M1 Collaborative Safety Planning. The support providers and the participant collaboratively participated in forming a safety plan. The support provided technical advice, from taking actions on their behalf to assisting the participant in taking conscious security and privacy actions on their devices and accounts. For some participants, their friends, family, and housemates acted on their behalf, confronting the abuser to stop the abuse, threatening to call law enforcement, and offering them physical safety and comfort. Regarding technical advice, the participants were advised to block the abuser, create alternative accounts and new mobile plans, enable two-factor authentication, restrict location sharing on their phone, change the account password, switch off the social media comment section, and make their profile private. One support provider helped the participant collect evidence of abuse "*my housemates had the idea of taking a picture of my phone with the chat open on the screen, so that we have a copy of it, and [abuser] doesn't know that I took a screenshot.*". Despite not being technology-savvy, the support networks were collaborative in their efforts to learn about the nuances of technology alongside the participants to support them. Some friends alerted participants about a password breach and worked with them to debug their technical issues. In one case, a participant's friends showed them the corresponding privacy settings on WhatsApp so that they could identify and disconnect the abuser's device and the IP address. Although technical actions taken by the support networks were practical, in some cases, the abuser persistently created new accounts and phone numbers to bypass their actions. Therefore, campaigns are needed to raise consciousness about the IPV threat models (§ 6).

M2 Support Groups. Due to the lack of availability and stigma, some participants joined support groups such as relationship advice groups on Facebook to learn from other's stories of abusive experiences and their coping mechanisms. The participants believed that support groups provided extra protection that allowed them to learn safer privacy and security practices that worked for others in defying coercion and control of the abuser. Although participants faced challenges of identification and abuser's retaliation, participants championed the use of support groups—

"I'm not the only one that's gone through this; it feels so unfair when I think I'm the only one. I joined Facebook support groups for people [who] are in this situation, and I read other people's stories. I shared my story, and I got a lot of support. It was just really helpful to realize that many ex-partners and co-parents do this. It made me feel a lot less alone in my struggles. . . so many other people have gone through this before, and they still managed to come out successful and achieve their dreams, raise their families, succeed in their careers, and achieve financial independence; . . . accomplish all the things that I'm trying to do. It was an emotional boost for me to realize that this is just another one of the hurdles in my way . . . making it difficult for me to get what I want, but still doable."

M3 Informal Networks of Care. Most importantly, almost all participants supported TFA survivors. They felt that prior experiences of helping others facing abuse were instrumental in seeking support and realizing the importance of a robust community that can provide support. Since informal networks are more accessible than formal networks, we press on the need for a community-oriented informal network of care, following the calls for action in prior work on formal networks of care [102, 114]. In a similar vein, Goodman et al. [52] call for a social network-oriented approach to services, thus making IPV a problem of the community rather than a problem between two individuals.

Even though an abuser controls the social networks (B3) and may retaliate (C7), the informal network of care may provide robust support to the survivor. We hope the existing formal networks such as law enforcement, Tech Clinic, DV organizations, and institutions can develop and foster these networks through awareness, education, and community engagement to create awareness among the survivors. The survivors may access these services from their next-door neighbors instead of long, burdensome walks to seek support from formal networks. A survivor turned DV advocate shared their story of abuse and providing support to others—

"I have an opportunity to share my story and create positive change, even support research efforts. It feels rewarding to be able to help benefit other people from my experiences. On my Facebook page, I share quite a lot about my stalking and harassment situation. I'm pretty public about it. I want people to know that this is what I'm experiencing because it makes it easier for me to seek help when I need it. . . . and so I ended up becoming a magnet attract other survivors. People think they're experiencing domestic abuse, but they're not sure, and they don't want to ask

for help because it's so embarrassing [and] stigmatizing. They talk to me because I won't judge them . . . as a champion for fighting domestic abuse, both personally and professionally."

M4 Referrals to Formal Networks. The participants were referred to formal networks such as law enforcement officers and legal attorneys in the Criminal Justice System, mental health professionals, and DV organizations. The support networks provided several resources that helped the participants seek formal support, e.g., a police information sheet upon the abuser's arrest, online resources found on the Internet, and referrals by their friends and local DV organizations. Some participants faced abuse as college students. Therefore, they had access to the formal network of the University's Title IX, campus police, and Resident Advisors, who all served as mandatory reporters. Friends and the resident advisor referred participants to the Title IX office at their University. This referral meant they had access to law enforcement, legal advocates with specialized court hearings for students, academic accommodations, and a mandatory counselor to help with their mental health. The participants described the interactions with the Title IX office as largely positive; it provided a 'one-stop-shop' solution to all their various needs [75].

In one case, the abuser obtained the survivor's cellphone number by calling the customer support executives of their mobile service provider to portray themselves as the victim and survivor as mentally unstable or declaring them dead. Moreover, they were sometimes effective when the participant contacted the IoT device's customer support executives. They received "*essentially step-by-step instructions that were readily available on Google that I had already found previously.*" Talking to an executive validated their suspicions and paranoia, which was the survivor's way of understanding the threat model and covering all bases to prevent attacks from the abuser. Zou et al. [128] examined the effectiveness of the support provided by the customer support executive and provided recommendations to improve them and provide trauma-informed support.

"I wanted to just make sure that I had fully removed and that there wasn't any opportunity for them to come in. . . I thought. . . I remove[d] them both [the abusers], [as] I couldn't see them there anymore. But the paranoia in me was not sure if I had done it fully, completely, accurately. And so I wanted just validation that I had done it and that they were gone [for good]."

M5 Convenience of Technology. Some participants contacted their friends over WhatsApp, Facebook Messenger, SMS, and Facebook Groups to seek help from friends and their social networks, especially those facing severe physical isolation. The abuse changed participants' relationships not only with their friends, family, and the people in the support networks but also with technology. On the one hand, the participants used it as an opportunity to filter out the people who did not support them and, on the other hand, form stronger relationships with those who did. Interestingly, a participant used technological means for "*reaching out to the people who had been isolated from me, the people I've been told I couldn't talk to [by the abuser]. Just as a way of reconnecting and being able to decide for myself if these were good friendships.*". Prior work highlights this dichotomy as technology may both act as a weapon of abuse and a shield for protection [59, 70]. A participant talked about the convenience of technology and remote communication when seeking help rather than, say, visiting a therapist

"If [you] want to disclose [the abuse] to a counselor, I think it's better said online, through. . . technology, because there's [a] fear factor about being scared, canceled, or blamed. . . . You're [going to] leave out some details. I think when typing, you have all the time to ask yourself about not leaving out details."

The participants talked about technology's inevitability, ubiquity, and convenience in their daily lives for communicating with their contacts and professional work. Although a few participants took a cautious approach to technology adoption, others used TFA as a learning experience to develop technical skills for their personal fulfillment and professional careers for financial independence. As one participant says "*my career aspirations in the tech field have benefited me in a way that I didn't even anticipate to begin with at the start*". However, the non-physical and ubiquitous features of TFA contributed to illegibility to outsiders who deny social recognition and validation, which makes survivors question their experiences [47, 123]. A participant described TFA as "*the ultimate form of power and control and termed it as insidious, insane, and isolator.*". Therefore, we echo participants' call for action to make TFA more "visible" to the survivor and their support networks.

6 Discussion

Survivors utilize effective coping mechanisms (§ 5.3) despite facing barriers (§ 5.1) and challenges (§ 5.2) in seeking social support. The survivors believed that there was not enough support available to resolve TFA. They provided recommendations for other survivors in a similar situation while emphasizing that it takes a "*village to make social change.*". Therefore, we offer recommendations for technology design (§ 6.1), community engagement (§ 6.2), and advocate for legislative and policy actions tailored to the US context (§ 6.3). We use the upstream parable (§ 3.3) to situate recommendations as **tertiary (down-stream, T), secondary (mid-stream, S), and primary (up-stream, P) interventions**. Finally, careful consideration is required to generalize and attune these interventions to reflect the socio-cultural norms of the survivors' community.

6.1 Improvements in Technology Design

Safer design cues. (S, T) The participants stressed the importance of technology design that supports the identification of TFA (B1) and heightens priority (B7). It is crucial to be precise to flag realistic ways an abuser can misuse the technology and avoid raising hypothetical dangers. Survivors

are under stress and may have high levels of paranoia while engaging with their technological devices. The last thing they need is another false positive sign that makes them question their decisions. Chen et al. [29] recommends providing "clear information for software updates that warns users ahead of time on any upcoming & settings changes, with options for whether and when to update"· Similarly, "for security warnings, reflect on the impacts of established 'best practices' (e.g., using harsh colors and forcing attention)" on survivors [29]. Mobile and smart devices should promote digital safety practices such as safe account sharing [29, 77, 79] and account security interfaces [37]. Explicit permission usage and privacy disclaimers in dual-use applications on the mobile operating system can support survivors against non-consensual location tracking [46].

Onus on Tech Companies. (S, P) The participants critiqued Meta's content moderation and report abuse policy in the face of defamatory posts from an abuser. The participants generally struggled with the privacy preferences and report abuse functionality, as the abuser frequently kept deleting the posts. They did not receive adequate support from Meta's customer support. The participants stressed that the onus is on platforms to provide safety and privacy and reduce the onus on the survivor (C3). Prior works indicate the need to empower survivors with control and agency [29, 46] through online safety features to recognize and deal with risks of online harassment [4, 5, 19, 63, 87]. Survivors look for accountability (C3,C5) and evidence-based mechanisms (C6) from social media platforms to ensure safety [4, 110].

Safe communication for seeking support. (S, T) Survivors need intelligent guidance for safer responses, with nudges for seeking support (B2, B4) [4, 46, 62, 71, 81]. End-to-end messaging apps are often marketed as "secure" solutions but are primarily designed to protect against traditional network-based adversaries. However, this approach creates a disconnect in threat models when users assume "secure" means protection from TFA. Slupska et al. [103] notes that the presence of an abuser in the home complicates the safety of survivors. Chen et al. [29] recommends working with survivors to surface adversarial goals and adding "causing psychological distress" as a primary goal. The designers should aim to provide survivors with a secure means to seek support even in compromised device scenarios without opening further channels of abuse.

Informal safety planning. (S, T) Survivors seek support from their informal networks as one of their initial coping mechanisms (M1). The participants highlighted the need for their support networks to be more trauma-informed and tech-knowledgeable. As Zapor et al. [127] suggests, informal networks are a critical avenue to explore the usability and safety challenges. Community-engaged solutions require preventive instead of reactive design interventions to support potential abusers and make digital spaces safer (B3, C7) [4, 5, 16, 112].

In addition, the participants discussed how the support networks could learn more about the support guides and resources on TFA to help them effectively. The participants talked about how search engines can provide personalized advice by tuning their algorithms to be more trauma-informed.

> *"When you look up DV, technology, or whatever on Google, I understand Google has a particular way they want to show results, but it's always overwhelmingly hotline, resources for survivors, etc. And it's never resources for service providers; it is very hard; you have to dig through resources online to search for something geared towards service provision. That's very harmful for anyone who wants to try to be supportive sometimes, which is just an algorithmic thing."*

Majed et al. [7] found that resources for abusers are significantly more understandable and actionable than survivor support resources. The ever-evolving design of technical systems requires community support. Discoverability of community-generated tutorials and guidelines for search engines is essential to inform the support providers.

Effective formal support networks. (S, T) Survivors noted DV hotlines and social media platforms to be quite effective, as noted in prior studies [53]. There is a greater need for anonymity and content moderation to ensure participants feel safe in these support groups. Although self-organized support groups are understanding and compassionate, social media companies can reinforce trauma-informed principles to remind members to support survivors who share intimate stories of abuse [96]. Furthermore, we observed that the abusers retaliated when the survivor "cold-turkey" blocked them on digital platforms. Prior works in behavioral psychology proposed the Grey Rock and Yellow Rock techniques to protect against an emotionally abusive person by slowly becoming unresponsive and disinterested [25]. Platforms can adopt similar practices to limit interactions with the abuser. Gregory et al. [53] explore the dynamics of support sought on behalf of the survivor from DV hotlines. We believe that hotlines could provide adequate tech support.

6.2 Community Engagement

Some barriers (B2, B4, B5) and challenges (C1, C2, C5) are societal in nature.

> *"I feel transparency ... and knowing technology is a tool just like anything else for abuse. You have to address some underlying roots of violence. People fall into these situations because of things like low self-esteem, not having the self-confidence to say no, not being in the physical world, [and] being financially dependent. So many things that happen outside of technology are really hard."*

Collaboration with community. (S, T, P) Community-driven social change is needed to raise consciousness in the community to promote safer coping mechanisms (M1, M3, M2, M4). The participants emphasized the importance of education and raising awareness through lexicon common in DV circles, such as gaslighting, surveillance, and coercive control,

to make it easier for providers to understand the signs of abuse (B1). Taking inputs from fraud and cyberharassment campaigns [126], educational content and awareness campaigns should center themes about consent around technology, informational support resources, and digital safety. Formal support services could work with local tech-support groups to distribute these trainings. In college campuses, prior works show the effectiveness of interventions in communities such as violence awareness campaigns, bystander interventions, supportive residential committees, and survivor-support services [20]. Moreover, faculty, staff, and the Title IX office can foster informal groups to support students [21]. Munro et al. suggest that support service models should use a "one-stop-shop" strategy to provide support for health, financial, and housing services that a survivor requires to cope with abuse [75].

Marginalization experienced by the survivors. (P) Socioeconomic factors amplify the risks to digital safety and privacy [33, 54, 64, 73, 95, 104]. The participants stressed that technology creates more significant disparity among marginalized communities—

> *"Disproportionately, [TFA] happen[s] to women and marginalized communities. Most technology is [used by] upper-middle class and highly educated people. It makes those tools even easier to create a bigger disparity and what people know and can't know. [I was] sitting next to a lady at the airport, who was pointing out a USB port 'Is this where you connect to the Wi-Fi?' when Wi-Fi is literally wireless."*

Gupta et al. [54] suggest that an intersectional analysis is needed to untangle the complex web of marginalization. Black women are 35% more likely to experience IPV than White women [76]. Further, 84.3% of Indigenous women face IPV, significantly from a non-indigenous partner (97%) , due to colonial and generational trauma [68, 88]. Further, men may face a lot more stigma in disclosing abuse and seeking support [36, 119]. Gupta et al. found that college students who face TFA, 68% of men do not seek support as compared to 47% of women [54] Ybarra et al. found that fewer men (21%) sought support from friends and family than women (43%) and LGBTQ+ (48%) [125]. Moreover, 81% of women who face physical or sexual IPV disclose to at least one informal network, but only 57% of men disclose abuse [11]. Prior works highlight the importance of socio-cultural norms and family dynamics in the online abuse contexts [94]. Therefore, future research is needed to understand the barriers, challenges, and coping mechanisms used by survivors in non-western contexts.

Participatory perspectives. (P) Most participants were interested in contributing to the research. Therefore, we follow a participatory approach to incorporate participants' calls to action. Bellini et al. suggest that research in IPV spaces should be treated as interventions [17, 18, 118]. Even though semi-structured interviews have proven to be insightful, they naturally establish a power dynamic relationship between the research and the participant [12, 82, 101]. Slupska et al. have championed a participatory-focused framework for threat modeling with at-risk stakeholders in S&P [100, 101]. More at-risk populations should be brought into the knowledge construction system to reduce the power imbalance. Moreover, we use Glaserian Grounded Theory [51] instead of Constructionist Grounded Theory (CGT) [26]. In CGT, neither data nor theories are "discovered" but are constructed by the researcher due to their interactions with the participants. The data is collected before building a hypothesis, hence the participatory nature of the research. Therefore, the S&P community needs active involvement from the survivors and stakeholders of support providers in designing research studies [116].

6.3 Legal and Policy Interventions

Informed formal support. (S, T, P) The participants emphasized the need for support providers in positions of power, such as Title IX, law enforcement officials, advocates, and judges, to provide practical and informed assistance that fits their needs. Further, in the face of receiving dismissive and misogynistic comments from formal networks, the participants highlighted that providers need to check their biases and misogyny when providing support. The survivors faced frequent institutional betrayal and disenfranchisement (C5) in presenting digital evidence (C6) and sharing intimate details about the abuse. To build trust, Woodlock et al. [123] suggest that instead of deprivation, survivor grief should be met with understanding, acceptance, and acknowledgment of the potential of transformative healing. Policymakers must plug legal loopholes used by the abusers to subpoena confidential documents and support interactions of the participants. Moreover, while visiting the courts, a trusted companion can provide emotional safety and reassurance and help explain technical and legal nuances. At the time of writing (June 2024), many US states have started Court Watch programs where community members are trained in civic engagement to raise awareness [1]. Therefore, a future study is needed to understand the effectiveness of the technological evidence of TFA and CourtWatch programs. Moreover, a survivor turned DV advocate underscored the lack of monetary resources and awareness among the DV advocates. Given the prevalence of TFA (63-80% of IPV cases [54, 73]), DV organizations should equip advocates to deal with TFA through training.

> *"I work a lot with nonprofit DV agencies, and they have no idea what's going on in technology. ..They're not trained in technology, and it's a lot to ask of them. I really wish that there were more technologists and IT support staff for DV. Or have it embedded into the design of systems, to make it easier for people to find stuff."*

Policymakers must recognize TFA. (P) The participants who sought help from the US criminal justice system highlighted that the US state and federal courts are way behind in acknowledging TFA. They found that the legal stakeholders are dismissive and frustrating, and the laws around technology

"favored the abuser quite nicely". Stephenson et al. [105] propose that the requirements for prosecuting TFA can be more explicit. Most US states follow one-party consent for video and call recording, which means that an abuser does not need consent to film the survivor. Therefore, a participant called for a "*restorative justice-oriented framework*" to place the survivors' lived experiences and the disenfranchisement and fear at the core of policies around TFA to inspire trust in the criminal justice system. A participant highlighted the challenge of technology as a form of communication:

> *"My restraining orders and bail conditions say no direct or indirect communication with me. How is it then that you can call me out by title and history and sometimes by name [on social media posts], and that is not considered a violation? How is it that you can publicly defame me continuously, and there are no repercussions? And no one can even tell you to stop? How is it that they can literally post 'breaking the law' and no one cares? because the Internet is not a person, is what I was told."*

The prosecutors may face difficulty in proving the abuser's intent of harmful communication that causes emotional and psychological distress. As abusers often manipulate their devices, the prosecution based on exceeding authorization through current computer fraud laws becomes meaningless [35]. Therefore, significant legislative changes are needed to discourage TFA and incentivize tech companies. At the time of writing, the policymakers in the US have proposed legislative changes. Federal Communications Commission (FCC) successfully adopted laws that provide different forms of support to survivors, such as no-cost separation of mobile phone lines shared with an abuser [44]. In addition, they released a call for comments to aid the survivors with affordable connectivity access [45].

Acknowledgment

We appreciate the participants' time and willingness to share their lived experiences with us. Without whom, our research, recommendations, and discussion for future research wouldn't be possible. We acknowledge the Ho-Chunk Nation on whose ancestral lands we are grateful to work and live as guests. We deeply respect the knowledge embedded in the Ho-Chunk's custodianship of Teejop and recognize their continuing connection to land, water, and community here at the University of Wisconsin-Madison. Further, we acknowledge funding from the Office for Victims of Crime, Office of Justice Programs, U.S. Department of Justice (Grant # 15POVC-23-GK-01414-NONF). The opinions, findings, and conclusions or recommendations expressed in this paper are those of the contributors and do not necessarily represent the official position or policies of the U.S. Department of Justice. Finally, we thank the reviewers, Ruhani Amin, Jessica Melnik, and Sophie Stephenson, for their reviews and suggestions.

From the Childhood Past: Views of Young Adults on Parental Sharing of Children's Photos

Tania Ghafourian

Sameer Patil
University of Utah

Abstract

Parents increasingly post content about their children on social media. While such sharing serves beneficial interactive purposes, it can create immediate and longitudinal privacy risks for the children. Studies on parental content sharing have investigated perceptions of parents and children, leaving out those of young adults between the ages of 18 and 30. We addressed this gap via a questionnaire asking young adults about their perspectives on parental sharing of children's photos on social media. We found that young adults who had content about them shared by their parents during childhood and those who were parents expressed greater acceptance of parental sharing practices in terms of motives, content, and audiences. Our findings indicate the need for system features, policies, and digital literacy campaigns to help parents balance the interactive benefits of sharing content about their children and protecting the children's online footprints.

1 Introduction

Children are a vulnerable population[1] with the potential for experiencing harms to a disproportionately greater extent [45, 68]. Parents are the stewards of their children's online presence and privacy as children are too young to create a digital presence on their own and ineligible to create accounts on most online platforms [50]. The practice of parents sharing content (e.g., photos, videos, status messages, etc.) about their children is often referred to as "sharenting," a portmanteau of the words "sharing" and "parenting" [24, 55]. Although the term is often used with a negative connotation, especially by the viewers of the shared content, sharing content about their children is a common everyday practice for many parents [14, 71]. Such sharing provides parents with various benefits, such as keeping in touch with family and friends [6, 38, 39, 76], getting parenting support and advice [6, 76], monetizing the shared content [5, 16], etc.

[1] https://unglobalcompact.org/what-is-gc/our-work/social/childrens-rights

Parental sharing of content about their children is connected to harms related to digital technologies [28] and to the impact of an individual's actions on the privacy of *others* [49]—both aspects are receiving greater research attention. Content shared by their parents has the potential to result in negative consequences for the children—in childhood and beyond—by increasing the surface and vectors for privacy and security violations, such as identity theft [47], unwanted information disclosure [54], embarrassment [57], cyberbullying [71], digital kidnapping [72], generation of synthetic child pornography based on the content [56], creation of deepfake content mimicking a child [30], etc. For instance, 14% of American parents have reported that the identities of their children were stolen, and 21% have found that their children were cyberbullied [74]. Moreover, excessive parental sharing of content about them can frustrate children [31] and harm their relationships with their parents [54]. To avoid such risks, some parents choose to refrain from sharing *any* content related to their children [17].

However, many parents feel that the benefits of sharing content about their children outweigh the potential risks [10, 79], especially if they follow basic risk mitigation strategies such as not sharing "inappropriate" content [38] or not making the content accessible to anyone except their "Friends" [37]. In a recent survey, 77% of American parents reported sharing photos of their children online [72]. As a result of the content shared by their parents, as many as 80% of American children have a digital presence by the age of two, with an average of 1,500 photos of them posted online by the age of five [50].

While the literature on parental sharing of content about their children captures the perspectives of parents, children, and adolescents, there has not yet been an investigation of the views of young adults (i.e., those between 18 to 30 years of age [42, 65]). Moreover, studies in the literature have focused on understanding the impact of parental sharing of their children's content in the short term. Understanding the perceptions and practices of young adults whose parents might have shared content about them during their childhood can shed light on longer-term influences of such practices given that childhood experiences can often linger on and influence

life during adulthood [33]. To fill the gap in the literature, we investigated the perceptions and practices of young adults related to parental sharing of their children's content to answer the following research questions:

RQ1: How do young adults perceive parental sharing of content about their children?

RQ2: Do perceptions of young adults regarding parental sharing of content about their children vary based on experiencing parental sharing of content about them during childhood?

RQ3: Do perceptions of young adults regarding parental sharing of content about their children vary based on their relationship with the child whose content is shared?

RQ4: Do perceptions of young adults regarding parental sharing of content about their children vary based on being a parent?

We addressed the above questions in the context of photo sharing because parents make heavy use of social media platforms for photo sharing [44] which has made it the predominant focus of inquiry in the literature on parental sharing of content about their children. To answer the research questions, we designed an online questionnaire inspired by prior work on parental photo sharing [7, 20, 38, 76]. We distributed the questionnaire to young adults between the ages of 18 and 30 on the Amazon Mechanical Turk (AMT) crowdwork platform and via online forums. We collected and compared views on photo sharing from multiple perspectives by randomly assigning participants to one of three between-subjects study conditions corresponding to three scenarios: (i) one's parents sharing photos of oneself during childhood; (ii) oneself sharing photos of one's own (real or hypothetical) child; and (iii) *any* parents sharing photos of their own child.

We found that young adults determine the acceptability of parental sharing of photos of their children based on the motives for sharing the photo, the scene depicted in the photo, the age of the child in the photo, and the audiences with whom the photo is shared. However, the views of young adults about parental sharing of photos of their children are mostly independent of their relationship with the child in the shared photo. Importantly, we observed that having one's photos shared by one's parents during childhood can make young adults view parental sharing more favorably and make them more likely to engage in it themselves when they become parents. Based on these findings, we make the following contributions:

- we fill a gap in the literature by providing perspectives of young adults on parental sharing of photos of their children;
- we show that having one's photos shared online by one's parents during childhood can influence one's parental sharing perceptions and practices as an adult; and
- we offer suggestions for system design, regulatory interventions, and digital literacy campaigns grounded in the findings to help protect children's digital footprints resulting from parental sharing.

In the sections that follow, we situate our research in the literature on parental sharing of content about their children. Subsequently, we describe our study design, participant recruitment, and sample characteristics. We then present analyses of the participant responses to answer our research questions. We proceed to a discussion of the main takeaways of our findings followed by applying the insight to facilitate safer parental sharing of content about their children.

2 Related Work

We first provide the contextual background for parental online sharing of content about their children, with a particular focus on the popular practice of sharing photos on social media [21, 34, 36]. Afterward, we discuss existing research on the privacy perceptions of parents and children regarding parental sharing of content about their children.

2.1 Perceptions of Parental Sharing of Content about Their Children

Several studies carried out to understand why parents share content about their children on social media collectively reveal that such sharing is driven by one or more of the following reasons: keeping in touch with family and friends, seeking parenting advice, getting affirmation and support, showing pride in their children, making others envious, portraying themselves as good parents, archiving the childhood of their children, increasing their online popularity, earning money by advertising, and attracting followers [5, 6, 16, 38, 39, 48, 51, 73, 76]. While some parents report refraining from sharing *any* information about their children due to the potential for future embarrassment for the children [20], others believe that the joy their children may derive from viewing these photos in the future would compensate for potential future embarrassment [4]. Moreover, researchers have found that parents tend to feel that *they* should maintain control over posting about their children online, rarely seeking their child's consent before sharing [4]. These findings underscore a potential disconnect between parental sharing practices and their children's preferences [53]. Our research aims to examine this aspect by investigating the views of young adults regarding parental sharing of their children's photos.

A number of studies focus specifically on parental sharing of photos of their children to understand the motives of parents [38, 39, 76], the type of photos of their children that parents share [38, 76], and the audiences with whom parents share photos of their children [7, 20]. In addition to the perspectives of parents, researchers have investigated how children and adolescents perceive parental sharing of their photos on social media. These investigations highlight the varying and nuanced perspectives of children and adolescents regarding the types of photos shared by their parents, with preferences dependent mainly on the content of the photo, the age of the child, and the recipient(s) of the shared photo. For instance, Moser et al. [54] found that 10–17-year-olds

report general acceptance of parents sharing photos that portray a positive parent-child relationship and a happy family life. Conversely, the adolescents objected to parental sharing of photos that are embarrassing (e.g., "naked butt baby pictures") or unflattering (e.g., "hair isn't fixed"), those that reveal personal information (e.g., photos containing "private stuff"), and those that expose body parts (e.g., "kids in their underwear in a bathtub") [54]. Similarly, Ouvrein et al. [57] found that 12–14-year-olds prefer that their parents avoid sharing unflattering or embarrassing photos, especially those in which they look or behave oddly. The children in Ouvrein et al.'s [57] research were accepting of parents sharing photos that capture special events, such as birthdays, games, milestones, family trips, or vacations, and found it reasonable for parents to share photos of babies, primarily due to their cuteness. Another study has noted that middle-school-age children determine the acceptability of parental sharing of their photos and videos based on the recipient(s) of the content and the content itself [53]. With regard to teenagers, Bell [8] found that teens do not mind their parents sharing socially and physically attractive photos of them. More specifically, teenagers find it acceptable for their parents to share photos of them when they were babies, photos showing their achievements, and photos that portray their happy family life [8]. In addition, teenagers have reported finding it acceptable for their parents to share photos of their family activities and vacations as long as they are well-dressed and in good poses in the shared photos [78]. However, teenagers in the same study regarded photos in which they do not look good as embarrassing and were against their parents sharing their personal information online [78]. To refine these findings from the literature, we asked separately about four distinct stages of childhood.

Based on an analysis of the perceived sensitivity of the types of photos shared on social media, Li et al. [41] found that photos containing children are considered sensitive "when the child is nude, is wearing inappropriate clothes, or in a dangerous situation" [41]. The categories identified as sensitive by Li et al. [41] overlap with the photo types that children prefer not to share as reported in various other studies [8, 54, 57, 58, 78]. We investigated the perceptions of young adults regarding parental sharing of their children's photos by using the 19 photo types relevant to children out of the 28 included in Li et al.'s [41] taxonomy of sensitive photos. For instance, we excluded work-related photo types (e.g., "activities that break work rules") because children do not work.

2.2 Perceptions about Privacy

Sharing photos of children can impact the children's privacy in a variety of ways [3, 29]. For instance, those beyond the intended audience(s) might view the shared photos [3, 40, 62]. Children express worries about who might see their photos online, especially if the audience includes "strangers" [53]. Nevertheless, some parents report no concerns about sharing their children's photos with a broad audience [4, 7, 20].

Researchers have noted, however, that many parents are aware of the risks associated with online sharing of personal information of their children [10, 79]. Parents report a variety of strategies aimed at balancing the benefits of sharing photos of their children while respecting the children's (privacy) preferences [10, 79]. These strategies often entail limiting the sharing of children-related content [61] or restricting who can access the content [44]. For instance, Brosch [14] found that parents tend to share pictures that reflect joyous occasions, such as holidays and special events, thereby emphasizing the positive aspects of their children's lives. Conversely, Wagner and Gasche [76] have reported that parents avoid sharing photos of their children that they deem sensitive, such as those that could be construed as offensive, or may engage in additional protective actions, such as obscuring children's faces prior to sharing. Further, Kumar and Schoenebeck [38] found that parents often refrain from sharing photos that could be seen as overly exposing the child or the mother (e.g., images of naked babies, newborns, or intimate mother-baby moments) or those that might portray their children in a negative light (e.g., showing them crying or in potentially embarrassing situations). Parents typically do not share low-quality photos (e.g., blurry or out-of-focus images) either [38].

As Kumar and Schoenebeck [38] have noted, parents follow various strategies to manage risks and trade-offs when sharing content about their children online. For example, some parents share content about their children only with their friends [7]. Nonetheless, it is important to note that such actions may not always be accurately enacted because a large proportion of parents report a lack of proficiency in modifying privacy settings [44]. Another study further suggests that some parents do not fully comprehend the risks to themselves and their children that can arise because of sharing content about their children [18]. Paradoxically, even parents who express higher privacy concerns may not reduce their sharing of content about their children [10]. For instance, Livingstone et al. [44] noted that British parents concerned about privacy were the ones who shared more content about their children. Relatedly, Ranzini et al. [61] found that the amount of content parents shared about their children was uncorrelated with the privacy concerns and privacy self-efficacy of the parents.

From the children's perspective, concerns regarding online content about oneself begin to appear as children start to grasp the concept of privacy when growing up [46]. For instance, teenagers have reported caring a lot more about the quality of the content their parents share about them online [54]. Further, when children start sharing content on their own, they seek to broaden their social media connections [70] and may therefore wish to present themselves differently from how their parents portray them on social media [55, 57].

After transitioning from teenage into young adulthood, individuals tend to manage their online activities by using privacy settings and controls to a greater extent than adults in

other age groups [12,70]. During young adulthood, one might have heightened concerns about the content about oneself that others might encounter online because it is the life stage during which people tend to pursue higher education, seek employment, and engage in romantic relationships [70]. Such concerns naturally extend to content about oneself posted by one's parents during childhood [55]. Yet, there is little research on the perceptions of young adults regarding such content. Our study aims to fill this gap.

3 Method

We used an online questionnaire to address the research questions listed in Section 1. The following subsections describe the questionnaire design, participant recruitment, sample characteristics, and our data analysis approach. All study procedures were reviewed and approved by the Institutional Review Board (IRB) of Indiana University Bloomington.

3.1 Questionnaire Design

Figure 1 shows the organization of the various components of the questionnaire. Those who consented to participate after reading information about the study and committed to answering attentively [26] proceeded to the questions to determine eligibility to participate in the study. The inclusion criteria for study participation were: (i) being 18 to 30 years old; (ii) having lived in the United States for the entire life; and (iii) being familiar with photo sharing on at least one of the two most popular social media platforms (i.e., Facebook[2] and Instagram[3]). We limited participation to those from the United States to ensure that the results would not be affected by cultural differences in privacy preferences and online sharing practices [9, 22, 80]. Only those who met all inclusion criteria were allowed to proceed and participate in the study.

In the initial part of the questionnaire, we asked participants about their personal practices regarding sharing photos on social media. Next, we asked participants if any of their parents had ever shared their photos on social media during childhood. If one of the parents of a participant had shared the participant's photos on social media during childhood, we presented a set of questions about that parent regarding motives for sharing the photos, types of shared photos, and acceptable audiences for the shared photos. If both parents of the participant had shared the participant's photos on social media during childhood, we asked about one of them chosen at random. The questions listed the parental photo-sharing motives we compiled from the literature (see Section 2.1). As mentioned earlier, the photo types were the 19 categories of sensitive photo types relevant to children from the taxonomy of sensitive photo types provided by Li et al. [41]. For each of these photo types, participants indicated whether they find it acceptable to share such photos of children or adolescents in various age groups: Infant or Toddler (0–3 years); Preschooler (4–6 years); Middle childhood (7–12 years); Teenager (13–17 years); and None. We formed these groups based on guidance from the Centers for Disease Control and Prevention (CDC)[4] with slight adjustments to avoid overlap in ages. Participants whose parents did not share their photos on social media during childhood did not receive this set of questions.

Afterward, we randomly assigned participants to one of three between-subjects study conditions based on their relationship with the child in the photos shared by parents: (i) oneself as a child, (ii) one's (real or hypothetical) child, or (iii) anyone's child in general. In each condition, we asked participants to answer questions about parental sharing of photos of the corresponding child. We modified the wording for each photo type according to the study condition (e.g., Condition (i): 'you as a child or adolescent'; Condition (ii): 'your child or adolescent'; Condition (iii): 'their child or adolescent'). In all other aspects, the questions in each condition were identical and covered the same motives, photo types, and audiences regarding parental sharing practices. We additionally asked participants to indicate the acceptability for sharing a particular type of photo of a child during the different stages of childhood mentioned above. Toward the end, we used questions from the literature to ask participants about their privacy preferences and practices when sharing photos on social media [3, 7] and the closeness of their relationships with their parents [73]. We concluded the questionnaire by collecting standard demographic information.

When constructing the questionnaire, we were mindful of the potential effects of the order of response options. To counter order effects, we randomized the order of the options for most questions, including those for photo-sharing motives. However, we did not randomize the order of photo types when asking about their acceptability to be able to spread the large number of photo types across multiple pages. Nevertheless, we verified that these responses were unaffected by order effects (see Section 4). In a few additional cases, we presented response options in a fixed order to ensure clarity and consistency by adhering to a conceptual ordering (e.g., Close friends to Public, Infant to Teenager, etc.).

Before deploying the study, we piloted the questionnaire in two phases ($n = 15$ and $n = 25$, respectively). Feedback from the two pilots led to several refinements to improve the clarity, consistency, and coherence of the questions and helped us confirm that the questions and corresponding answer choices were understood as we intended.

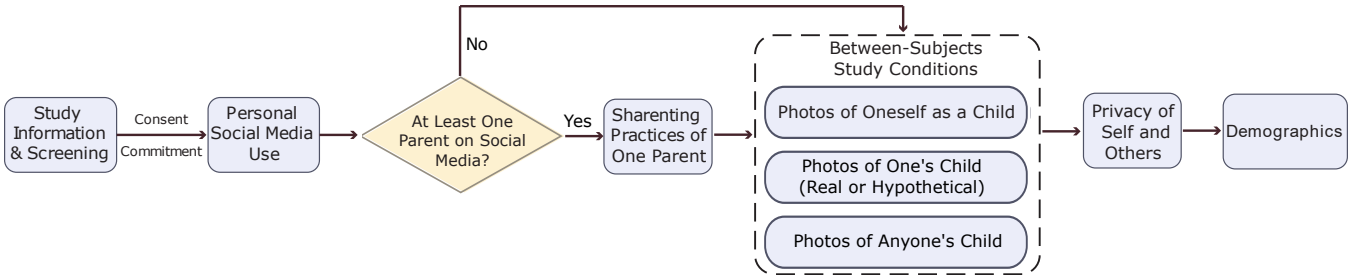

Figure 1: The overall flow of the study depicting the main components of the questionnaire.

3.2 Participant Recruitment

We recruited participants in two ways: (i) posting a Human Intelligence Task (HIT) to AMT workers between the ages of 18 and 30 residing in the United States with at least 50 approved HITs and an approval rating of 95% or higher [32]; and (ii) advertising on Reddit (in r/PaidStudies[5] and r/paidstudy[6] subreddits), in online classifieds at Indiana University, and at physical locations in/around Bloomington, Indiana. We used AMT for access to a large pool of crowd workers in the United States [59, 64]. AMT workers are a reasonable proxy for Americans between the ages of 18 to 50 with some college education, but not for the general US population [63]. By soliciting participants via channels other than AMT, we ensured a broad, diverse sample of individuals from the United States.

We collected responses to the questionnaire from January–May, 2022. The median time for completing the study was 14.5 minutes. AMT workers who completed the study attentively and provided the correct completion code received $1.80 for their participation, translating roughly to US$7.5/hour which is above the minimum wage of US$7.25/hour in Indiana. For those recruited via other sources, we held a random drawing at the end of the study for twenty Amazon gift certificates of $10 each. Prior work suggests that a raffle-based approach is less prone to abuse, promotes voluntary participation, and tends to yield high-quality responses [13]. In fact, such an approach often encourages a larger number of individuals to participate thereby increasing the diversity and representativeness of the sample.

We removed the responses of those who failed the two attention checks (1 explicit and 1 indirect) included in the questionnaire to catch inattentive participation that can compromise data quality. Such checks and filtering are common in research that employs online and crowd worker samples (e.g., [60, 67, 69]). Three-hundred and four respondents failed the explicit attention check that required selecting a specific answer for a question. Fifty respondents failed the indirect attention check that involved cross-checking the year of birth asked at the beginning with the age asked at the end (within the margin of a year since birthdays do not align precisely with calendar years). Based on the inclusion criteria listed above, we next filtered out 27 respondents who reported not living in the United States their entire lives. To ensure high data quality and validity, we additionally excluded 13 respondents who marked *all* answer choices when asked whether their father, mother, or neither used social media. After applying these filters in series, we were left with 382 valid responses in total (238 from AMT and 144 from other sources), all of which were from IP addresses in the United States.

[6] https://www.reddit.com/r/paidstudy/

3.3 Sample Characteristics

The 382 valid responses were distributed roughly equally across the three study conditions: 'oneself as a child' ($n = 124$), 'one's child' ($n = 136$), and 'anyone's child' ($n = 122$). Overall, the mean age of the participants was 25.28 (sd $= 3.45$), with a median of 25. The sample included a slightly higher proportion of women, with 212 (56%) participants identifying as women, 164 (43%) as men, and 6 as non-binary. Close to half ($n = 163$; 43%) of the participants reported being parents. In terms of ethnicity, 253 (66%) participants identified as White/Caucasian, 71 (25%) as Black/African American, 11 (4%) as Asian/Pacific Islander, 10 (3%) as Hispanic/Central American/South American, 9 (3%) as European, 4 (1%) as from the Indian subcontinent, 4 (1%) as Native American, and 1 (0.26%) as Middle Eastern/North African. Nineteen participants did not provide information on their ethnic background. More than two-thirds ($n = 263$; 69%) of the participants reported completing college education, while a little less than a third ($n = 117$; 30.6%) indicated completing high school or vocational training as their highest level of education. Only 10% ($n = 40$) of the participants lived in rural localities with the rest living predominantly in urban ($n = 210$; 55%) and suburban ($n = 132$; 35%) locales. Seventy-eight percent ($n = 299$) of the participants used social media multiple times a day while the rest ($n = 83$; 22%) were less frequent social media users. A large majority ($n = 264$; 69%) of the participants reported having had content about them shared online by their parents during their childhood: 59 (22%) when they were infants or toddlers; 88 (33%) when they were preschoolers, 128 (48%) during their middle childhood; and 176 (67%) when they were teenagers.

3.4 Data Analysis

Prior to conducting analyses, the first two authors jointly consolidated the ten photo-sharing motives in the questionnaire into six higher-level categories: (i) Keeping in touch with family and friends, (ii) Archiving childhood (iii) Showing pride in the child, (iv) Communicative utility, (v) Outcome-driven sharing, and (vi) Impression management. The first three categories correspond to the top three motives selected by the participants. We grouped 'Seeking parenting advice' and 'Getting affirmation and support' as 'Communicative utility' since they involve communicating about parenting. We placed 'Attracting followers,' 'Making others envious,' and 'Earning money by advertising' under 'Outcome-driven sharing' based on self-interest. We treated 'Portraying as good parents' and 'Increasing online popularity' as 'Impression management' to project a positive image. These categories offer a conceptual scaffold for a better understanding of the manifold motives that drive parental sharing of content about their children. Despite minor potential overlap among categories due to the intricate nature of human motivations, we found the categories valuable for organizing and interpreting our results. Moreover, our categorization aligns with the categories identified in prior research on parental sharing [73].

As mentioned above, a part of the questionnaire varied between-subjects based on the study condition (see Figure 1). Since we found only a few minor differences across the three between-subjects conditions (see Section 4.3), we were able to pool the responses for the three conditions for a larger sample size and greater statistical power in other statistical analyses. When conducting statistical analyses related to the factors pertaining to our research questions, we examined the impact of each factor on: (i) acceptable motives for parental sharing of their children's photos; (ii) types of children's photos deemed acceptable to share across different age groups of children; and (iii) acceptable audiences for children's photos shared by their parents. Our sample size was large enough to tolerate violations of the assumption of normality [11, 66]. Moreover, in most cases, skewness and kurtosis were close to normal benchmarks [15, 27], and the variance ratio was less than 1.5 [35]. Therefore, in most analyses, we compared relevant groups using one-way analysis of variance (ANOVA) coupled with post-hoc Tukey tests to test for differences between pairs of groups (with 95% familywise confidence level). To address the few instances where skewness and kurtosis were not close to normal benchmarks or the variance ratio was greater than 1.5, we used the non-parametric Kruskal-Wallis test followed by post-hoc pairwise Mann-Whitney tests with Bonferroni correction to account for multiple testing.

3.5 Limitations

Before proceeding to present the findings of the analyses, we point out a few limitations. Self-selected study participation and self-reported responses both involve inherent limitations that may have affected our data. We included a commitment question at the beginning of the questionnaire to motivate truthful self-reporting. Nevertheless, further studies are needed to verify whether the self-reported sharing preferences and practices match actual sharing behavior in real-world systems. To minimize the influence of cultural backgrounds on the findings, we restricted recruitment to those who had lived in the United States their entire lives [9, 22, 80]. Therefore, the extent to which the findings generalize to the population of the United States and beyond requires verification.

When asking about parents, we did not make an explicit distinction between biological parents and others (e.g., stepparents, foster parents, adoptive parents, etc.). The participants were free to associate the terms "parent," "father," and "mother" with any type of parent they deemed appropriate. Examining whether differences in the type of parental relationship influence parental sharing of content about their children could be an interesting avenue for future research. Note that our questionnaire design accounted for households with same-sex parents since the wording of the questions did not assume that participants had only one father or mother. For the sake of clarity, we phrased all questions about parents in the present tense given the negligible chances of a participant's parent being deceased based on the age restrictions for the sample. Upon checking the open-ended comments at the end of the questionnaire, we did not find any mention of the questions being non-applicable because of a deceased parent.

We used sharing motives and shared photo types taken from the literature. While such an approach facilitates comparing our findings with prior work and building upon the literature, it makes our findings subject to any limitations that might arise from using these specific categories. Moreover, our study is limited to photo-sharing practices on two specific platforms (i.e., Facebook and Instagram). Future work can build on these findings by exploring parental sharing of other types of content (e.g., videos, posts, comments, etc.) about their children and by including other social media platforms.

4 Findings

To answer our research questions, we investigated the overall perceptions of the young adult participants of our study regarding parental sharing of their children's photos (RQ1). Afterward, we examined how these perceptions are influenced by the following factors: experiencing parental sharing of one's photos during childhood (RQ2), relationship with the child in the photos shared by parents (RQ3), and being a parent (RQ4). Table 1 summarizes the main findings for each research question (see Section 1), grouped by the aspects relevant to parental sharing of their children's photos (i.e., motives, photo types, and audiences). The subsections below detail the findings pertaining to each research question.

Table 1: Main findings for each research question, grouped by aspects relevant to parental sharing of their children's photos.

RQs	Motives	Photo Types	Audiences
RQ1	Young adults find motives about typical social media use more acceptable than those driven by material or negative outcomes.	Young adults consider it less acceptable for parents to share photos of their children with negative or revealing content.	Young adults find it less acceptable for parents to share photos of their children with socially distant audiences.
RQ2	Young adults who experienced parental photo sharing during childhood consider it more acceptable to share children's photos to keep in touch with family and friends and to project a positive image of themselves and the children.	Young adults who experienced parental photo sharing during childhood find it acceptable to share more types of highly sensitive photos of children of all age groups except infant/toddler.	Young adults who experienced parental photo sharing during childhood are more accepting of parental sharing of children's photos with diverse audiences.
RQ3	The acceptability of various motives for parental sharing of children's photos is independent of the relationship between a young adult and the child in the shared photos.	Young adults are less protective of highly sensitive photos of themselves during their teenage years and more protective of moderately sensitive photos of their own infants or toddlers.	When sharing with close friends, young adults are more careful about photos of their children compared to photos of themselves during their childhood.
RQ4	Young adult parents find outcome-driven and impression management motives for parental sharing of children's photos more acceptable than young adult non-parents.	Compared to young adult parents, young adults who are non-parents are more accepting of sharing less sensitive photos of children.	Young adult parents find it more acceptable than young adult non-parents to share children's photos with socially distant groups.

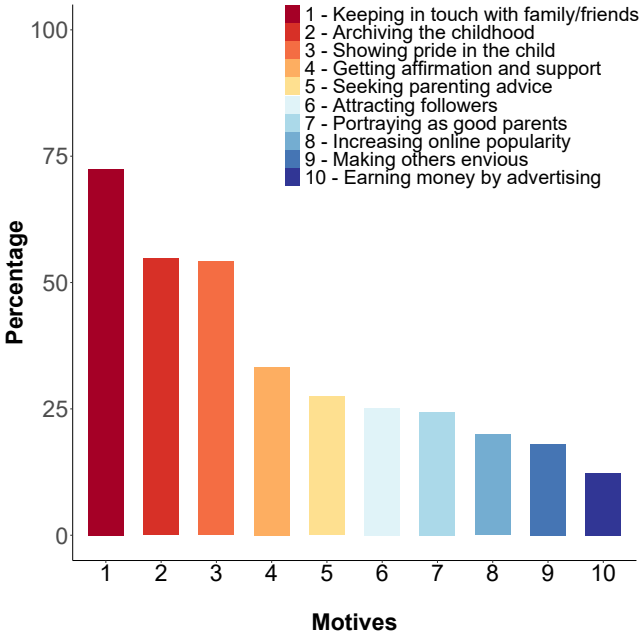

Figure 2: Percentages of participants who found each motive for parental sharing of content about their children acceptable.

4.1 Perceptions of Parental Photo Sharing (RQ1)

The young adults who participated in our study found the motives connected to typical social media use (i.e., 'Keeping in touch with family/friends' – 72.51%, 'Archiving the childhood' – 54.71%, and 'Showing pride in the child' – 54.19%) to be more acceptable than motives driven by material outcomes (i.e., 'Earning money by advertising' – 12.30% and 'Increasing online popularity' – 19.89%) or negative intentions (i.e., 'Making others envious' – 18.06%) (see Figure 2). Using a one-way ANOVA, we found that these differences are statistically significant ($F(9,3810) = 76.88$, $p < 0.001$). A post-hoc Tukey test showed that the motives connected to typical social media use were statistically significantly more acceptable than others (adjusted $p < 0.001$ in all cases). In addition, the least acceptable motive (i.e., 'Earning money by advertising') was found to be statistically significantly less acceptable than all other motives (adjusted $p < 0.01$) except 'Making others envious' and 'Increasing online popularity.' For the rest of the analyses, we used the higher-level categories of motives (see Section 3.4). For categories that included multiple motives, we averaged the scores for the individual motives.

Given 19 sensitive types of photos of children, the participants selected those they deemed acceptable to be shared for four age groups: infant/toddler, preschooler, middle childhood, and teenager. We found that the highest number of photo types was selected for middle childhood (mean = 5.71), followed by teenager (mean = 5.16), preschooler (mean = 4.71), and infant/toddler (mean = 3.62). A one-way ANOVA for the number of acceptable photo types yielded statistically significant differences across the four age groups ($F(3,1524) = 23.47$, $p < 0.0001$). A post-hoc Tukey test showed that the number of acceptable photo types for the infant/toddler group was statistically significantly lower (all adjusted $p < 0.001$) than that for the other three (preschooler: 95% C.I. = $[0.42, 1.75]$, middle childhood: 95% C.I. = $[1.42, 2.75]$, and teenager: 95% C.I. = $[0.87, 2.20]$). In addition, the number of acceptable photo types for the preschooler group was statistically significantly

lower than that for middle childhood (adjusted $p < 0.001$, 95% C.I. $= [0.33, 1.66]$). However, there were no statistically significant differences when comparing the teenager group with the preschooler or the middle childhood groups (see Figure 3). In general, the participants deemed a low number of photo types as acceptable, perhaps because the photo types represented sensitive content. This finding aligns with the literature which found that parents tend to consider it inappropriate to share photos portraying negative situations [3].

To delve deeper into the acceptability of photo types for each age group, we compared the number of participants who selected each photo type. As shown in Table 2, we found that for all four age groups, the photo types considered acceptable to share by fewer than a quarter of the participants were those with negative or revealing content. We refer to these photo types as *highly sensitive*. Moreover, we noted that the photo types deemed acceptable to share for all age groups by more than a quarter and fewer than half of the participants seemed to depict more moderate content (see Table 2). We refer to these photo types as *moderately sensitive* because the participants seemed to consider sharing these types of photos to be more acceptable than those belonging to highly sensitive photo types. The rest of the photo types, i.e., photos of children with other people or with personal assets, were not selected similarly across the four age groups of children. Further, we found that sharing group photos seemed more acceptable for older children.

We additionally performed a regression analysis for each age group with the number of participants who considered each photo type acceptable to share as the dependent variable and the fixed order in which the photo types were listed in the questionnaire as the independent variable. We found no statistically significant order effects for any age group, with all p values well above the standard 0.05 threshold.

We asked the young adults who participated in our study to rate (on a 7-point scale, with 1 being the least acceptable and 7 being the most acceptable) the level of acceptability for parents sharing photos of their children with four audiences: close friends, friends/followers/connections, current/potential employers, and general viewers/public. As shown in Figure 4, we found that close friends (mean $= 5.05$) were the most acceptable audience for children's photos, followed by friends/followers/connections (mean $= 4.40$), current/potential employers (mean $= 3.28$), and general viewers/public (mean $= 3.36$). A one-way ANOVA testing the level of acceptability across the different audiences revealed statistically significant differences ($F(3,1524) = 83.95$, $p < 0.001$). A post-hoc Tukey test found statistically significant differences (all adjusted $p < 0.001$) between close friends and the other three audiences (friends/followers/connections 95% C.I. $= [-0.99, -0.32]$, current/potential employers 95% C.I. $= [-2.11, -1.43]$, and general viewers/public 95% C.I. $= [-2.03, -1.35]$). In addition, sharing with friends/followers/connections was statistically significantly more acceptable (both adjusted $p < 0.001$) than with current/potential employers or general viewers/public (current/potential employer 95% C.I. $= [-1.46, -0.78]$ and general viewers/public 95% C.I. $= [-1.38, -0.70]$). However, there was no statistically significant difference between the acceptability of current/potential employers and general viewers/public as audiences for shared photos of children. These findings highlight that the acceptability of sharing photos of children decreases with increasing social distance, thus echoing prior work that found that people in distant social circles are less acceptable audiences for family information [2, 37].

4.2 Experiencing Parental Photo Sharing (RQ2)

We examined whether having one's photos shared by one's parents during childhood influences the acceptability of parental sharing of photos of their children. A one-way ANOVA showed that a statistically significantly higher proportion of participants who had experienced parental sharing of their photos during childhood chose the most popular parental sharing motive (i.e., 'Keeping in touch with family/friends') to be more acceptable than those who had not had their photos shared by their parents when they were children (80% vs. 56%, respectively $F(1,380) = 25.95$, $p < 0.001$). Similarly, 'Showing pride in the child' and 'Impression management' were statistically significantly more acceptable motives for the participants who had experienced parental sharing of their photos during childhood than for those who did not (Showing pride: 61% vs. 40%, respectively $F(1,380) = 14.66$, $p < 0.001$; Impression management: 51% vs. 29%, respectively $F(1,380) = 10.19$, $p < 0.01$). For the rest of the motives, the differences based on having experienced parental sharing of photos during childhood were not statistically significant ($p > 0.05$). These findings indicate that experiencing parental sharing of their photos during childhood can lead young adults to deem it more acceptable to share children's photos to keep in touch with family and friends and project a positive image of themselves and their children.

Next, we investigated the influence of having one's photos shared by one's parents during childhood on the number of photo types considered acceptable to share for the four age groups of children. For the preschooler and teenager groups, the participants who had experienced parental sharing of their photos during childhood selected statistically significantly more photo types as acceptable than those who had not had their parents share their photos during their childhood: (preschooler: 5.29 vs. 4.14, respectively $F(1,380) = 8.33$, $p < 0.01$; teenager: 5.15 vs. 4.16, respectively $F(1,380) = 6.31$, $p < 0.05$). However, a one-way ANOVA did not indicate any significant differences for the infant/toddler and middle childhood age groups ($p > 0.05$). Moreover, we found that for all age groups except infant/toddler, the participants who had experienced parental photo sharing during child-

Table 2: Photo types similarly acceptable across all the four age groups of children (Infant/Toddler, Preschooler, Middle childhood, and Teenager).

Acceptable to <25% of the participants *(Highly sensitive)*		**Acceptable to 25–50% of the participants** *(Moderately sensitive)*
- Unflattering close-up of the child's body parts	- Child in an unkempt home	- Child with an unpleasant
- Child (partially) in the nude	- Child in the bathroom	appearance or facial expression
- Showing irresponsibility toward the child	- Containing other people's information	- Child while sleeping or grooming
- Drawing attention to the child's bad clothing	- Containing personal and private	- Child with food
- Child with a medical condition or visible blood	information	- Child relaxing at home
- Child under medical treatment	- Containing a gun	- Bad quality photos of the child

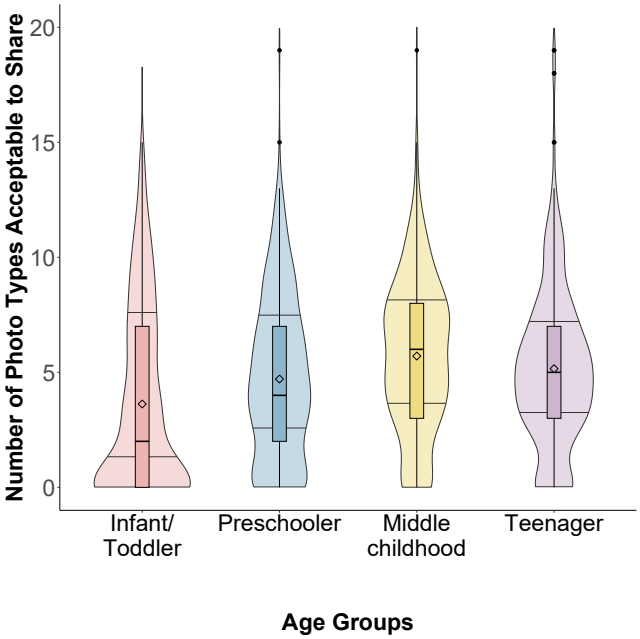

Figure 3: Violin plots showing the number of photo types that the participants deemed acceptable for sharing for different age groups of children.

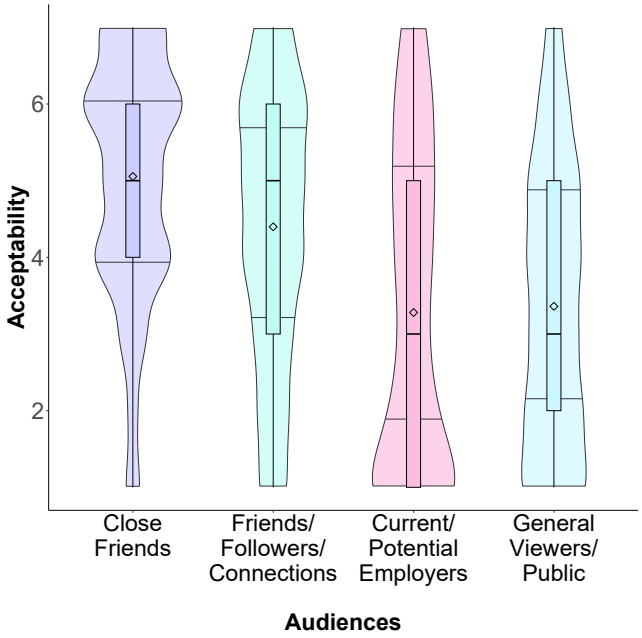

Figure 4: Violin plots showing participant ratings for acceptability of sharing photos of children with various audiences. Acceptability was measured on a 7-point scale, with 1 being the least acceptable and 7 being the most acceptable.

hood selected a statistically significantly higher number of highly sensitive photo types as acceptable than the other participants: preschooler means 1.73 vs. 0.82, respectively ($F(2,379) = 26.86$, $p < 0.001$); middle childhood means 2.48 vs. 1.09, respectively ($F(2,379) = 33.85$, $p < 0.001$); and teenager means 1.88 vs. 1.27, respectively ($F(2,379) = 7.68$, $p < 0.01$). In contrast, a statistically significantly higher proportion of participants who had not had their photos shared by their parents during childhood found the photo types 'Containing child's objects or personal assets' and/or 'Event' acceptable to share for the infant/toddler (Assets: 43% vs. 33%, respectively $F(2,379) = 3.96$ $p < 0.05$; Event: 50% vs. 36%, respectively $F(2,379) = 6.91$, $p < 0.01$), preschooler (Assets: 52% vs. 41%, respectively $F(2,379) = 4.26$, $p < 0.05$; Event: 62% vs. 46%, respectively $F(2,379) = 9.36$, $p < 0.01$), and teenager (Event: 72% vs. 59%, respectively $F(2,379) = 6.03$, $p < 0.05$) age groups. We did not observe such differences for the acceptability of sharing the moderately sensitive photo types (see Table 2).

We examined whether experiencing parental sharing of one's photos during childhood influences the audiences one considers acceptable for children's photos. A one-way ANOVA found that the acceptability of sharing children's photos with all audiences was statistically significantly higher for those who had experienced parental sharing of their photos during childhood than those who had not: close friends means 5.41 vs. 4.29, respectively ($F(2,379) = 46.9$, $p < 0.001$), friends/followers/connections means 4.87 vs. 3.36, respectively ($F(2,379) = 69.73$, $p < 0.001$), current/potential em-

ployers means 3.74 vs. 2.28, respectively ($F(2,379) = 45.19$, $p < 0.001$), and general viewers/public means 3.79 vs. 2.43, respectively ($F(2,379) = 51.41$, $p < 0.001$). The results suggest that experiencing parental sharing in childhood can influence the acceptability of such practices regardless of audience.

We further measured the influence of having one's photos shared by one's parents during childhood by investigating whether the young adults who participated in our study reported sharing practices similar to their parents. Using Spearman's rank-order correlation, we compared the number of motives and photo types the participants reported to explain the sharing practices of their parents with the number of motives and photo types they selected as acceptable for parental sharing from their own perspective. We found a statistically significant weak positive correlation for motives ($r(260) = 0.55$, $p < 0.001$) as well as photo types ($r(260) = 0.32$, $p < 0.001$). In other words, the participants who had experienced parental sharing of their photos during childhood were more likely to develop perceptions of sharing similar to those of their parents.

Taken together, the above results suggest that having one's parents share one's photos during childhood contributes to increasing the acceptance of such sharing practices in adulthood, including the sharing of highly sensitive photos with more diverse audiences. However, the influence does not seem to extend to all photo types. Notably, the participants without a history of having their photos shared by their parents during childhood found it more acceptable to share photos of types 'Containing child's objects or personal assets' and 'Event.' Such a divergence may stem from perceiving such photos as less invasive or less revealing of personal information.

4.3 Relationship with the Child (RQ3)

We investigated whether the acceptability of sharing children's photos is influenced by the relationship with the child in the photo. As mentioned earlier, the three study conditions covered the following relationships: (i) oneself as a child; (ii) one's (real or hypothetical) child; and (iii) anyone's child. We started by analyzing whether the differences in relationship with the child in the shared photos influenced the acceptability of the six categories of motives (see Section 3.4). A one-way ANOVA found no statistically significant differences across the three conditions ($p > 0.05$), indicating that perceptions of young adults regarding the acceptability of various motives behind parental sharing of children's photos seem independent of their relationship with the child in the shared photos.

Afterward, we examined whether the relationship with the child in the shared photos influences the number of photo types acceptable to share across children's age groups. A Kruskal-Wallis test found statistically significant differences across the three study conditions for highly sensitive photo types (see Table 2) for the teenager group ($F(2,379) = 10.70$, $p < 0.01$). Post-hoc Mann-Whitney tests with Bonferroni correction for multiple testing showed that the number of highly sensitive photo types of teenagers acceptable to share for 'anyone's child' (mean = 1.08) was statistically significantly lower than that for 'oneself as a child' (mean = 1.88, $p < 0.05$) and for 'one's (real or hypothetical) child' (mean = 2.05, $p < 0.01$). Additionally, a one-way ANOVA found that the number of moderately sensitive photo types (see Table 2) acceptable to share for the infant/toddler age group was statistically significantly different across the three study conditions ($F(2,379) = 3.87$, $p < 0.05$). A post-hoc Tukey test showed that these differences were statistically significant (adjusted $p < 0.05$, 95% C.I. $= [0.09, 1.15]$) only when comparing the responses for 'one's (real or hypothetical) child' (mean = 1.26) with those for 'anyone's child' (mean = 1.88). The relationship with the child in the photos did not impact the responses of the participants for the other photo types and age groups. Overall, we found that young adults seem less protective of highly sensitive photos of themselves during their teenage years and more protective of moderately sensitive photos of their own infants or toddlers.

Next, we investigated whether the relationship with the child in the shared photos influences the acceptability of sharing with different audiences. Using a one-way ANOVA, we found that the relationship with the child in the shared photos has a statistically significant influence on the acceptability of sharing photos of children with close friends ($F(2,379) = 3.02$, $p < 0.05$). A post-hoc Tukey test indicated that sharing children's photos with close friends was statistically significantly less acceptable (adjusted $p < 0.05$, 95% C.I. $= [0.01, 0.91]$) for 'one's (real or hypothetical) children' (mean = 4.78) than for 'oneself as a child' (mean = 5.24). Comparisons for the other three audiences were not statistically significant. These findings indicate that young adults appear to be more careful about sharing photos of their own children when sharing with close friends compared to sharing photos of themselves taken during their childhood. Whether young adults consider it acceptable to share children's photos with more distant audiences seems to be independent of the relationship of the sharer with the child in the photos.

4.4 Parental Status (RQ4)

Compared with the participants who were parents, a statistically significantly lower proportion of the participants who were not parents selected 'Outcome-driven sharing' and 'Impression management' as acceptable categories of motives for sharing children's photos. In contrast, a statistically significantly more proportion of non-parent participants selected 'Archiving the childhood' as an acceptable motive for sharing children's photos compared with those who were parents.

A one-way ANOVA to investigate whether parental status is associated with the acceptability of sharing for various photo types showed that non-parents selected a statistically

Table 3: ANOVA results across children's age groups for the three photo types: Event, Containing child's objects or personal asset (Assets), and Child along with other people (With others). Compared with the participants who were parents, a significantly higher proportion of non-parent participants deemed it acceptable to share children's photos of these types.

Age Group	Photo Type	Non-parent	Parent	F (2, 379)
Infant/ Toddler	Event	50%	27%	**22.07*****
	Assets	47%	22%	**25.80*****
	With others	47%	23%	**25.28*****
Preschooler	Event	59%	40%	**13.05*****
	Assets	52%	34%	**11.30*****
	With others	54%	34%	**16.59*****
Middle childhood	Event	76%	50%	**31.16*****
	Assets	60%	49%	**4.78***
	With others	58%	42%	**10.11****
Teenager	Event	74%	51%	**20.76*****
	Assets	60%	35%	**25.40*****
	With others	63%	48%	**9.47*****

$^{***}p < 0.001$, $^{**}p < 0.01$, $^{*}p < 0.05$

significantly higher number of moderately sensitive photo types (see Table 2) for the infant/toddler and preschooler age groups: infant/toddler means 1.92 vs. 1.01, respectively ($F(2,379) = 24.88$, $p < 0.001$); preschooler means 2.16 vs. 1.44, respectively ($F(2,379) = 18.13$, $p < 0.001$). Similarly, compared to the participants who were parents, a statistically significantly higher proportion of non-parent participants found it acceptable to share photos across all age groups of children for the following photo types: Event, Containing child's objects or personal assets, and Child along with other people (see Table 3 for the full statistical results). The above findings indicate that young adults who are yet to experience parenthood tend to be more accepting of sharing less sensitive photos of children. The only exception is the middle childhood age group for which young adult parents found a statistically significantly higher number of highly sensitive photo types (see Table 2) acceptable to share: means 2.45 vs. 1.74, respectively ($F(2,379) = 9.39$, $p < 0.01$).

A one-way ANOVA to examine the acceptability of sharing children's photos with different audiences showed that parents rated the acceptability of sharing such photos with the following audiences statistically significantly higher than non-parents: friends/followers/connections means 4.72 vs. 4.16, respectively ($F(2,379) = 9.66$, $p < 0.01$), current/potential employers means 4.01 vs. 2.74, respectively ($F(2,379) = 37.64$, $p < 0.001$), and general viewers/public means 3.84 vs. 3.00, respectively ($F(2,379) = 20.7$, $p < 0.001$). Contrary to our expectations, young adult parents seem to find it more acceptable than young adult non-parents to share children's photos with socially distant groups.

5 Discussion

Below we discuss the salient insight gained from our findings.

5.1 Influence of Parental Photo Sharing and Parenthood

Our findings show that young adults who experienced parental sharing of their photos during childhood are more open to engaging in sharing photos of children to keep in touch with others and to portray a positive image of themselves even if the shared photos of children are highly sensitive and viewable by distant connections. Moreover, these young adults deem more types of photos of children as acceptable to share. It may be the case that children whose content is shared by their parents internalize the sharing practices of their parents. Moreover, it is plausible that young adults who grew up with parents who shared content about them during childhood consider parental sharing of children's content as a means of validation of good parenting [19,53,76]. Our findings seem to provide evidence for Brosche's [14] expectations that children whose content is shared online by their parents may grow up with a different concept of privacy.

Compared to young adult non-parents, young adults who have children seem to deem it more acceptable to share highly sensitive photos of children and harbor fewer concerns about sharing photos of children with socially distant people. Although it might be counterintuitive that parents, who are expected to be protective of their children, are less cautious about their children's privacy, the observation is in line with previous work noting that parental sharing is uncorrelated with privacy concerns [44,61]. A plausible explanation might be that the time and effort involved in childcare change priorities and consequently affect choices regarding the optimal balance between the benefits of sharing and the corresponding risks to children's privacy. For instance, being a parent may lead people to prioritize the immediate benefits of sharing content about their children, such as maintaining social connections or seeking support and validation for parenting decisions, over uncertain and unclear privacy risks that may arise in the future. As Seberger et al. [67] found in the case of mobile apps, acceptance of privacy-invasive practices tends to have a reinforcing effect, leading to the normalization of such practices over time. Our findings similarly indicate that parental sharing of content about their children can shape the practices and norms of future generations.

Overall, our findings call for a nuanced understanding of the role of parenthood in shaping parental sharing of content about their children and exploration of solutions that support

parents in making informed decisions about balancing the benefits of sharing such content with protecting their children's privacy. Further, the difference in the perceptions of parental sharing of content about their children based on differences in childhood experiences with such sharing underscores the value and necessity of considering longitudinal influences.

5.2 Comparison between Views of Young Adults and Children

Our findings show that the perceptions of young adults about parental sharing of their children's photos are mostly in line with the perspectives of children reported in the literature. For instance, our findings regarding the motives for parental sharing that young adults find acceptable align with the findings of studies on children's perceptions. These studies showed that children find it important to consider how their peers perceive their online images, so they prefer parental sharing of content that presents them in a positive light (e.g., photos of their achievements or their happy families) [43,57]. Moreover, we uncovered that young adults find 'Communicative utility,' 'Outcome-driven sharing,' and 'Impression management' to be the least acceptable motives for parental sharing of their children's photos, echoing prior work that found that children have a negative opinion about parental sharing of their content based on self-centered motives of the parents [77,78].

Further, the low levels of acceptability by young adults for sharing highly and moderately sensitive photo types (see Table 2) match children's desires for not sharing unflattering and embarrassing photos and not revealing sensitive personal information [43,54,57,78]. In addition, we found that young adults consider it more acceptable to share photos of children with closer connections than with socially distant audiences, echoing the findings from previous studies showing that children desire careful audience selection for content about them shared by their parents [1,75].

5.3 Effect of Relationship with the Child

Surprisingly, our findings indicate that the views of young adults regarding parental sharing of a child's content are mostly the same regardless of whether the child is themselves, their child, or anyone's child. These relatively uniform perceptions regarding parental sharing of children's content indicate that the norms and perceptions related to such sharing are driven primarily by the fact that the content pertains to a *child*—a specific *class* of individuals deserving specific consideration regardless of one's relationship with the child in question. At the same time, our findings suggest that parental sharing of content about their children can gradually shift norms to tilt the balance toward favoring the benefits of sharing over avoiding potential harm. The uniformity in perceptions regarding children could be leveraged to draw attention to children as a vulnerable population worthy of special protective measures when parents share content about them.

6 Implications

By including a previously unstudied population (i.e., young adults), our findings show that having one's content shared on social media by one's parents during childhood can influence one's own sharing perceptions and practices as a parent. Our findings imply that habituation to privacy violations begins in childhood and surface longitudinal influences that reinforce and normalize parental sharing of content about their children. At the same time, our findings suggest that people tend to be uniformly protective of children. Moreover, the findings show that the perceptions of young adults regarding parental sharing of children's content are aligned with children's views, thus confirming, reinforcing, and refining several findings from the literature. Taken together, the insight from our findings points to a number of solutions that could help parents benefit from sharing content about their children while enhancing the privacy and security of the children whose content they share.

6.1 System Design

Since parental sharing of children's content typically takes place on social media platforms, we offer several suggestions for system design grounded in our findings to assist parents in protecting the online content about their children. These solutions can be implemented by the platforms themselves or offered as plugins developed by third parties. For instance, computer vision can be used to detect photos containing children and seek additional confirmation from parents before sharing the photos. Implementing such a feature should be straightforward since many online platforms and other systems are increasingly applying computer vision functionality for a variety of purposes. Since our findings suggest that the sensitivity of a child's photo influences the acceptability of sharing the photo, social media platforms could additionally consider employing machine learning techniques to estimate the sensitivity levels of photos that contain children. Parents about to share highly sensitive photos of their children could then be alerted and asked to confirm their intent to share. Parents could additionally be provided the option of being alerted when the level of sensitivity of a photo containing a child is higher than a specified threshold.

While existing audience controls on social media platforms typically allow users to share photos with select audiences, these features require users to set the audience manually each time they post photos to any audience other than the default. Automatic detection of content about children can be applied to make such settings less burdensome when sharing content about children. For instance, content detected to be about children can default to sharing with only restricted, trusted audiences, such as family and friends. That said, we found

that young adults who experienced parental sharing when they were children and young adults who are parents find it more acceptable to share children's photos with socially distant groups. System designers could temper such a practice by adjusting their algorithms to make highly sensitive content shared by parents less visible on social media feeds of distant connections. Further, our findings show that young adults find sharing different types of children's photos differentially acceptable based on the age of the child in the photo. This observation could be useful for implementing a feature that encourages parents to engage in more responsible sharing based on the age of the child whose content they are about to share. In addition, social media platforms could proactively alert parents about the potential security and privacy risks associated with oversharing content about their children. Researchers could conduct user studies to help understand the most effective timing and frequency for such alerts.

People's general tendency to be protective of *all* children revealed by our findings can be leveraged to implement peer-based [25] features that enable *any* user to participate in protecting the privacy of content about children posted on social media. For instance, system designers could provide anonymous mechanisms for flagging potentially inappropriate parental sharing of content about their children. Such mechanisms could be integrated with existing content moderation functionality and processes of the platform. Feedback from the audience could also be shared with the parents to increase their awareness of the potential risks of sharing content about their children and facilitate appropriate corrective actions. Similarly, social navigation [23] features could help temper the influence of exposure to the sharing practices of one's parents by providing anonymized aggregated statistics on the sharing practices of a diversity of parents. For instance, platforms can indicate the percentages of parents who share their children's photos, the average daily number of children's photos posted by their parents, the 'reaction' counts for specific types of children's photos, etc. Such features are analogous to social feedback mechanisms to incentivize individuals to reduce their energy consumption [52].

6.2 Regulatory Policy

Given the growing regulatory attention on protecting children from harms related to social media, our findings are timely for informing appropriate policy measures to regulate online practices. The focus of existing or proposed public policy in this space has so far been on regulating children's use of social media (e.g., limiting children's social media use and demanding greater parental supervision[7]), protecting personal data of children (e.g., restricting data processing and mandating parental approval based on age[8]), preventing children from being exposed to harmful online content (e.g., regulating children's access to sexual and abusive content [9]), or stopping the spread of illicit content containing children (e.g., policing content that depicts child sexual abuse[10]). However, there has so far been little attention specifically on public policy regarding content about children shared by others in ostensibly trusted relationships, such as parents. In fact, many current and proposed laws and regulations implicitly or explicitly grant parents the ultimate decision-making authority with no consideration of the risks posed by parental sharing of content about their children.

Our findings could help fill the gap in regulatory attention to matters related to children's online privacy and safety. For instance, our findings about the longitudinal influences and consequent normalization of parental sharing practices suggest that a more nuanced approach to consent and agency may be warranted to achieve more effective privacy outcomes for children whose parents share content about them. For example, laws and regulations could be designed to raise the obligations of care and due diligence when adults share content about children (their own or anyone else's). Similarly, policy measures could mandate greater agency to children who are old enough to obtain social media accounts and enable them to provide (or withhold) consent to others (including parents) to share content about them. Online platforms could additionally consider adding policies to govern the practices of parents who share content about their children.

6.3 Digital Literacy

Our findings show that childhood experiences with parental sharing of content about oneself play a role in shaping a young adult's perceptions and practices regarding parental sharing of content about their children. This influence suggests that parental sharing of content about their children ought to be a part of digital literacy campaigns and curricula that can complement the regulatory approaches proposed above. For example, educators could implement digital literacy campaigns emphasizing the importance of online privacy for children, guiding young adults to reflect on their childhood experiences with parental sharing and the associated disclosure of their personal information. Our findings further underscore the need to target such initiatives at the demographics more likely to engage in parental sharing of content about their children, specifically young adults who are parents. The personalization capabilities of social media platforms could be leveraged to embed such campaigns directly within the platforms, thus boosting their contextual relevance and immediate applicabil-

ity. The impact of digital literacy campaigns on parental sharing of content about their children could be further boosted by including them within school curricula for children and teenagers as well.

Our findings reveal a nuanced shift in sharing practices and privacy priorities upon becoming a parent. This observation underscores the importance of educating new parents about potential privacy risks, such as identity theft [47] and cyberbullying [71], associated with the online sharing of content about their children. Apart from known risks, educational interventions should ensure that parents are made aware of *emergent* risks, such as Generative AI techniques that use content about children shared online to create malicious and harmful synthetic content resembling the children (e.g., synthetic sexual content depicting the children, etc.) [30]. To facilitate the protection of children's privacy as an integral consideration in parenting practices, such information could be embedded within the resources provided to expecting parents and distributed with children-related consumer products.

7 Conclusion

By studying the perceptions of young adults, we addressed a gap in the literature on parental sharing of content about their children. We found greater acceptance of parental sharing of children's photos among young adults who experienced parental sharing of their photos during childhood and young adults who are parents. Interestingly, the perceptions of young adults are independent of whether the child in the shared photos is themselves, their own child, or someone else's child. We applied the insight to contribute suggestions for system design, policy regulation, and digital literacy campaigns. These suggestions can provide young adults with control and agency over content about them posted by their parents when they were children and assist parents in balancing the benefits of sharing content about their children and protecting their children from the risks posed by the shared content. While our investigation focused on parental sharing of their children's photos, we believe that the findings and the proposed solutions apply to the sharing of other types of content about children as well. Our findings reflect a tendency for normalization of parental sharing of content about their children, making it pressing to design solutions that can facilitate similar normalization of considerations for protecting the privacy and security of the children whose content parents share.

Acknowledgments

We thank the participants of the study for their time and effort. We are grateful to the anonymous reviewers and the participants of the Human-Centered Computing seminar at the University of Utah for extensive feedback that helped improve the paper.

Abstract

Apple introduced the App Tracking Transparency (ATT) framework in iOS 14.5. The goal of this framework is to mitigate user concerns about how their privacy-sensitive data is used for targeted advertising. Through this framework, the OS generates an ATT alert to request user permission for tracking. While this alert includes developer-controlled alert text, Apple mandates this text adheres to specific guidelines to prevent users from being coerced into unwillingly granting the ATT permission for tracking. However, to improve apps' monetization, developers may incorporate dark patterns in the ATT alerts to deceive users into granting the permission.

To understand the prevalence and characteristics of such dark patterns, we first study Apple's alert guidelines and identify four patterns that violate standards. We then develop ATTCLS, an ATT alert classification framework that combines contrastive learning for language modeling with a fully connected neural network for multi-label alert pattern classification. Finally, by applying ATTCLS to 4,000 iOS apps, we reveal that 59% of the alerts use four dark patterns that either mislead users, incentivize tracking, include confusing terms, or omit the purpose of the ATT permission.

We then conduct a user study with 114 participants to examine users' understanding of ATT and how different alert patterns can influence their perception. This study reveals that ATT alerts used by current apps often deceive or confuse users. For instance, users can be misled into believing that granting the ATT permission guarantees better app features or that denying it protects all of their sensitive data. We envision that our developed tools and empirical results will aid mobile platforms to refine guidelines, introduce a strict vetting process, and better design privacy-related prompts for users.

1 Introduction

In-app advertising is a primary source of revenue for mobile app developers. To optimize ad revenue, developers use targeted advertising strategies to increase user engagement (e.g., ad clicks and views). This is done by presenting users with ads that align with their preferences and behaviors.

Developers can achieve this by leveraging user identifiers, e.g., device IDs, IP addresses, which link users to detailed user profiles on ad networks. Ad networks collect data about users' browsing habits and interests, which is then used to target users with ads more likely to be of interest to them. iOS facilitates this process by sharing a unique identifier with app developers, the Identifier for Advertisers (IDFA) [1]. The IDFA is a 128-bit number assigned to each device that runs iOS. App developers can use the IDFA to track users' activities in a single app or across apps.

While IDFA enables the delivery of relevant ads to users, it can also be used to track users' online activities and build profiles of their personal lives. This raises privacy concerns for many users, who express concerns about the lack of transparency on data collection and usage practices [2,5,23,55,72].

To address such privacy concerns, Apple has recently introduced the App Tracking Transparency (ATT) framework in iOS 14.5 [8]. App developers must now explicitly ask users for permission before tracking their activity. To request permission for ATT, Apple requires developers to specify their purpose for tracking through an OS-provided permission alert. Developers can also optionally display a custom pre-alert screen to provide additional information to users to help them make an informed decision. If the user grants the ATT permission, iOS shares the IDFA with the app.

The unavailability of IDFA makes it more difficult for developers to track users and deliver personalized ads. To convince users to grant permission, developers customize the purpose string in the ATT permission alert and the pre-alert screen. In this regard, Apple provides guidelines for developers to create clear and straightforward *ATT alerts* (purpose strings and pre-alert screens) that describe the purpose of tracking. Yet, no system-level enforcement mechanism prevents developers from violating these guidelines. As a result, as we expose in this paper, the developers use (dark) "patterns" in ATT alerts.

Previous research has defined dark patterns as deceptive design techniques or practices used by developers or designers to trick users into taking actions unwittingly, often to benefit the developers [24]. In this paper, we focus on those dark

patterns used by app developers to violate Apple's design guidelines regarding the ATT permission.

Prior work has explored various dark patterns that mobile and IoT app developers can use to deceive users into taking unintended actions [16,26,34,35,49,54]. In the context of ATT permissions, recent work has focused on how developers track users when ATT permission is denied [48] and the general perception and decision-making process of users on ATT permission [39]. However, less is known about the patterns that real-world iOS apps adopt in ATT alerts to deceive users into granting permission, and it is unclear how these patterns impact users' perception of ATT permission.

In this paper, therefore, we focus on characterizing how developers embed dark patterns in ATT alerts and how this impacts users by answering the following research questions:

RQ1: Do app developers use ATT alerts in a way that conforms to Apple's guidelines? If not, what are the different dark patterns they use?

RQ2: How do different ATT alert patterns impact the perception and understanding of users on ATT permission, and what are the implications for user privacy?

To answer these questions, we first conduct a large-scale analysis of ATT alerts by analyzing 4K iOS apps on the App Store. To achieve this, we develop dedicated static and dynamic analysis tools to automatically collect ATT alert texts for each app that contain the purpose strings in the ATT permission alert and pre-alert texts in the pre-alert screen.

Thereafter, we use Apple's app store review [7] and human interface design [38] guidelines to create an annotation guide for ATT alert texts. We then annotate the texts with five labels that characterize the different alert patterns (e.g., misleading, ambiguous) identified as violating the guidelines. We discover that only 41% of the apps follow Apple's guidelines, while 53% violate Apple's guidelines, and 6% do not clearly describe the purpose of the ATT permission.

To automate the classification of ATT alert texts, we develop a classification framework that extends a contrastive learning loss function [31] to transform alert texts into sentence embeddings. We then employ a fully-connected neural network multi-label classifier to predict the labels for each ATT alert text. Our framework achieves 90% accuracy on the annotated ATT alerts, and yields an average 8.6% increase in accuracy compared to the three baseline approaches.

Given the large number of apps displaying alert patterns that do not conform to ATT guidelines, we conducted an online user study with 114 iOS users to gauge their understanding and perception of ATT permission through different patterns used in ATT alerts. We find that users have a fundamental misconception about ATT, believing that denying ATT permission protects all of their sensitive data, such as their email address and location, when in reality, only IDFA is strictly protected by the OS. Additionally, depending on the dark patterns, (*a*) users are *more likely* to believe they will receive rewards/discounts or better app features, and they are *more likely* to misunderstand what the permission does by (*b*) being unfamiliar with common terms used in alerts, such as IDFA and identifiers, and (*c*) finding the alert texts confusing.

Overall, we expose that most developers do not follow best practices for explaining ATT permission; instead, they use deceptive or manipulative patterns to coerce users into granting permission. The use of such patterns exacerbates user confusion on ATT permissions. This leads to users having unrealistic expectations about their privacy and tracking transparency, such as earning rewards if they allow tracking. Our findings highlight the need to improve the current iOS ecosystem and future efforts to better align user understanding of iOS privacy and tracking transparency with the actual reality.

In summary, we make the following contributions:

- We analyze 4K iOS apps to study the different patterns used by app developers in ATT alerts and categorize them based on Apple's design guidelines.
- We develop a multi-label classification framework that leverages contrastive learning techniques to create a language representation model for ATT alert texts and automatically classify them into five different alert patterns.
- We conduct a 114-participant user study to gauge users' understanding and perceptions of the ATT permission given the different alert patterns. We summarize our findings and provide recommendations to improve Apple's developer guidelines for ATT alerts.

Responsible Disclosure. Given our study exposes dark patterns in ATT alerts, we have provided Apple with a comprehensive report of our findings. Apple has responded by asking for the app IDs from our dataset, and they are currently in the process of investigating the reported issue.

2 Background and Motivation

2.1 Advertising in iOS

In-App and Targeted Advertising. In-app advertising, where ads for other apps or websites are displayed, remains a prominent method for mobile app developers to profit [71]. Developers generate revenue when a user either passively watches the ad or actively clicks on it. This revenue is maximized with more user engagement, such as when a user visits the app store to download an app shortly after exposure. App developers, therefore, aim for ads that target users' interests.

Targeted ads encourage user engagement with ads, yielding higher ad profit. However, for targeted advertising, apps rely on linking users with detailed user profiles [66]. These profiles are built by tracking user activities across apps and maintained by ad networks. In iOS, this linking occurs using an identifier known as Identifier For Advertisers (IDFA) [1], which is unique to a user's device. Additionally, app developers use IDFA to link users to the ads from which they downloaded

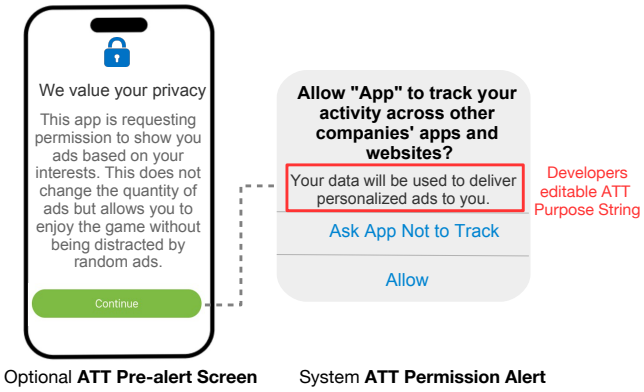

Figure 1: An illustration of ATT alerts.

their apps; a process known as attribution [10]. This helps developers evaluate their investments in ad campaigns and tailor their campaigns to reach more users.

Tracking Transparency Efforts. Despite the potential benefits of targeted advertising (e.g., exposure to ads that solely pertain to one's interest), users have raised many concerns about their privacy-sensitive data being collected by tracking and the lack of control and transparency over their tracking data [23, 56, 72]. In an attempt to address these concerns, Apple introduced a system-wide limited ad tracking (LAT) privacy setting on iOS devices. The LAT setting allows users to opt out of sharing their IDFA with advertisers and third parties [6]. This setting was disabled by default, and when enabled by the user, the OS shares a string of zeros instead of the IDFA to prevent apps from tracking the user. However, prior work has demonstrated that most users were unaware of this system-wide LAT setting [30, 61].

To provide users with better transparency and control over individual apps, Apple has recently introduced the App Tracking Transparency (ATT) permission in iOS 14.5 [22]. With the ATT permission, Apple introduces an opt-in policy where it requires all iOS apps to explicitly request users' permission to use their data for tracking. Apps prompt users at runtime by the ATT request with the option to allow tracking or ask the app not to track. If the users deny the permission, apps are not allowed to access their IDFA. This gives the users more control over how app developers track and collect their data.

2.2 Apple's Design Guidelines for ATT Alerts

To request ATT permission, Apple shows a system-provided *permission alert* with a customizable string to show the permission purpose, known as *purpose string*. Apple requires app developers to provide a clear, straightforward string to describe the purpose of requesting ATT permission and the use of tracking data. Moreover, due to the sensitivity of app tracking, Apple's guidelines encourage developers to display an optional custom screen preceding the system ATT permission alert [38], defined as a *pre-alert screen*. The pre-alert screen serves as an extension of the purpose string, as developers have the flexibility to describe the tracking permission purpose textually as well as visually. An example of the pre-alert screen and the ATT permission alert is shown in Figure 1.

Table 1: Apple's guidelines for ATT permission requests, with relevant portions of each guideline highlighted.

#	Description
G1	Apps should not require users to enable tracking in order to receive monetary or other compensation, including but not limited to gift cards and codes. Don't offer incentives for granting the request. You can't offer people compensation for granting their permission.
G2	Apps should not require users to enable tracking in order to access functionality, content, or use the app.
G3	Aim for a brief, complete sentence that's straightforward, specific, and easy to understand.
G4	Ensure your purpose strings clearly and completely describe your use of the data.

Apple provides several guidelines for the tracking permission and the design of the ATT alerts. Generally, Apple requires that developers design clear and informative alerts that clearly inform the users about how the app uses their data for tracking [38]. We aggregate tracking permission alert and pre-alert design standards from Apple's App Store review guidelines [7] and human interface design guidelines [38] Through this, we extract four different guidelines (**G1-G4**) for ATT alerts, as shown in Table 1.

The guidelines restrict app developers from providing monetary compensation (**G1**) or access to extra functionality or content (**G2**) based on users' decision for the tracking permission. It also explicitly mentions that alerts should be straightforward and easily understood by standard users (**G3**). Alerts should also clearly mention the purpose of the permission and how tracking data will be used (**G4**).

2.3 Problem Statement

Apple's guidelines require developers to craft their own purpose strings to provide the purpose for requesting permission. Developers also have the freedom to design a custom pre-alert screen where they have more room to provide additional information and describe the benefits of tracking to users. This flexibility encourages developers to be more transparent to users about how and why they are tracking them. However, it also brings into question whether developers comply with Apple's guidelines when designing these alerts.

Due to the sensitivity of the tracking permission and the necessity of obtaining the IDFA for app developers (as discussed in Section 2.1), we anticipate that some developers may violate Apple's guidelines to influence users' decisions. Developers may include dark patterns [24] that violate Apple's guidelines in their ATT alerts to deceive users into granting permission to track. Dark patterns refer to user interface design techniques or practices that are intentionally deceptive or manipulative. These design patterns are used to trick users

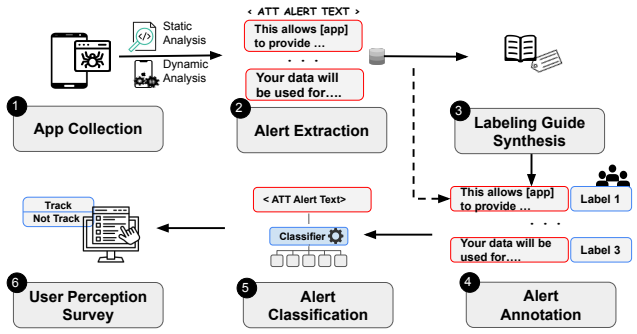

Figure 2: Overview of our approach to understanding ATT patterns and their influence on users.

into taking actions unwittingly, often to benefit developers. Additionally, such use of dark patterns may result in users having misconceptions about the tracking permission, e.g., what it is for, and what happens if permission is granted.

Therefore, our goal is to study the dark patterns that app developers use in ATT alerts and how these patterns do not conform to Apple's guidelines. From understanding the characteristics and prevalence of such patterns, we further study how alert patterns affect the perception of users of the ATT permission. Understanding the prevalence of dark patterns and their influence on users is pivotal to implementing countermeasures and designing ATT permissions that effectively communicate and instill trust among users.

3 Approach Overview

Figure 2 presents an overview of our study methodology. We build an app collection pipeline (❶) which automatically extracts the ATT purpose strings and pre-alert texts from apps on the App Store. To achieve this goal, we first design a static analysis tool, ATTSExtr, to parse the app bundles and extract the ATT purpose string (❷). Since pre-alert screens cannot be extracted directly from app code, we build PREAExtr tool that dynamically executes app bundles on an iPhone, simulates automated touch events, and takes periodic screenshots to capture the pre-alert screens.

We then study Apple's design guidelines for alerts to develop an annotation guide and identify alert patterns that violate these guidelines (❸-❹). Based on these guidelines, we develop ATTCls, an ATT alert classification framework, which leverages contrastive learning for language modeling and a fully connected neural network for multi-label classification of alert texts into one or more patterns (❺).

Guided by our findings from our ATT alert analysis, we conduct a 114-participant online user study to understand how the different alert patterns affect users' perception of the ATT permission (❻). To demonstrate to participants how ATT permissions work in a real scenario, we embedded interactive iOS app prototypes built using Marvel app interface prototyping tool [53] in an online survey.

4 ATT Alert Extraction and Analysis

To understand the different patterns used by app developers in ATT alerts and their conformity with Apple's guidelines (**RQ1**), we conduct a large-scale analysis of the ATT alerts collected from 4K apps available on the Apple App Store. Conducting this analysis involves several challenges that include (1) collecting purpose strings and pre-alerts of ATT alerts automatically, (2) identifying and annotating the alert patterns used by developers in these apps, and (3) automated classification of the ATT alerts.

4.1 Extraction of Alerts from Apps

We develop a static analysis tool ATTSExtr, which analyzes the property file of each app to extract the static purpose strings from ATT alerts. However, since pre-alerts are custom screens shown to the users before the ATT permission alert at run-time, they cannot be obtained through static analysis. Therefore, we complement our static analysis tool with a dynamic analysis tool PREAExtr.

ATT Purpose Strings. ATTSExtr starts analysis by executing the `IPA-tool` [40] to download the app packages. The `IPA-tool` is a command line tool that allows ATTSExtr to search for iOS apps on the App Store and downloads a copy of the app bundle, known as the IPA file. We analyzed the "`Info.plist`" file, which is a structured text file with a collection of key-value pairs of configuration data and included by default in the app bundle. We statically parse the file and extract the ATT purpose string stored under the key `<NSUserTrackingUsageDescription>`.

ATT Pre-alerts. The ATT purpose strings are statically accessible from the app bundles; however, collecting pre-alerts is more challenging. Pre-alerts are custom screens arbitrarily designed by developers; thus, the app bundles must be executed to capture screenshots of the pre-alert screens in real-time. To automate this process, we developed PREAExtr, which dynamically executes the app bundles on an iPhone, simulates random touch events, and periodically captures screenshots while running the app. The injection of touch events requires a rooted device (i.e., jailbreak); thus, PREAExtr runs on a jailbroken iPhone 6 (iOS 14.8).

To detail, PREAExtr leverages `CFGUTIL` [19], Apple's configurator command-line tool, to install the collected IPA files on the phone. We use SSH to control the phone from a server and send system-wide touch events using `ZXTouch` [75], an open-source touch simulation tool. We run each app for 30 secs. This interval is likely to reach ATT since apps usually request permissions when they start. To maximize the chance of clicking the correct buttons, PREAExtr divides the screen into a grid of 45 cells in the center of the screen. During the 30 secs interval, it iteratively picks a cell and simulates a touch event in its center. This approach increases the likelihood of clicking the buttons of other prompts that appear before the ATT permission, such as other permissions or privacy policy

Table 2: Summary of ATT purpose strings collection.

	All collected apps	Apps w. ATT	Non-english / Placeholders filtered	Unique ATT strings
Popular apps	3,156	1,633	4,000	1,605
Random apps	19,579	3,235		
Total apps	**22,735**	**4,868**	**4,000**	**1,605**

Table 3: Summary of ATT pre-alerts collection.

	All apps w. ATT	Apps tested	Reached ATT	Pre-alerts	Unique pre-alerts
Total apps	**4,868**	**4,680**	**2,836**	**273**	**153**

consent popups. PREAEXTR then captures screenshots every second to ensure it obtains ATT pre-alerts and transfers them to the server for further analysis.

After screenshots are recorded, PREAEXTR leverages Google's Tesseract tool [59] to extract the pre-alert text from the screenshot. We use a simple keyword search to identify tracking-related screenshots, such as pre-alert screens and privacy popups. The keywords include *"tracking", "personalized", "ads", "advertisements", "promotions"*. We then manually select the pre-alert screens for further analysis. We note that the pre-alerts may appear as on-screen popups. In such cases, PREAEXTR first crops the popup by detecting the image contours and masking the image using the contour with the maximum area. This process reduces the clutter from the popup's background. An example is shown in Appendix A.

Alert Text Collection Results. To analyze the different patterns used by app developers in ATT purpose strings and pre-alert texts, we start by crawling app IDs from the App Store. We collected two sets of apps, `popular` and `random`.

For `popular` set, we queried the top 100 popular apps in 32 different genres. This search results in a total of 3,156 app IDs. To capture a random set of apps representative of the Apple App Store, we collect `random` set using "`robots.txt`" [62] file, which is designed to assist the navigation of search bots on the store website. We randomly sample the robots file to crawl a large collection of 19,579 apps. Our combined set of apps contained a dataset of 22K apps.

We note that we abide by ethical considerations when we collect data from the Apple App Store. To collect 22K apps, we make at most 1 query per minute. Additionally, we did not circumvent rate limits or use proxies.

We run ATTSEXTR on our dataset. Among the `popular` set, we found 1,633 apps that have ATT permission strings in their property list files, and, for the `random` set, 3,235 of the apps included ATT strings. We detail the distribution of app genres for each set in Appendix A. In our analysis of ATTSEXTR results, we found that a few of our collected apps use a placeholder in the property list instead of the actual purpose string or are not in English. We removed such apps from our dataset, resulting in a total of 4K apps with ATT strings. Additionally, we found that some of the purpose strings used in the Apps are repetitive. We further filtered the non-unique strings, which resulted in a total of 1,605 unique purpose strings.

