantify the problem related to alert filtering and investigation and study the longitudinal changes of a SOC's threat investigation practice. Based on our analysis, we believe some of the observations and findings have broader/generalized implications, which will be further discussed in §8.