We summarize our data collection for purpose strings and pre-alerts in Tables 2 and 3. For pre-alerts, we run PREAEXTR on a total of 4,680 apps. We note that, in total, we collected 4,868 IPA files. Yet, 188 of them required an updated version of iOS, which did not have a jailbreak at the time of our analysis. PREAEXTR is able to reach the ATT permission alert for 2,836 apps (60.6%) at run-time. Among the 2,836 apps, it recorded 273 apps that have pre-alerts. Lastly, we filter the repetitive pre-alerts, yielding 153 unique pre-alerts.

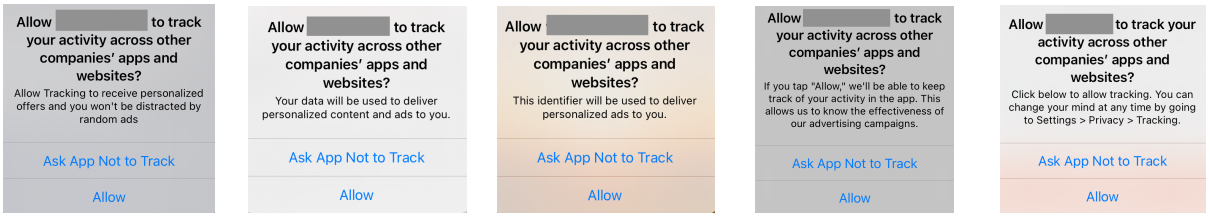
To evaluate the effectiveness of PREAEXTR in extracting the pre-alerts, we assess it on a random sample of 480 apps. Out of 480 apps, 63.3% of the apps show the ATT permission alerts. For the rest of the apps that did not obtain the ATT permission alert, we manually reinstalled them on the phone and used each app for approximately one minute. We found that 14.4% of the apps do not show the ATT permission, and 5.2% of the apps require users to sign in. Additionally, PREAEXTR does not click the correct buttons to display the ATT permission alert for 17.7% apps. We analyzed these cases and found that the ATT alert appears after other popups or ads, which are displayed in full-screen mode with a small exit/skip button that is hard to capture due to its small size or unconventional placement. The ATT alert is only displayed after exiting these screens. We also evaluated the pre-alert screenshot detection by our keyword search tool on over 50 apps. We found that the tool has a negligible false-negative rate (FN=0.02). The tool results in a high false-positive rate since it detects other popups (such as privacy policy consent popups), which we manually filtered in our analysis. Overall, out of the 81% apps that show an ATT permission request, PREAEXTR triggers the permission for 77.8% of them.

4.2 Identifying ATT Alert Patterns

We use Apple's App Store review [7] and human interface design [38] guidelines to produce a labeling guide. This guide contains questions that allow an annotator to label an ATT alert text into five different labels.

4.2.1 Annotation of ATT Alerts

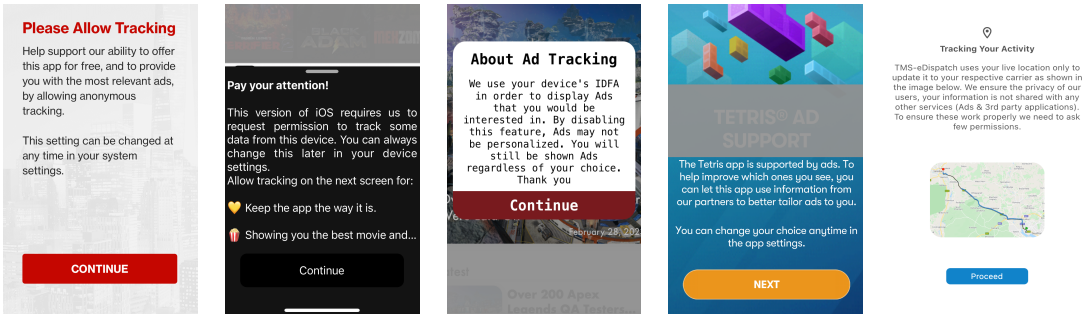
Developing ATT Alert Annotation Guide. To annotate alert texts with an appropriate label, two authors performed an initial study on alert texts of 250 random apps and created a labeling guide. We create this guide by checking the patterns in ATT alerts based on how these alerts do not conform to Apple's official guidelines (**G1-G4** in Table 1). In Table 4, we present example alert texts with their associated labels and detail our annotation process below.



We found apps that *directly* incentivize users by promising rewards, coupons, and special offers ((a) and (b)). Additionally, some apps *indirectly* incentivize users by mentioning that granting ATT permission will enable them to use apps for free ((c)). We label such alerts `Incentive`.

Some apps indicate that users will get better content or user experience if they allow tracking ((d)). Another set of apps

Table 4: Examples of ATT alerts of real-world apps assigned to five different labels with our data annotation guide.



Label	ATT Alert Text[†]
Incentive	(a) *This allows [app] to determine if you are eligible to receive a reward after creating your account.* (b) *This helps us serve relevant coupons and ads that are tailored to you.* (c) *We can offer our service for free to you only by delivering personalized ads.*
Misleading	(d) *This will allow us to offer more relevant content and provide you with a better experience throughout the app.* (e) *It will help us deliver a more personalized experience, and fewer ads.* (f) *This will help [app] to recruit only professional delivery partners like you. Bonus: the app will send fewer irrelevant messages.*
Ambiguous	(g) *App would like to access IDFA for tracking purpose.* (h) *Identifier will be used for attributing installs (from Facebook, Google) and performance measurement in marketing companies.*
Complete	(i) *This helps [app] and our ad partners provide you with a more personalized ad experience.* (j) *By clicking "Allow Tracking", your consent to your data being used for analytics purposes and personalized advertisements.*
Other	(k) *Your data allows for the optimization of the in-app ad experience for you.* (l) *We personally do not track any user information.*

[†] We redact app names in this table.

(a) `Incentive` (b) `Misleading` (c) `Ambiguous` (d) `Complete` (e) `Other`

Figure 3: Examples of ATT permission alerts with purpose strings of different patterns.

(a) `Incentive` (b) `Misleading` (c) `Ambiguous` (d) `Complete` (e) `Other`

Figure 4: Examples of pre-alert screens with different patterns.

promises that granting permission will yield fewer ads ((e)) and allow them to receive a bonus of an app-related feature ((f)). We label such alerts `Misleading`.

We also discover that some developers use technical terms or descriptions vague or difficult to understand for a standard user. For instance, some alert texts contain *IDFA* or *device identifiers* ((g)), and others mention attribution of marketing campaigns ((h)). We label such apps `Ambiguous`.

If an app is not labeled with `Misleading`, `Ambiguous`, or `Incentive`, we check whether the alert informs the user about the purpose of the ATT permission request and how their data will be used. Apps passing this check are labeled `Complete` ((i) and (j)). If no label matches the alert text, we label the alert as `Other`. With `Other`, we refer to alerts that do not have misleading, ambiguous, or incentive patterns, yet still do not explicitly express the ATT permission purpose ((k) and (l)).

During our annotation process, we found some alert texts that fail to conform to multiple ATT guidelines. For instance, an alert includes both `Incentive` and `Misleading` statements, e.g., *"We cannot send you gifts and offers without your permission, we will try to send you only the most important and attractive content!"*. Thus, our annotation guide allows associating a single alert with multiple labels. We present our labeling guide in our project repository [9].

To further illustrate the disclosures of ATT alerts, we provide examples for the different patterns of ATT purpose strings and pre-alert screens in Figures 3 and 4, respectively. For `Incentive` patterns, Figure 3a presents an example mentioning personalized offers, while the pre-alert in Figure 4a indirectly incentivizes the user by mentioning offering the app for free. Similarly, the examples in Figure 3b and Figure 4b mention patterns as "*personalized content*" and "*showing the*

Table 5: Distribution of annotated ATT alerts.

Label	Unique Alerts Purpose Strings	Unique Alerts Pre-alerts	App Alerts Purpose Strings	App Alerts Pre-alerts	Avg. Rate† Counts (Std)	Unique Vendors
Incentive (Inc)	109 (6.8%)	38 (24.8%)	168 (4.2%)	96 (35.2%)	571,278 (1.78M)	92
Misleading (Misl)	591 (36.8%)	38 (24.8%)	810 (20.2%)	76 (27.8%)	169,518 (1.24M)	527
Ambiguous (Ambg)	138 (8.6%)	5 (3.3%)	989 (24.7%)	5 (1.8%)	34,210 (164K)	857
Inc, Misl	53 (3.3%)	11 (7.2%)	66 (1.7%)	22 (8.1%)	206,700 (422K)	31
Inc, Ambg	8 (0.5%)	0 (0%)	8 (0.2%)	0 (0%)	81626(159K)	5
Misl, Ambg	68 (4.2%)	3 (2%)	91 (2.3%)	4 (1.5%)	119,862 (319K)	67
Inc, Misl, Ambg	3 (0.2%)	0 (0%)	3 (0.08%)	0 (0%)	27,153	1
Complete	437 (27.2%)	51 (33.3%)	1631 (40.7%)	62 (22.7%)	115,857 (594K)	1,351
Other	198 (12.3%)	7 (4.6%)	234 (5.9%)	8 (2.9%)	471,607 (2.39M)	157
Total	**1,605**	**153**	**4,000**	**273**	—	—

† Represent the number of ratings for the app. Standard deviation is presented in parentheses.

best movies". Both examples fall under the `Misleading` pattern since they refer to better functionality. The `Ambiguous` examples (Figures 3c and 4c) mention vague terms e.g., "*identifier*" and "*IDFA*". Moreover, the examples labeled with `Other` (Figures 3e and 4e) do not fit any of the aforementioned patterns, yet they fail to explicitly state the permission purpose.

Guide Validation and Annotating Alerts. Before labeling alert texts from our dataset of unique 1,605 purpose strings and 153 pre-alerts, we first validate our labeling guide. To do so, two authors independently label a random sample of 105 purpose strings and all 153 pre-alerts.

To measure agreement between annotators, we use Krippendorff alpha [50], which supports multi-label annotations. Authors achieved high agreement ($\alpha > 0.8$), reconciled differences and make necessary modifications to the annotation guide, e.g., providing examples and additional clarifications for each labeling guide question. After guide validation, to label the remaining 1,500 alert texts, we sought volunteer annotators through internal posts in the Slack channel of our institution. Through this method, we recruited four security and privacy researchers. We first met with volunteers to explain our labeling methodology and guideline. After clarifying doubts, annotators expressed confidence in the labeling guide.

These four volunteers and two authors were divided into three groups comprising two annotators each. We leverage the open-source tool Doccano [27] for collaborative annotation. Each group labeled 500 alert texts over three sessions (100 in the first session and 200 in the second and third sessions). Annotators within each group independently labeled alerts. The annotators met after each session to resolve the annotation conflicts. We note that in the first round, each group achieved sufficient agreement ($\alpha > 0.667$) [50], and, by the second and third rounds, each group achieved high agreement ($\alpha > 0.8$).

4.2.2 Findings from Annotated Data

Table 5 shows the distribution of labels for the annotated purpose strings and pre-alerts. For the unique purpose strings, we find that 27.2% are `Complete` while 36.8%, 6.8%, and 8.6% alerts are `Misleading`, `Incentive`, and `Ambiguous`, respectively. To better understand and characterize alert patterns used by app developers in the wild, we reflect the annotations to the entire dataset of 4K apps, including both popular and random apps. We, thus, mark all the non-unique alert texts with the same labels as their corresponding alert text labels in the annotated dataset. We summarize our data collection and labeling results for the full apps dataset in Figure 5.

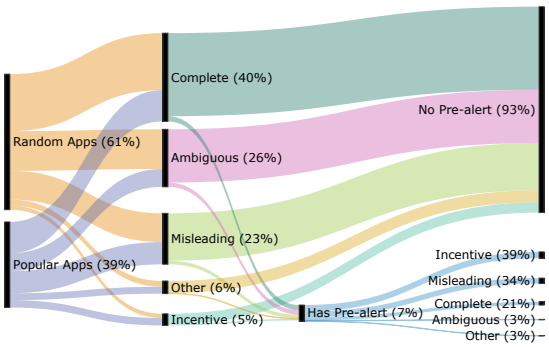


Figure 5: Summary of apps collection and labeling.

To detail, 60% of the apps use repeating alert texts, with the `Ambiguous` pattern repeating most often (86% of `Ambiguous` patterns are repeating). In Table 5, we show the distribution of apps after mapping the annotations to the complete dataset. We also show some app statistics, including the average rating counts (and std), which reflects the popularity of apps. We note that the std values are high for all patterns since we use diverse data sets with popular and random apps. We also report the number of unique vendors per app pattern. When examining label distribution across app categories (e.g., games, business, social networking), we find no correlation between app category and pattern labels. We show the mapping between labels and app categories in Appendix A (Figure 3).

Observing the app patterns, we find that 40.7% of the ATT purpose strings are `Complete`, 25% are `Ambiguous`, 20% are `Misleading`, 4% are `Incentive`, and 6% are annotated as `Other`. As anticipated, more than 60% of app developers are using patterns that violate Apple's guidelines, which can influence users' decisions to grant ATT permission.

Similarly, for the pre-alerts, we show the analysis results for the unique and repeated pre-alert texts. The unique pre-alerts show 33.3% `Complete`, 3.3% `Ambiguous`, 24.8% `Misleading`, 24.8% `Incentive`, and 4.6% as `Other`. Interestingly, the pre-alerts of the full apps' set show that only 22.7% are `Complete`, while the remaining 77.3% are distributed among the rest of the patterns, with 35.2% `Incentive`, 27.8% `Misleading` and 8.1% both `Incentive` and `Misleading`. We also notice that while the `Incentive` pattern is the least common among purpose strings, it is the most frequent pattern in pre-alerts. This highlights that most apps that show customizable pre-alerts leverage them to persuade users into granting the ATT permission by using these patterns.

Finally, we study the combinations of pattern labels among purpose strings and pre-alerts. We detail the distribution of labels for both purpose strings and pre-alerts in Appendix A (Table 1). We found that only 36.6% of the apps use similar patterns in the purpose strings and pre-alerts, with the rest using different patterns. We also found that among the apps with `Complete` purpose strings that show pre-alerts, about

73.5% have `Incentive` or `Misleading` pre-alerts, while only 20.7% show `Complete` pre-alerts. This indicates that even apps with `Complete` purpose strings still try to manipulate users by showing dark patterns in their pre-alerts.

4.3 Automated Classification of ATT Alerts

To automate the classification of ATT alerts, we develop a multi-class classification framework, ATTCLS, which predicts the labels for each ATT alert text.

ATT Alert Embedding Representation. To accurately classify the ATT alerts, we first extract semantic features from the alert text. To achieve this goal, we extend a contrastive learning-based sentence embedding framework, SIMCSE [31], to transform each alert text into an embedding space representation. This framework uses a contrastive objective on top of pre-trained language models such as BERT [44] or ROBERTA [52] to produce sentence embeddings from limited labeled data. We leverage this contrastive objective to learn an effective sentence representation for each alert text, even with a small training dataset, such that alerts with the same class label are closer to each other while alerts with different class labels are farther apart in the embedding space.

Our sentence embedding framework learns from pairs of ATT alerts that are semantically related. To generate positive pairs, we consider combinations of alerts with the same class labels as they are contextually similar. Therefore, assuming a set of m paired examples $\mathcal{D} = \{(x_i, x_i^+)\}$ for $i \in \{1, m\}$, where x_i and x_i^+ is considered as the positive pair, we first extract language representations em_i and em_i^+ for x_i and x_i^+, using a pre-trained language model. We then fine-tune these representations using a cross-entropy training objective computed for a mini-batch of N pairs:

$$l_i = -\log \frac{e^{\text{sim}(em_i, em_i^+)/\tau}}{\sum_{j=1}^{N} e^{\text{sim}(em_i, em_j^+)/\tau}} \quad (1)$$

Here τ is a temperature scaling hyperparameter and $\text{sim}(a,b)$ is the cosine similarity between vectors of a and b ($a^T b/(\| a \| \| b \|)$). The output of the framework is a sentence embedding for the ATT alert that captures the semantic and contextual meaning of the alert text.

ATT Multi-Class Pattern Prediction. Given that ATT alerts may fail to conform to multiple guidelines, we consider the problem of inferring the ATT pattern as a multi-class prediction task. We design a fully-connected neural network as part of ATTCLS that takes an ATT alert embedding extracted through SIMCSE and predicts its class labels.

The model leverages a sigmoid objective function for label prediction. Specifically, we add a sigmoid function for each of the five labels (identified in Section 4.2) as $\text{sigmoid}(h_i) = \frac{1}{1+e^{-h_i}}$ which outputs a score in the range $[0, 1]$.

In this way, the network outputs a vector $\hat{y}_i$ with a length equal to the number of class labels. An alert is assigned the label j if its sigmoid function score $\geq T$. This vector is then fed into a logistic cross-entropy loss function, which outputs the final class predictions for the alert.

At inference time, if the sigmoid score is the highest for the `Complete` or `Other` class, we only assign a single class label corresponding to the highest sigmoid function. This is because the alerts containing these patterns do not display the other three patterns, `Misleading`, `Incentive`, or `Ambiguous`.

Implementation. We implement ATTCLS in Python 3.10 using Simple Transformers library [65] and SimCSE model implementation [31]. We leverage our full labeled ATT alert dataset consisting of 4K ATT purpose strings and 273 pre-alerts to train and test our framework. We use stratified sampling to split the ATT strings into 90% for training and 10% for testing. To train the contrastive embedding framework, we generate 150K positive pairs from our training data set. We leverage ROBERTA [52] as the pre-trained language model to obtain the intermediate language representations. We use the fine-tuned hyperparameters provided in [31] for training the supervised SIMCSE on our ATT alerts dataset. We do not fine-tune the model on the test set or pre-alerts. We set the sigmoid function score T in our multi-class classifier to 0.5 as it yields the best accuracy in our validation dataset.

Table 6: Classification results for [purpose strings / pre-alerts].

Model	Precision	Recall	F-measure
ATTCLS	**0.90 / 0.79**	**0.90 / 0.82**	**0.90/ 0.80**
$\text{ATTCLS}_{\text{SIMCSE}_{\text{BERT}}}$	0.88 / 0.75	0.87 / 0.77	0.88 / 0.76
$\text{ATTCLS}_{\text{BERT}}$	0.88 / 0.76	0.89 / 0.77	0.89 / 0.77
Random Forest	0.92 / 0.86	0.68 / 0.68	0.78 / 0.76

Table 7: F-measure results per alert label.

Alert Label	Purpose strings	Pre-alerts
`Incentive`	1.00	0.87
`Misleading`	0.88	0.81
`Ambiguous`	0.97	0.57
`Complete`	0.90	0.66
`Other`	0.78	0.60

4.3.1 Effectiveness of ATTCLS

We measure the framework's effectiveness through precision, recall, and F-measure. We compute each metric as the average of the corresponding metric per class label. Table 6 (row 1) shows the average precision, recall, and F-measure for the ATT purpose strings and pre-alert texts. For the purpose strings, ATTCLS achieves a 90% accuracy. We show the F-measure results per alert label in Table 7. The accuracy is slightly lower for the `Other` label since alerts labeled as `Other` do not cover a specific pattern and lack semantic structure.

For the pre-alerts, ATTCLS achieves an accuracy of 78%. The accuracy of pre-alerts decreases compared to purpose strings as the app developers have the flexibility to explain the purpose of ATT permission with more words and phrases. This results in pre-alert texts that contain patterns with lexical and semantic ambiguity, yielding lower accuracy.

Comparison with Baseline Approaches. We compare the ef-

fectiveness of ATTCLS with three baseline approaches. These approaches are widely used for similar text classification tasks, such as mobile privacy settings and policies classification [36, 45] and phishing detection [21]. The first baseline is a Random Forest classifier that leverages vectorization to obtain a text representation of the alerts. Second, we train a classifier that uses the BERT model to extract the embedding representation of alerts and then perform multi-label classification through a fully connected neural network. Lastly, we replace the ROBERTA model with the BERT model in SIMCSE model of ATTCLS as the pre-trained language model.

Table 6 (row 2-4) shows the results for these baseline models compared to our classification framework for both purpose strings and pre-alerts, respectively. ATTCLS achieves a higher accuracy of 90% compared to all three baseline models.

5 User Attitudes Towards ATT Alerts

In this section, we pivot to studying user understanding of the ATT permission and how different alert patterns influence user perception of ATT permission alerts. To achieve this goal, we designed an online survey and divided our second research question **RQ2** (*How do different ATT alert patterns impact the perception and understanding of users on ATT permission, and what are the implications for user privacy?*) into the following four sub-research questions:

SQ1: How do users perceive the purpose of the ATT permission for different alert patterns?

SQ2: How do users' tracking preferences change for different alert patterns?

SQ3: What is the influence of `Misleading` and `Incentive` alerts on users' understanding of ATT?

SQ4: Do users find different alert patterns vague or difficult to comprehend?

5.1 Study Design

Our study's objective is to measure users' perception of the ATT permission given different patterns used in alerts. Therefore, we perform a between-subjects study with five groups corresponding to the five alert patterns. We conducted an online user survey using Qualtrics [60]. To simulate a realistic scenario, we embedded an interactive iOS app prototype in our survey implemented using the Marvel app tool [53]. We implemented interface prototypes for 20 real-world apps, four apps per alert pattern. Selected apps represent common textual patterns exhibited in each alert pattern.

We randomly selected one app prototype for each participant (all alert texts displayed to different participants are in Appendix B.3). We then requested participants to interact with the prototype. We displayed the initial screens in the app, including the ATT alert. After making a selection on the alert, we displayed the message *"You finished using this app!"* and a random code of 8 digits and letters. This code is used as an attention check; we asked the users to use the app until they see this message and type the displayed code in a text box.

We divide our survey into two main blocks. First, we display the Marvel app prototype and ask questions related to the alert displayed in the app (`Alert-Questions`). Questions comprised Likert scales (to measure user preference/familiarity/confidence) and open-text questions (where users were able to justify their responses or provide further detail). Second, we ask general questions about prior knowledge of users on app tracking and ATT (`Tracking-Questions`). We also collect demographic data and users' technical experience. `Tracking-Questions` were asked at the conclusion of the survey to prevent influencing participants' responses.

Ethics. We obtained IRB approval prior to our study. Our study was deemed as "IRB exempt" by our institution's IRB office. IRB defines exemption as not requiring the study to be reviewed by IRB board members in a convened meeting. To minimize harm, our study was reviewed by a primary reviewer and analyst from the IRB office, who worked with the authors to ensure ethical protocol design. Before starting the survey, we ask the participants to accept an online consent form where we explain the study details and participants' rights. We avoid collecting personally identifiable data other than demographic data. We remove any other identifiers and store the responses in an encrypted online storage.

5.2 Recruitment

After conducting pilot studies to carefully revise our survey (detailed in Appendix B.1), we recruited participants on Prolific [58], specifying three criteria: (1) Participants were required to use iOS as their primary phone operating system, (2) reside in the US, and (3) be above 18 years of age. Our study was advertised as a perception study of permissions in iPhones. We recruited a total of 121 participants. We rejected responses from 7 participants who failed attention checks (in accordance with Prolific guidelines). The accepted 114 participants received a $3 reward upon survey completion.

Participants are 46.5% males and 50% females. 21% of the participants have technical experience, either by receiving an education in computer science, software development, or other technical fields. Complete demographic breakdown of the survey participants are presented in Appendix B.2 (Table 3).

5.3 Data Analysis

Qualitative Analysis. We thematically analyze participants' responses to open-text questions. Two authors conducted inductive coding independently. They generated iteratively refined codes before grouping them under themes. Authors met to reconcile differences. We note that authors achieve high inter-rater agreement (Cohen's Kappa [37], $\kappa > 0.80$).

Quantitative Analysis. We employed three statistical significance tests to measure significant differences and associations (between categorical data). We use a one-way ANOVA test [29] to test for significant differences across alert patterns (between subjects). We use the Wilcoxon signed-rank test [29] to test for significant differences within subjects (e.g., how

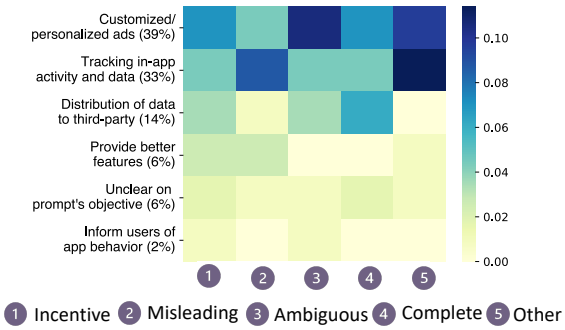

Figure 6: Users perception of what permissions are for - percentages with respect to total participants.

scores change in *"Allow"* vs. *"Not track"* scenarios). To test for association between alert patterns and themes extracted from inductive coding, we use the Fisher-Freeman-Halton (FFH) test [11]. We note that the Fisher's Exact test only considers association in 2-by-2 tables, yet our study has five alert patterns and more than two themes for inductively coded responses, which the FFH test supports.

For all tests, we assume a null hypothesis (H_0) of no difference/association and an alternative hypothesis of significant difference/association (H_1). We reject H_0 and accept H_1 when the p value is less than a threshold, and we report p values when there is a significant difference/association. For most tests, we assign a threshold of 0.05. We do note in relevant subsections when we leverage Bonferroni correction [63], which we apply to a family of tests to adjust the corresponding p value. When results are significant, we report the effect size using the Common Language Effect Size (CLES) [57].

5.4 Results and Findings

General Understanding of ATT. We asked participants to score familiarity with app tracking and ATT (1 and 5, with 5 being very familiar). They report, on average, moderate familiarity with app tracking (mean=3.1, std=1.2) but a lack of familiarity with ATT (mean=1.7, std=1.1).

When prompted to divulge how they had heard of these terms, 31% and 24% had heard of app tracking from social media and the app store, respectively. Lesser common sources comprised other blogs or websites, e.g., tech-related blogs, forums, (22%) and Apple's Website (8%), additional sources such as news or online classes (8%). When asked how they had heard of ATT, 12% mentioned social media and 13% mentioned other online blogs or websites. Participants also mentioned Apple's app store (10%), Apple's website (1%), and other sources (e.g., Facebook/news, 3%).

When comparing participants with and without claimed technical experience, a one-way ANOVA test reveals no significant differences in their familiarity with app tracking ($p = 0.54$) or ATT ($p = 0.18$). This suggests that technical experience is a poor indicator of familiarity with ATT.

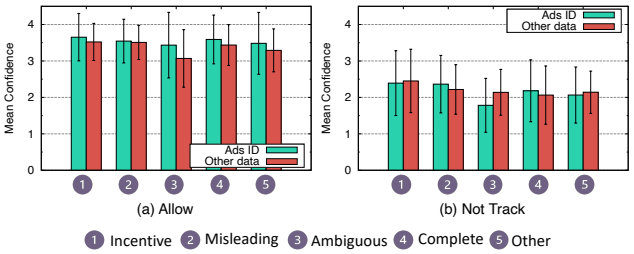

Figure 7: Participants' mean confidence about whether ad IDs vs other data types could be used for tracking.

5.4.1 SQ1: *Users' Perceptions of ATT Alert Purpose*

User Interpretations of the ATT Permissions. We asked participants what they believed the permission was used for in an open-text response. Figure 6 presents the six themes of how they interpret ATT permissions. We found no association between alert patterns and perception of the permission ($p > 0.05$). Broadly, they believe permissions are either for customized/personalized ads (39%), tracking in-app activity/data (33%), or distribution of data to third-party (14%). A minority of them believed it was intended to inform users of app behavior (2%) or provide better app features (6%) through tracking. Participants also occasionally note the uncertainty in what permissions are used for (unclear on alert's objective, 6%). Although customized advertising is the most prevalent theme, none of the participants who associate ATT permissions with ad support mention IDFA or identifiers.

Data Sharing. We asked participants to report how confident they were that certain data types could be used for tracking in both possible scenarios; when the permission response is either *"Allow"* and *"Not track"*. They were asked to score their confidence level as one of four options ("I am sure it can be used" encoded as 4, and "I am confident it cannot be used" as 1), for the advertising ID and other common data types (IP address, email, location, phone name, and phone model).

Figure 7 presents the mean confidence level for advertising ID and aggregate of all other data types in the *"Allow"* and the *"Not track"* scenarios. Interestingly, participants report high confidence that **both** advertising ID and other data types could be used to track them, if *"Allow"* is selected, irrespective of the pattern (no significant difference, $p > 0.05$, between patterns in both advertising ID and other data types). This confidence drops in the *"Not track"* scenario. Table 8 presents confidence levels in finer granularity across patterns and for each data type. We apply a multiple-test correction (Bonferroni correction) to reduce family-wise error as we consider different tests across data as a family. After correction, we independently tested each pattern and each data (e.g., *Is there a difference in confidence level between "Allow" and "Not track" for advertising ID in* `Ambiguous` *alert?*), we observe a significant confidence level decrease ($p < 0.0083$), for all data types across each pattern except for two data types in the `ambiguous` label: (1) phone model and (2) phone name.

Table 8: Participants' confidence level of whether different data items could be accessed for tracking, assuming the user selected *"Allow"* or *"Not track"* in the ATT permission prompt. 4: "I am sure it can be used", 3: "I think so", 2: "I am not sure", 1: "I am confident it can't be used". We aggregate values and present the mean and standard deviation (Mean [±Stdev])

	Assuming the user selected *"Allow"*					Assuming the user selected *"Not track"*				
Data type	**Incentive**	**Misleading**	**Ambiguous**	**Complete**	**Other**	**Incentive**	**Misleading**	**Ambiguous**	**Complete**	**Other**
Advertising ID	3.7 [± 0.7]	3.6 [± 0.6]	3.4 [± 0.9]	3.6 [± 0.7]	3.5 [± 0.9]	2.4 [± 0.9]	2.3 [± 0.8]	1.8 [± 0.7]	2.2 [± 0.9]	2.0 [± 0.8]
IP Address	3.6 [± 0.6]	3.6 [± 0.7]	2.9 [± 1.0]	3.5 [± 0.6]	3.4 [± 0.9]	2.7 [± 1.1]	2.2 [± 0.9]	2.2[± 0.9]	2.1 [± 0.9]	2.3 [± 0.9]
Email	3.3 [± 0.7]	3.3 [± 0.8]	3.1 [± 0.9]	3.3 [± 1.0]	3.2 [± 0.8]	2.4 [± 0.9]	2.2 [± 0.7]	2.1 [± 0.9]	2.0 [± 0.9]	2.2 [± 0.9]
Location	3.8 [± 0.5]	3.8 [± 0.5]	3.6 [± 0.8]	3.7 [± 0.7]	3.7 [± 0.6]	2.5 [± 1.0]	2.2 [± 0.9]	2.0 [± 0.8]	2.0 [± 1.1]	2.2 [± 0.9]
Phone Namel	3.6 [± 0.6]	3.7 [± 0.5]	3.0 [± 1.0]	3.4 [± 0.8]	3.3 [± 0.7]	2.3 [± 0.9]	2.2 [± 0.9]	2.3 [± 0.8]	2.1 [± 0.9]	2.2 [± 0.8]
Phone Model	3.3 [± 0.9]	3.4 [± 0.8]	2.8 [± 1.0]	3.3 [± 0.8]	3.2 [± 0.8]	2.3 [± 0.9]	2.2 [± 0.8]	2.1 [± 0.9]	2.1 [± 0.9]	2.0 [± 0.7]

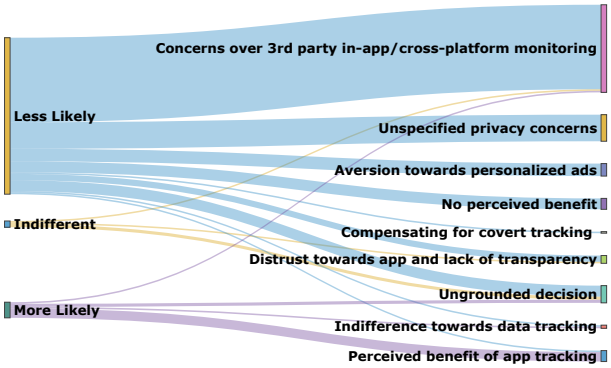

Figure 8: Participant justification for preference towards/against tracking.

Effect sizes for significant results are moderate (CLES ~0.6).

We posit that this general decrease is due to users holding an (incorrect) belief that denying the ATT permission protects **all** of their sensitive data from being used for tracking instead of solely their advertising ID. On the contrary, ATT permission only automatically protects the advertising ID (as explained in Section 3). Other data types are only protected by Apple's privacy policy and the operating system does not prevent apps from accessing them. Hence, apps may still use other data to track users even without users granting explicit permission. In fact, this behavior is common, as pointed out by related research on app tracking in iOS [48].

`Finding-1:` Participants predominantly attribute ATT permissions to (1) customized advertising (2) tracking app activity/behavior or (3) distributing data to third parties. Irrespective of alert pattern, participants incorrectly believe that selecting *"Not track"* protects various data types beyond Advertising ID.

5.4.2 SQ2: *Users' Preferences of Tracking*

We measure participants' preference towards selecting *"Allow"* or *"Not track"* and whether their preference changes between alert patterns. Since they are not using their personal device, we opt for a Likert scale with 1 referring to *more likely to select "Allow"* and 5 referring to *more likely to select "Not track"* instead of binary options (*"Allow"*, *"Not track"*).

We find that participants express a general disinterest towards tracking regardless of the alert, with most leaning towards *"Not track"*. Mean scores range between 4.4 to 4.7 (no significant difference between alert patterns, p= 0.7240).

We also asked participants to provide reasoning for their scores, as presented in Figure 8. We map the reasons they provide to their tracking preference scores, which we grouped into three categories: (1) *less likely* to allow tracking, scores $>$ 3, (2) *indifferent*, score $=$ 3, and (3) *more likely* to allow tracking, score $<$ 3. We observed an association between the reasons and scores ($p = 0.0001$).

A lesser likelihood is associated with a negative perception of data tracking. As seen in Figure 8, the negative perception is expressed among six themes. 49% have concerns over third-party in-app/cross-platform monitoring (e.g., *"I don't want this app tracking me or giving my info to 3rd parties"*, *"Whatever I do outside of that app is none of that app's business"*). Other reasons include aversion towards personalized ads (7%), no perceived benefit of tracking (6%), and distrust towards the app and lack of transparency (4%). Interestingly, one participant (1%) avoids data tracking on apps to compensate for covert tracking that occurs in other online spaces (*"There's enough stuff online tracking my activity that I don't know about. The ones I do know about, [I say] please do not."*) We also note that 15% attribute their scores to unspecified privacy concerns, since they note being generally cautious about privacy but avoid providing explicit reasons. Participants who are indifferent or more likely to opt for tracking provide a variety of other reasons, including the perceived benefit of app tracking (6%) and indifference towards data tracking (2%). 10% of them admit not having a concrete reason for their score (e.g., *"I don't care which I pick"*).

`Finding-2:` Participants are *more inclined* to select *"Not track"*, regardless of alert pattern, with most attributing this choice to a strong preference against data tracking.

5.4.3 SQ3: *Influence of Misleading and Incentive Alerts*

For *"Allow"* and *"Not track"* scenarios, we asked participants to score likelihood (1-5, with 5 being extremely likely) of (1) getting a reward or extra discount and (2) getting access to better app features. Results are shown in Table 9. Participants provide low likelihood for rewards/discounts across all patterns in *"Not track"*. Those exposed to `Incentive` alerts provided

Table 9: Participants' self-reported likelihood for receiving better rewards or discounts (Mean [±Stdev]).

Scenario	Better Rewards/Discount				
	Incentive	Misleading	Ambiguous	Complete	Other
"Allow"	2.1 [± 1.5]	1.8 [± 1.0]	1.3 [± 0.7]	1.8 [± 0.9]	1.5 [± 0.7]
"Not track"	1.2 [± 0.4]	1.4 [± 0.8]	1.1 [± 0.3]	1.4 [± 1.0]	1.2 [± 0.9]
Scenario	**Better App Features**				
	Incentive	Misleading	Ambiguous	Complete	Other
"Allow"	1.7 [± 1.0]	2.1 [± 1.3]	1.4 [± 0.7]	1.6 [± 1.0]	1.8 [± 1.0]
"Not track"	1.2 [± 0.5]	1.3 [± 0.7]	1.1 [± 0.3]	1.4 [± 1.0]	1.1 [± 0.4]

the highest likelihood in the *"Allow"* scenario. Similarly, for app features, participants provide low scores (mean=1.2). `Misleading` alerts elicit the highest (still modest, mean=2.1) likelihood for app features with *"Allow"* scenario.

To better understand if users' opinion of tracking changes from *"Not track"* to *"Allow"*, we measure the difference in likelihood between these two scenarios. We note that we conducted separate Wilcoxon tests instead of using a unified model as we found no correlation between (1) participants' belief towards the impact of extra features/rewards and (2) the likelihood score of allow-vs-not-track. For better reward/discount likelihood, a Wilcoxon signed-rank test reveals a significant difference (p = 0.0069 , CLES= 0.64) in likelihood for `Incentive` alerts. This shows that users are more likely to believe they will get better rewards/discounts if they change their decision from *"Not track"* to *"Allow"*.

Expectedly, participants exposed to `Misleading` patterns display a significant difference (p = 0.0065, CLES= 0.67) in the likelihood of receiving app features between *"Not track"* and *"Allow"*. These users were more likely to believe they would get better app features if they provided consent to tracking. Surprisingly, we also find a significant difference in the likelihood of better app feature between *"Allow"* and *"Not track"* for both `Other` (p = 0.001, CLES= 0.69) and `Incentive` (p = 0.02, CLES= 0.62) alerts. We note that for significant results, effect sizes (CLES) are moderate (~0.60).

We posit that, in the `Incentive`/`Other` alerts, confusion caused by the alert text may lead to misconceptions surrounding app features. For instance, one participant exposed to `Incentive` alerts believed *"allowing [app] to know your interests across other platforms [...] ties in to possibly [...] better app features."* Similarly, another participant exposed to an `Other` alert stated *"If you do not allow [tracking], then they have no reason to give you anything in return."* These findings suggest that, when the purpose of tracking is not mentioned (`Other` pattern) or when rewards are promised (`Incentive` pattern), participants may incorrectly infer better app features are given when consent to tracking is granted, although this is not explicitly mentioned.

`Finding-3:` Participants believe they will *more likely* receive rewards when alerts have `Incentive` patterns.

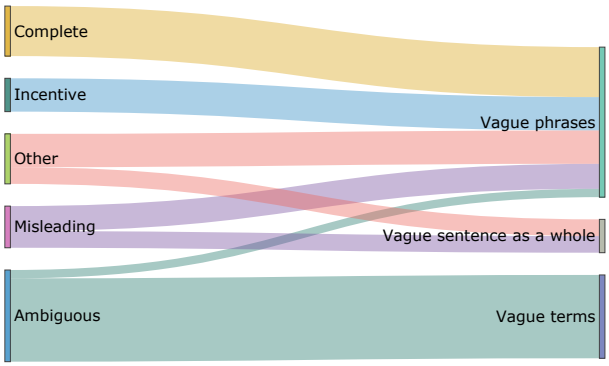

Figure 9: Participants reported confusion about the whole sentence, phrases within alerts, or specific terms.

`Finding-4:` Participants are *more likely* to believe they will receive better app features when alerts have `Misleading`, `Incentive`, or `Other` patterns in alerts.

5.4.4 SQ4: *Comprehension of Alerts and Vague Terms*

We asked participants to disclose if they found any portion of the alert vague or unclear. 28% of the participants respond to this optional open-text question to express confusion. We found that 47.8% of those who saw `Ambiguous` alerts note vagueness. Percentages of other alerts are 25% for `Misleading`, 27% for `Complete`, 17.4% for `Incentive`, and 23% for `Other`. After inductive coding, we discovered this confusion occurs at one of three levels, which we mapped to alert patterns as shown in Figure 9. We find an association between alert pattern and confusion type ($p = 0.0008$). Among those who noted vague alerts, 31.25% associated vagueness to specific words. Words noted surrounded advertising IDs (e.g., *"IDFA"*, *"Identifier"*). Unsurprisingly, all who noted vague terms were exposed to `Ambiguous` alerts.

For other alert patterns, we find participants expressed confusion in one of two ways. First, 56.25% expressed confusion due to vague phrases (e.g., *"Third party partners are vague as it could be anyone at all."*, *"what is partner information?"*). Second, 12.5% expressed confusion around the entire sentence (e.g., *"The whole sentence is vague"*).

In `Tracking-Related Questions`, we also explicitly asked participants about their knowledge of "IDFA" and "Identifiers" on a Likert scale of 1 to 5 (5 being very knowledgeable). We selected these terms after our analysis in Section 4 revealed them to be common in `Ambiguous` alerts. Participants expressed low familiarity with both "IDFA" (mean = 1.2, ±0.6) and "Identifiers" (mean = 1.68, ±1.1).

`Finding-5:` 28% of the participants find ATT alerts confusing, with the `Ambiguous` group noting vague alerts the most (47.8%). Participants are also largely unfamiliar with common terms in `Ambiguous` alerts. For other alert patterns (e.g., `Misleading`, `Incentive`), participants may be confused by vague phrases or the sentence as a whole.

6 Discussion and Limitations

6.1 Takeaways and Recommendations

Clarity in Guidelines. Instructions and recommendations for tracking, permission purpose strings, and pre-alerts are dispersed in multiple documents and webpages via Apple's Developers Guidelines. For instance, to view violations, developers would have to access the "Patterns" section of the "Human Interface Guidelines"; however, appropriate tracking uses are listed in the "App Privacy Details" section. This makes guideline adherence difficult, as developers do not have a single information source they can reference. To rectify this, we first recommend that Apple provide a single source of documentation for ATT permissions that addresses tracking and design guidelines (for alerts and pre-alerts).

Additionally, current guidelines only have (1) limited positive examples (appropriate ATT alert texts) and (2) no negative examples (alert texts that violate guidelines). Guidelines should be expanded to include **more detailed** positive examples beyond the default alert text provided, e.g., alert texts should specify what type of ad tracking is conducted if permission is granted. Similarly, guidelines should be periodically updated to include real-world negative examples that contain dark patterns, e.g., sample alert texts that include incentives.

Proactive Vetting of Alerts. The extent to which they are ATT guidelines are enforced remains in question. The prevalence of dark patterns violating Apple's guidelines suggests that, if enforcement exists, it cannot detect discovered dark patterns. Therefore, we strongly suggest proactive enforcement of guidelines through a strict vetting process.

We envision that ATTCLS can be integrated into this vetting process, given its reliable performance. Similarly, PREAEXTR can detect apps that include ATT purpose strings in the "`Info.plist`" file yet never display an ATT permission alert. Leveraging these automated tools can ensure that violating apps can be flagged before they are publicly available.

User-Centered Design of ATT Permissions. ATT purpose strings should effectively express the purpose of the prompt. Given possibility of multiple purposes (e.g., cross-platform tracking, sharing IDFA with 3rd party), further study is required to carefully design texts effective in informing users of each purpose. However, clear purpose strings may not be sufficient. As our study reveals, users do not necessarily trust developers to adhere to what is listed in the prompt. To resolve this, Apple could enforce a predetermined list of texts that developers can select from, and that can only be minimally modified. If the selected text aligns with how the app uses the IDFA, this should be communicated to the user to instill trust.

Similarly, enabling system-generated pre-alerts would improve user trust in ATT. This would incorporate a developer-defined pre-alert text but also display data types used for tracking in both *"Allow"* and *"Not track"* scenarios, to better inform the users of the permission implications.

6.2 Limitations

Pre-alert UI Violations. Apple guidelines include specific UI guidelines for the design of the pre-alert screens. These guidelines restrict developers from using visual cues in the pre-alert screens that can trick users into clicking *"Allow"* unintentionally. The guidelines label these practices as: (1) *Imitation Request*, (2) *Alert Image* and (3) *Alert Annotation*. (details and examples in Appendix C).

We manually analyzed the 273 apps that show a pre-alert screen and found that 22 apps violate UI guidelines. Specifically, 9 pre-alerts violate the *Imitation Request*, 9 violate *Alert Image* guideline, and 6 apps show pre-alerts with *Alert Annotation* violations. To automate the detection of UI guidelines violations, future work will explore computer vision techniques to identify visual cues that simulate permission alerts or annotations in the pre-alert screen.

Automated Alerts Classification. We introduce a multi-label classification framework to automatically classify the ATT alerts into five different patterns. We manually labeled the entire dataset of unique ATT alerts to test our model's effectiveness. This framework will help the research community to conduct further analysis on ATT alerts. It can also be integrated into the app-vetting process implemented by Apple's App Store for continuous monitoring of apps' guideline violations. However, to increase the effectiveness of this model, several methods can be integrated to increase its accuracy. We notice that the model's accuracy slightly decreases for `Other` label (78%), since this label does not contain a specific textual pattern as compared to the rest of the labels. Our model also is less accurate for the pre-alerts classification as compared to the purpose strings. This occurs because developers have the flexibility to explain the permission purpose with more words and phrases in pre-alert texts, resulting in patterns with lexical and semantic ambiguity. By collecting a larger dataset, the model can better learn to differentiate the `Other` label from the rest of the labels. Moreover, data augmentation techniques can be applied to increase the dataset size for pre-alerts, allowing training and testing a model on pre-alert texts. Finally, more advanced text filtering techniques can be added to filter the irrelevant words and phrases in the pre-alert text.

Evasion of Violations Detection. Our patterns detection model can be integrated into the vetting process of apps on Apple's store. However, developers can use different techniques to evade this tool. For instance, developers can adopt adversarial attacks for text data [3, 32]. These techniques use perturbed versions of the original text, which are not recognizable by humans but misclassified by NLP models (as BERT). Developers can also hide text in pre-alert screens using adversarial watermark attacks [20, 67], which are undetectable by human eyes while evading OCR detection techniques. To defend against these attacks, the language model can be trained using adversarial training methods [73] or modified to detect adversarial examples [12, 68, 74].

7 Related Work

Web and Mobile Tracking. Data tracking has long been explored in mobile/web contexts. Several works attempted to analyze apps' data usage purposes including tracking [17,18,41]. Others studied tracking data transparency and how it affects targeted ads [13,42,46]. A recent study [48] performed a dynamic network analysis of 1,759 iOS apps before/after ATT and showed that the number of tracking libraries has roughly stayed the same for both versions, where many apps still collect device IDs after ATT for cohort tracking or fingerprinting. Our work contrasts prior research in that we focus on developer non-conformance to tracking prompt (ATT) guidelines instead of determining data flows with ATT.

Studies on Privacy and Permissions. Early studies [14,28] evaluated users' understanding of installation-time and runtime permissions given the permission dialogs [4,15]. Shen et al. identified users' misunderstanding of runtime permission models and highlighted the additional information required to make informed decisions [64]. A comparison study [69] showed confusion about permissions reasoning from the perspectives of developers and users. Few studies were conducted on the developers' permission prompts. In [43], it was found that providing clear and real-time permission information assists users in making more informed decisions. In [70], a study was performed on the developer-specified purpose strings of iOS permissions, including location, contacts, photos/videos, calendars, reminders, and Bluetooth, showing that users are more likely to approve clear purpose strings. A similar analysis studied permission rationale messages in Android [51], showing that purposes stated in a majority of rationales are incorrect. Our work focuses on the ATT permission alerts, studying how dark patterns in alerts can affect user perception.

Several works have studied maliciously crafted dark patterns in UIs that deceive users/trick them into giving consent [16, 26, 34, 35, 49, 54]. Dark patterns in mobile applications and their impact on users have been studied in [26], showing that most apps have dark patterns that are not recognized by users. In [47], a large-scale analysis on mobile apps' privacy consent dialogues showed that many apps employ dark patterns to coerce the user to consent. Moreover, dark patterns were also acknowledged by the European Data Protection Board, which recently released guidelines in the GDPR [33] for regulating dark patterns on social media.

Recent studies investigated ATT permission in iOS and how it affects users. Hutton et al. [39] measured which apps users grant ATT permission and how it correlates with users' privacy concerns/motives. However, their work does not consider the permission alerts and their effects on users' perceptions. Another work studied the design patterns used for tracking permission in 200 popular iOS apps [25]. This work measures the effect of users' likelihood of tracking with different design patterns (e.g., permission purpose, framing, priming). In our work, however, we identify the ATT alert patterns based on Apple's guidelines and perform a large-scale analysis of apps to measure how they comply with the guidelines. We, hence, focus our user study on the perceptions of users and how their perceptions are affected by different alert types.

8 Conclusions

In this paper, we perform a large-scale analysis of the ATT permission alerts in iOS. We leverage static and dynamic analysis to extract ATT alert texts and pre-alerts. We then synthesize a labeling guide to identify ATT alert patterns and discover that over 59% of apps contain dark patterns used by app developers. We subsequently use advanced NLP techniques to detect dark patterns in alert texts automatically. Finally, via a user study, we discovered that regardless of alert patterns, users have misperceptions about ATT, and they often find alert texts confusing. Moreover, certain patterns (e.g., `Incentive`, `Misleading`) can influence the users' perception of receiving benefits (e.g., rewards, app features). Our findings motivate the need for improved developer guidelines, app vetting process, and designing user-centered ATT alerts.

(b) Random apps

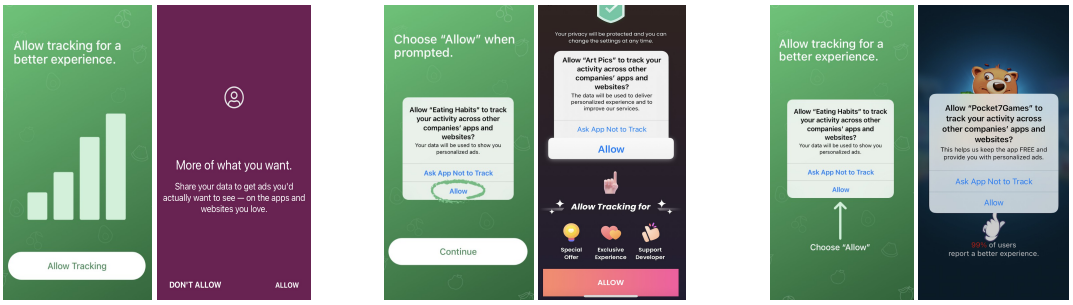
Figure 3: Distribution of app genres among pattern labels.

A Apps Analysis

Figure 1 shows an example of a pre-alert screen. We crop the pre-alert by detecting the image contours and masking the image using the contour with maximum area. We extract the text from the cropped image. The detailed distribution of app labels for purpose strings and pre-alerts is shown in Table 1.

Figure 3 shows the distribution of patterns among different app genres for the popular and random app sets. We found no correlation between the app categories and pattern labels.

B User study Details



B.1 Pilot Studies

We test our survey design by conducting two rounds of pilot studies. First, we posted a call for participants on a university campus; we conducted the study with 7 volunteers and stepped through the survey to incorporate feedback (e.g., revise unclarities, remove leading questions). We clarified the wording of some questions pointed out as unclear.

In the second round, we recruited 17 participants on Prolific [58] to test the participants' response quality and their level of engagement with the survey. We found that participants would not effectively engage in the open-text questions when asked to justify their selections. To encourage engagement, we added *"In two or more sentences,"* as a prefix to these questions. Additionally, we found that only displaying the alert once before questions on the alert limited the participants' ability to recall the alert text. To correct this issue, we split the survey's `Alert-Questions` into multiple pages and displayed the alert text at the top of each page.

B.2 Survey Demographics

Table 3 presents the demographics of our participants.

(a) Imitation Request. (b) Alert Image. (c) Alert Annotation.

B.3 Survey Alerts

Table 2 displays the alert shown to different participants. We implemented prototypes for 20 apps using Marvel app [53], with four apps per alert pattern.

C Apple's ATT UI Guidelines

Apple's ATT UI guidelines define three practices to guide developers design of pre-alert screens: (1) *Imitation Request*, (2) *Alert Image* and (3) *Alert Annotation*.

Imitation Request states that developers should not display a custom screen that mirrors the functionality of the OS-generated ATT permission alert. *Alert Image* guideline states that pre-alert should not show an image of the OS-provided permission alert and modify it in any way, such as by circling or highlighting the *"Allow"* button. *Alert Annotation* guideline states that developers should not draw a visual cue on the actual permission alert that attracts users' attention to the permission alert's *"Allow"* button.

Figure 4 shows examples of the violation of Apple's guidelines for the UI design of ATT pre-alert screens.

Voice App Developer Experiences with Alexa and Google Assistant: Juggling Risks, Liability, and Security

Abstract

Voice applications (voice apps) are a key element in Voice Assistant ecosystems such as Amazon Alexa and Google Assistant, as they provide assistants with a wide range of capabilities that users can invoke with a voice command. Most voice apps, however, are developed by third parties—i.e., not by Amazon/Google—and they are included in the ecosystem through marketplaces akin to smartphone app stores but with crucial differences, e.g., the voice app code is not hosted by the marketplace and is not run on the local device. Previous research has studied the security and privacy issues of voice apps in the wild, finding evidence of bad practices by voice app developers. However, developers' perspectives are yet to be explored.

In this paper, we report a qualitative study of the experiences of voice app developers and the challenges they face. Our findings suggest that: 1) developers face several risks due to liability pushed on to them by the more powerful voice assistant platforms, which are linked to negative privacy and security outcomes on voice assistant platforms; and 2) there are key issues around monetization, privacy, design, and testing rooted in problems with the voice app certification process. We discuss the implications of our results for voice app developers, platforms, regulators, and research on voice app development and certification.

1 Introduction

In the decade since the arrival of Amazon Alexa and Google Assistant, voice assistants have significantly increased in functionality and accuracy and are now widely integrated into smartphones, TVs, speakers, and many other devices. The nature of the technology—always-on and always-listening—has sparked significant interest in the privacy of voice assistants and people's associated perceptions, with a growing body of work investigating these concerns both qualitatively [2, 37, 53, 71, 74] and quantitatively [3, 15, 16, 32].

At the same time, mirroring societal and legislative attention around the moderation of online platforms such as the EU Digital Services Act [69] and the UK Online Safety Bill [50], researchers have started to investigate how third-party voice apps are approved for distribution on voice stores by voice assistant platforms (*skills* for Amazon Alexa and *actions* for Google Assistant). To date, studies have begun to map out the opaque and poorly documented use of human and automated testing of voice apps by voice assistant platforms [72], criticizing the effectiveness of the voice app certification process [14, 56]. Focusing on the largest platform in the space (Amazon Alexa), this has led to a consensus amongst researchers that current efforts are insufficient, with studies continuing to show that violation of content policies [14, 75], privacy regulation violations [17], poor separation of adult- and child-focused voice apps [38], and circumvention of the permission system [29] are prevalent on the Alexa voice app store despite responsible disclosure efforts by researchers to Amazon [18].

Thus far, this line of research has focused on *user* perspectives and Amazon and Google as platform owners; to the best of our knowledge, none have considered the experiences of third-party *developers* of voice apps for Alexa and Google Assistant. Rectifying this is crucial, given that developers are the group with primary control over voice apps, content, and privacy policies that appear on the platform. Understanding the circumstances that lead to the creation of problematic voice apps is, therefore, vital in understanding what can be done to improve the health of the wider ecosystem.

To investigate this and explore the reality of developing for the platform, we conducted semi-structured interviews with 30 voice app developers with varying levels of expertise about the challenges they face in creating skills and actions. Starting with the development process, we then asked more focused questions on data & privacy, security & testing, certification, their relationship with the major platforms, and the developer economy. Through thematic analysis of the transcripts, we answer the following research questions:

RQ1 What are the main challenges faced by voice app developers that are specific to voice app development?

RQ2 How do these challenges relate to security and privacy on voice assistant platforms?

RQ3 How do these challenges and developer responses to them differ across developers with varying levels of experience?

And, in so doing, we make the following main contributions:

- We identify key issues around monetization, privacy, design, and testing and show how many of these are rooted in problems with the voice app certification process.
- We show how issues around, e.g., liability and certification are linked to negative privacy and security outcomes on voice assistant platforms.
- We discuss the implications of our results and make recommendations for developers, regulators, and researchers on voice app development and certification.

Key findings include developers' feeling that the risk and liability of developing skills had been pushed onto them with little support, widespread reuse of privacy policies, and the extreme difficulty of monetizing voice apps. The poor discoverability of voice apps was felt by all developers and intensified existing problems around design, user experience, and monetization. Certification, the key point where privacy and security issues can be identified before voice apps become publicly available, was seen as arbitrary, inconsistent, and open to influence from internal contacts, leading several developers to create mitigation strategies to reduce the coverage of certification checks. We then discuss the implications of these findings for privacy and security on Alexa and Google Assistant platforms, regulatory compliance, the developer economy, and for future research into the security and privacy of voice assistant platforms.

2 Background

2.1 Voice App Architecture

Voice assistant platforms allow developers to create voice apps using dedicated APIs and tools for which they offer comprehensive documentation. For example, Amazon maintains the Alexa Skills Kit (ASK) and Google provides the Assistant SDK. These complex ecosystem components allow developers to execute code, namely, skills or actions, in response to user requests. Figure 1 illustrates the position of voice apps within the voice assistant ecosystem.

Unlike smartphone apps, voice apps do not run any code on user-controlled devices. Instead, audio from the assistant, such as the audio captured by an Amazon Echo smart home device, is streamed to the associated platform (e.g., Amazon Alexa). The platform then transcribes the audio and attempts to match it to the best voice app to serve the user command via a pipeline of machine learning models running in the cloud to process voice commands. Moreover, the platform will also

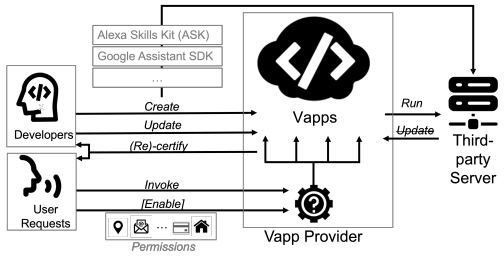

Figure 1: Overview of the interaction between developers and voice assistant architecture components.

determine which of the voice app's 'intents' (similar to functions) should be invoked. The code for the voice app itself is run in the cloud either as an Amazon Web Services (AWS) Lambda function, on Google Cloud, or on a server controlled by the developer. An API is provided by the platform to ensure that the voice app's endpoints can be correctly reached, and responses are piped back through the platform and transformed into speech, which is then sent back to the device (e.g., Amazon Echo) to be played for the user. This cloud-based architecture allows developers to easily update voice apps and scale their capabilities to accommodate changing demands.

2.2 Accessing user information

Both Amazon and Google provide developers with ways to programmatically request access to user information, such as location data, name, and contacts via API calls. In most cases, these data are provided by the platform rather than the user's device. To obtain consent from users, platforms display the types of data that the voice app will request access to in their marketplace, as is the case with smartphone apps. Users must explicitly grant access to these data when enabling these voice apps.

While the use of the permission framework is normally the only approved means of accessing user data, prior work has found that some developers request information directly from users through the conversational interface. In this case, platforms are unable to perform runtime checks, and do not have a mechanism to ensure that developers have declared the intention to collect specific data [17].

2.3 Voice App Certification

Third-party voice apps on both Alexa and Google Assistant have to undergo and pass a certification process to ensure compliance with platform policies and security and privacy requirements [6, 26]. If and when voice apps are approved, they become available to users through the store, and users can ask the assistant for them by name. Once certified, developers cannot make changes to the interaction model, including the utterances that a user can say to the app, without first sub-

mitting the app for re-certification. However, updates to the back-end of a voice app—i.e. the part that generates responses to user input—*do not require re-certification* [14].

2.4 Voice App Security and Privacy Issues

A key area of research on voice apps and assistants centers around privacy and security issues, including several unique to voice apps. We offer a summary of those issues as a way of introduction and background, but details can be found in Section 6. For instance, due to the way discoverability works in the ecosystem, voice app *impersonation* is possible, where the invocation name of a voice app can be selected to match that of the target voice app or be similar enough phonetically [36]. Other security issues include voice squatting, a voice app faking or ignoring the termination command and continuing to operate stealthily [62, 78]; and voice masquerading [78], a voice app pretending to hand over control to another voice app to eavesdrop user conversations.

When it comes to privacy, large-scale static [17, 40] and interrogative [29, 75] traceability analyses of voice apps reveal bad privacy practices and misleading privacy policies. Research has also revealed a prevalence of voice apps gathering and storing medical data in clear violation of platform policies [59]. Whilst current voice app ecosystems only support permission-based access control for sensitive data, this has been shown to be insufficient to control how voice apps use data once they have access [18, 19, 29]. Finally, account linking can be exploited to obtain sensitive user information [17, 18].

These security and privacy issues are often facilitated as the code of a voice app can be modified at will by third-party developers, bypassing the skill certification process [14,40], as it may reside on remote web services under their control [62, 64]. The certification process for voice apps has been found to be flawed and ineffective, leaving space for many malicious or policy-violating apps to be published [14, 40].

The issues mentioned above are compounded by users' limited comprehension of the voice app ecosystem and the intricate dynamics of the information flow within it [2,3,25,37, 53, 71]. While previous research has extensively investigated the security and privacy concerns associated with voice apps, the motivations and circumstances behind the development of problematic voice apps remain unexplored.

3 Methods

To answer our research questions, we designed a qualitative user study based on semi-structured interviews with voice app developers that we analyzed using thematic analysis. All parts of the study were approved by our institution's IRB and supplementary material for the study is available at `https://osf.io/yj7es` to aid replication and promote open science.

Number of Developers:		Number of voice apps developed:	
Professional	15	1	15
Hobbyist	15	2-4	6
		4-6	2
		6+	7
Number of developers and voice app categories:			
Gaming	8	Productivity	2
Health and Well-being	3	Lifestyle	3
Education	3	Travel & Transportation	1
Weather	1	Music & Audio	3
News	1	Novelty & Humor	2
Food & Drink	3		

Table 1: Participant Demographics.

3.1 Recruitment

We recruited 30 developers of Amazon skills and Google actions via publicly available contact information on the respective stores, as well as in-person through a local voice app developer network in London. Interviews were conducted in person or online via Microsoft Teams, depending on the location of the participant. Following best practices for sampling in qualitative research for security and privacy studies [52], we prioritized achieving a balance of demographics relevant to our focus, such as: platform developed for, types of skills developed, number of skills developed, and diversity of experience.

We classified developers as either hobbyists or professionals based on whether they had ever developed a voice app as part of their main employment — yes for professionals, no for hobbyists. This is because when choosing how to categorize developers in terms of their experience, we felt it important to decouple this definition from characteristics such as the number of voice apps developed or whether they had been monetized, as these were distributed across the participant pool owing to factors laid out in Section 4—e.g., monetization of voice apps ranged from a few dollars a month through to tens of thousands.

As it can be seen in the full summary of participants given in Table 1, our participants covered a broad range of voice app categories and levels of experience, with half having developed skills or actions in a professional capacity. Some participants, particularly the hobbyists, had developed a single voice app, with a clear group of professional developers who had developed more than 6 voice apps. The voice apps developed by our participants covered a wide range of categories (11+), with games being the most common category.

3.2 Interviews and Protocol

The interview protocol was semi-structured, which is known to be very good at allowing interviewees to fully express their opinions and encouraging them to provide more useful information, while giving the interviewers reliable, comparable qualitative data [34]. The full version of the initial script

used can be consulted in the "Interview Outline" file in the repository linked at the beginning of this section. It contains questions on the following topics:

- Motivation for developing voice apps, and general level of experience.
- Decisions around voice assistant platforms, hosting arrangements, and experiences with those platforms.
- Privacy and security arrangements for voice apps, including data collection, requested permissions, and privacy policies.
- Experiences publishing voice apps (certification, updates, etc.)

As standard in semi-structured interviews, beyond the questions in the script, researchers asked follow-up opportunistic questions in each interview, as appropriate, to fully draw out participants' experiences. For instance, this included interviewers restating and summarizing the interviewees' answers to confirm their opinions as well as formulating new questions based on interviewees' answers [73]. Interviewers also used open-ended questions, avoiding dichotomous questions that only led to two opposing answers, leading questions, or why questions [73].

In order to refine the interview protocol, we used the first three interviews as pilots, taking time to refine the interview questions based on participants' responses and realign them with the research questions. For example, we changed the order of some of the questions, such as current questions 3 and 4, by first asking about the platforms used and then the development, as this would lead to a more natural conversation flow. The three pilot interviews were excluded from the final data set for analysis, leaving 27 transcripts for full analysis (referred to as P1–P27 in-text). Participants received a $20 gift card upon the completion of the interview.

3.3 Analysis

Interviews were recorded and transcribed by researchers before being analyzed using thematic analysis [11]. On average, each interview took 30 minutes, with a total of circa 900 minutes worth of recorded audio. After familiarizing themselves with the data, two researchers coded the first transcript before discussing and arriving at the initial codebook. They then refined these codes in the second interview, discussing and agreeing on the final codebook that was applied to the remainder of the interview transcripts.

Following best practice, interviews were then conducted in batches, with researchers considering the extent of "rich, complex and multi-faceted" results being obtained, before making an in-situ decision based on the data obtained to keep increasing the sample size [54]. However, there is widespread acknowledgment that raw sample size is not the main factor affecting data quality in qualitative research [12, 54], so we also developed the composition [70] of the sample to be as diverse as possible with regard to the aspects crucial in this domain as detailed in Section 3.1, e.g.: by continuing to increase the sample size until we had as many professional developers, who were much more difficult to recruit, as hobbyists.

After all of the interviews were completed, two researchers reviewed the coded transcripts and searched for and reviewed potential themes. These were incrementally written up as brief notes, an initial summary, and then as a report. Throughout the analysis process the entire research team met regularly to review progress and resolve disagreements.

When reviewing the transcripts, a correlation was noted between the depth of descriptions given by participants and their level of development experience; in many cases, hobbyist developers used ambiguous terminology and/or sparse answers that became clearer when reviewed alongside the richer context and more precise definitions given by professionals. As such the reporting of quotes is weighted towards the latter group for clarity even though the concepts they describe were encountered more widely. Where the results are specific to a particular group of developers or only one of the voice assistant platform studies, we indicate this in the text —e.g. by referring to *skills* and *actions* rather than *voice apps*. Reported quotes have been edited to remove filler words and guggles (e.g., 'umm', 'like', 'ah-ha'), with [..] used to indicate where quotes have been condensed for brevity.

4 Findings

4.1 Money, Power, and Platform Influence

4.1.1 Challenges Around Monetization

Almost all the hobbyist developers we interviewed had not made money from developing voice apps, although many were open to the possibility: *"I was planning to monetize, but [the skills] I built it didn't generate any income"* [P08]. Instead, these developers were much more likely to be 'paid' with non-monetary items such as AWS credits — which often equated to them not having to pay for the privilege of developing skills — or with other items: *"I did it for some for some bounties to get some T-shirts or socks from Amazon"* [P16].

Those who had managed to generate regular incomes described the significant challenges involved. On other online platforms, developers commonly earn a living through advertising and payments for or within-apps. As advertising is prohibited on Google Actions and was only recently allowed in some cases for Alexa skills after the interviews had concluded,[1] this left in-app payments as the obvious choice.

But professional participants complained that the functionality for in-app purchasing had been neglected on both plat-

[1] https://developer.amazon.com/en-GB/docs/alexa/custom-skills/policy-requirements-for-an-alexa-skill.html (Section 5, accessed 16/03/2023).

forms, and was *"pretty painful from a usability point of view"* [P21], having not received the refinements necessary to prevent it from being a frustrating and/or scary experience for customers. This, in turn, meant that the 'freemium' model that supports many apps on other platforms did not work for voice apps: *"you lose about two-thirds of your users at the skill connection, then lose another two-thirds in your payment flow. And these are people who have already said yes to the fact that they want to purchase"* [P21].

The above, coupled with generally lower user counts meant that the economies of scale leveraged by e.g. mobile apps were considered infeasible. On this note, one participant suggested that concerns around the *security* of being able to spend money via voice were also partly to blame; that other people being able to use your voice assistant felt *"like someone just getting hold of your phone"* [P22]. This helps explain why users may be more hesitant to make purchases through voice vs smartphone apps, and suggests a direct connection between issues raised by developers around fundamental difficulties with monetization on voice assistant platforms and fears around voice assistant security that have been captured in the literature [2].

4.1.2 The Intersection of Money and Power

Another key option for making money on the Alexa platform was the Developer Rewards Program, where Amazon sends payments to developers of the top-performing skills on the platform. Whilst originally representing a considerable portion of overall developer compensation, it has since been reduced in size to the point where it no longer supports full-time development:

> *"I think that at its peak, we used to get nearly 30 grand a month out of developer rewards, so it was quite a sizable amount of money. And now that's super tailed off. Despite having a lot more usage [now], I think you're lucky to get over a thousand for it"* [P21]

The final means of earning money was responding to bounties offered for developers of voice apps in sectors of interest or implementing beta functionality in exchange for the promotion of their skills, although the rewards were seen as being too low to be sustainable as an income (we discuss this more in Section 4.2). In practice, the de jure or de facto lack of monetization had driven away many smaller developers who might have gone on to develop the next big thing for Alexa:

> *"It's a car crash, a total car crash. And it's part of the reason why I moved away from running my own business and took the job at the bank. [..] [At a voice gaming conference] there was a guy there talking about his Alexa games [..] and after 4 or 5 years he's making dozens of dollars a month"* [P22]

The total control of these means of monetization by platforms highlights the power they wield over developers. Especially for those dependent on the development of voice apps for their jobs, *"the platforms are very powerful players in the market, we're entirely reliant on them for access to our customers. Having multiple platforms helps mitigate the imbalance in the relationship"* [P21]. In relation to this, several participants mentioned the decision by Google to deprecate conversational actions for Google Assistant in order to focus on app actions (where voice commands perform actions within apps on the Google Play Store).[2]

To mitigate the power held by platforms, some utilized middleware applications that allow the same business logic to be deployed across multiple voice assistants. This software also enabled voice apps to mix and match functionality between providers by, for instance, swapping out the product used for intent matching, and to be deployed across a range of other chat-based platforms including WhatsApp and Facebook Messenger. For small-scale developers, the neglect of in-skill and platform-provided monetization options increases the incentives for developers to pursue 'riskier' monetization strategies, enabled by platform negligence in identifying and removing skills with non-compliant or illegal privacy practices as described in Section 2.4 and further explored with our participants in Section 4.2.2.

4.1.3 Indirect Monetization

In contrast, the most effective means of monetizing voice apps was indirect. For larger companies looking to divert support requests that would usually be handled by, for instance, a call center through a voice app, the effective returns were much higher: *"if we can channel half a percent of users who would have called to Alexa, we're saving thousands a day"* [P23]. In practice, the exact manifestation of this kind of cost-saving voice app depends on the particular situation being considered:

> *"Sometimes a chat bot on a website is much better than [a voice app] because the user is already on the website [..] and they're looking up the contact number for someone so they can call. No, we don't want them on the call center. That costs company [X] pounds per user per call [..] whereas other things would be, actually, what we want is we want a device-free experience. So for example, it's not necessarily now about working out what's wrong with my device. It's working out how do I fix it, what do I need to do [..] and at that point, we'll go, well, actually, you don't want to be having your phone up and scrolling through, you just want Alexa to tell you"* [P23].

[2] https://developers.google.com/assistant/ca-sunset (accessed 16/03/2023).

And in some cases, it was suggested that the most profitable option was not to make a voice app at all, instead opting for what was described as 'voice SEO': *"we're [often] saying the smartest thing that you could possibly do with your money right now is investing in making sure that Google [Assistant] and Alexa are saying the right answers to your [product] rather than whatever else"* [P23].

4.2 Privacy, Risk, and Liability

4.2.1 Pushing Risk and Liability onto Developers

The need for competition was also highlighted by developers feeling unfairly burdened with liability and risk as a defining feature of their relationships with platforms. A prime example was how Amazon offered small bounties for skills in sectors of interest or offered early access to new functionality that developers could implement in exchange for the promotion of their skills. For less experienced developers this could appear as a gesture of goodwill: *"they also even give us advance notice of certain things that they're going to develop in the future before even the wider public knows about it."* [P20], but those more experienced were less positive:

> *"There's a quid pro quo thing and they were like, do this and we'll promote you [..] so I asked them, well, what research have you done around this? Have you seen users asking for this? And they said, oh at Amazon, we see it as our job to invent on behalf of the customer. So we kind of come up with ideas and then we'll get partners like you to implement it. And then you will then see whether it works or not. [..] I heard from people that did go into that beta that it was a complete nightmare. The product didn't work at all. And it basically got put on ice and never formally launched."* [P21]

Those who did opt to implement beta functionality sometimes encountered additional problems when this had not been communicated to those responsible for certification: *"depending on where it is in the beta functionality will depend on how polished it is. So sometimes we get really buggy beta functionality for Amazon. That then goes into certification process. And the certification team haven't been briefed on the functionality. So you then deploy, you then send it to certification team and they go, what is this? [..] we've had absolute nightmares with that."* [P23].

Further reinforcing the importance of platform choice, some developers described the way that Amazon was seen to be predatory around third-party developers 'competing' with it, leading to reticence on the part of developers to create skills for the platform: *"they can be quite a predatory company, they can come into sectors and then through a combination of pricing, reduced cost of delivery through technology, they can just dominate a sector"* [P22].

This phenomenon was partially enforced through the certification process, and included an instance where a developer had a skill certification held up and ultimately rejected as a new item was added to the certification policy. Shortly afterward, an Amazon company launched a skill with the same feature: *"they changed the policy, they added a policy point that it wasn't allowed. And then about six weeks later [an Amazon-owned company] launched a [feature]-based skill"* [P21].

Those more content with their relationship with Amazon tended to either be developing skills for fun/to satisfy their curiosity or in agencies/companies established enough that either clients or Amazon were paying *them* to develop for their platforms, and thus not dependent on direct income from their voice apps.

4.2.2 Personal Data Use and Privacy Policies

For privacy (and specifically privacy policies), while all participants understood that a voice app's privacy policy was their responsibility, for hobbyists it was often conveyed as a requirement imposed by platforms rather than required by regulations such as the GDPR [68]. At all levels, participants avoided writing their own privacy policies, with a variety of strategies depending on the situation: *"I found some really good privacy policies online and copied them."* [P06], *"My approach there was always just to send a link to [the client's] privacy policy, just the one that's linked on their website."* [P22]. Several participants reported using a Google-provided template when making Google actions, which could then be re-used in future voice apps:

> *"I think that the privacy policy was originally a template that we got from somewhere. In fact, I think the original template even came from Google [..] and so I think we took that and then I think we adapted it over the years."* [P21]

This seemed to satisfactorily discharge developers' responsibilities—no participants described being worried that they might face consequences for inadequate privacy policies. This confirms evidence of 1,500 Alexa skills found with a privacy policy that was used by another skill [17]. Reused privacy policies very often lead to the privacy issues mentioned in Section 2.4, as they often lack clear traceability to actual privacy practices. In fact, most of the 1,500 reused privacy policies of skills found in the wild had incomplete or broken traceability with their privacy practices [17].

When asked more broadly about their use of data participants always saw themselves on the right side of a line, often believing that what they had collected was not personal enough to 'count': *"But it's not really personal information, right? [..] I never consider it as personal information."* [P09]. In particular, the terminology and architecture of the Alexa permissions system caused some confusion here; not all Alexa

'permissions' reveal personally identifiable data, and any information available to developers has already been collected by Amazon: *"I mean I'm only using the email address and [people using Alexa have] already given their email address to Amazon or Alexa, so I'm only using that."* [P12]. Unlike smartphone permissions that relate to device *functionality* through device sensors (and that developers have more experience with, particularly as users), Alexa permissions operate instead at the level of *information* (e.g. the user's postal address), potentially causing further misunderstandings. Relatedly, Alexa permissions involve the disclosure of information about the user *from Amazon* to the developer, rather than directly to a developer from the user.

Professional developers universally framed this in terms of compliance: *"As a general of thumb, I don't want your personal data. It just opens me up to too much risk. As little personal data you can give me is better in order to get the job done. Companies want to know everything and we push back quite strongly on that."* [P23]

Ironically, the poor user experience of many Alexa operations around data access meant that data minimization was often the best strategy to avoid the large drop-off in engagement that would be caused by requiring users to link accounts or grant permissions: *"I think that in reality [we] struggle to get more than one percent of people to link their account"* [P21], with requests for permissions also resulting in similarly reduced engagement.

Where account linking was required — e.g., where users had existing service accounts or in the case of skills being used as a cost-saving measure for product support as described in Section 4.1.1 — data and interactions collected through Alexa tended to draw on and supplement off-platform profiles. In this sense, skill permissions were less relevant, as these data had already been collected off-platform, with user interactions used to enrich external profiles and analytics. This is likely to increase given the introduction of Alexa advertising IDs after the conclusion of the interviews.[3]

4.3 Security, Testing, and Certification

4.3.1 Security Mechanisms Used

When asked about security, participants also referred to the insensitivity of the data they held as a justification for not having given additional consideration to securing their voice apps. In contrast to privacy, however, when we asked about security, developers often pointed to the fact that their voice app was hosted on a platform-provided service (e.g., AWS). This meant that it was the platform's responsibility to take steps towards ensuring security and applying any pertinent security mechanisms, and that the liability was not with the developer: *"I try to keep everything within the AWS Cloud. It's easier, it's straightforward, and I don't have to worry as much about security"* [P18].

Beyond this, developers had generally not considered whether they should implement additional security measures or what those would be: *"We do use two-factor authentication and stuff to try and make sure that you shouldn't be able to get into it unless you're supposed to [..] I mean, I've been curious if there are other things that we should be doing that would be better"* [P21]. This situation is understandable given that the Amazon-provided security requirements for most Alexa skills only mention verifying that requests come from the right Alexa skill, which only requires checking that the provided skill ID is correct.[4]

4.3.2 Testing

When it came to testing, there was a distinct split in perspectives between hobbyists and professionals. Professionals saw a voice app's release as a milestone in, rather than the end of, the development process: *"I think at the point that you release, you're about halfway there, generally. Maybe you're 30% of the way there, maybe 70%, it depends on how good a job it is and how big and varied your audience of users is gonna be"* [P22].

As part of this, a large amount of effort and resources were dedicated to catching errors through different logging and testing methods post-release: *"[we] log errors that are not just technical errors, but usability errors. And then it just gives you a list of how many of these errors you show it [are] showing up in [the skill] in the last week and you just kind of go through the top ones"* [P21].

User testing for hobbyists was usually carried out with friends and family: *"My kids are young, my oldest is 13. So I would sit down and discuss with them what I'm trying to do, and usually, they have good creative ideas or they will criticize"* [P18]. For professionals, user testing at an early stage was seen as crucial and their resources allowed them to recruit a more representative pool of testers. More experienced developers were able to use this knowledge to design voice apps that were less susceptible to usability errors or edge cases in the first place: *"We're getting a lot better at building the edge cases into the 'happy path' [..] we know that user will probably have the inclination to fall off here, so we might build some guard rails in to prevent that from happening"* [P23].

4.3.3 Certification is Inconsistent

Testing spilled over into the certification process, with hobbyist developers often seeing certification as a means to *"get*

[3] https://developer.amazon.com/en-GB/docs/alexa/custom-skills/policy-requirements-for-an-alexa-skill.html (Section 5, accessed 16/03/2023).

[4] https://developer.amazon.com/en-US/docs/alexa/custom-skills/security-testing-for-an-alexa-skill.html (Accessed 23/05/2023).

feedback from the Alexa developer certification team" [P01] on the quality of their code. In general, these participants did not have to go through the process often enough to identify systemic issues, often attributing problems to their own work. There was a general consensus amongst all developers that certifying ordinary 'run of the mill' functionality proceeded largely without issue but that complicated or unusual functionality was much more likely to generate problems.

Despite this, the amount of time taken for Alexa certification (re)submissions still varied considerably: *"sometimes it goes most smoothly, it only takes one or two days, and sometimes it takes them two weeks"* [P17]. Hobbyists were generally more tolerant of this as they lacked the time pressures associated with launching new business features. This was part of a wider theme where the entire certification process was seen as arbitrary and inconsistent, with certification teams rejecting updated skills because of functionality that had previously passed certification: *"you say 'well it's been like that for two years, why have you only just noticed this now?', and then you end up having an argument with them and they're like 'oh well it's always been against the rules' and you're like 'then why have you allowed it through certification like 20 times?!"* [P21].

Another time that this came into the spotlight was when skills were published simultaneously in different regions. Each region's team would have to independently certify the skill, and they may not agree on whether the skill was ready for publication: *"France would reject the certification based on a certain point, no other territory would have picked up on that, but then Mexico would have an issue with something else that no one else had a problem with. There were some issues that were consistent [..] but I found inconsistencies between different markets"* [P22]. Each time a skill is changed as part of this process it might have to be resubmitted in each market, and each submission might then take several weeks to be processed by Amazon.

More dynamic voice apps that utilize a variety of unpredictable data sources add an additional layer of problems, as they might be tested at any time. When certifying P15's booking app *"[Amazon] wouldn't commit to when they go and test the application [..] they [might not] get the expected flows because of the state of the backend data, because I had other users using a variety of different interaction mechanisms to go and actually book those resources"* [P15]. This meant that a member of the certification team might test the voice app at a time when nothing was available to book and refuse certification as it did not fulfill its stated function.

Finally, professional developers believed that more popular Alexa skills were subject to more stringent certification procedures: *"we go through enhanced certification processes [..] if I log into a non [company] developer console, write a skill, and stick it out there I think it honestly gets a couple of automated checks and as long as it passes that I wouldn't be surprised if it just goes live [..] those skills just don't get any usage, they don't get any traffic pointed to them. So the process for [skills with] more traffic is also more intensive"* [P21]. Developers with high-profile skills were also able to skip steps like auto-enablement, allowing users to invoke their skill without explicitly enabling it in the companion smartphone app.

4.3.4 Attempts to Finesse Certification

As a result of the problems described above, we observed several strategies used by developers to mitigate friction in the certification process. Most professional Alexa developers were able to leverage internal contacts at Amazon to expedite certification or access extra functionality: *"we do have people within Amazon that can be very useful and kind to us [..] if you've got a couple of people's email addresses in Amazon, you can sometimes wiggle it. We try not to do it too often."* [P23]. These contacts were often developed at in-person conferences and events that hobbyists lacked the awareness, time, or resources to attend:

> *"'At one of the developer events I was having a conversation with someone and he said, 'I'm from Amazon', and he said 'what skills are you working on?' and I mentioned [celebrity] and it was really funny, it was like, alright, okay, come out of the muggle space let's have a grown-up conversation. And at that point I was given the email address and phone number of a contact [at Amazon]"* [P22].

Across all developers, it made sense to try and minimize the number of certification passes required by a voice app. This was achieved by crafting updates that did not change the front-end interaction model, thus circumventing recertification: *"I try to create just a single intent and have all the possible variations as slots in that specific intent only, so that that allows me to kind of short circuit Alexa's NLP model"* [P04], *"if you can get away with doing a back end change you always would, or [..] putting in dynamic entities or something so that you can do it at runtime rather than having to update the interaction model"* [P21].

While the ineffectiveness of voice app certification is a known issue [14, 40] (see Section 2.4), this shows *how* and *why* developers avoid following the spirit of the process. It also highlights a major difference with development for smartphone platforms: instead of app code being hosted by the platform and distributed through the skill store,[5] forcing recertification when this changes, popular voice apps do not have any code running on the user's physical device.

[5] While many smartphone apps do have functionality based in the cloud, all such apps *must* have code hosted on-platform.

4.4 Challenges in Designing for Voice

4.4.1 Asymmetric Access to Knowledge

Smaller developers without connections often struggled when seeking guidance to develop voice apps: *"I didn't have anyone around me that had even begun to write an Alexa skill, I could not ask anyone [..] I use a lot of online resources like YouTube videos and forums and send mails to people and try to fill that gap in the local community"* [P09]. This divide also covered knowledge sharing, with in-person events as a key way to exchange best practices alongside the creation of a dedicated team within an organization: *"we've got a community of practice across the whole company [..] where people share updates from their projects or lessons learned"* [P24].

4.4.2 The Problem of Skill Names and Discoverability

A recurring way in which the asymmetric access to knowledge showed in the interviews was around the poor discoverability of voice apps compared to those on smartphones and the web: *"there's no icon on your desktop, there's no icon on your phone to press, so it instantly falls out of your brain"* [P23].

The first hurdle many faced was what to name their app. The obvious choice, particularly when the voice app was an extension of an existing service, was often not the best: *"I figured I would go with [website name] because branding, right? So you know, keep the same as my website, that kind of stuff. Horrible mistake."* [P13]. As these names had not been initially chosen with a voice in mind, there were often problems with recognition, they felt unnatural to ask for, and could also conflict with existing voice apps — invocation names do not have to be unique. This can lead to security issues as mentioned in Section 2.4 such as skill impersonation, by creating specific malicious skill invocation names, reusing the same as or (phonetically) similar names to other skills [36, 78]. In fact, over a quarter of Alexa skills in the wild have names identical or phonetically similar one another [17].

Taking this a step further, professionals spoke about trying to embed as much meaning into voice app names as possible, so that people knew what the app was about before they had even interacted with it: *"they really don't work if you have to explain before you start the conversation how it works, you need to be able to introduce people to the things that they can do as part of the conversation. And so when I was thinking about the first [voice app] to build, I said, well, something where you don't even have to explain anything"* [P21]. In general, anything more than a few sentences of introduction was seen as too long.

Because of this poor discoverability, rather than generating buzz themselves, voice apps needed to be promoted in order to become popular (*"if you build it, they won't come"* [P23]). Successful apps were seen to be those that solved a need in a very focused way: *"So it's really common with digital product design to just throw more features in, make it better by putting more in, more is better as a general thing [..] voice is the other way around, it's completely the opposite, and you have to be super focused"* [P22]. As described above, P23 considered voice SEO as an alternative means of making existing content accessible rather than a dedicated voice app.

4.4.3 An Evolving Development Landscape

The interviews revealed a landscape of best practices, tooling, and paradigms that were in constant flux. As mentioned in Section 4.1.2, the decision by Google to move from conversational actions to app actions represents a shift in the conceptualization of voice apps that had a big impact on some of our participants. While the shift to app-actions removes the duplicated effort to maintain separate smartphone and voice apps that fulfill the same purpose, for developers using middleware to create cross-platform voice apps it *increases* the workload by requiring the *creation* of an Android app.

Talk about these middleware platforms themselves revealed their significance and reinforced the impression of a still-evolving landscape: *"There were three main [middleware] platforms a year ago, one of them got bought by Walmart [..] which I guess is a signal of how important conversation design has become to Wallmart as a business—they just decided to buy one of the three main players"* [P22]

And while the technology driving the development of voice assistants had been benefiting from largely incremental gains in recent years, there were still breakthroughs, as we discuss in more detail in the next section, that demonstrated how the field has not yet stabilized:

> *"Absolutely guaranteed for the next 12 months it's all going to be generative AI, it's all going to be GPT-3 and how we can use GPT-3 [..] in half an hour today for each intent I've created about 20 utterances to train that intent just by asking GPT-3 to write me a training set for a chatbot for an intent. That took me less than an hour. There's only 20 utterances but ... to do it manually, that would have been probably two days"* [P22].

5 Discussion

5.1 Differences With Other Platforms

Our results point to a number of ways that voice assistant platforms (and thus development for them) differ significantly from other platforms such as smartphones and the web:

1. Options for monetization are fundamentally different and reflect deep-seated problems around discoverability in voice interfaces, increasing incentives for developers to find alternatives that violate platform policies and pressure to beta-test new functionality in exchange for support;

2. Certification is seen as inconsistent, arbitrary, and is often handled opaquely on an informal/ad-hoc basis, leading to reluctance to patch vulnerabilities in voice apps and encouraging circumvention;
3. Alexa permissions follow a different paradigm to those on other platforms, leading to developer uncertainty about whether they were using personal data or not;
4. Developers are made liable for many privacy and security matters and given little support by vendors, leading to GDPR violations and excess data use;
5. Voice apps need to be designed very differently to graphical experiences, but security, privacy, and other best practices are often shared within closed communities rather than publicly;
6. The development landscape changes fast enough to prevent the widespread formation and dissemination of security, privacy, and other best practices.

We discuss the implications of these differences further in the following subsections.

5.2 Compliance and the Infrastructure of Voice App Publishing

On several topics around data use and privacy policies it was clear that developers felt they had been left to their own devices when making privacy and security decisions, with little support from platforms and sometimes even confusion over where privacy and security requirements originated from.

To better understand the situation we can consider the challenges developers face through the role that platforms play as infrastructure. Drawing on [39], we see that voice app platforms possess many key characteristics of technical infrastructure. To users, the privacy, security, and certification mechanisms used are almost completely invisible. They are also fundamentally *relational*: while for developers the certification process was a task primarily of design and *articulation work* [63] to demonstrate compliance to certification teams, For platforms certification represented a balancing act between reducing spending and minimizing legal liability and the perceived need for additional regulation. We unpack these in more detail below before discussing how the values that underpin the infrastructure affect developer behavior.

5.2.1 Reducing Legal Liability

While infrastructure is usually seen as embodying the standards of the sector [39], which in this case would include the GDPR [68], CCPA [13], and/or the new EU Cyber Resilience Act,[6] what we found was a situation that made enforcement action by regulators exceedingly difficult. Firstly, the architecture of voice apps as discrete packages of third-party software means that developers in the US, EU, and jurisdictions with similar regulations are considered data controllers (CCPA: "businesses"), and as such are legally responsible for properly collecting and protecting data and any violations that arise. Secondly, the EU Cyber Resilience Act ensures that security features are independently verified by establishing a framework for secure development, a situation that can hardly be met when voice apps run in the cloud and with the re-certification issues discussed in Section 4.3.4.

At the same time, platforms offered little support to developers to navigate the privacy and security responsibilities placed onto them by these architectures, wary of being held liable for violations where developers had followed platform instructions. We saw this in Sections 4.3.1 and 4.2.2 where developers felt liable for privacy and security matters, understanding that privacy and security were their responsibility and not that of platforms. Developers noted a lack of guidance from platforms on how they should make decisions around privacy and security and often lacked the expertise/confidence to tackle these issues themselves. This in turn led to developers relying on others who were seen to be more knowledgeable wherever possible, copying privacy policies and assuming that security issues would be handled by their hosting provider, even when this was the platform they were using.

5.2.2 Reducing the Perceived Need For Regulation

Within the wider context of data protection enforcement, this approach by platforms of pushing liability onto developers makes sense. Smaller skills are very unlikely to be subject to attention from academics, journalists, or regulators, whereas platforms *are*. This leads to an optimal strategy of accepting as little liability as possible without prompting additional regulation of platforms (e.g., the unsuccessful US Platform Accountability and Transparency Act,[7] and as has happened with the EU Digital Services Act for social media — DSA [69]). To achieve this, we saw speculation that Amazon subjected more popular Alexa skills (i.e., those that are more likely to attract attention from academics, the press, and regulators) to more scrutiny, taking a calculated approach to moderate the platform as cheaply as possible. Contrast this with prior work that found hundreds of skills with inadequate or nonexistent privacy policies that remained so even after being reported [18].

As to why existing regulation like the DSA does not incentivize small and medium developers to follow good data practices, there are very few sanctions against developers of small and medium-sized skills with bad data practices. If vendors like Amazon are not checking that privacy policies are up to date, and data protection authorities are struggling to

[6] https://digital-strategy.ec.europa.eu/en/library/cyber-resilience-act (accessed 21/09/2023)

[7] https://www.congress.gov/bill/117th-congress/senate-bill/5339 (accessed 28/04/2023).

enforce complaints against even the biggest companies,[8] then for smaller companies the chances of being enforced against are very slim. As well as developers who do not know better or have made a calculated decision, this includes those who might seek to take advantage of the lack of regulator attention (e.g., by circumventing permissions frameworks by asking for personal data in-conversation [17]). In effect, by pushing liability downwards in the manner currently seen big platforms have created an environment that allows for poor data protection practices with a low risk of enforcement action for any party, possibly elucidating prevailing substandard methodologies and insufficiency of attention towards privacy concerns well known to platforms [18]. At the same time, platforms are able to claim that they have systems in place (and dictate the entire certification process from start to end), to counter arguments that tighter regulation is needed.

5.2.3 Trickle-down Values

Finally, we examine how the above values that underpin voice app infrastructure further influence developer behaviors by posing a counterfactual. The placement of compliance at the top of platforms' agendas in turn leads to developers prioritizing approaches perceived to be compliant over those that are usable and accessible. Consider the difference if Amazon or Google provided a privacy policy template that had an overview in the style of *Terms of Service; Didn't Read*, which provides a bullet point summary of website terms and conditions.[9] Future work could explore this design space, which would benefit users through more easily understandable privacy policies and developers through greater clarity.

The irony is that from the perspective of regulators, the systems that *are* in place actually fail to properly promote compliance. We describe in Section 4.3.4 how some participants had developed ways to avoid re-certification and highlighted some of the strategies used, the existence of which had been hinted at in prior work [14,40]. Combined with prior work on circumvention of the permissions framework and collection of personal data in-conversation [10,17,29,75], it is now clear that circumvention of both the permissions and certification processes on the Alexa platform is not just theoretically possible but present in the wild. Given the problems we found around monetization and the restrictive advertising policies on platforms, there is an incentive for developers to make use of these loopholes to make their skills more financially viable.

5.3 Developers' Lack of Security Awareness

Despite encouraging participants to discuss their security practices during the interviews by asking the questions described in Section 3.3, it was clear there were widespread knowledge gaps and difficulties identifying and articulating security practices/behaviors. The appeal of platform-provided services as a catch-all answer to issues of security is likely driven in part by platforms themselves marketing their hosting services as secure (e.g., AWS includes marketing lines such as "All data is stored in highly secure AWS data centers"[10]), though future work should investigate this further.

There is ongoing work in the nascent area of standards, guidelines, and best practices for voice application development. For instance, the Open Voice Network[11] is a non-profit community of the Linux Foundation pursuing technical standards in security and privacy specific to voice apps such as user privacy and voice data security which, if adopted, would represent a significant step towards improving voice developers' security and privacy knowledge/practices. Research is also developing more usable security and privacy mechanisms in voice assistants [77], which could be provided by the platform in the future to help with this endeavor.

5.4 Financial Incentives For Developers

There are often tensions between app stores and those who develop for them, particularly around commission rates and moderation. Third-party software represents a significant selling point of compatible devices, and the health of these platforms depends on the extent to which developers can support themselves financially. Throughout the interviews, we saw how this is incredibly difficult on voice assistant platforms. Voice interfaces offer poor discoverability, limiting user growth in the absence of expensive marketing campaigns. This increases the pressure on developers to accept promotions from Amazon in return for implementing riskier features that would not otherwise be to their advantage.

At the same time, platforms restrict the ability of developers to support themselves through advertising and provide unoptimized in-skill payment flows, which negates the benefit of Amazon paying developers "up to 80 percent of the marketplace list price"[12] for purchases made through their skills. This is higher than comparable platforms but ignores the fact that developers are driven to off-platform payment methods. This is less problematic for large services (e.g., Spotify), which already have established web and app payment flows, but is much more difficult for developers whose creations only exist on voice assistant platforms. Developers are also able to earn commission through the Amazon affiliate program—by placing items into the user's Amazon shopping cart—but prior work has shown that users are extremely hesitant to purchase items through voice assistants [2].

Finally, the cash injections from Amazon which kick-

[8] https://www.wired.co.uk/article/gdpr-2022 (accs 28/04/23).
[9] https://tosdr.org (accessed 28/04/2023).

[11] https://openvoicenetwork.org/our-work (accs 11/09/23).
[12] https://developer.amazon.com/en-GB/docs/alexa/paid-skills/payments.html (accessed 28/04/2023).

started the creation of third-party skills have slowly dried up, leading to a *de facto* end to the emergence of new skills that are financially viable. From our data, it is difficult to predict whether the Alexa platform can maintain an equilibrium with its current developers, or whether the unique circumstances around voice apps mean that the marketplace requires financial support from platforms in order to continue.

As previously mentioned, since the date of the interviews there has been a change to the Alexa advertising policy that permits developers to track users using an advertising ID similar to that used on mobile platforms. While this may be a welcome additional source of income for skill developers, the fact that skills can not provide general advertising unrelated to the skill means that this will not be as effective on approach as on mobile platforms where advertising alone can cause an app to be economically sustainable. As Alexa developers already receive a persistent user ID this is unlikely to affect services that already collect user data for use off-platform—these IDs are pseudonymous until a user links their off-platform account through the skill (cf. account linking in Section 4.2.2).

5.5 Recommendations & Implications

For Platforms A clear first step would be to review certification processes and staffing with the aim of providing greater consistency and clarity over certification response times and clearer communication when an app fails certification. As part of this, procedures and training should be systematized in order to make decisions less subjective (and thus less variable), and there should be a procedure for changing content policies that notifies affected developers and gives them ample time to modify already certified apps. When it is not possible to do this in advance, re-certification of existing code should take place in parallel with new changes, come with a grace period, and not block app updates. Finally, newly introduced functionality should be cleared with certification teams *before* being made available to developers.

For Regulators The way that the certification processes have been designed and subsequently evolved means that self-regulation is not appropriate to ensure user privacy and security (cf. Section 5.2). Tighter regulation is needed to ensure that platforms are not able to dodge responsibility for privacy and security.

Where platforms dictate the processes by which developers obtain and/or process data, such as by forcing them to use a given permissions/consent framework, then they should be obligated to provide guidance on using those processes. Platforms should also be obligated to regularly re-verify the compliance of voice apps on their platforms (e.g., by checking that they have privacy policies), notifying non-compliant apps and giving them a fixed amount of time to address any issues. This is similar to social networking sites, where users are responsible for the speech that they post, but platforms are also required to moderate that content.

Several of these issues stem from architectural decisions and could be most cleanly addressed by platforms requiring that code be hosted under their control (e.g., AWS or Firebase), as happens with smartphone apps. This would allow for greater automated analysis of apps through static and dynamic analysis of source code and mitigate functionality changes without triggering re-certification.

Regulators could also make use of the growing open-source tools being developed by the academic community such as SkillExplorer [29], SkillVet [17], and SkillDetective [75] to conduct independent audits on voice apps in the wild in voice assistant marketplaces/ecosystems. This could provide some evidence of the state of affairs without necessarily involving voice assistant platforms.

For Researchers Our findings lead us to reflect on the methods commonly used to conduct research on the privacy and security of voice apps. The potential existence of enhanced certification processes for higher traffic skills, as well as inconsistencies with certification within platforms, mean that popular methods within the research community may not fully capture the situation on the ground.

The main problem is one of scale; it is impossible to know how many users or activations a skill has unless you are the developer of that skill. The results of the interviews suggest that the currently observed privacy problems with skills may be concentrated on those with fewer activations, with more ad-hoc and opaque processes used to hold more popular skills to higher standards. The scraping and interaction [17, 29, 75] or sock puppet [14] approaches used in prior work treat skills as equal regardless of user engagement, meaning that the real impact may be overstated.

The interview data also suggested that in terms of accessing personal information, data account linking was potentially more useful than the permissions frameworks used by voice assistant platforms. However, work in this space has previously only focused on permissions, as data usage via account linking is exceptionally difficult to track at scale — privacy policies are the only publicly available information, and these are often vague or inaccurate [17, 29, 75].

5.6 The Potential for LLMs and Generative AI

Since exploding in popularity in 2022 with the release of ChatGPT, large language models (LLMs) will undoubtedly influence the evolution of voice assistants over the next decade. The research community has yet to fully understand the risks associated with LLM use; meanwhile the Italian Data Protection Authority (Garante) temporarily banned ChatGPT over its use of personal data, and the European Data Protection Board has set up a ChatGPT task force [65].

We observed in our interview how LLMs had already begun to change the development process, with P22 using ChatGPT to generate sample utterances for intents (Section 4.4.3). The conversational nature of these products positions them perfectly to disrupt the voice assistant market. Research has shown how voice apps already circumvent platform policies on data collection by asking for data verbally in-conversation rather than using permissions frameworks [17, 29, 75], and the ability to easily generate natural dialogue asking for personal data could see this practice increase, mirroring work on self-disclosure and computer-originated dialogue [47].

5.7 Limitations

There were only a few participants who had successfully managed to gain hands-on experience around monetization and beta functionality. As such, the sample size for these aspects of the results was smaller, although, as we note in Section 3, these participants tended to be the most experienced of the sample, which meant that their interviews usually led to richer, more nuanced, and more informed answers, opinions and explanations. This was very useful for the purposes of a qualitative study like ours, which precisely aimed to explore and understand in-depth participants' perspectives in order to generate hypotheses that can then be tested in follow-up quantitative studies; as with all qualitative work, our results represent the experiences of our sample.

6 Related Work

6.1 Voice App Developers: Existing Gaps

While a small amount of research has examined the development of voice apps using technical and policy framings, none have looked at the voice app ecosystem from the perspective of *developers*. By considering experiences from actual developers, **we address a gap in the literature that prevented a deep understanding of the circumstances that often lead to the creation of problematic skills**; to the best of our knowledge, this work is the first to offer a root-cause analysis of the underlying security and privacy issues of the development process, unveiling new issues that have been limiting the widespread proliferation of voice assistant technology.

This existing work has explored how voice app developers are given legal and other responsibilities without the corresponding control over how they can access user data [57], how Alexa certification works behind the scenes with human and automated testers [72], and how the Alexa and Google certification processes miss many policy-violating skills and actions [14]. These works explore how theoretical adversaries could potentially game voice app certification and permissions, offering insights into how market operators should fix vulnerabilities in the certification and consent mechanisms.

6.2 Voice App Vulnerabilities

Thousands of voice apps have been developed by third parties [18], but previous research has not explored the creation processes or practices of developers. Instead, studies have focused only on analyzing the vulnerabilities and privacy policies of these skills. For example, a study of 77,957 voice apps found that 5% of these applications could perform sensitive actions using hidden commands [60]. Others [29, 78] have shown that some skills may continue to listen even after the user has commanded them to stop listening. Cheng et al. [14] demonstrated that developers could exploit the discovery mechanism of voice platforms to increase the popularity of their apps. In [36], the authors show how developers could use the inherent errors in the NLP algorithms and words that are often misconstrued to create malicious skills and exploit the ambiguity in the skill invocation name method. The authors "hijacked" the skill invocation names of more than 50% of five randomly sampled vulnerable target skills. More recently, Young et al. [75] tested 54,055 Amazon Alexa skills and 5,583 Google Assistant actions, and found that 6,079 skills and 175 actions violated at least one policy requirement. This is not surprising considering the findings of our study, and highlights the need we emphasize in the discussion to better support developers in this space.

6.3 Certification and Violation of Policies

While exploring certification mechanisms, many studies have exposed gaps in the process and argue that many of the published voice apps violate their own privacy policies and platform requirements [56]. Some studies [14, 40] argue that the certification process is inconsistent, and verification relies heavily on the information provided by the developers instead of actually testing voice apps. Many studies have reported that developers often violate policies and requirements, causing concern. For example, Cheng et al. [14] submitted 615 policy-violating voice apps to the Alexa and Google Assistant stores. All Alexa skills and 39% from Google Actions passed certification and were made publicly available. They suggest that this may be due to too much responsibility placed on developers or unrealistic expectations.

Other studies [29, 40] have shown that some skills collect sensitive data outside of the permission ecosystem or data that do not align with the voice app description. Moreover, Edu et al. [17] discovered that some skills could bypass permission and breach their privacy policy despite the privacy settings being available. Meanwhile, Le et al. [38] found that while children's skills undergo an intensive verification process, some skills still expose children to inappropriate content and amplify or spread misinformation [9]. There is also some evidence [14, 40] that developers could make code changes after certification and collect more personal information.

Regarding privacy policies, several studies [5, 18, 29, 40, 43]

have highlighted issues around missing or broken links. For example, Liao et al. found 17,952 skills and 9,955 actions with broken links on Amazon and Google platforms, respectively [43]. In other instances, they found that some developers duplicated privacy links between several skills. Previous studies [29, 40, 43] have reported instances where developers requested private information without reporting it in their privacy policy. Instead, they directly asked users for private information during conversations. After reviewing various skills, Lentzsch et al. [40] revealed that around 23.3% of privacy policies did not address the data collected through the skills. In 2017, 70% of skills with privacy policies did not include any information specific to voice apps or systems [5]. Despite these findings, no previous studies have investigated the practices of developers from the *developer's perspective*, e.g., in creating privacy policies for voice apps.

6.4 Developers' Security & Privacy Practices in Other Platforms

As described in Section 6.1, while a plethora of security and privacy literature exists concerning developers in similar platforms such as the mobile app ecosystem, no prior studies have focused explicitly on the experiences of voice app developers. Within the domain of mobile app development, extant research reveals that developers are prone to engaging in risky practices, including the disregard of security implications [4], code reuse from online sources [33], excessive permission requests [23, 24, 66], privacy policy violations [7, 61, 76], neglect of Transport Layer Security (TLS) [21, 22], and improper usage of cryptographic APIs [20, 48].

Developers face several challenges when it comes to regulatory compliance, having trouble understanding privacy requirements [8, 41, 55]. Even when they know these requirements, they may not know how to use the provided SDK to implement the necessary privacy settings [28, 41, 42, 67]. Some developers expect platform support in this area [42], while others believe it is a shared responsibility between them and platforms [42, 67].

Bednar et al. [8] argue that though developers may intend to build secure software, implementing security requirements frequently presents daunting technical challenges. This is compounded by inadequate usability of tools and libraries, introducing system vulnerabilities [28], lack of secure alternatives [42], dearth of guidance regarding optimal configurations [67], and inscrutable documentation [1, 45, 51]. To assist developers, prior works have proposed diverse interventions, such as warnings [27], plugins [49], and the simplification of APIs [31, 35]. However, studies have not looked at the challenges that voice app developers face and how they impact security and privacy. Voice apps have key differences with other platforms (cf. Section 5.1) around monetization, liability, certification, and personal data collection that bring different challenges for developers.

6.5 Usable Voice App Privacy & Security

There is extant literature on user perceptions of the privacy and security of voice assistants, with data collection and scope, 'creepy' device behavior, and violations of personal privacy being reported as major concerns [15, 25, 30, 37, 46, 47, 74]. Research has shown that users often have incomplete mental models of how voice assistants work, leading to different (and often incorrect) perceptions about what data is shared and with whom. Common mistakes include assuming that all voice apps are first-party (e.g. part of Alexa itself), instead of having been developed and ran by third parties [2, 44, 58], and being unable to identify which voice app will be opened for a given command, with this uncertainty leading to a reticence around e.g. making purchases through voice assistants [2, 53]. This clearly links to our findings in this paper around the challenges developers encounter themselves around voice app discoverability and the name they choose for them — that is, the same model that makes it hard for developers to make their voice apps known could be facilitating the mental models users have that everything is the voice assistant, and the challenges developers find to monetize, particularly when it comes to voice app in-purchases, as shown in [2, 44, 58], could be due to this reticence that has been observed from the part of users due to security and privacy concerns. Future work should look more closely at these potential relationships between users and developers and how that may be mediated by the voice assistant platform.

7 Conclusion

In this paper, we conducted a user study that sheds light on the experiences of voice app developers. We made significant contributions to the understanding of the challenges they encounter. Firstly, we established a clear connection between issues such as liability and certification with negative privacy and security outcomes observed on voice assistant platforms. Our findings revealed the risks arising from misperceptions regarding the shifting of responsibility between developers and dominant platforms such as Amazon Alexa and Google Assistant. Furthermore, we identified critical issues related to monetization, privacy, design, and testing. In particular, we encountered connections between issues raised by developers around difficulties with monetization that include concerns around the security of being able to spend money via voice. We confirmed that many of these issues stem from fundamental problems within the voice app certification process. This highlights the need for improvements and streamlining in the certification procedures to address these challenges effectively. Finally, we discussed the implications of our study for various stakeholders, including developers who face risks associated with liability, regulators who need to consider the certification process's shortcomings, and researchers who can benefit from our insights for future studies on voice apps.

Swipe Left for Identity Theft: An Analysis of User Data Privacy Risks on Location-based Dating Apps

Karel Dhondt Victor Le Pochat Yana Dimova Wouter Joosen Stijn Volckaert
DistriNet, KU Leuven

Abstract

Location-based dating (LBD) apps enable users to meet new people nearby and online by browsing others' profiles, which often contain very personal and sensitive data. We systematically analyze 15 LBD apps on the prevalence of privacy risks that can result in abuse by adversarial users who want to stalk, harass, or harm others. Through a systematic manual analysis of these apps, we assess which personal and sensitive data is shared with other users, both as (intended) data exposure and as inadvertent yet powerful leaks in API traffic that is otherwise hidden from a user, violating their mental model of what they share on LBD apps. We also show that 6 apps allow for pinpointing a victim's exact location, enabling physical threats to users' personal safety. All these data exposures and leaks – supported by easy account creation – enable targeted or large-scale, long-term, and stealthy profiling and tracking of LBD app users. While privacy policies acknowledge personal data processing, and a tension exists between app functionality and user privacy, significant data privacy risks remain. We recommend user control, data minimization, and API hardening as countermeasures to protect users' privacy.

1 Introduction

Location-based dating (LBD) apps enable users to meet new people nearby and online, for relationships, casual encounters, or friendships. Since the launch of Grindr in 2009 and Tinder in 2012, these apps have become increasingly popular: for example, Match Group's app portfolio sees nearly 100 million monthly active users [75].

Users of these apps reveal highly personal and sensitive information in their profiles, making them susceptible to violations of their social privacy by other individuals [53, 54, 114]. Additionally, these LBD apps are unique in that users share this data with people they might not (yet) know, as opposed to other social networks where data sharing usually entails a prior social connection [48]. Adversaries in this scenario are focused on extracting personal information, including location data, of one or more LBD app users. They achieve this through normal interaction with the platform, regardless of whether the target is a prior acquaintance or an individual they encounter for the first time on the app. The adversary's malicious intentions can span a broad range. For example, they may want to gather identifying information, such as name, age, and photo, to engage in social engineering or steal a user's identity [30]. As another example, the adversary may want to learn a user's sexual orientation, to extort [90] or even prosecute them [17, 119]. Last but not least, sharing one's location is crucial to these apps, as users are shown profiles of people in their vicinity. However, the adversary can use that location to physically stalk people [30], and in extreme cases, carry out assaults and murder of LBD app users [106]. Given these potentially severe risks to a person's virtual and physical safety, and genuine user concerns about those risks [81], LBD apps must carefully protect users' personal data, in particular preventing any (inadvertent) leaks.

In this paper, we systematically analyze 15 popular LBD apps with at least 10 million downloads on the extent to which they cause privacy risks stemming from the sharing of personal and sensitive data with other users. We develop our evaluation in three steps. First, we analyze how easily the adversary can create an account on LBD apps to stealthily gather private user data. Then, we measure which personal data is shared by these apps, including sensitive attributes, dating-sensitive data, and users' exact locations. Finally, we examine how the privacy policies of these apps discuss the collection and potential leaking of personal data.

In our privacy risk analysis, we consider two types of data sharing. *Intended* sharing is known to an LBD app user, as the shared data is shown in the user interface (UI). Through our systematic manual traversal of each app's functionality, we find that LBD apps *expose* large amounts of *personal data* to other users, enabling the extraction of (sensitive) personal traits, including by our least sophisticated adversary who only uses the app's UI. Most apps *require* sharing identifying information such as name and age with others. Equally, the UI often displays legally protected *sensitive data* [115] such as ethnicity or sexual orientation.

Inadvertent sharing concerns data that is hidden in the UI but that the adversary can still retrieve, which stands in direct conflict with the user's perception of what they are sharing and what others can therefore learn about them, representing the most severe violations of the user's privacy expectations. We simultaneously examine the API traffic between the LBD app and its server, discovering several APIs that *leak* (sometimes explicitly hidden) personal data to an attacker who has capabilities to inspect or even modify traffic – or is aided by others or easy-to-use tools. API leaks are particularly prevalent for *app usage data related to the dating process*, which may cause particular embarrassment or stigma, e.g., by revealing another user's likes or preferences, or allow for fine-grained monitoring, e.g., by leaking the last activity time. Given its sensitivity, we extensively evaluate whether apps – again, unknowingly to users – allow extracting a user's exact location by being susceptible to one of three forms of trilateration. We find that 6 apps that do so, despite proven countermeasures that prevent such an attack, such as grid snapping on Tinder.

Together with the ability to retrieve multiple profiles at once, permanently request one user's profile at any time, and easily create accounts, all these data exposures and leaks enable targeted or large-scale, long-term, and stealthy profiling and tracking of LBD app users. While the privacy policies of these apps tend to be compliant with data protection law by outlining which data they process, and some even acknowledge the potential for leaks (including locations), they mostly place the burden of protecting privacy and cautious data sharing on the users themselves, with only some apps providing actionable privacy controls. To help users in preserving their privacy in light of our findings, our recommendations for countermeasures focus on two aspects. First, given the tension between app functionality and user privacy, where users may feel compelled to share data, and services nudge them to do so, LBD app users should gain more control over what they share and with whom. Apps could consider reducing data gathering, to improve user privacy regarding intended sharing. Second, given inadvertent sharing of potentially sensitive data, LBD apps should prevent data leaks by hardening APIs. After our analysis in January 2023, we disclosed our findings to all affected apps, leading to concrete fixes of our discovered leaks, therefore improving users' privacy and reducing the potential threats associated with using LBD apps.

In summary, our main contributions are:

- We conduct a systematic and broad privacy analysis of user data risks on 15 popular LBD apps, including how these risks are enabled by easy account creation and acknowledged by privacy policies.
- We find that the apps' UI exposes large amounts of personal and sensitive data to even unsophisticated adversaries.
- Particularly powerful API traffic leaks reveal very sensitive data that is otherwise hidden from users, violating their expectations of what they share with others.
- For 6 apps, these leaks include a user's exact location, enabling physical threats to personal safety.
- We propose countermeasures to better protect users' personal data and locations, and responsibly disclosed our discovered vulnerabilities to the LBD app vendors.

2 Background

2.1 Location-based Dating Apps

Location-based dating (LBD) apps [13, 58] are social matching systems [137] that recommend people to each other, usually based on their personal traits and preferences. These apps fall into the class of location-based social networks [26, 77, 159], location proximity services [103], or people-nearby applications [140, 143]. They tend to be accessed on mobile (although some services have web apps), and usually use the phone's GPS to determine the user's exact location and then show (only) other users in close proximity. While these apps are commonly referred to as 'dating apps', they allow users to search for and engage in a variety of interpersonal relationships, including long-term romantic relationships, casual sexual encounters, platonic friendships, or business networking. The motives for using these apps further extend to, a.o., entertainment, curiosity, social approval, and a sense of community [139, 143]. These apps differ from most (location-based) social networks, as LBD apps do not require a prior social connection to see another user's information – i.e., other users can be strangers –, whereas social networks usually only share such information with connected users [103].

Most LBD apps work as follows. A user registers with the platform and completes their profile, listing their own traits such as age, gender, or interests, and generally uploading one or more photos. They also set filters for the traits of others, such as maximum distance, gender, or age range. The app then displays other users' profiles, which often list their location or distance, with two possible ways of browsing profiles. In the *card stack* model, the app generates a queue of other users that fit the desired criteria. It then shows these users one by one as cards on a stack. The user indicates whether they (dis)like the currently shown other user (colloquially: "swiping"), requiring a decision before being able to move on to the next user. If the user likes another user, nothing happens until (and unless) that other user reciprocates the like, in which case the two users "match" and can start messaging each other through the app. In the *grid* model, the app shows all nearby other users at once, allowing the user to select and view profiles at their leisure. The user can usually immediately start a conversation with any user, without the need to explicitly match beforehand. Apps can offer both modes. Apps usually operate on a 'freemium' basis, with a paid subscription or individual purchases giving access to more features, some of which are privacy-related, such as hiding age or distance.

Table 1: Selected LBD apps, as of January 2023.
Legend: # DL: number of downloads on Google Play Store; C/G: Card stack/grid; W/M: Website/mobile app.

Name	# DL	C	G	W	M

Hily	10M	✓			✓
OkCupid	10M	✓		✓	✓
Meetic	10M	✓	✓	✓	✓

2.2 Related Work

Location-based social networks, such as LBD apps, have long been shown to be vulnerable to inference attacks that reveal users' current or sensitive locations (e.g., a home). Early works treated the topic more theoretically and formally [26, 73, 87, 122, 123, 149, 159], mainly using simulated behavior to prove location leaks. Later on, location inference through trilateration was shown to be possible on various real-world services [77, 103, 157, 158]. Other forms of location inference were also shown to be feasible, such as triangulation [148], trace fitting [60, 89], probabilistic heuristics [33, 72], clustering [37], or machine learning [154]. In Section 5.5, we assess whether previously discovered vulnerabilities to location inference attacks specific to LBD apps are still present.

Outside our threat model, LBD apps may persist personal data on a user's device, which may become a (surveillance) privacy risk when that data is retrieved from that device in a forensic investigation. Several works analyzed these forensic artifacts that LBD apps leave behind, focusing on, a.o., Tinder [39, 61, 68], happn [69], Bumble [11, 61], Grindr [39, 61], and other popular dating apps [20, 39, 68, 88]. An adversary that can intercept a victim's network traffic can also gather sensitive data sent and received by LBD apps [100, 120]. LBD apps may also share personal data with third parties, as was shown on, a.o., Tinder [18, 27, 61, 98, 153], Grindr [61, 65, 153], happn [18, 98], Bumble [61], and OkCupid [27, 98, 153]. Social engineering through conversations can also be used to elicit personal data from LBD app users [92].

To the best of our knowledge, our work is the first extensive privacy analysis across a large number of LBD apps. The closest works on the topic of data exposure in LBD apps treated either only 5 LBD apps in 2015 across 7 attributes [110], or only 3 LBD apps in 2019 with very limited coverage of exposure to other users [153]. Cobb et al. [29] covered, a.o., 8 LBD apps in their analysis of online status indicators. Location leaks through trilateration on LBD apps have been described in various works over the past decade [22, 34, 65, 103, 111], but none systematically evaluated the issue across a similarly large set of highly popular LBD apps as ours (15 apps with over 10 million downloads each). Analyses of LBD app privacy policies focused on third-party data sharing [18, 61], while we assess their description of sharing with other users. Our work also integrates these privacy dimensions – data exposure, (location) leaks, privacy policy analysis – to comprehensively examine these apps' privacy posture, situating itself in the space of cross-dimensional privacy analyses for specific app ecosystems [42, 57, 99]. Finally, our work expands and updates the state-of-the-art knowledge, providing crucial insights into the manner in which these LBD apps continue to handle users' personal and sensitive data.

3 Scope and Motivation

3.1 LBD Apps Selection

For our analysis, we select the most popular LBD apps, based on their download count in the Google Play Store. Through an initial exploration, we observe that LBD apps are primarily listed under the *Dating*, *Lifestyle*, and *Social* categories. We crawl metadata, descriptions, and the ranking for all apps in these three categories in four countries[1] that are leading markets for LBD apps [2], through an internal Play Store API [5]. We filter on dating-related apps in the *Lifestyle* and *Social* categories by searching the keyword 'dating' in the name or description. We then manually review the top apps on whether they provide location-based dating. For our in-depth analysis, we retain all apps with more than 50 million downloads as well as those in the *Dating* category with more than 10 million downloads and a top 10 rank in at least one country, if they fit our definition of an LBD app and appear to be genuine; we omit two apps for the latter reason.[2] Table 1 lists the final selection. Our analysis reflects the most recent versions of these apps as of January 2023 (Appendix A). We only analyze dating-related modes, i.e., not other modes such as *Bumble BFF* for finding friends. Almost all apps cater to a general audience; Tantan targets an Asian or Asian American audience, and Grindr targets LGBTQ users.

3.2 Threat Model and Analysis Scope

Our goal is to analyze which private information the adversary can obtain about another person who uses an LBD app. This differs from models where the adversary is the platform itself or an affiliated third party (e.g., improperly storing or forwarding private data) [18, 91, 98], an intermediate party on the network (intercepting the traffic containing private data) [8, 100, 120], or an outsider exploiting platform vulnerabilities (e.g., breaching databases or stealing credentials to retrieve private data) [16, 32, 86]. As such, we primarily study

[1] France, Germany, United Kingdom, United States.

[2] Despite their apparent popularity, we omit *iHappy* and *SweetMeet*, both operated by FlintCast, as they appear to contain mostly fake profiles with a gift-giving monetization model, appear to have fake positive app store reviews, and otherwise have no mainstream online recognition.

breaches of *social* privacy, i.e., towards other individuals, instead of *institutional* or *surveillance* privacy, i.e., towards service providers, governments, etc. [54, 114]. The adversary uses only the information that a regular user can retrieve through client-side interactions with the service, and as such cannot use any other means to retrieve the information, e.g., infiltrating the platform's servers or escalating the privilege of their account. The malicious intentions of the adversary can be diverse and can relate to both virtual and physical privacy and safety [30]: using personal data for social engineering or identity theft [21, 30, 35, 48, 117], stalking or harassing a person online or physically [21, 30, 38, 48, 109], monitoring their partner [25], searching real-life acquaintances [28, 30, 139], up to nation-state surveillance and prosecution of at-risk populations [17, 90, 119] or physical violence [106].

We assume an adversary can access both the web and mobile app when both exist, since some data may be exclusive to either one. We consider three levels of technical sophistication for the adversary, with the required abilities affecting the extent to which they can gather personal data:

1. The least sophisticated adversary only observes personal data that is readily visible in the (web or mobile) *user interface*. This adversary type has been called a "no-tech hacker" [80] or "UI-bound adversary" [46]. This adversary requires no special technical skills, i.e., *everyone* could fit this adversary model.
2. A more technically sophisticated adversary *inspects the network traffic* to discover additional data. For web apps, this is easily achieved using browser developer tools, regardless of whether traffic is TLS-encrypted. For mobile-only apps, the adversary will need to capture (possibly TLS-encrypted) mobile web requests, which may require circumventing measures such as certificate pinning [108].
3. The most technically sophisticated adversary *modifies and injects network traffic*, which requires reverse engineering the app's API and circumventing integrity checks, e.g., in the form of message signatures.

Our own analysis proves that, even despite the mentioned protection mechanisms, these adversary models are nearly always feasible for the apps in our scope, as we could inspect and modify network traffic for both web and mobile apps.[3] Moreover, adversaries who are less technically skilled themselves could receive support or use existing tools for inspecting and/or modifying traffic and thereby extract hidden private data from LBD apps. This model has been shown to exist in practice. In the context of intimate partner surveillance, which is a potential motivation for our adversary, discussions where users share tools and tactics to collaborate on technically sophisticated attacks have been observed on online infidelity forums [141] and TikTok [152]. (Proof-of-concept) apps previously executed trilateration for Tinder [144] and Grindr [94] users, while a browser extension displayed additional features hidden in OkCupid's API [67], all through an easy interface without requiring technical skills.

The adversary can target either one specific user or the entire (local) service user base for mass data collection [21, 117]. We assume that the adversary can discover a victim's profile, but not that they match. In case the adversary has a specific target, this may require (roughly) knowing where the target is located, such that the adversary can put themselves sufficiently close to see the target's profile. This is not an unreasonable assumption: stalkers and their victims usually know each other [126], and people often share their current city online [24]. Given the ability to spoof the location data sent to a service, the adversary does not need to be physically near the target(s).

We assume that the adversary is able to create one or more profiles on the service. In Section 4, we determine whether services verify that a user is real, and see that services may require a working phone number or a verified photo, but overall, the account requirement is not a high barrier for an adversary. In order to parallelize requests and speed up data gathering, the adversary may opt to create and deploy multiple Sybil accounts [145, 156], but only one account is required as a strict minimum for our attacks to work. The adversary sets up a minimally complete profile, to be maximally stealthy. This allows them to collect data while the target is not aware that they are being observed. Our victim can fill in their profile entirely, but will configure it to be as privacy-conscious as possible, i.e., hiding data whenever allowed by the service. We assume both our adversary and victim to use a free account, though we note that premium services often include additional privacy features, such as hiding additional fields.

3.3 Ethical Considerations

As we will show, users share very sensitive and personal data on dating apps. We therefore design our experiments to be as ethical and privacy-conscious as is feasible, while still allowing for executing our study. We abide by ethical standards that are established in our community, focused on providing maximal benefits while minimizing harm [10, 56, 85]. Our study was approved by our university's privacy and ethics board. Due to the lack of meaningful interactions with or data collection on real users, our study was not considered to be human subjects research.

For each service, we set up at least two fresh profiles,[4] using dedicated email addresses and phone numbers. After these profiles discover each other, we collect their metadata and possibly have them interact (e.g., like each other) to gather additional data. We do not gather or analyze any data on real

[3] Only for two apps (Tantan and Jaumo), we were unable to reverse-engineer the message signature with reasonable effort (i.e., without extensive disassembly), preventing the analysis of exfiltration leaks.

[4] We sometimes need more than two accounts, to validate all possible interactions, e.g., (dis)likes or colluding accounts, or when profiles are taken down between initial account creation and the final exploration, possibly because of us disclosing our research purpose.

Table 2: Overview of account creation requirements. *Legend*: ● Required, ◐ Optional, ○ Not available.

users and do not meaningfully engage with them. We disclose our academic research purposes on the profile picture and/or in the biography, and request to ignore the profile to discourage users from interacting with us. The only interaction we possibly have with real users is to dislike their profile in order to continue onto our self-made profiles. This also means we do not deploy meaningful deception towards the services or their users. While our fake accounts might violate the services' Terms of Service, we believe that this is warranted as our research is in the public interest and its benefits for user privacy and safety outweigh the potential minimal harm to the platforms or their users [104]. We responsibly disclosed our findings to the services that we study and worked with them to resolve their issues (Section 7.3).

3.4 Limitations

Our scope definition and ethical protocol limit which privacy breaches we (can) analyze. We do not analyze whether (free-form text) self-descriptive biographies or photos contain any personal data [96], nor do we attempt to understand whether profile data can be used to cross-reference users between services or with other social media platforms [22, 71, 130], in particular as this would entail collecting real user data.

We cannot be certain that our analysis or reverse engineering process fully uncovers all data leaks, e.g., if we miss an API endpoint through which such a leak would occur. In addition, we analyze apps in a European Union country, where the General Data Protection Regulation (GDPR) is in force, which may affect the extent of private data collection and exposure by apps. Our findings may therefore not fully reflect the data leaks that happen in other jurisdictions.

4 Account Creation Security

We first assess **how easy it is for an adversary to create a (fake) account** to browse profiles on an LBD app. Sufficient protections and requirements for account creation can *expose* the adversary to other users, and therefore reduce the adversary's ability to easily and stealthily gather private user data. We consider two types of undesirable exposure: the adversary may want to remain *anonymous* and limit the information held by the platform (institutional privacy), e.g., to avoid that platforms can share this with law enforcement agencies when actions may be prosecutable (e.g., stalking); and they may want to remain *hidden* from other users (social privacy) to avoid awareness that they are present on the platform. In this section, we analyze the account creation requirements from the *adversary*'s perspective, seeing them as *security measures*. Evidently, these requirements also cause friction for *legitimate users*, as they impose personal data sharing; in the next section, we therefore approach them as *privacy risks*. Table 2 lists our detailed analysis of account creation security across the 15 LBD apps in our scope.

All services require an email address, except Tantan and Bumble which do not support email login, Badoo which requires either an email address or a phone number, and Jaumo which only requires an email address once a user wants to log out (to create a persistent account identifier to log in again). An email address is easy to acquire (anonymously), yet for 7 services it is a sufficient identifier to create an account, access the service, and view other user profiles. The other 8 services require a valid phone number, which will be verified through an SMS One-Time Password [83]. Phone numbers are more cumbersome to acquire, and pose a higher barrier for the adversary to create accounts. In particular, most countries implement mandatory SIM card registration [1], making it impossible to legally acquire a phone number fully anonymously there, breaking institutional privacy.

Once the account has been registered, the adversary must complete the account's profile. While 8 apps require in their terms of service that the provided profile data such as a name must be real, no app appears to verify the user-provided data, therefore posing no barrier to an adversary. 12 apps require that a user uploads a photo, with all except Tinder requiring that it is a face photo. Of course, an adversary could upload any person's face photo to maintain social privacy. As an additional safety feature, 13 apps then provide face verification, although this is optional except on Bumble. This step results in a profile badge, increasing trustworthiness [3, 31]. A user needs to complete an app-specific challenge while showing their face to get verified: for example, on Tinder or Bumble they must strike a given random pose, and on LOVOO they must hold a piece of paper with their name and a unique code. This image is also compared to the user's profile photo; the verification is invalidated if the profile photo is later changed. This requirement for a genuine profile photo can expose the adversary to other users, breaking social privacy.

Overall, the strictest service appears to be Bumble with mandatory phone and face verification. Conversely, some apps enable the adversary to browse other profiles anonymously, e.g., by allowing a profile to be empty (Grindr), and/or stealthily, e.g., by only requiring an email address and not a photo (MeetMe and Tagged) or by hiding one's own profile from others because it is incomplete (Hinge).

5 User Data Privacy Risks

With our accounts, we can now examine **what private data an adversary can learn about one or all other users**. We consider four data categories: personal data, sensitive data, app usage data, and location. For each category, we distinguish three modes of data exposure and leaks, mapping to our three levels of adversary sophistication (Section 3.2):

1. *user interface (UI) exposure*, where the data is readily shown in the UI to a technically unskilled adversary.
2. a *traffic leak*, where additional data is included in network traffic that is automatically sent to the user, but not shown anywhere in the UI. Such leaks require that adversaries can (or are helped to) passively intercept and view traffic.
3. an *exfiltration leak*, where the adversary must actively extract data from the service. This can be achieved programmatically by forging network requests, or using automated API requests that are chained to use previous responses (e.g., extracting profile properties using filters).

These modes also map to our distinction between *intended* sharing, i.e., UI exposure, and *inadvertent* sharing, i.e., traffic and exfiltration leaks. For the former, intended sharing, LBD app users can observe this data themselves for other users, and can therefore reasonably be assumed to be aware that their own data is also shared with others. Nevertheless, there are still significant privacy risks attached to this data sharing, as the adversary can abuse this data for purposes such as social engineering, identity theft, or extortion. We evaluate the UI exposure of data fields based on their incidence: whether apps make the fields mandatory and then *always* show these to other users, whether apps either display fields but make them optional or provide the choice to show/hide a mandatory field (*if set/shown*), or whether apps do not display or support the field and it is thus *never* shown. This represents the agency users have regarding what data they want to share, and the extent to which the app desires to collect data.

The latter, inadvertent sharing, represents data hidden in the UI for which users are therefore not aware of the data being shared. This results in a severe violation of their expectations of privacy towards other users, and an information asymmetry, as only adversaries with the capability to discover this data can abuse this data. These leaks also represent genuine vulnerabilities in the implementation of LBD apps.

For Tables 3 to 6, we use the following symbols to represent each mode's incidence:

Incidence	UI Exposure	Traffic Leak	Exfiltration Leak
Always	◇	◈	⊕
If set/shown	○	⊙	⊕
Never	–		

5.1 Analysis Methods

We design our systematic app analysis to elicit the three types of data exposure and leaks that we consider. We opt for manually reverse engineering each app's API, rather than (semi-)automatically searching leaks [70, 78], to achieve maximum coverage across potentially leaked attributes, API endpoints, message formats, and possible obfuscation techniques. First, we interact with the various functionalities of the app and list the data displayed in the UI (searching *user interface exposure*). Simultaneously, we capture the associated API traffic and examine whether it contains additional data that is not displayed in the UI (searching *traffic leaks*). We also examine any API calls that access the user's own profile for any enumeration of fields that are not leaked to others by default (e.g., email). Then, we add these fields to requests for API endpoints that retrieve data on other users and observe whether the API then exposes the additional fields (searching *exfiltration leaks*). These exfiltration leaks also include the automation of the location attacks that we perform on the 15 services (Section 5.5), by developing scripts that reliably and repeatedly spoof our location with modified API requests. Lastly, we upload a photo with EXIF data and check whether the photo as seen by another user contains the original EXIF data (e.g., GPS data) [47]. Two authors independently conducted this process for each application and compared results, serving to minimize potential errors. The conclusive set of features, along with their respective sensitivity levels, was settled upon after a discussion with all authors. Where necessary, app analyses were (partially) repeated to verify results.

If the service provides a feature-complete web app, we use Google Chrome's browser developer tools to directly monitor the LBD app's API traffic. If the service or some of its core features are only available on mobile, we run the mobile app either in an emulator or on a real device running Android. We use HTTP Toolkit [101] to intercept and decrypt Android HTTPS traffic, using Frida [113] to circumvent certificate pinning where necessary. For the exfiltration attacks, we use the Python Requests library [116] to automate API traffic.

5.2 Personal Data

We first consider leaks of personal data or personally identifiable information (PII), which can lead to identifying a specific person, either on its own or when combined with other data. Services are required to adhere to legal principles before they are allowed to process such personal data. For example, article 5 of the European General Data Protection Regulation (GDPR) requires that personal data is "processed lawfully, fairly, and in a transparent manner" [115]. More broadly, users may have various levels of comfort in sharing such personal data with others [95]. Finally, knowledge of these attributes enables in part the malicious intents within our threat model (Section 3.2), e.g., social engineering or

identity theft. Table 3 lists our detailed analysis of leaks of personal data across the 15 LBD apps in our scope. We now summarize the main findings of this analysis.

5.2.1 User Interface Exposure

Name 11 services require that users provide their first name and show this to other users, immediately providing one important piece of identifying information. POF, Tantan, and Grindr only use a nickname; on Grindr, this can be an empty string. Tagged requires both a (unique) nickname that is shown to others, and a first name that is not shown. On MeetMe, the user has the option to set and make their last name visible to other users.

Gender All services require the user to set their gender[5], except for Grindr (but it will show the gender if set). Only Bumble and OkCupid will always show the gender. Tinder, POF, and Hinge let users explicitly show or hide their gender.

Age All services require setting a date of birth. All but Grindr will then always show the user's age. Hinge offers the option to show the date of birth in the UI.

[5]Note that most international data protection legislation does not recognize gender identity as "sensitive data" [44], even though it may be particularly sensitive for users with a non-binary gender identity or those who changed gender, or if gender could a basis for discrimination.

Curriculum vitae 13 services ask about a user's education (usually level and institution); 12 do so for employment (usually job title and employer). For POF and Hily, these fields are mandatory and will always be shown to others. Otherwise, they are usually optional but shown if set. In terms of languages spoken, 8 apps have it as an optional field that will then be shown. On POF it is again mandatory. Only Meetic allows setting and optionally showing a user's nationality. 6 services require that users set and show their current place of residence (at town level). 3 more services let this field be optional but will show it if set. Bumble and Hinge optionally show a user's hometown (where they grew up).

Family status 9 services allow a user to optionally set their current relationship status, and will then show it; in 7 of these, being married is among the relationship options. 11 services optionally show whether someone has children; on Hily, a user is required to set and show this. Finally, POF requires a user to set and show their number of siblings and birth order.

Miscellaneous We do not find any app that shows or leaks the email address or phone number used for registration. 9 apps integrate with other social networks such as Instagram, but usually only show the contents of profiles there without the possibility to visit them. Only Grindr lets users (optionally) show their identifiers on other platforms. As mentioned in Section 4, 12 services require photos and will show these to others; the remaining 3 show them if provided. Photos on MeetMe still contain the original EXIF metadata, therefore potentially leaking the time when or location where the photo was made. All other services properly strip (sensitive) EXIF metadata. 13 services optionally show any personal interests the user has set. On 8 apps, these interests comprise personal values: for example, Bumble users can select feminism, voting rights, or Black Lives Matter. Tantan and Meetic optionally allow to set and show one's income.

5.2.2 Traffic Leaks

Beyond UI exposure, several apps leak certain fields as part of API traffic leaks. Tagged leaks the (required) *first name* and the first letter of the (optional) *last name*. Most services that do not display *gender* leak it. Tinder leaks specifically non-binary gender identities, as these are represented by a different field from the gender field. Tagged leaks the (mandatory) *date of birth*. happn leaks the (optional) *place of residence*. On Jaumo, *employment*, *education*, *relationship status*, *marital status*, *children*, and *interests* are purportedly only shown to others if those have also set these fields themselves, but they are leaked in API traffic to all users. Similarly, on Badoo, the *relationship status* and *having children* are only shown to others if they have a sufficiently complete profile, but the fields leak. Finally, Hily leaks identifiers for *other platforms*.

5.3 Sensitive Data

Certain personal information is considered particularly sensitive, for example, because it could enable discrimination [160] or because users simply feel uncomfortable sharing it [95]. Such data also enjoys explicit legal protection: for example, article 9 of the GDPR generally prohibits the processing of "special categories of personal data" [115]; we use these categories for our analysis. However, LBD apps enable and sometimes encourage users to share such information, as they also form a basis upon which users may want to select potential partners. Table 4 lists our detailed analysis of leaks of sensitive data across the 15 LBD apps in our scope. We now summarize the main findings of this analysis.

5.3.1 User Interface Exposure

Racial or ethnic origin 8 services let a user optionally set their racial or ethnic origin, although for Tagged and Bumble this is not possible in all countries. 7 of these will then show it if set, while on Hinge a user can explicitly hide it.

Opinions and beliefs 4 apps allow users to optionally set and show their political leaning. 7 apps allow users to optionally set or show their religious or philosophical beliefs, with POF requiring it to be set and shown.

Health data Data related to a user's physical health is required for some services, including height, diet, eye or hair color, and smoking, alcohol, and recreational drug habits. Further attributes that are (only) optional are a user's figure, exact weight, and fitness level. 5 apps allow to optionally set and show whether a user is vaccinated; on all these services, this can be for COVID-19, while Grindr also supports mpox and meningitis. Grindr also has an optional field for a user's HIV status, including their last test date.

Sexual orientation and sex life 4 apps require that a user sets a sexual orientation but will then not show it in the UI. 3 apps let a user optionally set a sexual orientation, and will then show it. Grindr and OkCupid support optionally setting and showing labels related to a user's sex life, such as their preferred roles during sex or specific sexual practices. OkCupid only provides this option to LGBTQ users.

5.3.2 Traffic Leaks

As with personal data leaks, Jaumo leaks *health-related fields* to users for whom these fields are otherwise hidden in the UI as they have not set these themselves, and Badoo leaks *health-related fields* to those with an incomplete profile for whom the fields are hidden in the UI. The 4 apps that require to set a *sexual orientation* yet do not display it in the UI all leak it in API traffic.

5.4 App Usage Data

Next, we consider leaks of data that are related to app usage and the dating process, such as likes of others, recent activity, or the type of relationship sought. This data is strictly speaking not personal data, as they would not allow identifying a particular person. However, they are sensitive in the sense that users may not want (certain) other people to be aware of this data, e.g., to avoid stigma about their reasons for using LBD apps. Table 5 lists our detailed analysis of leaks of dating-sensitive data across the 15 LBD apps in our scope. We now summarize the main findings of this analysis.

5.4.1 User Interface Exposure

Activity All apps except Bumble show in their UI whether a user was recently active, which can be abused to track whether someone is actively using an LBD app (e.g., for stalking or monitoring a partner). 4 apps also display when the user was last active. Tagged displays when a user created their account.

Preferences All apps except Tantan allow a user to set the type of relationship they are searching for, such as a long-term relationship, casual encounter, or friendship. 5 apps require it and will always display it; 8 other apps will always display it if the user (optionally) sets it. Badoo and Hily require that a user sets whether they want children; Hily always displays it. 8 apps provide the option to set this field. 3 apps show in the UI what gender and age filters the other user has set. All these fields reveal the other's dating intentions and preferences, which they may not feel comfortable sharing.

Profile access 8 apps offer the ability to revisit a user's full profile using the UI at any time, as a user gets a link to a profile page. Some services also allow pausing the visibility of a profile to others. Of the 8 apps where this feature is free, 2 still display other profiles even when one's own profile is paused, allowing for stealthy browsing of other profiles.

5.4.2 Traffic Leaks

Profile access Even though the card stack model suggests that users can only see one profile at a time, in the background all apps except OkCupid receive data for more than one user in one API response. In the grid model, Grindr is the outlier by requesting 100 full and 500 partial (i.e., without distance) profiles at once. Given a user ID that is contained within the received profile data, all services then have a manner to request a user's full profile permanently and at any time. Next to the 8 apps that have full profile access in the UI (as discussed above), the 7 other apps offer a specific API endpoint that also enables continuous profile access. Only Badoo and Bumble generate a unique user ID for each other user, meaning user IDs cannot be shared between users (e.g., between the adversary's Sybil accounts). However, Bumble offers the option to share a profile with another user, circumventing this unique user ID. 4 apps that offer pausing profile visibility to others will display an error message in the UI, but still fetch profiles in background API traffic. All these leaks enable and simplify large-scale, long-term, and stealthy profiling: for the many users that are returned with few API requests, the adversary can continuously request their profile, and sometimes even while remaining invisible to other users.

User votes 12 apps leak in API traffic whether another user has liked the user,[6] before having voted oneself. (Only Tinder and LOVOO truly protect this field; Grindr does not have a truly similar concept of liking.) This leak of likes contrasts with users' perception that another (free) user must first vote before they can know whether the other likes them. Badoo, Bumble, and Hinge leak this in the user profiles of the card stack. The other apps leak the like by embedding user IDs or full profiles in the data retrieved for showing the blurred profile photos of users who like them. (13 apps show full profiles of likers only to premium users.) The API responses of POF, Tagged, Hinge, and Hily contain the timestamp of the like. POF's API additionally leaks how long the other user looked at a profile. Badoo, Tagged, Bumble, OkCupid, and Meetic leak whether another user disliked the user. Badoo and Tantan also leak another user's popularity score and (for Tantan) their number of likes/dislikes in API traffic.

[6] We only consider regular likes, not 'superlikes', which is a usually paid feature to force the display of one's like to the other in their UI.

Table 6: Overview of data leaks for location.

	Tinder	Badoo	POF	MeetMe	Tagged	Grindr	Tantan	Jaumo	LOVOO	happn	Bumble	Hinge	Hily	OkCupid	Meetic
Exact location	–	◈	–	–	–	◈	–	–	–	◈	◈	◈	◈	–	–
Trilateration type	–	O	–	–	–	E	–	–	–	R	O	O	O	–	–
Distance to other user	◇	◇	–	◈	◈	◈	◈	◇	◇	◇	◇	–	–	◈	◇
City of recent location	–	◇	–	◇	◇	–	◇	◇	◇	–	◇	◇	◇	◇	–

Other fields 7 apps leak the *last activity time* and 4 apps leak the *account creation time* in API traffic. Tinder will show the (optional) type of relationship to others only if they have also set the field, but leaks the value to all. For the *wanting children* field, Badoo leaks it to users with an incomplete profile, and Jaumo leaks it to users who have not set the field themselves. 4 apps leak gender and age *filters* in API traffic.

5.4.3 Exfiltration Leaks

Badoo and Bumble are vulnerable to an exfiltration leak where the 'projections' field in an API request can be altered to force the fetching of additional data fields. Through this avenue, Bumble then leaks whether a user was *recently active*, their *last activity time*, and their *filters*; for Badoo, this leaks the *last activity time* and *number of (dis)likes*.

5.5 Location

The apps in our scope rely on a user's location and the proximity to others to select those other users that will be presented. This implies that the service receives and stores the user's (usually exact) location. A leak of this location can be particularly sensitive [14, 41, 52], e.g., if it reveals that a user visited locations such as clinics that might cause embarrassment [12]. Tracking a user's location over time can also reveal frequently visited locations, which combined with temporal patterns may reveal, e.g., a user's home or workplace [37, 41]. Moreover, the transition into the physical world can make such a leak outright dangerous [36]. A location leak

enables personal safety threats (Section 3.2) such as stalking, harassment, physical violence, or prosecution.

While early versions of some LBD apps leaked exact coordinates to others [63, 77], our analysis shows that by now, only Tantan suffers such a leak, and then only the coordinates at the (one) time of matching someone, with only that match. Instead, apps use the distance between users, which they will display (Table 6) and/or provide as filters. However, lacking sufficient protections, the availability of distances can still lead to the inference of a user's location. This is done through *trilateration*: given three tuples of positions P and their distances D to the user's location L, L will be at the intersection of the three circles with radius D and center P.

We define three types of trilateration, and apply these definitions throughout the rest of the section:

1. *Exact distance trilateration*: Services reveal the *exact* distance (accurate to the meter) to other users. Adversaries can then spoof their location to three random positions. Using those locations and the distances to the victim as revealed by the service, the adversary can trilaterate the victim [66].
2. *Rounded distance trilateration*: As a countermeasure, some services only reveal *rounded* distances to another user (e.g., to 1 km). Adversaries then spoof their location to some random starting position, and then incrementally shift in a certain direction until the reported rounded distance changes, doing so three times [103]. If attackers can determine the rounding method (i.e., flooring, rounding, or ceiling) – e.g., by first trying the attack on their own controlled accounts –, they will subsequently know the corresponding *exact* distances to a victim, namely at the three positions where the reported distance changed. With these locations and exact distances, the adversary can trilaterate the victim.
3. *Oracle trilateration*: Adversaries use an *oracle* that indicates through a binary signal whether a victim is located within proximity, i.e., when they are within a defined "proximity distance" from the attacker. This distance can either be a fixed distance set by the service, or a distance that the attacker can select (e.g., through a filter). Initially, the adversary roughly estimates the victim's location (e.g., the city of the victim as displayed in the UI, Table 6), and places themselves in this location to be within proximity. The attacker then incrementally moves themselves until the oracle indicates that the victim is no longer within proximity, and this for three different directions. The attacker now has three positions with a known exact distance, i.e., the preselected proximity distance, and can trilaterate the victim. In our approach, we deviate from the state of the art [103] by using a simpler method. Our argument is that, in the context of LBD apps, we do not need to resolve the "Disk Coverage Problem" as we have an approximate location, leading to a reduction in API requests. Furthermore, we avoid any unusually large movements, as this could trigger detection [55]. The combination of these factors decreases the risk of malicious activity being detected.

Historically, LBD apps had a bad track record in terms of enabling trilateration and leaking users' exact locations. Exact distance trilateration was shown to work on Tinder (in 2014 [144]), POF (2014 [111]), Grindr (2014 [51, 138] and 2018 [74]), and LOVOO (2019 [135]). Rounded distance trilateration used to work on Bumble (in 2021 [64]). We now (re)evaluate these attacks to observe whether LBD apps have since reduced their location privacy risks. We find that we can successfully retrieve a (quasi) exact location for 6 apps.

Exact distance trilateration Grindr is susceptible to exact distance trilateration, accurate to at least a 111 m by 111 m square (at the equator). This accuracy is reduced by local generalization, implemented by rounding user (latitude/longitude) coordinates to three decimal places before sending them to Grindr's servers, meaning they will never know a user's exact location. Nevertheless, we consider this rounding insufficient, especially in sparsely populated areas. Moreover, while users can enable hiding their distance from other users, this distance can still be inferred as the grid is sorted by distance. It was previously known that two colluding accounts can put themselves before and after a user to bound the distance [65]. We find a novel way that enables distance inference with only one account, by iteratively manipulating the minimum distance parameter of the grid retrieval endpoint. This enables exact distance trilateration even for users with hidden distances, including in countries such as Egypt where Grindr considers the safety of its LGBTQ users at high risk and therefore always hides distances [59].

Rounded distance trilateration happn displays a rounded distance in the UI, while leaking a higher-precision distance in their API, rounded up to the nearest value in a set of incrementing distances: 249, 499, 999, 1999, ... m. Both enable rounded distance trilateration, the latter with fewer iterations.

Oracle trilateration Badoo, Bumble, Hinge, and Hily are all susceptible to oracle trilateration. In all these apps, the distance filters serve as the proximity oracle, as the filters use exact distances. For Hinge and Hily, this happens despite distances being hidden in the UI, highlighting how one cannot assume that hiding distances solves trilateration vulnerability, as subtle 'side channels' may still enable trilateration.

No vulnerability discovered Tinder and LOVOO thwart trilateration by implementing "grid snapping" [77, 103, 125] to significantly reduce the accuracy of displayed distances. This grid system divides the physical space into smaller grid cells (for Tinder: 1×1 mile, for LOVOO: 1×1 km). All coordinates inside a cell are then mapped to its center (Tinder) or right side (LOVOO), and these mapped approximate coordinates are used for distance calculation, making all forms of accurate trilateration impossible. This was previously confirmed for Tinder [22, 63] and LOVOO [135].

POF and Meetic do not access the exact GPS location, instead relying on user input for their location at the town level. MeetMe, Tagged, and OkCupid do access the exact GPS location, but convert it to the closest town. The distances used on these services are therefore between two users' town centers, making all forms of accurate trilateration impossible. We could not reverse engineer the API message signatures for Tantan and Jaumo. As a result, we could not systematically spoof our location to test trilateration.

5.6 App-centric Summary

We now summarize our findings from the perspective of the per-app privacy posture. In terms of *intended sharing*, we compare the extent of collecting personal and sensitive data, and the user freedom in doing so. Profiles on POF, Meetic, OkCupid can contain the largest amount of data, supporting up to 23 different fields, of which up to 11 fields are sensitive. This may be due to their origins as traditional online dating platforms that use more extensive profiles. All these apps are also owned by the same owner, Match Group (Appendix A), as is the app with the next largest amount of fields (Hinge, 21 fields). Comparatively, Tantan (9 fields) and LOVOO (12), and Tagged (13) support the fewest (sensitive) fields. Tagged also stands out in supporting no health-related fields. While Grindr also has few (13) fields, these comprise very sensitive attributes, including HIV status and sexual preferences. Nevertheless, disclosure of these fields is seen as beneficial by Grindr's primary audience of gay and bisexual men [143, 151]. Moreover, privacy and anonymity on Grindr may be preserved through other means: notably, all fields are optional. This may result in a lower prevalence of data sharing: for example, only 13% of Grindr users used their real name [127] (compared to 70% on Tinder [19]). However, from the perspective of the adversary, the possibility to leave their profile empty also increases their stealth. In terms of a user's choice to share data, POF, Hily, and Badoo go the furthest in requiring many fields that are optional or missing on other services, including sensitive data such as smoking, alcohol or drug use, and religious beliefs. All other apps except Grindr require 3 to 6 fields. Note that even if fields remain optional, other users might still expect that these are disclosed [150], potentially reducing the actual user choice.

In terms of *inadvertent sharing*, API leaks introduce privacy breaches, even though excessive leakage through APIs is a well-known issue, e.g., being part of the OWASP API Security Top 10 [155]. Even the largest apps are not immune to such vulnerabilities. Non-binary genders leak on Tinder, while Badoo (and Bumble) are vulnerable to exfiltration leaks. The latter two services have been aware of these leaks since 2020 [117], but do not appear to have fully fixed them. Apps do protect personal and sensitive data relatively well, with most traffic or exfiltration leaks affecting only app usage data. Notable exceptions that are leaked relatively often are gender (8 apps), and sexual orientation (4 apps), a sensitive field. Interestingly, almost all implementations of data sharing reciprocity fail. Tinder, Badoo, and Jaumo leak attributes that are hidden for other users while one's own profile is incomplete. Similarly, if the adversary hides their profile, they can still fetch profiles on 6 apps, enabling stealthy data gathering.

These privacy postures extend to *location data*. Oracle trilateration is the most powerful inference method: while most apps have implemented measures to protect distances, the ability to do binary proximity testing causes them to remain vulnerable. For all services where we were able to execute our experiments but that were not vulnerable to trilateration, users' locations were protected by calculating distances to a generalized point, i.e., a nearby town center or a point on a grid, therefore omitting exact location from the distance computation and making its retrieval impossible. Finally, all apps except OkCupid will also fetch multiple profiles at once. This may be for efficiency reasons, i.e., to reduce the number of server requests. However, together with the ability to permanently request a user's profile at any time, and easily create accounts, these data exposures and leaks enable large-scale, long-term, and stealthy profiling of LBD app users, allowing the adversary to collect personal data on many users at once as well as data that is presumed to be hidden.

6 Privacy Policies

In our final analysis, we examine **how privacy policies of LBD apps discuss and acknowledge personal data collection and potential leaks** and compare this with real-world behavior. One aspect of the lawful processing of personal data in the GDPR is transparency [115]. Articles 13 and 14 lay out the information that the data controller (here the LBD app's provider) must communicate to the data subject (here the user), such as the categories of personal data being processed and the legal basis. Typically, web services and applications include this type of information in a privacy policy. Together with the Terms of Service (ToS), the privacy policy is displayed to users before they create an account.

This raises the question of how LBD apps inform their users about the collection, sharing, and security of personal and sensitive data. To determine this, we read the privacy policies, ToS, and related documents for all 15 LBD apps in scope. We systematically check whether the documents meet the information requirements in the GDPR and whether they contain any information about the processing of personal data including special categories (per the GDPR's article 9), the use of location data, and (controls for) the potential risks of sharing personal data with the application or with other users.

Processing of personal data of users All apps have a privacy policy, and these policies generally meet legal requirements for informing users. However, the level of detail differs between apps. For instance, the privacy policy of Hily dis-

plays a detailed table with each specific piece of processed information, along with the source, purpose, and legal basis for the processing, while Tinder includes a non-exhaustive list of pieces of information being processed for each listed purpose. 12 privacy policies mention that the LBD app will be processing sensitive data. The legal basis for processing is mostly consent, and sensitive attributes are stated to be optional. However, it seems highly likely that the user would need to provide at least their sexual orientation in order for the app to properly function, contradicting that this sensitive attribute would be optional.

Location data For 9 LBD apps, the privacy policy contains information about revoking consent for the processing of personal data. Out of those apps, 3 mention that the user is free to decline geolocation permissions but that some services might then not work properly. happn and LOVOO's privacy policies state that an alternative way to determine location will be used if the application cannot access the GPS location of the phone. MeetMe and Tagged mention the possibility of hiding a user's exact location from others in the profile settings. Finally, the privacy policies of 6 apps do not inform users about the consequences of revoking the geolocation permission. When testing this in practice, only 3 applications will not show other profiles without the geolocation permission. For the other 12 apps, the user is proposed to manually specify the town they live in as an alternative location. Interestingly, Grindr's privacy policy warns users that a location inference attack might be possible; other than that, no application discusses the privacy risks or potential mitigations specifically for inference attacks on location data.

Privacy controls Some LBD apps provide more guidelines and control for privacy than others. 6 apps mention in their privacy policy that users can set at least part of their profile to private. This benefits the users' privacy in the sense that the user matching process is improved without making additional data visible to other users. In practice, 2 of those 6 apps allow the user to hide (at least part of) their profile, and POF provides the option to hide one specific attribute from other users (i.e., gender). The remaining 3 apps also include some profile hiding features, but only upon payment as part of their premium subscription. Additionally, the user can hide a single attribute in 3 more apps, but do not mention this possibility in their privacy policies.

Next to this, 7 privacy policies warn about sharing data with other users. They mostly advise users to be cautious when sharing personal information on their public profile or with other users. Only LOVOO and Bumble explicitly list which types of user data might be visible to other users. Some other apps discourage users from sharing certain types of personal information such as their address, full name, or email, and even prohibit the sharing of financial information such as credit card numbers in their ToS.

7 Discussion

7.1 Functionality versus Privacy

In LBD apps, there is an inherent tension between maintaining one's privacy and engaging in sufficient self-disclosure to enable forming relationships [48]. LBD app users find it important that profiles contain certain information [6], and use the (sensitive) profile data to filter potential partners on desired traits [28] and search for more information about them [48], to ultimately decrease uncertainty, increase trust, and improve feelings of personal safety [28, 30, 109, 140]. In return, users readily share information themselves [28, 45]. Information disclosure may also (be believed to) result in more success on the platform [58, 118, 142], potentially further encouraging data sharing. Some may opt to self-disclose even sensitive information upfront: e.g., transgender users to avoid physical danger when meeting in-person [43], and users with disabilities to filter out potential partners who would be uncomfortable with their disability [107]. Expectations on information disclosure depend on the context [112], and arguably, online dating is a context where a large amount of disclosure may be expected, not perceived as concerning, and even perceived as beneficial.

Nevertheless, LBD apps entail specific privacy risks [131, 132], and privacy has been found to be a main concern for LBD app users [30, 50, 84]. Users' concepts of social privacy violations were more concrete compared to institutional privacy [15, 49, 82, 97, 134], aligning with our adversary model. Users actively limit the information they disclose on LBD apps to maintain their (social) privacy [15], or provide false information for privacy reasons [19], e.g., if they worry about being recognized by people they know [15, 28, 48], or that an unknown individual tracks them down [109]. User sensitivity to data exposure also differs for each attribute [6]. Limiting disclosure may be particularly pertinent to certain (higher-risk) populations [102]. For example, women are at higher risk of online stalking and harassment [23], and were more concerned about (location) privacy than men [4, 50]. LGBTQ people also face higher risks [128], and they may not want to be discovered on LBD apps if they are not out [13, 30, 49, 143] or face prosecution [129]. In general, online dating represents a very sensitive context, encompassing intimate relationships and data sharing with strangers [48], with users generally being unaware of who is observing their data, due to the adversary's potential stealth.

LBD app users may also experience pressure to disclose data. On the one hand, they may feel forced by other users [48, 146], even for very sensitive data such as HIV status [151]. On the other hand, LBD apps nudge towards data sharing, purportedly to improve matching others [147]. For example, Hinge tells users that "the more you share, the better your matches will be". Default visibility may also lead to additional sharing: for example, out of Hinge's 20 hideable fields,

12 are visible by default; this is particularly important as the majority of users tend to not change default settings [53].

Ultimately, LBD apps users desire the choice to disclose personal or sensitive information [150]. We believe LBD apps should enable users to consciously make that choice (controlling intended sharing) as well as maximally protect users' data if they choose not to disclose (preventing inadvertent sharing). In this light, we consider our findings to be important in that they make users better aware of the actual data sharing practices on LBD apps. While (intended) data sharing is a crucial part of the functionality of LBD apps and may align with users' privacy expectations [79], and there are genuine benefits regarding safety, these must be balanced with the genuine privacy concerns and risks that users may face when using LBD apps. An interesting avenue for future work would therefore be to analyze users' privacy perceptions of LBD apps given awareness of our findings, both in terms of exposure (intended sharing) and leaks (inadvertent sharing). For example, such a user study has previously shown that mobile users find opaque data sharing with third parties "creepy" [121]. Similarly, our findings may make users reconsider their privacy stance regarding these apps and use more caution in sharing their personal data – including their location – on these apps, helping to reduce the mismatch between perceived privacy risks and actual behavior [28, 112, 130]. At the same time, we hope that our findings will lead to improved privacy precautions by the LBD apps themselves, including applying additional countermeasures to prevent user data leaks in the future.

7.2 Countermeasures

Our analysis shows that the APIs for several apps suffer traffic and exfiltration leaks that cause privacy breaches that users are unlikely to be aware of. To prevent these inadvertent data leaks that violate users' privacy expectations about LBD apps [79, 134], services should harden their APIs [155] by limiting the exposed API endpoints, enforcing proper access control, and ensuring that no unnecessary (i.e., not displayed) attributes are sent in API responses. Specifically for locations, services should implement techniques to prevent trilateration and other attacks that reveal a user's exact location. For example, they could apply spatial cloaking, such as snapping to grids [77, 103, 125] or nearby towns before computing distances between users; the real-world deployment of this mitigation (Section 5.5) shows that this does not overly impede functionality. A suite of academic work develops protocols for privacy-preserving proximity testing that allow for approximate location information to be released while protecting an exact location, see, e.g., [7, 93, 124, 136].

LBD apps could also increase friction for adversaries to gather data (at a large scale). This can range from requiring a phone number and email address, requiring account or face verification, rate limiting [105] or verifying API requests, detecting fake or rapidly shifting locations [9, 55, 105], to detecting malicious accounts [62, 133]. However, these techniques mostly serve to annoy the adversary, and may not meaningfully prevent a motivated attacker from executing their attack. For example, the advent of deepfakes and AI-generated images may make face verification decreasingly robust [76]. Some services sign messages to verify authenticity, although the inherent fact that this must occur client-side makes these signatures vulnerable to reversing (as we observed ourselves). Rate limiting is also easily circumvented by multiple (Sybil) accounts [145, 156], especially since there is no need for establishing a social connection beforehand [103]. Concurrently, these countermeasures increase friction for legitimate users to create accounts, and force them to share more data, defeating the privacy goals.

LBD app users should have maximal visibility and control over what they share with others. Profile data could be hidden by default, requiring that users consciously enable sharing it. Users could also have the option to show sensitive data only in a second phase (e.g., after matching), as to not broadcast this data to all users. Apps could also add the option to only see and be seen by verified accounts (as already exists on, e.g., Jaumo). All apps should clearly, explicitly, and repeatedly ask if users want to share their current location (especially if that location might be sensitive) [40], or provide the option to only share an approximate location (e.g., town center).

In the end, the most effective strategy is to not have data in the first place. The most popular LBD app, Tinder, lacks certain sensitive data attributes that are common on other apps, such as height, racial or ethnic origin, political opinions, and religious or philosophical beliefs, and snaps user locations to a grid, making the displayed distance only an coarse approximation; yet people still use it. By protecting data before it is sent to the service, it is impossible to expose or leak it, and users' privacy is maximally protected.

7.3 Responsible disclosure

We responsibly disclosed our findings to the vendors of all 15 apps, sending a draft of this paper and a list of concrete vulnerabilities (i.e., traffic and exfiltration leaks) for that app, by email to designated security addresses if available or else a general support address. Vendors for 10 out of the 15 apps immediately acknowledged receipt, indicating their responsiveness to security and privacy matters; after retrying our disclosure after five months, two more apps acknowledged receipt. Of these 12 apps, 9 engaged in substantial and productive discussions regarding our discovered leaks, and indicated that they had deployed concrete fixes. These interactions emphasize the tangible results of our collaborative engagement with these vendors, underscoring the concrete strides taken to enhance the overall privacy of the LBD app ecosystem.

8 Conclusion

Through a systematic analysis of 15 popular LBD apps, we find that they routinely expose personal data to other users. While users may feel compelled to share such data, there is a particular risk when APIs leak data hidden in the UI as well as exact user locations, as users will not be aware that they are sharing this data, which can lead to additional harm. Additionally, the apps' privacy policies generally fail to inform users about these privacy threats and leave the burden of protecting personal (sensitive) data to the users. We hope that the awareness that we bring of these issues will lead LBD app providers to reconsider their data gathering practices, protect their APIs from data leaks, prevent location inference, and give users control of their data and therefore ultimately their privacy.

A LBD App Versions

Table 7 lists the version numbers used for testing our LBD apps in scope, as of January 2023. For web apps, we search a version number on the web page or in its HTML source; we mark the version as 'unknown' if we do not find such a version number. For mobile apps, we use the version number of the APK downloaded from the Google Play Store.

Table 7: Tested version numbers of the LBD apps.

Name	Owner	Web app	Mobile app
Tinder	Match Group	4.3.1	14.1.0
Badoo	Bumble Inc.	1.0.00.28116	5.304.1
POF	Match Group	2.8.0-b9961	4.85.1.1510401
MeetMe	The Meet Group	5.44.3	14.49.0.3795
Tagged	The Meet Group	unknown	9.58.0

Spill the TeA: An Empirical Study of Trusted Application Rollback Prevention on Android Smartphones

Marcel Busch Philipp Mao Mathias Payer

EPFL, Lausanne, Switzerland

Abstract

The number and complexity of Trusted Applications (TAs, applications running in Trusted Execution Environments—TEEs) deployed on mobile devices has exploded. A vulnerability in *a single* TA impacts the security of the entire device. Thus, vendors must rapidly fix such vulnerabilities and revoke vulnerable versions to prevent *rollback attacks*, i.e., loading an old version of the TA to exploit a known vulnerability.

In this paper, we assess the state of TA rollback prevention by conducting a large-scale cross-vendor study. First, we establish the largest TA dataset in existence, encompassing 35,541 TAs obtained from 1,330 firmware images deployed on mobile devices across the top five most common vendors. Second, we identify 37 TA vulnerabilities that we leverage to assess the state of industry-wide TA rollback effectiveness. Third, we make the counterintuitive discovery that the uncoordinated usage of rollback prevention correlates with the leakage of security-critical information and has far-reaching consequences potentially negatively impacting *the whole mobile ecosystem*. Fourth, we demonstrate the severity of ineffective TA rollback prevention by exploiting two different TEEs on fully-updated mobile devices. In summary, our results indicate severe deficiencies in TA rollback prevention across the mobile ecosystem.

1 Introduction

On Android, Trusted Applications (TAs) are vendor-signed dynamically loadable modules that extend the features provided by a Trusted Execution Environment (TEE). The TA loader is responsible of verifying the TA's signature. Thus, only authentic TAs can be loaded. TAs provide many security-critical tasks including secret-based authentication (e.g., login via PIN, pattern, or password), biometric authentication (e.g., fingerprint and face identification), playback of protected digital content (e.g., digital rights management), disk encryption, mobile banking, and generic cryptographic key management. In this study, we are concerned with vulnerabilities in TAs putting these security-critical tasks at risk.

TEEs on Android devices leverage the ARM TrustZone architectural extension. TrustZone creates an isolated execution context separated from the commonly known Android software stack. This separated context provides integrity and confidentiality guarantees for its components (TEE OS and TAs). Code in the normal world can only interact with TAs through well-defined and protected interfaces. TAs can interact with the TEE OS through system calls.

Rollback Exposure. TAs are an attractive target for attackers. Their number and complexity is ever-increasing. TAs are a prime attack surface to breach the TEE because TAs are directly accessible from the Android context. Either an attacker breaches a specific TA and has direct access to confidential data, or the breach serves as a initial foothold to compromise the entire TEE [1, 35, 49]. Unsurprisingly, TAs of *all* major TEE implementations have been exploited in the past [1, 8, 31–33, 35]. Such breaches are usually followed by the rollout of updates that fix the underlying vulnerabilities. However, attackers retain access to the original, signed, vulnerable TA. Without *rollback prevention*, meaning to increase a *rollback counter*, this vulnerable TA may still be loaded into the TEE and exploited.

In this paper, we extend the existing vulnerability lifecycle model [2, 27, 43] to cover this underexplored rollback attack vector. The vulnerability lifecycle captures the phases from the point of introduction of a vulnerability into a codebase until the point where all systems affected by the vulnerability are patched. The study of the vulnerability lifecycle is important as it helps to mature software security practices and workflows, and provides insights into the impact of security efforts. While prior measurement studies on different targets than TAs have produced a number of valuable insights into the vulnerability lifecycle [2, 27], our study provides novel insights on the *rollback exposure* for TAs.

Challenges and Solutions. Studying the TA rollback attack vector poses several unique challenges.

- Capturing the complexity of the TA ecosystem. Several parties including vendors, chipset providers, third-party

TEE implementations, and third-party TAs as well as their interdependencies have to be taken into account.

- Understanding and measuring the implication of security-related events, like vulnerability disclosures and rollback counter increases. The impact of these events on individual products and the ecosystem is underexplored.
- Identifying reasonable past and present industry trends to extrapolate the future development of the ecosystem.
- Obtaining a representative ground truth of TAs and past security-related events. The (lack of) availability of historical firmware, proprietary file formats, and vague information on public TA vulnerabilities pose difficulties.

Our study is the first large-scale systematic measurement of its kind and addresses all of these challenges. To address these challenges, we systematize and model the TA ecosystem in Section 5 by surveying and reverse engineering the proprietary TEE software stacks of a representative subset of device series. This ecosystem model allows us to reason about the implications of security-related events and guides our discovery of real-world instances of rollback-counter-related side effects in Section 7. For these real-world instances, we obtain a representative ground-truth dataset of TAs and security-related events as described in Section 6.1 and Section 7.1. This dataset required us to define the criteria for representativeness, obtain and process 1,330 proprietary firmware images, and aggregate the heterogeneous information across these sources. Finally, from the past and current industry trends, we extrapolate and discuss future developments of the ecosystem in Section 8.

Study Outline. We present a large-scale cross-vendor study on the effectiveness of TA rollback prevention surveying the prevalence of rollback mitigations. First, we collect a representative dataset of 1,330 firmware images containing 35,541 TAs deployed on recent mobile devices spanning the five most common vendors. Next, we reverse engineer and fully automate the extraction of TAs and their metadata from these firmware images. Then, we establish a ground truth of 37 TA vulnerabilities that we leverage to investigate the effectiveness of TA rollback prevention. Conversely, we form a subset of TAs with rollback counter usages and investigate the corresponding leakage of security-critical information and its implications for the ecosystem. Lastly, we conduct a study on the effectiveness of TA rollback prevention by investigating if we can load and breach vulnerable TAs in the most widely-used TEEs, namely Samsung's TEEGRIS, Trustonic's Kinibi, Qualcomm's QSEE, and Beanpodtech's BeanPod.

Results. Our results indicate the lack of effective TA rollback prevention on an industry-wide scale and discovers a net-negative security impact on the entire ecosystem in the case of uncoordinated rollback prevention. Based on our ground truth of 37 vulnerabilities, we discovered 2,582 cases of rollback exposure out of which 265 remain vulnerable on the latest firmware images (note that one vulnerable TA can affect multiple device models). These rollback exposure cases affect all major TEE platforms. Consequently, all platforms can potentially be breached using n-day exploits.

Counterintuitively, we discover that the uncoordinated usage of rollback counters for individual products has implications for other products by *the same vendor* and potentially *the ecosystem as a whole*. We observe that the ad-hoc and uncoordinated usage of rollback counters correlates with severe vulnerabilities in TAs and, thus, leaks security-critical information affecting all products making use of the affected TA. We observe this phenomenon across products by the same vendor and anticipate this leakage to occur across products by different vendors.

Finally, to demonstrate the severity of the flawed state of TA rollback prevention, we carry out two case studies where we breach two major TEE platforms on fully updated devices.

Contributions. Our contributions are the following:

- We establish the largest dataset of TA images and vulnerable TAs in existence to investigate TA rollback prevention.
- We investigate the TA rollback exposure using 37 manually verified vulnerabilities by conducting a large-scale cross-vendor study on the effectiveness of TA rollback prevention. We discover that rollback prevention is not used securely across the entire industry.
- We discover that the uncoordinated usage of TA rollback prevention of individual products implies the leakage of security-critical information potentially leading to a net-negative security for the entire ecosystem.

Responsible Disclosure. In this study, we discovered several TA rollback attacks affecting recent fully-updated mobile devices. We responsibly disclosed our findings to all affected vendors. Samsung confirmed that TA rollback prevention is applied to models released after the Galaxy S22, since the patch required a huge update that included internal infrastructure. According to Samsung, this patch cannot be applied to the devices we reported to be vulnerable to TA rollback attacks. Although several recent devices stay vulnerable to TA rollback attacks, we were not assigned an official identifier for these issues (i.e., CVE or SVE). Further, we disclosed our findings to Xiaomi, Oppo, Vivo, and MediaTek, and inquired about how they will address TA rollback attacks on their products. We did not receive a response to our inquiry yet and are waiting for a response from these vendors.

2 Motivation for Up-to-Date TAs

In this section, we motivate the need for up-to-date TAs by reviewing ARM TrustZone and TA rollback prevention.

ARM TrustZone Preliminaries. ARM is the dominant CPU architecture on mobile devices. Thus, the vast majority

of available devices leverage ARM TrustZone as the hardware primitive for their TEE. Modern ARMv8-A CPUs, as typically used for mobile devices offer four privilege levels (i.e., exception levels in ARM terminology) where EL3 denotes the highest and EL0 the lowest level.

ARM TrustZone splits these exception levels into two execution modes, the untrusted normal world and the trusted secure world. For the OS level (EL1), this mode also results in a dedicated way to use the memory management unit, leading to the world split and logical components as illustrated in Figure 1. We commonly refer to the combination of the TEE OS (S-EL1) and TAs (S-EL0) as the *TEE*. Additionally, dedicated hardware protects the TEE memory and peripherals from normal world accesses.

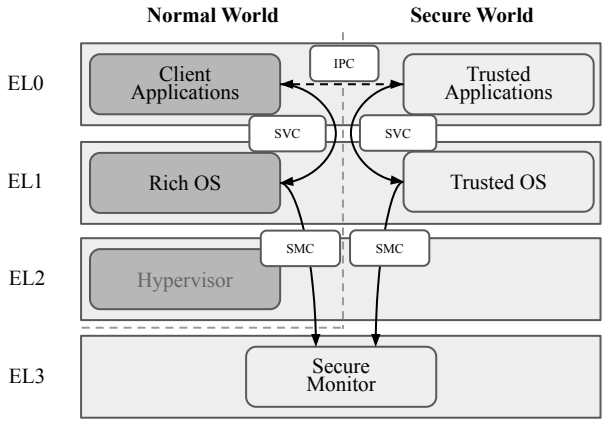

Figure 1: ARMv8 privilege levels.

Cryptographically signed TA images reside in the rich OS's file system and are dynamically loaded into the TEE at runtime. By design, TAs expose their services to the untrusted normal world. Thus, in comparison to the TEE OS, TAs comprise an attack surface that is directly accessible to attackers. Additionally, TAs constitute the largest attack surface of the TEE. As we show in Section 7, we identified 187 unique TAs available for Samsung devices, and 106 unique TAs available for Xiaomi devices, two popular brands in the mobile market.

Vulnerabilities in TAs have severe consequences. TAs have been used to directly compromise the integrity and confidentiality guarantees expected by security-sensitive services, including mobile payment [32], full-disk encryption [25], and biometric authentication [49]. Further, TA vulnerabilities served as initial footholds to compromise the entire TEE [1, 35, 49]. These breaches emphasize that vulnerable TAs can subvert the purpose of the TEE, and threaten the security guarantees expected by TEE-protected assets like biometric identifiers, payment data, and cryptographic keys. Given this threat potential, users and vendors have a great interest in fixing vulnerable TAs quickly, and deploying these fixes to devices as soon as possible.

TA Rollback Prevention. Figure 2 illustrates a simplified vulnerability lifecycle for a TA vulnerability. The solid section of the arrow indicates the time in which the vulnerable TA can potentially be exploited. The red solid section is especially interesting to attackers since publicly known vulnerabilities, or even readily available n-day exploits, can be used to compromise a vulnerable non-revoked version of a TA. Consequently, vendors *must* enforce the loading of up-to-date TAs.

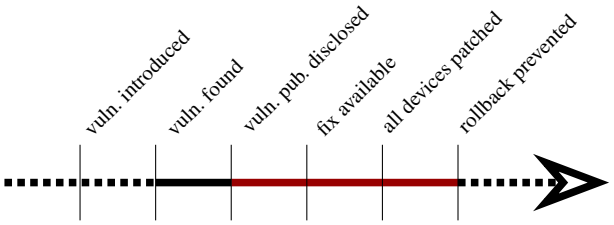

Figure 2: The TA vulnerability lifecycle. Attackers can leverage publicly disclosed vulnerabilities up until the rollback to a vulnerable TA version is prevented.

TAs, in contrast to the TEE OS, are dynamically loaded and unloaded from the untrusted normal world. Hence, the vendor has to ensure that *only up-to-date TAs can be loaded*. The mechanism of choice for OP-TEE and the majority of commercial TEEs (see Section 5) is *TA rollback prevention* based on a secure storage.

Rollback prevention is typically desired on a per-TA basis, as opposed to a group of TAs or all TAs on a given device. One major property achieved with per-TA rollback prevention is modularity. If certain features are not used, then the corresponding TA is not loaded, thus the trusted computing base is not unnecessarily increased. Additionally, TAs are developed individually and may originate from different sources as we discuss in Section 5. Per-TA rollback prevention facilitates the coordination of patching and increasing rollback counters. Thus, the TA loader needs to (1) uniquely *identify* a TA and (2) have access to a protected TA-specific *version counter*. This information needs to be part of a signed segment of each TA and securely persisted on the device. After verifying the TA's authenticity, the TA loader can leverage this information to distinguish TAs and keep track of each TA's version counter. If an attacker tries to load an outdated version, the loader will reject the corresponding TA.

In practice, taking OP-TEE as an example, platform designers can leverage a replay-protected memory block (RPMB) as a secure storage to enable TA rollback prevention [52]. RPMB is a feature of embedded multi-media cards (eMMCs), and introduced in the eMMC4.4 standard, a widely available technology. Figure 3 illustrates how a Client Application requests the helper daemon (`supplicant`) to load a TA from the regular filesystem (`FS`) in steps (1a)-(1b)-(1c). After verifying the TA's authenticity, the TA Loader requests the `ta_ver.db` from the `supplicant` ((2a)-(2b)). This file contains all TA identifiers and TA versions. The RPMB and the TA loader have

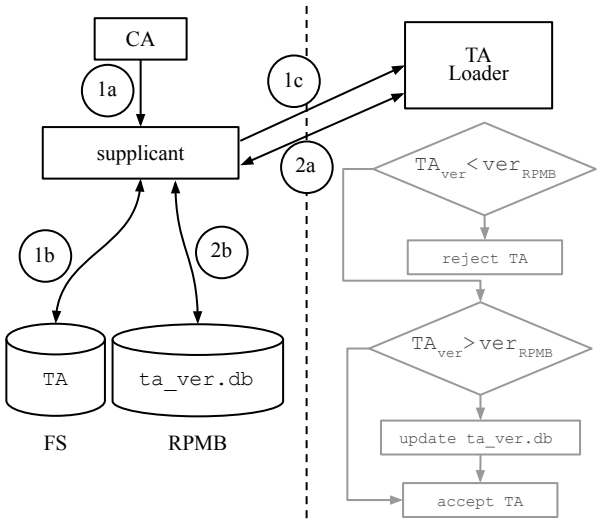

Figure 3: When a Client Application (CA) loads a TA (1a-1b-1c), the TA Loader keeps track of the TA versions using an RPMB-based database (2a-2b).

access to a shared key deployed by the manufacturer. This key, which is kept secret from the Normal World, is used to generate hash-based message authentication codes (HMACs) for messages exchanged between the RPMB and the TA Loader to guarantee authenticity. Thus, the TA loader can leverage the authentic `ta_ver.db` for TA version bookkeeping. The TA Loader must handle three scenarios. If the version found in the TA header (TA_{ver}) is lower than the version maintained in the `ta_ver.db` file (ver_{RPMB}), the TA is rejected. If the TA_{ver} is greater than the ver_{RPMB}, the TA Loader writes to the RPMB to update the `ta_ver.db`. This write operation makes use of the shared key and a write counter present in the RPMB to guarantee authenticity and freshness. Lastly, if the TA_{ver} is equal to the ver_{RPMB}, the Loader accepts the TA.

3 Research Overview

In this section, we outline the challenges of this measurment study and briefly discuss how we addressed them.

TA Ecosystem Complexity. The complexity of the TEE ecosystem is hidden by its lack of transparency, closed-source nature, absence of documentation, and inherent security-senstitive nature, making it challenging to comprehend and analyze without privileged insider knowledge. In fact, even when this insider knowledge is given, researchers are restrained by the secrecy requirements imposed by industry collaborators. For instance, the PartEmu prototype [22] cannot be publicly released because of non-disclosure agreements.

This lack of transparency makes it challenging to draw a clear picture of the ecosystem that includes vendors, chipset providers, third-party TEE implementations, and third-party TAs as well as their interdependencies.

Implications of Security-Related Events. Given the fact that TA code is shared amongst different parties in the ecosystem, security-related events originating from one party may affect another party. These events include the release of security advisories, rollback counter increases, third-party vulnerability reports, and updates in general. The implications of these events are unexplored, and require a thorough modeling and empirical validation. Creating a robust model that yields interesting insights for real-world TAs is a challenging task.

Identify Trends. Already in 2017 Google P0 discussed the issue of TA rollback attacks [4]. Since then, new players entered the TEE ecosystem and established ones evolved. The specific question regarding the effectiveness of TA rollback prevention in the ecosystem requires to gather, aggregate, and interpret historical and current data to distill the evolution and future trends, which is a non-trivial task.

Representative Dataset. The core of this study is a large and representative dataset of TAs and past security-related events. The availability of historical firmware, proprietary file formats, and vague information on public TA vulnerabilities pose difficulties for this task.

This study is the first to 1) systematize and model the TA ecosystem (Section 5), 2) relate this model to the implications of security-related events and discover real-world instances of rollback-counter-related side effects (Section 7), 3) obtain a representative ground-truth dataset of TAs and security-related events (Section 6.1 and Section 7.1), and 4) extrapolate and discuss potential future developments of the ecosystem (Section 8).

4 Threat Model

We base our threat model on the typical guarantees given to the TEE by ARM TrustZone, and refine the model in the specific context of a production mobile device running Android.

Attack Surface Chracterization. ARM TrustZone-based TEEs benefit from strong hardware-assisted isolation that provides integrity and confidentiality guarantees for all the components running in the secure world. In particular, this isolation prevents the execution of any unauthenticated code within the TEE (e.g., loading unsigned code or modifying existing code), and ensures that secrets that are not shared with the normal world stay confidential (e.g., cryptographic keys or biometric identifiers). Consequently, this attacker model assumes an attacker capable of executing code on N-EL0 and N-EL1, having access to the TEE-exposed interfaces.

On a typical production device running Android, this attacker model is realistic, given the history of privilege escalation exploits available for the Linux kernel (e.g., CVE-2016-5195, or CVE-2018-9568, CVE-2022-2602). Moreover, this attacker model can be refined and weakened, since typically a large list of user-space daemons have access to the TEE driver interface exposed by the kernel. In the best case, access

to this interface (N-EL0 only) is all an attacker needs to carry out the attacks described in our work.

Attack Objectives. In our specific scenario, the attacker is interested in breaching the integrity and confidentiality of a TA, and potentially use the TA's capabilities to further compromise the TEE (e.g., breach the TEE OS). Note that for the latter, an exploitable bug in *a single* TA (single point of failure) is enough to achieve this goal.

Bug Classes and Rollback. All TAs for major TEE platforms are implemented in memory-unsafe languages, namely C/C++. The C/C++ code is compiled to aarch32 or aarch64 ARM machine code. We found that most TEE platforms for ARMv8-based SoCs support 32-bit and 64-bit TAs, and follow standard calling conventions. These design choices expose the TEE to traditional memory corruption bugs like buffer overflows and dangling pointers that can lead to arbitrary code execution within the virtual address space of a TA, in the worst case.

The "*classic*" approach for an attacker to compromise the TEE is to search for unknown exploitable vulnerabilities (0-days) in TAs, which is non-trivial and requires deep knowledge of the target. The second attack vector, the focus of our work, is to load a properly signed but vulnerable TA. This attack vector option is easier, as in the best case, the attacker can simply reuse existing publicly-available proof-of-concept exploits. However, this option *must* be prevented by effective TA rollback prevention mechanisms, which leads us to the centerpiece of our research: the industry-wide effectiveness of TA rollback prevention mechanisms.

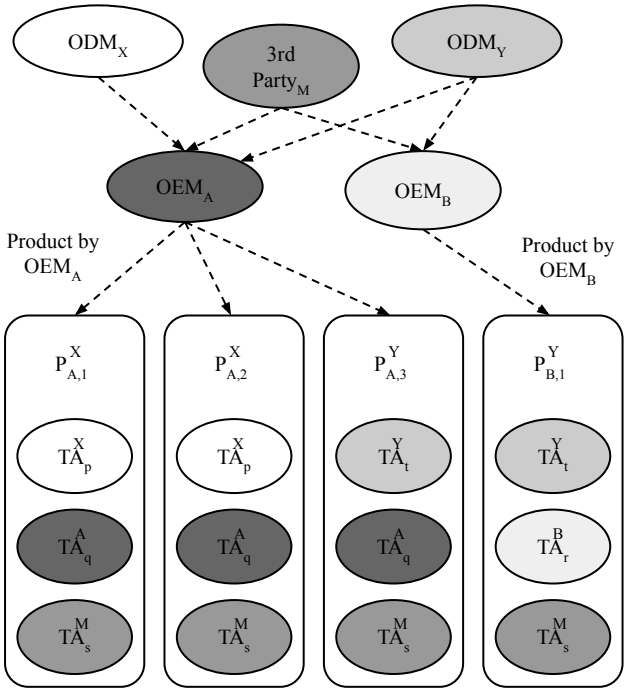

Figure 4: Ecosystem of Android mobile device TEEs with a focus on the origins of TAs. The shading indicates the origin of a TA used within a product. For instance, Product $P^X_{A,1}$ is a product by OEM_A based on ODM_X's chipset and ships with three TAs, TA^X_p (by the ODM), TA^A_q (by the OEM), and TA^M_s (by a third party).

5 Security Analysis of the TEE Ecosystem

The Android TEE ecosystem consists of several complex components. We focus our description on TAs and analyze security implications related to the effectiveness of TA rollback prevention that directly derive from the characteristics of the ecosystem.

5.1 TA Origins and Anti-Rollback Challenges

The Android TEE landscape is complex and growing. To understand this ecosystem, we concentrate on two important entities. The *Original Design Manufacturer (ODM)* provides the hardware platform (e.g., the SoC for a mobile device) and the initial firmware/software provisioning. This platform is rebranded by the *Original Equipment Manufacturer (OEM)* and further customized or provisioned with software components to create the customer-facing branded product. The following real-world examples illustrate the ecosystem further.

Xiaomi Mi series. The Xiaomi Mi series is a line of high-end mobile devices sold worldwide, where the two above-mentioned entities are relatively clear. The hardware of these phones is provided by Qualcomm, the ODM in this case. The consumer-facing branding and final customizations are done by Xiaomi, the OEM. The ODM usually determines low-level components. Thus, the TEE deployed on these phones is the Qualcomm Secure Execution Environment (QSEE). Further, a subset of TAs could originate from the ODM. OEMs can extend their TEEs by either developing their own TAs or integrating third-party TAs. For instance, a popular TA for digital content protection is Google's Widevine [55].

Samsung S series. We observe instances where the ODM leverages third-party TEEs. For instance, on the Samsung Galaxy S9 sold outside of the US, we find an Exynos chipset by Samsung and the Kinibi TEE by Trustonic. Samsung introduced its own TEEGris TEE in later models (e.g., the Samsung Galaxy S10).

Xiaomi Redmi series. We observe OEMs selling several series of products based on different ODM platforms. For instance, besides Xiaomi's high-end Mi series based on Qualcomm SoCs, their Redmi series is based on MediaTek SoCs. MediaTek utilizes a TEE stack called BeanPod by Beanpodtech for their chips.

All of these non-exhaustively mentioned TEE implementations (e.g., QSEE, Kinibi, TEEGris, or Beanpod) differ drastically in terms of features and, thus, affect the focus of our research—the capability to prevent TA rollbacks. We provide an overview of the different TA header formats indicating their rollback capabilities in Tables 8a, 8b, 8c, 5, and 7 in the Appendix. Furthermore, considering that TAs can have several origins, it is a challenge for the OEM to compose the final product's firmware image containing the latest TAs *and* ensure that rollback counters are updated accordingly. We illustrate the dependencies of TA deployment in Figure 4.

For the purpose of our research, surveying this landscape yields the following high-level insights:

- TAs are developed by several entities (e.g., ODM, OEM, or third-party).
- The ODM determines the TEE OS, which can be provided by a third party.
- The customer-facing brand (the OEM) alone does not reveal the underlying TEE implementation.
- The TEE OS implementations differ in terms of supported features.

5.2 Hypotheses for TA Anti-Rollback

Given the Android TEE ecosystem structure as described above, we derive a set of hypotheses that directly affect the effectiveness of TA rollback prevention.

HYP1: Leakage. When TA rollback counters are used in an uncoordinated way to enforce anti-rollback prevention for severely vulnerable TAs, the counter increase can inadvertently disclose information about the existence of a vulnerability in the TAs.

HYP2: Cross-Product Leakage. The leakage due to a rollback-counter increase affects devices of the same product series. Vendors often update their phone models yearly. Most of the software stack deployed on the previous generation within a product series remains the same. *Consequently, an increased TA rollback counter on one product of a series will directly leak security-critical information about the other products in this series.* In a product-centric organization, where rollback counters are increased in an ad-hoc and uncoordinated way, the vulnerability leakage will directly affect other products. Figure 5 illustrates this hypothesis.

HYP3: Cross-OEM Leakage. If two different OEMs are using the same ODM, the set of common TAs is prone to cross-OEM leakage in case of a TA rollback counter increase. *Consequently, the uncoordinated usage of TA rollback counters by one OEM affects other OEMs and may leak TA vulnerabilities affecting other OEMs' products.* Figure 6 illustrates this hypothesis.

HYP4: Cross-ODM Leakage. If a TA is supported on multiple ODMs, a rollback counter increase on one ODM

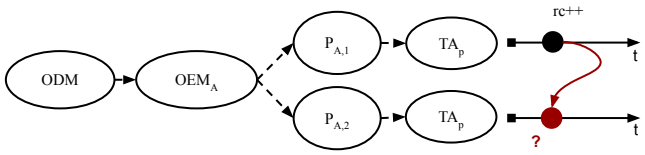

Figure 5: Cross-product leakage of security-critical information affecting TA_1^2 deployed on product P_2 due to increasing a rollback counter ($rc++$) for TA_1^1 on product P_1.

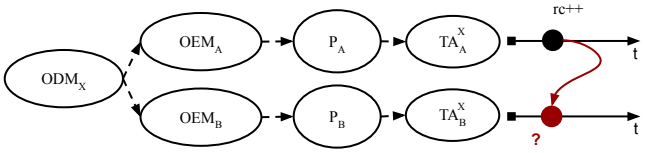

Figure 6: Cross-OEM leakage of security-critical information affecting TA_X^B deployed on product P_B by OEM_B due to increasing a rollback counter ($rc++$) for TA_X^A on product P_A by OEM_A. Both OEMs use the platform by ODM_X.

platform will leak security-critical information affecting the other ODMs' platforms. This leakage is especially relevant if ODM platforms lack support for proper rollback prevention or employ a different (weaker) set of exploit mitigations, putting this weaker platform at risk. Figure 7 illustrates this hypothesis.

6 Study Design

Our goal is to assess the industry-wide effectiveness of TA rollback prevention for Android smartphones. This section describes our analysis pipeline. Figure 8 serves as an overview. To carry out this study, we collect a representative dataset of firmware images containing TAs distributed to the most popular devices. We present our dataset selection criteria, elaborate on the extraction of rollback counters, and describe the collection of vulnerable TAs.

6.1 TA Dataset Criteria

In this study, we want to understand the current industry-wide state of TA rollback prevention for Android smartphones. The foundation for this assessment is a dataset addressing the following timeliness, representativeness, and diversity criteria.

Timeliness. Given that the average smartphone lifecycle is around 2.5 to 3 years [46, 48], we can establish a conservative upper bound by considering smartphone models released within the last 4 years to capture a set of phones that are relevant today.

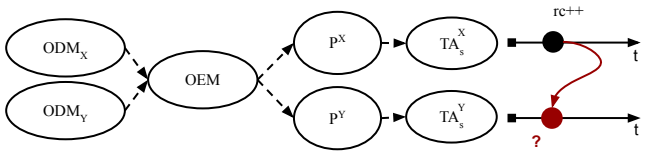

Figure 7: Cross-ODM leakage of security-critical information affecting TA_1^Y deployed on product P_Y based on the platform by ODM_Y due to increasing a rollback counter ($rc++$) for TA_1^X on product P_X based on the platform by ODM_X. The same TA is used on two different platforms.

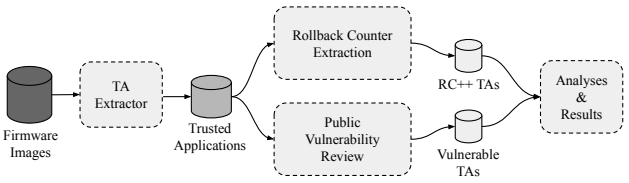

Figure 8: Overview of our firmware processing pipeline.

Representativeness. Further, our guiding principle to claim representativeness for our dataset is that the investigated devices are widely used. Thus, we base our selection on the market share of Android smartphone vendors [47].

Diversity. Each OEM typically employs a variety of platforms based on different ODMs. As explained in Section 5, the ODM determines the TEE. Thus, our dataset should take the diversity of TEEs into account.

6.2 Rollback Counter Usage

Our dataset contains TAs deployed on a diverse set of TEE implementations. Each implementation handles rollback prevention differently, but generally, all the relevant information can be found in the header of a given TA. Hence, we collected the publicly available information on TA header formats and reverse-engineered those formats that are not publicly known. The details on these header formats can be found in Tables 8a, 8b, 8c, 5, and 7 in the Appendix.

As a result of our rollback counter extraction, we obtain a chronologically ordered sequence of TAs for every phone in our dataset that shows the rollback counters for each TA.

6.3 TA Vulnerabilities

To establish the ground truth of vulnerable TAs, we survey known vulnerabilities broadly across all vendors in our dataset. The set of vulnerable TAs is based on publicly available information. Our collection of publicly known vulnerabilities relies on information from three different input sources. First, we systematically survey the programs of (non-academic) security conferences (e.g., DEF CON [13], Black-Hat [12], OffensiveCon [36], or C3 [9]). Second, we diligently review the blogs of companies and individuals known to conduct research on TEEs (e.g., Riscure [39], Quarkslabs [38], Google P0 [37], or Blue Frost Security [44]). Third, we scraped the security bulletins of vendors for TEE-related keywords (e.g., TEE, TA, TrustZone, and various vendor-specific keywords). Lastly, we aggregate this information, manually match the vulnerabilities to the TAs in our dataset, and verify the described issue.

This subset of vulnerable TAs is our ground truth and starting point to assess the rollout of patches and rollback prevention measures.

7 Analyses and Results

After introducing the study design in Section 6, this section discusses the study results. We first describe our dataset in detail and then focus on our research questions:

RQ1 What are TA rollback counters used for?

RQ2 Are TA rollback counters used correctly and consistently?

RQ3 What are the consequences of uncoordinated TA rollback increases?

RQ4 Can rollbackable TAs be loaded and exploited under real-world conditions?

7.1 Dataset Collection and Characterization

To create a timely, representative, and diverse dataset as explained in Section 6.1, we first take into account that smartphones have a lifetime of about two-and-a-half to three years [46,48]. Thus, we choose a conservative upper bound of smartphones released within the last four years to fulfill our timeliness criterion. Further, we focus on the top five Android smartphone vendors as reported bi-quarterly by Statista [47] over the last four years. These vendors are Samsung, Oppo, Vivo, Xiaomi, and Transsion covering a share of >65% of the Android smartphone global market for each reported quarter. Next, we leverage `gsmarena.com` to identify all smartphone models released within the last four years by these vendors. To address our diversity criterion, we group all phones by ODM for each vendor. `gsmarena.com` provides information on the chipset for each phone which allows us to perform this grouping. We select at least two phones from each of these groups to investigate their firmware images. We collect at least five firmware images for each of these phones spanning the firmware evolution of at least two years. We list the sources of these firmware images in Table 6 in the Appendix.

Firmware Dataset								Rollback Analysis		
ODM	TEE	Vendor	#Devices	Σ #Firmware	Σ #TAs	Σ #vulnerable TAs	Σ #TAs with rollback-counter change	average #days of rollback exposure†	Σ #rollbackable TAs§	Σ #rollbackable devices*
Qualcomm	QSEE	Samsung	6	88	2,834	132	13	0‡	13	4
Qualcomm	QSEE	Xiaomi	5	299	6,982	0	0	N/A	0	0
Qualcomm	QSEE	Oppo	4	28	215	0	0	N/A	0	0
Qualcomm	QSEE	Vivo	3	13	92	0	0	N/A	0	0

All	All	All	51	1,330	35,541	2,582	190	99	265	29

Table 1: The dataset used for our study. (†) This column measures the average number of days between advisory publication and rollback counter increase. N/A denotes that there are no instances of a vulnerable TA whose rollback counter is increased. (§) A rollbackable TA is a TA whose outdated and vulnerable version can be loaded due to a lack of rollback counter increase on the newest firmware version. (*) A device whose newest firmware version contains at least one rollbackable TA is considered to be rollbackable. (‡) All of the TA rollback counter increases for Samsung QSEE devices are on newer devices without any associated public vulnerabilities for TAs.

For each downloaded firmware image, we extract all enclosed TAs, parse the available metadata (e.g., rollback counters), and manually mark TAs with publicly known vulnerabilities. Table 9 in the Appendix shows all publicly known vulnerabilities systematically obtained from several resources as described in Section 6.3 [1, 5, 23, 24, 31, 32, 35, 40–42, 45, 56].

Table 1 summarizes our dataset. In total, we collect 1,330 firmware images recently deployed on 51 different phone models spanning five vendors (OEMs) and three ODMs. We obtained 35,541 TAs (293 unique TAs) for four different TEE implementations. We were able to mark 2,582 vulnerable TAs and found 190 rollback counter changes. We focus on the 65% most common vendors to represent the market. The remaining 35% consists of the long tail of the market. Including an additional vendor would only marginally contribute to the representativeness of our dataset, while obtaining and processing their historical firmware imposes a disproportional effort. For instance, vendors like Google, LG, Motorola, HTC, and Huawei each have a market share of lower than 5% [47].

Although the firmware for Google devices is readily available [19], we exclude Google devices from our study for the following reasons. Older QSEE based Google devices do not use rollback counters to support arbitrary firmware downgrades [4]. With the Trusty TEE, which replaced QSEE on newer Pixel devices (Pixel 6 and later), Google disabled runtime-loadable TAs. TAs are shipped as part of signed firmware images and cannot be modified [18]. This decision is a trade-off where Google sacrifices third-party TA support and their business opportunities for security.

Security-focused Android ROMs such as GrapheneOS [21] or LineageOS [29] rely on the device's existing TEE software stack. Hence, our findings apply equally to these ROMs.

7.2 RQ1: Rollback Counter Use Cases

Table 1 summarizes our results regarding the usage of TA rollback counters. Our first observation is that all vendors in our dataset except Samsung are *not* making use of rollback prevention. The reason is either that the TEE does not support rollback prevention (e.g., BeanPod) or the vendor does not effectively employ the TEE's rollback counter capabilities to prevent rollback—even if there are public security advisories for several TAs available.

Exploring the history of Samsung devices reveals an episode of ad-hoc and uncoordinated usage of rollback prevention, followed by a period of consistent rollback counter increases with every other firmware update shipped to customer devices. First, this observation shows that Samsung (the biggest player in the Android smartphone market by market share) attempts to address TA anti-rollback enforcement. Second, the history of ad-hoc and uncoordinated anti-rollback enforcement indeed shows a correlation between security-critical vulnerabilities and the increase of TA rollback counters. In Table 2 we list TAs with an increased rollback counter that correlates with a public security advisory. As we will discuss in Section 7.4, the threat of unwanted disclosure affecting other devices of the same vendor, or potentially other vendors in the ecosystem is real.

7.3 RQ2: Correct and Consistent Usage of Rollback Counters

To answer RQ2, we analyze TAs across all of a device's firmware versions to assess if the device was or still is exposed to rollback attacks. To track updates to a TA we compute the hash of the TA's `.text` section as a heuristic. If this hash changes in a firmware version, we register this as an update

TEE	TA	Vendor ID	CVE	Published	RC++
Kinibi	ESECOMM	SVE-2017-8889	2017-18655	2017-08	2017-10
Kinibi	TEE_keymaster	SVE-2019-14126	2019-20607	2019-05	2019-02
TEEGRIS	WVDRM	SVE-2020-17117	2020-13832	2020-06	2020-05
TEEGRIS	SKPM	SVE-2019-14892	2019-14892	2019-08	2021-01

Table 2: Four critical security advisories released by Samsung. TA rollback counter increases often coincide with advisories indicating critical vulnerabilities. The RC++ column shows the date of the rollback counter increase.

to the TA. This heuristic serves as upper bound and may have false positives, i.e., it may signal an update if the TA is recompiled in a different environment. For each firmware version, we also check if the rollback counter was increased and correlate this to the vulnerabilities in our dataset from Table 9. We consider a TA vulnerable in the time frame after a vulnerability disclosure and before a rollback counter increase. If no rollback counter increase takes place then the vulnerable version can still be loaded in the newest firmware version. Note that even if a vendor removes a TA from newer firmware releases, and the rollback counter of that TA was never increased, the attacker can still load this deprecated TA.

Figure 9(a)-(d) shows the updates and vulnerabilities for the TAs of four BeanPod devices in our dataset. Each of these devices has at least 3 vulnerable TAs that may be loaded on a fully updated device. Note that all TA vulnerability lifecycles ending with a ○ in Figure 9 represent TAs vulnerable to rollback attacks. The reason for this high number is that the BeanPod TA format does not contain a rollback counter. Even though the vulnerability may be patched in a newer firmware version, it is still available to the attacker in our threat model, who can simply load the old vulnerable TA.

Figure 9(e)-(h) shows the updates and vulnerabilities for the TAs for four Kinibi devices in our dataset. Note that there are a few version counter increases but no public vulnerability corresponding to the TA. In contrast, the version counter for vulnerable TAs is only increased in one instance.

Figure 9(i)-(m) shows the updates and vulnerabilities for the TAs for five TEEGRIS devices in our dataset. For all phones older than the S21, there are at least two vulnerable TAs that can be loaded and there are five occurrences of a rollback counter increase preventing the loading of a vulnerable TA. On the newer S21 device, Samsung periodically increased the rollback counter.

Figure 9(n)-(p) shows the updates and vulnerabilities for the TAs for three QSEE devices in our dataset. Note the difference of rollback counter increases between older devices and the more recent S21. The S21 also shows an example of deprecated TAs that still pose a threat to the device. The two QSEE example TAs, smplap64/smplap32 were shipped in the first firmware version and then removed from later firmware. However, the attack surface exposed by these TAs remains accessible to attackers who can load the TAs shipped in the first firmware version on a device with the newest firmware.

An overview of the results of this analysis can be seen in Table 1. In summary, we observe that rollback counters are rarely used. There are only 190 instances of a TA with a rollback counter increase out of the 35,541 TAs in our dataset. In total, we found 2,582 vulnerable TAs and only 22 TAs whose rollback counter increase prevents loading one of these vulnerable TAs. Leaving us with 265 rollbackable TAs on the latest fully-updated devices. As a consequence, we can load vulnerable TAs into *all* fully-updated TEE implementations and into 29 out of the 51 devices in our dataset.

We also observe that, in cases where the rollback counter was used to prevent rollback attacks, on average the update with the rollback counter increase is released 99 days after the publication of the vulnerability. Interestingly, for older Samsung devices using Kinibi, the average number of days is 0. This means that for these devices, on average the update with the counter increase was before the advisory publication. In these cases, there is no rollback exposure as the rollback counter increase precedes the advisory publication. It appears that Samsung moved away from these best practices on newer devices using TEEGRIS, resulting in an average rollback exposure time of 245 days. However, the newest generation of devices (Samsung S21 and Samsung S22) follows a systematic approach and increases rollback counters frequently.

7.4 RQ3: Consequences of Uncoordinated TA Rollback Increases

The uncoordinated usage of TA rollback counters can lead to the leakage of security-critical information which can affect several entities in the ecosystem. As we can see in Figure 9(j) the WVDRM TA on the Samsung A10 received a rollback counter increase after a critical vulnerability was fixed. Analyzing the other smartphone models by the same vendor during the time of the counter increase reveals that no other model received this update. The rollback counter for the WVDRM TA on the Samsung S10, A40, and S20 was never increased. The WVDRM TAs deployed on these models share the same codebase as the TA on the A10 with the counter increase. Thus, these models remain vulnerable to a rollback attack. We carry out a rollback attack against the S10 in Section 7.5.

Consequently, we can clearly see that cross-product leakage affects products of *the same* OEM, as hypothesized in HYP2 Section 5.2, is a real threat within the ecosystem.

Our dataset does not contain clear cases for cross-OEM and cross-ODM leakage as described in HYP3 and HYP4 in Section 5.2. To estimate the potential impact of HYP3 and HYP4 we estimate a lower bound on the number of TAs shared between OEMs. These shared TAs are either shipped by the ODM or third-party TEE provider. For this measurement we match the TA filename, and the strings in the TA. We then manually confirm matches by decompiling the TA and comparing the decompilation. Table 3 shows the number of TAs shared by different vendors. MediaTek maintains 14 TAs

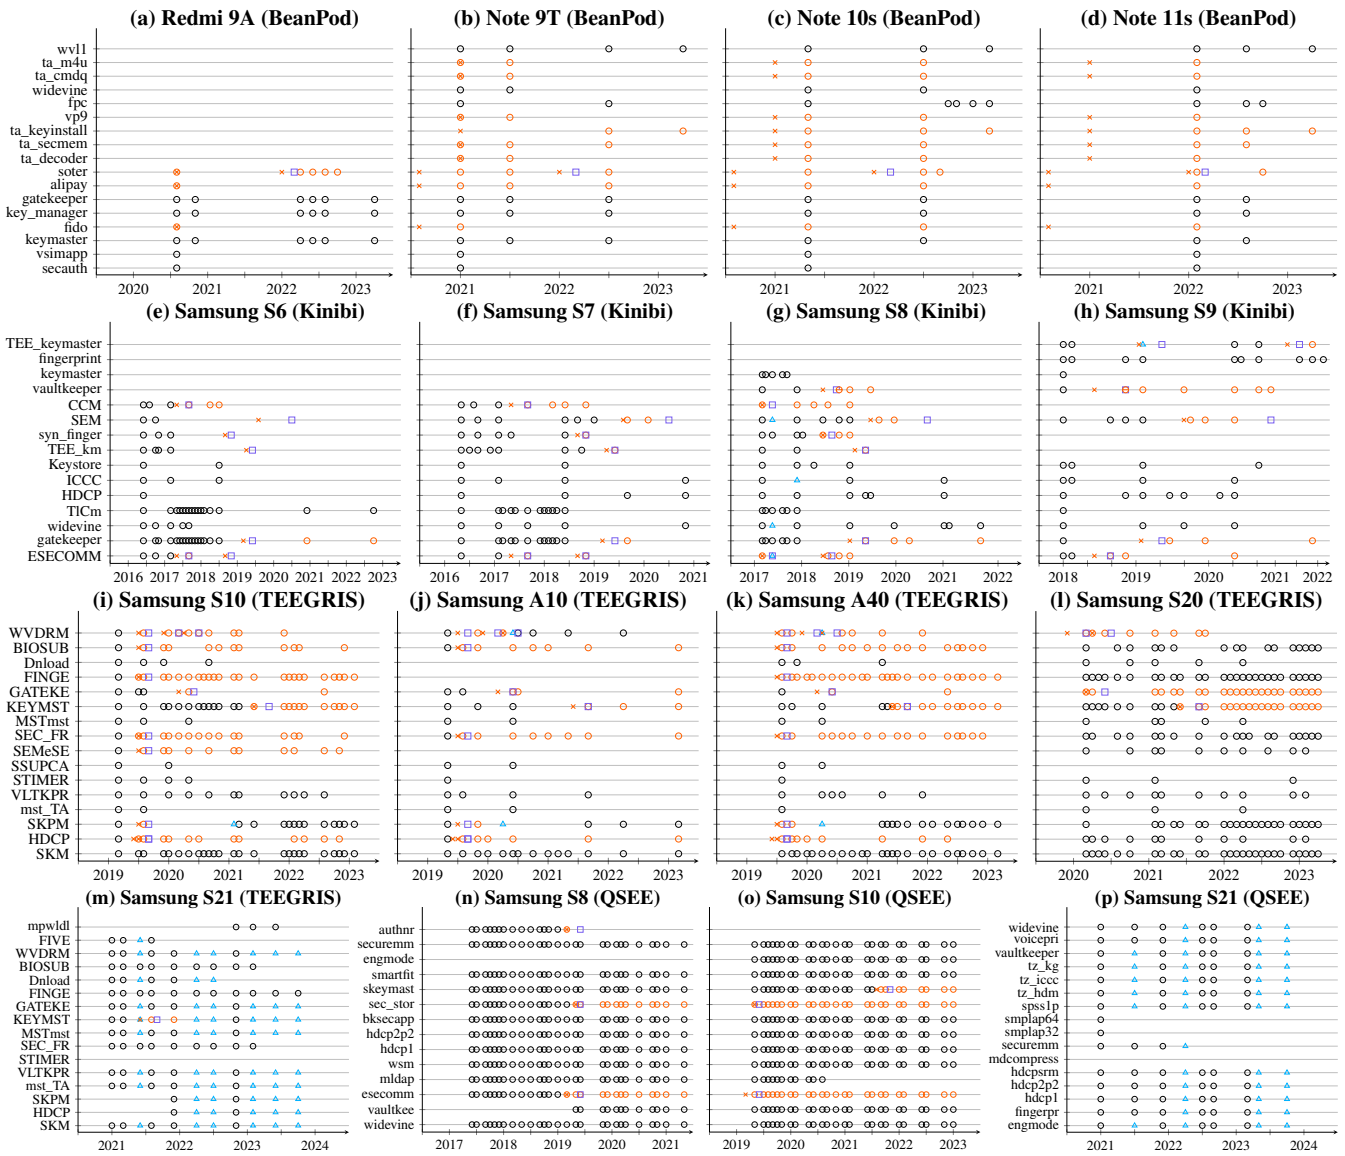

Figure 9: The TA vulnerability lifecycle for TAs found on 16 devices covering the four most widely-used TEE implementations. A circle ○ represents an update to the TA. A × represents a vulnerability. A square □ represents a published advisory. A triangle △ represents an update with a rollback counter increase. Orange circles ○ are updates to a vulnerable TA that do not increase the rollback counter. If the last update to a TA is marked with an orange circle, then a vulnerable version of that TA may be loaded on the latest firmware of that phone.

shared between Oppo, Vivo and Xiaomi. These TAs are deployed on both Kinibi and BeanPod TEEs. BeanPod does not support anti-rollback while Kinibi does. Thus, cross-ODM leakage from Kinibi to BeanPod would expose BeanPod devices to rollback attacks.

We anticipate that the demand for security as a feature will drive vendors to enforce rollback prevention. This upcoming episode will likely be uncoordinated amongst different entities in the ecosystem and result in the leakage of security-critical information that puts the TEEs of the ecosystem at risk.

7.5 RQ4: Rollback Exploitation under Real-World Conditions

After assessing issues with rollback counters quantitatively, we now assess them qualitatively by testing if outdated TAs can be loaded under real-world conditions, answering RQ4. We attempt to load, crash, and exploit TAs identified as vulnerable and rollbackable on our fully patched test devices. To simulate a compromised normal-world EL1, we manually root our devices using Magisk [51] with the newest available firmware version. To load old TAs we remount the vendor

Origin	Vendors	# shared TAs
MediaTek	Oppo, Vivo, Xiaomi	14
MediaTek	Transsion,Xiaomi	4
Kinibi	Oppo, Samsung, Vivo	1
Kinibi	Oppo, Samsung	1
QSEE	Oppo, Samsung, Vivo, Xiaomi	2
QSEE	Samsung, Vivo, Xiaomi	5
QSEE	Oppo, Vivo, Xiaomi	4
QSEE	Oppo,Vivo	5
QSEE	Vivo, Xiaomi	1
QSEE	Samsung, Xiaomi	3

Table 3: The shared TAs across different OEMs and third-party TEE implementations. Origin denotes the entity that provides the TA.

partition as writable and copy the old TAs to the folders where the TAs are stored. We then use a small program that interacts with the kernel driver to load the TA and invoke commands.

We use our Samsung S10 test device (FW version: G973FXXSGHWA1 from January 2023) and attempt to load the seven vulnerable TAs identified in Figure 9(i). We verify that the rollback counter increase does indeed prevent loading vulnerable TAs by attempting to load a vulnerable version of the SPKM TA. Table 4 shows the results. We successfully load all the vulnerable TAs and trigger a crash for six of the seven loaded TAs. To successfully rollback the FINGE TA, we need to first enable biometric authentication. Otherwise, the TEE refuses to load the TA, both the vulnerable and the current version. The SPKM TA cannot be loaded anymore due to the rollback counter increase.

We use our Xiaomi Redmi 9A test device (FW version: MIUI 12.5.7_RCDEUXM from November 2022) and attempt to load all vulnerable TAs identified in Figure 9(a)-(d). Note that this experiment is possible due to cross-device loading in devices using the Beanpod TEE. Table 4 shows the results. Overall, we successfully load all vulnerable TAs and trigger crashes in seven out of nine loadable TAs.

We use our Xiaomi Redmi Note 11 test device (FW version: 13.0.14 from February 2023). Since there are no public vulnerabilities for this vendor/TEE platform we attempt to load TAs from the earliest firmware version. We are able to load all the old TAs, see Table 4.

We use our Samsung S9 test device (FW version: G960FXXUHFVB4 from March 2022) and attempt to load the five vulnerable TAs identified in Figure 9(h). Table 4 shows the results. We successfully load all vulnerable TAs and trigger crashes for two out of five TAs.

Exploitation Case Studies. To further demonstrate the feasibility and impact of the rollback attack, we demonstrate two instances where we rollback to a vulnerable TA version on a fully patched device and then use the vulnerability to gain control of the TA's program counter.

We use our TEEGRIS Samsung S10 test device on the newest firmware version and exploit the vulnerable HDCP TA [35]. Since we can successfully install the vulnerable TA, we can rollback to the same TA version as used in the blog post and follow the detailed exploitation steps, gaining control over the program counter. Since exploitation is trivial and well-documented we omit the details of the exploit here.

For a second case study, we use our Xiaomi Redmi 9A test device on the newest firmware version, which uses the Beanpod TEE, to rollback, load and exploit the `ta_keyinstall` TA. Note that this TA is not shipped with the firmware of our test device but we found that we could nevertheless load the TA from another device's firmware. The `ta_keyinstall` is vulnerable to a type-confusion bug (CVE-2023-32835). We exploit this bug to obtain an ASLR oracle and an arbitrary write primitive. With these primitives, we get control over the program counter.

Figure 1 shows the relevant code inside the `ta_keyinstall` TA. When the TA is invoked with commandID 1, the TA calls the `DRMKEY_QUERY` function. This function reads data from the input buffer and writes

```
TA_InvokeCommandEntryPoint(void* sessionContext,
    uint32_t commandID, uint32_t paramTypes,
    TEE_Param params[4]) {
  ...
  if(commandID == 1) {
    pInput = params[0];
    nInputSize = params[1];
    pOutput = params[2];
    r = TEE_CheckMemoryAccessRights(5,pInput,nInputSize);
    if(r==0) {
      DRMKEY_QUERY(pINput, &count, pOutput);
    }
  }
  ...
}
DRMKEY_QUERY(void* keyblock, int* count,
    void* pOutput) {
  int keycount = *(int*)(keyblock + 0x44);
  void* src = (void*)(keyblock + 0x48);
  int buffer[0x16];
  if(keycount < 0x201){
    pOutput[0] = keycount;
    int ct = 0;
    while(ct != keycount){
      memcpy(buffer, src, 0x58);
      int encDrmKeySize = buffer[3];
      int keyblockLeng = encDrmKeySize + 0x60;
      keyid = buffer[0];
      // vuln: arbitrary write
      *(void*)(pOutput + 4*ct) = keyid;
      src = src + keyblockLeng;
      ct++;
    }
  }
  ...
}
```

Listing 1: Code in the `ta_keyinstall` TA relevant for the `DRMKEY_QUERY` function. The `paramTypes` parameter is never checked, thus the TA has no way of knowing whether the values in params are integers or pointers to shared memory. By supplying integers that are treated as pointers by the TA we obtain an ASLR oracle and arbitrary write.

Table 4: The results of attempting to load vulnerable TAs on our fully-patched devices.

part of it to the output buffer. Due to the missing parameter type check, the TA cannot ensure that the input or output buffers point to valid shared memory. We can use the `TEE_CheckMemoryAccesRights` call as an ASLR oracle. The function checks if `pInput` (the first of our parameters) points to valid memory. By setting the first parameter to an arbitrary pointer we can figure out if that pointer points to valid memory or not. For the arbitrary write, we simply supply the pointer where we want to write to as the third parameter (`pOutput`). The `DRMKEY_QUERY` function will then write data from the input buffer under our control to the output buffer. To get control over the program counter we first use the ASLR oracle to find the location of the stack. Then we use the arbitrary write to overwrite the return address of the `TA_InvokeCommand` by pointing `pOutput` to the corresponding stack address.

8 Takeaways

We now discuss the main takeaways, highlighting the primary results and their implications for the security community.

The State of TA Rollback Prevention. We examine the evolution of TAs along their lifetimes on several Android smartphones. Our study covers a representative set of TEE implementations deployed on the most popular smartphones, namely QSEE, Kinibi, TEEGris, and BeanPod.

We observe a division of the market. Either vendors have rollback attacks in scope (e.g., Samsung), or they remain oblivious to the problem (e.g., Xiaomi, Oppo, Vivo, and Transsion).

Samsung has a long history of advertising security features to the consumer market and especially the enterprise market. Thus, most of their recent models address the problem of rollback attacks. Although even on the newest Samsung devices, we still identified deficiencies (i.e., TAs that are not yet equipped with a version counter), Samsung effectively protects most TAs against rollback attacks.

However, Samsung's development until reaching effective TA rollback prevention presents a controversial picture. It is noteworthy that several of their still-supported smartphone models remain vulnerable to TA rollback attacks. Contrary, their newest generation of phones receives continuous rollback counter updates. The episode of uncoordinated, ad-hoc usage of TA rollback counters as depicted by many past Samsung TAs, provides the opportunity to gain several major insights for effective anti-rollback. First, and most obvious, the fix of a vulnerable TA, the increase of the corresponding rollback counter, and the rollout of these changes should precede the public disclosure of the vulnerability. Depending on the interdependencies of the organizational units involved, even this obvious observation needs to be explicitly taken into account. Second, when rollback counters are used to prevent rollback to severely vulnerable TAs, this effort should consider *all* affected products. Otherwise, the information about severe vulnerabilities is leaked for all products that did not receive a rollback counter increase. In our study, we demonstrated the cross-product dimension of this problem, and we anticipate seeing cross-OEM and cross-ODM instances of this problem occur frequently in the future because many code bases for TAs are shared amongst OEMs.

For the remaining vendors, we observe that rollback counters never change, and especially that they *do not* change when publicly known vulnerabilities are fixed in TAs. Note that while our ground-truth dataset of vulnerable TAs is likely incomplete, as no public repositories exist, we nevertheless identify several cases of ineffective rollback prevention across *all* TEE implementations. We conclude that, with the exemption of the latest Samsung models, *TA rollback prevention is ineffective at an industry-wide scale*.

TA Vulnerability Practices. Aside from our focus on TA rollback prevention, we encountered several supply chain flaws (Section 5). Vendors manage to successfully patch TAs internally but fail to roll out the patches to their full fleet of products. For instance, across all Xiaomi devices, we found patched versions of the soter, fido, and alipay TAs, but several individual devices remain vulnerable. The latest version of the firmware is vulnerable for, e.g., the Xiaomi Note 11S, Redmi

Note 9T, and Redmi 10A. A similar inconsistency applies to the Samsung S10 and A10 in our dataset. The widevine TA was found vulnerable on both devices in 2020. While the vulnerability was fixed on both devices in the latest firmware for these devices, the A10 widevine TA received a rollback counter update and the S10 version did not. This leaves the S10 vulnerable to a rollback attack.

A further unfortunate vendor practice is to patch security-critical bugs silently. We observed this practice for the soter, fido, and alipay TAs on Xiaomi devices employing Beanpod.

A further hiccup that might be overlooked by vendors is discontinued TAs that turn out to be vulnerable but remain loadable. For the Xiaomi Note 11S, we observed that a vulnerable version of the ta_decoder TA was deployed in 2021. This TA was discontinued mid-2022 and is not present in the latest firmware images for this device. However, the vulnerable version deployed in 2021 remains loadable and potentially exploitable on the latest firmware.

Transparency Regarding TA Rollback Prevention. A major challenge of our study was to establish a ground-truth dataset of vulnerable TAs, to extract their corresponding rollback counters, and to track these version counters over time. Monitoring this information reveals the lifetime of exposure to a potential exploit leveraging a rollback attack, and it sheds light on rollback prevention being effective at all, in case the counters are never updated. A widely adopted transparency covering this information would help consumers and vendors.

As a means of public communication and to keep track of security patches, Google established the Android security bulletins [20]. These bulletins summarize security-related patches on a monthly basis and provide details on each patched vulnerability, including CVE ID, type of vulnerability, severity, and affected components. Android users can check their current security patch level on their devices in the "Settings" app searching for "Security Patch Level". This patch level shows the system property `ro.build.version.security_patch` which corresponds to the security patch level dates published in the security bulletins (typically in YYYY-MM-DD format).

A common practice for vendors is to reference these security patch levels by Google and publish their own security patch levels containing vendor-specific patches. These vendor patch levels usually subsume the patch levels by Google.

To establish more transparency regarding the TA rollback prevention problem, we suggest two approaches. The first approach requires the cooperation of the vendor who just has to report the increase of the TA rollback counter (or other rollback countermeasures) as part of the publicly disclosed advisory. Typically, these advisories contain a "patch description" that can be used to communicate the handling of TA rollback. This practice would transparently communicate the consideration of TA rollback attacks.

The second approach does not require the vendor's cooperation and relies on community effort. For our empirical study, we created the infrastructure to continuously monitor new firmware releases for five vendors and automatically track TA version counters. Using this growing database, we can determine if a rollback counter was increased whenever a TA-related vulnerability is disclosed. As an artifact of this paper, we release the dataset used for this study at `http://hexhive.epfl.ch/spill_the_tea`.

Both of these solution sketches increase the transparency regarding TA rollback attacks and communicate the problem clearly to consumers and vendors.

9 Threats to Validity

Dataset Representativeness. The primary threat to the validity of our study is the representativeness of our dataset. Our dataset is representative as it covers a broad selection of the total market and focuses on recent Android-based mobile devices. The vendors and phones in our dataset cover over 65% of the Android market share for the last four years. We extended this dataset with phone models by vendors that received security audits with publicly available results. The resulting dataset ensures sufficient vulnerability data to make our study conclusive—which is the case given the large number of 37 vulnerable TAs in our dataset. Besides the representative market share and timeliness of our device selection, we also considered the diversity of hardware platforms used by all vendors in our dataset. Since the hardware platform often determines the TEE, we made sure to include a representative set of hardware platforms for each vendor.

Missing Firmware Images. In Section 7.3, we analyze firmware versions over time to demonstrate how vendors use rollback counters. However, we cannot guarantee that we have all firmware versions, i.e., we may miss some intermediary versions. These missing images are not a threat to the conclusiveness of our study, since in a realistic scenario, an attacker can always retrieve these intermediary images to obtain a specific version of a TA. For our study, it is sufficient to observe the usage of TA rollback counters over a longer period of time and associate images with the release of public vulnerability disclosures to derive our conclusions concerning the effectiveness of TA rollback prevention.

Other Rollback Prevention Mechanisms. In our study, we focus on the rollback counter as the primary defense against an attacker trying to load an outdated TA version. However, there may be other mechanisms to prevent TAs from being loaded. One straightforward mechanism is to re-sign a TA and not use the public key of the old signature in the TA loader anymore. We observed TA resigning for eight TAs out of 35,541 TAs in total, which suggests that resigning is not used as an anti-rollback mechanism. Moreover, we try to mitigate this threat to validity by running the experiments described in Section 7.5. However, due to a lack of physical

devices, we could not run this experiment for all devices in our dataset and acknowledge this practical limitation.

TA Vulnerability. We use public advisories to identify TA vulnerabilities. These advisories often specify the vulnerable TA and the affected firmware versions. Additional data points to pinpoint a vulnerable TA are the reporting and the advisory release dates. We assume that firmware images released past the release date contain patched TAs and firmware images released before the reporting date contain unpatched TAs. In Section 7.5 we investigate a range of vulnerable TAs selected using this method to demonstrate real-world rollback attacks.

10 Related Work

The issue of TA rollback prevention on TZ-based TEEs was discussed before. Beniamini studied rollback prevention in QSEE and Kinibi and demonstrated that in 2017 rollback counters were not used [4]. Also in 2017, Chen et al. presented a rollback attack and its consequences on a Nexus 6 device [11]. Unlike these works, we assess the current status of TA rollback prevention six years later and focus on a large-scale cross-vendor study encompassing several recent and popular devices to assess the effectiveness of current industry-wide practices. Beyond the study of TA rollback prevention effectiveness, we discover the leakage effects resulting from ad-hoc and uncoordinated rollback counter increases aimed at preventing rollback to severely vulnerable TAs on individual devices. To the best of our knowledge, we are the first to explore the negative leakage effects concerning different entities in the ecosystem (i.e., cross-product, cross-OEM, and cross-ODM vulnerability leakage).

Beyond TA rollback prevention, several researchers have studied and exploited vulnerabilities in TZ-based TEEs, including Beanpod [32], QSEE [24, 31, 40], TEEGRIS [35, 42, 45], Kinibi [1, 5, 23], and TrustedCore [8]. Moreover, researchers investigated software design flaws [30] and side-channel attacks [6, 26, 50, 54]. Most of these works were summarized and systematized by Cerdeira et al. [10].

The growing number of reported memory corruptions led to the work on automated vulnerability discovery in TEEs. While TEEzz [7] follows an on-device black-box fuzzing approach, PartEmu uses an emulation-based approach to enable coverage-guided fuzzing of TAs [22]. Instead of automatically finding memory corruptions, Wan et al. attempt to establish Rust as a memory-safe alternative for TA development [53].

Android's popularity has attracted many security researchers who have conducted studies on various aspects of Android's security architecture. Farhang et al. [17] study Android security bulletins across various vendors. Several studies investigate how updates are applied to either apps or libraries [3, 14, 34]. Further, multiple studies have focused on various Android security vulnerabilities [16, 28]. Finally, Egele et al. [15] studied how developers misuse cryptographic APIs in Android apps.

11 Conclusions

In our large-scale cross-vendor study, we evaluated the pervasiveness and effectiveness of rollback prevention on Android devices for TAs running in the TEE. We augmented the study with publicly known TA vulnerabilities to form a ground-truth dataset containing vulnerable TAs. These datasets allowed us to track the handling of patches and rollback prevention over time. We uncovered a severe ineffectiveness of TA rollback prevention across all TEE implementations covered in our study. Furthermore, our study shows that TA rollback counters are never updated in the majority of cases across the industry, with the exception of the latest Samsung devices. Our case studies show that ineffective TA rollback prevention can be leveraged to gain code execution inside the TEEs of two popular up-to-date mobile devices. Our findings call for an immediate improvement of update strategies to protect the mobile ecosystem against n-day attacks against patched but rollbackable versions of TAs. Our dataset is publicly available at http://hexhive.epfl.ch/spill_the_tea.

Abstract

We present an analysis of 12 million instances of privacy-relevant reviews publicly visible on the Google Play Store that span a 10 year period. By leveraging state of the art NLP techniques, we examine what users have been writing about privacy along multiple dimensions: time, countries, app types, diverse privacy topics, and even across a spectrum of emotions. We find consistent growth of privacy-relevant reviews, and explore topics that are trending (such as Data Deletion and Data Theft), as well as those on the decline (such as privacy-relevant reviews on sensitive permissions). We find that although privacy reviews come from more than 200 countries, 33 countries provide 90% of privacy reviews. We conduct a comparison across countries by examining the distribution of privacy topics a country's users write about, and find that geographic proximity is not a reliable indicator that nearby countries have similar privacy perspectives. We uncover some countries with unique patterns and explore those herein. Surprisingly, we uncover that it is not uncommon for reviews that discuss privacy to be positive (32%); many users express pleasure about privacy features within apps or privacy-focused apps. We also uncover some unexpected behaviors, such as the use of reviews to deliver privacy disclaimers to developers. Finally, we demonstrate the value of analyzing app reviews with our approach as a complement to existing methods for understanding users' perspectives about privacy.

1 Introduction

User perspectives are commonly measured through user studies (e.g., surveys, interviews, lab studies), which can provide rich data to answer focused research questions. Unfortunately, such studies do not scale beyond thousands of users, and the resulting measurements are heavily bound to the environment the studies were conducted in: user opinions may vary over time, between regions, and across different app types. Re-running user studies to understand these differences can be prohibitively costly, both monetarily and time-wise.

In this work, we present an alternate and complementary analysis approach, with a different set of research tradeoffs. Specifically, we trade the power of surveys in having the same (targeted) questions answered by many participants for the power of ecologically valid, large-scale analysis in uncovering unanticipated insights from open-ended reviews. We believe these insights can, in turn, motivate future investigations of user-centered privacy, including survey-based studies.

Getting input about users' perspectives on privacy issues from millions of user reviews from hundreds of countries has not been feasible until recently. Advances in natural language processing (NLP) and large language models (LLMs) permit complex analysis of enormous text corpora. Here, we leverage these advances to investigate users' privacy opinions and concerns from a novel perspective: we study 12.3M (million) privacy-related reviews, extracted from ∼2B (billion) public reviews on Google Play spanning 10 years (Jan. 2013–Feb. 2023). These privacy reviews come from more than 200 countries or regions, 25 languages, and 160K (thousand) apps that span every Play app category.

To analyze this extensive dataset, we leverage and extend NLP techniques recently introduced in Hark [29] to automatically extract all reviews that discuss a privacy topic, assign fine-grained issue tags to each review, aggregate related issues into larger thematic clusters, and classify the "emotions" expressed in these reviews. The resulting dataset of roughly 12.3M privacy-related reviews likely constitutes the largest body of privacy feedback ever evaluated at this granularity. Using this dataset, we address the following research questions:

- **RQ1:** Which privacy issues do users raise and discuss in app reviews?
- **RQ2:** How have these privacy issues evolved over time?
- **RQ3:** How do privacy issues vary across countries?
- **RQ4:** Which types of apps have privacy reviews with strongly negative or strongly positive emotions?
- **RQ5:** How do reviews as a source of understanding privacy perspectives complement prior work?

We find that privacy reviews have grown steadily over 10 years, both in terms of absolute volume (a 4.7x increase) and when normalized for review volume (9% biannual growth). We find that themes such as `Data Deletion` are growing in importance, while reviews relating to `Excessive [Privacy-Relevant] Permissions` (a popular research topic, e.g., [11, 22, 57, 77]) have seen a significant decline.

Our broad overview across the globe also shows that geographic proximity is a weak indicator of whether nearby countries discuss similar privacy issues. We find that the countries that contribute the largest volume of privacy related reviews tend to be countries with large populations, and not necessarily countries that drive privacy regulation (such as the EU). We uncover a handful of countries (typically understudied) that discuss unique distributions of privacy topics. For example, in Türkiye, we find a significant number of reviews using almost the same quasi-legal disclaimers—implying users might be under the mistaken assumption that this bolsters privacy protection.

The app types whose privacy reviews exhibit the most strongly negative emotions (e.g. anger, annoyance, fear) are social media apps, parental control and child monitoring apps, as well as simulation games that mimic users facial and vocal expressions (leading to anxiety about surveillance). On the other hand, reviews for security and privacy apps commonly express positive emotions.

Finally, we place our results in context of related research, adding context to prior findings and identifying new areas for further study. For example, we expand on previously documented privacy concerns related to loan apps [50], finding that these concerns arise in a number countries beyond the original one identified. We also observe strongly positive reviews of many apps that claim to secure or hide content on phones, especially in the context of multi-user devices [68], raising a number of questions for future research. We demonstrate the utility of automatically distilling user feedback at scale, as a complement to other methods of understanding users' opinions and concerns.

2 Background and Related Work

Interviews and surveys are the most common method of measuring privacy attitudes. They have been broadly used to understand users' mental models of security & privacy tools [2, 8, 42], to study privacy preferences for smartphone app permissions [11, 66], to measure privacy concerns with IoT and sensors [47, 60, 73, 78], and used in methods studies [1, 64, 72]—to name only a few in this vast field. While these methods are sound and routinely used, researchers also acknowledge limitations arising from social desirability, acquiescence, and demand biases. While behavioral measurements can circumvent some of these biases [9, 20], they depend on inferring what users think rather than being able to document exactly what users' attitudes are. Moreover, recent work presents evidence that problems with validity of privacy constructs (built from surveys) may be widespread [15]. Similar methods are used to measure developers' mental models of privacy threats [48], their understanding of app privacy [48], and their responsiveness to privacy nudges [71]. Studying developers themselves is out of scope of this work.

A key difference in our work is our method: namely, recently proposed LLM techniques, specific to the app reviews context [29], enabling us to analyze inputs from millions of users. This method, complementary to those above, offers a different set of tradeoffs. While interviews allow for in-depth questioning of what users think, they typically do not scale beyond a few tens of users. Surveys can scale to thousands (but not millions) of users and enable the development of verifiable privacy scales, but are very focused; a researcher cannot learn about an issue that wasn't posed in the questionnaire. Further, recruitment across multiple geographic regions is expensive and challenging, making such studies often costly to repeat. In contrast, our approach does not support controlled experiments or hypothetical questions about potential new designs. Still, it does allow for increased ecological validity and much larger and broader samples.

In this paper, we explore what users around the globe write about privacy in Android app reviews. A few works have explored app reviews [29, 53, 54]; however, they extracted a limited set of privacy reviews because their privacy classifiers relied on keywords [54], limited heuristics for data sampling [53], or a limited privacy taxonomy [29]. These works also only included English language reviews, whereas we include 25 languages. Our set of privacy-related reviews is 1000x, 20x and 2x larger (respectively) than these earlier studies.

Many cross-country studies focus on specific aspects of privacy, such as android permissions [11], social networks [74], phone locking behavior [28], incident response [63], or how much users are willing to pay for privacy for specific types of data [59]. Beyond these focused studies, some more general cross-country studies attempt to understand the influence of factors such as culture or country on privacy attitudes or privacy preferences [14, 26]. Some studies do show differences between non-Western and Western countries in terms of misconceptions around privacy [33] practices.

A recent survey [30] notes limited geographic diversity in usable security & privacy research, with participants primarily from Western, educated, industrialized, rich, and democratic (WEIRD) societies. While this may naturally occur due to geographic and linguistic barriers, our approach—using text from > 200 countries/regions and translations for 24 languages—offers an alternative. Most of the multinational surveys above include 3-7 countries; a few include 10-20. To our knowledge, our work is the first to report on data from more than 200 countries, with the top-50 explicitly compared.

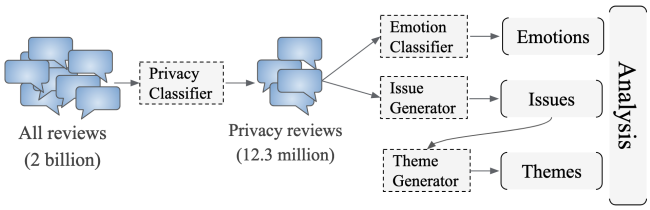

Figure 1: Our analysis pipeline overview, adapted from [29].

3 Data Analysis Pipeline

In this section, we describe our data-analysis pipeline that reuses several lessons from the Hark system [29], highlighting the modifications we made to fit the purpose of this study. We also discuss the resulting dataset and our analysis approach.

3.1 Text Analysis Pipeline

We build our analysis pipeline to leverage and extend the components in Hark, an end-to-end system for retrieval and analysis of privacy-related feedback leveraging state-of-the-art techniques in NLP [29]. An overview of our data-analysis pipeline is in Figure 1. First, the *privacy classifier* identifies the privacy-related feedback from unstructured text. The *issue generation* model takes in this privacy feedback and dynamically generates meaningful, fine-grained issues (covering both known and newly emerging issues) describing the privacy aspects discussed within each review text. The *theme creation* component groups these issues into thematic clusters and assigns a succinct title to each. Our data-analysis pipeline also includes an *emotion* classifier that dissects each review's text across 28 emotions (e.g., anger, fear, joy and confusion).

We obtained models and training data from Hark [29] and re-purposed most of the pipeline, with modifications to the privacy classifier to improve the breadth of topics identified. First, we expand the privacy taxonomy from the original paper (25 concepts) to include 89 privacy-relevant concepts.[1] The prior taxonomy already included concepts from multiple known taxonomies. However, when we asked five privacy experts (with at least 5 years of academic/industry experience in privacy research and development) to manually examine the original taxonomy [29], they observed many missing topics. For example, we added Data Hiding, Opt-out and Location concepts, and added specificity to the Anonymity and Personal Data types.

Second, we rely on these same experts, instead of crowdsourcing, to manually annotate a new training dataset for the privacy classifier, based on the expanded taxonomy and following the same *Natural Language Inference* approach and heuristics as in [29]. To best use the experts' time and generate high-quality training data without requiring multiple annotations per review, we used two labeling rounds. In the first round, we described the taxonomy to the experts and each annotator independently labeled a subset of reviews. Following the principles of *Active Learning*, we trained a classifier on the annotated reviews from the first round. The active-learning classifier is composed of Sentence-T5 frozen embeddings [55], a dense layer, and a binary classification head. The experts discussed cases where the model produced a different label from the expert as well as cases whose classification probabilities had high entropy. In the second round, all experts discussed these misclassifications or low-confidence predictions, thereby focusing their efforts on challenging examples. Overall, we generated a labeled dataset of 4.3K (nearly equal split of 2K *privacy* and 2.3K *not-privacy*) reviews, which we split into training, validation, and test sets. We fine-tuned T5-11B [61] on these datasets and use it as our privacy classifier.

Model evaluation: Our classifier has a 0.95 ROC AUC, 87% precision, and 86% recall on our new diversified test set,[2] and a similar ROC AUC of 0.88 (vs 0.92) on the original Hark test set [29]. In comparison, the privacy classifier from [29] has 0.87 ROC AUC, 89% precision, and 51% recall on our new test set, demonstrating that our classifier performs better at capturing the diversity of our taxonomy. (For additional experiments with a range of model architectures see Appendix B.) We also performed qualitative assessment of all 50 false positives/negatives of our classifier, noticing primarily issues with reviews that were short ($\leq$ 10 words) and ambiguous (missing context, causing multiple possible interpretations). For example, a short review "*Taking too much data*" was labeled as 'privacy,' when the privacy expert (based on other reviews seen) interpreted it to be a complaint about the app consuming the limited mobile data bandwidth and annotated it as 'not-privacy'; whereas an ambiguous review "*msgs have been deleted, but for some reason they remain in place*" was labeled as 'not-privacy' (could be seen as a bug in app functionality), when the privacy expert interpreted it as data deletion control not working as expected (a privacy concern). 13 of the 50 false positives/negatives were short; and the rest (though longer) were still ambiguous. Despite missing these short and ambiguous cases, our classifier had good performance.

Similar to [29], for ease of representation, we consolidated the 28 classifier-generated emotions into 8 emotions groups (plus a neutral option) based on Ekman's emotions taxonomy [21] and using Demszky et al.'s [17] grouping criteria.

3.2 Data Description

We obtained access to reviews directly from the Google Play team. Our initial dataset consists of all ~2B publicly visible Google Play app reviews for apps with >10K installs,

[1] See the extended paper for the expanded privacy taxonomy [3].

[2] We set a 0.8 prediction score threshold for best accuracy and verified results qualitatively.

spanning 10 years from Jan 2013–Feb 2023. The dataset was already anonymized (no user identifying information) and sanitized (any detected fake/spam reviews were removed). Each review is associated with the review text, its language, country, submission time, star rating, the corresponding app's package name, the app's developer-specified category information and (if available) finer-grained *app-type* information (such as 'Rideshare & Taxis' for a rideshare app, which belongs to the 'Maps & Navigation' developer-specified category). Note that we do not generally use developer-specified categories as they are too broad [57]. Instead we use the more specific app types that are displayed on Play when viewing apps.

In our dataset, ∼65% of reviews are non-English. Since our classifiers work on English texts, we leverage Google's Translation API to translate reviews in 24 non-English languages to English (see Appendix A for the full list) [5]. The final set of English reviews (including translations) constitutes 98% of the initial dataset and contains 1.9B reviews for 160K apps. These reviews come from all developer-specified categories and 445 app types, with representation from more than 200 countries and territories in the world.

Applying our data-analysis pipeline to this large review dataset, we identified 12.3M privacy-related reviews, which were organized into 227 themes with at least 5K reviews. To our knowledge, this constitutes the largest privacy-review dataset ever evaluated. In the following sections, we analyze these privacy reviews in depth across dimensions.

3.3 Metrics

Hereafter, we rely on two core privacy metrics. We first define the percentage of privacy reviews (PPR):

$$PPR = \frac{Number\ of\ privacy\ reviews * 100}{Total\ number\ of\ reviews}$$

When we compute PPR over *all* 12.3M privacy reviews, we notate it as $PPR_{(all)}$. We compute $PPR_{(country)}$, where both the numerator and denominator are limited to one country. Similarly, we use $PPR_{(app-type)}$ for the fraction of reviews within a particular app type that discuss privacy.

PPR is not applicable to themes, only privacy reviews have themes. To denote the ratio of a theme across all privacy reviews, we define percentage of theme privacy reviews (PTPR):

$$PTPR = \frac{Number\ of\ privacy\ reviews\ in\ a\ theme * 100}{Total\ number\ of\ privacy\ reviews}$$

$PTPR_{(theme)}$ is often used to denote the theme of interest.

3.4 Analysis Techniques

We visualize data and report descriptive statistics to make observations. We use simple hypothesis tests, clustering, and regressions to examine trends in the underlying data.

To understand if various subsets of privacy reviews significantly increase or decrease over time, we first perform a KPSS (Kwiatkowski–Phillips–Schmidt–Shin) test to check if the PPR/PTPR time series (30 day intervals) is stationary over the long term [43].We then fit a linear regression for each non-stationary item (e.g., theme), to check if the slope estimate is statistically significant (i.e., PPR/PTPR changes over time). Items that do not meet these requirements are assumed to not consistently trend. Further, we calculate the average two-year change in PTPR/PPR over the 10 years with a sliding window stride of 14 days.[3] Average two-year change mirrors regression results for every time-series analysis we conducted, and all items with significant KPSS values also had significant slope estimates. Thus, for increased clarity, we only report average two-year change.

When elaborating on subsets of reviews (mostly obtained through the intersection of themes, country, time, and app type), we quantify the most prominent issues and qualitatively assess a random sample of reviews to confirm. Our goal is to use examples to paint a more detailed picture of the issues and themes our data-analysis pipeline generates.

3.5 Ethical considerations

App reviews are public (and are denoted as such during submission[4]), and users submit reviews with the intention of sharing their views with other potential users. However, we take additional precautions before the review data is analyzed. First, all user identifiers (such as account IDs, emails, device information, etc.) are removed from the reviews dataset. Second, only reviews from apps with at least 10K installs and at least 1K reviews are included. Third, inline with recent suggestions, we paraphrase all quotes reported in this paper [40]. Additionally, we do not disclose app package names to prevent user deanonymization when joined with other sources. Our dataset did not leave Google's premises, ensuring compliance with Google's terms of service.

Our work uncovered reviews that contained ads for spying services. We disclosed our findings to Google Play and they removed these harmful reviews before publication.

3.6 Limitations

Our study is an observational one, i.e., we don't control who leaves privacy reviews when. The resulting selection bias is common in other work [49, 67]; however, the bias we observe in this large-scale study of real-world data is likely different from the biases common in survey or interview studies, offering a different view of similar research questions.

[3] We considered annual change but found two years to be more fluctuation resistant. Note that we do not report the compounded rates.

Jan & May 2021	Large messaging app privacy policy change (link)

Table 1: Widely discussed privacy events

Each review, taken by itself, is specific to the application it is left on. This might mean our dataset is too specific and not generalizable. We argue that the sheer number of apps, and observed similarities within large groups of apps, helps to smooth out this effect, and thus does reveal common themes among apps and countries. In isolation, feedback is specific; collectively, stories emerge. We rely on Google Translate APIs to translate non-English reviews. This API has been thoroughly evaluated, even on low-resource (and low-volume) languages, and has F1 quality scores of >97% for all languages with >2M native speakers (see Appendix E in [5]). Nonetheless, any translation errors might influence our results, though we believe the impact is minimal since we focus on 25 widely spoken languages.

Our work focuses on Android users; however, other sizeable platforms exist, raising generalizability concerns depending on the ratio of android users in a country. We note that Android is the most popular mobile operating system in the world and tends to be even more popular in non-WEIRD countries.[5] Coincidentally, these countries receive the least security & privacy research attention, some of which appear in our dataset but have received no prior privacy-focused academic interest [30], making our work instrumental in addressing this gap. We also note that, recent work has not found differences between Android and iOS users' privacy sensitivities [1], suggesting our results may provide hints beyond Android users. We leave the exploration of this hypothesis to future work.

4 Aggregate Growth

We start our dive into the 12.3M privacy reviews with an initial look at the aggregate data over the last decade. We first examine how privacy-related reviews have grown over time. The absolute volume of privacy reviews, in 30-day intervals, is shown in Figure 2. Figure 3 shows $PPR_{(all)}$ using the same intervals. Both figures trend upward over time, albeit non-uniformly, indicating that privacy reviews have increased over the last 10 years. Fitting a regression line on $PPR_{(all)}$ shows a significant increase ($R^2 = 0.44$, $p < 0.001$, KPSS $p \leq 0.05$). $PPR_{(all)}$ grows from 0.5% to 0.8% (4.7× increase in volume), a 9.3% relative growth every 2 years on average. To contextualize this growth in privacy reviews, we also fit a regression line on the absolute volume of all (both privacy and not-privacy) reviews in 30-day intervals, and see that reviews have generally increased ($R^2 = 0.71$, $p < 0.001$, KPSS $p \leq 0.05$) during the same period from 6.5M to 24.5M per month (3.7× increase in volume). This shows privacy review volume is increasing faster than overall review volume.

Figure 3 exhibits notable spikes in February 2014, August 2014, January 2021, and May 2021. Analyzing reviews during these periods, we identified a few apps contributing to these spikes. These apps had well-publicized events (Table 1) that heightened user privacy concerns or increased privacy awareness, resulting in the apps seeing a 2× to 25× increase in privacy review volume. Reviews of other themes and app types stay relatively stable (see Figure 6).

Finding 1: Over the last decade, global privacy reviews have increased in absolute numbers and in PPR, exhibiting a biannual relative growth rate in PPR of 9%.

5 Trends in Privacy Themes

We now focus on our first research question (RQ1), asking which privacy themes are raised in reviews. Table 2 shows the top 20 themes by volume. We indicate whether the trend is generally increasing, decreasing or staying the same, and briefly summarize the review content. The last column states

[5] https://worldpopulationreview.com/country-rankings/iphone-market-share-by-country

Privacy Theme	Trend	Reviews	Short Summary	# of Country Top-5 appear.
Data Deletion	⇑	893K	Data deletion requests, data misuse, inability to delete data.	47

Table 2: Top 20 themes in privacy reviews over the last 10 years. ⇑ / ⇓ indicates average PTPR change $> 1\%$ in two years. ↑ / ↓ indicates significant change (KPSS test $p \leq 0.05$). ⇝ indicates no detectable significant change (KPSS test $p > 0.05$).

the number of countries where this theme appears among the top 5 themes, capturing how widespread an issue is globally.

We see that Data Deletion is the top theme worldwide, that it has been increasing over the last decade, and that it is a top issue in 47 countries. We note that the top 3 privacy themes constitute 16% of all privacy reviews, the top 50 constitute 65%, and the top 200 cover 85%. From a volume perspective, this indicates that rather than a small number of dominant themes, we see a broad set of privacy topics raised across the Play store. However, from a geographic perspective, only 10 themes are a top issue in more than 10 countries (Table 2). This indicates that some themes, even if quite voluminous, may arise in a limited set of countries.

To address our second research question (RQ2), on how privacy issues evolve over time, we first determine which themes are either decreasing or increasing in significant way. In Figure 4 we plot the average 2-year change for themes among the top 20 that experience statistically significant change over the last decade (KPSS $p \leq 0.05$); stationary (non-changing) themes are excluded. The temporal evolution of five sample themes is shown in Figure 6. In Sections §5.1, §5.2, and §5.3, we continue to address RQ1 and RQ2 by focusing on the specific themes incurring long-term changes.

5.1 Themes Decreasing in Prevalence

Themes about privacy-sensitive permissions : Among the decreasing themes, (see Figure 4, left-most column), we find several themes related to privacy-sensitive permissions, namely `Excessive Permissions`, `Unneeded Camera Access`, `Unneeded [Permission] Access`. We include `Location Access Concerns` in this batch, although it has been stable over time, as concerns about the location permission are a long-standing and much written about (see §2) privacy issue.

Our data-analysis pipeline captures nuance in reviewers' discussion of permissions, sorting privacy-sensitive permissions reviews into distinct themes. For instance, within the `Excessive Permissions` theme, reviewers complain about too many privacy-sensitive permissions in general, without specifying which ones: e.g., "*what's up with the permissions requests, why don't you listen to us and keep your hands off of our data*". In contrast, reviews labeled `Unneeded Camera Access` and `Location Access Concerns` exhibit concerns about camera and location permissions respectively. `Unneeded [Permission] Access` captures all lesser mentioned privacy-sensitive permissions (47.5% contacts, 9.3% phone numbers, 7.5% call logs, etc.).

We document here, for the first time, the dominant emotions associated with privacy reviews about app permissions. Unsurprisingly, we find that negative emotions ('Anger', 'Annoyance', 'Sadness', 'Disgust', and 'Fear'), account for 45–68% of reviews most themes. (see Figure 5). Qualitative analysis shows that 'Anger' reviews commonly question the use case for privacy-sensitive permissions and express disapproval, such as: "*Horrible! it doesn't make sense to give permission for management of my email account, contacts, and images. All bad ideas.*" Among our top 20 themes, the 'Confusion' emotion appears most often with privacy-sensitive permission themes (7-14.4%). The permission-related reviews associated with 'Confusion' almost exclusively question privacy-sensitive permissions but are less confrontational (e.g., "*Why do you need identity and call information permissions?*").

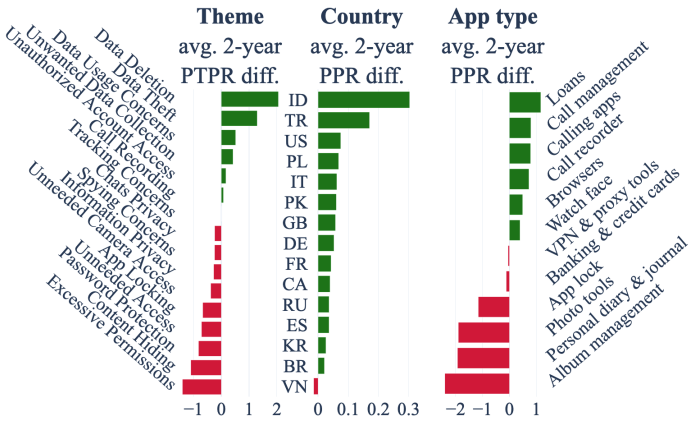

Figure 4: Avg. 2-year % point change in theme (PTPR), country (PPR), and app type (PPR). Green/red denotes increasing/decreasing trend (KPSS $p \leq 0.05$).

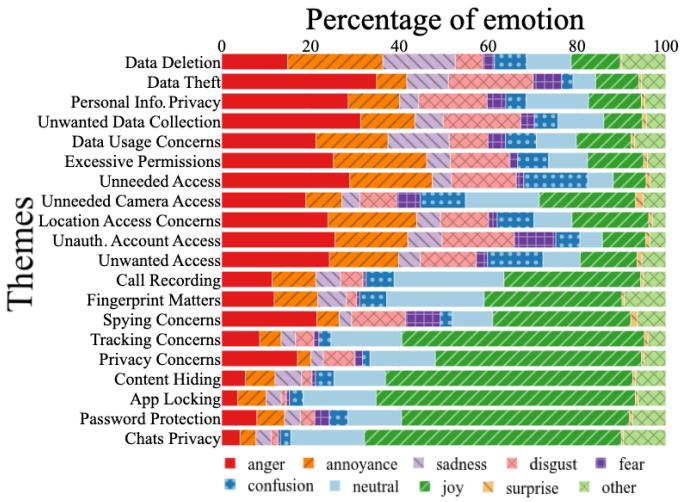

Figure 5: Percentage of emotions in top 20 themes, organized roughly by decreasing anger and increasing joy.

These themes on privacy-sensitive permissions have decreased significantly over time in PTPR (see Figure 4): going from 19% of privacy reviews to 8% between Feb 2013–Jan 2023. We hypothesize several explanations: (1) ongoing privacy enhancements in Android permissions (e.g., run-time permissions in version 6, restricting background usage in version 10, one-time grants in version 11); (2) Android's efforts in urging developers to reduce unnecessary permission requests [57]; and/or (3) the rise of other privacy concerns.

Figure 6 shows a brief increase in reviews about privacy-sensitive permissions around 2016; we speculate this relates to increased visibility of permissions with the introduction of runtime permissions in October 2015. The lag may be due to new Android versions being adopted over multiple years [46].

Finding 2: The fraction of privacy reviews related to privacy-sensitive permissions has decreased from 19% to 8%, in the last 10 years.

Themes related to device sharing: Other themes exhibiting significant decline in PTPR are `App Locking`, `Content Hiding` and `Password Protection`. These themes collectively have dropped from roughly 18% of privacy reviews in Feb 2013 to 5% as of Jan 2023.

We investigated the app types of these reviews, and found the reviews were predominantly for *App lockers/hiders*, *Album management*, and *Personal diary & journal*. Such apps typically allow protection of private content via password controls that are especially useful when a device is shared. South Asian countries contribute the most to these themes (e.g., India makes up 29.4% of `Content Hiding` reviews), and device sharing is a known challenge in these countries [68]). We speculate increasing smartphone adoption—and thus reduced device sharing—might explain the decline among south Asian countries [10]. However, more research is needed to confirm. We further explore these themes and app types in §7.2.

5.2 Themes Increasing in Prevalence

The top four themes that have shown statistically significant increases over time are: `Data Deletion`, `Data Theft`, `Data Usage Concerns`, and `Unwanted Data Collection`. These themes have risen in aggregate from 10% of privacy reviews in early Feb 2013 to 27.3% by Jan 2023. Collectively, these themes focus on PII and user-generated personal data. Our analysis methods discern the nuanced difference between PII and privacy-sensitive permission discussions.

Themes in this group capture feedback in nuanced ways. `Data Deletion`-themed reviews are almost exclusively requests to delete personal data (discussed in §5.3). In contrast, `Data Theft`-themed reviews express concern about data being stolen or an account hacked. `Data Usage Concerns` primarily refers to sharing data with third parties, and `Unwanted Data Collection` reviews express concerns with the app requesting unnecessary data (e.g., for showing ads).

These reviews occur in two styles. Many reference precise data types: national IDs (e.g., SSN, TCKN), financial data (e.g., credit cards), personally identifiable information (e.g., emails), or user-generated content (e.g., "*Requires EVERYTHING about you including your social security number to scan lottery tickets. Why wouldn't you use your local store instead of exposing yourself to a risk of data breaches?*"). Other reviews in these themes discuss personal data vaguely, without reference to specific personal data types (e.g., "*Warning! The app collects a lot of data. Personal data, device and usage-related data... The app then sells it*").

Understandably, the most common emotion with these reviews is 'Anger' (15-35% of privacy reviews per theme). `Data Theft` also contains a larger rate of 'Fear' (6.4% of privacy reviews). Interestingly, these reviews are not strictly negative; 9-12% of privacy reviews on these personal data themes ex-

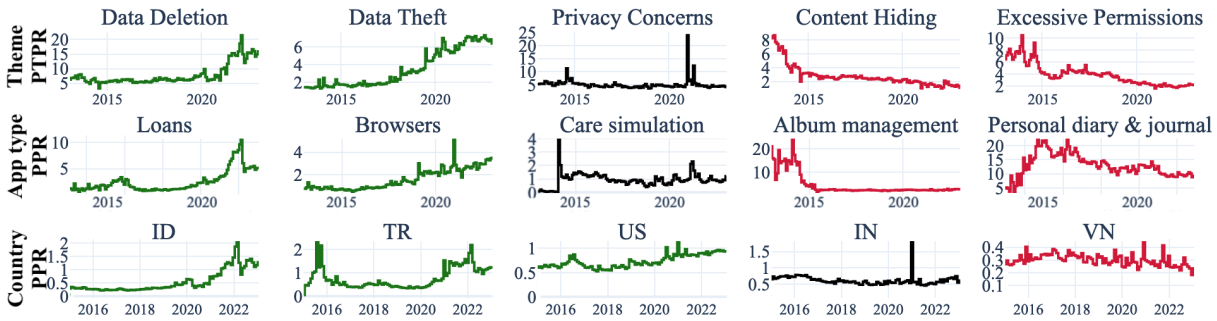

Figure 6: Selected themes, app types, and countries over time. Green/red denotes increasing/decreasing trend (KPSS $p \leq 0.05$)

hibit 'Joy.' Some express gratitude for apps that protect data, such as "*This app locks your personal stuff. Great app.*"

Finding 3: Over time, an increasing share of privacy reviews focus on personal information (e.g., PII). Our analysis uncovers privacy discussions about different types of personal data, such as privacy-sensitive permissions vs PII.

5.3 The rise in Data Deletion and Data Theft

Since `Data Deletion` and `Data Theft` are our two largest themes, and both show a statistically significant increase in volume over time, we now look at what the contributing factors may be. Our analysis enables us to break down our data along multiple dimensions, thus we looked at per-country contributions for these two topics and found that Indonesia (disproportionately) contributes 40% of the reviews in these two categories, whereas all other countries contribute less than 8% each. We also saw that Indonesia has the fastest PPR growth of any country, with 76% relative biannual growth and the third-most privacy reviews of all countries by volume. Considering only the `Data Deletion` and `Data Theft` themes for Indonesia, we next considered app types. We uncovered that 44% of these reviews came from financial loan apps, with other app types contributing less than 0.8% each.

Many `Data Theft` reviews complain that the app collects PII (social media accounts, photos of IDs), and then either loans are denied without reason, or threats are made leveraging their PII. One reviewer writes "*The app stole my data, including my facebook account. It told me that the loan process would be easier if I input all of my data. My loan was still denied even though I have a good payment history. Watch out people.*" Another reviewer says "*[COMPANY] pretends you'll get a loan with no hiccups. They say they just need your photo identity. If you're even a day late, their debt collector will harass you and threaten to leak your data (photo identity) to social media.*"

Most *Data Deletion* reviews we manually examined ask for personal information to be deleted because the user's loan was rejected. Some claim payment was requested when a loan was never applied for or received. For instance, one reviewer from Indonesia exclaims, "*Didn't receive a penny! Why do you threaten me with calling all of my contacts if I don't pay? DELETE ALL OF MY DATA PLEASE.*"

Munyendo et al. conducted a user study with 20 participants in Kenya and reported that loan apps were calling the contacts of people who had not applied for loans [50]. Our NLP analysis pipeline was able to uncover that this issue, first noted in Kenya, is in fact a more widespread problem. In addition to Indonesia, we observe many `Data Deletion` and `Data Theft` reviews on loan apps from India, Mexico and Thailand. In our data, Kenya contributes only a small portion of these reviews, which may reflect population size and/or selection bias in who leaves reviews on Google Play.

Figure 4 indicates that the loans app type is a growing concern, with the highest growth in privacy reviews among app types. In 2022, many such abusive financial loan apps were removed from the market.[6] Subsequently in 2023 Google announced a policy update prohibiting personal loan apps from accessing sensitive data such as photos and contacts.[7] Since our data collection ended in early 2023, we are unable to measure the impact of this policy.

Finding 4: We showed how our ability to break the data down along multiple dimensions (country, time, theme, app type) can be useful in understanding trends. This evaluation also illustrates how text analysis and user studies can complement each other: when a prior user study [50] identifies an unexpected issue, it can be followed up with text analysis to quickly examine the issue's geographic spread.

6 Trends in Countries

We now focus on our third research question (RQ3), examining how privacy themes discussed in reviews vary around the globe. Our 12.3M review data set includes more than 200 countries or regions. The top 10 contributing countries are the U.S. (15.4%), India (12.1%), Indonesia (10.5%), Brazil

[7] https://support.google.com/googleplay/android-developer/answer/9876821

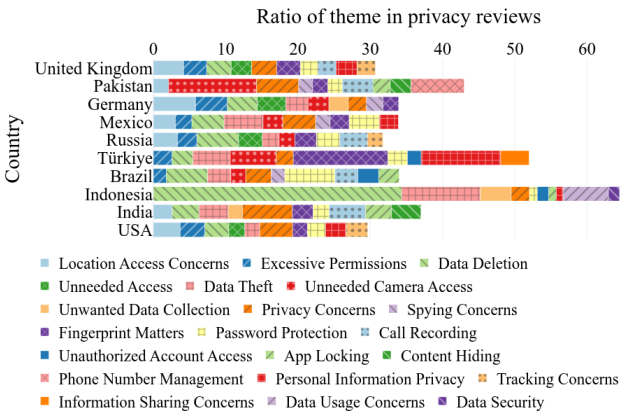

Figure 7: Top 10 themes per country (PTPR), showing variation in theme popularity across countries.

(7.7%), Türkiye (4.5%), Russia (4.4%), Mexico (4.2%), Germany (3.0%), Pakistan (2.6%), and United Kingdom (2.4%). These 10 countries together contribute 66% of privacy reviews, with the top 33 countries supplying 90%. Interestingly, 1) only two European countries are among the top 10 contributors by volume, 2) the top 33 countries come from every continent, and 3) there is a long-tail of privacy review percentages coming from more than 150 countries. Overall, while people from all corners of the world write about privacy, we find that 33 countries dominate this discussion. This distribution of privacy reviews across countries largely follows the trends in all (both privacy and not-privacy) reviews submitted, except for few minor shifts in country rankings. For instance, Brazil is second in terms of review volume, but drops to fourth with privacy reviews. Similarly, South Korea drops from eighth to 13th, while Spain jumps from 15th to 11th. Nonetheless, the top countries that contribute the highest number of reviews are also the ones that contribute the most privacy reviews.

In the rest of this section, we first cluster countries (§6.1) to understand where broad commonalities do and don't exist. We then take a closer look at countries with outlier patterns (distributions of privacy topics discussed) in §6.2, and other anomalous patterns such as high growth rates in Türkiye (§6.3) and unusual reviews about spying in Nigeria (§6.4). It is beyond the scope of this paper to carry out further detailed world-wide country comparisons.

6.1 Clustering Countries

Earlier research [13,26,33,63] has hypothesized and examined whether the influence of culture and geographic proximity changes privacy attitudes. While loose correlations are sometimes observed (e.g., [33, 63]), often it is difficult to identify strong predictors because there are so many factors that influence privacy [13, 26]. We explore the potential connection between geographic proximity and privacy opinions from a different angle: we examine expressed opinions, from people living in a country, over a range of privacy topics. We do not study underlying factors, such as culture; instead we offer direct data summaries of user-provided texts.

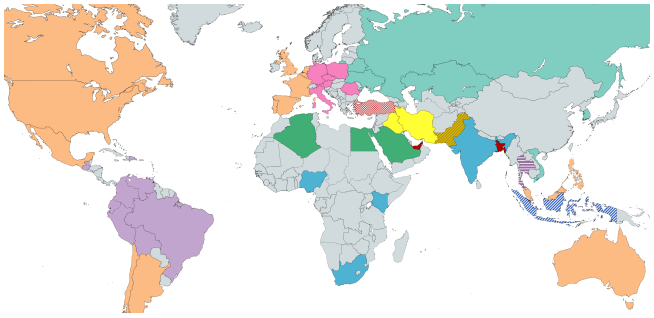

Figure 8: Countries clustered according to distribution of privacy themes discussed in app reviews.

We investigate the question of whether countries that are geographically close discuss similar app privacy issues, in an exploratory fashion. We cluster countries based on prevalence of privacy themes discussed.[8] As intuition for this approach, we provide a visualization in Figure 7 of the distribution of themes for the top 10 countries contributing the most privacy reviews. (We only include top 10 themes per country to facilitate readability.) We see that the U.S. and U.K. have quite similar distributions, while Indonesia, Türkiye and Pakistan have distinct patterns.

We now use these topic distributions to cluster countries. Specifically, we represent each country as a vector of size 50, where each element is the PTPR for a (country, theme) tuple, for the top 50 themes across the entire dataset. We then apply hierarchical clustering with complete linkage [51]. The resulting clusters are shown on a world map in Figure 8. A detailed breakdown can be seen in Figure 12 of the extended paper [3].

We see from this map that the question of whether geographically close countries write about the same privacy issues yields mixed results. On one hand, Russia, Ukraine, Belarus and Kazakhstan all cluster together (teal). We also see that most of the Anglo countries, namely the U.S., Canada, Australia and the U.K., are in the same (light orange) cluster. However, this light orange cluster also contains Mexico, Argentina, Spain, Portugal, and France. Interestingly, European countries divide between two clusters, with eastern European countries, Germany, and Italy in their own cluster (pink). Similarly, the Middle East and North Africa splits across three main clusters: Türkiye is alone, Iran and Iraq cluster together (yellow), and Saudi Arabia, Algeria, and Egypt cluster together (green). A detailed examination of our dendrogram shows that the Iran-Iraq cluster is surprisingly far away from

[8] While this is limited by those who chose to write reviews, it nevertheless is based on sizeable inputs from each country.

Country	Most Discussed Privacy Theme
Pakistan	`Unneeded Camera Access`
Indonesia	`Data Deletion` (mostly in loan apps)
Türkiye	`Fingerprint Matters`
Thailand	`Data Deletion` (broadly across app types)
Bangladesh & UAE	`VPN Matters`
Iran & Iraq	`Data Deletion` (comms & social media apps)

Table 3: Countries with unusual theme distributions

the Saudi Arabia-Algeria-Egypt cluster. Asian countries exhibit wide diversity. India clusters with some African countries (South Africa, Kenya, and Nigeria), and not with Pakistan or Bangladesh. Interestingly, we note that Indonesia, Pakistan, Thailand and Türkiye appear unique (cluster size 1).

Finding 5: Geographical proximity does not reliably indicate whether countries discuss the same set of privacy topics.

6.2 Unique distributions of privacy themes

As noted above, our clustering identified four countries that are alone in clusters of size 1: Indonesia, Pakistan, Thailand, and Türkiye. We also found two small clusters of only two countries: Bangladesh with the United Arab Emirates, and Iran with Iraq. In Table 3, we list the most frequently discussed issues for these countries.

Pakistan is the country with the highest rate of `Unneeded Camera Access` (12.2% of reviews from Pakistan). These reviews distinguish themselves from other countries by praising the abilities of `Hidden Camera Detection` (issue) apps, which claim to detect hidden cameras using device magnetometers (e.g., "*the app detects all hidden cameras in your vicinity, I love this app*"). Pakistan's focus on this issue could be a reflection of a higher adoption of this type of app.

The reviews from Indonesia were discussed in §5.3. The reviews from Türkiye are discussed in more depth in §6.3. Distinctively, Thailand exhibits a combination of the unique behaviors observed in reviews from Indonesia and Türkiye.

Bangladesh and UAE have a higher fraction of reviews categorized as `VPN Matters` than any other country. These reviews are overwhelmingly positive but predominantly non-specific, e.g., "*Love this app. It is a great vpn.*" We observe that 55.0% of `VPN Matters` reviews are for apps that contain 'Free' in the title. Prior work has found that "free" VPNs are often misconfigured or outright malicious [37, 58, 62]. A possible explanation for this theme's relative prevalence could be the common use of VPNs to circumvent the relatively high rate of censorship in Bangladesh and UAE [69].

For both Iran and Iraq the top theme is `Data Deletion`, with the vast majority of reviews applying to communication and social media apps (see §7 for more on apps).

6.3 Türkiye

Türkiye stands out as anomalous based on two metrics. First, its distribution of privacy topics does not cluster with any other country (cluster size 1). Second, Türkiye exhibits anomalous PPR growth over ten years. The middle column of Figure 4 shows the average 2-year change for countries, among the top 20, with statistically significant growth or decline in PPR (KPSS $p \leq 0.05$); stationary (non-changing) countries are excluded. Türkiye shows an unusually large increase, with an average 2-year relative growth of 62.1% between Feb. 2015 and Jan. 2023 (Figure 6 illustrates this). Türkiye also provides the 6th-most privacy reviews (502K) of all countries.

Figure 7 shows that Türkiye has an unusual distribution of privacy themes; `Fingerprint Matters`, `Personal Information Privacy` and `Unneeded Camera Access` appear more frequently than in other countries. The privacy reviews highlight user concerns around fingerprint collection (e.g., "*My fingerprint was scanned on [date], the company has the responsibility of my fingerprint.*") and abuse (e.g., "*If my fingerprint is used in something illegal, the app is responsible.*"). Although biometrics such as fingerprints are not shared with apps directly,[9] reviewers express concern about the potential for such sharing, e.g., when a banking app verifies authorization via a fingerprint.

In addition, we observed that 29% of privacy reviews from Türkiye include text we refer to as a "disclaimer": quasi-legal language asserting rights or claims. These disclaimers assert app developers' responsibility to safeguard information (e.g., "*This app is nice but you responsible for any inappropriate use of my personal data.*") or longer texts that threaten legal recourse for violations:

> "*This application was downloaded at [time] on [date]. I [give] no permission to share things (My photo, T.C. ID number, password, etc.) with third parties. And if such thing happens, . . . the app bears sole responsibility and I will take legal action against them.*"

These disclaimer reviews appear for multiple app types, including call management/recorders, physical activity trackers, investment/cryptocurrency apps, VPNs, and even antivirus apps; many of these typically require access to sensitive permissions or resources such as app usage patterns, files, and network control. The disclaimer reviews hint at nuanced mental models in which reviewers worry that an app might violate the privacy it claims to protect.

Overall, we hypothesize that reviewers in Türkiye use these disclaimers when they are uncomfortable with an app's privacy risks but feel compelled to use it, such that the disclaimer seems like the only protective option. Anecdotally, conversations with Turkish nationals suggest similar disclaimers circulate on messaging and social media apps with privacy

[9] https://source.android.com/docs/security/features/authentication/fingerprint-hal

protection promises.[10] These disclaimers raise additional research questions: Why are these reviews seen so frequently from Türkiye? Are reviewers who post these disclaimers unusually privacy-sensitive? Do they believe the disclaimers have legal value? Do they employ other privacy protections?

Finding 6: Over 150K reviews in Türkiye post quasi-legal disclaimers asserting privacy rights. We hypothesize a large-scale misunderstanding might cause such reviews.

6.4 Nigeria

Nigeria is the only country with `Spying Concerns` as the top theme. Surprisingly, many of these reviews are associated with 'Joy,' and unlike most `Spying Concerns` reviews from other countries, they aren't about games (see § 7.1). Manual inspection reveals that reviews for tracking related apps sometimes contain ads for spying services, for example:

> "*I can't find enough words to thank [email]! I tried lots of times to spy on my spouse . . . to no avail. This guy is magic, within three hours, he gave me access the calls and messages of my spouse.*"

Issues associated with `Spying Concerns` include `Spying on Spouse`, `Spying on Partner`, `Allows Unauthorized Calls Access`, and `Allows Unauthorized Messages Access`, suggesting these ads may primarily be targeted to intimate partner abuse perpetrators. Notably, many of these review ads use similarly formatted email addresses. Although we identified this pattern in privacy reviews, a simple regular expression[11] across all reviews yielded more than 10K matches. A random sample of 100 matches yielded only three false positives. Matching reviews appear on apps with developer-specified categories such as Lifestyle, Tools, Books, Communication, and Dating. Most are from Nigeria. We disclosed this issue to Google Play, and these reviews were taken down.

A simple web search for some of the email addresses from these reviews reveals similar ads posted as comments/reviews across the web as well as posts about the (in)effectiveness of the advertised spying,[12] suggesting these services are not unique to Google Play, and may be of interest to the digital intimate partner violence research community [6, 23, 31].

Finding 7: We detected a subset of reviews offering spyware services, primarily from Nigeria. These were reported to Google Play and have been removed before publication.

7 Stark Differences Across App Types

There are 445 app types in our dataset (functional categories displayed on Play app page), with some invoking strong emotional reactions from users. We address RQ4 by focusing on app types among the top 50 (by privacy review volume) that: (1) receive a high rate of negative-emotion privacy reviews, or (2) receive overwhelmingly positive reviews. We draw connections with previous research when possible (addressing RQ5), while also identifying areas that have been under-explored in the literature.

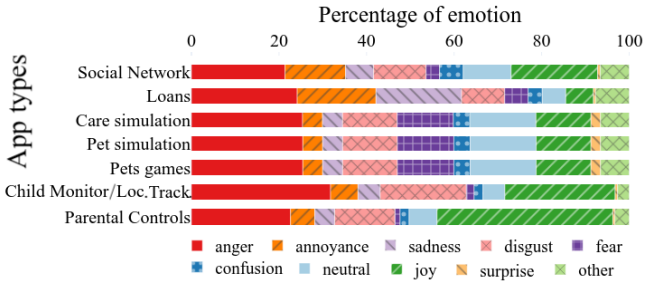

Figure 9: App types with highly negative privacy emotions.

7.1 App types with negative emotions

We define app types with strongly dominant negative emotions as those where more than 50% of privacy reviews were assigned to any of 'Anger', 'Annoyance', 'Sadness', 'Disgust', or 'Fear' (see Figure 9) Of the 25 app types that satisfy this condition, we highlight only a few below due to limited space (loan apps were already discussed in §5.3).

Social media: These apps receive the second-most privacy reviews (775K) of all app types, and ∼57% of these reviews are associated with negative emotions. Reviewers most frequently bring up `Invasion of Privacy` and `Data Deletion`. Non-specific comments, such as in `Invasion of Privacy`, include: "*You invade the privacy of people. Our privacy is sold for profits. You let fake news be posted by foreign countries.*" In `Data Deletion` reviews, users complain that they are unable to delete accounts, posted content, or the app itself (some social media apps come pre-installed and are not removable [25]). This latter feedback is more actionable for developers; for example, improving the UI to make data deletion controls more discoverable could help. The strongly negative emotions indicate users who are very frustrated with privacy properties of social apps.

Pet simulators: Several popular 'simulation' games that mimic users' facial and vocal expressions are grouped under the game categories *Care Simulation*, *Pet Simulation*, and *Pets*. These app types have a total of 199K privacy reviews, and 60% of these are associated with strong negative emotions. Reviews left on these games are often assigned themes including `Unneeded Camera Access`, `Spying Concerns`, and `Unauthorized Surveillance`. These reviews largely express concern that the 'pet' is watching the user through

[10] Similar disclaimers have circulated elsewhere for years [24, 41].

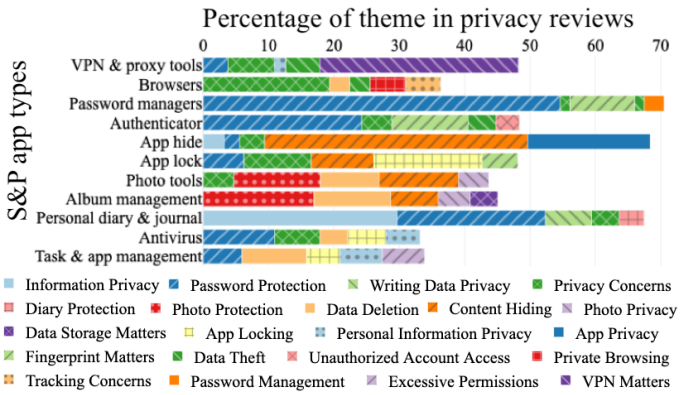

Figure 10: Top security & privacy app types themes (PTPR).

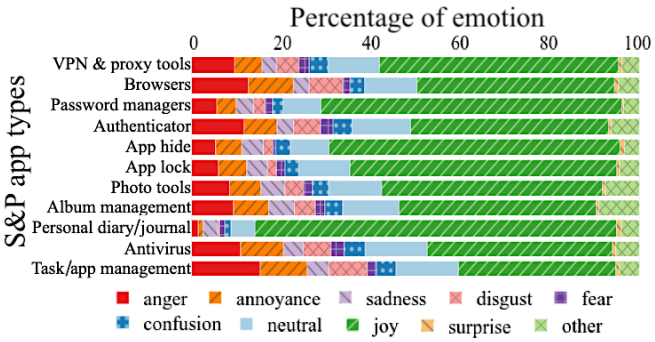

Figure 11: Top security & privacy app types with highly positive emotions.

cameras embedded in its eyes. For example: "*I don't recommend the app. She is immensely dangerous as she has cameras for eyes. She captured my picture. I was playing with it at 3am and she said she would come to my house.*" Though these reviews are based on misconceptions,[13] as these games are primarily intended for children, they often include heightened emotions. Reviews such as these were prevalent in the United States, Brazil, India, Mexico, and Italy. They first appear in early 2014 and have not diminished since.

Child monitors and location tracking: *Child Monitors & Location Tracking* and *Parental Controls* apps also receive a lot of negative feedback, with 52% of 135K privacy reviews associated with negative emotions. Generic `Privacy Concerns` is the top theme; somewhat less common, but more specific, themes include `Children Privacy Concerns` and `Monitoring Children`. Reviewers of these apps typically complain about being tracked by the app or object to the existence of this app type in general.[14] However, positive privacy reviews of child-monitoring apps are also common (36% contain 'Joy'). Positive reviews frequently praise the ability to `Track` and `Access Location`. Conflicts between children's privacy and parental supervision have been studied in a variety of contexts (e.g., [16, 76]), including a study of 736 reviews of child-monitoring apps [27]. In that study, which explicitly aimed to study reviews by children, most reviews were negative.

Other work has reported on the use of these apps for intimate partner abuse [12]. Our manual analysis did not identify any reviews explicitly acknowledging tracking adults, and we observe few reviews in related categories like `Spying concerns` or `Unauthorized surveillance`. This identifies a limitation of using our approach to complement user studies or surveys, namely that we cannot guarantee that reviews on a particular topic will be part of our data collection.

[13] https://www.usatoday.com/story/news/nation-now/2014/02/20/talking-angela-app-scare-hoax/5635337/

[14] Because these reviews may have been by children, we provide no quotes.

7.2 Privacy Protective Apps: Quite Positive!

One might intuit that when users write about privacy, they primarily complain, and hence those reviews are associated with negative emotions. Interestingly, 32% of all privacy reviews are associated with 'Joy' emotion. Often these reviews express appreciation for a particular privacy feature (e.g., private chat). To explore this further, we identified app types in the top 50 with at least 25% of reviews associated with 'Joy' (i.e., privacy positive reviews). Of the 23 app types satisfying this condition, the majority were privacy- and security-focused.

Below we summarize reviews from these privacy- and security-focused app types. Their dominant privacy themes are shown in Figure 10, and Figure 11 shows the emotion distribution. At a high level, users appreciate the (perceived) protections they receive from these apps. Our results confirm and extend prior work while also highlighting research gaps.

VPN & proxy tools: These apps received 128K privacy reviews, and 53% of these express 'Joy.' Reviewers broadly discussed `VPN Matters`, `Privacy Concerns`, and `Data Theft` themes. `VPN Matters` reviews frequently consist of short, vague endorsements (e.g., "*Great VPN, among the best out there*"). We looked at the fine grained issues within the VPN matters theme, such as, (`Best VPN`) and found the issue names similarly undescriptive. Broad affection for VPNs has been reported in prior measurements [4, 18]. Within `Privacy Concerns`, we also see fairly generic positive reviews, grouped under issues like `Privacy Protection` (e.g., "*Love the app. I get decent speeds and excellent privacy.*") and `IP Protection`. These comments are similar to terminology appearing in influencer VPN ads [4].

Differently from some prior work, reviewers in our dataset do not commonly mention benefits such as protection against internet surveillance [52, 62], utility for censorship evasion [18], or lack of server-side logging [62]. Further, while findings from prior work on VPNs tend to emphasize specific adversaries [4, 18, 62], we don't observe themes or issues with this emphasis. As expected from prior work [70], reviews

commonly show confused mental models, e.g., when one user claims a VPN "*Hides my IP address from my internet ISP.*"

Browsers: These apps receive the fifth-most privacy reviews (332K) of all app types, 44% of which express 'Joy.' The majority of these privacy-positive reviews apply to smaller browsers that advertise privacy-focused design. Reviews praise `Private Browsing` modes or private browsers and built-in tracking protection (`Tracking Concerns`), e.g., "*Amazing browser for your privacy, blocking trackers. They do not keep search records is just what people need recently.*" Overall, users seem to appreciate browsers with enhanced privacy protections. Browsers are the only security & privacy app type with significantly increasing (KPSS $p \leq 0.05$) privacy reviews: a two-year average growth of 0.5% points in $PPR_{Browsers}$ (46.5% average relative growth).

App Hide and App Lock: App hiders attempt to conceal a user-selected list of apps from appearing in the list of installed apps. They generally achieve this functionality by being a *launcher*, the default navigation app of the OS. App lockers provide access control mechanisms (e.g., a password) before a user is able to open an app, provided the user is using the app locker as the launcher. Although they have related functionality, app lockers do not attempt to hide apps.

These two app types together have 148K privacy reviews, of which ∼60% express 'Joy.' Themes and issues overlap almost completely across the two app types. Reviewers of *App Lock* apps praise `Content Hiding` (e.g., "*Perfect application. It hides videos, apps, and photos.*"). Similarly, reviews for *App Hide* apps express satisfaction with their hiding functionality under the theme `App Privacy`.

Despite their popularity and users' apparent satisfaction with app lockers/hiders, surprisingly little research has examined these tools. Sambasivan et al. found important use cases for app lockers among women in South Asia [68]. Though we do not have gender information, we find that India contributed the most reviews for these apps. Kenya, Nigeria, Zambia, Venezuela, Pakistan, and Türkiye also contribute a high rate of these reviews, but use in these regions has not, to our knowledge, been studied. Other work points out that device sharing creates important threats that are not always well supported by developers and security professionals [75].

Researchers have found some app lockers may be easily circumventable [45], suggesting that users may be less protected than they believe. Other research has shown app lockers' resemblance to malware [7, 65]. However, despite wide use, there is little research analyzing the security, privacy, and usability of these apps. We argue these apps remain an interesting research topic.

Photo tools and album management: The *Photo tools* app type has 208K privacy reviews, while *Album management* has 145K. Reviews for these app types frequently express 'Joy' (>45%), often praising `Photo Protection` (e.g., "*I love this app. Photos are ALWAYS protected*") and `Content Hiding` (e.g., "*Greatest application for hiding photos or vids*") features. Unlike app lockers and hiders, these apps allow users to secure media beyond the initial lock screen.

Diary apps: Apps in this category receive a perhaps surprising amount of privacy-relevant reviews (149K). These reviews carry an exceptionally positive tone (80.7% marked with 'Joy', the highest rate among all app types) and most often fall under the themes `Information Privacy` and `Password Protection`. Users most often find these apps useful to `Keep secrets` (within the `Information Privacy` theme): "*I really like this. I can keep my secrets. Seriously, thanks.*" Some users specifically praise the ability to password-protect diary entries. These apps are highly regarded and widely used. However, we are unaware of any recent technical analyses of these tools, though some older work exists [19]. We recommend future investigations into how secure these apps are.

Antivirus & task management: *Antivirus* app type has 106K privacy reviews, of which 41% express 'Joy.' `Password Protection`, `Privacy Concerns`, `App Locking`, `Personal Information Privacy`, and `Data Deletion` are the most common themes. Users comment about a variety of issues outside the traditional antivirus app functionality, which we posit relates to antivirus apps expanding their feature offerings.[15] For example, we see praise for app locking features not only in apps categorized as app lockers, but also in general antivirus apps, many of which offer such features. We see relatively fewer mentions of malware (the primary purpose of antivirus software); examples from issues like `Phone Protection` and `Malware Protection`, include: "*This is a perfect app. It finds and removes malware very fast. Further, it detects apps that are a threat to your privacy. I 100% recommend it.*"

The *Task & app management* app type has 51k privacy reviews, of which 35% are privacy positive. These apps exhibit similar trends to antivirus apps, perhaps because of large overlap in functionality: both managers and antivirus programs offer security and performance features. However, reviews of task management apps include more reviews about `Excessive permissions`. Though both app types require sensitive permissions to function (e.g., accessing all files), task & app management users may be more hesitant to grant these permissions outside a security context: "*what is up with these crazy permissions? thanks. nope.*"

Finding 8: Within the 32% of privacy reviews that are positive, users praise privacy-protecting mechanisms (data deletion, hiding, password-protected access) for several data types (photos, diary entries, app visibility, browsing history).

[15] https://www.pcmag.com/picks/the-best-security-suites

8 Discussion & Conclusion

In examining more than a decade of Google Play app reviews, we find that privacy reviews are growing at a biannual rate of 9%. `Data Deletion` is the number one privacy issue worldwide in terms of total reviews and is a top-5 concern in 47 countries. While this issue is growing, other prevalent issues such as those around permissions (e.g., `Excessive Permissions`) are declining. We further illustrated how an emotions classifier can illuminate which app types cause the most privacy concern and which receive the most privacy praise, across an entire app store.

User research on security & privacy tools rarely focuses on what users appreciate; rather, it highlights shortcomings (e.g., [36, 44, 62, 70]). Our analysis adds perspective by unearthing several potential **privacy wins**. First, we found a large body of positive privacy reviews for app lockers and hiders, VPNs, journaling apps, and album management. Many of these app categories are understudied; future work could investigate them in more depth, including improvements to support user workflows and technical analyses of whether apps are providing the privacy users expect. Second, we see that, over time, the ratio of permission-related complaints in privacy reviews has dropped by more than half (§5.1). This steep decline suggests permissions concerns could be abating, after concerted effort to improve permissions systems. This hypothesis would be well served by a future user study.

Our analysis can also be leveraged to **identify anomalous behaviors**, such as countries with unique patterns of topic discussions (e.g., Nigeria and Türkiye), or countries with abnormally high privacy-review growth rates (e.g., Indonesia). We uncovered large groups of reviewers who use reviews to communicate with developers in ways unlikely to achieve their goals [38]. Examples include ineffective quasi-legal privacy disclaimers in Türkiye, as well as data deletion requests for specific accounts in Indonesia.

As previously noted [29], this privacy-review analysis could **help developers**. Broadly speaking, we see two types of privacy feedback. Non-specific feedback, such as reviews that say "*this is privacy invasive, do not install*," are not directly actionable, but they do offer developers an understanding of privacy sentiment, and their volume matters since they often discourage other users from installing an app. More specific feedback can be turned into actionable insights (e.g., "*please add private chat*"). Finally, privacy-positive reviews may offer developers a new kind of privacy success metric.

We argue that our analysis approach can be useful for a variety of **research purposes**. We have shown in this paper examples of: (1) *corroborating existing research*, such as the broad public support for VPNs [18] (in § 7.2), and the divergent views about child monitoring apps [16, 76]; (2) *adding context to prior work*, such as showing that privacy concerns about financial loan apps from Kenya [50] are being similarly reported in Indonesia, India, and Thailand (in § 5.3); and (3) *identifying unexpected or emerging privacy issues* that can seed future work using interviews (to enable direct discussion with users) or surveys (that can direct users to focus on specific aspects). Examples include examining if diary apps and app lockers actually deliver the privacy features offered, and whether users correctly understand the privacy offerings of those apps, in addition to exploring why permissions are a decreasing topic of discussion.

Recent advances in large language models (LLMs), such as OpenAI's GPT-4 [56] or Google's Gemini [39], have shown promising performance gains on multiple natural language tasks. However, these LLMs require significant prompt engineering (see Appendix B), have high inference costs, and cannot easily scale to large datasets, unless they have been distilled to smaller models [34]. Exploring such distillation approaches for the purpose of improving the models used in this work is a natural avenue of future work.

In summary, we show that large-scale text analysis, followed by zooming in to explore changing trends or unusual patterns, is useful to both summarize the privacy pulse as it ebbs and flows across much of the globe, as well as to surface privacy issues that may not be regularly tracked.

9 Acknowledgements

We would like to thank Kurt Thomas and Patrick Gage Kelley for their insightful comments on earlier manuscripts. We also thank the anonymous USENIX reviewers for their feedback, and the Google Play team for providing data access and removing spying reviews we identified.

A Translated Languages

These 24 languages were translated (percentage of our data): Spanish (13.3%), Indonesian (9.3%), Portuguese (7.8%), Russian (5.8%), Turkish (4.2%), German (3.3%), Arabic (2.5%), French (2.3%), Italian (1.7%), Korean (1.7%), Vietnamese (1.1%), Polish (1%), Persian (0.6%), Thai (0.5%), Dutch (0.5%), Romanian (0.2%), Czech (0.2%), Hungarian (0.2%), Ukrainian (0.1%), Greek (0.1%), Chinese (0.1%), Japanese (0.1%), Malay (0.07%), Hindi (0.06%).

B Privacy Classifier Baselines

We investigated various modern transformer architectures (excluding traditional models, such as BiLSTM, which are inferior), and selected six models based on comparisons made within the recently published and extensively cited DeBERTaV3 paper [32]. In addition, we also considered BART, T5, and FLAN-T5 models for their popularity. We chose the largest available variant of DeBERTaV3, and chose other models' sizes accordingly. We use Hark's [29] T5-11B model as a comparative baseline; our T5-11B model only differs in the diverse training dataset used (§3.1). This list of models is not exhaustive, but we believe it offers a reasonable baseline.

All models were trained and tested on the datasets created in §3.1. Each model was trained with parameter optimization and 'early stopping' (using validation loss as the metric) to avoid overfitting. Each model's best trained variant (highest obtained F1) are reported in Table 4. Our findings suggest that our T5-11B model delivers the best performance across the board, with a highest ROC-AUC of 0.95 and F1 of 0.87.

In addition, we also experimented with Gemini 1.0 Pro, a state-of-the-art (closed-source) LLM [39]. Despite our prompt engineering (i.e., trying multiple prompt variants and using few-shot examples), we could not better the performance T5-11B. Our prompts described our privacy taxonomy, where each high level concept was defined using fine-grained aspects. The prompts further included instances of reviews and their labels as few-shot examples. For the best performing prompt (see the extended paper [3]), the Gemini Pro performed well on recall (0.83) but precision suffered (0.77), with a ROC-AUC of 0.87. We hypothesize that the poor precision arises because the privacy nuances captured in our carefully annotated training dataset are hard to establish using constrained prompts. Exploring LoRA techniques [35] to finetune an LLM for this task is outside the scope of this paper.

Abstract

Due to the prevalence of scalping and the promotion of real-name ticketing systems, user-oriented mobile ticket grabbing apps have become a popular pattern for scalpers. Compared with traditional scalper-oriented scalping, ticket grabbing apps pose security and privacy risks to users directly. In our study, we take the first step towards revealing the ticket grabbing app ecosystem from the perspectives of app developers, app users, and target platforms synthetically.

We built a large-scale dataset of ticket grabbing apps in the wild within China, containing 758 Chinese ticket grabbing apps with 3,121 versions. Based on the detailed analysis of these apps, we found that ticket grabbing has formed a mature industrial chain, with various specialized technical characteristics to enhance the success rate, such as the abuse of Android accessibility services. We also revealed the profit model of ticket grabbing apps, and disclosed severe security and privacy hazards they pose to end users, including the collection of sensitive information and continuous screenshots. We further conducted an online survey involving 184 participants to get users' usage and privacy concerns on ticket grabbing apps, and regrettably found that users prioritize "tickets" over "privacy". Finally, we proposed an "Indirect Combat" approach to assist in the defense mechanisms. In summary, our findings provide target platforms and users with a better understanding of the ticket grabbing app ecosystem in China, enabling them to better detect and combat these apps.

1 Introduction

For some limited resources such as train tickets, concert or sports tickets, the resource providers frequently fall short of meeting market demands. However, people often exhibit significant enthusiasm towards these sought-after resources. In order to fulfill the intense demand of consumers, "scalping"[1] behavior came into being. Scalping behavior is a global phenomenon with significant negative consequences. It could disrupt market equilibrium and impose economic losses on original consumers [50, 73, 77]. It is a very frequent and frustrating reality when fans go to the ticket websites in the first time, only to find that there are no more tickets left [41]. Facing the prevalence of scalping, many countries and regions have published legislation to clarify the illegality of scalping [7, 17, 33], such as the "Better Online Ticket Sales (BOTS) Act" [7] in the United States.

As technology advanced, scalpers turned to automate their purchasing behavior. Ticket bots were once the most frequently used tools by scalpers. They snapped up a large number of limited resources in advance and made a profit through price differences during the resale process in the secondary market. We call this traditional scalping *"Scalper-driven model"*. According to the 2023 Bad Bot Report [1] on entertainment websites, 83.4% of total global traffic came from automation. However, with the promotion of the real-name ticket systems [91, 92], it is more difficult for scalpers to directly acquire numerous resources using ticket bots. Moreover, some research has explored the detection measures against ticket bots [90]. Therefore, the scalpers changed their grabbing method [68]. They developed user-oriented mobile "ticket grabbing apps" that allow users to directly access specific resources and the scalpers can generate profit from users during the usage. These apps do not acquire large quantities of resources in bulk. Instead, they collect users' personal information in advance and subsequently make purchases on behalf of the users. We call this scalping *"User-driven model"*, which is the primary focus of our research.

Motivation. In our work, we concentrated on the ticket grabbing apps and tried to explore the ecosystems behind these apps. Ticket grabbing apps, compared to ticket bots, represent an upgraded version that adapts to real-name ticket systems. Ticket bots are run by scalpers, while the ticket grabbing apps interact directly with users, posing more immediate risks to them and some apps themselves are even viruses [31]. Moreover, despite the government's continuous advocacy to the

*Corresponding author: Baojun Liu.

[1]Scalping refers to the "acquisition of goods or services in a manner that a normal user would be unable to undertake manually." [24]

public not to use unofficial channels to buy tickets, the usage of ticket grabbing apps has not been effectively alleviated. Users' understanding of ticket grabbing apps, and their privacy concerns are still unclear.

Due to the potential risks and chaos posed by ticket grabbing apps, it is of great significance to understand the ecosystem of ticket grabbing apps which can help maintain market fairness and protect the privacy of consumers. However, there is currently a lack of research focusing on ticket grabbing apps. Although some work [68, 73] has analyzed the implementation of ticket bots based on real cases, there has been no large-scale measurement of ticket grabbing apps. Therefore, our work marks the first exploration of the ecosystem of ticket grabbing apps, investigating both their software implementation and user privacy perception. Certainly, the ecosystem of mobile ticket grabbing apps involves three parties: app developers, app users, and target platforms (which supply resources to be snapped up). So, we raised our research questions from the perspectives of these three parties separately.

• RQ1: [App Developers] What technical tricks do developers employ to implement their grabbing functions? How do they make money from ticket grabbing apps?

• RQ2: [App Users] What security risks do ticket grabbing apps pose to users? Are users aware of these risks?

• RQ3: [Target Platforms] How is the relationship between ticket grabbing apps and target platforms? What methods do the apps utilize to evade detection by target platforms?

Our work. Considering that there is no publicly available dataset for ticket grabbing apps and the apps might be swiftly removed or frequently updated, we collaborated with a renowned security vendor in China to build a large-scale dataset. The dataset consists of 758 distinct ticket grabbing apps, totaling 3,121 versions. Then, using a combination of static and dynamic analysis methods, we gained insights into the technical characteristics of these apps and the potential security risks. Additionally, we conducted an online survey involving 184 participants to gauge the social characteristics of the apps and assess participants' privacy concerns. Finally, according to the analysis results, we summarized the gang characteristics and bypass tricks of ticket grabbing apps. Additionally, we proposed suggestions on cracking down the development and distribution of ticket grabbing apps. While our research focused on a China-wide dataset, yet ticket grabbing apps are not exclusive to China. Similar tools are used worldwide [34, 35] and our findings have broader applicability. We chose China as a representative case due to the substantial demand and usage for ticket grabbing apps in this region.

Specifically, from the perspective of developers (Section 4), we found that ticket grabbing apps are highly automated. Some apps use scalper servers as intermediaries to send purchase requests to target servers, while others abuse Android accessibility services to achieve automated grabbing directly at the user end. In addition, we identified the profit models employed by ticket grabbing apps, often using the free version as bait. Then, from a user's perspective (Section 5), we revealed that ticket grabbing apps have certain security and privacy risks, such as the acquisition of numerous dangerous permissions and the collection of sensitive information. Although 70.59% of the participants are aware of the risks of ticket grabbing apps, due to the strong desire for tickets, 84.5% of the participants still used ticket grabbing apps. Finally, from the perspective of the target platforms (Section 6), we noticed that different ticket grabbing apps may have similar user interface (UI) designs, and they commonly conceal developers' identity information within their signatures. We also summarized the bypass tricks used by ticket grabbing apps to evade the continuously improving detection mechanisms of target platforms, such as CAPTCHA solving services, multiple IP proxies, etc. Furthermore, we proposed an "Indirect Combat" method to prevent the development and spread of ticket grabbing apps. Overall, our work is the first to examine the ecosystem of the ticket grabbing apps in China, providing new insights into understanding these apps.

Contributions. Contributions of the paper are as follows:

•*New underground industry.* We take the first step towards analysis of ticket grabbing apps ecosystem, which is a rapidly developing underground industry. Our work built the largest dataset of Chinese ticket grabbing apps to date, unveiling both the technical and social characteristics behind the apps.

•*New privacy risk.* Our work revealed for the first time the security risks posed by ticket grabbing apps and obtained users' usage and privacy concerns about the apps.

•*New insights.* Our analysis of gang characteristics and bypass methods provides new insights into the governance of ticket grabbing apps. We put forward an "Indirect Combat" approach and three specific suggestions that could indirectly crack down on the emergence of ticket grabbing apps.

2 Background

Workflow. Figure 1 illustrates the typical workflow of ticket grabbing apps. To delegate the grabbing task, users need to provide the order information and other necessary information (e.g., login credentials) to the app. Typically, this step entails an additional payment to the developer (①) to activate the grabbing functionality. Subsequently, the ticket grabbing apps interact with the target platforms to procure the desired goods on behalf of users (②), and relay the result back to them (③). Upon successful acquisition of the goods, users can find their pending orders on the target platform and complete the necessary payments to finish the transaction (④). Note that step ④ can be skipped, as certain apps offer users the option to directly input their payment passwords in step ①, thereby facilitating automated payment processing.

Comparison with ticket bots. Both ticket bots and ticket grabbing apps are tools for acquiring tickets, yet their operational models vary significantly. Ticket bots employ mass account creation to increase their chances of securing more

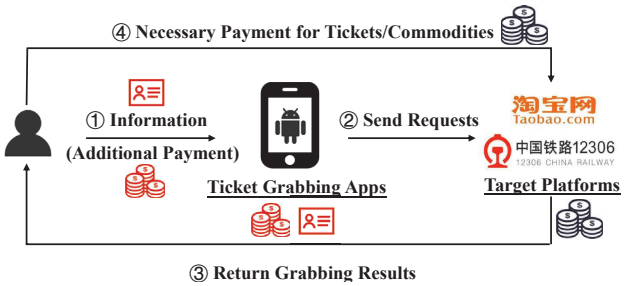

Figure 1: Typically workflow of ticket grabbing apps.

resources. They are primarily operated by scalpers, who then profit by reselling tickets. In contrast, ticket grabbing apps are operated directly by users, and profit from their promised ticket acquisition capabilities. These apps can be seen as successors to ticket bots, adapting to the ongoing improvements in ticketing systems, particularly the real-name authentication mechanism that restricts bulk registration.

Threat model. Ticket grabbing apps severely disrupt the order of market transactions, putting anyone at risk of falling victim. Those who do not use these apps may miss out on desired tickets due to others using such apps. For app users, ticket grabbing apps could directly access their private information and control their devices. Our research focuses on the security threats of ticket grabbing apps, with app users emerging as the direct victims, i.e., individuals who are eager to acquire sought-after tickets or commodities. These users turn to ticket grabbing apps with the expectation of increasing their chances of successful purchases. However, as depicted in Figure 1, using ticket grabbing apps requires users to disclose necessary information, including credentials and sometimes payment passwords. This raises privacy risks concerning the potential disclosure of personal information to unauthorized third parties and also instills security concerns for users regarding their devices being abused for malicious operations. Besides, users may be enticed to pay an additional fee to activate the grabbing feature (see Section 4.2). However, it remains uncertain whether this payment results in more successful grabbing endeavors, potentially leading innocent users into scams.

3 Methodology

To answer the above research questions, we first built a large-scale dataset of Chinese ticket grabbing apps, then performed app analysis to uncover their technical features and privacy implications. We also conducted an online survey to get the usage and social characteristics of ticket grabbing apps from the user's perspective. The results of RQ1 and RQ2 are based on the app analysis and user study synthetically. The results of RQ3 are obtained separately from app analysis. In this section, we will introduce the methods of data collection and app analysis, as well as the design of the user study.

3.1 Dataset

Currently, there is no publicly available dataset specifically targeting ticket grabbing apps. Furthermore, considering that the ticket grabbing apps might be swiftly removed or frequently updated, it is difficult to directly crawl the apps from app stores. Therefore, we collaborated with a renowned Chinese security vendor named "Qihoo 360" to build up the first dataset of Chinese ticket grabbing apps in the wild. We first obtained some typical ticket grabbing apps from the search engines as the seed dataset, then expanded our dataset with more apps in "360 App Assistant" using snowball sampling [56]. The process of data collection is depicted in Figure 2.

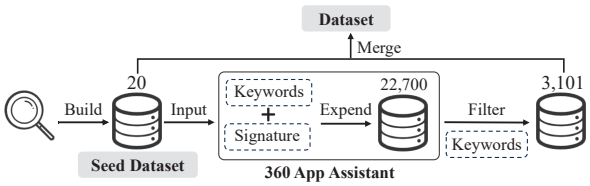

Figure 2: The steps of data collection.

Specifically, we first simulated a user's behavior who is eager to search for a ticket grabbing app. Utilizing Baidu, the most widely used search engine in China, we entered the keyword "ticket grabbing apps" and identified four common types of ticket grabbing apps according to the results, including (1) train grabbing apps, (2) concert/sports grabbing apps, (3) hospital appointment grabbing apps, and (4) commodity grabbing apps. Then, we conducted a manual selection process based on descriptions from the search results and finally selected the five most typical ticket grabbing apps for each type. A total of 20 apps were selected as the seed dataset for the next phase of data collection.

Then, we used the snowball sampling method to expand the seed dataset. We searched apps with similar application names from "360 App Assistant", a well-known free app store in China. The keyword we used was "grabbing" as almost all the application names in the seed dataset contain this word. Among the queried apps, we sorted them according to the number of installations and selected the top 200. Leveraging the app signatures, we established connections with other apps that shared the same signature, as it indicated that they likely originated from the same developer and offered similar functionalities. This step resulted in the expansion of the dataset to a total of 22,700 apps.

Finally, we again filtered the apps by application name using more precise keywords as there are a lot of apps unrelated to ticket grabbing. The keywords we used include "Maotai grabbing", "Shoe grabbing", "Ticket grabbing", "Appointment grabbing", and we finally got 3,101 apps after filtration.

Dataset overview. The data collection spanned April 2023 and we collected 3,121 ticket grabbing apps, including the 20

apps in the seed dataset. Within the dataset, "Ticket Grabbing Assistant" was the most prevalent application name, accounting for 43.7%. The average installation count for these apps was 16,198. Furthermore, to provide a basis for contrasting ticket grabbing apps with other benign apps, we randomly selected 50 apps from the top download lists of both "Google Play" and "360 App Assistant" (the same source as the selected grabbing apps) respectively, amounting to 100 apps in total. The selected ticket grabbing apps and the list of benign apps are publicly available on the online appendix [22].

3.2 App Analysis

After data collection, to obtain the technical characteristics of ticket grabbing apps, as well as the privacy and security risks posed by them, we conducted a synthetical analysis of the apps in our dataset. To avoid non-redundant analysis [69], we excluded the apps sharing identical package names, signatures, and app names, considering them as different versions of the same app. We chose the apps with the highest number of downloads as the representative and finally selected 758 unique apps as the primary subjects of our analysis. In addition, among the rest of the apps with duplicate versions, we chose seven app groups that have more than 100 versions for additional version analysis. Details of these app groups are provided in Table 2 in Appendix A. Analysis methods include simulated runs, static analysis, and dynamic analysis. Note that the primary conclusions in this paper are derived from 758 distinct applications. We only use the seven groups of applications for version analysis.

• **Simulated runs.** To gain an intuitive understanding of the functionality of ticket grabbing apps, we conducted simulated runs using LDPlayer [18], a free Android emulator. By creating a virtual runtime environment, we gained insights into how the apps are used and explored the various functions they offer. To ensure compatibility, we utilized a rooted Android 9 (64-bit) phone, as some apps require a rooted environment to function properly. In our experiments, we manually selected a set of representative apps that encompassed the four types of ticket grabbing apps for simulation.

• **Static analysis.** AndroGuard [3] provides robust capabilities for comprehensive analysis of various aspects of an Android application. We leveraged this tool to extract crucial information such as the application's signature, requested permissions, and embedded strings. By utilizing AndroGuard, we were able to gain valuable insights into the inner workings and characteristics of the ticket grabbing apps.

• **Dynamic analysis.** Our work incorporates two components of dynamic analysis. Firstly, during the simulated runs, we used Fiddler [13] to capture the traffic data generated by the apps. Additionally, we employed the Qianxin sandbox [27] to conduct more extensive dynamic analysis on 758 apps in our dataset. Based on the sandbox results, we can retrieve the requested domain names, dynamic behaviors, and real-time screenshots of the apps. With the comprehensive results of dynamic analysis, we gained deeper insights into the apps' behavior, interactions, and potential security vulnerabilities.

3.3 User Study

In addition to the app analysis, we conducted an online survey to uncover the real impact of ticket grabbing apps on users and gain a more comprehensive understanding of the ecosystem.

3.3.1 Survey Instrument

The questionnaire was divided into three parts, and the full questionnaire is provided in the online appendix [22].

• **Usage details.** To get users' experiences with ticket grabbing apps, we initially asked participants if they had ever contacted scalpers or used mobile ticket grabbing apps. For those who had used ticket grabbing apps, we asked about their usage scenarios and whether they had successfully obtained the desired goods. We also inquired about the channels through which they downloaded such apps and whether they incurred any additional charges during usage.

• **Privacy concerns.** For those who ever used ticket grabbing apps. We inquired about the types of information participants provided to ticket grabbing apps and their privacy concerns regarding the apps. For all the participants, we finally investigated their awareness of the legality of ticket grabbing apps.

• **Demographic collection.** As customary, we collected participants' demographic information at the end of the questionnaire, including age, gender, level of education, and whether they were employed in computer-related occupations.

3.3.2 Recruitment

To eliminate potential bias in the questionnaire, we conducted a pre-test within our laboratory. We gathered 17 responses and subsequently refined the questionnaire's content and wording based on their feedback. Afterward, we distributed the questionnaire through social media and got 66 responses. Then we recruited more participants via Wenjuanxing [37], the most popular online survey platform in China. The survey lasted from early September to late September 2023, culminating in 184 responses and the participants were all from China. The average completion time for the questionnaire was 163.66 seconds. Based on the local hourly wage standard, we provided each participant with 3 CNY as a reward. The demographic distribution is summarized in Table 3 in Appendix A.

3.4 Ethic

Although our institution does not have a formal ethics committee like an Institutional Review Board (IRB), we proactively sought approval from organizations that served similar functions in our institution. Specifically, in the process of app collection, we followed a similar approach to previous studies

on cybercrime [58, 74, 81] by collaborating with security companies to obtain ticket grabbing apps. For the user study, we followed the standard ethical research procedures [52, 65, 71] to ensure the confidentiality of information provided by participants. We conducted informed consent before the questionnaire and allowed users to quit the questionnaire any time they felt uncomfortable. We did not collect any personal information and the results were saved on the local computer of the researcher.

3.5 Limitations

• **App collection.** All our analyses were conducted exclusively on Chinese ticket grabbing apps. Ticket grabbing tools are also utilized in other countries [34, 35]. However, due to the highly dynamic nature of ticket grabbing apps, collecting such apps from app stores at scale is challenging. Our research has been facilitated by collaborating with a Chinese security company that has extensively collected historical versions of ticket grabbing apps. Nevertheless, China has been widely reported [11, 12, 25] for its extensive usage of ticket grabbing apps. Hence, our analysis of Chinese apps could serve as one representative example to reveal key aspects of this industry. Our preliminary investigation [36] also revealed that some popular automation apps [6, 20, 30, 32] share similar implementation principles with ticket grabbing apps, suggesting our analytical findings could offer insights for them as well.

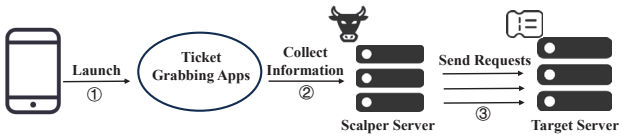
Additionally, we only focused on Android apps and did not include IOS apps. This is mainly because of the more stringent requirements imposed by the IOS app store, resulting in a limited number of ticket grabbing apps available. Besides, we primarily gathered apps according to the names of apps. Although we expanded the scale of the dataset as much as possible, apps with unconventional names may be overlooked. Similarly, for the selection of benign apps, we strive for best-effort coverage of more apps and enhance sample diversity. However, we need to admit that the dataset we set up cannot cover all ticket grabbing apps and benign apps on the market, but can adequately represent commonly used ones.

• **App analysis.** During the simulated runs, we opted to employ emulators rather than physical devices. It is important to acknowledge that emulator-based simulations may not completely mirror real-world conditions, as certain apps can detect the emulator environment. Consequently, we excluded the apps that did not perform adequately in the emulator during the simulated runs. Nevertheless, considering that some applications require rooted devices to run, emulators can offer this environment without adding extra complexity.

Moreover, when using the Qianxin sandbox for dynamic analysis, due to the limited interaction of the sandbox, the traffic generated and the behavior displayed are limited. However, the sandbox we utilized operates in an out-of-the-box analysis mode, surpassing other in-the-box sandboxes like Cuckoo [9] in terms of analysis capabilities.

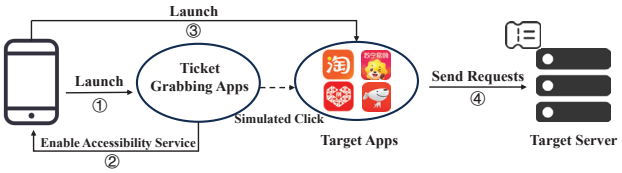
• **User study.** Lastly, in the online questionnaire, the results are based on the participants' own reports, which may lead to potential omissions regarding their usage and specific details of ticket grabbing apps. The actual situation can be more serious and widespread than the answers we received.

4 RQ1: From the Perspective of Developers



From this section, we systematically addressed our research questions and presented our findings. In this section, we showed the results from the perspective of developers, including the technical characteristics of ticket grabbing apps and the profit model designed by app developers.

4.1 Technical Characteristics



The network traffic patterns generated during the runtime of an application can provide great insights into observing its workflow, especially the backend domains it connected. Based on the sandbox results from 758 apps, we extracted 866 domain names from the Domain Name System (DNS) queries. We further categorized these domains by either accessing them directly or investigating them in search engines. After removing certain noisy domain names (e.g., reverse DNS queries and echo requests), we categorized the accessed domain names into three groups: (1) scalper servers (2) target servers, and (3) third-party services. By combining domain name information and our observation on simulated runs, we have summarized three technical characteristics of the ticket grabbing apps, which are introduced in detail as follows.

4.1.1 Automated Grabbing Modes

The core function of ticket grabbing apps is to automatically snap up the desired goods from target platforms. By integrating the connected domains and service calls made during the simulated run, we identified two distinct automated grabbing modes employed by ticket grabbing apps.

(a) Automated request submission.

(b) Automated simulation click.

Figure 3: Two grabbing modes of ticket grabbing apps.

• **Automated request submission.** We found several apps that leverage dedicated "scalper servers" for automated grabbing operations. As shown in Figure 3a, instead of directly connecting to the target platforms, the ticket grabbing apps will submit the collected user credentials and order information to scalper servers. These servers are usually cloud-based servers with significantly better performance and concurrency than normal cellphones. Then, scalper servers would repeatedly submit purchase requests to the target server on behalf of the users, acting as an intermediary.

• **Automated simulated click.** This method leverages the Android accessibility service to simulate clicks and directly submit purchase requests to target platforms from the user end. Accessibility service is an inherent Android feature that provides convenience for users with disabilities, especially those with visual impairments. Unfortunately, in recent years, this service has been widely abused in the underground industry [69]. As depicted in Figure 3b, the ticket grabbing apps first prompt users to modify system settings on their devices, i.e., enable the accessibility services. Then, users need to set specific trigger conditions on the ticket grabbing apps, such as the start time of grabbing. Afterward, they have to open the target app and navigate to the desired page. Once the trigger conditions are met, the accessibility service automatically performs user actions like clicking buttons and filling out forms to complete the purchase process. Additionally, Auto.JS Pro is commonly employed in conjunction with accessibility services to accomplish automated tasks through the utilization of automated JavaScript scripts on Android devices.

Based on our simulated runs, we observed that the first mode was adopted by various ticket grabbing apps, including train ticket grabbing apps, concert/sports ticket grabbing apps, and hospital appointment grabbing apps. In contrast, the second mode was primarily utilized by commodity grabbing apps. This is because commodity grabbing apps' target servers are more likely to verify the traffic source to ensure it originates from their own apps. As a result, scalpers face challenges in using the first grabbing mode, prompting commodity grabbing apps to employ accessibility services for automated clicks on users' devices directly.

We then classified the dataset based on the grabbing modes, using whether the accessibility service needs to be enabled as the classification criterion. This can be identified in the static analysis through the *manifest.xml* as apps that require the accessibility service are obligated to register this service in the *manifest.xml*. Utilizing this approach, we identified that 540/758 (71.2%) apps had the accessibility service enabled, falling into the second kind of ticket grabbing apps. Conversely, 218 apps belonged to the first kind.

Clearly, both grabbing modes involve specific security and privacy risks. In the first mode, users are required to provide their credentials and personal information to the untrusted scalper servers, posing privacy concerns. The second mode necessitates users to grant the app extensive permissions, as

(a) A train ticket grabbing app. (b) A commodity grabbing app.

Figure 4: The screenshots of different ticket grabbing apps.

it enables accessibility services. The apps could then monitor user actions, access current windows, capture entered text, and perform actions like tapping, swiping, and clicking. A more detailed examination of the security and privacy risks of ticket grabbing apps will be provided in Section 5.2.

4.1.2 Grabbing Tricks

Different target platforms have different business logic, so ticket grabbing apps perform different automated grabbing modes and creatively propose different grabbing tricks to improve the success rate of automated purchasing behaviors. Next, we put together some tricks taken by the ticket grabbing apps to improve the grabbing ability.

• **Integrated grabbing platforms.** For the commodity grabbing apps, the target platforms are diverse, including Taobao (*"taobao.com"*), JD (*"jd.com"*), Suning (*"suning.com"*), and other popular shopping websites in China. To minimize development costs, we found that these apps generally provide integrated support for multiple platforms in one app, as shown in Figure 4b. Based on the results of simulated runs, each commodity grabbing app supports 2.64 shopping platforms on average, with Taobao being the most common. Such integration stems from the diverse e-commerce landscape of commodities in China. In contrast, since "12306" holds an exclusive train ticketing platform in China, train ticket grabbing (as shown in Figure 4a) apps do not need to support multi-platform. Their target domain would only be *"kyfw.12306.cn"*.

• **Time synchronization.** Due to the time delay between the user's devices and the target servers, the start time of grabbing could be delayed compared to the actual release time. Even though the time difference is only a millisecond, the target goods may be grabbed by others just in this time gap [23]. Therefore, some ticket grabbing apps perform time synchronization. Most of them utilize time synchronization APIs provided by the target platforms if available, such as Taobao's

"api.m.taobao.com/rest/api3.do?api=mtop.common.getTimestamp" and Suning's *"quan.suning.com/getSysTime.do"*. Through these APIs, the delay time between the target server can be determined. Based on the results of simulated runs on 50 commodity grabbing apps, 40/50 (80%) offer this feature.

As for the other kinds of apps, since the target platforms like "12306" do not provide such APIs, we found that six apps directly employ the Network Time Protocol (NTP) to obtain Coordinated Universal Time (UTC) by accessing *"2.android.pool.ntp.org"*, instead of aligning with the target server time. Furthermore, two apps were observed accessing *"time.tianqi.com"* to determine the time offset relative to "Beijing Time" for time synchronization.

• **Customized configuration.** For commodity grabbing apps, they allow users to personalize the grabbing start time (even before the release time), duration, and frequency as shown in Figure 4b, all of which contribute to an increased likelihood of successfully getting the target goods. In the case of other apps, users have the option to simultaneously grab tickets for multiple trains as shown in Figure 4a, thereby enhancing their chances of successful booking.

• **Bypass (BP) links.** As shown in Figure 4b, the apps offer various grabbing ways, including cart-based grabbing, page-based grabbing, and bypass (BP) link-based grabbing. The BP link is a URL that includes all the specifications of the product to be purchased. When clicking on the link, it directly takes users to the order submission page, eliminating the need to go through the process of selecting parameters. This minimizes delays caused by extensive interactions and provides users with a more convenient grabbing experience. Each product has its unique BP link, and the apps offer precise guidelines to users for generating the corresponding BP links.

• **High-performance support.** Apart from well-known cloud server providers, we observed that the ticket grabbing apps also utilize services from other cloud service providers to deliver higher performance. For example, "Xiequ Network" (*"xiequ.cn"*) offers millions of high-quality IP addresses and fully anonymous HTTPS proxy services. These features are sought after by ticket grabbing apps to evade detection and enhance grabbing performance. Additionally, certain apps utilize "Hexin Cloud" (*"hexiny.com"*), a group control platform that allows users to control hundreds of cloud machines on one physical device. This enhances the success rate of grabbing through high concurrency.

4.1.3 Third-Party Services

We assessed the dependence of ticket grabbing apps on third-party services according to the domain names in DNS queries. We mainly analyzed the identified app development platforms, image hosting platforms, and third-party SDKs.

• **Development platforms.** Our observations revealed that several app development platforms were used by ticket grabbing apps to simplify their development processes, such as *"appbsl.com"*, *"yimenyun.cn"*, *"dcloud.io"*, *"apps.xiaok1.cn"*, and *"longxinboke.top"*. These platforms provide the fundamental elements for app development, including integrated development environments (IDEs), frameworks, databases, cloud services, and the like. Notably, in addition to normal development support, they also offer paid services to help underground apps succeed. Regardless of whether an app complies with the platform policies and legal requirements, they can assist the developer to successfully release the app on mainstream markets by providing the regulation materials. Some of the development platforms even guarantee a "full refund in case of any issues during the app market release process". Such illicit support has strongly contributed to boosting underground industrial apps like grabbing apps.

• **Image hosting platforms.** Image hosting platforms provide reliable services for image uploading, sharing, and storing. As previously mentioned, some ticket grabbing apps do not have scalper servers, leading them to rely on image hosting platforms. Among the top ten domain names, we recognized four image hosting platforms, namely *"s1.ax1x.com"*, *"s3.bmp.ovh"*, *"images.shejidaren.com"*, and *"pic1.win4000.com"*. In addition, based on our analysis of the app groups, we also noted that some apps may change the image hosting platform due to business adjustments. For example, from *"shejidaren.com"* to *"pic.imgdb.cn"*. Moreover, these image hosting platforms could also support other illegal activities, such as child sexual [57] and phishing emails [28].

• **Software Development Kits (SDKs).** We first utilized LibRadar [19] to identify the third-party libraries within ticket grabbing apps. In total, 4,962 third-party libraries were detected, with 14 of them found in at least 50 apps. Combined with these results, we used the keywords in domain names to match the third-party SDKs within ticket grabbing apps and manually categorized them based on the functionality.

Map-related SDKs are the most commonly used especially in train ticket grabbing apps as they always provide users with a series of additional services related to travel, such as online taxi services. They generally integrate Baidu map SDK (*"api.map.baidu.com"*) and Amap SDK (*"abroad.apilocate.amap.com"*) to provide positioning functions. Another common category of SDKs is used for data statistics, such as Umeng (*"alog.umeng.com"*), Talkingdata (*"tdcv3.talkingdata.net"*), and Tencent Statistics (*"av1.xdrig.com"*). The third category pertains to message push, including Baidu push (*"api.tuisong.baidu.com"*), Xiaomi push (*"register.xmpush.global.xiaomi.com"*), and JPush (*"s.jpush.cn"*). Additionally, some apps integrated customer service SDKs to support online customer service, such as Qiyu (*"qy-swallow.qiyukf.com"*) and Meiqia (*"meiqia.com"*). We also observed SDKs related to payment, such as Alipay (*"openapi.alipay.com"*). This suggests that certain apps integrated online payment functionality, facilitating direct payments within the apps. Moreover, we also found SDKs for single sign-on (SSO) (*"oblog.ctobsnssdk.com"*, *"opencloud-*

wostore.cn") and Tencent Bugly (*"android.bugly.qq.com"*), which offer error monitoring and crash analysis services. These results align with Gao et al.'s [55], highlighting that the ticket grabbing apps abuse numerous third-party SDKs and those SDK providers do not conduct any review before offering the services.

4.2 Profit Model

Rather than profiting through resale, ticket grabbing apps sell users the ability to secure tickets. They directly act on the user end to assist in purchasing. According to our observation, all the apps we collected are free to download. However, these free versions of apps are just used to attract potential users. Developers gain money from users during their usage. Following are two types of profit models.

4.2.1 Paid Versions

Generally, the free version provides a trial opportunity, and if users wish to continue using it, they need to purchase a license key to activate the apps as shown in Figure 7a in Appendix A. Similarly, certain commodity grabbing apps induce users to purchase the latest version of the app through the pathways (e.g., links or chat groups) provided in the free version. Users could receive a key or the latest app upon completing payment, enabling them to begin using the full functionality of the ticket grabbing apps. Based on the domain names requested by the apps, we found the developers primarily utilized two web-based authentication systems, Paojiaoyun (*"paojiaoyun.com"*) and Eydata (*"eydata.net"*), to support the fee-charging feature. We also found that apps could switch from free to paid during version iteration. Taking "com.app.coomc" as an example, versions released after November 2022 have started accessing the "Rukey Network Verification" API (*"api.ruikeyz.com"*) to verify if the users have purchased the paid license keys.

According to our results, 14/50 (28%) of the simulated commodity grabbing apps employed this profit model. We then checked on the pathways provided by these apps and obtained the prices. We found that apps offer various service durations, including daily, monthly, quarterly, and yearly. Among these, daily service cater to short-term users, with an average price of 28.5 CNY. Yearly services are the most expensive, ranging from 50 CNY to 2,458 CNY, with an average price of 494.1 CNY. The prices are set by the app developers and may be related to the difficulty of grabbing target commodities.

4.2.2 Paid Services

Additionally, ticket grabbing apps provide some paid additional services in the free versions, such as the acceleration packages in train ticket grabbing apps as shown in Figure 7b in Appendix A. By buying this service, users can enhance the success rate of ticket purchases as claimed. In the online questionnaire, 38.82% of participants stated that they have made additional payments during the usage of ticket grabbing apps (Q9), and they are more likely to pay when using train tickets grabbing apps. These payments were not for acquiring the apps but rather for the mentioned paid service.

According to our observations on simulated runs, apps offer varying prices corresponding to different capabilities, ranging from 10-80 CNY. In order to attract more users to purchase paid services, ticket grabbing apps commonly employ persuasive tactics on the payment page to instill anxiety in users. They lead users to believe that only by paying can they successfully secure tickets, with a higher payment equating to a greater chance of success. Examples of such persuasive statements include "It's highly difficult to grab tickets at low-tier (free) services", "52% of users have paid for the top-tier(highest price) grabbing services", etc. Besides, to increase revenue, ticket grabbing apps also provide other paid services, such as the use of high-speed CDN servers (49 CNY), manual ticket grabbing services (20-40 CNY), and compensation services for unsuccessful grabs (60 CNY). These services can be used in combination, and users can spend up to 229 CNY to obtain the highest guarantee for ticket grabbing.

4.2.3 Effectiveness of Paid Features

Additional payments are purported to increase the likelihood of securing tickets. However, from the user end, it's hard to assess the effectiveness of a "probabilistic" service. Users could only observe two outcomes: "grabbed", or "missed", without insight into whether the probability has indeed increased. Given the difficulty of evaluating the effectiveness systematically, we conducted a preliminary case study.

We targeted one train with no available tickets, which is the most common scenario for using grabbing apps. In this scenario, the apps persistently send purchase requests to target servers, monitoring ticket availability and conducting the grabbing operations. We randomly selected 5 train ticket grabbing apps that offered paid services and purchased various acceleration packages ranging from 10 CNY to 80 CNY. We also established a control group to purchase the same train ticket directly from the official platform. Note that despite the official platform displaying no available tickets, it offers a wait-listing feature to provide tickets to users who join the list when others are returned. According to our tests, none of the apps succeeded in grabbing the designated tickets, even the one with the top-tier acceleration packages (80 CNY). However, the control group, which directly queued on the official platform, successfully purchased the corresponding tickets. In other words, at least for this case study, the paid service failed to provide any advantage or achieve the desired "acceleration". The official platform also explicitly discouraged users from using ticket grabbing apps and recommended its free waiting list mechanism. Nonetheless, there were still

users who opted for paid ticket grabbing services due to their urgent need for tickets, as we revealed in Section 5.1.

Answers to RQ1: We found that ticket grabbing apps are highly automated. Some apps use scalper servers as intermediaries to automatically send purchase requests, while others abuse Android accessibility services to directly achieve automated clicks. There are several grabbing tricks used by the apps to improve the success rate, such as using time synchronization and BP links. We revealed that the apps may rely on a large number of third-party services to support their functions and bypass the censorship. In addition, we found that app developers could make money through the usage and they only use the free version as a way to attract potential users.

5 RQ2: From the Perspective of Users

In this section, we first presented the popularity and usage details of ticket grabbing apps. Then, we delved into the prevalent risk behaviors associated with these apps and investigated users' privacy concerns.

5.1 Usage of Ticket Grabbing Apps

In the online survey, we first asked participants whether they have used any ticket grabbing apps or contacted scalpers for ticket purchases. 46.2% of the participants indicated that they had ever used ticket grabbing apps, while 26.63% of the participants resorted to direct contact with scalpers. Ticket grabbing apps, due to their ease of access and user-friendly operation, tend to be preferred by users. For participants who did not use ticket grabbing apps or contact scalpers, we further inquired about their future intentions. Among them, 55.13% (43/78) of the participants expressed the possibility of using ticket grabbing apps or engaging with scalpers for future purchases. This indicates that scalping behavior is quite common in practice and has a considerable number of potential users.

For participants who had previously used ticket grabbing apps, we additionally inquired about some usage details.

• **Usage scenarios.** 89.41% of the participants used ticket grabbing apps for purchasing train tickets, while 42.53% used them for concert or sports tickets. This is probably attributed to the Spring Festival travel rush in China, involving a significant number of individuals engaging in ticket purchases.

• **App sources.** According to participants' responses, 83.35% of them obtained the ticket grabbing apps from popular app stores provided by major smartphone manufacturers, e.g., Xiaomi App Store [38], Huawei AppGallery [16]. This indicates that ticket grabbing apps are currently disseminated through mainstream app markets and these app markets do not effectively detect or intervene in the ticket grabbing apps. Meanwhile, a considerable number of participants acquire them through unregulated channels. 12.94% of the participants directly downloaded it through search engines, and 21.18% of the participants found the apps on social media. The security of these apps has not undergone any scrutiny either.

• **Success rate.** Although ticket grabbing apps utilize technical methods to surpass original customers in obtaining the hot resources, they do not guarantee a 100% success rate. In the survey, only 10.59% of the participants reported being successful in each grabbing attempt. The majority of participants (81.18%) indicated a mix of successful and unsuccessful attempts, and even 8.24% of the participants had not succeeded in obtaining the target goods despite using the ticket grabbing apps. Moreover, 90.91% of the participants reported that they were still unable to successfully grab tickets even after payment. Through the Chi-square test [84], we found that participants who paid fees during the ticket grabbing process did not exhibit a higher success rate ($p > 0.05$). This indicates that the paid services offered by ticket grabbing apps may not improve the success rate as claimed, aligning with the results of our analyses detailed in Section 4.2.2.

5.2 Security and Privacy Risks

Similar to malware, ticket grabbing apps may introduce uncertain security and privacy risks as well. Based on the results from the sandbox, 89/758 (11.74%) apps were identified as malicious. Combining the results of static analysis, we identified five typical security risks and other malicious behaviors.

• **Abuse of dangerous permission.** With the help of AndroGuard [3], we found each app requests 83.7 permissions on average, including 9.4 dangerous permissions. Figure 5 shows the requested dangerous permissions. Compared to the analysis results of mobile gambling apps [62], ticket grabbing apps request more dangerous permissions, especially on SMS-related permissions, indicating greater security risks. That is probably because ticket grabbing apps need to read the SMS code sent to the phone to complete the purchase. Besides the necessary permissions for ticket grabbing functionality, dangerous permissions like CAMERA, CALL_PHONE, and READ_CONTACT are also obtained by over 50% ticket-grabbing apps, posing serious privacy risks to users [10]. For instance, granting CAMERA permission can lead to the capture of unauthorized images or videos once misused.

In addition to the dangerous permissions, 685/758 (90.4%) of the apps request the android.permission.WAKE_LOCK permission, which could control the wake lock of the device and prevent it from entering sleep mode. By requesting this permission, ticket grabbing apps can continuously perform grabbing process without interruption, potentially resulting in battery drain and adverse effects on device performance.

• **Get root.** In simulated runs, the emulator we used was rooted. Throughout the experiment, we observed that some apps requested root privileges, gaining the highest level of control over the device. Based on the results from the sandbox, 577/758 (76.1%) of the apps applied for root privileges. In contrast, as shown in Figure 8 in Appendix A, among the

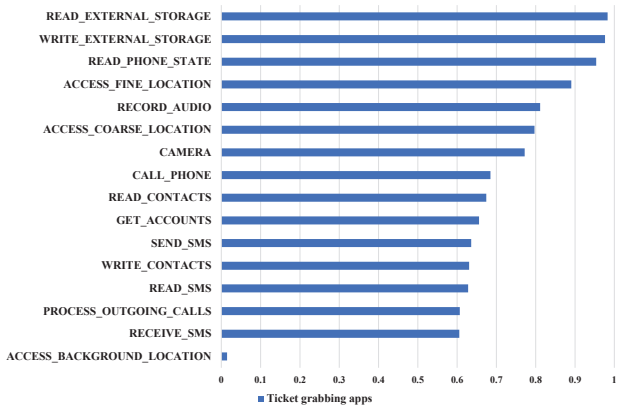


Figure 5: The percentage of dangerous permissions requested by ticket grabbing apps.

benign apps we selected, only 18/100 (18.0%) requested root privileges. These apps are all utility-type applications, such as "360 Mobile Security", "ZArchiver", "Sohu Input Method", etc. They request root permissions to access and manipulate system files stored on the device, as well as to optimize device settings by optimizing startup items. In the case of ticket grabbing apps, using root access could activate accessibility services without user confirmation. However, gaining root can also lead to other sensitive activities beyond the claimed scope and without any precautions.

Furthermore, we also observed that some apps contain "rikka.shizuku.ShizukuProvider". Shizuku [29] is an open-source project that allows applications to access sensitive system-level operations on the device without requiring root privileges. This presents a similarly high-security risk as root privileges. Our data reveals that 446/758 (58.8%) apps utilize Shizuku, while no instances were found in benign apps.

• **Insecure configuration.** We found that lots of ticket grabbing apps had insecure configurations. Firstly, our results revealed that 161 apps (21.2%) set "allowBackup" to "true", allowing backup of the app data to the cloud or local storage. While it is beneficial for data restoration across different devices, it poses a disadvantage for safeguarding sensitive data as user information can be at risk of leaking to untrusted locations. Secondly, 596 (78.6%) apps have configured "networkSecurityConfig" to "none", which means the apps will ignore all network security configurations, such as certificate validation and other network security measures. This would allow the apps to establish connections with insecure or untrusted servers and potentially expose the apps to "man-in-the-middle" attacks [75]. Thirdly, 105 (13.9%) apps set "requestLegacyExternalStorage" to "true" to access the external storage (i.e., "/sdcard"). However, ticket grabbing apps typically do not need to require access to external storage. This configuration could cause unnecessary access to files stored by users and provide the necessary attacking conditions for the "man-in-the-disk" attack [21].

• **Lack of privacy policy.** According to legal requirements [8, 15, 26], privacy policy is required to clearly inform users about the types and purposes of collected information. Additionally, the use of third-party SDKs should be disclosed in the privacy policy, as these SDKs may also collect users' personal information. However, based on observations during the simulated runs, we found that some ticket grabbing apps do not have a dedicated privacy policy and fail to transparently disclose the information collection to users. To further validate the presence of privacy policy in ticket grabbing apps, we filtered the URL strings obtained from the static analysis of *strings.xml* and counted the URLs containing "privacy". According to the statistics, only 57/758 (7.5%) apps have privacy policies.

• **Information collection.** While most ticket grabbing apps lack privacy policies, it doesn't imply that they do not collect any information. During the simulated runs, we found that some apps require users to provide the login credentials of the target platforms (e.g., usernames and passwords) to facilitate the ticket grabbing process. These credentials are then sent to the scalper server, posing significant security risks. If the information is leaked or shared, it could potentially compromise the user's passwords on other platforms [64]. Moreover, to enhance the speed of ticket grabbing, 18/50 (36.0%) of the simulated commodity grabbing apps implement the "quick payment" feature, which requires the user to input their payment passwords in advance within the ticket grabbing app. Upon successfully getting the target goods, the apps can directly use these passwords to complete the transaction on target platforms without further user actions.

• **Other malicious behaviors.** In addition to the representative security risks, we also uncovered certain malicious behaviors that are not widespread but occur in a few apps. For instance, we found two apps that persistently captured screenshots and uploaded them to remote servers. They use the MediaProjection API provided by Android for implementation. User's operations on other apps would also be obtained by the ticket grabbing app making the app transformed into spyware. Furthermore, the sandbox analysis revealed that three apps monitor the incoming SMS messages, corresponding to the requests for dangerous SMS-related permissions (e.g., SEND_SMS and READ_SMS). The apps use "SELECT _id, address, person, body FROM content://sms" to query all the message information on the mobile phone, which is a serious violation of the user's privacy.

5.3 Users' Privacy Concerns

In the online survey, we asked all participants about their perception of the legality of ticket grabbing apps. 39.13% of them believed that such apps are illegal, while 8.7% held the opposite attitude. 38.59% of the participants thought that the legality of ticket grabbing apps is not absolute. Among participants who had previously used ticket grabbing apps, 64.71% of them had shared their personal information with

these apps. We further asked these participants to specify the types of personal information provided. Nearly all of them mentioned the identification number and mobile phone number, both of which are considered sensitive information.

Subsequently, we employed the 5-point Likert Scale method [44] to assess the level of users' privacy concerns. The results revealed an average score of 3.67/5.0, indicating that the majority (70.59%) of participants have privacy concerns regarding ticket grabbing apps. Specifically, 58/60 (96.67%) of the participants expressed concerns about the potential leakage or misuse of their provided personal information. Similarly, for participants who had not used the ticket grabbing apps, this is also the main reason why they chose not to use the apps, cited by 29/78 (37.18%) of the participants.

In summary, through the comprehensive analysis of our online survey, we can observe no matter whether participants have used ticket grabbing apps or not, over half (70.59%) of the participants were aware of the security risks of scalping (Q13). However, due to users' urgent need for the tickets, 84.5% of the participants still opt to use ticket grabbing apps despite their privacy concerns (Q1). They actively sought out ways to acquire the efficient apps through various channels (Q8) and were willing to pay additional fees to enhance the success rate (Q9). They also overlooked the collection and use of personal information by the ticket grabbing apps, providing their personal information on their own initiative (Q12).

Answers to RQ2: We found that ticket grabbing apps have a significant user base, with train ticket grabbing apps being the most prevalent in practice. Ticket grabbing apps request more dangerous permissions than mobile gambling apps and have several security and privacy risks. We revealed that more than half of the participants were aware of the privacy risks posed by ticket grabbing apps. Nevertheless, due to the pressing need for these apps, the majority of users continue to utilize them and willingly provide personal information during usage, as they prioritize tickets over privacy.

6 RQ3: From the Perspective of Platforms

In this section, we analyzed the gang characteristics and bypass tricks of the ticket grabbing apps, which can help target platforms to better identify and detect this kind of apps.

6.1 Gang Analysis

Through the gang analysis, we tried to reveal the clustering characteristics of ticket grabbing apps. Additionally, our analysis showed the communication channel and provided valuable intelligence about the exposed gangs.

6.1.1 Clustering Characteristics

In the app analysis, we obviously found that some different ticket grabbing apps exhibited a similar UI design. In order to further verify the prevalence of this phenomenon and identify the clustering characteristics among these apps, we employed FSquaDRA [14] to calculate code similarity between the apps. The results revealed 14 distinct groups, encompassing a total of 205 apps. Each group consisted of apps with a similarity exceeding 90%, indicating that these apps share similar purposes and usage scenarios. These apps are basically commodity grabbing apps, showing a development trend of the apps. Additionally, we found different ticket grabbing apps with the same signature often exhibit similar appearances and higher code similarity. Among the apps with the same signature, 24.7% of them demonstrated a similarity over 90%.

In order to figure out more gangs characteristics, we used the signature-based grouping method to group our dataset. As is well-known, the signature of an app generally contains the developer's identity information, such as the developer's name, organization, and location. We used AndroGuard [3] to obtain the signature and extract the developer's identity information, as apps with the same developers can be considered from the same gang. According to the grouping results, 37 apps (4.9%) were not signed jar files, indicating that they were potentially risky. Of the remaining 721 apps, there are 269 signatures, containing 167 developer's identity information.

Next, we tried to do gang clustering by the developer information in the signatures. However, we observed that some signatures used by certain groups do not contain any developer's identity information. (1) Some groups use default signatures provided by the IDEs, such as "emailAddress=android@android.com, CN=Android, OU=Android, O=Android, L=Mountain View, ST=California, C=US" and "CN=Default, O=Auto.js Pro". (2) Additionally, there are cases where the groups use custom signatures, but the signature is not in compliance. For example, "CN=inject.keystore, OU=inject, O=inject, L=inject, ST=inject, C=inject". Each parameter of the signature is an invalid placeholder and does not include any developer information. This situation is quite common, which suggests a tendency among ticket grabbing apps to conceal their developer identity. (3) Furthermore, we found that some groups use the signature "CN=Android Debug, O=Android, C=US". It is an Android debug signature, indicating that the app is just a debug version. This type of signature is usually not used for official release on Google Play or other app distribution channels as it lacks the security required for formal release. The above illustrated that ticket grabbing apps tend to hide the developer information in the signature. It is challenging to trace the gangs of ticket grabbing apps through signatures.

6.1.2 Communication Channel

During the simulated runs, we observed that some ticket grabbing apps always set a chat group encouraging users to join. These groups have been used as a more covert app distribution and could help scalpers facilitate long-term customer

relationships. They solve users' problems during usage and provide the paid versions of ticket grabbing apps. Therefore, we can use different chat channels as the identifier to distinguish different gangs, as unrelated developers are unlikely to gather in the same channel for user communication. In total, we identified 20 chat groups during the simulated runs and utilized these chat groups to gain insights into the exposed gangs of ticket grabbing apps.

By inputting the numbers of chat groups, we could retrieve the group names and member counts without joining the groups. We discovered that these group names usually have numerical values at the end, serving as an index to represent a series of related sub-groups. The highest number encountered was "83" indicating the possibility of another 82 sub-groups. Interestingly, sensitive keywords such as "ticket grabbing" were generally avoided in the group names. Instead, they used terms like "information exchange" or "pre-sales communication". Some group names appeared entirely unrelated, such as "salted fish security team", "fangfang's learning welfare", or "octopus brother's pink pillow", likely to evade detection by the chat platform. Additionally, we collected the number of members in each group, which averaged 919.71 individuals per group. Seven groups had more than 1,000 members, indicating a significant user base of ticket grabbing apps.

In Section 4.2, we explored the profit model and individual payment amounts of ticket grabbing apps. However, to understand the whole profitability scale, we also need to know the amount of paying users, which is hard to ascertain in this study. Nonetheless, the number of chat group members can serve as a conservative estimate of the paying user base. Since the aim for users to join the chat group is to gain paid versions, its membership size is reasonable for estimation. Moreover, considering that there may be other paid channels other than the chat groups we identified, this number should be viewed as a minimum estimation. Thus, using the average number of users per chat group (919.7 users) and the average fee amount (494.1 CNY), we estimate that a single ticket grabbing app could make an average annual profit of at least 454,429 CNY.

6.2 Tension Between Platforms and Apps

Ticket grabbing apps could undermine the profit model of target platforms and harm their reputation. Consequently, platforms are motivated to protect their users and maintain a fair ecosystem. Meanwhile, developers of ticket grabbing apps persistently seek ways to evade detection measures, resulting in an ongoing tension between platforms and the apps.

6.2.1 Detection and Interception on Target Platforms

The target platforms constantly improve their detection capabilities, striving to intercept the relevant traffic originating from abnormal users. Most target platforms deploy a cost-effective solution known as the "Completely Automated Public Turing test to tell Computers and Humans Apart" (CAPTCHA) to differentiate between humans and machines, thereby preventing ticket grabbing apps. Furthermore, target platforms may employ more advanced detection systems for identifying the machine traffic. For example, through the deployment of the MTEE system [2], Taobao has repelled 18.87 million scalpers' behaviors and protected 800 million purchase orders from normal customers. Generally, the detection system employs machine learning techniques to identify machine traffic synthetically, including the device environment, account profile, and behavioral patterns of the traffic [4].

6.2.2 Bypass Tricks of Ticket Grabbing Apps

In the face of the target platform's continuously evolving detection methods, the ticket grabbing apps also improve technical implementation to bypass the detection of the platform. To determine the update intervals across various versions, we extracted the compiled time from *manifest.xml* of apps with different versions and presented the update timestamps in Figure 6 in Appendix A. On average, the update cycle for each app is approximately 41.73 days. Based on the version update notes within a few apps, we determined that the version iterations primarily focused on 1) increasing the supported grabbing platforms, 2) optimizing functionalities (e.g., adding "quick payment"), and 3) updating circumvention measures (e.g., implementing automatic IP address switching).

As mentioned, ticket grabbing apps updated at a rapid pace to counter the detection mechanisms. When faced with CAPTCHA challenges, ticket grabbing apps resort to CAPTCHA solving services to bypass the verification. These CAPTCHA solving services employ crowdsourcing or machine learning to recognise the CAPTCHA in very few seconds and offer convenient APIs for app developers to integrate into their apps. Generally, these services are not offered for free. The ticket grabbing apps necessitate users to purchase the CAPTCHA solving services in advance, and then require them to enter their service credentials into the ticket grabbing apps to enable the utilization of these CAPTCHA solving services within the apps. In our dataset, we identified three CAPTCHA solving services supported by the ticket grabbing apps, including "TTshitu" (*"ttshitu.com"*), "Fateadm" (*"fateadm.com"*), and "Ruokuai" (*"ruokuai.com"*).

To against the detection system deployed by the target platforms, the core idea behind the bypass methods is to closely replicate the environment and behavior of genuine human users. Those detection systems are primarily designed for large-scale machine traffic, focusing on detecting organized scalpers involved in bulk purchasing activities. However, ticket grabbing apps are mainly used by the original customer, which generates a smaller scale of traffic. These apps run on users' mobile devices and use their personal accounts for ticket purchases. Therefore, it becomes challenging to detect the ticket grabbing app users through the device and

account dimensions. Additionally, in order to mimic user behavior as much as possible, some ticket grabbing apps use accessibility services to simulate the click actions of users as mentioned in Section 4.1.1. The traffic generated by this approach closely resembles human-generated traffic, making it difficult to distinguish from the traffic dimension.

Additional bypass tricks were also discovered during the app analysis and we already revealed them. For example, ticket grabbing apps employ multiple IP proxies to avoid being intercepted and leverage development platforms to bypass the content review when releasing on the app markets.

Answers to RQ3: We discovered that some ticket grabbing apps have similar UI designs and the apps intend to hide the developer's identity in the signature. Ticket grabbing apps use social media as a covert communication and distribution channel. Even though the target platform has already deployed robust detection systems, ticket grabbing apps are still active in the app markets. They take advantage of ever-improving bypass tricks, such as CAPTCHA solving services, accessibility services, multiple IP proxies, and so on.

7 Discussion

When faced with tickets and privacy, similar to users' choices on the loan apps in Kenya [72], users prioritize privacy at a significantly lower level of consideration. Due to the significant supply-demand disparity, the urgency of securing tickets surpasses concerns about channel legitimacy. Even though ticket grabbing apps offer no guarantees of success rate or information processing, users willingly assume responsibility for the risks tied to their authorized proxy actions. Many public announcements urging consumers to use official channels for high-demand purchases, however, their impact seems limited. Nevertheless, it is still necessary to continue strengthening user education and ensure they are fully aware of the security and privacy risks tied to ticket grabbing apps.

Besides, one of the most efficient strategies to deter users from resorting to ticket grabbing apps is to impede the development and distribution of such apps. According to the analysis, ticket grabbing apps rely on a series of tools to realize the grabbing function and bypass the detection system. Therefore, those tools serve as the bottleneck of ticket grabbing apps. We proposed an "Indirect Combat" approach for the interception of ticket grabbing apps. The core idea is to impose restrictions on these bottleneck, which can indirectly disrupt the ticket scalping ecosystem and promote fairer access to tickets for genuine customers as a result. Table 1 shows auxiliary tools used by ticket grabbing apps. In particular, we propose the following three practical suggestions.

• **Strengthen the review of service recipients.** We found that ticket grabbing apps may abuse some legitimate services such as accessibility services and third-party SDKs. These service providers should conduct a more comprehensive review of the purpose of the objects to be served, to avoid providing services to malicious applications and becoming accomplices. This suggestion is practicable as Auto.JS Pro has currently implemented business compliance rectification measures since 12 February 2023. They conducted code reviews and mandated real-name authentication for developers [5]. Similarly, those third-party SDK providers should also introduce measures (e.g., pre-service disclosure and review mechanism), akin to the actions taken by Auto.JS Pro, to ensure that services are not abused for illegal purposes.

• **Prohibit services catering to illegal industry.** As shown in Table 1, ticket grabbing apps employ a range of support services, including CAPTCHA solving services, development platforms, image hosting services, and specific cloud servers. Typically, most of these services cater to malicious apps and are not employed by benign apps. Hence, detecting these services can be an effective means of identifying ticket grabbing apps. Specifically, a unified reporting interface is required for users to report services found to be used in the illegal industry. Prohibiting these support services through strong national measures can potentially stifle the development of ticket grabbing apps at their core.

• **Enhance the review on the app release.** Based on the user surveys, it is evident that ticket grabbing apps primarily originate from mainstream app markets, suggesting a lack of specialized categorization and review processes for these apps. In order to deter the release of apps using fraudulent credentials provided by the development platforms, it is essential to strengthen the review process. Our publicly available dataset and surveys on ticket grabbing apps can serve as a reference for app markets in detecting similar applications. Firstly, by verifying developer information and UI design, app markets can reduce the likelihood of ticket grabbing apps entering their platforms. This is because most of these apps tend to conceal their developer information and have typically similar interfaces. In addition, analyzing app composition, including indicative features like Android accessibility services and Shizuku, can aid in identifying ticket grabbing apps. Overall, app markets should perform a better investigation and app analysis to block such illegal apps, thereby maintaining a healthy and trustworthy app ecosystem for users.

8 Related work

8.1 Analysis of Ticket Bots and Ticket Systems

Before the popularity of ticket grabbing apps, ticket bots served as a focal point for studying scalpers' behavior. Many researchers focused on scalping and ticket bots from the perspectives of economic and legal [40, 59, 60, 83, 87]. They highlighted the disruptive impact of ticket bots on the regular market order. As for the technical analysis, extensive research has been dedicated to comprehending the behavior of these ticket bots. For example, Nissan et al. [73] gave a high-level

Table 1: The auxiliary tools used by ticket grabbing apps and their purposes.

Type	Auxiliary tools	Purpose
Ubiquitous and legal	Third-parity SDKs	Provide additional features such as data analysis, payment, message push, etc.
	Accessibility services	Support simulated click.
	Auto.JS Pro	Create the script for automatic simulated click.
	Time synchronization APIs	Get the timestamp of the target server to reduce the time delay.
Catering to illegal industry	Development platforms	Simplify the development process and provide app releasing services.
	Image hosting platforms	Host image resources and realize image sharing.
	Multiple IP proxy services	Provide multiple IPs to prevent detection.
	Group control platforms	Control multiple devices on a single physical device.
	CAPTCHA solving services	Bypass the CAPTCHA challenges on target platforms.

analysis of a ticket-check-bot, and Lin et al. [68] introduced the behavior of ticket bots through a real case solved by Criminal Investigation Bureau (CIB). Accordingly, it is important to detect the bots by analyzing their characteristics. Rahman et al. [78] proposed a forensic framework to verify if the crime is done using automated bots and whether the bots are good or bad. Xie et al. [89] used the event logs of the mobile system and Wu et al. [88] proposed a new integrated method based on network traffic characteristics to identify the ticket bots.

In addition to the analysis of ticket bots, some work tried to make changes to ticket systems. Yang et al. [90] proposed a safe, usable, and easy-to-deploy ticket system to prevent scalpers and restore fair competition. Feulner et al. [53] demonstrate that the self-sovereign identity based ticket system can enable efficient secondary market control. Moreover, Elefant et al. [51] discussed the possibility of moving the ticket system onto an open source blockchain. Additionally, Isaksson et al. [63] reviewed the potential benefits blockchain applications may have in the ticket market, including the prevention of ticket bots and fake tickets. Nevertheless, such ticket systems are unable to completely prevent the presence of ticket grabbing apps. Within our dataset, we identified 147 apps with the ".nft" suffix. These apps are specifically designed for making purchases on NFT marketplaces, which operate on blockchain technology.

8.2 Analysis of Applications

App analysis is a prevalent research method used to comprehend app functionality and identify security issues. A significant amount of work focused on analyzing the reviews of apps in the app market. By performing sentiment analysis on these reviews [76], bad reviews can be identified [85], and useful feedback can be provided to the developers [48]. In addition, emerging issues such as new bugs can be detected timely by analyzing the reviews [54]. As for the analysis of security, static analysis is the frequently used method and there are many high-performance tools proposed by researchers to recognize the dangerous behaviors of the apps. For example, COVERT [42] for permission leakage, CHEX [70] for component hijacking vulnerabilities, AspectDroid for possible unwanted activities [39], and ApkCombiner [67] for information leakage on inter-component communication. Klieber et al. [66] and Ravitch et al. [79] gave an information flow analysis that can show potentially dangerous data flows.

There is also research that analyzed specific types of apps, particularly focusing on health-related apps [43, 49, 82, 86] and education-related apps [46, 61, 80]. Likewise, some work analyzed the ecosystem of specific underground industries through the apps. For instance, Hong et al. [62] and Gao et al. [55] analyzed the mobile gambling scam ecosystem, identifying strategies to disrupt such fraudulent activities. Chatterjee et al. [47] provided the first in-depth study of the intimate partner surveillance (IPS) spyware ecosystem and Bivens et al. [45] analyzed the features present in anti-rape apps to prevent sexual violence. Our research shares similar goals with these studies, focusing on a novel scenario involving mobile ticket grabbing apps, which has not been previously explored.

9 Conclusion

With the promotion of real-name ticketing systems, ticket grabbing apps have become a popular pattern for scalpers, especially in China. Our work takes the first step toward revealing the ecosystem and building up the large-scale dataset of ticket grabbing apps in the wild. According to the results of app analysis on 3,121 apps and our online survey on 184 participants, we revealed the technical and social characteristics of ticket grabbing apps. In addition, we highlighted that ticket grabbing apps have a number of security and privacy risks. Although the majority of users have privacy concerns about ticket grabbing apps, they still use the apps and provide them with their sensitive information. Finally, we summarized the auxiliary tools used by ticket grabbing apps and proposed an "Indirect Combat" approach. In summary, our work brings new insight into the mobile ticket grabbing ecosystem, which can help better detect and intercept such scalping behaviors.

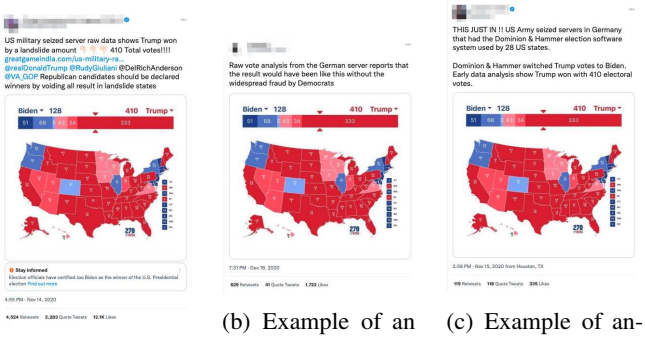
Abstract

Images are a powerful and immediate vehicle to carry misleading or outright false messages, yet identifying image-based misinformation at scale poses unique challenges. In this paper, we present PIXELMOD, a system that leverages perceptual hashes, vector databases, and optical character recognition (OCR) to efficiently identify images that are candidates to receive soft moderation labels on Twitter. We show that PIXELMOD outperforms existing image similarity approaches when applied to soft moderation, with negligible performance overhead. We then test PIXELMOD on a dataset of tweets surrounding the 2020 US Presidential Election, and find that it is able to identify visually misleading images that are candidates for soft moderation with 0.99% false detection and 2.06% false negatives.



1 Introduction

Online users are constantly bombarded with false and misleading information, whether it is inaccurate and shared without malice (i.e., *misinformation*), or deliberately crafted to achieve a malicious goal, for example by state actors (i.e., *disinformation*) [71, 76]. To help their users better distinguish between accurate and misleading or false information, online platforms like Twitter have introduced *soft moderation* measures, where they add labels to posts that include inaccurate information, with the goal of providing better context to these claims. Unfortunately, little is known about how these moderation decisions are made by the platforms, and recent work found glaring issues with Twitter's soft moderation approach [15, 91].

While previous work on automated soft moderation [61] builds a solid foundation for the soft moderation of textual content, false information is not only spread through text, but images are commonly used to convey false and misleading narratives [28, 54, 88, 93]. While Twitter applies soft moderation decisions to posts containing images, the way in which this is done is not publicly known, and a preliminary analysis that we conducted shows that these labels are not applied uniformly and pervasively. For example, in Figure 1, we show three tweets that contain identical images discussing the same debunked electoral map claiming Trump's landslide victory with 410 votes after elections servers were seized in Germany by the U.S military [16].The first tweet (Figure 1a) received a warning label, while the other two tweets containing the same image (Figures 1b and 1c) did not receive any intervention, despite discussing the same misleading narrative.

These observations highlight the need for effective automated approaches to identify image content that should receive soft moderation. Moderating images, however, poses unique challenges. First, the sheer amount of data published on social media makes this a particularly challenging task, especially on platforms like Twitter, where 50 million tweets are posted every day [72]. Previous work has dealt with this problem by adapting *perceptual hashing* algorithms [28, 89, 93]. These algorithms identify visually similar images by leveraging syntactic embeddings, which are lightweight to calculate. Even if the calculation of hashes is relatively cheap, comparing an image against a large number of potential candidates is inefficient and does not scale. In addition to the computational costs of comparing images, previous research has shown that image-based false information is highly contextual and that similar images can be misinformation, satire, or even completely benign based on the context in which they are used [88, 89]. Existing approaches using perceptual hashing lack the nuance to determine this context, making them prone to false positives and unfit for the misinformation moderation use case.

Technical Roadmap. In this paper, we aim to address the limitations of previous approaches and develop a scalable, performant, and effective system able to analyze images posted on social media and identify candidates for soft moderation. We present PIXELMOD, an image search system designed to assist platform moderators by flagging visual content that is similar to the content they have previously applied moderation labels. PIXELMOD takes as seed input a list of images initially moderated by Twitter and encodes the images using percep-

(c) Example of another unmoderated tweet containing the same image

Figure 1: Three tweets discussing a false electoral vote map showing Trump landslide victory based on false reports of seized election servers in Germany. Twitter added a warning label only to the first tweet.

tual hashing [24, 57]. To allow efficient hash comparisons, PIXELMOD leverages Milvus [85], a vector database that is optimized for searching among millions of hash records. After finding visually similar images, PIXELMOD leverages OCR to identify the context in which an image is used, allowing it to rule out false positives.

PIXELMOD successfully identifies both tweets in Figures 1b and 1c when queried with the image in Figure 1a. Additionally, PIXELMOD not only identifies images identical to the seed images but also visual variants of the images such as memes and fauxtography, which are commonly used for spreading misleading information [29, 89, 92].

Main Contributions & Findings. PIXELMOD addresses the limitations of previous image-based moderation approaches proposed in the academic literature, is platform-independent, and only requires a single misleading image already intervened by human moderators. With the ability to identify thousands of posts spreading misleading images, we show that an image search system like PIXELMOD can be used as a foundation for a large-scale soft moderation intervention system for images. While a large amount of research has been conducted on perceptual hashing and OCR, the novelty of our work lies in combining and tuning the two into a working end-to-end soft moderation system which achieves a much larger coverage than perceptual hashing alone. Besides content moderation, the takeaways offered by our work can be helpful for researchers and practitioners in building image similarity search systems for related security problems like phishing [47] and CSAM detection [22, 33].

We compare PIXELMOD with alternative approaches to assess visual similarity, showing that PIXELMOD outperforms them in terms of F1-score. In particular, the use of OCR to determine the context of false images allows PIXELMOD to operate using a higher similarity threshold than existing approaches only based on perceptual hashing, increasing recall while keeping precision high as well, suffering only a negligible runtime performance hit in return.

We then test PIXELMOD on Twitter data discussing the 2020 US Presidential Election. Starting from a seed set of 959 tweets containing misleading images, we use PIXELMOD to retrieve 40,244 tweets in the wild that are candidates for moderation. Performing a thorough manual analysis, we find PIXELMOD has a false negative rate of 2.06% and a false detection rate of 0.99%. These findings are a positive step towards building automated systems that complement Twitter's existing systems to moderate misleading images and improve the state of content moderation.

To better understand how soft moderation was adopted by Twitter during that period, we perform a qualitative measurement study of the content flagged by PIXELMOD, comparing it to tweets that received soft moderation labels from Twitter. We categorize the images identified by PIXELMOD based on Twitter's Platform Policy, finding that although different types of platform policies were moderated at different rates by Twitter, none of the policy violations exceeded a moderation rate of 5.96%.

2 Overview of PIXELMOD

PIXELMOD takes a *query image* that a platform wants to investigate for further moderation actions and retrieves images that are both visually and contextually similar. This allows a platform to quickly identify a large, high-certainty candidate list of posts for moderation. PIXELMOD has four stages, as illustrated by Figure 2: i) *generating* image embeddings, ii) *indexing* image embeddings, iii) *retrieving* visually similar images through approximate nearest neighbor search, and iv) *refining* contextually matching images via Optical Character Recognition (OCR).

We demonstrate PIXELMOD in the context of Twitter, identifying visually misleading information related to the 2020 US Presidential Election. However, PIXELMOD's architecture is designed to be portable to any social media platform.

2.1 Background

Identifying visually similar images given a query image is a reverse image search problem, which falls under the broader research area of Content-Based Image Retrieval systems [35]. The goal is to efficiently collect, index, and search for visually similar images over an index of millions of images, and there are several publicly available solutions (e.g., TinEye [81], Google Vision AI [32]). We conducted a preliminary exploration of these systems and identified two major limitations: 1) they require a paid subscription for programmatic access, and 2) they perform poorly for returning images from Twitter, Facebook, and other social media platforms because of platform restrictions on their crawlers. To address these

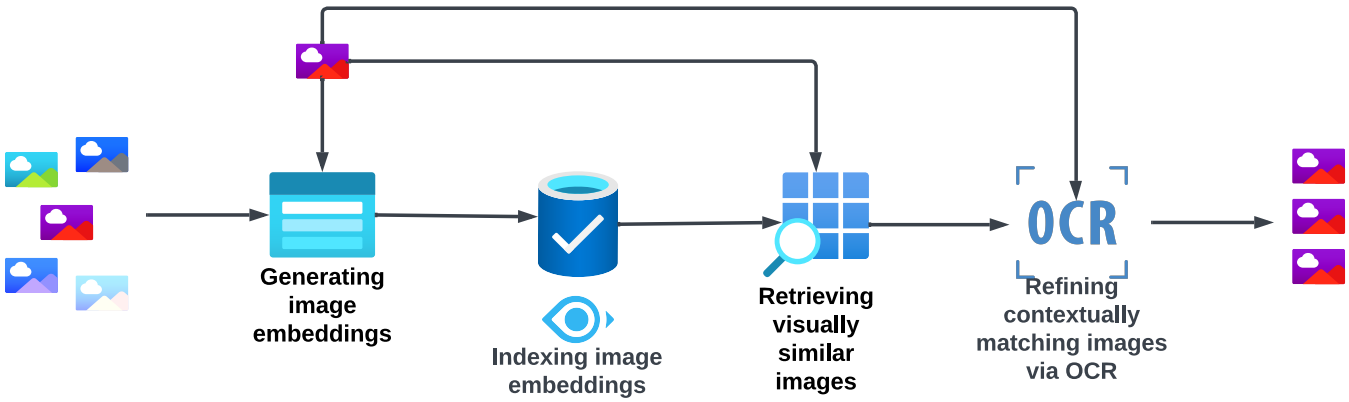

Figure 2: Overview of our image analysis pipeline.

limitations, we built a custom image search system focused exclusively on social media that collects images, generates syntactic embeddings (pHash and PDQHash), and indexes them (using the Milvus [85] vector database).

Motivating the need for multi-modality in visual similarity search. Prior works have discussed that incorporating contextual information within images is important when identifying when they have been manipulated or miscaptioned [89]. Zanettou et al. [92] discuss similar existing shortcomings of image similarity systems and the need to incorporate semantic components like OCR in image detection pipelines to effectively identify image memes. Another work studying misinformation images on WhatsApp in India [29] used semantic features like OCR from Google Cloud Vision to identify differences between different types of misinformation images (images taken out of context, photoshopped images, and memes) after retrieving images visually similar to fact-checked images. However, no existing work uses contextual information as a part of the detection system or pipeline itself.

Existing detection systems can identify images that are very similar to misleading images upon querying, but are unable to verify if the identified images are used in the same misleading context as the query image. We illustrate this case with an example in Figure 3. When we query existing image similarity systems with Figure 3a, they will typically return Figure 3b, and Figure 3c as matching results with strong confidence. However, Figure 3b, and Figure 3c are not related to the query image under question, which contains the text of "Fraud. The Biggest Disgrace In Our History", despite being visually similar to the query. Figure 3b is an image used in a different context, with no connotation to the narrative of "Election Fraud" during the 2020 Elections, whereas Figure 3c is used in another context: Fox News projecting a win for Joe Biden. Thus, the results returned are used in entirely different context than the query image, lacking the connotation of "Election Fraud" which makes the query image misleading. A similar problem occurs when dealing with *fauxtography*, where images are manipulated with the inclusion of visual

(a) *Query* image

(b) Visually similar match #1

(c) Visually similar match #2

Figure 3: Example query image and results retrieved.

changes, overlay text, or are used out of context to mislead the user [89]. This highlights the need for incorporating context when using image similarity systems to improve misinformation detection systems.

To address this issue, PIXELMOD analyzes the overlay text included in images by using optical character recognition (OCR) to better capture the context in which an image is used and then incorporate this context as a part of our image similarity pipeline. Including this context also helps overcome existing limitations of prior work using perceptual hashes that have to rely on lower similarity thresholds for matching [29, 89]. Incorporating context allows us to increase image similarity thresholds while at the same time achieving better recall without hurting precision.

2.2 Generating image embeddings

There are two types of embeddings we can extract from images for retrieval purposes. The first, *syntactic embeddings*, are fingerprints of an image's visual features, computed such that two visually similar images will have identical, or very similar fingerprints. The second, *semantic embeddings*, capture features within the images (for example, if a given image is a chart or a portrait), and match images that are visually dissimilar, but still have similar meanings.

For our purposes, syntactic embeddings are more useful for two reasons. First, images identified through them are minor variations of the query image, making them easy to in-

terpret and take action on. Second, semantic embeddings use complex deep learning architectures [37, 73], while syntactic embeddings are relatively fast and cheap to train and use. This means we can scale to millions of images with relatively few resources (e.g., PIXELMOD does not require a GPU.)

We generate our syntactic embeddings via *perceptual hashing*. We make use of two different *perceptual hashing* embeddings: i) pHash [57], and ii) PDQHash [24]. pHash encodes images as 64-bit vectors by extracting geometry-preserving feature points using Discrete Cosine Transform (DCT). The resulting vectors are invariant to simple image transformations and minor coloring differences. PDQHash is an improvement over pHash, encoding images as 256-bit vectors. Prior work studying the spread of misleading images in social media has used both pHash and PDQHash [41, 44, 66, 89, 93]. We evaluate pHash and PDQHash with respect to precision, and recall, as well as the time taken to generate an embedding, index it, and eventually query the index.

2.3 Indexing image embeddings

The most similar image to a query is the one whose embedding is the shortest distance from the query image's embedding. While we could perform a pairwise comparison with the query image and all candidate images, this is intractable at the scale at which social media platforms operate. To address this, there are specialized vector databases that can be used to perform queries over embeddings. For PIXELMOD, we chose to use Milvus [85] a purpose-built vector management system. Milvus abstracts away lower-level details (e.g., index creation and item insertion) via a higher-level API and Facebook's Faiss [43] library for efficient dense vector similarity search.

Milvus has two types of indexes: i) `BIN_FLAT` and ii) `BIN_IVF_FLAT`. `BIN_FLAT` guarantees a 100% recall rate by exhaustively searching for matches to a query embedding. `BIN_IVF_FLAT` is quantization-based, dividing embeddings into multiple cluster units and comparing the query embedding to the center of each cluster. `BIN_IVF_FLAT` is faster than `BIN_FLAT` but requires tuning hyperparameters to find an optimal recall rate. Milvus recommends using `BIN_FLAT` for datasets in the order of a few million vectors, which fits the datasets we use to evaluate PIXELMOD

2.4 Retrieving visually similar images

Vector databases like Milvus scale by leveraging approximate nearest neighbor search across their indices. Milvus determines the nearest neighbors by scoring candidates with a similarity metric. We use Hamming distance, leaving us with the next challenge of choosing an appropriate threshold to treat as "visually similar." We select Hamming distance over cosine similarity as prior works on perceptual hashing have predominantly used this metric to assess visual similarity on both PHash and PDQHash (e.g. baseline systems [89] and [92]). Additionally, we index the perceptual hashes on Milvus as binary hashes, and using Hamming distance as the similarity metric allows us to efficiently compare the binary representations of images. Previous works using pHash to study misinformation on a variety of social media platforms have recommended a Hamming distance of six [89], and eight [92]. The developers of PDQhash suggest a distance of 32, which has been used to study misinformation on WhatsApp [44, 66]. Other work using PDQHash has used a threshold of 40 to study the spread of COVID-19-related media in Pakistan over WhatsApp [41]. Ultimately, choosing a threshold depends on the dataset used and the particulars of how "visual similarity" is defined. In Section 4, we experimentally evaluate the choice of the visual similarity threshold (θ_{visual}) by optimizing over both precision and recall.

2.5 Refining matched images using OCR

The final component of PIXELMOD involves processing the results retrieved as "visually similar" to the query image by comparing text extracted via an Optical Character Recognition (OCR) engine. For the rest of the paper, we refer to the output text from an image extracted from an OCR engine as OCR label. The advantages of applying this OCR-driven post-processing to the matched results are two-fold: i) it eliminates the limitations of underlying perceptual hashing algorithms by filtering out their false positives and ii) it allows us to explore relatively larger distance thresholds for visual similarity matching, thus allowing us to minimize false negatives. Prior applications of perceptual hashing algorithms for identifying visually similar images have used conservative thresholds [41, 44, 89] to minimize false positives. In contrast, we aim to exploit larger thresholds to increase our recall as well as have a more tuneable mechanism with respect to precision trade-offs. In Section 4, we first validate the choice of Google Cloud Vision API as the underlying OCR engine [32], and experimentally evaluate the calibration of the similarity metric for the extracted OCR labels as our OCR engine) and corresponding threshold for similarity ($\theta_{textual}$).

3 Datasets

We use three different datasets to evaluate PIXELMOD (summarized in Table 1). Our first dataset, $\mathbf{D}_1$, contains 7.6M tweets collected via the Twitter Streaming API using a set of 2020 US Election hashtags (e.g., #ballotfraud, #voterfraud, #electionfraud, #stopthesteal) curated by Abilov et al. [4]. To comply with Twitter's terms of service, this dataset only provides tweet IDs, therefore, we need to retrieve the full tweet content from the Twitter API through a process called *hydration*. Out of the 4,017,259 tweets we were able to rehydrate, about 218K have at least one "media" entity: either an image or a video (tweets with videos also contain a thumbnail image, which we include in our dataset).

Dataset	# Tweets with Images
VoterFraud Dataset ($\mathbf{D}_1$)	217,868
1% Twitter Stream ($\mathbf{D}_2$)	12,560,319
Twitter Context Annotations ($\mathbf{D}_3$)	6,952,300

Table 1: Overview of our dataset.

Our second dataset, $\mathbf{D}_2$, consists of 13M tweets with media collected via the 1% Twitter stream from November 1 to December 31, 2020. Unlike $\mathbf{D}_1$, we do not filter any keywords, therefore $\mathbf{D}_2$ is a uniform 1% sample of Twitter.

Finally, we collect $\mathbf{D}_3$ via Twitter's Academic Research full-archive search endpoint in late 2022, by querying *context annotations* [62] associated with the 2020 US Elections. Twitter annotates tweets with context annotations by semantically analyzing their content and metadata, categorizing them into a nested structure of domains and entity labels. The more than 80 domains cover things like politics and TV shows, while the nearly 145K entities cover details of the domains ranging from elections to festivals, to politics and media personalities.

We identify two context annotations related to the 2020 election by retrieving the context annotations of all tweets from $\mathbf{D}_1$: 1) "2020 US Election Day" and 2) "2020 US Presidential Election," both in the *Events* domain. We also found other context annotations from the tweets, but they were associated with "Political figures" and "Politics" in general, not the 2020 elections specifically. To minimize the noise that can be introduced when using such a broad context, we do not include those annotations when building $\mathbf{D}_3$. In the end, $\mathbf{D}_3$ consists of the 6.9M tweets that we retrieve using the "2020 US Election Day" and "2020 US Presidential Election" context annotations and limiting our search to November 1st, 2020 to December 31st, 2020.

Index building. We build two different Milvus indices for pHash and PDQHash embeddings, using all the images in our datasets. The index size for both types of embeddings is 19.7M, after combining all the tweets from $\mathbf{D}_1$, $\mathbf{D}_2$, and $\mathbf{D}_3$.

4 System Validation

In this section, we present the validation strategy for PIXELMOD. First, we discuss how we build a ground truth dataset. Then, we describe our experimental setting to determine the best hashing mechanism, and the best string similarity algorithm for the OCR labels, and the corresponding θ_{visual} and $\theta_{textual}$ to use with the hashing algorithms and string similarity algorithms. The goal is to experimentally determine the best operating values for PIXELMOD by optimizing both precision and recall for the overall system.

Building ground truth. First, we randomly sample 50 images from $\mathbf{D}_1$. For each of these 50 images, we query both the pHash and PDQHash indexes for similar images, limiting the results to the maximum threshold for each algorithm (10 and 90). We select 90 as the maximum threshold for PDQHash as its developers experimentally verified it as the upper bound for images that are known to be different. For pHash, we select 10 as the maximum threshold because previous work has found that higher thresholds produce results that are too noisy [92]. This results in 11,825 unique images retrieved as similar across both indices for the same set of 50 *query images*. Then we manually annotate the results using a pairwise image annotation tool developed by [26]. Note that the goal of this annotation was to verify that images were *visually* and *contextually* similar to the original one (i.e., their overlay text contained similar words). For this reason, we did not need to build a codebook and have multiple annotators agree on the results as we did for more subjective experiments later in the paper. In the end, we find 9,785 images that are similar to our 50 source images. We refer to these 9,785 images as $\mathbf{GT}_{viz}$.

Determining θ_{visual}. Next, we use the images in $\mathbf{GT}_{viz}$ to determine the accuracy of the results returned by the two hashing algorithms when using different thresholds for θ_{visual}. Our Milvus indexes return the closest set of embeddings for a query image, scored by the Hamming distance to the candidate image. For pHash, we experiment with a range of Hamming distance thresholds from *4* to *10*, which is in line with previous works that found an optimal threshold between *6* [89] and *8* [92]. For PDQhash, on the other hand, it is recommended to use a range of pairwise distances for identifying similar images [24]. Therefore, we test multiple threshold ranges, some used by previous work using PDQHash [41, 44, 66] (*32*, *48*) as well as three additional ranges to take us up to the maximum possible threshold (*64*, *80*, and *90*).

Validating Google Cloud Vision API for OCR. To validate the ability of Google Cloud Vision API to correctly extract the OCR labels in a query image, we sample 50 images from $\mathbf{GT}_{viz}$ and create a ground truth of the text contained in the images. These are examples of images occurring "in the wild," which contain text in specialized fonts, small text in lower quality images, or text in artistic fonts, and are therefore a good test for the OCR component of PIXELMOD. On this dataset, the median Jaccard similarity of the ground truth text and the one extracted by Cloud Vision OCR is 1.0, and the mean is 0.95. This validates that Google Cloud Vision API can be successfully used as the underlying engine for identifying the contextual text contained in the images of PIXELMOD. Upon doing some error analysis of the OCR text, we find that the output of the Cloud Vision API is not missing any text present in the images, but is sometimes parsed in a different order than the ground truth. This is an artifact of how the OCR engine works on different regions of the image. We argue that this would not pose a problem when using the system for PIXELMOD as the method will work consistently across all the source images and the potential matches retrieved through perceptual hashing.

Determining $\theta_{textual}$. After validating that Cloud Vision API can be successfully used to extract the contextual text contained in images, we aim to determine the appropriate text similarity metric and corresponding similarity threshold to compare the OCR labels of the retrieved visual matches with the *query* images. We first check if the *query* image contains any OCR label, which we call $label_{query}$, using Google Cloud Vision API. If $label_{query}$ is not empty, then, for each visually matching image, we compute the corresponding OCR labels ($label_{match}$) using the same API endpoint. We experiment with multiple text similarity metrics, and multiple similarity thresholds to assess if $label_{match}$ is similar to $label_{query}$. The similarity metrics we experiment with are: i) Normalized Levenshtein similarity, ii) Jaro-Winkler similarity, iii) similarity metric based on Longest Common Subsequence (Metric LCS), and iv) Jaccard-index similarity. For each similarity metric, we measure F1 scores on the similarity threshold range of $0, 0.05, 0.1, 0.15, \ldots, 0.75, 0.8$ Note that, for Jaccard index, we experiment with values of n-grams ranging from 1 to 5 as this algorithm converts strings into a set of n-grams when computing the similarity.

Grid search setup for θ_{visual} and $\theta_{textual}$ to determine the best operating values for PIXELMOD. To identify the best set of components for PIXELMOD, we experimentally determine the best hashing method, the corresponding distance threshold for that hash, the similarity metric for the OCR label, and accordingly the similarity threshold for comparing $label_{query}$ and $label_{match}$. We perform a grid search over these four different components of PIXELMOD, scoring the combinations of the components by their corresponding F1-score, evaluated on $\mathbf{GT}_{viz}$. We present the results of the grid-search experiment in Figure 4. For space reasons, we only present the best-performing text similarity method for each θ_{visual} and the two hashing methods. We analyze how the F1 score of the embeddings with θ_{visual} changes as we increase the $\theta_{textual}$.

We can see that the combination of PDQHash with θ_{visual} of 90, and the OCR component using Jaccard similarity ($ngram = 4$) with $\theta_{textual}$ of 0.05 produces the best F1 score of 0.980. This setting yields a precision of 0.990 and a recall score of 0.979. The next best performing metrics are PDQHash with θ_{visual} of 80 and pHash with θ_{visual} of 10 using normalized Levenshtein similarities. We observe the immediate returns of expanding the θ_{visual} to the maximum bound to retrieve as many relevant results as possible, without compromising on the false positives. We will further evaluate this configuration with previous state-of-the-art image detection methods in Section 5.1. We also note that we can improve the performance of pHash embedding by using a wider θ_{visual} of 10, compared to the thresholds of 6 and 8 used in the prior works.

In the rest of the paper, we set PIXELMOD to use an image embedding of **PDQHash** with a θ_{visual} of 90 and an OCR post-processing component of Jaccard similarity ($ngram = 4$) with $\theta_{textual}$ of 0.05.

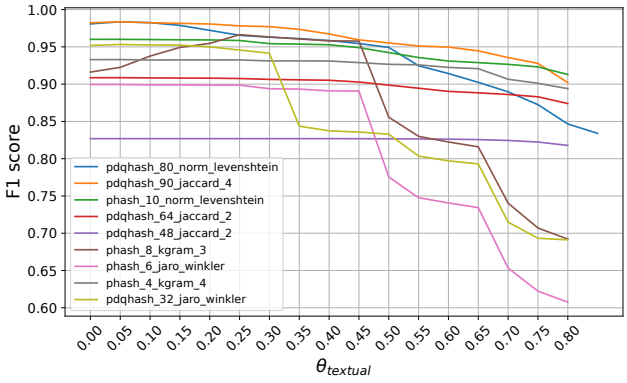

Figure 4: F1 score of different grid search components.

5 Evaluation

In this section, we first compare PIXELMOD with various other image similarity systems as baselines, showing that PIXELMOD is the best-performing approach for content moderation. Next, we use PIXELMOD to identify misleading images during the 2020 US Presidential Election in the wild and compare its effectiveness with the existing moderation system of Twitter. Finally, we perform a qualitative characterization of the misleading images by analyzing the images through the lens of Twitter's platform policies in detail.

5.1 PIXELMOD vs. baselines

We compare the performance of PIXELMOD against various image similarity systems as a baseline for evaluation. We use four different families of image similarity systems for comparison. First, we compare PIXELMOD against semantic embeddings that use Deep Neural Networks (DNNs) based methods. These include features extracted from final layers of DNN architectures specializing in image classification such as Inception-v3 [79] and ResNet [37]. The features extracted from these methods have been shown to be useful for visual search and similarity tasks [7, 74]. The next family of methods that we compare PIXELMOD against is image descriptors, which can be considered as "deeper syntactic hashes" [24]. This set of methods is popular in computer vision tasks such as object recognition, scene recognition, and work by extracting a large number of *keypoints* in an image. Matatov et al. [53] use ORB descriptors for identifying the spread of visual misinformation to assist journalists. We use ORB [70], SIFT [51], and DAISY [82] as image descriptors. Another family of methods we compare PIXELMOD with is the list of prior works that have used perceptual hashing algorithms for identifying images spreading misinformation. These include Phash and PDQHash with multiple distance thresholds [41, 44, 89, 92].

Finally, we evaluate the performance of PIXELMOD with

multi-modal embeddings. While there is a rich body of work and systems existing in the vision-language literature, the majority of these works are trained with an objective of explaining the visual concept contained in the image [50]. On the other hand, OCR texts occur as semantic context to the image itself and can be much longer, noisy, and nuanced. Thus it is not possible to directly adapt models such as Universal Image Text Representation Learning (UNITER) [18], or Visual-BERT [49] that have been trained on vision-language tasks for our problem, in the same way adapting Inception-v3 or ResNet is possible. However, to assess the potential of a multi-modal embedding that leverages text from an OCR engine, or text from the accompanying tweet with DNN-based features, we experiment with "concatenated" vision-language embeddings. First, we concatenate the embeddings obtained from Inception-V3 (a 2048-dimensional vector) and Sentence-BERT [65] (a 768-dimensional vector) to create a joint embedding from the two modalities.

We experimented with two different techniques for unifying the embeddings: i) concatenating, and ii) stacking, further reporting the best results. While much more sophisticated mechanisms of combining embeddings such as attention mechanisms exist, the dataset size of $\mathbf{GT}_{viz}$ limits us in evaluating methods that combine embeddings or modalities. Fully leveraging multimodal embeddings requires an end-to-end deep learning training setup, and accordingly, large-scale datasets designed for the problem of soft moderation, which currently does not exist.

In the same way, we also combine textual and visual embeddings using the CLIP model from Open AI [64]. CLIP consists of a text and an image encoder which encodes textual and visual information into a multimodal embedding space by using contrastive learning. The model is trained on various text/image pairs from Web sources, and has demonstrated impressive zero-shot capabilities for classification purposes and has been used to detect hateful content on social media [31, 63]. Alongside the OCR text, we also experiment with using the tweet text as part of the multi-modal embedding to evaluate if using the tweet text as further context can improve model performance for image retrieval. To this end, we concatenate the visual information encoded through the image encoder with three different variants of textual information: i) tweet text, ii) tweet text + OCR text, and iii) OCR text. After extracting the joint embeddings using CLIP, we further normalize the multi-modal embeddings for evaluation.

For the neural network-based image embeddings (Inception-v3, ResNet-50, ResNet-101, and ResNet-152) we experiment with multiple resolutions of input (1x, 2x, etc.), reporting the best performing F1 score for each method. Similarly, for the neural network-based image embeddings and the multi-modal embeddings, we experiment with multiple similarity thresholds $(0, 0.05, 0.1, 0.15, \ldots, 0.75, 0.8)$ and report the best performing score for each method (except for the methods that use perceptual hashes with pre-determined similarity thresholds). For the image descriptors, we experiment with a different number of features (30, 60, 90, and 120) and report the best-performing F1 score for each method. We compare these methods on $\mathbf{GT}_{viz}$.

Method	Prec.	Rec.	F1	Runtime
Inception v3 [79]	0.679	0.878	0.766	0.031s
ResNet-50 [37]	0.518	0.938	0.667	0.027s
ResNet-101 [37]	0.617	0.932	0.742	0.030s
ResNet-152 [37]	0.440	0.962	0.604	0.034s
ORB descriptors [70]	0.491	0.535	0.512	0.040s
SIFT descriptors [51]	0.935	0.0136	0.026	0.253s
DAISY descriptors [82]	0.484	0.431	0.456	0.257s
PDQHash (thr. 32) [44]	0.992	0.798	0.885	0.020s
PDQHash (thr. 40) [41]	0.975	0.838	0.901	0.020s
Phash (thr. 6) [89]	0.995	0.596	0.746	0.017s
Phash (thr. 8) [92]	0.991	0.707	0.826	0.017s
Inception v3 [79] + SentenceBERT [65]	0.711	0.972	0.820	0.076s
CLIP (tweet text) [64]	0.814	0.787	0.800	0.149s
CLIP (tweet text + OCR) [64]	0.862	0.810	0.835	0.149s
CLIP (OCR) [64]	0.883	0.828	0.855	0.149s
PIXELMOD	**0.990**	**0.979**	**0.980**	0.223s

Table 2: Comparison of PIXELMOD with baselines.

The results of the comparison of PIXELMOD with the baselines are presented in Table 2. Image descriptor methods perform poorly when used for soft moderation. This is because these approaches are designed for higher-level tasks like object and scene recognition. Deep neural network approaches work well in identifying the subjects of moderated images (e.g., Donald Trump or Joe Biden) and therefore report a high recall. At the same time, however, their precision is low, because they flag any image containing the same subjects as similar. We find that leveraging multimodal embeddings slightly improves the performance over DNN-based methods, but still has a very low precision (0.711) for Inception-v3+SentenceBERT. In the same way, using concatenated embeddings from Open AI's CLIP significantly increases the precision over single-modality DNN methods, but has a very low recall (0.828). Among the three different variants of CLIP embeddings leveraging different channels of modalities, we find that encoding the simplest channel, i.e. CLIP (OCR) has the best performance. Surprisingly, encoding tweet text alongside the OCR text, i.e., both CLIP (tweet text) and CLIP (tweet text + OCR) does not improve the performance of the CLIP model. This can be attributed to how state-of-the-art multi-modal embeddings like CLIP are designed to match image and caption pairs, and therefore fail to capture the nuances of text and media co-usage in social media. Perceptual hashing approaches, on the other hand, identify visually similar images and therefore report a high precision. At the same time, the need to exclude images that are visually similar but contain text that is contextually different forces these approaches to use low similarity thresholds, which limits their recall.

PIXELMOD overcomes the limitations of all three types of approaches. The use of perceptual hashing allows our ap-

proach to have better precision than neural network-based ones. At the same time, the use of OCR to determine the context of an image allows PIXELMOD to operate at a higher threshold than existing systems based on perceptual hashing, addressing the low recall reported by these methods. While PIXELMOD's precision is slightly lower than the best-performing perceptual hash method (0.990 vs. 0.995), its recall is the highest among all tested approaches. As a result of this, PIXELMOD reports the best F1-score among the tested approaches, balancing false negatives and false positives better than previous work.

We also compare the runtime of different systems in Table 2. For each method, we report the combined time of generating the image embeddings and indexing those embeddings on Milvus, averaging over 5 independent runs on identical system load. The time for retrieving visually similar images from Milvus is not considered as Milvus optimizes the retrieval time across all embeddings of different sizes (average of 0.27 seconds) for all of the systems. We can observe that the runtime of PIXELMOD is around 8 times slower than DNN-based methods, and about 10 times slower than perceptual hashing-based methods. Computing the OCR label of an image is the most time-consuming operation of PIXELMOD compared with other methods as it takes an average of 0.223 seconds per image. While this is a large overhead incurred by PIXELMOD, we need to keep in mind that its OCR component is only triggered when a similar image to a seed one is identified within the threshold of θ_{visual}, which only occurs for 0.973% of the images in $\mathbf{GT}_{viz}$. When there is no match, the time overhead of PIXELMOD is the same as PDQHash. Therefore, we argue that this slowdown of 0.2 seconds every 100 images on average is an acceptable trade-off, allowing PIXELMOD to improve its F1-score by 8% over the second best performing algorithm and allowing for more comprehensive soft moderation.

To further check the impact of the OCR component of PIXELMOD, we examine how the latency of OCR changes with increasing amount of text in the images. We characterize the amount of text by using the percentage of image area covered by it. Figure 5 shows a scatter plot of the OCR runtime against the percentage of image covered by text in $\mathbf{GT}_{viz}$. The Pearson's correlation coefficient (r) between the percentage of image covered by text and runtime is 0.401, suggesting a moderate positive correlation between runtime and the amount of text contained in an image. This moderate correlation indicates that the fraction of image covered by text plays a role in the OCR runtime.

5.2 Detecting Visual Misleading Information on Twitter using PIXELMOD

In this section, we evaluate PIXELMOD in the wild to further identify images that, while spreading false information, were not moderated by Twitter. This showcases the utility of our approach while also highlighting the serious need for scalable and automated techniques to identify visually misleading information. We first build a set of seed images spreading misleading information, using the 2020 US Presidential Election as a case study. We then apply PIXELMOD to find more images that are similar to the seeds that *should have been* moderated but were not. Finally, we perform a thorough qualitative analysis of the types of images detected, providing a characterization of image-based misinformation in the context of the 2020 US Presidential Election and how they align with Twitter's platform policies.

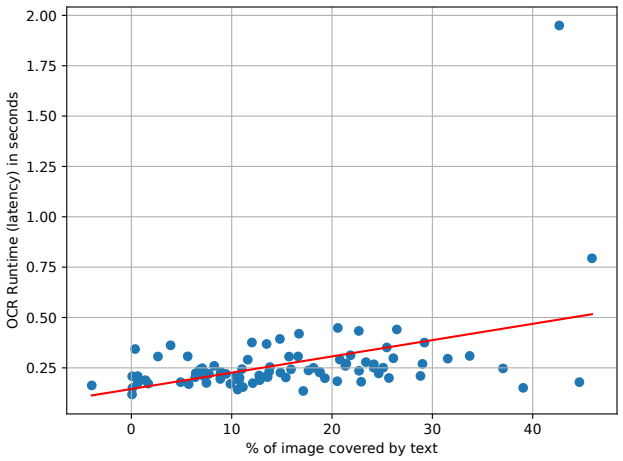

Figure 5: Latency of OCR by changing the percentage of text covering images in $\mathbf{GT}_{viz}$.

5.2.1 Identifying and Filtering 2020 US Presidential Election misleading images

In this section, we first describe how we select a dataset of images that received soft moderation from Twitter in the context of the 2020 US Presidential Election. We then present the results reported by PIXELMOD when looking for similar images in the wild and compare these results with the coverage of the moderation applied by Twitter.

Building a seed set of misleading images. To build a seed set of misleading images contained in tweets that were moderated by Twitter, we use datasets $\mathbf{D}_1$ and $\mathbf{D}_3$. Following the methodology of [91], we check the moderation status of all tweets in $\mathbf{D}_1$ during late 2022 and find 1,133 tweets that were moderated by Twitter. Unfortunately, $\mathbf{D}_3$ is too large (6.9M tweets) for us to check the moderation status of each tweet, given the limitations imposed by the Twitter API. Therefore, we only check for the tweets containing an image that occurred more than 5 times in $\mathbf{D}_3$, based on their PDQhash, resulting in 542,700 candidate tweets. From these, we identified a further 3,134 tweets with images that were moderated. Combining the moderated tweets from these two sources, we

(a) Comfy Pepe meme used as media on a tweet.

(b) A cartoon illustration used as media on a tweet.

Figure 6: Moderated images irrelevant to the 2020 election.

end up with a final seed set of 4,267 images.

An issue that we face at this stage is that our dataset contains tweets that were moderated by Twitter, but we do not know if the moderation decision was made based on the image included in the tweet or based on the text. In fact, it is rather common for social media users to include generic images (e.g., memes or GIFs) in their posts that do not contain false information themselves. Two examples of these types of tweets are presented in Figure 6. Neither image conveys false information, but the text is clearly supporting false claims of election fraud. If we kept these images in our seed dataset, PIXELMOD would flag many unrelated tweets that just happen to include them, greatly reducing its effectiveness.

To avoid this issue, we manually annotate the 4,267 tweets with images that were moderated by Twitter, discarding those not directly related to false claims about the 2020 US Presidential Election. We first sample 200 images from the 4,267 seed images and have two annotators independently label them as being relevant or not. The annotators then discuss their results, finding that 186 out of 200 images were relevant with nearly perfect agreement (Cohen's Kappa score of $\kappa = 0.9177$ [55]). This indicates that an image's relevance to the 2020 US Election is clearly understood between the two annotators. We then split the remaining 4,067 seed images between them and wind up with a total of 959 relevant images.

Detecting misinformation images using PIXELMOD. Finally, we use PIXELMOD to retrieve more tweets from the index that contain similar images to the seed misleading images. To this end, we initially retrieve 50,439 images visually similar to the 959 seed misleading images, out of which 40,244 are further filtered to be contextually similar to the query images, and hence candidates for moderation.

To check for the accuracy of these moderation candidates identified by PIXELMOD, we perform a false positive and false negative analysis. First, we randomly sample 50 *query images* from the 959 seed misleading images. Since the 50 *query images* are already manually verified to contain misleading images related to the 2020 US Presidential Election, we can assume that visually and contextually similar images to the images will be misleading images as well. We retrieve and annotate all the images from our index visually similar to the 50 *query images* following the similar methodology used to build $\mathbf{GT}_{viz}$ in Section 4, resulting in a reference set of 10,387 images. Upon querying PIXELMOD with the same 50 *query images*, it retrieves 10,172 images both visually and contextually similar to the *query images* as moderation candidates. We find that 96 of these detected images are both visually and contextually dissimilar to the corresponding *query images*, resulting in a false detection rate of 0.99%. This is due to the well-known limitations of perceptual hashing algorithms [92], for example when dealing with images where a solid color background dominates. On the other hand, we find that PIXELMOD has a false negative rate of 2.06% as it could only successfully detect 10,172 images out of the possible 10,387 images. Based on these results, PIXELMOD performs a lot better than Twitter's internal soft moderation approach, which moderated only 521 of those 10,387 images (94.98% false negatives).

Finally, we check if the candidate tweets containing the images identified by PIXELMOD were also moderated by Twitter. Following the methodology in [91], we extract the relevant metadata related to soft moderation interventions for the tweet. Out of the 40,244 tweets checked, we find that only 2,950 tweets received soft moderation interventions by Twitter. We were unable to check the intervention-related metadata for 2,479 tweets as they were inaccessible during the time we conducted the study. This analysis indicates that Twitter's soft moderation approach is inadequate, with a large proportion of tweets (92.66%) containing misleading images left without moderation, and it showcases the utility of automated approaches like PIXELMOD.

5.2.2 Characterizing misleading images about the 2020 Presidential Election on Twitter

In this section, we perform an in-depth analysis of the images identified by PIXELMOD. To aid human annotation, we first group visually similar images into *Image Stories*. We then code the extracted *Image Stories* according to Twitter's platform content policies [83, 84], with the goal of understanding how the detection performed by PIXELMOD aligns with the platform's existing moderation guidelines. Finally, we investigate whether misleading images violating different types of content policies get moderated differently by Twitter.

Aggregating misleading images into *Image Stories*. To help manually code the images detected by PIXELMOD, we aggregate them into *Image Stories*. We define an "Image story" as a set of similar images that convey the same misleading message in the same context. For example, the three images

included in three different tweets in Figure 1 are visually similar and should be grouped together. To this end, we follow a grouping approach similar to the one adopted by Zannettou et al. when studying image memes [92].

First, we apply clustering to the PDQhash embeddings of the images detected by PIXELMOD to group visually similar images by using the DBSCAN clustering algorithm [27]. To use the DBSCAN clustering algorithm, we need to select parameters for two parts of the process: i) distance threshold for assessing similarity, and ii) minimum number of elements in a cluster. Through the experimental validation performed in Section 4, we have already established that using PDQhash as the syntactic embedding, with a θ_{visual} of *90* is best suited for identifying visually similar images. We use this empirically informed distance threshold as the Hamming distance difference threshold for the first clustering parameter and set the minimum number of elements in a cluster to be 1, to allow for misleading images that occur in isolation, without visual variants. Upon using the DBSCAN algorithm to cluster the 40,244 images detected by PIXELMOD, we obtain 258 clusters of images. These image clusters represent the misleading images aggregated into visually similar claims conveying the same misleading message.

Analyzing misleading images through the lens of Twitter's Platform Policies. We present our codebook, which guides our annotation process for characterizing *Image Stories* used during the 2020 Presidential Election. We develop the codebook such that it aligns with the platform policies of Twitter [83, 84]. We use two different policies outlined in Twitter's *Platform Integrity and Authenticity* resources: i) Synthetic and manipulated media policy [83] and ii) Civic Integrity Policy [84]. Each policy contains multiple categories of violations, and each category is broken down into multiple rules. The Civic Integrity Policy outlines how "Twitter should not be used for the purpose of manipulating or interfering in elections or other civic processes such as refereed, censuses." We include 3 different categories from the Civic Integrity Policy out of the four available, which we discuss in further detail. The fourth category, "False or misleading affiliation" is related to the use of fake and parody accounts, and thus not related to misleading images. Similarly, we include the "Synthetic and Manipulated Media Policy" as this policy covers the usage of media on Twitter, which is the major modality of content in our study. The details of the individual rules and categories are listed in Appendix A.

To begin the process, we first randomly sample 100 *Image Stories* out of the 258 extracted to guide us in developing the codebook. First, we take each of the 16 different rules of Twitter's Civic Integrity Policy [84], divided into four major categories as the draft of our initial codebook. Two annotators independently code the sampled images, considering additional contextual information learned from fact-checking articles associated with them. We discussed these codes, repeating the process three times until the final codebook reached a point

(a) Participation in civic processes.

(b) Intimidate people from civic processes.

(c) Outcomes of civic processes.

(d) Synthetic and Manipulated Media.

Figure 7: Example images violating four major categories of Twitter's Civic Integrity Policy.

where further iterations would not improve it. Note that we use the 16 different rules to help us identify the closest violation of Twitter's platform policy by the images while annotating the *Image stories* with the granularity corresponding to the four categories associated with the rules. We reach a nearly perfect agreement (Cohen's Kappa score of $\kappa = 0.9$ [55]).

Positioning the extracted *Image Stories* alongside the platform policies of Twitter helps us re-evaluate the content moderation decision based on Twitter implementations and policies. We present an example image violating each of the four categories discussed in Figure 7. In the rest of this section, we describe the four categories in our codebook in detail, along with their definitions and our evaluation for matching images with the corresponding category.

1. ***Misleading information about how to participate in civic processes***: This category refers to images that mislead people about "election participation procedures and requirements, cause confusion about officials, or discuss threats to voting locations." Note that we did not find any images related to threats at voting locations in the extracted *image stories*. For election participation procedures and requirements, misleading images aim to spread false claims about the irregularity of the criteria by which votes are being cast. For example, dead people are casting votes; votes are cast multiple times; votes are being cast after the closing of polls. Misleading images may also claim that mail-in ballots are insecure, illegal, and a

source of voter fraud. Figure 7a aims to intimidate voters from voting by mail, casting doubts over the security of mail-in ballots despite mail-in ballots proven to be safe to use [1].

2. ***Misleading information intended to intimidate people from civic processes***: This category contains images that mislead people about "how votes are being counted (or not counted), problems with ballot equipment, disruption at voting locations, and the closing of polls". Misleading images in this category aim to make claims about legitimately cast ballots getting invalidated, malfunction of voting machines, switching of votes between candidates, and deleting of votes on the machines. We find images spreading misleading claims about disruptions at voting locations like poll workers filling ballots, poll workers forcing voters to use Sharpies, and ballot observers not being allowed to observe the counting process. The example in Figure 7b is spreading false claims about ballots using Sharpies in Arizona being invalidated and poll workers forcing people to use Sharpies [75].

3. ***Misleading information about the outcomes of civic processes***: This category refers to the images that mislead people about "election rigging, ballot tampering, vote tallying, declaration of premature victory, casting doubt on the outcome of civic processes, calling for interference with the implementation of election results, and undermining public confidence in the methods and results of the election." Misleading images in this category aim to make claims about the illegal processing and handling of ballots, which include alteration, manipulation, destruction, forging, counterfeiting, stealing, and pre-filling ballots. We also find false claims about voter registration and turnout, and visual and statistical anomalies in patterns of vote counting. By casting doubt on the outcome of civic processes, misleading information aims to question the integrity of the election process, discredit different stages of election processes, and call for interference with the implementation of election results using slogans such as "Stop the Steal," "Fraud." The misleading image in Figure 7c casts doubt over bipartisan vote tallying process, suggesting that Trump ballots were discarded in garbage bags [1].

4. ***Synthetic and Manipulated Media***: This category refers to images that are "significantly and deceptively altered, manipulated, or fabricated, and images shared with deliberate intent to deceive people". For this category, included images are significantly and deceptively altered, manipulated, or fabricated. On the other hand, images shared with malicious intent include out-of-context tweets sharing the media. For example, adding quotations shared in the past that are taken out of context to spread election misinformation or images from the past that are re-used in the present context, like discarded ballots from the 2018 election being repurposed to say ballots are being tampered with in the 2020 election. Figure 7d is a doctored image in connection to the "Bush-Gore Florida recount" during the presidential race in 2000 [9], shared by a Trump campaign spokesman.The Washington Times later confirmed that they never published such a story [69].

We assign each *Image Story* to *one* category. There are some observations from our annotation process: We notice that the use of memes is common in spreading misleading information. They are designed for people to add text to them to make a variation. During the annotation process, we first assess the overlay text on the memes to see if it falls into any of the categories other than the fourth: Synthetic and Manipulated Media. If it does not, we classify it as an image altered to be shared with malicious intent.

We also find that a large portion of images are used out of context and could potentially be categorized into the fourth category: Synthetic and Manipulated Media. However, out-of-context information is widely used to push narratives related to the other three themes. Thus, we take precedence of annotating the images into the first three categories if it suits any. Otherwise, it is annotated as the fourth category. We annotate these images according to their primary content to expand and deepen the qualitative analysis of these moderated images. For example, a screenshot of a video clip in which ballot workers are transcribing ballots is used out of context and spread with the misleading content of "ballot stuffing." In this example, the medium of spreading the misleading image is taking it out of context. However, the primary content being spread is related to vote counting and ballot tampering, which falls under the Twitter Civic Integrity Policy. Thus, we annotate it as Category Three: Misleading information about the outcomes of civic processes.

Moderation of misleading images by violation category. After associating the misleading images with the corresponding platform policy violations, we want to understand whether Twitter is more likely to moderate images violating some of them. Table 3 reports the breakdown of the rate of moderation by Twitter of images belonging to the different categories of violations, among the tweets identified by PIXELMOD. A high-level overview of the breakdown by category suggests that Twitter moderated specific types of misleading *image stories* more aggressively, while the moderation rate on other categories appears to be laxer. Misleading *image stories* of the categories "Intimidation from Civic Processes" and "Participation in Civic Processes" are moderated the most, with 5.96%, and 4.16% of the images getting moderated. Surprisingly, the most popular category of content violation among *image Stories*, "Misleading information about outcomes of civic processes" has the lowest moderation rate of 1.77%. Finally, images violating the category "Synthetic and Manipulated Media" have a moderation rate of 2.76%. While we can make overall observations that different types of platform policy violations might have been disproportionately moderated from Twitter's end, we find concerning results of overall moderation rate across the categories being very low.

Category	# *Image stories*	Moderation %
Participation in Civic Processes	57	4.16%
Intimidation from Civic Processes	78	5.96%
Outcomes of Civic Processes	81	1.77%
Synthetic and Manipulated Media	42	2.76%

Table 3: Moderation rate of images breakdown by category.

6 Related Work

Soft Moderation Approaches by Social Media. Social media platforms namely Facebook and Twitter have increasingly shifted their approach towards warning labels as a tool for content moderation, and additionally, provide surrounding context to the users when interacting with potentially false information. These platforms have applied warning labels on false information shared ranging from Covid-19 pandemic [21, 23, 67, 68], 2020 US Presidential Elections [5, 14, 19, 34] to climate denial misinformation [17, 20]. Twitter has reported that approximately 74% of the tweet viewership happened after the warning labels were applied to the tweets and, warning labels were effective in decreasing users quoting the misleading tweets by an estimated 29%. Savvas Zannettou [91] performed empirical analysis on a sample of 2,244 tweets with warning labels related to the 2020 US Presidential Elections. Paudel et al. proposed LAMBRETTA, a system that aims to improve soft moderation of textual content on Twitter by leveraging Learning to Rank [61]. To the best of our knowledge, PIXELMOD is the first end-to-end approach to perform soft-moderation of images on social media that has been proposed by the research community.

Applications of Perceptual Hashing in Computer Security. Perceptual hashing techniques have been widely used in computer security, leveraging them to detect phishing websites [47], scam websites [46, 56], fraudulent services [60], and to identify impersonators on social media [30]. Perceptual hashes have also been used for content authentication [6, 86], and tamper detection on images [80, 94]. Alkhowaiter et al. [8] evaluated six types of perceptual hashes on their ability to detect image manipulation and transformation over two major social media platforms: Facebook and Twitter. Historically, Microsoft developed PhotoDNA [40], a type of syntactic embedding to identify and report the distribution of child exploitation material. Facebook currently uses PDQHash in the "ThreatExchange" platform[1] to share "signals" of harmful media on their platform.

Image-based misinformation in social networks. Several studies are focusing on developing automated detection methods to identify images containing misinformation, either manipulated images [2, 12, 95], or images that are taken out of context or misinterpreted on social media [3, 10, 25, 42, 96]. Most of the works on multi-modal misinformation tackle classifying or detecting a single image as misinformation, while very few works have focused on studying the spread, and diffusion of misleading images within and across social media. The closest work to PIXELMOD is a system called DejaVu [53], which is designed to assist journalists in collaboratively addressing the spread of visual misinformation by using ORB descriptors [70] (another type of syntactic embedding) to encode the images, and FAISS [43] to index the images. Additionally, other works study the spread of COVID-19 media through WhatsApp in Pakistan [41], and other types of visual misinformation in WhatsApp [44, 66]. On the other hand, works by [59, 93] study the usage of images in state-sponsored influence campaigns. Wang et al. [89] analyzed the spread of *Fauxography* images on social media, which are images that are presented in an incorrect or untruthful fashion, by using ground truth fact-checked images from fact-checked organization Snopes [2]. Similarly, Zannettou et al. used visual similarity (i.e., perceptual hashing) and images annotated by the website KnowYourMeme to study the evolution and diffusion of image memes posted on social media [92].

7 Discussion and Conclusion

In this paper, we presented PIXELMOD, a scalable system able to identify images that are candidates for soft moderation on Twitter. PIXELMOD overcomes the inability of perceptual hashing to discern the context of an image by incorporating OCR into the matching process. Our results show that PIXELMOD outperforms three types of image-matching systems based on perceptual hashing, image descriptors, and deep neural networks. With the highest F1-score among competitors, PIXELMOD places itself as the state of the art in automated image-based soft moderation.

We believe that PIXELMOD (which we make publicly available)[3] will be an inspiring foundation for researchers and online platforms aiming to improve content moderation on social media. In the rest of this section, we first discuss the ethical considerations of our work and design implications that online platforms should keep in mind when deploying PIXELMOD. We then discuss the limitations of our approach and some directions for future work.

Ethical Considerations. Our work only uses publicly available Twitter data that was collected from the official API while it was still open to academic researchers, and we do not interact with users. As such, this work is not considered human subject research by our institution. We also preserve the privacy of Twitter users as we do not analyze any personally identifiable information (e.g., location data, account names) and blur the regions of example tweets used in the paper containing identifiable (meta)data. Additionally, we take steps to blur the example images used in the paper unless i) they

[1] https://developers.facebook.com/docs/threat-exchange/

[2] https://www.snopes.com/fact-check/

[3] https://github.com/idramalab/pixelmod

are public figures, ii) they are an illustration, and iii) they are stock images. As with any content moderation system, PIXELMOD could be used for malicious purposes like censorship and surveillance. We advocate that the system should be used with ethical principles in mind, following the *respect for public interest* and *beneficence* principles from the Menlo report [45].

Design implications. Our experiments found that Twitter soft moderation misses most images that should be labeled. This means that leveraging PIXELMOD would help Twitter's moderators cover more false information on their platform. However, when deploying PIXELMOD, Twitter or other online platforms should take several aspects into consideration. First, while PIXELMOD's detection performance exceeds that of existing approaches, a false detection rate of 0.99% may still be considered too high by online platforms to consider its adoption as a fully automated soft-moderation system. We envision PixelMod to be used by platform moderators as a tool to identify a set of candidates for soft moderation with limited false positives, which then receive manual vetting. The ultimate decision on whether to apply the moderation labels, however, should remain with the human operator. This is not dissimilar from what online platforms are doing already, but our approach would allow them to obtain a more comprehensive view of misleading content on their network. Additionally, PIXELMOD could help address the main pain points of relying on human moderation, which is the latency in decision-making and having limited moderator resources [11, 78].

Second, PIXELMOD is an inherently reactive system: it requires a set of images already identified by the platform as misleading. This process could be streamlined by using example images that have been fact-checked by dedicated organizations [89]. When curating the set of seed images in Section 5.2.1, we found that querying images directly from a list of moderated tweets can be tricky, since all of the moderated images might not be of misleading nature. In such cases, moderators using PIXELMOD should take an additional step to ensure the query images are misleading in nature, rather than ambiguous images not related to the events being studied, to get the most relevant results as candidates for moderation.

Misleading images can spread across multiple social media platforms, propagating with different contexts and forms [39, 90]. Platforms can use PIXELMOD as a tool alongside an industry-shared database of known misleading image hashes for tracking the spread of misleading images on their service and across other online communities. Platforms already use shared databases for tracking Child Sexual Abuse Material (through the National Center for Misleading and Exploited Children) and terrorism content (through the Global Internet Forum to Counter Terrorism) [22, 33, 58]. A tool like PIXELMOD backed by a centralized database could easily be added to major social media platform's existing efforts to combat fraud and misinformation [77].

Runtime implications. As discussed in Section 5.1, the increased runtime overhead of PIXELMOD is due to the OCR component, which only gets triggered for 0.973% of the images in $\mathbf{GT}_{viz}$. This rate is 1.450% among the 19.7M images used in our 'in-the-wild' evaluation in Section 5.2.1. It is to note that factors like image resolution, background, and font complexity could also impact the runtime of the underlying OCR engine. The overhead reported is an upper bound on the runtime of PIXELMOD and the average runtime of our system is in the same order as other baselines. This occasional slowdown is a tradeoff we make for increased recall for PIXELMOD, which allows us to achieve a much higher coverage of soft-moderation candidates than the ones achieved by Twitter. However, PIXELMOD can be adapted according to the content moderation budget of the platform. The initial set of results retrieved by PIXELMOD (visual matches to query images) can be sorted or filtered through metadata such as the popularity of the account posting the images, or other metadata aligning with specific content moderation strategies of a platform, before passing through the contextual similarity component.

Applying PIXELMOD to other platforms and topics. We could not test PIXELMOD on other topics and platforms due to the lack of reliable datasets across platforms and topics. First, we are not able to test our system on other social media platforms due to the lack of access to a uniform sample of posts (like the 1% sample that forms our $\mathbf{D}_2$ dataset) While datasets containing misleading images exist for other platforms like WhatsApp and Telegram, these are not suited for our evaluation since they only contain a single instance of labeled misleading images, making the visual similarity research process that is at the center of PIXELMOD moot. Even though Twitter applied warning labels on COVID-19 misinformation, these were unreliable and inconsistent [48, 52], which we independently confirmed in our preliminary analysis. Despite the limitations on evaluation settings, we expect PIXELMOD to generalize well across multiple platforms and topics. The only requirement for a platform to apply PIXELMOD to a new campaign is a set of seed images that are known to be misleading, and the system should generalize well to other platforms and topics, as the underlying image embeddings are syntactic in nature, and do not incorporate any domain-specific metadata (e.g. number of retweets, number of likes available on tweets).

Limitations. Despite the promising performance of PIXELMOD in identifying visually similar images at scale, the embedding used by PIXELMOD (PDQHash) is vulnerable to adversarial manipulations [36, 38]. An adversary could modify images to have a PDQhash that is very far from the one of the corresponding seed image, generating a false detection by PIXELMOD. This is a serious risk, and future research should investigate defenses against these attacks. Some potential avenues of defense are utilizing an ensemble of hashes: combining results from both pHash and PDQHash [36], and adversarial training of embeddings [87]. Using an ensem-

ble of hashes would force an attacker to jointly optimize the adversarial attacks against an ensemble of hashing methods as opposed to a single method, thus increasing the operation cost on the end of adversaries. Future works can also look at incorporating the contextual information (OCR text) contained in the images as part of generating the syntactic embeddings themselves, making it difficult for adversaries to modify the images without deviating from the contextual messaging of the images. At the same time, the threat model here assumes centralized coordination by an adversary. While this is within reach when dealing with state-sponsored disinformation actors [59, 71], it is not applicable to content spread autonomously and in good faith by regular users, for example in the wake of the uncertainty surrounding the COVID-19 pandemic. In the case of crisis scenarios, misleading content with significant risk factors might proliferate as many different variants of the original content as a consequence of the broad and diverse vector of sharing by people. This might render the initial set of seed hashes and similarity threshold being used ineffective in tracing the spread of the images. One such example of this was the spreading of videos of the Christchurch mosque shooting, where Facebook reported that their systems were defeated by variants of the original videos as bad actors started sharing it [58]. Platforms could use methods from online learning to update the seed set of hashes to flag, and dynamically adjust the distance threshold in specific crisis cases to better handle such events.

Apart from applying soft moderation warning labels, Twitter outlines "reduced visibility" as a possible consequence for tweets violating their Civic Integrity Policy [84]. This means it is possible Twitter could have identified all of the images subsequently identified by PIXELMOD, and chosen to reduce visibility of tweets including them instead of applying warning labels. However, we cannot analyze this phenomenon due to the lack of any public metrics regarding the visibility of tweets. Due to the nature of the evaluation datasets, images containing multi-lingual text could not be evaluated. Therefore, future applications of the system in multi-lingual settings might require further configuration of the underlying OCR engine (e.g. specifying *"languageHints"* parameters in Cloud Vision OCR engine with the intended language of evaluation).

Future work. In the future, we plan to apply PIXELMOD to other online platforms. The approach is platform-independent, and this could give interesting insights on how misinformation spreads across different online communities, and which communities are particularly influential in generating viral image misinformation. For example, we believe quite strongly that because of its low computational overhead and high performance, it makes a good fit for deployment by decentralized social networks (e.g., Mastodon), an environment where recent work has shown the potential to actually help *improve* PIXELMOD's performance via federated model sharing [13]. Since our approach does not require any platform-specific information, it is particularly interesting as a basis for further research, especially at a time where academic research is being seriously threatened by the discontinuation of the Twitter Academic API as we know it. Regardless of the specifics of future work, our presentation of PIXELMOD provides a roadmap for measuring, tuning, and benchmarking soft moderation systems; critical for any moderation tool's success. We strongly believe that the computer security community has a lot to say in this space, and hope that more researchers will get into this space.

Acknowledgments. We would like to thank the anonymous reviewers and the anonymous shepherd for their feedback, and Primah Muwanga for her help setting up the PIXELMOD artifact after the paper was accepted. This work was supported by the NSF under grants CNS-1942610, CNS-2114407, CNS-2114411, CNS-2247867, CNS-2247868, and IIS-2046590, and by a grant from the Media Ecosystems Analysis Group (MEAG).

Abstract

BGP is the de facto inter-domain routing protocol to ensure global connectivity of the Internet. However, various reasons, such as deliberate attacks or misconfigurations, could cause BGP routing anomalies. Traditional methods for BGP routing anomaly detection require significant manual investigation of routes by network operators. Although machine learning has been applied to automate the process, prior arts typically impose significant training overhead (such as large-scale data labeling and feature crafting), and only produce uninterpretable results. To address these limitations, this paper presents a routing anomaly detection system centering around a novel network representation learning model named BEAM. The core design of BEAM is to accurately learn the unique properties (defined as *routing role*) of each Autonomous System (AS) in the Internet by incorporating BGP semantics. As a result, routing anomaly detection, given BEAM, is reduced to a matter of discovering unexpected routing role churns upon observing new route announcements. We implement a prototype of our routing anomaly detection system and extensively evaluate its performance. The experimental results, based on 18 real-world RouteViews datasets containing over 11 billion route announcement records, demonstrate that our system can detect all previously-confirmed routing anomalies, while only introducing at most five false alarms every 180 million route announcements. We also deploy our system at a large ISP to perform real-world detection for one month. During the course of deployment, our system detects 497 true anomalies in the wild with an average of only 1.65 false alarms per day.

1 Introduction

The Border Gateway Protocol (BGP) is the de facto inter-domain routing protocol to achieve global connectivity in the Internet. BGP establishes Internet-wide routing paths by exchanging route announcements among the networks operated by different organizations, referred to as Autonomous Systems (ASes). Each route announcement carries AS-level path information for reaching certain prefixes (*i.e.,* a block of IP addresses). At its steady state, every AS learns an AS-path to reach every globally routable Internet prefix. Despite its global adoption, BGP itself has no built-in authentication mechanism. As a result, a misbehaved AS can announce arbitrary routes in the Internet, either due to deliberate attacks or misconfigurations. These bogus routes form serious threats to routing security, namely BGP hijacking (*i.e.,* forcing certain traffic to go through a malicious AS) and BGP route leaks (*i.e.,* redirecting traffic over unintended links). Over the past decade, the Internet has witnessed several severe BGP incidents. For example, a Swiss company leaked over 70,000 routes in 2019 [1] and a British company hijacked more than 31,000 prefixes in 2021 [2]. A cryptocurrency platform recently confirmed the loss of $1.9 million after a BGP hijacking attack [3]. Although several security extensions have been proposed to counter these threats, *e.g.,* BGPsec [4], psBGP [5] and S-BGP [6], they are not widely deployed, possibly due to incompatibility with the current Internet architecture. Besides, while RPKI [7] has gained traction in providing authoritative information about IP prefix ownership, its effectiveness is largely limited by the incomplete deployment of ROV [8]. More importantly, RPKI is not designed to mitigate route manipulation attacks or route leaks.

Detecting routing anomalies in the global Internet is the first step towards secure Internet routing. The community has proposed significant research in this regard [9–18]. However, they typically rely on extensive analysis of routing data from multiple sources. More crucially, these methods require non-trivial human supervision to produce reasonable results. The advance in Machine Learning (ML) motivates the community to apply ML techniques to automate and simplify anomaly detection by recognizing different patterns of route announcements [19–29]. However, existing methods require large datasets with manual labels and/or handcrafted features, imposing significant overheads on data collection and model update. Moreover, many of these methods learn deep latent features for classification, producing largely uninterpretable results. As a consequence, these methods provide limited prac-

tical guidance for network operators to fix routing anomalies.

To address these challenges, we present a routing anomaly detection system centering around a novel network representation learning model, BEAM (**B**GP s**E**m**A**ntics aware network e**M**bedding). Instead of learning any latent or opaque features, BEAM enables interpretable and accurate routing anomaly detection based on the intrinsic routing characteristics of ASes that are derived from the *domain specific knowledge of BGP semantics*. Specifically, we propose the concept of *AS routing role* to meaningfully characterize ASes in BGP route announcements. The design of routing role is derived from the AS business relationship graph (rather than any handcrafted features), because an AS's business relationship with its neighboring ASes determines how the AS chooses to update the route announcements received from neighbors, and how the newly generated route announcements are further propagated [30]. Given accurate modeling of ASes' routing roles, anomaly detection is reduced to a matter of detecting unexpected AS routing role churns from the original route to the new route announcement.

The key design challenges in obtaining routing roles are two-fold. First, the available dataset of route announcements could contain non-trivial noises due to the unrevealed routing anomalies in the Internet [31]. For instance, AS 4134 leaked over 70,000 routes in 2019 [1] and AS 55410 hijacked more than 31,000 prefixes in 2021 [2]. As a result, computing routing roles directly from the noisy route announcement dataset (using either raw announcements or statistical features) could lead to high false positive rates [20, 24, 25]. Second, due to the dynamism and scale of Internet routing, AS routing roles are evolving over time.

To address the above challenges, BEAM employs a novel embedding mechanism to learn an embedding vector for each AS based on the AS graph constructed from AS relationships. The key of BEAM's embedding is to preserve an AS's proximity and hierarchy properties that are essential to its routing role. The exact definitions of proximity and hierarchy are given in §3.2. The embedding vectors are further employed to uniquely represent and interpret the routing roles of ASes, based on which our routing anomaly detection system reports routing anomalies upon observing abnormal routing role churns. Further, we design our learning mechanism to ensure that the embedding vectors can properly capture routing roles despite the ever-changing Internet routing and topology.

We validate our system on 18 real-world route announcement datasets collected from global vantage points[1]. The entire datasets include over 11 billion route announcement records spanning from 2008 to 2021. The experimental results show that BEAM produces interpretable results regarding AS routing role changes, based on which our system correctly identifies all previously-confirmed routing anomalies, while only incurring at most five false alarms every 180 million route announcements (about 1.61 false alarms per day). We also deploy our system at a large ISP to detect routing anomalies over a one-month period. We further visualize AS routing roles to achieve interpretable routing behavior analysis. Our work can serve as a complement to existing BGP security extensions, such as RPKI, to protect against both BGP hijacking and BGP route leaks.

[1] A vantage point is a BGP participant (*e.g.,* a router) that provides public access to its routing table and/or its received route announcements.

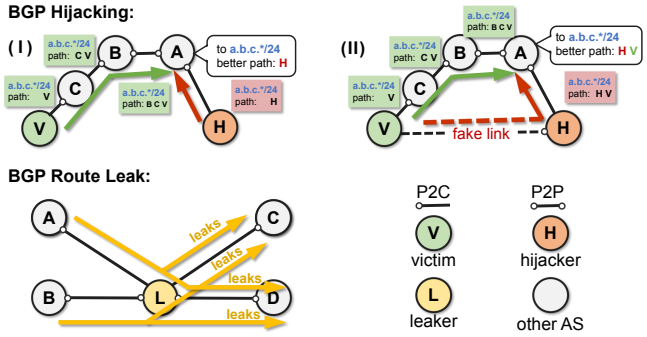

Figure 1: **Illustrations of BGP anomalies.** In BGP hijacking, the adversary can either (I) falsely claim the ownership of a prefix, or (II) announce a fake yet more preferable route. In BGP route leak, routes are propagated to unintended ASes.

To summarize, our contributions are four-fold:

- We design the first BGP semantics aware network representation learning model, BEAM, that accurately captures the routing roles of ASes.
- We develop an unsupervised routing anomaly detection system based on BEAM, which achieves real-time detection in an interpretable manner without requiring labeled routing data or feature engineering.
- We validate our system by conducting experiments on 18 RouteViews datasets with more than 11 billion route announcement records. Our system can detect all confirmed anomalies with minor false alarms.
- We deploy our system at a large ISP to collect real-world detection results for a month. The system detects 497 true anomalies in the wild from over 150 million live route announcements, with only 1.65 daily false alarms on average.

2 Background

Inter-domain Routing Protocol. The Internet contains over 73,000 advertised Autonomous Systems (ASes) as of Jun 2023. Each AS consists of several networks under the management of the same organization and is identified by a uniquely allocated non-negative integer called AS Number (ASN). BGP is the de facto inter-AS routing protocol to achieve global connectivity of the Internet. BGP is a path-vector routing protocol that maintains AS-level path information, which gets updated as BGP announcements propagate in the network. Upon receiving a BGP announcement, an AS, following

its *routing policy*, may stop further propagating the announcement, or append its ASN to the AS-path and send the updated announcement to a *selective* set of neighbors.

Business relationship largely determines one AS's routing policy [30, 32]. Two neighboring ASes typically have three types of business relationships[2]: provider-to-customer (P2C), peer-to-peer (P2P) and customer-to-provider (C2P), where a customer AS pays its provider for connectivity while two peering ASes forward traffic to each other free of charge. Thus, the inter-domain routing system of the Internet can be reconstructed as an AS graph based on AS relationships. This AS-level topology exhibits hierarchy [30], with several well recognized Tier-1 (large-scale) ASes. However, the topology is not strictly hierarchical and is flattening over time [34].

BGP Anomalies. Although widely deployed, BGP lacks built-in authentication, *i.e.,* one AS can broadcast virtually arbitrary BGP announcements to disrupt the security and reliability of Internet routing. BGP anomalies can be classified into two categories: hijacking and route leak, as illustrated in Fig. 1. BGP hijacking itself has two subcategories: (i) falsely claiming the ownership of a prefix or (ii) announcing fake paths (usually more preferable than real paths) to prefixes. The first type of hijacking is solvable by Route Origin Validation (ROV) [7], which is experiencing gradual deployment. Yet, the second type of hijacking usually needs per-hop path validation protocols such as BGPsec [4] that has very limited deployment. Also, BGP hijacking can be classified as *prefix hijacking* (targeting a prefix of others) or *subprefix hijacking* (targeting a subset of others' prefix, *i.e.,* subprefix).

The other category of BGP anomalies is route leak: a misbehaved AS propagates BGP announcements to another AS in violation of the intended policies, resulting in traffic forwarded through unintended links. The Gao-Rexford model [30] describes the restrictions on BGP route propagation and can be used to identify BGP route leak (*i.e.,* the valley-free criterion). For example, in 2019, AS 21217 (*Safe Host*) broke the valley-free criterion by propagating announcements received from its providers (*e.g.,* AS 13237 (*euNetworks GmbH*)) to another provider AS 4134 (*China Telecom*), redirecting large amounts of Internet traffic destined for European mobile networks through *China Telecom* [1].

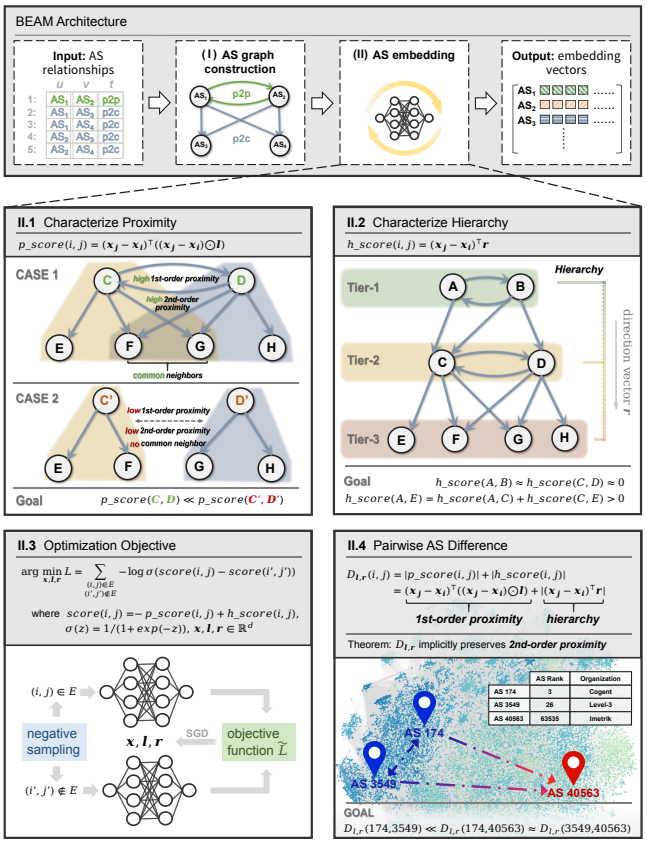

Figure 2: **Learning AS routing roles via BEAM.** BEAM takes AS relationships as the input and outputs the embedding vectors that represent AS routing roles. (**II.1**) BEAM characterizes the proximity between ASes by *p_score*. If two ASes are directly connected and have the same business relationships with many common neighbors, their proximity tends to be high, *i.e.,* a lower *p_score*. (**II.2**) BEAM characterizes the hierarchy among ASes by *h_score*. If an AS must traverse multiple consecutive P2C links to reach another AS, their hierarchy difference should be large, *i.e.,* a higher *h_score*. (**II.3**) BEAM utilizes one joint objective to optimize both *p_score* and *h_score*; negative sampling is also applied. (**II.4**) The function $D_{\boldsymbol{l},\boldsymbol{r}}$ measures the routing-role difference between two ASes. A higher $D_{\boldsymbol{l},\boldsymbol{r}}$ value means higher difference.

3 Semantics Aware Analysis

3.1 BEAM Overview

We propose a novel network representation learning model, BEAM, to learn the routing roles of ASes. The routing roles meaningfully characterize the ASes in BGP route announcements and are utilized to detect Internet routing anomalies. As shown in Fig. 2, BEAM takes the AS business relationships as the input and generates the embedding vector for each AS by (i) constructing an AS graph, and (ii) performing AS embedding. To compute AS embedding vectors, BEAM designs distance functions to measure two routing characteristics of the ASes: the proximity (see Fig. 2(II.1)) and the hierarchy (see Fig. 2(II.2)). The exact definitions of the two characteristics are given in §3.2. We design a dedicated optimization objective such that BEAM preserves both the proximity and the hierarchy through the embedding (see Fig. 2(II.3)). After obtaining the optimized embedding vectors, we can further measure the pairwise AS difference in terms of their routing roles (see Fig. 2(II.4)).

[2] We ignore complex AS relationships [33]. They are much more unusual and play a minor role in defining the overall routing behavior of an AS.

To our best knowledge, BEAM is the first dedicated network representation learning model that fully integrates BGP semantics into the training process and enables meaningful and accurate representation of ASes' routing roles. Applying network representation learning, rather than using "raw" AS business relationships, is essential to characterize ASes' routing roles. In particular, our network representation learning model can capture the global routing characteristics of each AS and translate them into embedding vectors, while the original AS business relationships can only indicate the local routing policy between two directly connected ASes. Further, with the embedding vectors, we can quantify the difference in routing roles between *any* pair of ASes, regardless of whether they are connected or not. This enables us to detect the unexpected AS routing role churns in the global Internet that capture routing anomalies.

3.2 Model Formulation

Definition 1 (AS Graph)**.** An AS graph is a directed graph $G = (V, E)$ where each vertex $v \in V$ represents an AS and each directed edge $e = (u, v) \in E$ represents a P2C relationship from u to v.

We regard each unique AS (identified by its ASN) as a vertex, and the P2C relationship between two vertices as a directed edge from provider to customer. Accordingly, a C2P relationship is viewed as a reversed P2C one, and a P2P relationship is represented via two edges in opposite directions.

We define two types of AS proximity to represent the similarity between two ASes according to their local connections/relationships with their neighbors.

Definition 2 (First-Order AS Proximity)**.** The first-order proximity between two ASes is their pairwise connection in the AS graph. For a pair of vertices (u, v), the first-order proximity between them is 1 if they are connected by an edge $e = (u, v) \in E$; otherwise it is 0.

Definition 3 (Second-Order AS Proximity)**.** The second-order proximity between two ASes is the similarity between their neighborhood network structures. Given vertices u, v, let $\boldsymbol{p_u} = \langle \boldsymbol{w}_{u,1}, \ldots, \boldsymbol{w}_{u,|V|} \rangle$ denote the first-order proximity of AS u with other ASes, the second-order proximity between u and v is quantified based on the consistency between $\boldsymbol{p_u}$ and $\boldsymbol{p_v}$.

While the concept of proximity has been proposed before [35], BEAM is the first to extend its interpretation to BGP semantics. As illustrated in Fig. 2(II.1), ASes C and D have high first-order proximity due to the P2P relationship (*i.e.,* two edges in the AS graph), and also high second-order proximity since they provide Internet transit services for a similar set of customers. We also confirm our interpretation via a real-world example: AS 8903 and AS 12541, owned by cloud service provider *Evolutio*, serve as each other's backup and hence have very similar routing roles. In terms of proximity, they have 25 common customers and their neighbor AS sets are highly similar (with a Jaccard index of 86.2%); thus, the proximity is consistent with routing role similarity.

As discussed in §2, the Internet topology exhibits hierarchy. Typically, a provider AS is considered on a higher level than its customers. Thus, we define AS hierarchy as follows:

Definition 4 (AS Hierarchy)**.** The hierarchy of an AS is its tendency to establish P2C relationship with other ASes. For two vertices u, v, if there exists a directed edge $e = (u, v)$, the hierarchy from u to v is positive.

In real world, AS 7018 (*AT&T*) lies on the top of the Internet since it establishes either P2C or P2P relationship with other ASes, while AS 140061 (*China Telecom*) is a stub AS without any customers. Thus, AS 7018 and AS 140061 have very different routing roles in BGP, which is aligned with the positive hierarchy between them.

To quantify the AS proximity and hierarchy, we embed ASes into low-dimensional representations.

Definition 5 (AS Embedding)**.** Given $G = (V, E)$, AS embedding is to map each vertex $v \in V$ into a low-dimensional vector space $\mathbb{R}^d$, *i.e.,* learn a mapping function $f_{G;\theta} : V \to \mathbb{R}^d$, where θ contains learnable parameters and $d \ll |V|$.

Finally, we define our BEAM model as follows:

Definition 6 (BGP Semantics Aware Network Embedding)**.** Given AS relationships, the BEAM model constructs the AS graph $G = (V, E)$ and performs AS embedding, such that the embedding vectors $\boldsymbol{x} = \{\boldsymbol{x_v} | v \in V, \boldsymbol{x_v} = f_{G;\theta}(v)\}$ preserve the first- and second-order proximity and the hierarchy of ASes.

3.3 AS Graph Construction

The first step of training BEAM is to construct the AS graph. We use the real-world CAIDA AS relationship dataset [36][3] to construct the AS graph G. A business relationship between two ASes can be denoted as a tuple (u, v, t), where u and v are two ASNs and $t \in \{\text{P2P}, \text{P2C}, \text{C2P}\}$ refers to the relationship type. For each tuple (u, v, t) in the CAIDA dataset, if $t = \text{P2C}$, we add a directed edge $e = (u, v)$ into E. If $t = \text{C2P}$, we add a directed edge $e = (v, u)$ into E. And if $t = \text{P2P}$, we add two directed edges $e = (u, v)$ and $e' = (v, u)$ into E.

The rationale for using AS business relationship to construct the AS graph is that it primarily determines how an AS chooses to update the routing paths received from neighbors, and how the new generated route announcements are propagated [30]. Hence, it has direct impacts on ASes' routing roles. Moreover, the AS business relationship is a relatively stable property determined by real-world commercial agreements between connected ASes. Thus, it is challenging to impersonate a specific AS without simultaneously changing or faking multiple AS relationships. Besides, unlike historical route announcement data, the AS business relationship dataset contains fewer incorrect entries [34].

[3] CAIDA is not the only source of AS business relationships. Other sources like TopoScope [37] are also available for training our system.

3.4 AS Embedding

With a constructed AS graph, we embed ASes into a vector space while preserving proximity and hierarchy. To this end, we design two distance functions to measure the difference between ASes regarding proximity and hierarchy, respectively.

Proximity Distance. The proximity distance, indicated by *p_score*, models the first-order proximity between ASes: a small distance between two ASes means that their proximity is large. Per Def. 2, given a pair of directly linked vertices (u,v) and another pair of vertices (u',v') without a direct edge, *p_score* should reflect the difference between their first-order proximity, *i.e.,* $p\_score(u,v) < p\_score(u',v')$. Therefore, we define *p_score* as follows:

$$p\_score(u,v) = (\boldsymbol{x_v} - \boldsymbol{x_u})^\intercal \big((\boldsymbol{x_v} - \boldsymbol{x_u}) \odot \boldsymbol{l}\big), \tag{1}$$

where $\boldsymbol{x_u}, \boldsymbol{x_v} \in \mathbb{R}^d$ denote the embedding vectors of u,v, respectively. $\boldsymbol{l} \in \mathbb{R}^d$ is a learnable weight vector for the d components. $\intercal$ and $\odot$ denote matrix transpose and Hadamard product, respectively. Intuitively, $\boldsymbol{l}$ projects the embedding vectors into a subspace intended for preserving the proximity. To explicitly preserve the first-order proximity, BEAM learns $\boldsymbol{x}, \boldsymbol{l}$ by decreasing the *p_score* of two vertices with an edge, while increasing the *p_score* of two vertices that are not directly connected. Since this training strategy also preserves the second-order proximity implicitly (elaborated later in this section), we do not define a dedicated distance function for the second-order proximity.

Hierarchy Distance. The hierarchy distance, indicated by *h_score*, quantifies the hierarchical difference between ASes. Per Def. 4, given a pair of vertices (u,v) where $(u,v) \in E, (v,u) \notin E$, and another pair of vertices (u',v') without a directed edge, *i.e.,* $(u',v') \notin E$, the *h_score* should reflect the difference between their hierarchy, *i.e.,* $h\_score(u,v) > h\_score(u',v')$. To this end, we design *h_score* as follows:

$$h\_score(u,v) = (\boldsymbol{x_v} - \boldsymbol{x_u})^\intercal \boldsymbol{r}, \tag{2}$$

where $\boldsymbol{x_u}, \boldsymbol{x_v} \in \mathbb{R}^d$ denote the embedding vectors of u,v, respectively. $\boldsymbol{r} \in \mathbb{R}^d$ is a learnable unit vector indicating the descending direction of hierarchy. Intuitively, $\boldsymbol{r}$ projects the embedding vectors into a subspace intended for preserving the hierarchy, and thus the *h_score* calculates the projected length of $\boldsymbol{x_v} - \boldsymbol{x_u}$ on the specific direction vector $\boldsymbol{r}$ such that it has two important properties, *i.e.,* $h\_score(u,v) = -h\_score(v,u)$ and $h\_score(u,v) = h\_score(u,w) + h\_score(w,v)$. To explicitly preserve the hierarchy of ASes, BEAM learns $\boldsymbol{x}, \boldsymbol{r}$ by increasing the *h_score* of two vertices with a directed edge (*i.e.,* a P2C relationship), while decreasing *h_score* of two vertices not directly connected. Since ASes with P2P relationship is connected by two edges in opposite directions, their *h_score* would approach zero under this training strategy, which is consistent with the BGP semantics that two peering ASes are typically on the same hierarchy of the Internet.

Training Objective. With the two distance functions, we design the training objective of BEAM to ensure that a trained BEAM preserves both proximity and hierarchy. We consolidate the two distance functions as follows:

$$score(u,v) = -p\_score(u,v) + h\_score(u,v). \tag{3}$$

Since a small *p_score* means large proximity and a large *h_score* means large hierarchy, we subtract *p_score* in Eq.(3) so that *score* increases monotonically with the difference between ASes in terms of proximity and hierarchy. This design allows BEAM to preserve the two routing characteristics better. Although *score* may become zero in some cases, it will not affect BEAM 's training since the training objective is to enlarge the difference of *score* between observed edges and nonexistent edges. Per Def. 2 and 4, given an observed edge (u,v) and a nonexistent edge (u',v'), our model should assign $score(u,v) > score(u',v')$ with the optimal $\boldsymbol{x}$, $\boldsymbol{l}$ and $\boldsymbol{r}$. To this end, we formulate the optimization problem as follows:

$$\arg\min_{\boldsymbol{x},\boldsymbol{l},\boldsymbol{r}} L = \sum_{\substack{(u,v)\in E \\ (u',v')\notin E}} -\log \sigma(score(u,v) - score(u',v')), \tag{4}$$

where E is the edge set of the AS graph, $\sigma(z) = \frac{1}{1+exp(-z)}$ is the sigmoid function, and L is the objective function to be minimized. We solve this problem via a fully connected neural network, which has an embedding layer and two linear layers. The embedding layer generates the embedding vectors ($\boldsymbol{x}$) that represent ASes' routing roles and the two linear layers project the embedding vectors into two subspaces that preserve proximity ($\boldsymbol{l}$) and hierarchy ($\boldsymbol{r}$), respectively. For each edge $(u,v) \in E$, we sample 10 negative (nonexistent) edges $(u',v') \notin E$ and each $((u,v),(u',v'))$ forms one training instance. The neural network generates the embedding vectors of u and v, computes the loss via Eq.(4), and uses SGD [38] to optimize itself. When the training is complete, the neural network learns the ASes' routing roles. We empirically set $d = 128$ and train the network for 1,000 epochs. The batch size is 1024 and the initial learning rate is 10^{-5}.

Computing Pairwise AS Difference. The pairwise AS difference represents their difference in the routing roles, which we define between the embedding vectors of two ASes using the BEAM model (including its parameters $\boldsymbol{x}$, $\boldsymbol{l}$, and $\boldsymbol{r}$):

$$\begin{aligned} D_{\boldsymbol{l},\boldsymbol{r}}(u,v) &= |p\_score(u,v)| + |h\_score(u,v)| \\ &= \underbrace{(\boldsymbol{x_v} - \boldsymbol{x_u})^\intercal ((\boldsymbol{x_v} - \boldsymbol{x_u}) \odot \boldsymbol{l})}_{\textit{the first-order proximity}} + \underbrace{|(\boldsymbol{x_v} - \boldsymbol{x_u})^\intercal \boldsymbol{r}|}_{\textit{the hierarchy}}. \end{aligned} \tag{5}$$

Note that this pairwise AS difference directly reflects the first-order proximity and the hierarchy between ASes. Moreover, per the definition of the second-order proximity (Def. 3), the pairwise AS difference between two vertices should be small if their neighbors and the business relationships with their neighbors are similar. In Appendix A, we prove a theorem

that this pairwise AS difference does preserve the second-order proximity between ASes. Thus, our BEAM model can preserve the first-order proximity, the second-order proximity and the hierarchy between ASes.

3.5 Embedding Results Analysis

We train BEAM with the CAIDA AS relationship dataset collected on 06/01/2018 to study the routing roles of ASes. The dataset contains 61,549 ASes and 439,981 business relationships, and is randomly selected from the CAIDA datasets collected before historical BGP incidents (see §5).

Visualizing Embedding Vectors. We visualize the embedding vectors computed by BEAM in a 3-D space to illustrate the overall characteristics of AS routing roles. Since BEAM learns the unit direction vector $\boldsymbol{r}$ that represents the descending direction of hierarchy, we decompose each embedding vector into two parts: the projection on $\boldsymbol{r}$, and the projection on the plane orthogonal to $\boldsymbol{r}$ (*i.e.,* the rejection). We use the length of the projection as the coordinate value of the Z-axis to represent the hierarchy level of each AS. We further transform the rejection into a 2-D space by the widely used dimension reduction method t-SNE [39], and hence obtain the coordinate values of the X-axis and the Y-axis.

We visualize all embedding vectors in Fig. 3(A), where each vertex represents a unique AS and the color of the vertex indicates the AS hierarchy level. We observe that a few vertices are densely located (*i.e.,* high proximity) on the highest and the lowest levels of the Internet, while more medium-level vertices are sparsely distributed (*i.e.,* low proximity). For a better illustration, we show the terrain plot of the same 3-D space in Fig. 3(B) via Inverse Distance Weight [40], which is an interpolation metric widely used for estimating the spatial distribution of scatter points. The observations are consistent with the BGP fact that a small number of ASes on the highest hierarchy level have similar routing roles, since they all provide transit services for other ASes and establish P2P relationships with the ASes on the same level to form "Internet backbone". On the contrary, it takes multiple C2P links for another small set of ASes to reach the backbone ASes. Thus, they lie on the lowest hierarchy level, forming several clusters with lower Z-axis coordinate values. The rest ASes are located on the medium hierarchy. They have different providers and customers, and serve diverse routing roles.

Routing Role Analysis. We further study the routing roles of specific ASes to check if the computed embedding vectors reflect their actual routing properties in the Internet. In particular, we choose 16 Tier-1 ASes (*e.g., AT&T*), 9 major yet not Tier-1 ASes (*e.g., Telstra*), and 50 other randomly selected stub ASes (*i.e.,* the ASes connected to only one other AS). We present the projections of their routing roles on both YZ-plane (Fig. 3(C)) and XY-plane (Fig. 3(D)). The results show that the Tier-1 ASes form dense clusters on the highest hierarchy level, the major yet not Tier-1 ASes form several dense clusters on the levels relatively lower than those of Tier-1 ASes, and the stub ASes are dispersed on the much lower levels. This confirms that the computed embedding vectors preserve both the proximity and hierarchy of ASes. Figure 3(C), however, does not exhibit distinct hierarchies, which is expected since the Internet topology is not strictly hierarchical [34]; for example, AS 4134 (*China Telecom*) has P2P relationship with the Tier-1 AS 1299 (*Arelion*), yet it also keeps a route with 2 consecutive C2P links to reach AS 1299.

Pairwise AS Difference Comparison. We measure the difference of routing roles between two ASes. We choose AS pairs in three categories: (i) We randomly sample a subset S_0 from all pairs of ASes with the P2P relationship while enforcing the following constraint. In particular, given an AS pair, we obtain the neighbor AS set of each AS in the pair. The AS pair is eligible only if the Jaccard index (*i.e.,* the similarity) of the two neighbor AS sets is between 0% and 10%. We also sample another subset S_1 without enforcing this constraint. (ii) We randomly sample six subsets (denoted as N_0 to N_5) from all pairs of ASes that are not connected directly, where the Jaccard indices of the two neighbor AS sets are between 0% and 10%, 0% and 20%, 20% and 40%, 40% and 60%, 60% and 80%, and 80% and 100%, respectively. (iii) We randomly sample seven subsets (denoted as H_0 to H_6), where the shortest path between two ASes in one pair is a direct P2P link, and 2, 3, 4, 5, and 6 consecutive P2C links, respectively. For instance, if two AS pairs (*e.g.,* AS1 and AS2, AS2 and AS3) are both in the P2C relationship, then AS1 and AS3 form two consecutive P2C links. Please see Appendix B for a summary of these sampled subsets.

For each sampled subset, we compute the difference of routing roles between two ASes and obtain Cumulative Distribution Function (CDF) curves. We make three types of comparisons among the CDF curves of different subsets. The comparisons of the P2P AS pairs (S_0), P2C AS pairs (H_0) and no-relationship AS pairs (N_0) show that S_0 has the smallest difference and N_0 exhibits the largest difference (see Fig. 3(E)). It reveals that BEAM preserves the first-order proximity. The comparisons among the subsets with different degrees of neighbor intersection (N_1 to N_5) show that if two ASes have more common neighbors (*i.e.,* high second-order proximity), they tend to have similar routing roles (see Fig. 3(F)). In Fig. 3(G), the difference of routing roles increases with the number of consecutive P2C links between two ASes, which is consistent with the nature of AS hierarchy.

4 The Anomaly Detection System

In this section, we develop a semantics aware routing anomaly detection system built upon BEAM[4].

[4]Our system is open source at this GitHub repository.

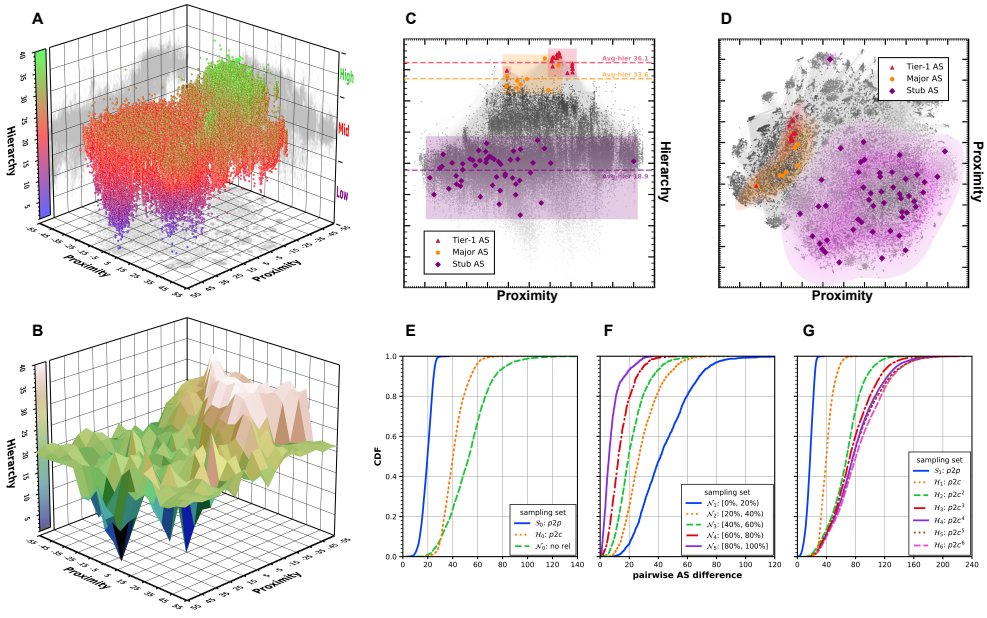

Figure 3: **Embedding results.** (**A**) All embedding vectors visualized in a 3-D space. The Z-axis represents the hierarchy level and the XY-plane reflects the proximity. (**B**) The terrain plot of the embedding vectors. The estimated spatial distribution shows the overall characteristics of AS routing roles. (**C**) The YZ-plane projection of the embedding vectors. The X-axis and the Y-axis of the projection plane indicate the proximity and the hierarchy, respectively. The areas with different colors illustrate the distribution of typical ASes (*i.e.,* vertices with different colors), and the dashed lines show their average hierarchy levels. (**D**) The XY-plane projection of the embedding vectors. (**E**) The routing role difference regarding the sampled subset S_0, H_0 and N_0. (**F**) The routing role difference regarding the sampled subset N_1 to N_5. (**G**) The routing role difference regarding S_1 and H_1 to H_6.

4.1 System Overview

Our routing anomaly detection system is designed to detect global-scale Internet routing anomalies. As shown in Fig. 4, our detection system consists of three components: the routing monitor, the BEAM engine, and the anomaly detector. The routing monitor establishes connections with global vantage points to capture route changes in real time. The BEAM engine utilizes our BEAM model to compute the *path difference scores* of the route changes, which quantifies the routing role difference between the new and the original routing paths. Based on the path difference scores, the anomaly detector identifies suspicious route changes, and groups the suspicious route changes sharing the same prefix into anomalous prefix events. This is necessary to identify the prefixes impacted by widespread routing anomalies. It further locates the ASes responsible for each anomalous prefix event and correlates the events caused by the same set of responsible ASes. Since the BEAM model used in our detection system is pretrained with AS relationship data (instead of labeled routing anomaly data), our detection is unsupervised.

4.2 BEAM Engine

Not all route changes are caused by routing anomalies. For instance, different ASes of the same organization may claim the ownership of a specific prefix simultaneously, thus generating two routing paths with different origin ASes. This is called multiple origin AS (MOAS) [41] and should not be considered as anomalous. Thus, the BEAM engine relies on *path difference score* to identify suspicious route changes.

To compute the path difference score for a route change, we design a method based on the dynamic time warping (DTW) algorithm [42], an effective way of measuring the overall difference between two ordered sequences of unequal length. Specifically, given two routing paths $S = \langle v_1, \ldots, v_m \rangle$ and $S' = \langle v'_1, \ldots, v'_n \rangle$, the DTW algorithm repeatedly selects a pair of ASes from S and S', and generates eligible sequences of AS pairs by satisfying the following conditions: (i) Each AS in S (S') should be paired with one or more ASes from S' (S). (ii) The first (last) AS in S should be paired with the first (last) AS in S'. (iii) Given $i < j$, if v_i and v_j from S are paired with v'_k and v'_l in S', then there keeps $k \leq l$; S and S' are symmetric. For example, if $S = \langle v_1, v_2, v_3 \rangle$, $S' = \langle v'_1, v'_2, v'_3 \rangle$, then $((v_1, v'_1), (v_2, v'_2), (v_3, v'_3))$ and $((v_1, v'_1), (v_1, v'_2), (v_2, v'_2), (v_3, v'_3))$ are both eligible, but $((v_1, v'_1), (v_1, v'_2), (v_2, v'_1), (v_3, v'_3))$ is ineligible because the two pairs (v_1, v'_2) and (v_2, v'_1) violate the condition (iii). For each eligible sequence, we sum the pairwise AS difference (given by BEAM) of its AS pairs. Then, we choose the minimum value from all summed values as the path difference

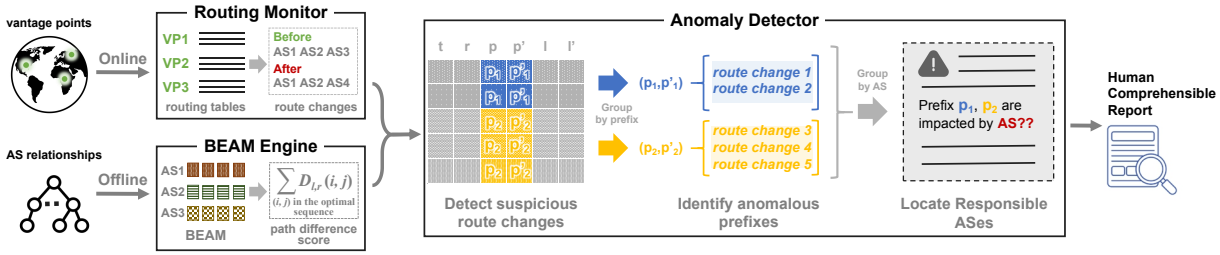

Figure 4: **The workflow of our routing anomaly detection system built upon BEAM.**

score. The sequence of AS pairs with the minimum value is referred to as *the optimal sequence*. Let $S[1:i]$ ($S'[1:j]$) denote the first i (j) ASes in S (S'). We apply dynamic programming to obtain the optimal sequence of AS pairs for $S[1:i]$ and $S'[1:j]$ based on prior states as follows:

- Given the optimal sequence for $S[1:i]$ and $S'[1:j-1]$, add a new AS pair $(S[i], S'[j])$ to the sequence.
- Given the optimal sequence for $S[1:i-1]$ and $S'[1:j]$, add a new AS pair $(S[i], S'[j])$ to the sequence.
- Given the optimal sequence for $S[1:i-1]$ and $S'[1:j-1]$, add a new AS pair $(S[i], S'[j])$ to the sequence.

We choose the operation yielding the minimal sum of pairwise AS difference as the optimal AS pair sequence for $S[1:i]$ and $S'[1:j]$. The induction base, *i.e.,* the optimal AS pair sequence for $S[1:1]$ and $S'[1:1]$, is trivial to compute. For details of this algorithm, please see our additional technical report [43].

4.3 Anomaly Detector

Detecting Suspicious Route Changes. The anomaly detector first identifies suspicious route changes caused by routing anomalies. Specifically, for a route change, the anomaly detector checks whether its path difference score is greater than a threshold th_d, which is dynamically computed using historical legitimate route changes (detailed in §5.2). If so, the route change is regarded as *suspicious*.

Identifying Anomalous Prefixes. It is necessary to prioritize the widespread routing anomalies captured by multiple vantage points. Towards this end, the anomaly detector groups the suspicious route changes that impact the same prefix into different *prefix events*, where each event is associated with a specific prefix and sorts the suspicious route changes by their occurrence time. For each event, the anomaly detector applies a sliding window to count the number of individual vantage points that observe suspicious route changes within the window. If this number is above a threshold th_v (detailed in §5.2), we consider the prefix event is associated with a widespread routing anomaly and regard the event as anomalous.

Locating Responsible ASes. The misbehaved ASes that are responsible for routing anomalies may impact multiple prefixes simultaneously. To obtain comprehensive information about the affected prefixes in each routing anomaly, the anomaly detector correlates all anomalous prefix events based on their responsible ASes. In particular, for each suspicious route change associated with an anomalous prefix event, our detector identifies the ASes that either appear in the new path or in the original path. Then, we compute the intersection of these ASes from all route changes as the responsible ASes for the anomalous prefix event. Given two prefix events, if their time ranges have overlaps and they have common responsible ASes, we consider they are correlated. Thereby, we can divide all anomalous prefix events into multiple sets, where each event only correlates with the other events in the same set (*i.e.,* no cross-set correlation). Finally, our anomaly detector treats each set as an individual routing anomaly and outputs an alarm that specifies both the affected prefixes and the responsible ASes. Due to space limitations, the implementation details are provided in our additional technical report [43].

5 Experimental Results

In this section, we evaluate the path difference scores and perform experiments with real-world BGP data. We also deploy our system at a large ISP to verify its effectiveness in practice.

5.1 Measuring Path Difference Score

We use real-world route announcements to analyze both legitimate and anomalous route changes in terms of path difference scores. We collect 18 reports on historical routing anomalies spanning from 2008 to 2021, including 15 BGP hijacking (2 prefix and 13 subprefix hijacking) and 3 BGP route leak incidents. For each anomaly, we obtain manually confirmed information (*e.g.,* the time of anomalies and the affected prefixes) from two authoritative sources, the Oracle blogs [44] and the BGPStream monitor [45]. Based on the information, we fetch all route announcements 12 hours before and after the anomalies from RouteViews [46] and obtain 18 datasets. The total number of collected route announcements is 11,861,377,951. In each dataset, we identify the anomalous route changes with the confirmed information of the anomaly. The anomalous route changes in our datasets cover both *origin change* (*i.e.,* two routing paths have different origin ASes)

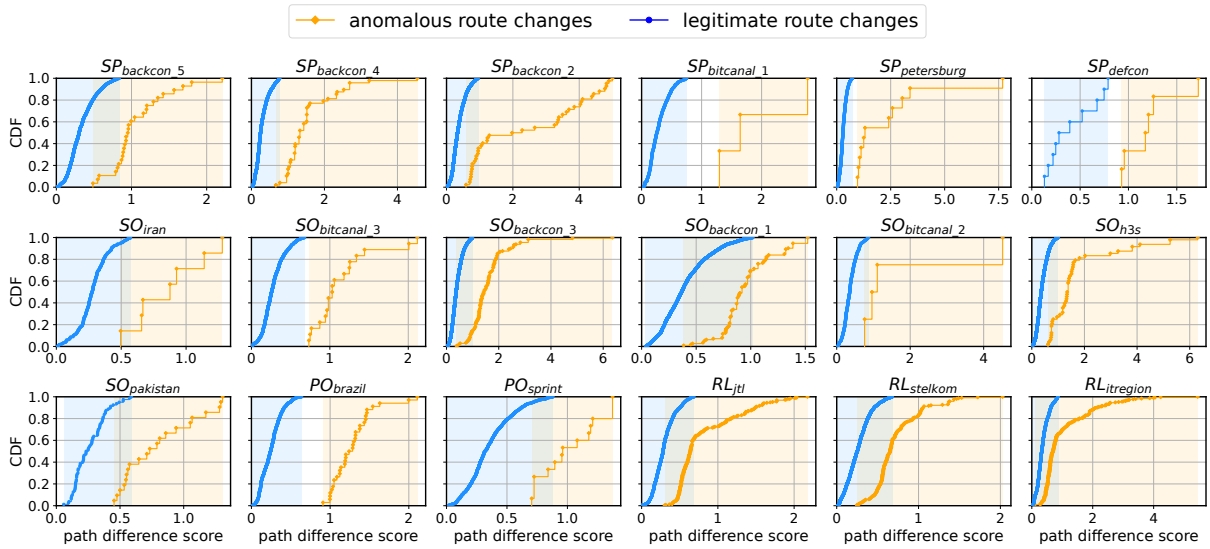

Figure 5: **Statistical comparisons of path difference scores between anomalous and legitimate route changes.**

and *path change* (*i.e.,* two routing paths share the same origin yet traverse different ASes). We name each dataset (*e.g.,* PO_{brazil}) accordingly. We also locate legitimate route changes such as origin changes incurred by the multiple origin AS issue [41]. See details in our additional technical report [43].

Figure 5 shows the path difference scores measured by the BEAM engine on the 18 datasets. The path difference scores of anomalous route changes are much higher than those of legitimate ones, indicating that routing anomalies would significantly change the routing roles of ASes on the routing paths. For instance, the anomalous route changes in $SO_{pakistan}$ changed the origin AS from AS 36561 (*YouTube*) to AS 17557 (*Pakistan Telecom*). These two origin ASes are significantly different in their neighbors, geographic locations and hierarchical levels in the Internet. In contrast, the different origin ASes in a legitimate route change often belong to the same organization and their neighbors are more similar (*e.g.,* the same upstream AS), resulting in much smaller routing role churn between the original and new routes.

5.2 Routing Anomaly Detection Results

We now validate the performance of our detection system. Since RouteViews archives the RIB data (*i.e.,* the snapshot of routing table) of global vantage points bi-hourly, for each dataset, we fetch the most recent RIB data before the confirmed anomaly to initialize the routing tables that our detection system monitors. Then we use the route announcements observed within two hours as input, which include all routes associated with the confirmed anomaly and enough legitimate route changes. We set the sliding window length to two hours for the same reason. The thresholds th_d and th_v are decided by historical data. Specifically, we use the observed path difference scores for all legitimate route changes two hours before the current window as a reference distribution, and set th_d as the knee point of its CDF curve. th_v is determined similarly. The calculation of the knee point is automated via kneed [47].

To systematically evaluate our system, we substitute the BEAM engine with other commonly used features or representation learning models to create variants of our detection system. In particular, we create 6 variants: ED uses the edit distance [48] to measure path difference; JI uses the Jaccard index of neighbor AS sets to measure the similarity of two ASes; Li, Ma, NV and SD uses the general network representation model Line [35], Marine [49], node2vec [50] and SDNE [51] to train embedding vectors, respectively, and utilize Euclidean distance of embedding vectors to measure the similarity of two ASes. All these variants are well-trained and use the same settings as our detection system. Moreover, we compare our system with two state-of-the-art ML-based BGP anomaly detection approaches: AV [28] and LS [22]. AV and LS identify anomalous route changes and the time intervals where anomalies occur, respectively. For fair comparisons, we apply our anomaly detector to aggregate their detection results into different alarms (see Appendix C). We do not compare our work with the active probing-based systems like [10, 15] because they heavily rely on the real-time probing results collected by many data-plane facilities. These real-time probing results are not available for our historical datasets.

Each detection system may raise multiple alarms for a dataset. Each alarm reports a potential routing anomaly. If any alarm matches the confirmed information, *i.e.,* the target prefix is reported as one of the anomalous prefixes and the misbehaved ASes are also identified as responsible, we consider the confirmed anomaly in this dataset as *detected*. Besides the confirmed anomaly, there could be other alarms

Table 1: **Detection results on the 18 real-world datasets.** The ✓/✗ indicates whether the confirmed anomaly of a dataset is *detected*. If *detected*, the number of all raised alarms (#Alarms) and that of false alarms (#FalseAlarms) are presented in bold.

that indicate unrevealed routing anomalies or are simply false alarms. It is difficult to contact the operators to further confirm these potential anomalies since most anomalies occurred long ago. To verify these unknown alarms, we define four anomalous route change patterns that represent typical routing anomalies based on domain knowledge and authorized data such as RPKI validation states. If an alarm matches at least one pattern, we consider it a true alarm with high confidence, otherwise it is a *false alarm*. These patterns are as follows:

- P1 (Unauthorized Route Change): The origin ASes before and after the route change belong to different organizations and have different RPKI validation states, *i.e.,* one in the *invalid_ASN* state and the other in the *valid* state [7].
- P2 (Route Leak): The routing path before or after the route change violates the valley-free criterion [30].
- P3 (Path Manipulation): The routing path before or after the route change contains reserved ASNs or adjacent ASes that have no business relationship records between them [11].
- P4 (ROA Misconfiguration): The origin ASes before and after the change are from the same organization but have different RPKI validation states, *i.e.,* one in the *invalid_length* or *invalid_ASN* state and the other in the *valid* state [52].

These patterns are endorsed by the domain experts from a large ISP where we deployed our system. They also apply these patterns to verify our real-world detection results (see §5.5). Note that these patterns alone *should not* be used to detect routing anomalies directly because they cannot correlate massive route changes with the same root cause, which would result in too many false alarms. We discuss the rationale behind these patterns in our additional technical report [43].

Table 1 shows that all previously-confirmed 18 routing anomalies are correctly detected by our system within tens of alarms. Further, our system reports no false alarms for 6 datasets that cover the confirmed anomalies, and only 5 false alarms in the worst case. These false alarms are mainly related to route engineering practices such as AS prepending [53], while some involve stub ASes with limited connections. In contrast, the baselines cannot detect all these anomalies and raise more false alarms than ours (except for SD that cannot detect any anomalies). Besides, the baselines require many extra data to train the models, *e.g.,* AV needs RIB entries in every two hours and LS requires a large amount of training data to eliminate the negative impacts of label noises. Moreover, AV cannot detect transient anomalies and LS incurs high FP due to per-minute anomaly detection. Please see the details in Appendix C. Overall, our detection system outperforms these baselines by significant margins. In summary, (i) our system addresses the key challenges of ML-based detection methods and realize effective Internet routing anomaly detection. (ii) compared with our BEAM model, general network representation learning models are not able to effectively capture BGP semantics for routing anomaly detection.

5.3 Runtime Overhead

Our system runs on a Linux server with Intel Xeon E5-2650v4 (2.20GHz). We present its runtime overhead in Fig. 6. The X-axis displays the datasets in their chronological order, with

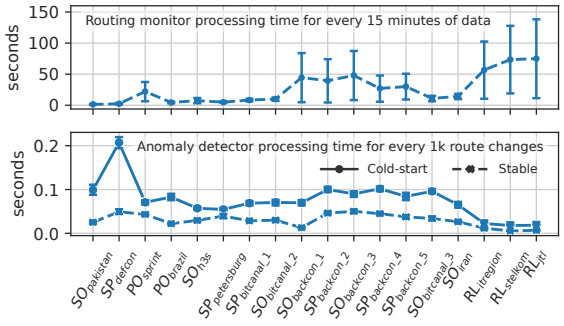

Figure 6: **The runtime overhead of our detection system.**

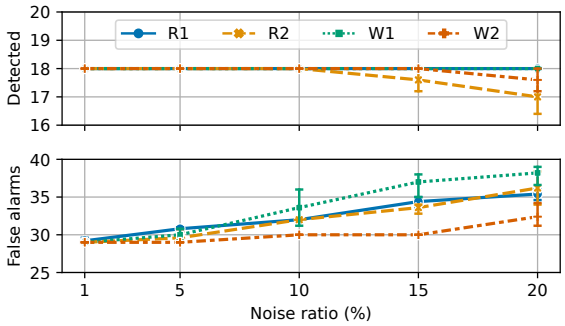

Figure 7: **Detection results given noisy AS relationships.**

the later datasets containing more ASes in operation. The number of ASes in our datasets increases from 27,588 to 73,014 over the entire period. The top figure shows the average time it takes to process every 15 minutes of data from each dataset. The error bar reflects the 95% confidence interval. The variance in processing time is mostly caused by the variance in the sizes of 15-minute data. The processing time is less than 100 seconds in most cases, indicating that the increase of ASes only slightly impacts our system's runtime overhead. The largest processing time (∼140s in RL_{jtl}) is still much smaller than 15 minutes, meaning that our system can effectively process the stream of global route announcements in real time. The bottom figure plots the average time it takes to process every 1,000 route changes. Due to the caching employed by our system (*e.g.,* the caching of path difference scores), the anomaly detector spends much less time at the steady state (∼0.05s per 1,000 route changes), compared with the cold start (∼0.2s).

5.4 Robustness Analysis

We analyze the robustness of our system given noisy AS relationship data, which is created by modifying or deleting the original AS relationships in the CAIDA dataset. We consider four types of noisy datasets. In particular, given a noise ratio r, we first randomly select r% AS relationships, and then flip their labels (*i.e.,* changing P2P to P2C and P2C to P2P) to produce the R1 dataset, or delete them to create the R2 dataset. R1 and R2 represent the noisy dataset caused by inaccurate and incomplete AS relationship inference, respectively. To create another two types of noisy datasets, we first select top-r% AS relationships with the fewest BGP routes that use their underlying AS-to-AS links and create the W1 dataset by flipping their labels and W2 by deleting them. These two types of noisy data are common in the Internet because the AS relationships serving fewer routes are more likely to be mislabeled due to their limited Internet visibility.

We train our system with each noisy dataset independently and evaluate its detection performance following the same steps in §5.2. We repeat each experiment for 5 times to avoid bias and plot the results in Fig. 7. The error bar shows the 95% confidence interval. Even when the noise ratio reaches 20%, our system still detects at least 17 true anomalies (18 in total) and only generates less than 40 false alarms across all datasets. Note that such a high noise ratio is rare in practice. These results demonstrate the robustness of our system under noisy AS relationship data.

5.5 Real-World Deployment

We deploy our detection system in the main operational AS of a large ISP to evaluate its performance in practice. Based on the customer cone size, the AS rank is in the global top 100 [54]. At the time of our deployment, the AS maintains live BGP sessions with about 500 neighbors, including 14 Tier-1 ASes. Thereby, the AS has a fairly comprehensive view on the Internet-wide routing paths. We set up our detection system in a server that receives real-time incoming route announcements from all BGP routers within the AS via the iBGP protocol. We train the BEAM engine of our system using the latest CAIDA AS relationship dataset collected at the time of our deployment, which includes 74,923 ASes and 505,927 AS business relationship records. The sliding window length of our system is one hour. We use the same parameter settings and the method of identifying false alarms as described in §5.2. To reduce the repetitive alarms raised in different time windows, we aggregate the alarms sharing the same anomalous prefix and responsible AS.

The system is online since Jaunary 1, 2023. We analyze the generated results from January 1 to February 1, 2023. In total, the system processes 152,493,303 live route announcements during this month, detects 5,106,442 route changes and raises 548 alarms. We show the alarms' impact and daily statistics in Table 2 and Fig. 8, respectively. On average, our system identifies 17.68 alarms per day. The domain experts of the ISP carefully verify the correctness of each alarm based on the patterns described in §5.2. They find that most alarms (497 out of 548) indicate real routing anomalies, *i.e.,* true alarms. These true alarms, not detected by the ISP's existing routing security mechanisms, include 84 unauthorized route changes

Table 2: **The overall impact of the detected anomalies.**

#Affected Routes	#Affected Prefixes	#Affected Origins
1,202	961	477

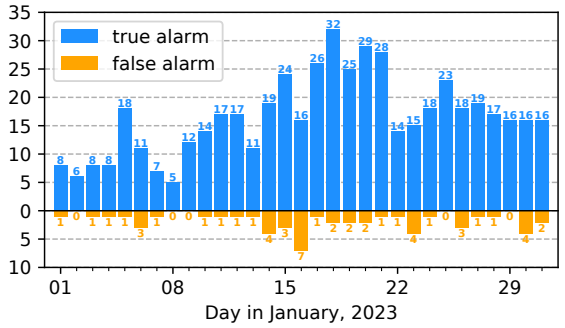

Figure 8: **Daily alarm number in real-world deployment.**

(P1), 123 route leaks (P2), 270 path manipulations (P3) and 20 ROA misconfiguration (P4). The interpretability of these alarms greatly facilitates the identification of anomaly sources (see §6 for detailed case study). More importantly, our system only raises an average of 1.65 false alarms per day. These false alarms can be further eliminated with minimal intervention (see discussions in §7). Overall, our detection system demonstrates promising results in real-world deployment.

We further investigate *how many anomalies are caught by an existing security mechanism but not our system*. First, we check whether our system misses the anomalies detected by the ISP's existing security mechanism. The ISP detects invalid routes based on its customers' IRRs. However, due to the incomplete coverage of prefixes, the ISP's security mechanism does not generate any alarm during our system's deployment. Thus, our system does not miss any alarm raised by the ISP itself. Next, we check whether there are real routing anomalies missed by both our system and the ISP itself. This requires a reliable source for BGP incidents. Although BGPstream is a promising candidate, we cannot use it in our paper because its vantage points are quite different from those of the ISP, which would introduce non-negligible experimental bias. Therefore, we use the RPKI validation results as a reference. Specifically, among all the RPKI-invalid announcements that are generated during our system's deployment, our system only misses about 2.25% of them and most of the missed ones are due to the limited Internet visibility, *i.e.,* only a few vantage points observe these invalid announcements. Overall, this result indicates our system has very low false negatives.

Ethics. We operate our detection system in compliance with the ISP's policy/agreement and under the close supervision of ISP's administrators. Our evaluation does not involve any sensitive or privacy data. We only collect results for analysis and do not interfere with Internet routing operations.

6 Case Study

In this section, we illustrate the interpretability of our detection results by analyzing four detected anomalies: three from historical events (Cases 1-3) and one from our real-world deployment (Case 4). Cases 1-3 each cover a different category of routing anomalies, *i.e.,* origin change, path change, and route leak. In each case, we compare a representative anomalous route change with a legitimate one that occurred on the same day. To interpret the difference between routing paths, we apply two visualization techniques: the heat map of the path difference scores and the embedding map of the routing roles. In particular, the heat map shows the path difference scores for the eligible sequences of AS pairs and marks the optimal sequence identified by DTW. The embedding map, generated by t-SNE [39], visualizes the routing roles of the ASes to illustrate the deviations between two paths.

Case 1. Figure 9(A) shows the origin change in $SO_{pakistan}$, where AS 17557 (*Pakistan Telecom*) hijacked a subprefix of AS 36561 (*YouTube*) by announcing 208.65.153.0/24. Figure 9(A)(I) sees the anomalous pattern that most ASes on the new path are different from those on the old path. The two origin ASes, AS 17557 and AS 36561, are far apart in the embedding map with few common neighbors, indicating very different routing roles. Thus, their route announcements would traverse quite different paths before they eventually converge on AS 5503. This pattern also appears in the heat map, where the path difference score rises sharply as the AS pairing operation proceeds, because the ASes from two paths are completely different after a few steps. In contrast, Fig. 9(A)(II) shows a legitimate route change on the same day with low path difference scores and almost overlapping paths in the embedding map, because the legitimate route update changes the origin from AS 6198 to AS 6197, both operated by *BellSouth Network* and with similar routing roles.

Case 2. Figure 9(B) shows the path change in $SP_{backcon\_2}$, where AS 203959 (*BackConnect*) hijacked a subprefix of AS 25761 (*Staminus Comm.*) by faking a nonexistent routing path to the real origin AS. The embedding map reveals that the fake path detours significantly from the real one, as AS 203959 is neither on the real path nor similar to any ASes on it in terms of routing roles. The heat map also indicates an upsurge in the path difference score in the AS pairing. The optimal sequence of AS pairs greatly deviates from the diagonal of the heat map because no AS is similar to AS 203959 in the counterpart. In contrast, the paths in the legitimate route change are similar in routing roles; we leave the analysis to the reader.

Case 3. Figure 9(C) shows the route leak in RL_{JTL}, where AS 36866 (*JTL*) received the route to 156.0.233.0/24 from its provider AS 8966 (*Emirates Tel.*) and leaked it to its another provider AS 37662 (*WIOCC*). The leaked route results in a much longer path through AS 37662 that detours significantly from the original one. It also violates the valley-free criterion. Accordingly, the heat map shows high path difference scores

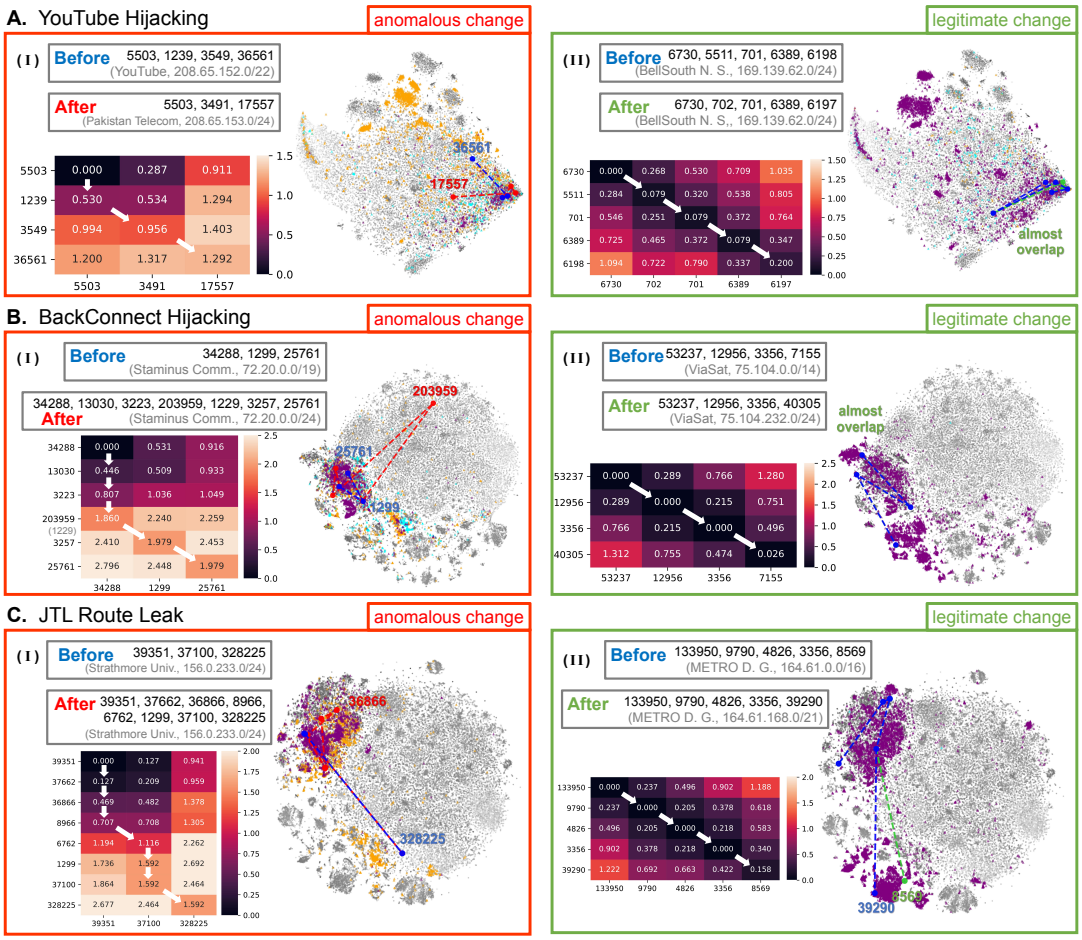

Figure 9: **Typical anomalous/legitimate route changes.** In each plot, the heat map (left) displays the path difference score at each AS pairing step of DTW in a top-to-bottom and left-to-right order. The white arrows show the optimal sequence of AS pairs. The embedding map (right) represents embedding vectors in a 2-D plane. The purple dots denote the common neighbors of the two routing paths, while the orange and cyan dots correspond to the exclusive neighbors for the new and old paths, respectively.

and the optimal sequence forms a hump-like pattern away from the diagonal. In contrast, the legitimate route change has minor path difference; we leave the analysis to the reader.

Case 4. We represent the first alarm reported by our system during its real-world deployment in Fig. 10. This alarm, labeled Alarm 0, starts at 01:04:40, January 1, 2023, and lasts about 1 hour and 24 minutes, affecting three prefixes and six routes observed by two individual vantage points. The top part of Fig. 10 provides an overview of this alarm. The bottom part of Fig. 10 further plots a representative route change event captured by this alarm observed from AS 6453. In this event, AS 42440 (*RDG-AS*) announces 185.88.179.0/24, which is owned by AS 201691 (*WEIDE*), without authorization (its RPKI validation state is *invalid_ASN*). Moreover, AS 42440 is also on the path before the route change, indicating a Type-5 route leak as described in RFC 7908 [55]. This pattern also appears in the heat map. The optimal sequence before AS 42440 follows the diagonal and the path difference score increases sharply after AS 42440, indicating a significant change of routing roles. The embedding map also demonstrates the clear difference between AS 42440 and AS 201691.

7 Discussion

Per-Prefix Threshold. Our system uses the same detection threshold values (*i.e.,* th_d and th_v) for all prefixes. Assigning an individual threshold for each prefix may gain better results. But it will incur significant computational overheads and large detection delays due to the large number of prefixes in the Internet (*i.e.,* over 940k IPv4 and 200k IPv6 prefixes in November 2023), which is inappropriate for online detection.

Reducing False Alarms. We can apply two heuristics to further reduce our system's false alarms. (i) Since most route hijacks and route leaks are short-lived [10], we can label the long-lived routes as normal. (ii) The different origin ASes in a legitimate MOAS event usually have similar routing

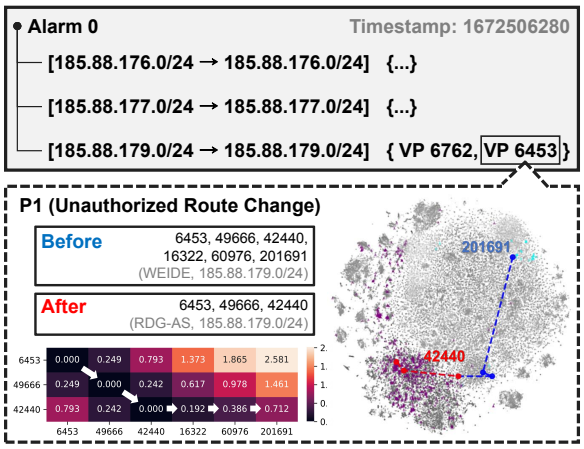

Figure 10: **An anomaly report in real-world deployment.**

characteristics [41] (*e.g.,* from the same organization) while the malicious ASes do not. We leave the application of both heuristics in our system to future work.

Adaptive Attacks. An adaptive attacker may attempt to bypass our system by mimicking the normal ASes' routing roles, yet it is very difficult in practice. Specifically, to imitate a normal AS's routing role, a malicious AS has to establish business relationships with the normal AS's neighbors, which is time-consuming and would reduce the malicious AS's stealthiness due to the possible scrutiny required for establishing neighboring relationships. Further, to make the routing roles of a forged path similar to those of a real path, the attacker has to control multiple ASes on the forged path. Our empirical study (presented in detail in Appendix D) reveals that it requires the attacker to control at least two ASes and establish hundreds of new AS relationships to make the routing roles of a forged path similar to those of a real path. This is considerably intractable in practical scenarios.

Evolving Routing Roles. AS routing roles evolve as ASes update routing policies. Our system is resilient against routing role evolution. Per §5, even if the time gap between training and detection is over 30 days (*i.e.,* the dataset update cycle), our system still performs well. Moreover, we can retrain BEAM with latest AS relationships to keep up with the routing role evolution. It takes ∼10 hours to train the model on our platform with GeForce RTX 2080 Ti, which is acceptable since CAIDA releases a new dataset roughly every month.

Detection with Unknown ASes. BEAM cannot learn routing roles of ASes whose relationships with other ASes are unknown (*i.e.,* unknown ASes). Fortunately, the existing study [34] has revealed AS relationships for most ASes absent in the dataset. For instance, there are only 368 unknown ASes in the most recent events that we analyze, which is only 0.5040% of the total ASes. Further, our measurement study discovered that some unknown ASes use the AS numbers that are reserved for private use [56]. The routing paths containing such unknown ASes should be regarded as anomalous.

8 Related Work

Traditional Routing Anomaly Detection. The existing studies consist of the control-plane based [11, 17, 18], the data-plane based [9, 14, 16] and the hybrid methods [10, 12, 13, 15]. The control-plane based methods maintain the normal/authoritative route information for each prefix and check if the newly received route contradicts it. The data-plane based methods identify routing anomalies by analyzing the reachability from multiple hosts to the target prefix. However, these traditional approaches require non-trivial manual investigation from network operators, *e.g.,* collecting the normal route information of each prefix, and deploying vast network probes to monitor the prefixes in the world, which incurs unacceptable operation overhead for deployment.

ML Based Routing Anomaly Detection. Machine learning is utilized to detect routing anomalies [19–29]. Shapira *et al.* [28] (AV) use unsupervised word embedding to model routes. But AV fails to detect transient anomalies due to its reliance on RIB snapshots and suffers from non-trivial retraining overheads. Dong *et al.* [22] and Hoarau *et al.* [27] perform supervised classification on BGP time series. Both require large-scale labeled datasets, which is hard to achieve in practice. Moreover, all these methods cannot provide interpretable results, incurring great manual efforts for validation.

Application of Network Representation Learning. Network representation learning (NRL) [57] aims to learn latent, low-dimensional representations of network vertices, while preserving network characteristics, *e.g.,* the structure information and vertex content, where the learnt representations can be used for downstream tasks. NRL has been applied in various domains, *e.g.,* social network analysis [58], recommendation system [59], and anomaly detection [60]. In this paper, we develop a BGP semantics aware NRL model to measure ASes' routing roles for routing anomaly detection.

9 Conclusion

In this paper, we present a routing anomaly detection system centering around a novel network representation learning model named BEAM. The core design of BEAM is to accurately learn the routing roles of Internet ASes by incorporating the BGP semantics. As a result, routing anomaly detection, given BEAM, is reduced to discovering unexpected routing role churns upon observing new route announcements. We implement a prototype of our routing anomaly detection system and extensively evaluate its performance using 18 real-world RouteViews datasets containing over 11 billion route announcement records. The results demonstrate that our system can detect all previously-confirmed routing anomalies within an acceptable number of alarms. We also perform one month of real-world detection at a large ISP and detect 497 true anomalies in the wild with only 1.65 daily false alarms on average, demonstrating the practical feasibility of our system.

A Preservation of the Second-Order Proximity

In practice, we derive the weight vector $\boldsymbol{l}$ (see Def. 2) from the softmax transformation of a learnable variable $\boldsymbol{l'} \in \mathbb{R}^d$, and ensures that the minimum value of its components is above α ($\alpha > 0$) to avoid trivial solutions:

$$\boldsymbol{l} = [l_0, \ldots, l_{d-1}]^\intercal = \big(softmax(\boldsymbol{l'})\big)_{\alpha+}. \tag{6}$$

Accordingly, $\boldsymbol{l}$ is differentiable with respect to $\boldsymbol{l'}$ and satisfies the following criteria:

$$\|\boldsymbol{l}\|_1 = \sum_{i=0}^{d-1} |l_i| = 1, \quad l_{min} = \min\{l_0, \ldots, l_{d-1}\} \geq \alpha. \tag{7}$$

In practice, we set $\alpha = \frac{1}{d} \times 10^{-6}$, a rather small positive number. Now, we prove the theorem that the pairwise AS difference does preserve the characteristics of the second-order proximity between ASes[5].

Theorem 1. *The distance function (5) preserves the second-order proximity.*

Proof. Given two vertices u, v ($u \neq v$) having similar neighbors and business relationships, there must exist at least one vertex w ($w \neq u, w \neq v$) such that $(u,w) \in E, (v,w) \in E$. Then after sufficient optimization of the objective function, there must exist two thresholds $\varepsilon_1, \varepsilon_2 > 0$ such that

$$0 \leq p\_score(u,w), p\_score(v,w) \leq \varepsilon_1,$$
$$h\_score(u,w), h\_score(v,w) \geq \varepsilon_2.$$

According to Equation (7), we have

$$p\_score(u,w) \leq \varepsilon_1 \tag{8}$$
$$\Longrightarrow (\boldsymbol{x_w} - \boldsymbol{x_u})^\intercal((\boldsymbol{x_w} - \boldsymbol{x_u}) \odot \boldsymbol{l}) \leq \varepsilon_1. \tag{9}$$
$$\Longrightarrow \|\boldsymbol{x_w} - \boldsymbol{x_u}\|_2 \leq \sqrt{\frac{\varepsilon_1}{l_{min}}} \leq \sqrt{\frac{\varepsilon_1}{\alpha}}. \tag{10}$$

Similarly, we have $\|\boldsymbol{x_w} - \boldsymbol{x_v}\|_2 \leq \sqrt{\frac{\varepsilon_1}{\alpha}}$. Thus $|h\_score(u,v)|$ is upper bounded:

$$\begin{aligned} |h\_score(u,v)| &= |h\_score(u,w) - h\_score(v,w)| \\ &\leq |h\_score(u,w)| + |h\_score(v,w)| \\ &= |(\boldsymbol{x_w} - \boldsymbol{x_u})^\intercal \boldsymbol{r}| + |(\boldsymbol{x_w} - \boldsymbol{x_v})^\intercal \boldsymbol{r}| \\ &\leq \|\boldsymbol{x_w} - \boldsymbol{x_u}\|_2 \cdot \|\boldsymbol{r}\|_2 + \|\boldsymbol{x_w} - \boldsymbol{x_v}\|_2 \cdot \|\boldsymbol{r}\|_2 \\ &\leq 2\sqrt{\frac{\varepsilon_1}{\alpha}}. \end{aligned}$$

Also, $p\_score(u,v)$ is upper bounded by $2\varepsilon_1$:

$$p\_score(u,v) \leq p\_score(u,w) + p\_score(v,w) \leq 2\varepsilon_1$$

Thus, we have $D_{\boldsymbol{l},\boldsymbol{r}}(u,v) = |p\_score(u,v)| + |h\_score(u,v)| \leq 2\varepsilon_1 + 2\sqrt{\frac{\varepsilon_1}{\alpha}}$. That is, there exists an upper bound for the distance between u, v in terms of the distance function (5). Moreover, when the objective function is sufficiently optimized, ε_1 is a rather small positive number approaching zero and α is a constant, and then the distance $D_{\boldsymbol{l},\boldsymbol{r}}(u,v)$ should approach zero, which means the two vertices u, v are at a close distance to each other in the low-dimensional vector space. □

[5] Note that this is a theoretical proof under ideal conditions. In the actual training process, the convergence of the embedding vectors would also be affected by initial values and sampling techniques.

B Sampled AS Pair Datasets

Notation in the table: *No rel* stands for no relationship. *Ngbr JI* refers to the Jaccard index of two neighbor AS sets.

Feature	Name	#AS pair	Sampling rule
1st-order proximity	S_0	10,000	P2P, Ngbr JI $\in [0\%, 10\%)$
	H_0	10,000	P2C, Ngbr JI $\in [0\%, 10\%)$

C Comparison with ML-based Methods

We implement two baselines, *i.e.,* AV and LS, according to their papers [22, 28]. Here, we describe their experimental setup and compare them to our system in detail.

AV Setup. In accordance with the original setup in the paper [28], for each dataset, we train an AV detection model based on the most recent RIB snapshots collected from all vantage points before the confirmed anomaly occurs, and perform detection on the next RIB snapshots in the next two hours. To reduce the training time, the model is trained offline on all two-hour RIB snapshots in parallel. Note that this strategy is not realizable for an AV model deployed for real-world online detection task, because the model has to be trained on the RIB snapshot collected 2 hours earlier and perform detection on the latest RIB snapshot. We set the hyperparameters the same to the original paper. The outputs of the AV detection model are anomalous route changes. For fair comparisons, we further apply our anomaly detector (see §4.3) to aggregate these route changes into alarms, *i.e.,* identifying anomalous prefixes and locating responsible ASes.

LS Setup. The LS method aggregates all BGP announcements in each two minutes into a time interval and extracts

Table 3: **Comparison with ML-based methods.** *Vol.*, *Req.* and *Ann.* are short for Volume, Requirement and Announcement.

Method	Training				Detection	
	Training Data	Training Data Vol.	Retraining Req.	ML Model Type	Detection Data	Anomaly Type
Ours	AS relationships	∼500K	Monthly	Unsupervised	Ann.	Short & Long-lived
AV [28]	RIB entries	∼10M	Bihourly	Unsupervised	RIB entries	Long-lived
LS [22]	Ann. time series	∼100M	Unknown	Supervised	Ann. time series	Short & Long-lived

86 features. Note that LS is a supervised detection method. Thus, for each dataset, we use the other 17 datasets as the training data to train an LS model, and then classify the time intervals (*i.e.,* normal or anomalous) in this dataset. The labeling method of the training data and the parameters of the LS detection model are the same to the original paper. All route changes in the detected anomalous time intervals are considered anomalous. Finally, we also utilize our anomaly detector to aggregate these anomalous route changes into alarms.

The Comparison. We compare our system with AV and LS in Table 3. Specifically, since AV performs detection in the RIB snapshots of every two hours, it cannot detect transient routing anomalies that occur within the period between two RIB snapshots. Besides, AV requires frequent model updates because tens of millions of RIB entries are updated bihourly, which incurs significant retraining overheads. To the best of our knowledge, there is no technique that can be directly applied to accelerate the training of AV. By contrast, our system directly checks every route change collected from each real-time BGP announcement such that it can detect both transient and long-lived routing anomalies. Further, our system only requires the AS relationship data for training, which is much smaller than the RIB snapshots and more stable, ensuring a small retraining overhead.

LS characterizes announcements as time series and applies a supervised neural network to detect if each data point in the time series is associated with routing anomalies. However, each data point in the time series, *e.g.,* the data in a two-minute time interval, may include a large number of legitimate announcements, leading to much more false alarms than our system. Besides, since LS utilizes a supervised model, it requires a large amount of BGP anomaly data for training, *e.g.,* more than 2,000 BGP anomaly events [22], which is difficult to achieve in practice. By contrast, our system performs detection in an unsupervised manner and gets rid of the reliance on anomalous training data.

D An Empirical Study on Adaptive Attacks

We empirically study how many ASes an adaptive attacker needs to control and how many AS relationships need to be established to make the routing roles of a malicious path[6] similar to those of a legitimate path. Specifically, for each legitimate routing path from the 18 real-world datasets (described in §5.1), we start from the vantage point of the legitimate path and search for the malicious path that has the most overlapping segments with the legitimate path. Then, we choose the ASes that appear on the malicious path but not on the legitimate path. These ASes have to be controlled by the attacker to mimic the legitimate path ASes' routing roles. Next, we compare the neighbors of the malicious and the legitimate path and calculate the minimum number of relationships that need to be established to make 10% neighbors the same. In this study, we assume that having 10% common neighbors is sufficient to make the routing roles of a malicious path similar to those of the legitimate path. This reduces the difficulty for the attacker, such that the result is a lower-bound estimate.

We show the result in Fig. 11, where the top and bottom figures display the average number of ASes that must be controlled and the average number of AS relationships that need to be established, respectively. The error bar shows the 95% confidence interval. In most cases, an adaptive attacker has to control at least two ASes and establish hundreds of new AS relationships to make the routing roles of a malicious path and a legitimate path similar. Note that, the cost for an adaptive attacker to bypass our system in practice would be much higher than the above result, because our system monitors multiple vantage points simultaneously, *i.e.,* the attacker has to make the routing roles of multiple malicious routing paths similar to those of normal paths. Thus, it is very difficult for adaptive attackers to bypass our system's detection.

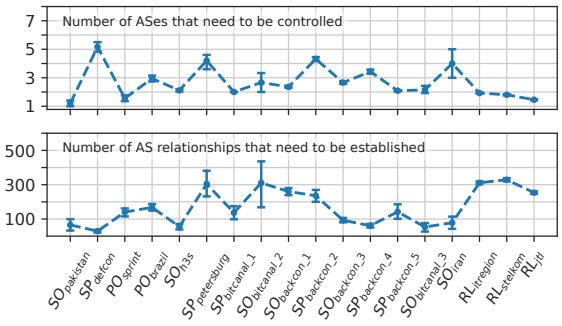

Figure 11: **The empirical estimate of the cost for an adaptive attacker to make the routing roles of a malicious path and a legitimate path similar.**

[6] A malicious path refers to a routing path that contains the known malicious AS in the BGP anomaly event.

Enhancing Network Attack Detection with Distributed and In-Network Data Collection System

Abstract

The collection of network data poses a significant challenge for machine/deep learning-driven network defense systems. This paper proposes a new paradigm, namely In-network Serverless Data Collection (ISDC), to eliminate the bottleneck between network infrastructure (where data is generated) and security application servers (where data is consumed). Considering the extremely mismatched scale between traffic volume and in-network resources, we stress the need to prioritize flows based on the application's interests, and a sublinear prediction algorithm is proposed to prioritize specific flows to optimize resource consumption effectively. Additionally, a negotiation-free task migration mechanism with task-data isolation is introduced to allocate tasks dynamically across the network to enhance resource efficiency. Furthermore, ISDC incorporates a serverless data migration and aggregation mechanism to ensure data integrity and serves as a reliable and distributed data source for network defense systems. We present two use cases to demonstrate the feasibility of ISDC, namely covert channel detection and DoS/DDoS attack detection. In both scenarios, ISDC achieves significantly higher flow coverage and feature accuracy compared to existing schemes, leading to improved attack detection accuracy. Remarkably, ISDC's data integrity addresses a model self-poisoning issue caused by duplicated and fragmented flow measurements generated during collaborative measurements.

1 Introduction

Network traffic measurement system is an essential source of data for diverse northbound security applications, including fingerprinting [1, 2], network provisioning [3–5], and anomaly detection [6–17]. Notably, many security applications leverage machine/deep learning (ML/DL) technologies to boost performance [6, 8, 18–22], raising the demands of richer data representations, namely per-flow distribution features [6, 12, 23–26]. However, the measurement and migration of such features come at a high cost, leading to a unique challenge, namely data availability for security (see section 2.1).

Emerging In-Network Computing (INC) technologies enabled flow feature measurements within onsite switches [27, 28] for *real-time* data collection and in-network defenses [6, 12, 15–17, 29–31]. Recent efforts realized measurement of per-flow distribution features using standalone switches [6, 12], focusing on single-point measurement by optimizing resource utilization of data plane functions. Naturally, one can extend single-point measurement solutions [6, 12] to multiple switches to form a distributed flow measurement. Considering imbalanced and dynamic network traffic patterns, a collaborative flow measurement is essential to balance the workload and consolidate resources across the network. Unfortunately, existing collaboration mechanisms [32–34] encounter severe resource inefficiency issues owing to the slow reaction of remote decision-making (i.e., control loop) or limited view of local decision-making (i.e., duplicated tasks).

For learning-based security applications, data migration from distributed switches to a centralized server is the norm, since data aggregation is essential to address data integrity issues (i.e., fragmentation) caused by collaborative flow measurements. However, the data migration triggers unacceptable overheads for northbound links [35–37], which is a critical resource for network operations, but also discourages the collaboration of different network parties due to privacy concerns during raw data sharing. Recent discussions on data migration pay more attention to in-network and real-time convergence of simple counting-based volume measures for the collaborative defense of link flooding attacks (LFA) [13, 14], but not for establishing a data source for ML/DL-based security.

In this paper, we introduce a new paradigm, namely **I**n-network and **S**erverless **D**ata **C**ollection (**ISDC**). As shown in Figure 1, ISDC is a middleware that resides in distributed switches' network operating system (NOS), forming a *data layer*, with the main mission of eliminating the bottleneck between the infrastructure layer and application layer. Interacting with its data plane functions, ISDC is responsible for task allocation and migration to effectively and efficiently utilize in-network resources. Meanwhile, ISDC performs *serverless* data migration and aggregation for data integrity to serve as a

reliable and distributed data source for ML/DL-based security applications.

Our security use cases combine ISDC with the distributed learning concept, delivering various benefits, including eliminating the burden of data migration toward the northbound and opening a possibility for privacy-preserved collaboration among different network organizations. With these insights, we tackle multiple technical challenges to improve ISDC's data collection scalability and quality for security.

Contributions. Our main contributions are as follows:

1. We introduce an in-network data collection framework to enable switch-wise collaboration and engagement of distributed learning techniques for network defense.
2. We propose a sublinear flow size prediction resource-efficient algorithm to prioritize flow measurement.
3. We introduce a negotiation-free task migration mechanism with task-data isolation design to reduce the burden in dynamic task reallocation for efficient utilization of resources across the network.
4. We unveil a data fragmentation issue caused by distributed and collaborative flow measurement, which further triggers a model self-poisoning issue in distributed learning scenarios. Then, we design a data migration and aggregation mechanism for data integrity.
5. We deployed ISDC[1] in a commercial programmable switch and conducted extensive simulations to assess the enhanced data scalability and quality by ISDC.

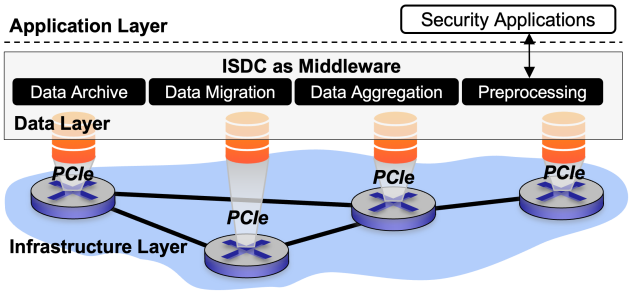
Two use cases are demonstrated: covert channels and DoS/DDoS attack detection. For covert channel detection, ISDC achieved 94.1% (50.6% higher) flow coverage and 7.8x better feature accuracy compared to state-of-the-art schemes on average, leading to boosted covert attack detection accuracy, F1 0.960 (0.117 higher) and AUC 0.938 (0.176 higher). In DoS/DDoS detection, we unveiled a model poisoning issue caused by duplicated and fragmented measurements. We showed ISDC with data integrity outperforms the state-of-the-art scheme, yielding an AUC of 0.945.

Organization. The rest of the paper is organized as follows. In section 2, we discuss the motivation and challenge for ISDC. Next, we present the ISDC's working flow, functions, and protocols throughout sections 3–5. Then, in section 6, we evaluate system performance and demonstrate security use cases, followed by discussions of system design choices in section 7. Lastly, we discuss related works and conclude our work in sections 8 and 9, respectively.

2 Motivation and Challenges

In this section, we motivate ISDC from a new perspective: data availability (DA) for security. Then, we discuss the technical challenges and design goals of ISDC.

[1]The source code is at https://github.com/NIDS-LAB/ISDC



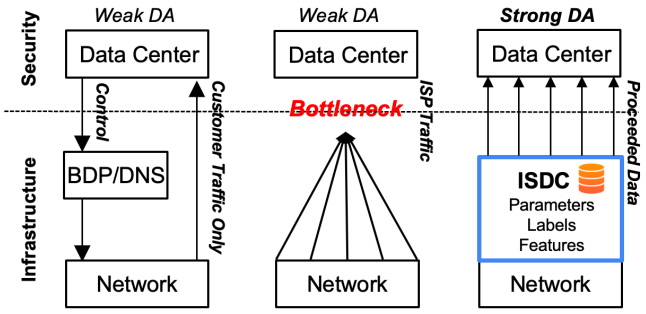


Figure 1: Architecture: ISDC is network storage distributed in network switches. It archives data measured by the switch's data plane functions and performs serverless data migration and aggregation to provide a reliable data source foundation for northbound security applications.

2.1 Data Availability for Security

Cloud Computing-based Defense. The network defense is more challenging than ever. The advance of recent attacks neutralizes signature-based defenses [38], raising demands of advanced ML/DL technologies for defense guidance [22, 35]. Moreover, advanced network devices improve data transmission capacity and empower malicious network parties. Therefore, cloud-based attack mitigation is widely believed to be practical due to the *resource availability* for high-volume traffic processing and heavy ML/DL functions. *However, we stress that a crucial factor of the success is more of its data availability (***DA***) in the cloud.* As illustrated in Figure 2 (a), cloud-based defenses leverage the Border Gateway Protocol (BGP) or Domain Name System (DNS) to direct inbound network traffic to a scrubbing center, which enables continuous data collection for security functions (i.e., DA for security). Nevertheless, the data availability of cloud defense vanishes easily by moving the attack target from endpoints to intermediate infrastructures, e.g., critical network links [13, 39, 40] or Internet Exchange Points (IXPs) [41].

Internet Service Provider (ISP)-level Defense. The weakened data availability of the cloud framework naturally brings our attention to network infrastructure-layer (or ISP-level) solutions. As shown in Figure 2 (b), an ISP with direct access to the in-network switches has the strongest data availability at the infrastructure layer, simply because switches are carriers of network raw data (i.e., packets). However, the major challenge for ISP-level data collection is the data migration from the infrastructure layer to the application layer (i.e., the venue of data consumption) for the following reasons. First, unlike the cloud-based approaches that have a narrow interest in network traffic (i.e., traffic towards customers), the ISP is responsible for the full population of traffic coming through the network with a mission of data transmission, but not complex security due to the vast amount. Second, the northbound bandwidth is reserved for latency-sensitive network operation functions (i.e., policy updates). Continuous data migration towards the northbound adds tremendous burdens to such a

(a) Cloud (b) ISP (c) ISP with ISDC

Figure 2: Motivation: data availability (DA) for security. (a) The cloud-based defense has narrow interests in network traffic, (b) ISP traffic migration towards the application layer is challenging, and (c) ISDC resides in the infrastructure layer and has direct access to network data.

crucial resource and great uncertainties to network control. To these ends, the ISP-level solution with a centralized data collection strategy has weak DA at the application layer.

Vision: In-network Serverless Data Collection (ISDC). The lessons are that 1) the infrastructure layer has the strongest data availability for security by nature and 2) data migration toward the application layer is challenging because of either the inherent nature of weak data availability of the cloud or the large overhead of northbound traffic of ISP, which necessitates a paradigm change of data collection for security applications. With these insights, we propose the concept of in-network serverless data collection (ISDC) with the essential argument that raw data migration towards the northbound is unnecessary. As shown in Figure 2 (c), ISDC resides in the infrastructure layer (i.e., distributed switches) to enjoy strong data availability (DA). Furthermore, instead of migrating raw data towards the northbound, our vision is to migrate partial security functionality from the application layer to the infrastructure layer,e.g., data prepossessing and even local model training. The intuition is that this paradigm change is aligned with the distributed learning paradigm addressing overhead and privacy challenges in terms of data communication [42, 43], as shown in Figure 2 (c). However, multiple technical challenges have to be addressed to achieve ISDC.

2.2 Challenges

Data-Plane Resource Constraint. With adversarial attack patterns, existing in-network security with volume feature [13–15, 17, 44] has shown limitations in identifying application-layer attacks. Therefore, recent works prefer richer data representations, namely per-flow distribution features, for robust attack detection. FlowLens [6] showed the potential of per-flow distribution features in various application-layer attack detections. To accommodate the hardware constraint (i.e., memory and computation) of in-network switches, FlowLens quantized the distribution data leading to fewer per-flow data points, but still showed its feasibility with ML technologies. Nevertheless, the hash table data structure used for per-flow measurement becomes a barrier due to scarce memory space in the switch. Netwarden [12] also uses per-flow distribution data for covert channel detections. It adopted a sketch approach [45] with memory random sharing to scale up per-flow measurement. Unfortunately, the sketch also suffers saturation issues, vanishing its error-bound guarantee. As such, although it is clear that per-flow distribution data is a viable feature, a single-point (switch) measurement encounters severe scalability issues limited by hardware resources.

Resource Wasting during Collaboration. A body of research has explored collaborative and distributed flow measurement leveraging distributed network devices. Coordinated Sampling (CSAMP) [32] and Network-wide Switch Probability Assignment (NSPA) [33] are representative and state-of-the-art works empowered by the global view of the network for optimizing resource utilization. The downside of such approaches is slow adaptation to dynamic shifts in network traffic. Especially considering the massive amount of short-living and mice flows existing in modern networks, massive memory resources will be wasted intermittently during the remote decision-making process (i.e., control loop). Orthogonal to the central management approach, Cooperative Flow Selection (CFS) [34] performs onsite decision-making based on the local view at each switch. Such a strategy eliminates the control loop issue and adapts to dynamic traffic changes timely. However, the limited view causes duplicated measurement tasks launched at multiple switches, triggering memory-wasting issues, as shown in Table 1. The memory inefficiency hurts the data collection scalability, resulting in poor attack detection performance (see section 6.3 for the covert channel detection case study and the associated performance).

Data Fragmentation caused Model Poisoning. Additionally, we report a model poisoning issue when employing a local view-based dynamic task allocation approach [34] as a data source of distributed learning. That is, a single flow can be measured on inclusive or exclusive timelines at different switches on its routing path, which results in the generation of multiple feature fragmentation (i.e., partially measured or overlapped flow features), as shown in Table 1. Especially in a distributed learning system, the presence of such fragmented and inconsistent data can lead to biased local model training and eventually generate a poorly aggregated model (see section 6.4 for DoS/DDoS attack detection performance).

2.3 Design Goals

Table 1 compares the design of existing data collection systems with ISDC. The drawbacks of previous approaches motivated us to design our system with the following goals:

Optimizing Network Resource Usage. Given the finite computational and memory resources in the distributed switches

Measurement Task Coordination				
	CSAMP [32]	NSPA [33]	CFS [34]	**ISDC**
Decision	Remote	Remote	Onsite	Onsite
Task Duplication	✗	✗	✓	✗
Task Priority	✗	✗	✓	✓
Task Migration	✗	✗	✗	✓
Overhead	High	Medium	Very High	Low
Flow Coverage	35.4%	36.9%	58.1%	94.1%
Data Collection				
	CSAMP [32]	NSPA [33]	CFS [34]	**ISDC**
Data Migration	Central	Central	Central	Serverless
Fragmentation	✗	✗	✓	✗
Overhead	High	High	High	Low
Detection AUC	0.718	0.709	0.857	0.938

Table 1: Comparison of designs. The experimental results of our security use case, namely covert channel detection, are shown with two metrics (flow coverage and AUC) to compare the data collection efficiency and quality.

for the flow feature measurement (i.e., tens of Megabyte memory space and tight processing deadline [27, 28]), optimizing the resource utilization is crucial. To do so, we first aim to prioritize flow measurement tasks with security applications' requirements to relax the resource competition in the data plane. Next, we encourage active task migration to address the traffic imbalance and dynamicity in different network nodes to maximize resource usage. Lastly, we target a coordinated task migration to prevent duplicated tasks and resource wastes, as shown in Table 1.

Reliable Data Source for Security. Data integrity is crucial for any data-driven security applications. The traditional approach is to migrate data from the data plane, where the data is generated, to the application servers, where the data is consumed, for data aggregation. However, this decision adds burdens to the northbound links. To overcome this bottleneck, we aim to build a distributed network storage to form a data layer to serve northbound applications with pre-processed data. For data quality, we design a data-layer communication protocol for serverless and in-network data migration to aggregate data fragmentation, as shown in Table 1.

Low-overhead Task/Data Migration. Task and data migration are the primitive functions of ISDC for resource optimization and data integrity. However, the more active these actions are, the more overhead is added to the network links; i.e., trade-off. To tackle this issue, our design goal is to minimize the footprint of task migration and data migration to reduce the burden added to network links, as shown in Table 1.

3 System Design: ISDC

3.1 Framework

As shown in Figure 3, IDSC's data plane functions, namely Flow Identifier (FI) and Feature Meter (FM), are placed in each switch's packet processing pipeline, namely Application-Specific Integrated Circuit (ASIC). IDSC's storage is integrated into the network operating system (NOS) running with offline resources, i.e., general CPU and large DRAM. The communication between data plane functions and storage utilizes a high-bandwidth Peripheral Component Interconnect Express (PCIe) for data archiving. We highlight that ISDC's distributed storage forms a data layer and serves northbound applications.

3.2 End-to-End Design

ISDC system is built on top of distributed network switches with the following essential functions:

❶ **Flow Identification.** As shown in Figure 3, ISDC's first step is identifying targeted flows. Here, we prioritize flows with their sizes, with the key insight that super mice flow, with one or two packets, contains sparse data points of distribution feature is disfavored by ML/DL applications due to difficulty in learning. The flow size is not known beforehand, but the flow feature measurement must start instantly from the first packet. However, predicting flow size in an ad-hoc manner is challenging, especially with a resource constraint. In this work, we propose a Flow Identifier (FI), a simple but efficient flow size prediction algorithm leveraging the burstiness feature to prioritize flows for task allocation (see §4.1).

❷ **Feature Measurement.** Once FI identifies a flow, the flow feature measurement task will be performed at a separate data structure, Feature Meter (FM), a simple hash table. We stress that it is essential for distributed and collaborative flow measurement systems to use a general hash table structure for flow feature measurement since flows must be evictable for task and data migration, for collaborations, and to avoid task duplication (see section 4.2 for details).

❸ **Task Migration.** We stress that narrowing the scope to the targeted flows is insufficient to optimize resource utilization in network switches. Upon collision in FM's hash table, tasks must be handed over (i.e., task migration) to the follow-up switches on a flow's routing path, not to miss feature measurement, as shown in Figure 3. Dynamic task migration allows ISDC to utilize idle resources of switches on flows' routing paths for a collaborative measurement. ISDC's task migration event is triggered by a hybrid eviction policy integrated into FM (see section 5.1 for details).

❹ **Data Archive.** We note that the migrated tasks are often handed over along with the data for an accumulated and continuous measurement [13], which triggers extra in-band (i.e., network link) overhead with frequent task migrations. Our design choice is called *task migration with data isolation*, which archives data at the present switch and then migrates tasks only with negligible overhead (see section 5.2 for details).

❺ **Data Migration.** An issue triggered by task-data isolation is that a flow may be measured at multiple locations *exclusively*, namely flow feature fragmentation. For data aggregation, ISDC migrates all distributed flow features back to their edge switch (i.e., a flow's entry point of the network) [13],

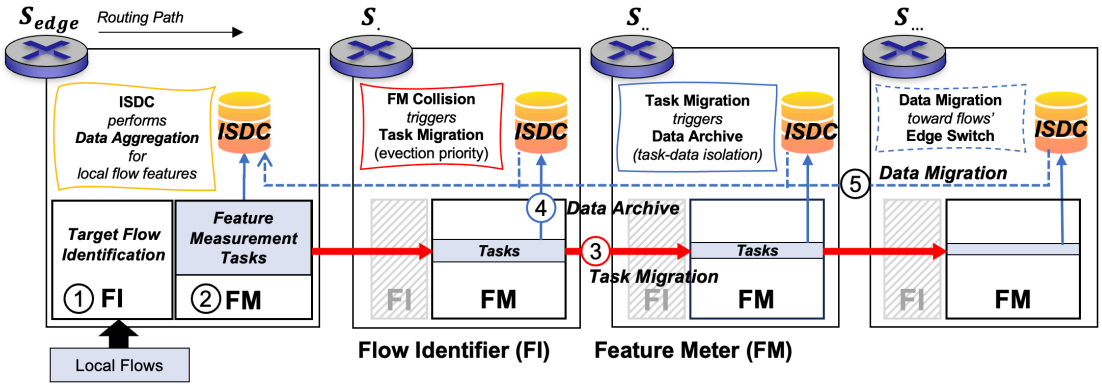

Figure 3: ISDC's workflow: (1) Flow Identifier (FI) is active for local flows only for flow prioritization and target flow identification. (2) Feature Meter (FM) is a simple hash table for per-flow feature measurement of identified flows. (3) FM evicts a task upon collision and migrates the task for collaborative measurement. (4) Data archive is a task-data isolation design to reduce task migration overhead. (5) Data migration is offline towards each flow's edge switch.

combined with the greedy task allocation strategy [34], for minimizing data migration footprints, as shown in Figure 3. Furthermore, we design a novel data migration mechanism, a simple source routing function, to return the flow features to their edge switches. Our data migration is lightweight and works without prior knowledge of network topology (see section 5.3 for further details).

3.3 Distributed Learning/Detection of Attacks

The same processes 1∼5 repeat independently at all edge switches and consistently maintain local flow feature data. With ISDC, network operators can either perform distributed learning of up-to-date traffic or conduct in-network attack detection [6] and mitigation [46], empowered by a federated model with up-to-date knowledge. Furthermore, with the greedy and edge-centered task allocation strategy, attack flows can be detected and mitigated at the network's border (i.e., early intervention), which can help reduce the network link flooding [13]. Our use case combined ISDC with a standard federated learning scheme [43] for covert channel detection and DoS/DDoS attack detection for evaluating the feasibility of our ISDC as a data source for security applications. ISDC data collection and aggregation are performed in the data plane. In our security use cases (see §6.3 and 6.4), ISDC communicates model parameters with a data center but not raw data. However, raw feature data can also be migrated to the northbound for aggregation-free and centralized learning.

4 Function Design

In this section, we describe ISDC's core function designs, including flow size prediction sketch (i.e., Flow Identifier) and feature measurement data structure (i.e., Feature Meter).

4.1 Flow Identifier (FI)

FI addresses a real-time top-K prediction challenge, operating within a very narrow time window and with $O(1)$ memory and computational complexity. Particularly, FI exploits the bursty nature of larger flows occurring within short timeframes, as observed in literature such as [47,48], to forecast deterministic top-K flows for immediate task allocation, which typically demands $O(K)$ counters for post-hoc analysis [44,49]. Burstiness is defined as the continuous arrival of packets with a small inter-arrival interval time (e.g., less than 1 ms).

Data Structure and Algorithm. Figure 4 illustrates FI's data structure and Algorithm 1 outlines its operations. FI maintains a hash table with w slots, each maintaining three variables: a 32-bit Flow ID (*key*), a 4-bit burst counter (B), and a 4-bit burst counter combining other concurrent flows ($\hat{B}$). As shown in Figure 4, FI distributes flows to w slots permanently for relaxing collisions of concurrent flows, and the follow-up operations fall into five cases. First, when a slot is empty, FI serves in a first-come-first-serve manner, and the first flow is treated as a top-K by recording its Flow ID in the slot (see f_1 in Figure 4). Next, in the event of a flow match, B is increased by one (see f_2). However, if B overflows, B is reset to one, and $\hat{B}$ is reset to zero (see f_3). The packet will be tagged as "targeted" in both events and passed to the feature meter (FM) for feature measurement. Lastly, when a flow is mismatched, $\hat{B}$ is increased by one, and then the packet is tagged as "untargeted", which will not be measured by FM. Instead, a competition will be triggered in the event of $\hat{B}$ update. If $\hat{B} > \lambda \cdot B$ (see f_4) or $\hat{B}$ is saturated (see f_5), the new flow evicts the old flow and becomes a new target.

Analysis. We start with an observation that recent real-world trace CAIDA [50] follows the Zipf distribution, with 87% of flows being mice (i.e., <10 packets). Figure 5 shows the analysis of burst size and flow size using the CAIDA dataset with real timestamps, varying intervals from 100 *us* to 100 *ms*. As shown in Figure 5 (a), with the interval set to 10 *ms*,

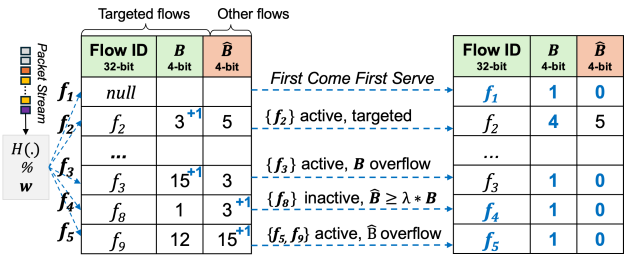
Algorithm 1: Flow Identifier (FI)

```
1  Function Flow_Identifier(Packet pkt):
2      key ← H(pkt), idx ← key mod w;
3      item ← {KEY, B, B̂} ← HashTable_FI[idx];
4      if item == null then
5          item ← {key, 1, 0};                          ▷ See f1 in Figure 4
6      end
7      else if item.KEY == key then
8          if item.B<15 then
9              item.B ← item.B + 1;                     ▷ See f2 in Figure 4
10         end
11         else
12             item ← {key, 1, 0};                      ▷ See f3 in Figure 4
13         end
14         Tag_Targeted(pkt, Tag(10_2));
15         Feature_Meter(pkt);
16     end
17     else if item.KEY != key then
18         if item.B̂<15 then
19             item.B̂ ← item.B̂ + 1;
20             if item.B̂/λ == item.B then
21                 item ← {key, 1, 0};                  ▷ See f4 in Figure 4
22             end
23         end
24         else
25             item ← {key, 1, 0};                      ▷ See f5 in Figure 4
26         end
27         Tag_Untargeted(pkt, Tag(00_2));
28     end
```

96% of bursts contain only 1 or 2 packets. Among flows with a small burst size (i.e., ≤ 2 packets), 91% of flows' sizes are smaller than 10 packets and 67% are smaller than 4 packets, as shown in Figure 5 (b). Also can be seen in Figure 5 (a), only 4% of flows have a larger burst size (i.e., > 2 packets). Among these bursty flows, however, only 5% of flows' sizes are smaller than 10 packets, as shown in Figure 5 (b). The results support our assumption that larger flows tend to be more bursty than smaller flows.

Intuition 1: Small λ for Fast Prediction of New Top-K. Based on the above observations, FI's design is grounded on two fundamental assumptions. First, according to our real-world trace analysis, B is filled with super mice in most cases. Second, based on the first assumption, the number of packets of combined counter $\hat{B}$ is approximately the total number of concurrent flows. Therefore, our empirical parameter λ represents the number of flows sharing a counter for averaging combined burstiness (i.e., averaged burstiness $\hat{B}/\lambda$), which approximates the *1-on-1* competition with the current top-K candidate. With this insight, we can expect that FI terminates the burstiness competition within a very small time window by using a small λ=4 (see f_4 in Figure 4).

Intuition 2: Small Counters for Fast Eviction of Old Top-K. Our design takes advantage of small counters for fast takeover and retention of a competing counter B by an active top-K candidate. For example, a new burst flow can quickly build up the $\hat{B}$ to evict inactive flows with a larger burstiness, or a still bursty flow can retain its counter value in B (see f_5 in Figure 4). The reduced counter size also allows FI to enlarge w, reducing the collision of burst flows.



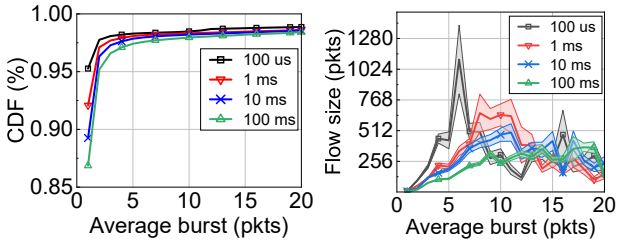


Figure 4: FI operations fall into five cases: a flow takes an empty slot (f_1), the active targeted flow keeps occupying the slot (f_2 and f_3), and concurrent flows evict old flows and become new targeted flows (f_4 and f_5).

(a) CDF of avg. burst (b) Flow size vs. avg. burst

Figure 5: Real-world trace analysis indicates small flows tend to be less bursty than large flows: (a) CDF of averaged flow burst sizes and (b) relationship between flow and burst size.

4.2 Feature Meter (FM)

FM performs per-flow feature measurement tasks for identified flows by FI. We note that the flow feature measurement algorithm is not the main focus of this work. However, we note that it is crucial to employ a scheme based on a general hash table for flow entry eviction and migration, which is essential and straightforward for collaborative flow measurement. In this work, we utilize the feature collection solution of a state-of-the-art scheme, called FlowLens [6], as an add-on module of ISDC system for covert channel detection and DoS/DDoS attack detection. As illustrated in Figure 6, ISDC's FM maintains a simple hash table for per-flow packet size distribution (feature) measurement. According to FlowLens, we quantify the packet size with an interval of 16, resulting in 94 bins. Then, FM records the frequency quantified bins for each flow to represent the packet size distribution (PSD) feature. Each slot (row) in the table records the Flow ID (32-bit), feature distribution, and time-to-live (TTL) value (8-bit).

FM collects features for the FI-predicted top-K flows only, saving scarce memory by ignoring untargeted super mice flows. When a packet of a flow arrives at a slot, FM records the flow feature for the matched flows. If miss-matched, the packet's TTL value is used, with a hybrid eviction policy, to determine which flow to evict for task migration. The evicted flow will be handed over to other switches for collabo-

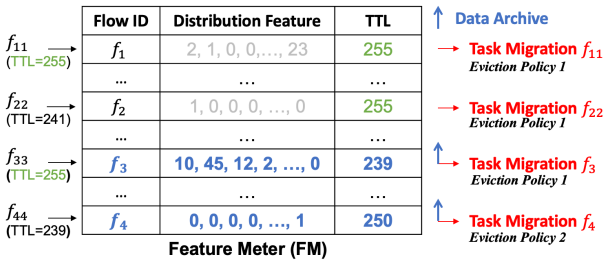

Figure 6: Feature Meter (FM): task migration with a hybrid eviction policy (red) and data archiving event (blue).

rative measurement. In all cases, the eviction policy enforces a higher priority for local over non-local flows, which ensures a flow is measured closer to its edge node to reduce footprint and missing risk when the routing path is short (see section 5.1). Furthermore, a task-data isolation design is proposed for a lightweight task migration (see section 5.2). Eventually, data migration is performed towards edge switches for in-network data aggregation (see section 5.3).

5 Protocol Design

Next, we explain our task migration and data migration mechanism and protocol designs, including the task-data isolation design. Figure 7 shows the customized headers attached to the network packets, namely `Tag` and `Stack`, for task migration and data migration, respectively.

5.1 Task Migration

Event Trigger. To maximize resources utility, we design a task migration (handover) logic based on a simple hash table for collaborative flow feature measurement, as shown in Figure 6. The task migration event is triggered by FM's eviction function with a hybrid policy where FM also has a constant number of slots, and flows are permanently distributed to each slot for resource competition. Our eviction function applies two opposing policies depending on local and non-local flows.

Policy 1 (Local Flow First): Local flows with $TTL = 255$ win the competition and evict non-local flows (i.e., $TTL < 255$). If the existing and newly incoming flows are both local, this policy evicts (handovers) the incoming one to avoid the context switch-caused overhead. This policy aims to retain most flow measurement tasks at the edge switch.

Policy 2 (Lower TTL First for Non-local Flows): When non-local flows compete for the same slot, FM gives a higher priority to lower TTL flows, which is the opposite of Policy 1; i.e., more flows measured before reaching the end of the path.

Protocol. For task migration, ISDC requires only 2-bit tags attached to each packet header, thanks to programmability [51], where the first bit is for FI to tag the targeted flows and the second is for FM to indicate the measured packets and prevent

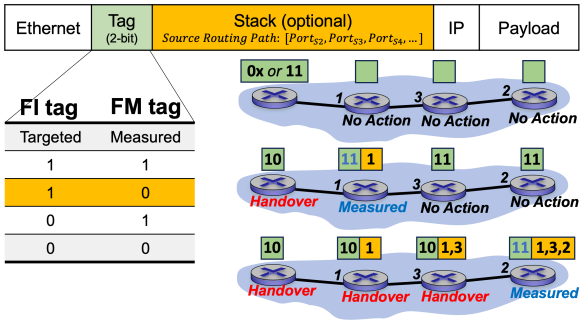

Figure 7: An illustration of task migration with 2-bit tagging. The stack header is only active for packets of unmeasured target flows, with task handover, to record the routing path to the flow's origin (edge) switch for collecting results of migrated tasks (i.e., data migration of fragmentation).

duplicated flow measurement. Figure 7 shows the combination of the 2-bit tags and corresponding taken actions.

(1) `Tag(0x)` → *Untargeted Flows (no action)*: For untargeted flows tagged by FI, all switches on the flow's path bypass the feature measurement and forward to the flow's destination.

(2) `Tag(11)` → *Targeted Flows (measured)*: If a targeted flow has been measured by any FM, no additional action is required for the rest of the switches on the flow's path.

(3) `Tag(10)` → *Targeted Flows (handover)*: If a targeted flow is not measured by its local FM, a task migration event occurs and `Tag(10)` is attached. All switches that observe the tag will allow the flow to compete at their local FM.

To sum up, with the hybrid policy, ISDC aims to maximize the resource utilization of the network while minimizing the footprint of task migrations. With the simple and lightweight tagging mechanism, ISDC's task migration bypasses packets of untargeted flows and measured flows to reduce data plane overhead. Meanwhile, it prevents the duplicated recording of packets from eliminating the overlapping of features for the same flow, which makes data aggregation easier through data migration (see section 6.5 for system evaluation).

5.2 Task-Data Isolation Design

To further reduce task migration overhead, we introduce a task-data isolation design. Upon a task migration event, if the evicted flow has a flow feature measured in FM, the data will not be migrated along with the task but is archived in local and offline DRAM storage through PCIe communication, which significantly saves network bandwidth caused by task migrations (see section 6.5.3 for overhead analysis). Our task migration logic is that once a local flow finds a room at its edge-switch's FM for measurement, it is unlikely to be evicted by other flows and handed over to other switches (i.e., Policy 1). However, as shown in Figure 8 (t_2), if a flow is measured at a non-edge switch (i.e., migrated task), the measurement task can be interrupted and migrated again (i.e., Policy 2), which leads to the fragmentation of flow features distributed

among multiple switches of the flow's routing path, as can be seen in Figure 8 (t_2 and t_4). We note that the distributed and fragmented features for the same flow may trigger model self-pointing issues in the distributed learning scenario (see section 6 for use cases). Therefore, data migration for aggregation is crucial. Lastly, even if a flow is active in the data plane, the flow's data in the control plane can be sent to its edge node immediately due to the task-data isolation design.

5.3 Data Migration

Recall that ISDC aims to be a reliable foundation (data source) with serverless data collection for security applications. To address the feature fragmentation issue, we propose a stack-based source routing to migrate the fragmentation back to the flows' edge switches for data aggregation, namely serverless data collection for data integrity, as demonstrated in Figure 8. The unique challenge posed here is that data migration to the edge often relies on the heavy IP protocol and a strong assumption that every switch has prior knowledge of the entire network topology and routing path [13, 14].

Stack Header for Source Route Tracing. For data migration towards flows' edge switches, ISDC uses stack structure attached to the packet header, which is realized by the built-in function of data plane programming language (i.e., P4 [52]) and supported by commercial programmable switches [53]. Therefore, no extra accommodation is needed to realize the stack function. As shown in Figure 7, the stack header is attached only when a switch observes a packet with unmeasured targeted flows (`Tag(10)`). The functional goal of the stack is to identify the source routing path of a flow at any switch on the flow's path for later data migration towards flows' edge switches (i.e., serverless data aggregation). As shown, whenever a packet reaches a new switch, the switch pushes the packet's incoming port into the stack. As a result, every switch is aware of the physical layer routing path back to the flow's edge (origin) switch by referring to the stacked port numbers. For data migration, as shown in Figure 8, when a switch measures non-local flows, it archives the stack into the local DRAM storage. Therefore, the data migration can be easily achieved by reusing the stack information.

Event Trigger. The data migration is initiated by ISDC actively from the switch's user space of its network operating system. The non-blocking function runs periodically to 1) scan the local DRAM storage, 2) identify inactive non-local flows' data, 3) craft a special packet with the stack as header and data as payload, and 4) eventually inject the packet into the switch's data plane for the source routing.

Understanding the Costs. It is worth mentioning that both source route tracing and data migration are not free but increase network link utilization. The stack size varies according to 1) the number of physical ports available for the switch and 2) the number of task migrations (i.e., hops). For instance,

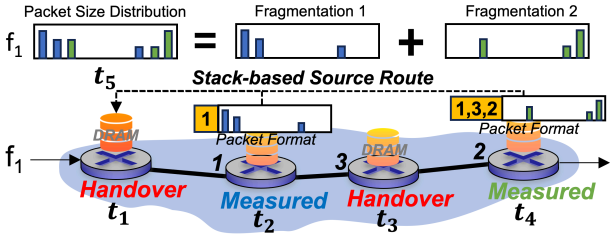

Figure 8: An illustration of data migration using stack-based source routing. A flow f_1 is measured at time t_2 and t_4 by two switches, and each generates a feature fragmentation. The data migration is an active process that sends fragmentation back to the flow's origin (edge) switch for aggregation. The routing path (i.e., incoming switch ports) is collected during task migration with the tag and stack headers.

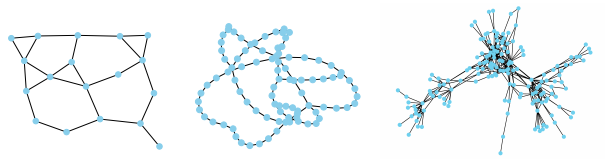
the widely used switch has 32 ports. Thus, 8-bit is required for each stack slot to distinguish the ports. Moreover, the amount of ports pushed into the stack is determined by the distance of task migration from the flow's edge switch and the non-edge switch that measures the handed-over flow, as shown in Figure 7. However, we reemphasize that the stack is only attached to the unmeasured packets of targeted flows from other switches and eliminated once the packet is measured by any switches. Moreover, combined with the edge-centric task allocation strategy (i.e., Policy 1), ISDC minimizes the network-link overhead of source route tracing for data migration (see section 6.5.3 for overhead analysis).



6 Evaluation

This section shows experimental results of ISDC, including security use cases and system performance.

6.1 Experimental Setup

Hardware and Software Implementations. We deployed ISDC prototype on a commercial switch [53] with Intel Tofino-1 Fabric [27] to show the feasibility of ISDC and for function evaluation. The used switch equips 120 MB SRAM and 6.2 MB TCAM memory. Furthermore, we implemented a software version of ISDC with 733 lines of P4 code (P4-16 language [52]) for the data plane and 839 lines of Python code for the control plane. We used `bmv2` model [54] for Mininet simulation [55]. Our simulations were conducted on a server with two 3.2 GHz 20-core CPUs and 512 GB of memory.

Topology. Figure 9 visualizes three network topologies used with Dijkstra routing algorithm [56]. ASN [57] is the smallest topology containing nodes and 25 links and is featured by short but balanced network paths. Vlt Wavenet [57] is a medium-sized topology with 92 nodes and 96 links, featuring significantly imbalanced path lengths. Tiscali [58] is a backbone topology consisting of 161 nodes and 328 links, which is large and complex.

(a) ASN [57] (b) Vlt Wavenet [57] (c) Tiscali (AS 3257) [58]

Figure 9: Real-world topologies used in the experiments.

Dataset and Traffic Generation. We used Facet [59], DeltaShaper [60], and CovertCast [61] for covert channel attacks. We also used CIC-IDS-{2017-2018} [62, 63] and CIC-DDoS-2019 [64] for DoS/DDoS attacks. Moreover, we used an eight-minute CAIDA [50] trace as background traffic from benign clients to add noise during attack data collections. The attack and benign traffic were balanced with the total number of packets. For flawless ML settings, particularly to avoid temporal snooping issues [65], we preserved the order of flows/packets when processing the dataset. Lastly, each network node is attached to a traffic generator for generating traffic using Tcpreplay [66], where all generators send the same number of flows simultaneously without duplication.

Parameters. For fairness, we allocated the same amount of memory space to ISDC and compared schemes [32–34]. Moreover, the total memory budget was equally divided and allocated to each network node. We followed the work guidelines for each switch to configure memory within each network node (switch). Per the guidance, the packet size distribution (PSD) feature is quantized with interval 16 (Quantization Level 4 in FlowLens [6]); thus, 94 bins per flow considering the maximum packet size of 1504 Bytes.

Learning Models. We utilized the Federated Averaging (FedAvg) algorithm [67] to aggregate local models from each node. FedAvg is designed to lessen the impact of training loss on multi-layer neural network [68] in federated learning, where the training data in each node exhibit heterogeneous distributions. Our binary classifier, a simple neural network [69], consists of two hidden layers with 64 and 32 neurons, respectively. These layers utilize the Rectified Linear Unit (ReLU) activation function and incorporate a dropout rate of 20% to prevent overfitting. For decision-making, the network's output layer employs the sigmoid activation function with a threshold of 0.5. Finally, the global model was tested with over 50 runs with an imbalanced ratio of 10/90 for attack/benign samples to reflect real-world settings and reliable results.

6.2 Metrics

Metrics for system and security evaluations are as follows:

Flow Coverage. The coverage quantifies data collection scalability, as $\hat{N}/N$, where $\hat{N}$ is the total number of measured top-K flows and N is the total number of actual top-K flows.

Fragmentation Ratio. Fragmentation ratio is the number of flows measured more than once at different switches (duplicate flows) over the total number of distinct flows. $Frag = \frac{\sum_i \#\text{duplicate flows}}{\sum_i \#\text{distinct flows}}$ for all node i.

Memory Waste. The memory waste is used to quantify the amount of memory wasted for measuring untargeted flows (non-top-K flow in this work). It is defined by U/M, where U is the total number of untargeted flows measured, and M is the total number of slots allocated for the per-flow measurement.

Weighted Mean Relative Error (WMRE). WMRE quantifies data collection quality for per-flow packet size distribution (PSD) features. Accordingly, WMRE in our setting is defined as $\sum_{i=1}^{b} |n_i - \hat{n}_i| / \sum_{i=1}^{b} (\frac{n_i + \hat{n}_i}{2})$, where b is the largest bin, $\hat{n}_i$ is the observed frequency of each bin, and n_i is the ground truth.

F1 Score. We used the F1 score to evaluate attack detection models' performance in our security use cases. It is a harmonic mean of precision and recall to denote the trade-off.

Area Under the ROC Curve (AUC). We further evaluate attack detection models with AUC for a comprehensive measure. The metric summarizes the model performance with various classification thresholds in the ROC curve.

6.3 Use Case 1: Covert Channel Detection

In this experiment, we examine the ISDC's performance with a covert channel detection use case. We first compare ISDC with a strawman approach, a naive extension of FlowLens [6] to a distributed setting, to explain the importance of collaborative and application-focused flow measurement under resource constraints. Then, various state-of-the-art collaboration schemes, such as CSAMP [32], NSPA [33], and CFS [34], were compared to show ISDC's data collection quality. In all use cases, we let each edge switch train a local model independently using locally collected per-flow features, followed by a standard federated learning setting to build a single global model without sending the feature data. Lastly, we conducted an offline evaluation of the global model to measure the impact of the data quality for learning-based covert channel detection. For fairness, we allocated the same amount of memory resources and workloads to all schemes, noting that NSPA, CSAMP, and CFS are real-time decision-making schemes that are directly comparable with ISDC.

Preprocessing. We used 1.1k covert channel attack flows from three datasets [59–61], where 0.88k attack flows were used for data collection simulation and attack model training. Then, the remaining 0.22k attack flows were mixed with 1.98k benign flows to create an imbalanced testing dataset (i.e., 10/90 for attack/benign) to reflect a real-world setting. We note that the model testing is performed offline to measure the impact of data quality in attack detections. Since covert channel attacks are independent, a temporal snooping issue [65] is not a major concern when splitting the flows. Also, we note that these flows have a relatively larger size (e.g., $>$ 1,000 packets). For the background traffic, we matched the packet number with our attack trace from CAIDA benign trace (i.e., 6.5 M packets, 479k flows) with preserved order of packets

and flows. For network topology and traffic generation, we used ANS [57] with 18 nodes, and the mixed attack/benign flows are evenly assigned to all generators without duplication; thus, the traffic imbalance is negligible.

Setting. The memory configuration of all security use cases is determined by the smallest attack flow size in the dataset. In covert channel detection, 76k flows out of 480k total flows are larger than the smallest covert channel flow in size; thus, 76k slots equivalent memory space (i.e., 14.7 Megabyte) was assigned to the entire network. With ANS topology, each node used 836.8 Kilobyte (KB) of memory space. We note that the memory setting is identical for all schemes within the same use case. For ISDC only, 12.2 KB of memory space was taken by FI (1.4% of memory space) for target flow prediction and the remaining was used by FM for per-flow feature data collection. After traffic generation, we used the collected feature data in each node to train a local model and then built a global model from all 18 local models using the standard federated learning framework FedAvg [67]. To analyze the impact of data quality in model training, we conducted experiments with two settings: 1) a single round of training with all nodes involved for a model aggregation and 2) ten rounds of training with 50% nodes randomly selected.

Strawman (Naive) Approach. To enable distributed per-flow feature collection, one naive approach is to deploy FlowLens [6] in a distributed manner, with each switch working independently. We start by showing that this naive deployment, which lacks collaboration and optimization mechanisms, is impractical for overcoming the imbalance of traffic distribution. Table 2 demonstrates the result of the naive approach compared with ISDC. As shown, the strawman approach covers 30.6% flows only among top-76k flows, and 52.5% of memory space was wasted by super mouse flows consisting of one or two packets. Accordingly, the strawman approach achieved a poor F1 score of 0.295 and AUC of 0.246 in the single-round training setting, which is much lower than the ISDC archived F1 score of 0.960 and AUC of 0.938. We noticed that ISDC-based model training converges even with one training round because of the excellent feature engineered in the original work FlowLens (used as FM of ISDC). However, efficient training is unachievable without ISDC's scalable and high-quality data collection. However, we can observe that the naive approach-based model's performance also converges with more training rounds. Still, computation power costs remain inefficient compared to high-quality data-based training.

Compared with Collaboration Schemes. In the following, we used FlowLens [6] feature measurement function as an add-on module to all schemes. Table 2 summarizes the performance of models varying schemes. With a centralized collaboration for task balancing, CSAMP and NSPA improved the flow coverage slightly to 35.4% and 36.9%, respectively, with similar amounts of memory waste. Although unsatisfiable, the central coordination partially addressed the traffic imbalance issue in the network and led CSAMP and NSPA to cover more attack flows in the collected data. As a result, the trained attack detection model achieved higher F1 scores (0.824 and 0.816) and AUCs (0.718 and 0.709), compared to the naive approach (F1 score of 0.295 and AUC of 0.246), in a single-round federated learning setting. As expected, CFS with local but more reactive decision-making achieved a higher coverage up to 58.1% but suffered from low feature accuracy (i.e., WMRE 1.67), mainly because 53% of flows are fragmented, which will be explored more in section 6.4. However, CFS still achieved a higher F1 score of 0.887 and AUC of 0.857, compared to NSPA and CSAMP, in the single-round training setting, which is mainly because of the high coverage of CFS.

Schemes	Cov.	Frag.	Mem. Waste	Avg. WMRE	F1		AUC	
					1 rd.	10 rd.	1 rd.	10 rd.
Strawman	30.6%	0%	52.5%	1.37	0.295	0.927	0.246	0.869
CSAMP	35.4%	0%	51.8%	1.27	0.824	0.923	0.718	0.862
NSPA	36.9%	0%	51.3%	1.25	0.816	0.927	0.709	0.868
CFS	58.1%	53%	62.1%	1.67	0.887	0.942	0.857	0.894
ISDC	**94.1%**	**0%**	**8.02%**	**0.18**	**0.960**	**0.970**	**0.938**	**0.967**

Table 2: Comparing ISDC with a strawman and collaboration schemes in covert channel detection. ISDC, with higher flow coverage (Cov.), superior feature accuracy (averaged WMRE of all flows), and without data fragmentation (Frag.), achieved the best model performance among all schemes.

Lastly, the proposed ISDC achieved the highest flow coverage of 94%, thanks to FI's precise flow size prediction. With a dynamic but duplication-free (fragmentation-free) task migration, ISDC achieved the highest feature quality of WMRE 0.18, as shown in Table 2. Accordingly, ISDC achieved a much higher F1 score of 0.960 and AUC of 0.938, with the same feature and single-round training. An interesting observation is that with a multi-round training setting, the model performance of all schemes improved more or less but was still worse than the ISDC-based model in single-round training, which proves the importance of data quality for training.

6.4 Use Case 2: DoS/DDoS Attack Detection

We further explore ISDC's performance in DoS/DDoS attack detection using CIC-{2017-2019} attack datasets [62–64]. Unlike covert channel trace which mainly consists of large flows, the average flow size in CIC datasets is much smaller (e.g., < 20 packets), requiring more precise feature measurement since missing even one packet may affect overall flow feature quality significantly. With this characteristic, we unveil a model self-poisoning issue caused by a dynamic task allocation [34] and report that data inconsistency for small-sized flows is more critical in model training due to the sparse data points. To verify, we compared ISDC with the state-of-the-art CFS [34], which allocates flow measurement tasks dynamically with local decision-making and achieves the highest flow coverage among existing schemes.

Preprocessing. We randomly selected 10k attack flows from three categories, namely reflection, flooding, and brute force (see appendix B for more details). We used 8k attack flows for simulation and federated learning of attacks. Then, the remaining 2k attack flows were mixed with 18k benign flows to create an imbalanced testing dataset (i.e., 10/90 for attack/benign) to reflect real-world settings. When we split the attack dataset, we preserved time order to avoid a temporal snooping issue [65]. For the background noise, we matched attack traffic with the same number of packets from the benign CAIDA trace (i.e., 2.5 M packets and 232k flows).

Setting. In the mixed dataset, 36k flows are larger than the smallest CIC attack flows in size; thus, 36k slots equivalent memory space was assigned for both ISDC and CFS. With the ASN topology (18 nodes) [57], each node was assigned 395 KB of memory space. For ISDC only, 12.2 KB (3% of memory space) was assigned to FI and the remaining to FM. We used the same federated learning setting as in use case 1.

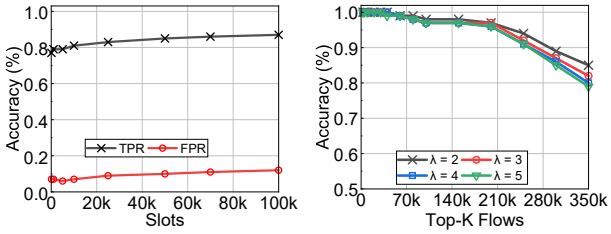
Compared with Dynamic Decision-Making Scheme. As can be seen in Table 3, CFS achieved a coverage of 49.9%, however, 62% of them are fragmented flow features. To analyze the impact of fragmentation on the model performance, we manually removed the feature fragmentation and retrained the model, denoted as CFS-clean in Table 3. As shown, without fragmentation, the F1 score was improved slightly from 0.617 to 0.620 with the one-round training. Moreover, with ten-round training, the model performance increases significantly in terms of F1 score from 0.613 to 0.756, which infers the model self-poisoning issue is caused by the inconsistency of flow features (i.e., fragmentation) during collaborative flow measurement. An interesting observation is that with the fragmentation elimination, the AUC decreases from 0.828 to 0.777 in the one-round training, which proves our assumption that the fragmentation is more critical for smaller flows; recall that CIC attack flows are mostly less than 20 packets. The results also support ISDC's design of data aggregation, which played an important role in efficient model training. Although the AUC of CFS-clean improves slightly compared to CFS with fragmentation, with ten-round training, the training cost becomes a critical downside.

Lastly, ISDC's fragmentation-free collaboration with flawless aggregation led to a high-quality and scalable feature data collection (see averaged WMREs in Tables 2 and 3), which allows the model to improve the F1 score from 0.730 to 0.809 and AUC from 0.860 to 0.945, with ten-round training setting.

Schemes	Cov.	Frag.	Mem. Waste	Avg. WMRE	F1		AUC	
					1 rd.	10 rd.	1 rd.	10 rd.
CFS	49.9%	62%	67.6%	0.989	0.617	0.613	0.828	0.891
CFS-clean	49.9%	0%	67.6%	0.868	0.620	0.756	0.777	0.892
ISDC	**93.1%**	**0%**	**3.5%**	**0.297**	**0.730**	**0.809**	**0.860**	**0.945**

Table 3: Comparing ISDC with CFS [34], the state-of-the-art dynamic task distribution approach, in DoS/DDoS attack detection. Data duplication and fragmentation in CFS degraded the model's performance, whereas ISDC, with the in-network data aggregation mechanism, boosted the data quality and achieved better model performance.

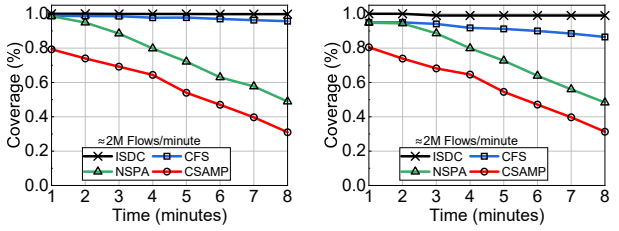
6.5 System Performance



In the following, we use a large topology, namely Tiscali (AS 3257) [58] with 161 switch nodes and 328 links, to evaluate the ISDC's system performance. We first analyze the key function FI in terms of flow prioritization. Next, we verify the data scalability and integrity of ISDC at scale and compare it with other schemes. Then, we systematically evaluate overheads of ISDC, including task/data migration and data archive, to support the feasibility of ISDC. Lastly, we measure the impact of topology by involving two more real-world topologies with different sizes and characteristics (see Figure 9). Worth noting that we show the performance snapshot for all schemes in the progress of the simulation for varied workloads (i.e., from idle to heavy) to compare all schemes fairly.

6.5.1 Flow Prioritization with FI

Recall that FI works with two parameters (w, λ): w is assigned a number of slots and λ is a threshold for prediction. For analysis, we mixed $140k$ attack flows from CIC datasets [62–64] with $\approx$1.8 million benign flows from CAIDA [50]. We use true and false positive rates (TPR and FPR) to show FI's reliability in flow size prediction but not attack detection. TPR correctly predicts top-K flows over the ground truth of top-K, whereas FPR incorrectly predicts top-K flows over the ground truth of non-top-K. Figure 10 shows top-K prediction performance varying w from $0.1k$ to $100k$ with $\lambda = 2$. As shown, the TPR grows quickly as w increases and achieves TPR rates of 81%, 85%, and 87% with $10k$, $50k$, and $100k$ slots, respectively. Remarkably, the TPR of 81% is extraordinary, considering the massive amount of mice flows in the CAIDA trace and the large $K = 350k$ targeted (i.e., the smallest top-K flow has 10 packets only). Moreover, even with a small number of counters (i.e., $w = 10k$), FI shows low FPR, as shown in Figure 10 (a). Furthermore, FI shows stable performance varying λ from 2 to 4, as shown in Figure 10 (b). It is important to note that FI's flow prediction consumes a few packets for burst measure (see appendix A for details), which becomes an inevitable cost for feature measurement in FM. The impact, however, is negligible, as proven by the high feature accuracy in the following section.



6.5.2 Data Collection Performance

Setting. We used an eight-minute CAIDA benign trace containing around 14.5 million flows. For all compared schemes, we assign 1.1 MB of memory space for each node, which is enough to measure half of the CAIDA trace's flow features. For ISDC, we assign 5 KB of memory space to FI for target

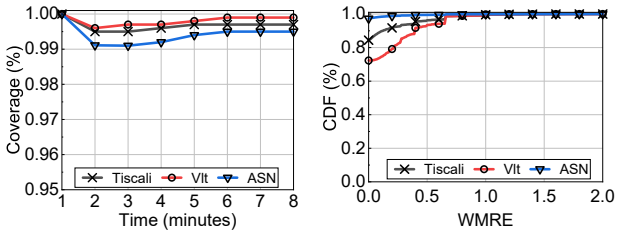
(a) Top-100k (b) Top-500k

Figure 11: Comparing flow coverage varying amount of traffic from 1 to 8 minutes of CAIDA traffic. Flow coverage of top-100k and top-500k flows are shown in varying schemes.

(a) Top-100k (b) Top-500k

Figure 12: Comparing feature accuracy of top-K flows varying schemes using Weighted Mean Relative Error (WMRE).

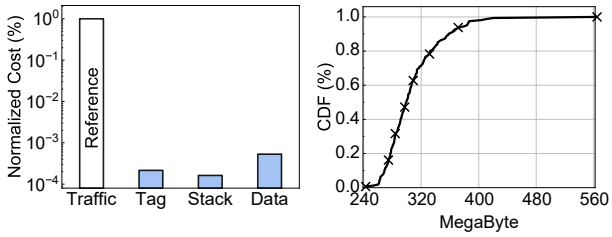
flow prediction and the remaining memory to FM for per-flow feature measurement. For FM, we follow FlowLens [6] standard configuration that measures the most significant ten bins. The system performance snapshots are given at each minute; thus, before the four-minute checking point, data plane resources are enough to measure all flow for all compared schemes. This is to eliminate the impact of FI and show the effectiveness of ISDC's collaboration strategy.



Flow Coverage. Figure 11 shows the coverage of flow feature measurement targeting top-100k and top-500k flows, varying the amount of traffic from 1 to 8 minutes of CAIDA. Notably, ISDC stands out as the top performer, achieving a remarkable full coverage at all times and across all Ks. These results verify the superior performance of FI and ISDC's task migration strategy, which effectively scales up the measurement capacity. On the contrary, the absence of a dynamic collaboration of CSAMP and NSPA on flow measurement resulted in flow omissions when a collision occurs. As can be seen, with dynamic task prioritization, CFS could measure more per-flow features than CSAMP and NSPA. However, the presence of fragmented flows in CFS contributed to approximately 50% of the duplication and inconsistency of flow measurements, further diminishing feature measurement accuracy.

Feature Accuracy. Figure 12 shows the cumulative distribution function (CDF) of WMRE (lower is better) for per-flow feature measurement for top-100k and top-500k flows in the eight minutes of traffic. As illustrated in Figure 11, ISDC easily outperformed other methods by capturing up to 70% more flows in all top-K while achieving WMRE 0 for 60% in top-100k and 80% for top-500k flow feature measurement. Remarkably, 95% of the flows measured by ISDC showed WMRE less than 0.5 among all the top-K, which is clear evidence of the closeness of the measured flow features to ground truth. In contrast, CFS encountering fragmentation issues measured only 35% of the flows with WMRE 0, with a majority exhibiting higher WMRE values. NSPA outperformed CFS in capturing more flows without loss in the top-100k and top-500k flows (see Figure 12). However, both CSAMP and NSPA exhibited high error rates due to flow missing (i.e., WMRE 2), accounting for 50% of flows. To sum up, among all the top-K flows, ISDC achieved an average WMRE of 0.05, while CFS scored 0.54, NSPA 1.04, and CSAMP 1.38.

Topology Impact. We measured the impact of network topologies on ISDC performance. To do so, we conducted experiments using three different real-world network topologies with varied sizes and characteristics (see Figure 9). Figure 13 shows the coverage and the feature quality of top-500k targeted flows for three topologies. ISDC achieved near full coverage consistently across all topologies of more than 99%, which indicates the impact of topologies in ISDC scalability is negligible, as shown in Figure 13 (a). For feature quality, we also observe exceptional accuracy of ISDC across the three topologies, as shown in Figure 13 (b). Even under Vlt topology with extremely imbalanced network path length, ISDC achieved a WMRE of 0 for over 70% flows. In all topologies, over 92% of flows achieved WMREs under 0.5. Therefore, we conclude that ISDC suppresses topology impact well on its stable performance.

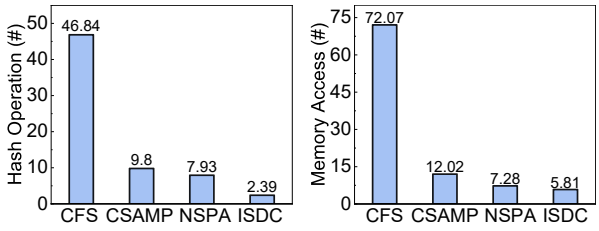


6.5.3 Overhead Analysis

Task and Data Migrations (Network Link). Figure 14 (a) shows the overheads of data and task migrations normalized by the total amount of traffic used for the simulation. The in-band overhead refers to the in-network bandwidth consumption caused by the data and task migrations. The overheads can be categorized into three types: tagging header, stack header, and feature data, where the tagging is for task migration, stack header, and data are for data migration. As shown, ISDC's in-band overhead is negligible compared to the total amount of traffic, considering the tag header is attached to all the packets. Moreover, considering 17% of flow fragmentation generated by ISDC, the overhead triggered by data

(a) Coverage (b) Feature Accuracy

Figure 13: ISDC coverage and feature accuracy comparison for top-500k flow measurement in three real-world topologies.



(a) Task-Data Migration (b) Data Archive

Figure 14: Overhead analysis: (a) ISDC's in-network bandwidth consumption for task and data migrations (tag, stack, and data as blue bars), compared with the total amount of network traffic as a reference. (b) CDF of data communication volume through PCIe at all 161 switches for data archiving.

migration (i.e., 0.01% for stack header and 0.05% for data) is also negligible. We can conclude that ISDC adds insignificant overhead to in-network bandwidth resources while eliminating the need for a central collector for data aggregation and saving northbound bandwidth significantly (see appendix A for northbound overhead).

Data Archive (PCIe Bandwidth). Figure 14 (b) illustrates the in-switch communication overhead of ISDC for data archiving from the switch's data plane to the switch's control plane via PCIe. The graph depicts the PCIe utilization of all 161 switches in our large-scale simulation. This overhead arises during the eviction process triggered in the data plane (active data archive) when tasks are transferred to the next switch or when the control plane (passive data archive) releases the data plane memory occupied by those small but bursty flows (short-lived flows). Our analysis revealed that this overhead is minimal compared to the gigabyte capacity of PCIe channels in programmable switches [27, 28]. Remarkably, 90% of switches transfer less than 358 MB during the data archiving process for the eight minutes of CAIDA traffic. This negligible overhead is attributed to the narrowed scope of feature measurement realized by FI's design.

Data Plane Complexity (ASIC). Next, we evaluated the overhead introduced by ISDC on the data plane. Figure 15 depicts ISDC's data plane complexity, comprising per-packet processing tasks such as hash operations and memory access. The computational load in a measurement system is influenced by two key factors: the complexity of data structures in the data plane and the number of hops a packet must traverse to reach the monitoring point. CFS exhibited the highest computational load due to its intricate data plane structure, requiring 11 memory accesses per switch in the worst-case scenario. Although CSAMP and NSPA have less complex data plane designs, they still incur memory access and computation for nearly every packet as it traverses each switch in the path. In contrast, our local eviction policy ensures that most flows are measured at the edge switches. Moreover, our FI design and the tagging mechanism reduce hash computations in subsequent FM switches by bypassing flow feature measurement for all untargeted flows. Consequently, ISDC significantly reduced complexity, resulting in an average of 2.3 hash computations and 5.8 memory accesses.

(a) Hash Operation (per-packet) (b) Memory Access (per-packet)

Figure 15: Data plane complexity: (a) hash operation and (b) memory access required per-packet processing in data plane.

6.5.4 P4 Implementation

We deployed FI and FM into a hardware switch's data plane for feasibility validation. Besides, we used the standard BFRuntime API of Tofino [27] in the switch's control plane to interact with our data plane functions, especially for ISDC's data archiving. We highlight that FI and FM used SRAM memory only and advanced Ternary Content Addressable Memory (TCAM) is not required.

Implementation Issues. We encountered two issues with FI implementation. The first issue is that the hardware switch does not support multiple variables in the same logical structure. Particularly, each slot of FI has three variables, namely the Flow ID (*key*), burst count (B), and combined burst count ($\hat{B}$). To workaround, we adopted the same approach outlined in [44] by approximating $\hat{B}$ with B^{all}. By doing so, B^{all} tracks both B and $\hat{B}$ and counting them simultaneously. Accordingly, the eviction policy will change when the condition $\frac{B^{all}}{\lambda} == B$. The second issue is that the length of variables cannot be varied. Recall that three variables of FI maintain two different bit lengths; thus, we had to match the bit length with the largest variable (*key*). Although this hardware limitation causes some bit waste and is not being used, the total unused memory is negligible, considering the small size of FI.

Hardware Resource Utilization. Table 4 shows the hardware resource utilization of ISDC breakdown with components. Notably, FM that is based on FlowLens [6] exhibits the highest resource utilization, consuming 6.25% of SRAM and

Resources	Flow Identifier	Feature Meter	Protocol	ALL
Stages	3	11	4	12
VLIWs (%)	6.25	3.12	6.25	7.03
ALU (%)	16.67	20.45	0.00	22.92
SRAM (%)	2.50	6.25	0.31	7.19

Table 4: Hardware switch resource utilization of ISDC.

20.45% of Arithmetic Logical Units (ALUs), making it the most resource-intensive element in the system. Conversely, FI primarily relies on computational resources, including Very Long Instruction Words (VLIWs) and ALUs, with minimal SRAM memory and zero TCAM usage. The protocol component also handles header computations for reporting and measurement processes, utilizing 6.25% VLIWs. In summary, ISDC utilizes 7.19% of SRAM, with the majority allocated to FM, along with 2.50% SRAM for FI, in total 22.92% ALUs and 7.03% VLIWs. All these components are successfully fitted into 12 stages of the switch, which infers the line-rate packet processing capacity of ISDC's data plane.

7 Discussions

Impact of Attack Characteristics. We consider two types of attacks: bursty and slow attacks. Bursty attacks exploit the resource constraints of hardware switches by sending numerous burst flows to saturate the data plane. Thanks to ISDC's collaborative and application-focused measurement, saturating all switches across the flow routing path is not trivial. A potential downside is that, with FI design, ISDC mainly considers large and bursty flows. Therefore, adversaries may launch a slow or less bursty attack to evade FI's identification as targeted flows, which we will explore in future research.

Feature and ML Algorithm Selection. The proposed ISDC aims for a scalable and high-quality data collection of richer flow distribution features concerning the resource scarcity of measurement systems but not feature engineering. We opted for FlowLens [6] as our feature extraction module (FM) due to its generalizable hash table-based approach and versatility capable of capturing per-flow features, such as packet size distribution (PSD) and inter-packet delay (IPD). Recently, such distribution features received much attention due to their ability to catch application layer behavior reflected in higher-dimension representation, which benefits attack detections significantly [6, 12, 23, 25, 26]. With the high-quality and rich feature support by ISDC, various advanced ML/DL algorithms [6, 8, 18–22] can be integrated for advanced detection of more sophisticated attacks without a compatibility issue.

8 Related Work

Programmable switches have been used for various applications such as network traffic measurement [29, 44, 70–77] and attack detection [6, 12–17, 25, 30, 46]. Typically, these works concentrate on the switch's inner functionality but often face scalability challenges. Software-defined networking (SDN) is one of the viable approaches for distributed traffic measurement and has been widely discussed [78–83]. However, despite the dynamic nature of SDN solutions, these works suffer from bandwidth overhead and latency issues for measurement tasks [17]. Recent efforts in distributed traffic measurements leveraging programmable switches have been explored for tailored security applications, namely mitigating link flooding attacks [13, 14]. These works focused on consolidating in-network resources for collaborative measurement for fast attack mitigation, focusing on the fast convergence of distributively measured volume data for instant decision-making. Unfortunately, the aim is mismatched with the recent trend of using machine learning technologies with complex features to defeat advanced work. Notably, a large body of research has used ML/DL for network security. These works [8, 23, 26, 84–86] primarily focus on feature engineering and the construction of dedicated models for identifying malicious traffic. Our work is closely related to network-wide task distribution and resource allocation schemes, such as CSAMP [32], NSPA [33], and CFS [34], which aim to achieve full flow measurement coverage by maximizing resource utilization.

9 Conclusion

This paper introduces ISDC, an in-network serverless data collection system for enhancing network defense. ISDC's goal is to serve as a data layer setting in the middle of infrastructure and application layers, aiming to alleviate the bottleneck associated with data flow towards security applications in the northbound. With this objective, we introduced various designs to enhance distributed and collaborative measurement flow features, specifically focusing on consolidating and efficiently utilizing distributed in-network resources. We propose a serverless data migration approach to enable in-network data aggregation, ensuring data integrity for more resilient security applications. Through ISDC, we aim to inspire researchers to integrate advanced machine learning and deep learning technologies into large-scale network attack defense.

Appendix A Other Issues

FI Overhead. For a better understanding of FI's overhead, we extend our FI flow prioritization analyses (see section 6.5.1) and analyze the average packet loss across different attack types, as shown in Figure 16 (a). The results indicate that for most attack types, FI successfully predicts over 96% of flows. However, reflection attack types (e.g., DNS attack) exhibit relatively lower prediction coverage, 87% on average, suggesting a decrease in the attack rate due to flow reflection. On average, attack flows had a 23% packet loss which is inevitable cost for flow size prediction. However, considering the small size of attacks in the dataset (i.e., 34 packets on average), the cost is negligible.

Northbound Overhead. The northbound overhead refers to the amount of data communication towards security applications, essential for collecting and preprocessing data to facilitate the construction of a single model for learning network traffic patterns. NSPA [33] and CSAMP [32] already rely on a central controller for data collection and decision-making, making it trivial to send the feature data to the collector as well. In contrast, CFS [34] necessitates a central collector to remove the fragmentation effect. On the other hand, ISDC does not require data communication with a northbound server but only local model parameters for model aggregation. With the size of the model we employed in our simulation, ISDC can save out-of-band (northbound) overhead up to 94% compared to CFS, as shown in Figure 16 (b). For CFS, the amount of data transmission is even higher than the full population flow feature migration to the northbound server due to the massive amount of fragmentation generated during the flow feature measurement process.

(a) FI Overhead (b) Northbound Overhead

Appendix B Dataset Description

We used three datasets from CIC for evaluations [62–64]. To preprocess and extract attack flows, we adopted Liu et al.'s approach [87] for dataset sanitization. In our endeavor to select attack traffic from various attack types, we encountered three challenges that necessitated excluding certain attack types from our evaluation. Firstly, sparse flows of layer-7 attacks, like Slowloris, exhibit a slow nature. Secondly, several attack types had an inadequate number of flows (less than 1k) or were small in size, with 5-tuple definition for meaningful assessment. Lastly, certain attack traffic posed difficulty differentiating from benign traffic when utilized in machine learning models for training purposes. Given that the feature and machine learning are not the focus of this work, we opted to discard these attacks. After the aforementioned preprocessing procedure, the selected attacks fall into three groups, namely reflection (NTP, LDAP, SSDP, DNS, SNMP), brute-force (SSH), and flooding (UDP, UDP-Lag). Table 5 shows the number of flows selected for our evaluation.

Attack type	# of packets	# of flows	Trace
LDAP	5.4M	2K	CIC-DDoS2019 [64]
DNS	17M	161K	CIC-DDoS2019 [64]
NTP	10M	131K	CIC-DDoS2019 [64]
SSDP	1.3M	66K	CIC-DDoS2019 [64]
SNMP	7.3M	28K	CIC-DDoS2019 [64]
UDP-Lag	74K	2.5K	CIC-DDoS2019 [64]
UDP	1.7M	86K	CIC-DDoS2019 [64]
SSH	163K	5.9K	CIC-IDS2017 [62]
SSH	4.3M	188K	CSE-CIC-IDS2018 [63]
Benign	250M	14.5M	CAIDA [50]

Abstract

Cyberattacks have grown into a major risk for organizations, with common consequences being data theft, sabotage, and extortion. Since preventive measures do not suffice to repel attacks, timely detection of successful intruders is crucial to stop them from reaching their final goals. For this purpose, many organizations utilize Security Information and Event Management (SIEM) systems to centrally collect security-related events and scan them for attack indicators using expert-written detection rules. However, as we show by analyzing a set of widespread SIEM detection rules, adversaries can evade almost half of them easily, allowing them to perform common malicious actions within an enterprise network without being detected. To remedy these critical detection blind spots, we propose the idea of adaptive misuse detection, which utilizes machine learning to compare incoming events to SIEM rules on the one hand and known-benign events on the other hand to discover successful evasions. Based on this idea, we present AMIDES, an open-source proof-of-concept adaptive misuse detection system. Using four weeks of SIEM events from a large enterprise network and more than 500 hand-crafted evasions, we show that AMIDES successfully detects a majority of these evasions without any false alerts. In addition, AMIDES eases alert analysis by assessing which rules were evaded. Its computational efficiency qualifies AMIDES for real-world operation and hence enables organizations to significantly reduce detection blind spots with moderate effort.

1 Introduction

Enterprise networks increasingly face severe cyberattacks [27], e.g., illustrated by the 2020 SolarWinds hack affecting thousands of companies and government agencies [26]. Besides considerable efforts to roll out preventive measures, enterprises additionally depend on threat detection to uncover successful adversaries breaching their line of defense [38]. For this purpose, many enterprises utilize *Security Information and Event Management* (SIEM) systems to collect and automatically analyze large numbers of security-related events (e.g., user authentications, program executions, network connections, and file manipulations) from endpoints and network appliances. To discover potential intruders from these events, organizations predominantly rely on expert-written SIEM rulesets [1, 9, 53]. Such rulesets implement the concept of *misuse detection* (also called *rule-based* or *signature-based* detection), i.e., they contain definitions of known malicious behavior. The main reasons to rely on misuse detection are its effectiveness in finding known attacks, simplicity of operation, and ability to ease investigation by providing alert details such as name and description of detected attacks [47].

However, these advantages come at the cost of potential detection blind spots, as rules typically fail to cover all possible variations of an attack. Adversaries may thus *evade* detection either by purposefully modifying attacks or inadvertently performing attacks in a subtly different way. These detection blind spots are particularly dangerous when using publicly available rulesets, e.g., the widespread *Sigma* rules [51]: Due to public availability, adversaries can test attacks against rules and, in case of detection, modify them to evade any matches, thereby reducing the risk of being detected. This issue of rule evasions is well known in related fields [15, 31, 44, 62], but has not been studied for SIEM rules until now.

In this paper, we show that widespread SIEM rules are indeed prone to evasions and present a novel method to detect such evasions with few or even no false alerts. For this purpose, we first analyze 292 publicly available and widely used SIEM rules, showing that at least 44 % of them can be evaded using straightforward techniques, thus creating critical detection blind spots. To remedy this situation, we introduce *adaptive misuse detection*, which is an extension of (conventional) misuse detection that aims to detect SIEM rule evasions and otherwise undetected variants of known attacks in addition to (conventional) rule matches. This is achieved by comparing incoming events to SIEM rules on the one hand and known-benign events on the other hand and deciding which of the two categories they are more similar to. Beyond that, if a potential evasion has been identified, adaptive misuse detection assesses which rule(s) were attempted to evade.

This *rule attribution* aims to ease alert investigation for security analysts by showing them potentially attempted attacks, similarly to conventional rule matches.

As a proof-of-concept implementation of adaptive misuse detection, we present AMIDES, an open-source ***A***daptive ***Mi***suse ***De***tection ***S***ystem, which detects activity that is similar to known attacks, yet does not trigger the respective SIEM rules (i.e., evasions). AMIDES is based on supervised learning from SIEM rules versus benign events, allowing it to classify new events depending on their similarity either to known-malicious or known-benign activity. Notably, by learning from existing SIEM rules, we overcome a common issue of supervised learning, namely, the necessity to manually create a comprehensive set of attacks for the training process. For each potential evasion, AMIDES suggests a list of SIEM rules that an adversary likely attempted to evade (rule attribution).

We evaluate AMIDES using four weeks of SIEM events from an enterprise network with more than 50 000 users and 512 manually generated evasions. Our evaluation focuses on the most prevalent rule type in our SIEM ruleset (i.e., rules targeting malicious Windows process creations), but we also show that AMIDES is applicable to other rule types as well.

At its default sensitivity, AMIDES successfully detects a majority of our crafted evasions (70 %) without any false alerts, despite a realistically unbalanced validation dataset with ~145 000 times as many benign as malicious events. We also show that our approach of learning from SIEM rules is a better choice for practical application as compared to a conventional supervised approach that learns from attack events instead. Finally, we show that AMIDES is fast enough for operation in large enterprise networks and still performs reasonably in case of training data tainted with evasions.

In summary, to overcome the inherent problem of detection blind spots of SIEM rules while preserving the wished-for advantages of misuse detection, our contributions are:

- We perform an analysis of almost 300 widespread open-source SIEM rules and show that approximately half of them can be evaded with minor effort, thus enabling adversaries to potentially avoid detection (Section 3).
- We propose the concept of adaptive misuse detection, an extension of misuse detection that aims to detect SIEM rule evasions and undetected variants of known attacks by classifying events based on their similarity to either SIEM rules or historical benign events (Section 4).
- We design and implement AMIDES, an open-source, proof-of-concept adaptive misuse detection system for practical application in enterprise networks (Section 5).
- We evaluate AMIDES using data from a large enterprise network, showing its ability to detect a majority of our crafted SIEM rule evasions with zero false alerts and a computational performance that allows for real-world operation even in very large networks (Section 6).

2 Background: Detection of Cyberattacks in Enterprise Networks

Cybercriminals, state-sponsored groups, and other cyberattackers are causing vast damage by infiltrating enterprise networks and subsequently conducting data theft, espionage, and sabotage [10, 60]. Among the victims are companies, authorities, and military institutions from all over the world [63]. Experience shows that purely preventive measures (such as timely patching, restrictive access control, and raised user awareness) are not sufficient to thwart all attacks [38]. Sooner or later, attackers usually succeed in finding a vulnerability they can exploit (be it technical or social), allowing them to gain a foothold in the network for subsequent operations [20]. Consequently, organizations need to establish comprehensive capabilities for detecting adversarial activity in their networks [64]. These capabilities are crucial as detection is a prerequisite for reaction, i.e., stopping an attack, analyzing its impact, and attributing it to an adversary [61].

However, detecting adversarial activity in enterprise networks is a challenging task due to the sheer amount and noisiness of potential attack indicators [1]. Traditional sources of such indicators include alerts from firewalls, network-based intrusion detection systems, and anti-virus software [9]. Yet, since adversaries and malware increasingly make use of encryption and obfuscation techniques to evade traditional detection, more and more behavioral data need to be collected from endpoints, i.e., client and server computers [13]. Such behavioral data comprise low-level events such as process creations, network connections, and file manipulations, all of which are valuable indicators of malicious activity despite their large volume [6]. To make sense of this vast amount of data, organizations utilize *Security Information and Event Management* (SIEM) systems, which centrally collect, store, and analyze all security-related data [9]. SIEM systems usually collect data from log files or logging daemons/agents on the source systems, mostly in Syslog and Windows Event Log format. Since their volume renders manual inspection impossible, SIEM systems need to automatically analyze the data for threats [1]. In case a potential threat is found, an alert is generated and needs to be sifted by human analysts, usually in the context of a security operations center [61].

The predominant method used by operational SIEM systems to automatically detect malicious activity is *misuse detection* (also called *rule-based* or *signature-based* detection) [1, 9, 53]. Misuse detection applies a set of *rules* written by security experts to each collected event (or correlations thereof). Each rule contains one or more *signatures*, which describe conditions that trigger the rule (e.g., a regular expression matching a certain event field). In addition, each rule usually has an expressive title, a description, and optionally references to further information on the respective attack. Some SIEM systems also utilize *anomaly detection* in addition to misuse detection [9]. However, experience shows that

this method often produces prohibitive numbers of false alerts (cf. Section 5). Hence, misuse detection is currently the prime means for detecting cyberattacks in enterprise networks [1].

Still, misuse detection is not a silver bullet. Research in the related fields of network-based and host-based intrusion detection as well as malware detection has shown that rules can often be *evaded*, i.e., attacks can be performed successfully without triggering a rule by slightly modifying the attack, e.g., by inserting dummy characters into malicious strings to avoid matching a signature [15, 31, 44, 62]. Common reasons for evadable rules are that (1) the rule author tailored the rule to a concrete attack and did not anticipate all possible variations and obfuscations and (2) matching all possible variations and obfuscations would make the rule (or the underlying analysis engine) too complex or computationally infeasible. Therefore, evasions are a fundamental and inherent problem of misuse detection, which leads to *detection blind spots*, i.e., attacks may remain undetected despite appropriate rules being deployed [15]. Note that an evasion can either be purposeful (i.e, an attacker anticipates that a certain rule is deployed and deliberately evades it) or incidentally (i.e., an attacker unknowingly performs an undetected *attack variant*, e.g., by executing a command line with slightly different arguments than covered by the respective rule). For brevity, in the remainder of this paper, we subsume both kinds under the term *evasion*, thereby meaning a purposeful or incidental evasion of a SIEM rule, including undetected variants of known attacks.

To the best of our knowledge, there is no research yet that analyzes SIEM rules for potential evasions. Possibly this is due to the fact that there has been no large public corpus of SIEM rules for a long time. However, this changed significantly with the advent of *Sigma*, which is a generic and open signature format for SIEM systems [51]. In the last few years, following the general trend of open-source information security [33], Sigma has become a highly active project with a large number of contributors [41, 51]. While this trend enables organizations to make use of a large corpus of comprehensive and up-to-date SIEM rules, it also bares the risk of purposeful evasions in case an adversary correctly assumes that public Sigma rules are being used by a potential victim.

In the following, we will show that Sigma rules are indeed prone to evasions and thus measures for evasion detection are required to reduce critical detection blind spots in enterprises.

3 Analysis of SIEM Rules for Evasions

To lay the foundation for our work, we analyze a representative set of SIEM rules with respect to potential evasions. For this purpose, we chose a subset of *Sigma rules*, which are probably the most widely used corpus of open-source SIEM rules at the moment. In the following, we give a short introduction to Sigma, describe our analysis goals and methodology, and finally present our findings, showing that evasions indeed induce significant detection blind spots.

Introduction to Sigma Rules Sigma is a generic and open signature format for SIEM systems. It allows for flexible rules in YAML format that can detect malicious or suspicious behavior in any type of text-based log data. Sigma rules can be automatically converted to queries for common SIEM products (e.g., Splunk or Elasticsearch). Aside from these conversion tools and Sigma's specification, its GitHub repository [51] contains a large corpus of detection rules, which are continuously revised and extended by a large community. According to the Open Source Security Index, the Sigma project is among the most popular and fastest growing open source security projects on GitHub (sixth place overall, highest ranked project with detection focus as of January 2023) [41]. In our professional experience, Sigma rules are widely used by organizations in practice.

Analysis Goal and Methodology The goal of our analysis was to quantify the risk of detection blind spots for existing Sigma rules by finding concrete evasions for them. We had to restrict our analysis to a subset of rules from the Sigma repository due to the high effort of manual analysis and the fact that some types of rules act on log data of software or hardware that is not generally available (e.g., commercial cloud services or appliances). We thus chose to analyze the subset of rules that act on *process creation events* on Windows systems. This rule type is the most frequent (making up 41 % of all rules at the time of analysis) and does not depend on log data from proprietary products except for Windows. Furthermore, process creation events are known to be a valuable source for threat detection [6]. They comprise information on newly created processes and are generated either by Windows itself [57] or by the tool Sysmon [46, 56]. The contained fields most often searched by the Sigma process creation rules are `CommandLine` (the full command line of the process creation; 45 % of all search expressions in the considered rules), `Image` (the full path of the executed image; 29 % of search expressions), and `ParentImage` (the full path of the parent process image; 10 % of search expressions). There are ~20 more fields that are searched by only a few rules, e.g., `Description`, `ParentCommandLine`, and `User`.

The analysis was conducted as follows. We analyzed all process creation rules that were contained in the Sigma repository on February 4, 2021 (commit ID 12054544). First, we reviewed each rule in detail, including potential references given within the rule (e.g., threat reports describing the malicious behavior that should be detected by the rule). Next, we tried to re-enact the malicious process creation as described by the rule on a Windows 10 system (e.g., by running `powershell.exe /C Clear-EventLog System`). We manually reviewed the Windows event log to verify our commands and then ran scripts to check for Sigma rules matching these events. In case we succeeded to match the current rule, we then tried to find command lines that perform the exact same action, but without matching the rule (i.e., evasions).

Table 1: Almost half of the analyzed SIEM rules (129 of 292) can be evaded using the five straightforward evasion types presented in this table (each with one concrete example), thus causing critical detection blind spots in enterprise networks.

Evasion type	Sample affected rule	Affected search term	Sample match	Sample evasion
Insertion	win_susp_schtask_creation	* /create *	schtasks.exe /create ...	schtasks.exe /"create" ...
Substitution	win_susp_curl_download	␣-O␣	curl -O http://...	curl --remote-name http://...
Omission	win_mal_adwind	*cscript.exe *Retrive*.vbs *	cscript.exe ...\Retrive.vbs	cscript ...\Retrive.vbs
Reordering	win_susp_procdump	* -ma ls*	procdump -ma ls	procdump ls -ma
Recoding	win_vul_java_remote_dbg	*address=127.0.0.1*	...address=127.0.0.1,...	...address=2130706433,...

For this to work, we assumed that an attacker who can create a process with command line arguments is also able to alter these arguments (e.g., `curl.exe --remote-name example.com` instead of `curl.exe -O example.com`). We made sure that successful evasions did not match any additional Sigma rules (i.e., rules not triggered by the original match). Finally, we assigned one of four labels to each rule: (1) *full* if we were able to completely evade the rule, (2) *partial* if the rule contains OR-branches of which we could evade at least one, but not all, (3) *none* if we could not find an evasion, and (4) *broken* if we found the rule to be faulty.

Analysis Results Of the 292 analyzed Sigma rules, we found that 110 (38 %) can be *fully* evaded and 19 (7 %) can be *partially* evaded. For another 51 rules (17 %), we found that evasion might be possible but could not confirm any concrete evasion instances either due to unavailable target software (mostly malware) or excessive effort for conclusive analysis.

We achieved all evasions by adapting the processes creation command line in multiple ways. For this purpose, we found a total of five evasion types during our analysis as exemplified in Table 1: (1) *Insertion* of ignored characters into the command line (e.g., double quotes or spaces), (2) *substitution* of synonymous characters or arguments (e.g., a hyphen instead of a slash before an argument), (3) *omission* of unnecessary characters (e.g., shortening arguments), (4) *reordering* of arguments, and (5) *recoding* of arguments. We created at least three matching and three evading events for each evadable rule to achieve variability, ending up with 461 matches and 512 evasions in total, which were later used in the context of our evaluation (cf. Section 6). Summarizing, we were able to evade almost half of the rules, each with multiple variants.

We would like to emphasize that generally our results come as no real surprise and are not necessarily specific to the analyzed Sigma rules. Instead, evasions are an intrinsic problem of misuse detection due to the impracticality of covering every possible mutation with hard-coded signatures (cf. Section 2). This makes it practically impossible to "fix" the affected rules in the sense of adapting them to detect all possible evasions. However, a subsidiary result of our analysis is that we found 12 of the 292 rules to be *broken*, i.e., failing to detect what was intended by the rule author. We excluded these rules from our evasion analysis. Furthermore, we provided fixes to the Sigma maintainers for all broken rules that had not yet been fixed or removed by the Sigma community in the meantime, resulting in four rules that were fixed through our feedback.

In conclusion, we find that the risk of detection blind spots through rule evasions is indeed high for the analyzed Sigma rules, which are widely used in practice. Even small attack mutations using simple techniques suffice to evade detection. Consequently, adversaries might remain undetected despite performing commonly known attacks. In the following, we therefore present our main idea, *adaptive misuse detection*, which aims to solve this dilemma of easily-evadable rules by classifying incoming SIEM events based on their similarity to SIEM rules versus historical benign events.

4 The Case for Adaptive Misuse Detection

The results of our analysis lead to the question of how the discovered detection blind spots can be remedied. Therefore, we propose *adaptive misuse detection*, a novel methodology to significantly reduce blind spots by detecting rule evasions *in addition* to conventional rule matches. The components of our methodology are depicted in Figure 1 and described in the remainder of this section, followed by a conceptual comparison with related detection approaches.

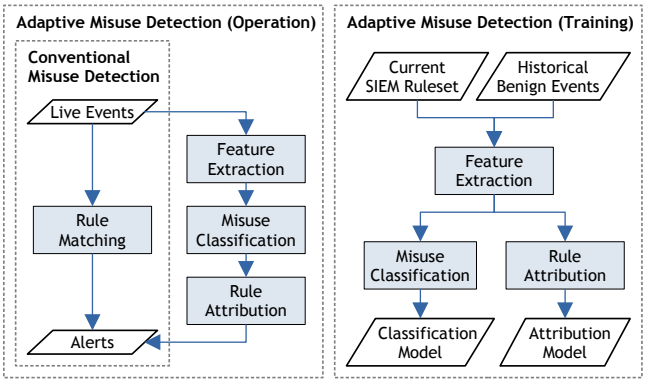

Figure 1: Our concept of adaptive misuse detection extends conventional misuse detection by components that aim to detect rule evasions and attack variants. For this purpose, classifiers are trained on SIEM rules versus benign events.

Rule Matching First of all, adaptive misuse detection is an extension of (conventional) misuse detection with additional machine learning components (described below). In other words, conventional rule matching is still performed and matching rules still trigger alerts. This is because the machine learning components are only applied to a subset of incoming events where evasion detection is sensible (cf. Section 5). Hence, adaptive misuse detection executes rule matching and the machine learning components in parallel and then merges the resulting alerts. This design ensures that no attack is missed that conventional misuse detection would discover, yet in addition evasions can be detected (which are, by definition, missed by conventional misuse detection).

Rationale for Evasion Detection Adaptive misuse detection is based on the assumption that SIEM events of successful evasions are still very similar to those of the original attack. In our experience, an analyst can often quickly spot an evasion when reviewing the respective event. This is because the SIEM events that are predominantly used for attack detection (i.e., endpoint events, cf. Section 2) are captured at kernel level, immediately before or after the respective action is executed by the operating system. At this level, most obfuscations (as often seen in malware binaries or scripts [5,11,12]) must already be resolved, else the operating system would not be able to execute the desired action. For example, in the case of a malicious process execution, the executable name (e.g., `powershell`) ultimately has to be passed to the operating system in plaintext for execution. The same holds for command line parameters of executed processes (e.g., `set-executionpolicy unrestricted`), which ultimately need to be parsed by the started process, thereby restricting the set of possible evasions in the captured SIEM events.

As a consequence, a promising approach for evasion detection is to look for events that are *similar* to one or more signatures contained in the ruleset. However, there is an important constraint, which is the *avoidance of false alerts*: Large enterprise networks often deal with millions or billions of SIEM events per day [9] and typically, only a small number of analysts handle security alerts generated by multiple security systems [18]. Many analysts report to be overwhelmed by false alerts, impairing their ability to discover actual attacks [1, 18]. Since the number of benign events is usually several orders of magnitude larger than the number of attack-related events [7], a practical approach thus requires an extremely small false positive rate. Consequently, when aiming to detect evasions based on their similarity to rules, it is crucial to avoid an overly broad definition of similarity.

Misuse Classification To unite these conflicting requirements of detecting as many evasions as possible while at the same time keeping false alerts low, we propose a machine learning based approach for finding potential evasions, i.e., events that are similar to SIEM rules but do not match them. More precisely, we propose to apply supervised learning to classify whether a new event is more similar to *deployed SIEM rules* or to *historical benign events*. In other words, we propose to train classifiers with features extracted from SIEM rules versus features extracted from benign events, both taken from the network where the system will be operated. We call this step *misuse classification*. To the best of our knowledge, this approach has not been studied before (cf. Section 8).

Notably, the idea of learning from already-existing rules overcomes a common issue of supervised learning, namely, the necessity to create a comprehensive set of attacks for the training process. Instead, the knowledge of what is malicious is taken from the ruleset, which – in case of Sigma – is publicly available, comprehensive, and regularly updated by a large community. We decided to call our approach *adaptive* misuse detection since it adapts to the target environment by training against its benign activity, thereby adjusting its features and sensitivity to properly distinguish attacks from benign events. Moreover, the approach allows to adjust its sensitivity (better detection rate or less false alerts), which is important in practice because the number of acceptable (false) alerts depends strongly on the number and workload of available analysts. Overall, misuse classification aims to enable a pinpoint detection of evasions while minimizing false alerts.

Rule Attribution A substantial reason for the popularity of (conventional) misuse detection is that each rule contains an expressive title, description, and possibly references to further information, which greatly eases alert investigation. Technically, we can say that each alert is *attributed* to one or more rules. This advantage is lacked by many machine learning based systems, which often generate alerts containing no further information on the potential attack [53].

Since adaptive misuse detection learns from SIEM rules (versus benign events), information on which features represent which rule is available during training. Consequently, when a potential evasion is detected by the misuse classification step, adaptive misuse detection allows to perform a further step that we call *rule attribution*: Even though an evasion, by definition, does not match any rule, we can still compare a potential evasion to all SIEM rules and thus estimate which rule(s) an adversary *probably* evaded. For example, when a command line is executed that is very "similar" to a signature of some rule (e.g., differing only in one parameter – see Section 5 for details), the respective rule should be proposed to the analyst within the alert as potentially being evaded.

Note that depending on the concrete evasion, there can be several rule candidates due to overlapping or redundant contents. Therefore, the rule attribution does not just output the most likely evaded rule but a *ranked list* of potentially evaded rules, which is then added to the alert to ease investigation. Even though the rule attribution is inevitably uncertain, it may still significantly help analysts to verify if an alert is true and better understand the context of an attack.

Table 2: Enhancements of adaptive misuse detection over conventional misuse detection

	Misuse Detection	Adaptive Misuse Detection
Goal	Detect known malicious behavior	Additionally detect rule evasions and attack variants
Rationale	Malicious behavior is explicitly defined, everything else is considered benign.	Behavior is additionally classified by its similarity to known malicious versus known benign behavior.
Method	Matching of expert-written rules	Additional classifiers trained on rules versus benign events
Customization	Addition, removal, or customization of rules	Additional adjustment of sensitivity
Alert details	Matching rule(s) name, ID, and further attack details	Identical for rule matches; estimate for potentially evaded rules

The idea of adaptive misuse detection and its differences to (conventional) misuse detection are summarized in Table 2. The training process will be further described in Section 5.

Conceptual Comparison to Related Detection Approaches Adaptive misuse detection has some properties that make it very promising for real-world application. Compared to *conventional misuse detection*, its obvious benefit is the ability to detect evasions. This benefit comes at the expense of a higher operational and computational effort: Benign events must be extracted from the target network first to then perform the training. This training should be repeated when SIEM rules change or when the benign behavior changes significantly. However, as most organizations already utilize conventional misuse detection, adaptive misuse detection constitutes a straightforward way to reduce detection blind spots.

Adaptive misuse detection also shares conceptual properties with *anomaly detection*, in the sense that historic events are used for training the system. However, while anomaly detection methods learn from unlabeled, historic events *only* to then detect everything that is *not normal* [47], adaptive misuse detection leverages comprehensive and ever-growing rulesets (such as Sigma) of known-malicious behavior. Anomaly detection systems, on the other hand, are built on the assumption that attacks correspond to anomalous behavior in the trained model and benign activity corresponds to normal behavior [23]. This assumption has repeatedly been questioned and criticized [23, 53]: Since anomaly detection systems have no knowledge about what is malicious, they tend to produce an unacceptable number of false alerts in real-world applications, thus causing threat alert fatigue that can lead to missed attacks [1, 18, 25]. Even worse, they can also miss actual attacks because they are not necessarily being recognized as anomalous [23]. Furthermore, (adaptive) misuse detection has the significant advantage of providing alert details such as the relevant rule's name and description, whereas anomaly detection only reports that *something* unusual has happened [47]. This makes root cause analysis much harder, especially in large networks with many users and systems.

Another approach to detect malicious events is *conventional supervised learning* in the sense that a classifier is trained on malicious versus benign events. The problem with this approach is its dependence on a comprehensive, realistic, and up-to-date set of malicious events (i.e., logged attacks). Experience shows that such data are extremely difficult and labor-intense to create and maintain [55], thus casting doubt on the practical utility of this approach [53]. Adaptive misuse detection avoids this issue by utilizing community-maintained SIEM rules as malicious samples, which are inherently comprehensive, realistic, and up-to-date.

Finally, there is the idea of *synthetic signature generation*, i.e., similar signatures are automatically created from existing ones to detect variants of known attacks [52]. The systematic problem with this approach is that it may result in prohibitive numbers of false alerts since there is no tuning process to automatically adjust sensitivity to a concrete environment. Adaptive misuse detection avoids this problem by training against benign data from the concrete environment to automatically find sensible features and decision thresholds.

In conclusion, our discussion indicates that adaptive misuse detection is a promising approach for detecting SIEM rule evasions in enterprise networks, thus reducing critical detection blind spots. Yet, it remains to show that its theoretical benefits can be transferred to practical application.

5 AMIDES: Effective and Efficient Detection of SIEM Rule Evasions

To verify the practical applicability and benefits of adaptive misuse detection, we designed and implemented AMIDES, a proof-of-concept ***A***daptive ***Mi***suse ***De***tection ***S***ystem. Our main goals are (1) the detection of as many evasions as possible (effectiveness) and (2) false positive rates and resource requirements that are both low enough for real-world operation of the system in large enterprise networks (efficiency). In the following, we give a brief overview of the system and then describe its principal components in detail, finishing with a consideration of the computational performance.

Overview AMIDES is a proof-of-concept implementation of adaptive misuse detection, as proposed in Section 4. It is meant to extend conventional misuse detection components of SIEM systems in enterprise networks. As described, this implies that conventional rule matching will still be performed while additional machine learning components aim to detect

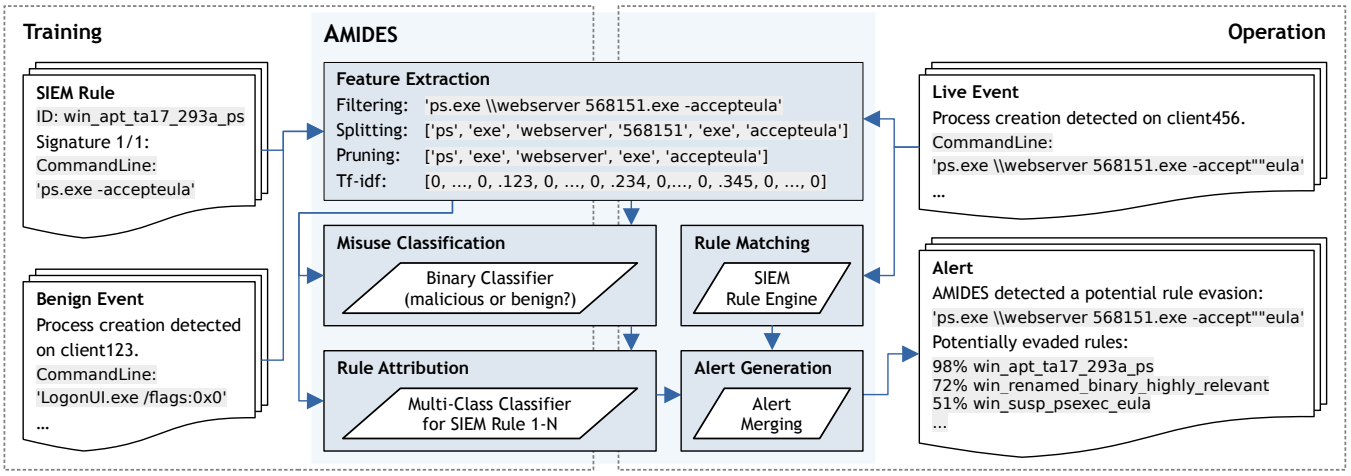

Figure 2: AMIDES is a proof-of-concept adaptive misuse detection system aiming to detect attacks that evade SIEM rules as well as otherwise undetected attack variants in addition to conventional SIEM rule matches. It learns from SIEM rules on the one hand and historical benign events on the other hand and can thus even estimate which SIEM rule an adversary attempted to evade.

rule evasions. Figure 2 shows an overview of AMIDES, including exemplary input data for both training and operation. AMIDES is trained using the current SIEM ruleset and historical benign events of an organization. The training should be repeated when either the SIEM ruleset or the benign activity change significantly (e.g., due to major software changes).

During operation, incoming SIEM events are passed to the rule matching component (as for conventional misuse detection) *and* the feature extraction component, which generates a feature vector from the event that is suited for the subsequent components. This vector is first passed to the misuse classification component, which classifies the event as either malicious or benign. If classified as malicious, the feature vector is also passed to the rule attribution component, which generates a ranked list of rules potentially evaded by the event. Finally, potential alerts of the rule matching and machine learning components are merged by the alert generation component to create one single alert per malicious event.

Since we limited our detailed Sigma analysis (cf. Section 3) to Windows process creation rules due to the high manual effort of creating evasions, we also focused on this rule/event type during the design of AMIDES (e.g., influencing its feature engineering). However, AMIDES is also applicable to other types: While our evaluation focuses on process creations (cf. Section 6), we also prototypically evaluated three additional Sigma rule types that we found to be inherently evadable, namely, those addressing web requests, Windows registry changes, and PowerShell scripting (cf. Section 6.3).

AMIDES is designed and implemented with performance in mind for application in large enterprise networks (cf. Section 6.3). We implemented AMIDES in Python, with principal third-party packages being `sklearn` and `numpy`. AMIDES is freely available under the GPLv3 license [3]. In the following, we describe the system in more detail.

Input Data and Feature Extraction According to our concept of adaptive misuse detection, AMIDES requires a SIEM ruleset and a set of benign events for the training process. Since we assume that organizations adopting AMIDES are already using conventional misuse detection (cf. Section 2), they can simply use their current SIEM ruleset with AMIDES. For now, AMIDES only supports Sigma rules, but other formats such as Splunk could be added in the future. In addition, AMIDES also requires a set of benign events for the training process. Since organizations store large numbers of events in their SIEM systems anyway (usually for a few days up to several years), the required events can be obtained by extracting the latest few days or weeks from the SIEM system. Ideally, these events should not contain any attacks. However, in practice, the data might be tainted with undetected attacks (including evasions), which we consider in our evaluation (cf. Section 6.3). We thus recommend to sift the benign dataset before training and only update it when required.

Features are extracted from SIEM events using established methods to obtain an appropriate input vector for the machine learning components (cf. Figure 2): First, relevant fields (here: `CommandLine`) are extracted and specific characters are removed that can be used to evade signatures (regex `["'/^\´]`). The resulting string is split by non-word characters (regex `\W`), yielding a sequence of terms. Then, a pruning step is applied to remove likely irrelevant terms such as timestamps and unique IDs (more precisely: decimal and hexadecimal numbers over three digits as well as strings over 30 characters). Finally, the term sequence is transformed into a weighted numeric vector using tf–idf [49], thereby assigning higher values to rarely occurring terms. The calculated idf values are stored for later use during the operation phase, in which the exact same feature extraction is applied to live events. For further discussion on our implementation choices see Appendix A.

The feature extraction from Sigma rules is more complex. Each rule contains at least one signature, consisting of one or more *search identifiers*, coupled by logical conditions, where each search identifier can contain required keys, values, and modifiers such as `endswith`. An exemplary signature is `Image|endswith: "\schtasks.exe" AND CommandLine: "* /create *" AND NOT User: "NT AUTHORITY\SYSTEM"`. For now, AMIDES performs a simplified signature parsing that extracts from a rule all strings being searched for in an event's command line, as long as they are not part of an exclusion (i.e., within a `NOT` branch of a signature). While this implementation does not cover Sigma's full potential, it suffices to capture the essence of most process creation rules, as shown by our evaluation (cf. Section 6). After extraction, the search strings are processed by the feature extraction component in the same way as the command lines from SIEM events (cf. Figure 2).

Misuse Classification and Rule Attribution AMIDES implements the two machine learning components proposed in our adaptive misuse detection concept, namely, misuse classification and rule attribution. The former decides if an incoming event is malicious or benign whereas the latter enriches an evasion alert with a ranked list of SIEM rules that were likely evaded by the event (cf. Section 4). The misuse classification component consists of a supervised binary classifier, which is trained with all feature vectors extracted from the SIEM rules (labeled as malicious) versus all feature vectors extracted from the benign events (labeled as benign). During training, AMIDES calculates a sensible decision threshold range and maps it to $[0,1]$ to allow for intuitive configuration of its sensitivity even by non-expert users, with 0.5 being the default value (see Appendix A for more details).

The second machine learning component, i.e., rule attribution, consists of multiple supervised binary classifiers, more precisely, one per SIEM rule of the supplied ruleset. Each classifier is trained with the feature vectors extracted from the respective rule (labeled as malicious) versus all benign events (labeled as benign). During operation, for each incoming event classified as malicious by the misuse classification component, the rule attribution runs all its classifiers and creates a ranked list of classifier confidence values. The more similar a rule is to the event, the higher is its confidence value and the higher it appears in the list. By default, the top 10 rules are shown to allow analysts a comprehensive investigation without overwhelming them with likely irrelevant rules.

On a technical level, we utilize support vector machines (SVMs) [17] as classifiers for both misuse classification and rule attribution since they are well suited for our highly imbalanced datasets [54] of high-dimensional, sparse feature vectors [29]. Training and hyperparameter tuning are performed using established methods, i.e., grid search with stratified 5-fold cross validation, optimizing for F_1 score. Our implementation choices are further discussed in Appendix A.

Rule Matching and Alert Generation The rule matching component performs the task of conventional misuse detection, i.e., matching incoming events against the chosen SIEM ruleset. As described in Section 4, this component complements the machine learning components, since the latter focus on specific SIEM event types that are prone to evasions (e.g., process creation events). Technically, we utilize the open-source log processor Logprep [37] for Sigma rule matching.

The subsequent alert generation component simply merges alerts of the rule matching component and the machine learning components into just one alert per event. Consequently, an alert can contain none, one, or multiple rule matches as well as none or one evasion alert, in this case including the top 10 most likely evaded rules (cf. Figure 2).

Performance Considerations A detection system is pointless if its performance requirements are infeasible under real-world conditions. Hence, AMIDES implements several measures to enable high event throughput. In particular, we assume that the number of benign events in operation is orders of magnitude larger than the number of attack-related events and thus optimize for high benign event throughput. In addition, since many users in an organization often perform the same tasks (e.g., opening a browser), the fraction of unique actions is usually quite small (cf. Section 6). Therefore, we implement an in-memory cache to avoid repeated classification of already-seen feature vectors. The cache size is configurable and AMIDES periodically outputs performance metrics to monitor cache utilization and efficiency (hits and misses). All results of the misuse classification and rule attribution steps are added to the cache along with the associated feature vector, thus alerts can be reproduced from the cache instead of repeating the costlier classification steps.

Secondly, the pruning step of the feature extraction further reduces the number of unique command lines because it removes variable, yet irrelevant parameters such as unique IDs from otherwise frequent command lines, thus making caching more efficient. Thirdly, since the rule attribution step requires to run one classifier *per rule per event* whereas the misuse classification step only involves one classifier *in total per event*, the rule attribution is only executed if an event is classified as malicious by the misuse classification step. Lastly, we implemented performance optimizations for the training phase as well. For example, AMIDES deduplicates benign feature vectors before training, which greatly reduces SVM training time without impairing classification performance. Furthermore, instead of performing an SVM parameter optimization for each rule attribution classifier, we inherit the optimized parameters from the misuse classifier, since its training set is a superset of the rule attribution training sets.

Without such optimizations, operation in large enterprise networks would likely be infeasible. To show that AMIDES can handle realistic event volumes, we present performance measurements as part of our evaluation in the following.

6 Evaluation

AMIDES aims to significantly reduce detection blind spots in enterprise networks by automatically detecting SIEM rule evasions. However, good detection performance alone is not sufficient to be beneficial under real-world conditions. In this section, we measure key properties of AMIDES to evaluate its overall practical value. More precisely, we subdivide our evaluation into three research questions (RQ) of interest:

RQ1: *How well does* AMIDES *detect SIEM rule evasions?* To address this question, we apply AMIDES to a realistic dataset, quantify true and false classifications, and present a practical interpretation of the results. Moreover, we compare it to a benchmark approach that is trained with attack events instead of SIEM rules against the same benign events.

RQ2: *How accurate is the rule attribution?* While RQ1 focuses on binary detection performance (i.e., whether an alert is raised or not), AMIDES additionally suggests SIEM rules that might have been evaded by an adversary. We evaluate the accuracy of this rule attribution by comparing its output against ground truth data, i.e., we check if the truly evaded rule is suggested and how high it is ranked within the suggestions.

RQ3: *Is* AMIDES *suited for real-world operation?* Practical operation induces requirements beyond good classification and attribution performance. We analyze three important aspects: First, we assess if AMIDES' training and operation are fast enough for typical enterprise event volumes. Secondly, we check if AMIDES still performs reasonably under tainted training data that inadvertently contain evasions. Thirdly, we evaluate AMIDES' generalizability to different event types.

Answering the three research questions requires realistic data to evaluate against, which we describe in the following.

Datasets and Ethical Considerations To the best of our knowledge, there exists no dataset yet that contains SIEM events with rule evasions or undetected attack variants. We thus decided to create an own dataset. For this purpose, we had the opportunity to collect SIEM events from a large enterprise network with more than 50 000 users. The data comprise four weeks of process creation events from May 2022, collected from Windows machines running a remote-controlled browser system and associated applications (such as PDF and image viewers) for all users of the enterprise. In total, we collected 155 373 027 events, containing 266 unique executable filenames. We processed the data only within the premises of the enterprise and only exported evaluation results. All user names were already pseudonymized. We carefully sifted the events to make sure they do not contain any attacks. Thus, we use them as *benign* events in the course of our evaluation. For further details on the dataset collection and analysis process, see the supplementary document in our code repository [3].

Since the dataset cannot be shared with the research community due to security and privacy concerns, we created an additional set of benign events using the open-source testbed SOCBED [55], thus enabling researchers and potential users to test AMIDES. However, in this paper we solely present results for the enterprise dataset since the benign events of the testbed dataset are synthetically generated by a simple user emulation and therefore not as realistic. Results for the synthetic dataset are available with the AMIDES code to facilitate reproducibility [3]. Our set of evasions will not be made freely available due to ethical concerns, but can be shared with other researchers upon personal request.

Next, we describe how we utilize the enterprise dataset and our evasions for training and validating AMIDES.

Training and Validation For the purpose of our evaluation, we first trained AMIDES with a set of benign events versus a set of SIEM rules as described in Section 5. Then, to simulate live operation and validate AMIDES' detection performance, we provided AMIDES with a disjoint set of benign events versus a set of events containing evasions. We used Weeks 1 and 2 of the enterprise dataset for training and Weeks 3 and 4 for validation, which is more realistic than a randomized partitioning since in real-world operation, the training is always performed on historic data and detection is then performed on future events. As SIEM rules (training) and evasion events (validation), we used the Sigma process creation rules and the evasion events that we crafted for these rules as described in Section 3, respectively. Note that the resulting training and validation datasets are highly imbalanced on purpose to reflect realistic ratios of benign activity to attacks [1].

Since our validation dataset is semi-synthetic (because the evasion events were created in a testbed environment), we need to make sure that AMIDES cannot inadvertently learn from artifacts of the dataset generation process. (Note that we could not generate the evasions within the enterprise network due to security concerns.) Therefore, in the course of our evaluation we decided to solely use the `CommandLine` field as input to AMIDES' feature extraction, since other fields could indicate whether an event stems from the enterprise network (and is thus benign). For example, computer names differ between benign and evasion events, so the model could utilize them for classification, which would be a form of unwanted *data snooping* [4]. Since all of our evasions are based on command line manipulations (cf. Section 3), restricting the input to this field still enables AMIDES to detect all evasions. In practice, more fields could be used if deemed useful for further improving the detection performance.

In the following, we present the results of our measurements concerning AMIDES' training and validation process.

6.1 AMIDES Detects Most SIEM Rule Evasions without Any False Alerts (RQ1)

To answer the first research question, we now present and discuss AMIDES' classification results. Afterwards, we compare these results to those of a benchmark approach.

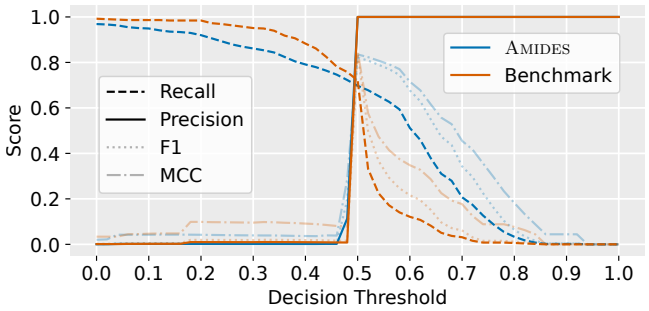

Figure 3: AMIDES detects most SIEM rule evasions (70 %) with zero false alerts at default sensitivity (0.5), thus significantly reducing detection blind spots in enterprise networks. It keeps up with an (impractical) benchmark trained on attack events, showing the eligibility of learning from SIEM rules.

Classification Performance In the following, we present results for AMIDES' misuse classification step. Since its sensitivity is configurable, we start with results for the default threshold and then discuss the influence of threshold changes.

In absolute numbers, AMIDES detected 358 events containing evasions (true positives) and missed 154 (false negatives), so 70 % of our evasions were successfully detected. AMIDES correctly ignored 74 431 740 benign events (true negatives) and raised zero false alerts (false positives). Hence, AMIDES clearly fulfills our classification goals (cf. Section 5), namely, detecting many evasions (that would otherwise remain undetected) without overwhelming analysts with false alerts. It thus achieves a significant reduction of detection blind spots as revealed by our SIEM rule analysis. Notably, the false positive rate (i.e., fraction of incorrectly detected benign events) is zero despite the realistically unbalanced validation set with ~145 000 times as many benign as malicious events.

In case false alerts are acceptable in exchange for a higher detection rate, AMIDES' sensitivity can be adapted, which is visualized in Figure 3. (Note that the "benchmark" graph will be described later.) The figure shows the recall (i.e., ratio of detected evasions to all evasions) and precision (i.e., ratio of true alerts to all alerts) with respect to the decision threshold, along with the common classifier evaluation metrics F1 score and Matthew's correlation coefficient (MCC) [16] (both semi-transparent). Note that AMIDES automatically selects a sensible threshold range and maps it to $[0, 1]$ to ease configuration for non-expert users (cf. Appendix A).

We can see in Figure 3 that the recall slowly declines when the threshold increases whereas the precision sharply increases around 0.5. The latter is caused by the extreme imbalance of the dataset because a slightly increasing false positive rate quickly leads to a large number of false alerts (cf. Appendix B for an extended discussion). Therefore, most users will probably choose thresholds near the default value to avoid significant numbers of false alerts without sacrificing too many detected evasions. In practice, since an organization does not know the true number of attempted evasions, they should therefore set the threshold to a value that produces an acceptable number of false positives with respect to their analysts' resources. For example, a detection rate of 75 % could be achieved on our dataset by selecting a lower threshold so that approximately one in ten alerts is a true evasion. In this context, please also note that we would end up with significantly higher detection rates (at still few false alerts) if we had chosen a more balanced (but hence less realistic) dataset, since the precision curve would decline much slower.

Now that we quantified AMIDES' classification performance, we will aim to improve the intuition on these results by comparing them with a benchmark approach.

Comparison with Benchmark Approach To the best of our knowledge, there is no related work on SIEM rule evasion detection, thus we cannot directly compare AMIDES to related methods (cf. Section 8). However, since we created all of our evasions from formerly detected attack events (i.e., *matches*) in the course of our Sigma rule analysis (cf. Section 3), we can compare AMIDES with a supervised classifier that learns from *these matches* versus benign events (whereas AMIDES learns from *SIEM rules* versus benign events). The rationale behind this comparison is to find out if SIEM rules might be missing information that is contained in the actual attack events, which would result in an inferior detection performance of AMIDES as compared to this benchmark approach.

To perform this comparison, we repeated AMIDES' training but instead of SIEM rules we used our matches as malicious samples. As shown in Figure 3, learning from these matches gave us similar results to those of AMIDES. At the default threshold, which corresponds to the highest possible recall without false alerts, both approaches perform almost identically (70 % detection rate), indicating that the information contained in SIEM rules is equally suited for evasion detection as the information contained in malicious events triggering these rules. However, we deem the benchmark approach to be unrealistic in practice because it requires to manually create attack events for each SIEM rule, which is a tedious task and thus unlikely to be carried out whenever SIEM rules change (cf. Section 4). We are thus convinced that AMIDES is a better choice for practical application in enterprise networks.

Next, we go beyond mere binary classification and assess AMIDES' rule attribution component. For this purpose, we evaluate whether AMIDES succeeds in identifying the evaded SIEM rules when provided with evasions.

6.2 Rule Attribution Helps Making Sense of Evasion Alerts (RQ2)

Rule attribution is a unique feature of our adaptive misuse detection approach. For each potential evasion (as detected by the misuse classification), AMIDES suggests a ranked list of SIEM rules that were potentially evaded (cf. Section 4). Since

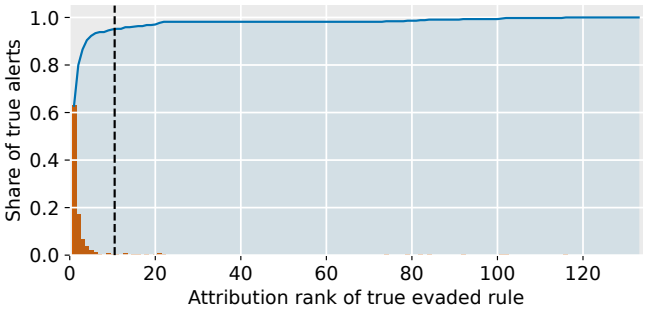

Figure 4: For each evasion alert, AMIDES outputs a ranked list of likely evaded SIEM rules (rule attribution). Evaluated with our manually created evasions, the truly evaded rule is within the top 10 propositions for 95 % of the evasions.

we created at least three evasions for each evadable Sigma rule within the scope of our rule analysis, we can use these as ground truth, i.e., we know for each evasion which rule was evaded. If the rule attribution worked perfectly, the evaded rule would be the highest-ranked for each evasion.

We evaluated this expectation by applying the rule attribution to all detected evasions from the misuse classification step. For each evasion, we checked the resulting rank of the true evaded rule. The results are visualized in Figure 4. The bars show a stack plot of the rank of the true evaded rules. Ideally, all of these rules would appear in the first position. We can see that this is the case at least for a large fraction of the evasions (63 %). The blue curve shows the accumulated results, allowing to check the share of true rules that are contained in the top n results. Particularly, a vast majority of the true rules (95 %) are contained within the top 10. This result indicates that the rule attribution largely succeeds in helping analysts to find out which rules were evaded.

Finally, after studying AMIDES' performance in terms of classification and rule attribution, it remains to show that operation in an enterprise network is indeed feasible.

6.3 AMIDES Is Fit for Application (RQ3)

To show that AMIDES is well-suited for operation in an enterprise network, we evaluate three further aspects. First, we show that AMIDES is computationally efficient enough to handle enterprise-level throughput on commodity hardware. Secondly, we examine the influence of evasions inadvertently contained in benign training data, showing that detection performance degrades gracefully. Thirdly, we show that AMIDES and the general concept of adaptive misuse detection are not restricted to Windows process creations but are also applicable to other rule and event types.

Computational Performance To find out if AMIDES is efficient enough for practical application, we measured the time required for training as well as the event throughput during operation. Both measurements were taken on a commodity Linux server with 40 physical CPU cores (80 virtual), 384 GiB RAM, and a single SSD drive. The *training* was performed as described in Section 5 and the beginning of this section, i.e., using two weeks of benign events (80 940 832 events) and the Sigma rules described in Section 3. It took 42 minutes on average ($n = 10$, $\mu = 2506$ s, $\sigma = 112$ s), which allows for daily (re)training if desired. However, most organizations will probably not update their SIEM rules that often, so a weekly training (or even less) probably suffices in most cases.

To measure the throughput during *operation*, we let AMIDES process our *whole* dataset (i.e., four weeks of benign process creation events and 512 evasions, yielding 155 373 539 events in total). AMIDES required 0.0763 ms per event on average ($\sigma = 3.19$ ms) *on a single core*, corresponding to 13 102 events per second. The overall processing took 994 s on average ($n = 10$, $\sigma = 16.4$ s) *on all cores*, including reading the events from disk and storing them back to disk after adding the classification results and metrics. The overall throughput on this server is thus 156 311 events per second. The peak number of (process creation) events per second in our dataset is 473, therefore AMIDES is 330 times faster than required for live operation. Much larger networks might require scaling up to multiple servers, which is straightforward because both training and operation can be parallelized.

Influence of Tainted Training Data Next, we consider the case that supposedly benign training data inadvertently contain evasions, which might arise when data from a productive network are used for training without careful review. The purpose of this experiment is to find out how much detection performance degrades in this case, thereby verifying that AMIDES is still useful if some missed evasions end up in the training data. Since we could not find any reliable data on the prevalence of SIEM rule evasions in the wild, we added three different fractions (10-30 %) of our evasions to the *benign* training set (and accordingly removed them from the validation set). The largest fraction (30 %) represents a scenario where AMIDES is already running during the data collection period, detecting 70 % of evasions (cf. Section 6.1) and no manual review is performed *at all*, thus leaving 30 % of the attempted evasions in the benign training data.

We performed training and validation in the same way as described before, executing 10 runs per fraction with pseudo-randomly sampled evasions. The results are depicted in Figure 5, showing all runs as semi-transparent lines and their respective means as opaque lines. As expected, since AMIDES is based on two-class supervised learning, detection performance decreases with an increasing fraction of tainted data. These measurements support our intuition that it is indeed advisable to manually check the benign data for potential evasions prior to training. However, AMIDES still detects many evasions without false alerts, thus succeeding to significantly reduce detection blind spots even under heavily tainted data.

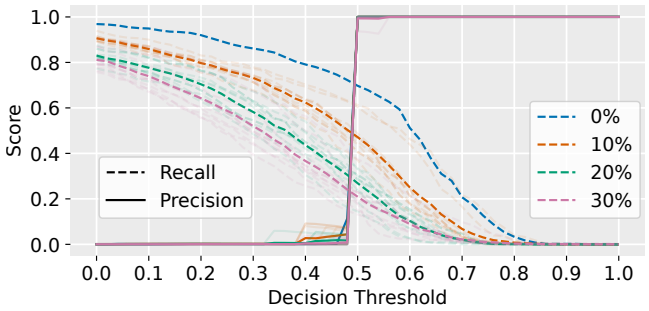

Figure 5: We added different fractions of our evasions to the benign training data to simulate heavy tainting with undetected evasions. As expected, classification performance significantly declines but still many evasions are detected.

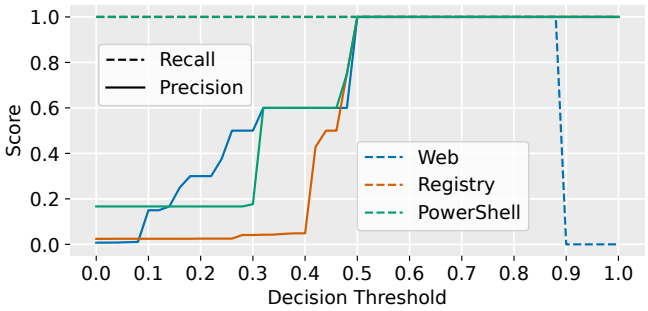

Figure 6: AMIDES correctly classifies three additional datasets (each comprising synthetic benign events from a testbed and three prototypical evasions), indicating its applicability to other rule and event types than Windows process creation.

Applicability to Other Rule and Event Types Our quantitative analysis of SIEM rules for evasions as well as our previous evaluation steps are based on one type of Sigma rules, namely, those acting on Windows process creation events (as argued in Section 3). While this rule/event type is the most prevalent in the Sigma ruleset (292 out of 707 rules at the time of analysis) and highly prone to evasion (cf. Section 3), we also looked through all other Sigma rules and found that at least some of them can be evaded in similar ways. Due to the high effort of manual rule analysis, we could not analyze all of them in detail to achieve statistically significant results, but still succeeded to find three prototypical evasions for rules acting on three fundamentally different event types, respectively: (1) web requests (47 rules in total), (2) Windows registry changes (40 rules), and (3) PowerShell script executions (25 rules). Examples are given in Table 3.

To demonstrate that our concept of adaptive misuse detection and particularly AMIDES are applicable to other rule and event types than process creation, we evaluated AMIDES against each of the three aforementioned types. For this purpose, we utilized synthetic benign events from the testbed SOCBED [55] since we did not have access to events of these types from the enterprise network. Training and validation were performed in exactly the same way as for the process creation rules/events, only exchanging the utilized rule and event fields with respect to the event type (see Table 4 for details). AMIDES achieved perfect misuse classification performance (i.e., no missed evasions or false alerts) on all three types, as shown in Figure 6. Furthermore, the rule attribution correctly ranked the evaded rules highest for each type. While these results are not statistically significant due to the small number of evasions and the synthetically generated benign events (having limited quantity and variability), they still indicate that adaptive misuse detection and particularly AMIDES are applicable to diverse rule and event types.

Overall, our evaluation has illustrated the feasibility of learning from SIEM rules versus benign events for the purpose of SIEM rule evasion detection, as proposed by our concept of adaptive misuse detection. We have shown that the benefits remain even under real-world constraints involving limited analyst resources, high event volumes, and tainted training data. Our proof-of-concept implementation, AMIDES, therefore significantly reduces detection blind spots as revealed by our analysis of widespread SIEM rules.

Table 3: The Sigma ruleset contains evadable rules for other event types than process creation. Three examples are shown here.

Event type	Sample affected rule	Affected search term	Sample evasion
Web request	proxy_ios_implant	*/list/suc?name=*	http://.../list//suc?name=foo
Registry change	susp_run_key_img_folder	*C:\Windows\Temp*	%%windir%%\Temp\foo.exe
PowerShell	clear_powershell_history	... -HistorySaveStyle SaveNothing	$foo="SaveNothing"; ... -HistorySaveStyle $foo

Table 4: We prototypically evaluated AMIDES on the three additional rule/event types shown here to assess its generalizability.

Event type	Event provider and IDs	Event fields	Sigma rule fields
Web request	All Packetbeat events containing url.full	url.full	c-uri*, cs-uri*, cs-host, r-dns
Registry change	Microsoft-Windows-Sysmon IDs 12-14	winlog.event_data.TargetObject, ...Details	TargetObject, Details
PowerShell	Microsoft-Windows-PowerShell ID 4104	powershell.file.script_block_text	ScriptBlockText, Message

7 Discussion and Limitations

In the following, we discuss the overall impact of our work as well as limitations of our concept and implementation.

To begin with, despite analyzing almost 300 widespread SIEM rules in detail, our work cannot draw a comprehensive picture of the detection blind spots arising from evadable rules in enterprise networks. **Further work is needed to analyze additional sources and types of SIEM rules.** Still, we showed that evasions pose a significant threat and organizations should strive to detect them, e.g., by using AMIDES.

Next, we reflect on our main idea to train a classifier on SIEM rules versus benign events. **Inherently, our approach can only detect evasions if (1) they manifest themselves in SIEM events and (2) these events are more similar to rule signatures than to benign events** (with respect to the extracted features). Therefore, our approach cannot detect fundamentally different classes of evasion attacks such as (undetected) code injection into benign processes [8].

Furthermore, since we deal with an adversarial classification task here, **attackers could try to evade AMIDES itself**, which is theoretically possible in two ways. First, by tainting the training data though a large number of evasions over a long time. We deem this to be unrealistic because AMIDES would likely detect these evasions and they could thus be excluded from the training set. Only when training for the first time, care should be taken to avoid a significant number of evasions in the benign data (cf. Section 6.3). Secondly, attackers could try to craft evasions that get classified as benign, e.g., by adding terms to malicious command lines that appear frequently in benign events but not in rules, while preserving a functioning command. While we deem this attack to be difficult in practice because attackers only have one shot to avoid detection, it should be studied in future work to account for the ongoing rat race between attackers and defenders.

From a similar perspective, **our approach is not meant to detect completely novel attack types** but otherwise undetected instances of attacks with already existing detection rules. To detect unknown attack types as well, adaptive misuse detection could be complemented with anomaly detection. However, the latter may produce large numbers of false alerts and its ability to detect unknown attacks is arguable [23, 53]. Hence, organizations should consider and evaluate whether additional anomaly detection is beneficial to them.

Shifting the focus away from the basic concept, **some aspects of our implementation leave room for future improvements**. In this work, we focus on Windows process creation events, particularly their command line field. While we prototypically evaluated three additional event types, future work could assess these and others in more detail to further reduce potential detection blind spots. Moreover, AMIDES does not yet support the full Sigma specification. For example, it correctly handles `NOT` statements within signatures, but does not yet support other statements such as `1 of them`.

Finally, we discuss the cost-benefit ratio for organizations extending a conventional misuse detection system with AMIDES. On the cost side, there is an initial effort to (1) install AMIDES, (2) establish an (automated) training process, and (3) manually examine the initial training data for potential evasions. Additionally, ongoing effort arises from sifting the raised evasion alerts (which, according to our evaluation, contain very few false positives). On the benefit side, AMIDES will likely detect a majority of SIEM rule evasions, which would otherwise go undetected. Thus, AMIDES reduces detection blind spots and enables a timely response to such cyberattacks. While there seem to be no reliable data on the prevalence of such evasions, **we expect the benefits to outweigh the costs of AMIDES for many organizations** in view of the significantly reduced risk of undetected cyberattacks.

8 Related Work

The main goals of our work are to *identify* and subsequently *reduce* detection blind spots in enterprise networks that arise from SIEM rule evasions. To the best of our knowledge, these issues have not been addressed by other work before, hence, conducting an empirical comparison with related work is not possible. Still, there are numerous works that share the overarching goal of threat detection in enterprise networks. We begin by discussing the most similar ideas, namely, approaches utilizing events of any kind (but not necessarily from a SIEM system) to detect evasions in a broad sense. Afterwards, we discuss approaches that also utilize events but do not address evasions. Lastly, vice versa, we discuss approaches related to evasion detection but utilizing other data sources than events.

Event-Based Evasion Detection Ongun et al. [40] address the challenge of detecting adversarial executions of benign programs, which is a use case also covered by various of the analyzed Sigma rules. The authors generate features from process creation command lines and train a multi-class classifier for five attack classes using an active learning approach. In contrast to AMIDES, attack classes must be defined manually and the active learning process requires ongoing analyst resources, whereas our approach leverages the ever-growing rule corpus of the Sigma community and therefore does not require any manual labeling. Buyukkayhan et al. [14] utilize a combination of event records, static program analysis, and contextual information to discover programs behaving similarly to known malware as well as programs impersonating known benign programs. While this approach can be seen as a type of evasion detection, it clearly differs from our goal to detect SIEM rule evasions. Dreger et al. [21] utilize web server logs to detect evasions of a network-based intrusion detection system (NIDS) by correlating host-based and network-based events. While this approach seems to work well for its specific use case, it cannot detect SIEM rule evasions.

Other Event-Based Threat Detection Numerous threat detection approaches utilize event records (just as AMIDES) but pursue other goals than finding (SIEM) rule evasions. Early works apply various learning methods to host-based audit logs for detecting anomalies or deriving detection rules [19, 22, 34]. In contrast, publications within the last ten years often consider events from a large number of systems in a network or from multiple event sources to find anomalies [28, 43, 45, 59, 65]. Particularly in the last few years, various works employ provenance graphs to model causal relations in system behavior, predominantly for finding suspicious activity [2, 24, 36, 66]. While all of these approaches address threat detection from events, they do not provide organizations with a straightforward way to reduce detection blind spots caused by SIEM detection rule evasions.

Other Evasion Detection The challenge of evasion detection has been studied for other data sources than event records as well, namely, network traffic and files (especially potential malware files). Considering network traffic, Sohi et al. [52] enhance the detection performance of an NIDS by generating signature mutations using a neural network. Varghese et al. [58] split NIDS signatures into smaller pieces to counter evasions by TCP fragmentation. Cheng et al. [15] survey NIDS evasion techniques and assess their effectiveness. Considering files, Shiel and O'Shaughnessy [50] as well as Li et al. [35] analyze fuzzy hashing to detect variants of known malware files. Kapravelos et al. [30] detect evasive behavior in malicious JavaScript files by comparing them to known malicious variants. Aslan and Samet [5] survey further malware detection approaches. Due to their fundamentally different data sources, the above approaches are not meant to detect SIEM rule evasions and are thus complementary to AMIDES.

9 Conclusion

This work addresses evasions of SIEM detection rules, which can lead to critical detection blind spots within enterprise networks. To quantify the risk of such evasions, we analyzed a set of widespread open-source SIEM rules, namely, Windows process creation rules from the official Sigma repository. We found that out of 292 analyzed rules, 110 can by fully evaded and 19 can be partially evaded, potentially enabling adversaries to perform a large number of known attacks without being detected. To remedy this situation, we proposed the novel concept of adaptive misuse detection, an extension of conventional (i.e., rule-based) misuse detection where incoming events are compared to SIEM rules on the one hand and known-benign events on the other hand to detect evasions and additionally estimate which rules were evaded. Notably, this approach is well-suited for implementation in enterprise networks because it relies on already existing data (i.e., a SIEM ruleset and a set of historical benign events).

Using our open-source proof-of-concept implementation AMIDES, we evaluated our approach on four weeks of benign process creation events from a large enterprise network and 512 manually created evasions. At its default sensitivity, AMIDES detected 70 % of the (otherwise undetected) evasions with zero false alerts. AMIDES processes ~156 000 events per second in operation and requires 42 minutes for training on a commodity server with our dataset, making it fast enough for operation even in very large enterprise networks. We also evaluated AMIDES' capability to attribute evasions to evaded SIEM rule(s) and found that for 95 % of our evasions, the actually evaded rule was within AMIDES' top 10 propositions, thus likely helping analysts in verifying and analyzing alerts. Furthermore, we showed that AMIDES still detects a significant share of evasions with no false alerts even if the benign training data are heavily tainted with evasions.

Future work should further examine widespread SIEM rules for potential evasions and expand the concept and implementation of adaptive misuse detection by additional event types and fields to increase the coverage of potential detection blind spots. Overall, we showed that organizations relying on SIEM rules for cyberattack detection are prone to critical detection blind spots but can significantly reduce them with moderate effort by utilizing adaptive misuse detection. Thus, our work contributes to an improved detection of cyberattacks in enterprise networks and ultimately to reducing the damage arising from data theft, sabotage, and extortion.

Acknowledgments

We would like to express our gratitude to the SOC managers of the enterprise in which we performed our experiments for greatly supporting our ideas and work. Moreover, we sincerely thank our shepherd and the reviewers for their comprehensive, nuanced, and encouraging comments and suggestions.

A Implementation Details and Discussion

This section extends our description of AMIDES' implementation in Section 5, justifies our choices, and discusses potential alternatives. Generally speaking, we see our main contribution in proving that our concept of adaptive misuse detection (particularly: learning from SIEM rules) succeeds in detecting evasions in enterprise networks, *despite* using straightforward machine learning techniques. Hence, we did not strive to (over-)optimize our results by tailoring the feature extraction to our specific evasion instances or comparing various classifiers and choosing the best one for our specific dataset. Yet, we considered and/or tested several alternatives that seemed sensible, which are discussed in the following.

Feature Extraction We designed AMIDES' feature extraction based on insights from creating evasions and sifting benign events. In the filtering step (cf. Figure 2), we remove characters from the command line string that adversaries can insert almost anywhere (even within words) to evade signatures without invalidating the command. (We also use this technique for many of our evasions.) While the exact character set for filtering is arguable, we chose characters known to allow for `cmd.exe` and PowerShell evasions [11, 12].

The subsequent splitting step tokenizes the command line into terms. We experimented with different splitting character sets optimized for command lines but eventually opted for a simple "word" splitting (regex `\W`) since we discovered too many edge cases where other splittings lead to undesirable results. Though removing some context information, we found word splitting to be the most robust and generalizable.

While sifting the enterprise events, we found a large number of command lines containing unique arguments such as timestamps or IDs, bloating the feature space without contributing relevant information. Hence, we implemented the two pruning rules described in Section 5 to remove the majority of such irrelevant arguments. We suppose that these rules fit other enterprise environments as well, but suggest to ensure for any new environment that they succeed in removing irrelevant terms while preserving the relevant ones.

Finally, the remaining terms are transformed into a tf-idf vector. Since we have an extremely imbalanced dataset, we found it desirable to assign lower weights to frequent terms (as tf-idf does) to counter potential benign terms within an evasion dominating the classification decision. We also tried regular and normalized bag-of-words vectorization, but got significantly worse results (as expected). So far, we did not experiment with context-sensitive methods such as word2vec [39] because the utilized Sigma signatures are often very short, consisting of only one or few words, whereas the benign events comprise full command lines. Together with the fact that argument positions are often exchangeable, we do not expect context-sensitive methods to perform well for our approach, hence leaving them to potential future work.

Classification Various classifiers come into question for intrusion detection tasks [32, 42]. Since a sound comparison would go beyond the scope of this work, we opted for linear SVMs according to a best-practice guide [48]. We found them to be suitable for our data both in terms of classification and computational performance. Moreover, linear SVMs enable straightforward analysis of the influence of input terms on the classification result, facilitating effective feature design.

For hyperparameter tuning, we perform grid search over 25 exponentially growing C values between 0.01 and 10, with class balancing (`class_weight` in scitkit-learn) on and off, respectively. We also tested other SVM kernels (RBF, polynomial, and sigmoid) but did not get significantly better results. Overall, we cannot rule out that other classifiers might yield better results, but leave their evaluation to future work.

Threshold Configuration The ideal decision threshold in operation usually differs from the one resulting from training, mainly because security analysts in enterprises need to investigate alerts from multiple security systems within limited time. Hence, both too many and too few alerts can lead to missed attacks (cf. Section 2). Therefore, we decided to set the default threshold for operation such that AMIDES raises a configurable number N of false alerts *per day on average*, thus matching available analyst resources. This feature is implemented simply by setting the threshold such that ND false positives occur in the training set, where D is the length of the training set in days. This method assumes similar statistical properties of benign events in training and operation, which we deem justified when performing regular retraining. For our evaluation, we chose $N = 0$ for the sake of simplicity, effectively placing the default decision threshold just above the worst-classified benign training sample (cf. Appendix B).

Furthermore, besides a sensible *default* threshold, we also calculate a sensible threshold *range* with the goal of providing non-expert users with a simple configuration parameter between zero and one, where 0.5 is the default threshold, allowing to put a strong emphasis on either recall or precision. We implement this by linearly mapping a subinterval of the SVM decision function values to $[0, 1]$ such that the default threshold lies at 0.5 and the MCC curve remains above 0.1 over most of the interval (note that MCC is more robust than F1 score or individual precision/recall limits [16]).

B Analysis of Classification Performance

To assess AMIDES' misuse classification performance, we statistically analyzed its output for all benign events, evasion events, and Sigma rules. Figure 7 shows the distributions of the resulting SVM decision function values. The dashed line depicts the default threshold as described in Appendix A for $N = 0$, which also yields zero false alerts on the validation set (which is not generally the case since there could be worse-

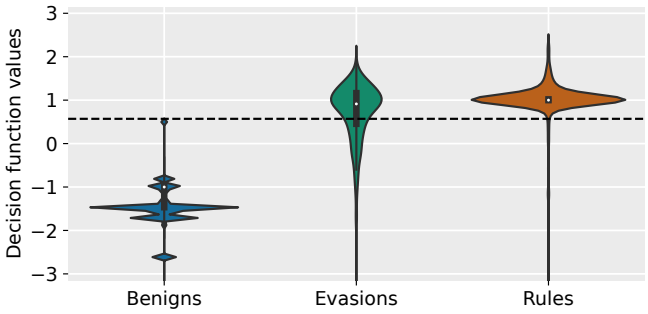

Figure 7: The imperfect class separability and high imbalance would result in a ~70 % evasion detection rate in practice.

classified benign events than in the training set). We can see that the classifier largely succeeds in separating the training classes (i.e., benigns and rules), with the median samples being located approximately at -1 and 1, respectively, but no perfect separation is achieved. Furthermore, the plot reveals an uneven distribution of the benign events, which we can attribute to large clusters of similar command lines.

Looking at the evasions, both median and average values are slightly below those of the rules. Particularly, we can see that a significant fraction (30 %) exhibits smaller values than the highest-valued benign cluster just below the default threshold. Even though this cluster comprises only a small fraction of the benign events, the extreme class imbalance (factor ~145 000) causes a sharp decline in precision (cf. Figure 3), rendering lower thresholds impractical due to many false alerts, thus yielding the reported 70 % detection rate.

We also analyzed the contributions of all features to the classification results. We found that many evasions contain terms that appear in benign events but not in rules, thus explaining their lower decision function values. Particularly, signatures often omit less relevant parts of malicious command lines (e.g., the full path of an executable), hence such terms in evasions influence their classification towards benignity. For example, the term `system32` has a strong weight towards benignity since it frequently appears in benign events but rarely in rules. Vice versa, there is a cluster of ~188 k misclassified benign executions of `winlogon.exe` close to the default threshold because this binary appears in several rules (with additional conditions that AMIDES currently ignores due to our restriction to the command line field). Consequently, a straightforward approach to improve AMIDES' detection performance in practice would be to filter its alerts by a list of known false positives (i.e., misclassified benign command lines), allowing to set a lower threshold and thus detect more evasions without increasing the number of false alerts.

Overall, while this analysis reveals potential limitations of learning from SIEM rules, we nonetheless consider our concept of adaptive misuse detection (and AMIDES in particular) highly beneficial in practice since it facilitates a significant reduction of detection blind spots in enterprise networks.

MAGIC: Detecting Advanced Persistent Threats via Masked Graph Representation Learning

Abstract

Advance Persistent Threats (APTs), adopted by most delicate attackers, are becoming increasing common and pose great threat to various enterprises and institutions. Data provenance analysis on provenance graphs has emerged as a common approach in APT detection. However, previous works have exhibited several shortcomings: (1) requiring attack-containing data and *a priori* knowledge of APTs, (2) failing in extracting the rich contextual information buried within provenance graphs and (3) becoming impracticable due to their prohibitive computation overhead and memory consumption.

In this paper, we introduce MAGIC, a novel and flexible self-supervised APT detection approach capable of performing multi-granularity detection under different level of supervision. MAGIC leverages masked graph representation learning to model benign system entities and behaviors, performing efficient deep feature extraction and structure abstraction on provenance graphs. By ferreting out anomalous system behaviors via outlier detection methods, MAGIC is able to perform both system entity level and batched log level APT detection. MAGIC is specially designed to handle concept drift with a model adaption mechanism and successfully applies to universal conditions and detection scenarios. We evaluate MAGIC on three widely-used datasets, including both real-world and simulated attacks. Evaluation results indicate that MAGIC achieves promising detection results in all scenarios and shows enormous advantage over state-of-the-art APT detection approaches in performance overhead.

1 Introduction

Advanced Persistent Threats (APTs) are intentional and sophisticated cyber-attacks conducted by skilled attackers and pose great threat to both enterprises and institutions [1]. Most APTs involve zero-day vulnerabilities and are especially difficult to detect due to their stealthy and changeful nature.

*Corresponding author: Yuhong Nan

Recent works [2–18] on APT detection leverage data provenance to perform APT detection. Data provenance transforms audit logs into provenance graphs, which extract the rich contextual information from audit logs and provide a perfect platform for fine-grained causality analysis and APT detection. Early works [2–6] construct rules based on typical or specific APT patterns and match audit logs against those rules to detect potential APTs. Several recent works [7–9] adopt a statistical anomaly detection approach to detect APTs focusing on different provenance graph elements, e.g, system entities, interactions and communities. Most recent works [10–18], however, are deep learning-based approaches. They utilize various deep learning (DL) techniques to model APT patterns or system behaviors and perform APT detection in a classification or anomaly detection style.

While these existing approaches have demonstrated their capability to detect APTs with reasonable accuracy, they encounter various combinations of the following challenges: (1) Supervised methods suffer from lack-of-data (LOD) problem as they require *a priori* knowledge about APTs (i.e. attack patterns or attack-containing logs). In addition, these methods are particularly vulnerable when confronted with new types of APTs they are not trained to deal with. (2) Statistics-based methods only require benign data to function, but they fail to extract the deep semantics and correlation of complex benign activities buried in audit logs, resulting in high false positive rate. (3) DL-based methods, especially sequence-based and graph-based approaches, have achieved promising effectiveness at the cost of heavy computation overhead, rendering them impractical in real-life detection scenarios.

In this paper, we address the above three issues by introducing MAGIC, a novel self-supervised APT detection approach that leverages *masked graph representation learning* and simple *outlier detection* methods to identify key attack system entities from massive audit logs. MAGIC first constructs the provenance graph from audit logs in simple yet universal steps. MAGIC then employs a graph representation module that obtains embeddings by incorporating graph features and structural information in a self-supervised way. The model

is built upon *graph masked auto-encoders* [19] under the joint supervision of both *masked feature reconstruction* and *sample-based structure reconstruction*. An unsupervised outlier detection method is employed to analyze the computed embeddings and attain the final detection result.

MAGIC is designed to be flexible and scalable. Depending on the application background, MAGIC is able to perform multi-granularity detection, i.e., detecting APT existence in batched logs or locating entity-level adversaries. Although MAGIC is designed to perform APT detection without attack-containing data, it is well-suited for semi-supervised and fully-supervised conditions. Furthermore, MAGIC also contains an optional model adaption mechanism which provides a feedback channel for its users. Such feedback is important for MAGIC to further improve its performance, combat concept drift and reduce false positives.

We implement MAGIC and evaluate its performance and overhead on three different APT attack datasets: the DARPA Transparent Computing E3 datasets [20], the StreamSpot dataset [21] and the Unicorn Wget dataset [22]. The DARPA datasets contain real-world attacks while the StreamSpot and Unicorn Wget dataset are fully simulated in controlled environments. Evaluation results show that MAGIC is able to perform entity-level APT detection with 97.26% precision and 99.91% recall as well as minimum overhead, less memory demanding and significantly faster than state-of-the-art approaches (e.g. 51 times faster than ShadeWatcher [18]).

To benefit future research and encourage further improvement on MAGIC, we make our implementation of MAGIC and our pre-processed datasets open to public[1]. In summary, this paper makes the following contributions:

- We propose MAGIC, a universal APT detection approach based on masked graph representation learning and outlier detection methods, capable of performing multi-granularity detection on massive audit logs.
- We ensure MAGIC's practicability by minimizing its computation overhead with extended graph masked auto-encoders, allowing MAGIC to complete training and detection in acceptable time even under tight conditions.
- We secure MAGIC's universality with various efforts. We leverage masked graph representation learning and outlier detection methods, enabling MAGIC to perform precise detection under different supervision levels, in different detection granularity and with audit logs from various sources.
- We evaluate MAGIC on three widely-used datasets, involving both real-world and simulated APT attacks. Evaluation results show that MAGIC detects APTs with promising results and minimum computation overhead.
- We provide an open source implementation of MAGIC to benefit future research in the community and encourage further improvement on our approach.

[1] MAGIC is available at https://github.com/FDUDSDE/MAGIC

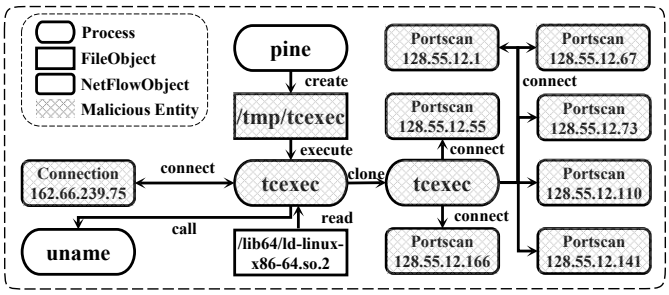

Figure 1: The provenance graph of a real-world APT attack, exploiting the Pine Backdoor vulnerability. All attack-irrelevant entities and interactions have been removed from the provenance graph.

2 Background

2.1 Motivating Example

Here we provide a detailed illustration of an APT scenario that we use throughout the paper. *Pine backdoor with Drakon Dropper* is an APT attack from the DARPA Engagement 3 Trace dataset [20]. During the attack, an attacker constructs a malicious executable (*/tmp/tcexec*) and sends it to the target host via a phishing e-mail. The user then unconsciously downloads and opens the e-mail. Contained within the e-mail is an executable designed to perform a port-scan for internal reconnaissance and establish a silent connection between the target host and the attacker. Figure 1 displays the provenance graph of our motivation example. Nodes in the graph represent system entities and arrows represent directed interactions between entities. The graph shown is a subgraph abstracted from the complete provenance graph by removing most attack-irrelevant entities and interactions. Different node shape corresponds to different type of entities. Entities covered in stripes are considered malicious ones.

2.2 Prior Research and their Limitations

Supervised Methods. For early works [2–6], special heuristic rules need to be constructed to cover all attack patterns. Many DL-based APT detection methods [11, 14–16, 18] construct provenance graphs based on both benign and attack-containing data and detect APTs in a classification style. These supervised methods can achieve almost perfect detection results on learned attack patterns but are especially vulnerable facing *concept drift* or unseen attack patterns. Moreover, for rule-based methods, the construction and maintenance of heuristic rules can be very expensive and time-consuming. And for DL-based methods, the scarcity of attack-containing data is preventing these supervised methods from being actually deployable. To address the above issue, MAGIC adopts a fully self-supervised anomaly detection style, allowing the absence of attack-containing data while effectively dealing

with unseen attack patterns.

Statistics-based Methods. Most recent statistics-based methods [7–9] detect APT signals by identifying system entities, interactions and communities based on their rarity or anomaly scores. However, the rarity of system entities may not necessarily indicate their abnormality and anomaly scores, obtained via causal analysis or label propagation, are *shallow feature extraction* on provenance graphs. To illustrate, the process *tcexec* performs multiple portscan operations on different IP addresses in our motivating example (See Figure 1), which may be considered as a normal system behavior. However, taking into consideration that process *tcexec*, derived from the external network, also reads sensitive system information (*uname*) and makes connection with public IP addresses (*162.66.239.75*), we can easily identify *tcexec* as a malicious entity. Failure to extract deep semantics and correlations between system entities often results in low detection performance and high false positive rate of statistics-based methods. MAGIC, however, employs a graph representation module to perform *deep graph feature extraction* on provenance graphs, resulting in high-quality embeddings.

DL-based Methods. Recently, DL-based APT detection methods, no matter supervised or unsupervised, are producing very promising detection results. However, in reality, hundreds of GB of audit logs are produced every day in a medium-size enterprise [23]. Consequently, DL-based methods, especially sequence-based [11, 14, 24] and graph-based [10, 12, 15–18] methods, are impracticable due to their computation overhead. For instance, ATLAS [11] takes an average 1 hour to train on 676MB of audit logs and ShadeWatcher [18] takes 1 day to train on the DARPA E3 Trace dataset with GPU available. Besides, some graph auto-encoder [25–27] based methods encounter *explosive memory overhead* problem when the scale of provenance graphs expands. MAGIC avoids to be computationally demanding by introducing *graph masked auto-encoders* and completes its training on the DARPA E3 Trace dataset in mere minutes. Detailed evaluation of MAGIC's performance overhead is presented in Sec. 6.4.

End-to-end Approaches. Beyond the three major limitations discussed above, it is also worth to mention that most recent APT detection approaches [11, 17, 18] are *end-to-end* detectors and focus on one specific detection task. For instance, ATLAS [11] focused on end-to-end attack reconstruction and Unicorn [10] yields system-level alarms from streaming logs. Instead, MAGIC's approach is universal and performs multi-granularity APT detection under various detection scenarios, which can also be applied to audit logs collected from different sources.

2.3 Threat Model and Definitions

We first present the threat model we use throughout the paper and then formally define key concepts that are crucial to understanding how MAGIC performs APT detection.

Threat Model. We assume that attackers come from outside a system and target valuable information within the system. An attacker may perform sophisticated steps to achieve his goal but leaves trackable evidence in logs. The combination of the system hardware, operating system and system audit softwares is our trusted computing base. Poison attacks and evasion attacks are not considered in our threat model.

Provenance Graph. A provenance graph is a directed cyclic graph extracted from raw audit logs. Constructing a provenance graph is common practice in data provenance, as it connects system entities and presents the interaction relationships between them. A provenance graph contains nodes representing different system entities (e.g., processes, files and sockets) and edges representing interactions between system entities (e.g., execute and connect), labeled with their types. For example, */tmp/tcexec* is a *FileObject* system entity and the edge between */tmp/tcexec* and *tcexec* is an *execute* operation from a *FileObject* targeting a *Process* (See Figure 1).

Multi-granularity Detection. MAGIC is capable to perform APT detection at two-granularity: *batched log level* and *system entity level*. MAGIC's multi-granularity detection ability gives rises to a two-stage detection approach: first conduct batched log level detection on streaming batches of logs, and then perform system entity level detection on positive batches to identify detailed detection results. Applying this approach to real-world settings will effectively reduce workload, resource consumption and false positives and, in the meantime, produce detailed outcomes.

- Batched log level detection. Under this granularity of APT detection, the major task is *given batched audit logs from a consistent source, MAGIC alerts if a potential APT is detected in a batch of logs*. Similar to Unicorn [10], MAGIC does not accurately locate malicious system entities and interactions under this granularity of detection.
- System entity level detection. The detection task under this granularity of APT detection is *given audit logs from a consistent source, MAGIC is able to accurately locate malicious system entities in those audit logs*. Identification of key system entities during APTs is vital to subsequent tasks such as attack investigation and attack story recovery as it provides explicable detection results and reduces the need for domain experts as well as redundant manual efforts [11].

3 MAGIC Overview

MAGIC is a novel self-supervised APT detection approach that leverages masked graph representation learning and outlier detection methods and is capable of efficiently performing multi-granularity detection on massive audit logs. MAGIC's pipeline consists of three main components: (1) provenance graph construction, (2) a graph representation module and (3) a detection module. It also provides an optional (4)

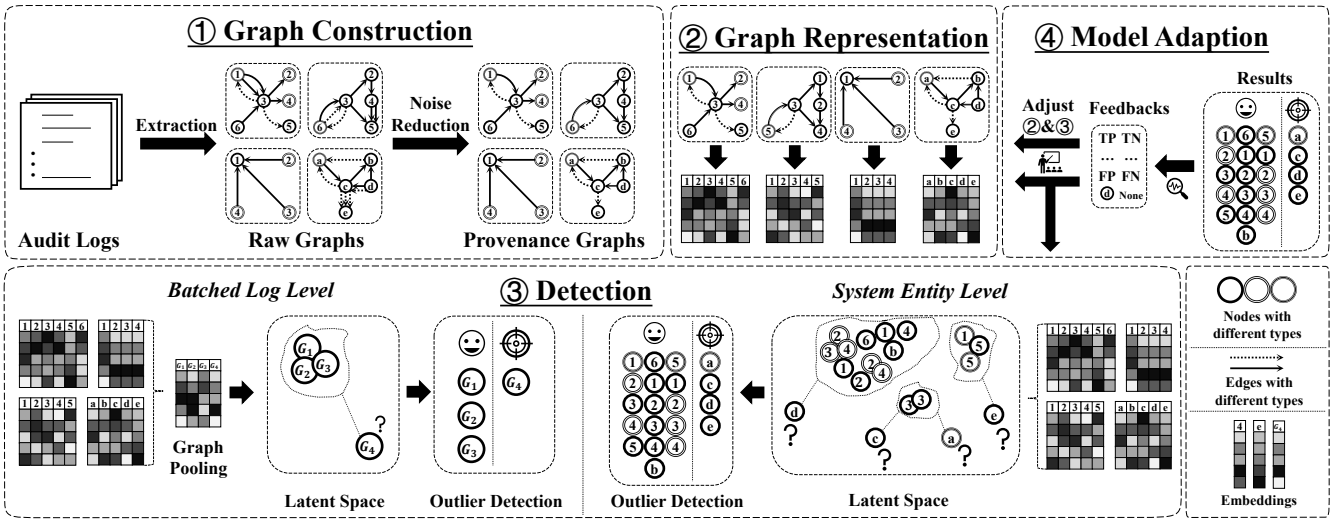

Figure 2: Overview of MAGIC's detection pipeline.

model adaption mechanism. During training, MAGIC transforms training data with (1), learns graph embedding by (2) and memorizes benign behaviors in (3). During inference, MAGIC transforms target data with (1), obtains graph embedding with the trained (2) and detects outliers through (3). Figure 2 gives an overview of the MAGIC architecture.

Streaming audit logs collected by system auditing softwares are usually stored in batches. During provenance graph construction (1), MAGIC transforms these logs into static provenance graphs. System entities and interactions between them are extracted and converted into nodes and edges respectively. Several complexity reduction techniques are utilized to remove redundant information.

The constructed provenance graphs are then fed through the graph representation module (2) to obtain output embeddings (i.e. comprehensive vector representations of objects). Built upon *graph masked auto-encoders* and integrating *sample-based structure reconstruction*, the graph representation module embeds, propagates and aggregates node and edge attributes into output embeddings, which contain both node embeddings and the system state embedding.

The graph representation module is trained with only benign audit logs to model benign system behaviors. When performing APT detection on potentially attack-containing audit logs, MAGIC utilizes *outlier detection methods* based on the output embeddings to detect outliers in system behaviors (3). Depending on the granularity of the task, different embeddings are used to complete APT detection. On *batched log level* tasks, the system state embeddings, which reflect the general behaviors of the whole system, are the detection targets. An outlier in such embeddings means its corresponding system state is unseen and potentially malicious, which reveals an APT signal in that batch. On *system entity level* tasks, the detection targets are those node embeddings, which represent the behaviors of system entities. Outliers in node embeddings indicates suspicious system entities and detects APT threats in finer granularity.

In real-world detection settings, MAGIC has two predesigned applications. For each batch of logs collected by system auditing softwares, one can either directly utilize MAGIC's entity level detection to accurately identify malicious entities within the batch, or perform a two-stage detection, as stated in Sec. 2.3. In this case, MAGIC first scans a batch and sees if malicious signals exist in the batch (batched log level detection). If it alerts positive, MAGIC then performs entity level detection to identify malicious system entities in finer granularity. Batched log level detection is significantly less computationally demanding than entity level detection. Therefore, such a two-stage routine can help MAGIC's users to save computational resource and avoid false alarms without affecting MAGIC's detection fineness. However, if users favor fine-grain detection on all system entities, the former routine is still an accessible option.

To deal with *concept drift* and unseen attacks, an optional model adaption mechanism is employed to provide feedback channels for its users (4). Detection results checked and confirmed by security analysts are fed back to MAGIC, helping it to adapt to benign system behavior changes in a semi-supervised way. Under such conditions, MAGIC achieves even more promising detection results, which is discussed in Sec. 6.3. Furthermore, MAGIC can be easily applied to real-world online APT detection thanks to it's ability to adapt itself to *concept drift* and its minimum computation overhead.

4 Design Details

In this section, we explain in detail how MAGIC performs efficient APT detection on massive audit logs. MAGIC con-

tains four major components: a graph construction phase that builds optimised and consistent provenance graphs (Sec. 4.1), a graph representation module that produces output embeddings with maximum efficiency (Sec. 4.2), a detection module that utilizes outlier detection methods to perform APT detection (Sec. 4.3) and a model adaption mechanism to deal with *concept drift* and other high-quality feedbacks (Sec. 4.4).

4.1 Provenance Graph Construction

MAGIC first constructs a provenance graph out of raw audit logs before performing graph representation and APT detection. We follow three steps to construct a consistent and optimised provenance graph ready for graph representation.

Log Parsing. The first step is to simply parse each log entry, extract system entities and system interactions between them. Then, a prototype provenance graph can be constructed with system entities as nodes and interactions as edges. Now we extract categorical information regarding nodes and edges. For simple log format that provides entity and interaction labels, we directly utilize these labels. For some format that provides complicated attributes of those entities and interactions, we apply multi-label hashing (e.g., xxhash [28]) to transform attributes into labels. At this stage, the provenance graph is a directed multi-graph. We designed an example to demonstrate how we deal with the raw provenance graph after log parsing in Figure 3.

Initial Embedding. In this stage, we transform node and edge labels into fixed-size feature vector (i.e., initial embedding) of dimension d, where d is the hidden dimension of our graph representation module. We apply a *lookup embedding*, which establish an one-to-one mapping between node/edge labels to d-dimension feature vectors. As demonstrated in Figure 3 (I and II), process a and b share the same label, so they are mapped to the same feature vector, while a and c are embedded into different feature vectors as they have different labels. We note that the possible number of unique node/edge labels is determined by the data source (i.e., auditing log format). Therefore, the lookup embedding works under a transductive setting and do not need to learn embeddings for unseen labels.

Noise Reduction. The expected input provenance graph of our graph representation module would be simple-graphs. Thus, we need to combine multiple edges between node pairs. If multiple edges of the same label (also sharing the same initial embedding) exist between a pair of nodes, we remove redundant edges so that only one of them remains. Then we combine the remaining edges into one final edge. We note that between a pair of nodes, edges of several different labels may remain. After the combination, the initial embedding of the resulting unique edge is obtained by averaging the initial embeddings of the remaining edges. To illustrate, we show how our noise reduction combines multi-edges and how it affects the edge initial embeddings in Figure 3 (II an III). First, three *read* and two *write* interactions between a and c

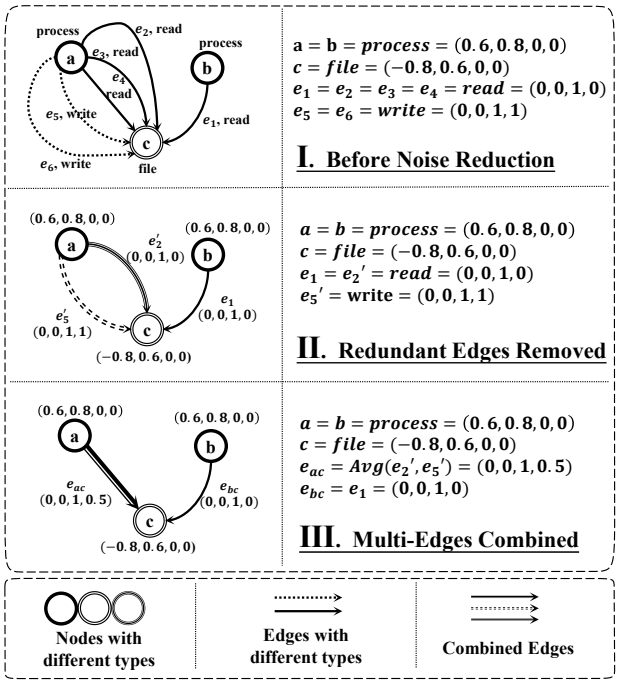

Figure 3: Example of MAGIC's graph construction steps.

are merged into one for each label. Then we combine them together, forming one edge e_{ac} with initial embedding equal to the average initial embedding of the remaining edges (e_2' and e_5'). We provide a comparison between our noise reduction steps and previous works in Appendix E.

After conducting the above three steps, MAGIC has finished constructing a consistent and information-preserving provenance graph ready for subsequent tasks. During provenance graph construction, little information is lost as MAGIC only damages the original semantics by generalizing detailed descriptions of system entities and interactions into labels. However, an average 79.60% of all edges are reduced on the DARPA E3 Trace dataset, saving MAGIC's training time and memory consumption.

4.2 Graph Representation Module

MAGIC employs a graph representation module to obtain high-quality embeddings from featured provenance graphs. As illustrated in Figure 4, the graph representation module consists of three phases: a masking procedure to partially hide node features (i.e. initial embeddings) for reconstruction purpose (Sec. 4.2.1), a graph encoder that produces node and system state output embeddings by propagating and aggregating graph features (Sec. 4.2.2), a graph decoder that provides supervision signals for the training of the graph representation module via masked feature reconstruction and sample-based structure reconstruction (Sec. 4.2.3). The encoder and decoder form a *graph masked auto-encoder*, which excels in

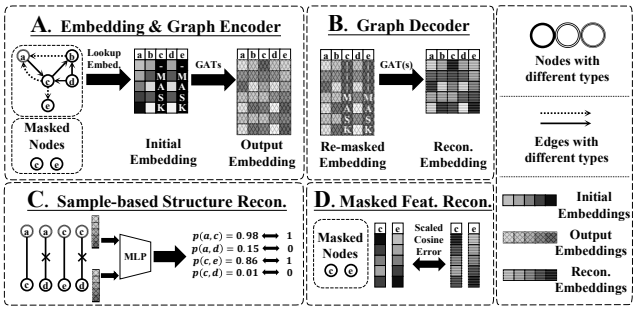

Figure 4: Graph representation module of MAGIC.

producing fast and resource-saving embeddings.

4.2.1 Feature Masking

Before training our graph representation module, we perform *masking* on nodes, so that the graph masked auto-encoder can be trained upon reconstruction of these nodes. Masked nodes are randomly chosen, covering a certain proportion of all nodes. The initial embeddings of such masked nodes are replaced with a special mask token x_{mask} to cover any original information about these nodes. Edges, however, are not masked because these edges provide precious information about relationships between system entities. In summary, given node initial embeddings x_n, we mask nodes as follows:

$$emb_n = \begin{array}{ll} x_n, & n \notin \widetilde{N} \\ x_{mask}, & n \in \widetilde{N} \end{array}$$

where $\widetilde{N}$ are randomly-chosen masked nodes, emb_n is the embedding of node n ready for training the graph representation module. This masking process only happens during training. During detection, we do not mask any nodes.

4.2.2 Graph Encoder

Initial embeddings obtained from the graph construction steps take only raw features into consideration. However, raw features are far from enough to model detailed behaviors of system entities. Contextual information of an entity, such as its neighborhood, its multi-hop relationships and its interaction patterns with other system entities plays an important role to obtain high-quality entity embeddings [29]. Here we employ and extend graph masked auto-encoders [19] to generate output embeddings in a self-supervised way. The graph masked auto-encoder consists of an encoder and a decoder. The encoder produces output embeddings by propagating and aggregating graph features and the decoder reconstructs graph features to provide supervision signals for training. Such encoder-decoder architecture maintains the contextual and semantic information within the generated embeddings, while its computation overhead is significantly reduced via masked learning.

The encoder of our graph representation module contains multiple stacked layers of graph attention networks (GAT) [30]. The function of a GAT layer is to generate output node embeddings according to both the features (initial embeddings) of the node itself and its neighbors. Differing from ordinary GNNs, GAT introduces an attention mechanism to measure the importance of those neighbors.

To explain in detail, one layer of GAT takes node embeddings generated by previous layers as input and propagates embeddings from source nodes to destination nodes into messages along the interactions. The message contains information about the source node and the interaction between source and destination:

$$MSG(src,dst) = W_{msg}^T(h_{src}||emb_e).$$

And the attention mechanism is employed to calculate the attention coefficients between the message source and its destination:

$$\alpha(src,dst) = LeakyReLU(W_{as}^T h_{src} + W_{am} MSG(src,dst)),$$
$$a(src,dst) = Softmax(\alpha(src,dst)).$$

Then for the destination node, the GAT aggregates messages from incoming edges to update its node embedding by computing a weighted sum of all incoming messages. The weights are exactly the attention coefficients:

$$AGG(h_{dst}, h_{\mathcal{N}}) = W_{self} h_{dst} + \sum_{i \in \mathcal{N}} a(i,dst) MSG(i,dst),$$
$$h_n^l = AGG^l(h_n^{l-1}, h_{\mathcal{N}_n}^{l-1}).$$

where h_n^l is the hidden embedding of node n at l-th layer of GAT, h_n^{l-1} is that of layer $l-1$ and $\mathcal{N}_n$ is the one-hop neighborhood of n. The input of the first GAT layer are the initial node embeddings. emb_e is the initial edge embedding and remains constant throughout the graph representation module. $W_{as}, W_{am}, W_{self}, W_{msg}$ are trainable parameters. The updated node embedding forms a general abstraction of the node's one-hop interaction behavior.

Multiple layers of such GATs are stacked to obtain the final node embedding h, which is concatenated by the original node embedding and outputs of all GAT layers:

$$h_n = emb_n||h_n^1||\cdots||h_n^l.$$

where $\cdot||\cdot$ denotes the concatenate operation. The more layers of GAT stacked, the wider the neighboring range is and the farther a node's multi-hop interaction pattern its embedding is able to represent. Consequently, the graph encoder effectively incorporates node initial features and multi-hop interaction behaviors to abstract system entity behaviors into node embeddings. The graph encoder also applies an average pooling to all node embeddings to generate a comprehensive embedding of the graph itself [31], which recapitulates the overall

state of the system:

$$h_G = \frac{1}{|N|} \sum_{n_i \in N} h_{n_i}.$$

The node embeddings and system state embeddings generated by the graph encoder are considered the output of the graph representation module, which are used in subsequent tasks in different scenarios.

4.2.3 Graph Decoder

The graph encoder does not provide supervision signals that support model training. In typical graph auto-encoders [25, 27], a graph decoder is employed to decode node embeddings and supervise model training via *feature reconstruction* and *structure reconstruction*. Graph masked auto-encoders, however, abandon structure reconstruction to reduce computation overhead. Our graph decoder is a mixture of both, which integrates masked feature reconstruction and sample-based structure reconstruction to construct an objective function that optimizes the graph representation module.

Given node embeddings h_n obtained from the graph encoder, the decoder first re-masks those masked nodes and transforms them into the input of *masked feature reconstruction*:

$$h_n^* = \begin{cases} W^* h_n, & n \notin \widetilde{N} \\ W^* v_{remask}, & n \in \widetilde{N} \end{cases},$$

Subsequently, the decoder uses a similar GAT layer described above to reconstruct the initial embeddings of the masked nodes, allowing the calculation of a feature reconstruction loss:

$$x_n^* = AGG^*(h_n^*, h_{\mathcal{N}_n}^*),$$

$$L_{fr} = \frac{1}{|\widetilde{N}|} \sum_{n_i \in \widetilde{N}} (1 - \frac{x_{n_i}^T x_{n_i}^*}{||x_{n_i}|| \cdot ||x_{n_i}^*||})^{\gamma}.$$

where L_{fr} is the masked feature reconstruction loss obtained by calculating a *scaled cosine loss* between initial and reconstructed embeddings of the masked nodes. This loss [19] scales dramatically between easy and difficult samples which effectively speeds up learning. The degree of such scaling is controlled by a hyper-parameter γ.

Meanwhile, sample-based structure reconstruction aims to reconstruct graph structure (i.e. predict edges between nodes). Instead of reconstructing the whole adjacency matrix, which has $O(N^2)$ complexity, sample-based structure reconstruction applies contrastive sampling on node pairs and predicts edge probabilities between such pairs. Only non-masked nodes are involved in structure reconstruction. Positive samples are constructed with all existing edges between non-masked nodes and negative samples are sampled among node pairs with no existing edges between them.

A simple two-layer MLP is used to reconstruct edges between node pairs samples, generating one probability for each sample. The reconstruction loss takes the form of a simple binary cross-entropy loss on those samples:

$$prob(n, n') = \sigma(MLP(h_n || h_{n'})),$$

$$L_{sr} = -\frac{1}{|\hat{N}|} \sum_{n \in \hat{N}} (log(1 - prob(n, n^-)) + log(prob(n, n^+))).$$

where (n, n^-) and (n, n^+) are negative and positive samples respectively and $\hat{N} = N - \widetilde{N}$ is the set of non-masked nodes. Sample-based structure reconstruction only provides supervision to the output embeddings. Instead of using dot products, we employ a MLP to calculate edge probabilities as interacting entities are not necessarily similar in behaviors. Also, we are not forcing the model to learn to predict edge probabilities. The function of such structure reconstruction is to *maximize behavioral information* contained in the abstracted node embeddings so that a simple MLP is sufficient to incorporate and interpret such information into edge probabilities.

The final objective function $L = L_{fr} + L_{sr}$ combines L_{fr} and L_{sr} and provides supervision signals to the graph representation module, enabling it to learn parameters in a self-supervised way.

4.3 Detection Module

Based on the output embeddings generated by the graph representation module, we utilize outlier detection methods to perform APT detection in an unsupervised way. As detailedly explained in previous sections, such embeddings summarize system behaviors in different granularity. The goal of our detection model is to identify malicious system entities or states given only a priori knowledge of *benign system behaviors*. Embeddings generated via graph representation learning tend to form clusters if their corresponding entities share similar interaction behaviors in the graph [19, 25–27, 32]. Thus, outliers in system state embeddings indicate uncommon and suspicious system behaviors. Based on such insight, we develop a special outlier detection method to perform APT detection.

During training, benign output embeddings are first abstracted from the training provenance graphs. What the detection module does at this stage is simply *memorizing* those embeddings and organize them in a *K-D Tree* [33]. After training, the detection module reveals outliers in three steps: k-nearest neighbor searching, similarity calculation and filtering. Given a target embedding, the detection module first obtains its k-nearest neighbors via K-D Tree searching. Such searching process only takes $log(N)$ time, where N is the total number of memorized training embeddings. Then, a similarity criterion is applied to evaluate the target embedding's closeness to its neighbors and compute an anomaly score. If its anomaly score yields higher than a hyper-parameter θ, the target embedding is considered an outlier and its corresponding system entity or system state is malicious. An example workflow of the detection module is formalized as follows,

using euclidean distance as the similarity criterion:

$$\mathcal{N}_x = KNN(x)$$
$$dist_x = \frac{1}{|\mathcal{N}_x|} \sum_{x_i \in \mathcal{N}_x} ||x - x_i||$$
$$score_x = \frac{dist_x}{\overline{dist}}$$
$$result_x = \begin{cases} 1, & score_x \geq \theta \\ 0, & score_x < \theta \end{cases}$$

where $\overline{dist}$ is the average distance between training embeddings and their k-nearest neighbors. When performing *batched log level detection*, the detection module memorizes benign system state embeddings that reflects system states and detects if the system state embedding of a newly-arrived provenance graph is an outlier. When performing *system entity level detection*, the detection module instead memorizes benign *node embeddings* that indicates system entity behaviors and given a newly-arrived provenance graph, it detects outliers within the embeddings of all system entities.

4.4 Model Adaption

For an APT detector to effectively function in real-world detection scenarios, concept drift must be taken into consideration. When facing benign yet previously unseen system behaviors, MAGIC produces false positive detection results, which may mislead subsequent applications (e.g. attack investigation and story recovery). Recent works address this issue by forgetting outdated data [10] or fitting their model to benign system changes via a *model adaption mechanism* [18]. MAGIC also integrates a model adaption mechanism to combat concept drift and learn from false positives identified by security analysts. Slightly different from other works that use only false positives to retrain the model, MAGIC can be retrained with all feedbacks. As discussed in previous sections, the graph representation module in MAGIC encodes system entities into embeddings in a self-supervised way, without knowing its label. Any unseen data, including those true negatives, are valuable training data for the graph representation module to enhance its representation ability on unseen system behaviors.

The detection module can only be retrained with benign feedbacks to keep up to system behavior changes. And as it memorizes more and more benign feedbacks, its detection efficiency is lowered. To address this issue, we also implement a discounting mechanism on the detection module. When the volume of memorized embeddings exceeds a certain amount, earliest embeddings are simply removed as newly-arrived embeddings are learned. We provide the model adaption mechanism as an optional solution to concept drift and unseen system behaviors. It is recommended to adapt MAGIC to system changes by feeding confirmed false positive samples to MAGIC's model adaption mechanism.

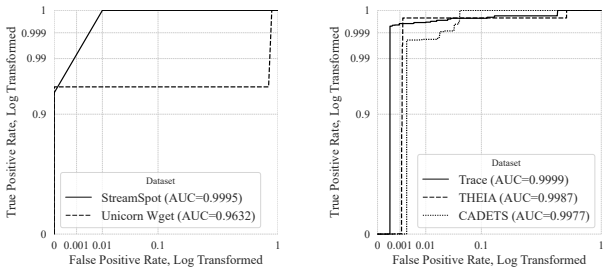
5 Implementation

We implement MAGIC with about 3,500 lines of code in Python 3.8. We develop several log parsers to cope with different format of audit logs, including StreamSpot [34], Camflow [35] and CDM [36]. Provenance graphs are constructed using the graph processing library Networkx [37] and stored in JSON format. The graph representation module is implemented via PyTorch [38] and DGL [39]. The detection module is developed with Scikit-learn [40]. For hyper-parameters of MAGIC, the scaling factor γ in the feature reconstruction loss is set to 3, the number of neighbors k is set to 10, the learning rate as 0.001 and the weight decay factor equals 5×10^{-4}. We use a 3 layer graph encoder and a mask rate of 0.5 in our experiments. The output embedding dimension d is different on two detection scenarios, batched log level detection and entity level detection. We use d equals 256 in batched log level detection and of and an we set d equals 64 in entity level detection to reduce resource consumption. The detection threshold θ is chosen by a simple linear search separately conducted on each dataset. The hyper-parameters may have other choices. We demonstrate the impact of these hyper-parameters on MAGIC later in the evaluation section. In our hyper-parameter analysis, d is chosen from {16, 32, 64, 128, 256} , l from {1, 2, 3, 4} and r from {0.3, 0.5, 0.7}. For the threshold θ, it is chosen between 1 and 10 in batched log level detection. For entity level detection, please refer to Appendix D.

6 Evaluation

We use 131GB of audit logs derived from various system auditing softwares to evaluate the effectiveness and efficiency of MAGIC. We first describe our experimental settings (Sec. 6.1), then elaborate the effectiveness of MAGIC in different scenarios (Sec. 6.2), conduct a false positive analysis and assess the usefulness of the model adaption mechanism (Sec. 6.3) and analyze the run-time performance overhead of MAGIC (Sec. 6.4). The impact of different components and hyper-parameters of MAGIC is analyzed in Sec. 6.5. In addition, a detailed case study on our motivation example is conducted in Appendix C to illustrate how MAGIC's pipeline work for APT detection. These experiments are conducted under the same device setting.

6.1 Experimental Settings



We evaluate the effectiveness of MAGIC on three public datasets: the StreamSpot dataset [21], the Unicorn Wget dataset [22] and the DARPA Engagement 3 datasets [20]. These datasets vary in volume, origin and granularity. We believe by testing MAGIC's performance on these datasets, we are able to compare MAGIC with as many *state-of-the-art*

Table 1: Datasets for batched log level detection.

Dataset	Scenario	Malicious	#Log pieces	Avg. #Entity	Avg. #Interaction	Size(GB)
StreamSpot	CNN		100	8,989	294,903	0.9
	Download		100	8,830	310,814	1.0

Figure 5: ROC curves on all datasets.

APT detection approaches as possible and explore the universality and applicability of MAGIC. we provide detailed descriptions of the three datasets as follows.

StreamSpot Dataset. The StreamSpot dataset (See Table 1) is a simulated dataset collected and made public by StreamSpot [34] using auditing system SystemTap [41]. The StreamSpot dataset contains 600 batches of audit logs monitoring system calls under 6 unique scenarios. Five of those scenarios are simulated benign user behaviors while the attack scenario simulates a drive-by-download attack. The dataset is considered a relatively small dataset and since no labels of log entries and system entities are provided, we perform *batched log level detection* on the StreamSpot dataset similar to previous works [10, 15, 17].

Unicorn Wget Dataset. The Unicorn Wget dataset (See Table 1) contains simulated attacks designed by Unicorn [10]. Specifically, it contains 150 batches of logs collected with Camflow [35], where 125 of them are benign and 25 of them contain *supply-chain attacks*. Those attacks, categorized as stealth attacks, are elaborately designed to behave similar to benign system workflows and are expected to be difficult to identify. This dataset is considered the hardest among our experimental datasets for its huge volume, complicated log format and the stealthy nature of these attacks. The same as state-of-the-art approaches, we perform *batched log level detection* on this dataset.

DARPA E3 Datasets. The DARPA Engagement 3 datasets (See Table 2), as a part of the DARPA Transparent Computing program, are collected among an enterprise network during an adversarial engagement. APT attacks exploiting different vulnerabilities [20] are conducted by the red team to exfiltrate sensitive information. Blue teams try to identify those attacks by auditing the network hosts and performing causality analysis on them. Trace, THEIA and CADETS sub-datasets are included in our evaluation. These three sub-datasets consist of a total 51.69GB of audit records, containing as many as 6,539,677 system entities and 68,127,444 interactions. Thus, we evaluate MAGIC's *system entity level detection* ability and address the overhead issue on these datasets.

For different dataset, we employ different dataset splits to evaluate the model and we use only benign samples for training. For the StreamSpot dataset, we randomly choose 400 batches out of 500 benign logs for training and the rest for testing, resulting in an balanced test set. For the Unicorn Wget dataset, 100 batches of benign logs are selected for training while the rest are for testing. For the DARPA E3 datasets, we use the same ground-truth labels as ThreaTrace [17] and split log entries according to their order of occurrence. The earliest 80% log entries are for training while the rest are preserved for testing. During evaluation, the average performance of MAGIC under 100 global random seeds is reported as the final result, so the experimental results may contain fractions of system entities/batches of logs.

6.2 Effectiveness

MAGIC's effectiveness of multi-granularity APT detection is evaluated on three datasets. Here we present the detection results of MAGIC on each dataset, then compare it with state-of-the-art APT detection approaches on those datasets.

Detection Result. Results show that MAGIC successfully detects APTs with high accuracy in different scenarios. We present the detection results of MAGIC on each dataset in Table 3 and their corresponding ROC curves in Figure 5.

On easy datasets such as the StreamSpot dataset, MAGIC achieves almost perfect detection results. This is because the StreamSpot dataset collects only single user activity per log batch, resulting in system behaviors that can be easily separated from each other. We further present this effect by visualizing the distribution of system state embeddings abstracted from those log batches in Figure 6. The system state embeddings are separated into 6 categories, matching the 6 scenarios involved in the dataset. Also, this indicates that MAGIC's graph representation module excels at abstracting system behaviors into such embeddings.

When dealing with the Unicorn Wget dataset, MAGIC

Table 3: MAGIC's detection results on different datasets. For batched log level detection, the detection targets are log pieces. And for system entity level detection, system entities are the targets.

Granularity	Dataset		Train Ratio	Ground Truth		#TP	#FP	#TN	#FN	Precision	Recall	FPR	F1-Score	AUC
				#Benign	#Malicious									
Batched log level	StreamSpot		80%	100	100	100.0	0.59	99.41	0.0	99.41%	100.00%	0.59%	99.71%	99.95%
	Unicorn Wget		80%	25	25	24.0	0.5	24.5	1.0	98.02%	96.00%	2.00%	96.98%	96.32%
System entity level	DARPA E3 Trace	All	80%	616,025	68,082	68,072	569	615,456	10	99.17%	99.98%	0.09%	99.57%	99.99%

	ThreaTrace	N/A	B	90%	95%	**99%**	0.2%
	MAGIC (Ours)	80%	B	**94%**	**97%**	99%	**0.2%**

yields an average 98.01% precision and 96.00% recall, significantly lower compared to that of the StreamSpot dataset. MAGIC's self-supervised style makes it difficult to distinguish between stealth attacks and benign system behaviors. However, MAGIC still successfully recovers an average 24 out of 25 log batches with only 0.5 false positives generated, better than any of the state-of-the-art detectors [10, 15, 17].

On the DARPA datasets, MAGIC achieves an average 99.91% recall and 0.15% false positive rate with only benign log entries for training. This indicates MAGIC quickly learns to model system behaviors. The test set in this scenario is unbalanced, which means the total number of ground-truth benign entities far exceeds that of malicious entities. Among 1,386,046 test entities, only 106,246 are labeled malicious. However, few false positives are generated, as MAGIC identifies malicious entities with outlier detection and anomalous entities are naturally detected as abnormalities.

Among the false negative results, we notice that most of them are malicious files and libraries involved in the attacks. This indicates that MAGIC excels at detecting malicious processes and network connections that behave differently from benign system entities. However, MAGIC finds it hard to locate passive entities such as malicious files and libraries, whose behaviors tend to be similar to benign ones. Fortunately, these intermediate files and libraries can be easily identified during attack story recovery, given the malicious processes and connections successfully detected.

MAGIC vs. *State-of-the-art*. The three datasets used to evaluate MAGIC are also used by several state-of-the-art learning-based APT detection approaches. For instance, Unicorn [10], Prov-Gem [15] and ThreaTrace [17] for Unicorn Wget and StreamSpot dataset, ThreaTrace and ShadeWatcher [18] for sub-dataset E3-Trace. Methods that require *a priori* information about APTs, such as Holmes [3], Poirot [5] and Morse [6], are not taken into consideration as MAGIC cannot be compared to them in the same detection scenario.

Comparison results between MAGIC and other state-of-the-art approaches on each dataset are presented in Table 4. Comparison between MAGIC and other unsupervised approaches (i.e. Unicorn and ThreaTrace) yields a total victory of our approach, revealing MAGIC's effectiveness in modeling and detecting outliers of benign system behaviors with no supervision from attack-containing logs.

Beyond unsupervised methods, Prov-Gem is a supervised APT detector based on GATs. However, it fails to achieve a better detection result on even the easiest StreamSpot dataset. This is mainly because simple GAT layers supervised on classification tasks are not as expressive as graph

masked auto-encoders in producing high-quality embeddings. Another APT detector mentioned, ShadeWatcher, adopts a semi-supervised detection approach. ShadeWatcher leverages TransR [42] and graph neural networks (GNNs) to detect APTs based on recommendation and is able to achieve the best recall rate on the E3-Trace sub-dataset. TransR, a self-supervised graph representation method on Knowledge Graphs, contributes most to the detection accuracy of ShadeWatcher. Unfortunately, TransR is extremely expensive in computation overhead. For example, ShadeWatcher spends as much as 12 hours training the TransR module on the E3-Trace sub-dataset. On the contrary, evaluation on the computation overhead of MAGIC(Sec. 6.4) shows that MAGIC is able to complete training on the same amount of training data 51 times faster than ShadeWatcher [18].

6.3 False Positive Analysis

For real-time applications, APT detectors must prevent false alarms at best effort, as those false alarms often tire and confuse security analysts. We evaluate MAGIC's false positive rate (FPR) on benign audit logs and investigate how our model adaption mechanism reduces those false alarms. Table 3 shows MAGIC's false positive rate on each dataset. Within each dataset, only benign logs are used for training and testing. MAGIC yields low FPR (average 0.15%) with large training data. This is because MAGIC models benign system behaviors with self-supervised embeddings, allowing it to effectively handle unseen system entities. Such a low FPR enables MAGIC's application under real-world settings. When conducting fine-grain entity-level detection only, MAGIC only yields 569 false alarms on the Trace dataset, with an average only 40 false alarms every day. Security analysts can easily handle this number of alarms and do security investigations on them. If the two-stage detection described in Sec. 3 is applied, the average number of false alarms every day can be further lowered to 24.

Our model adaption mechanism is designed to help MAGIC to learn from newly-observed unseen behaviors. We evaluate how such mechanism reduces false positives on benign audit logs in Table 5. Specifically, we test MAGIC on the Trace dataset under five different settings:

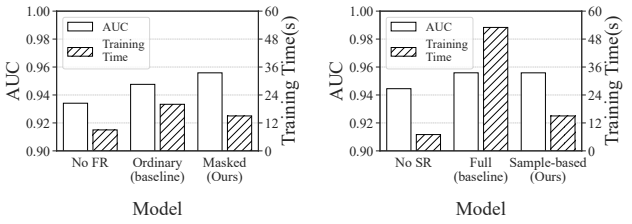
- Training on the first 80% log entries and testing on the rest 20% with no adaption, identical to our original setting.
- Training on the first 20% and testing on the last 20% with no adaption, for comparison purpose.
- Training on the first 20%, adapting on false positives generated from the following 20%, and testing on the last 20%.
- Training on the first 20%, adapting on both false positives and true negatives generated from the following 20% log entries, and testing on the last 20%.
- Training on the first 20%, adapting on both false positives and true negatives generated from the following 40% log entries, and testing on the last 20%.

Table 5: MAGIC's false positive rates on different datasets. The effect of model adaption mechanism is tested under different settings.

Dataset	Train Ratio	Adaption	Test Ratio	FPR
StreamSpot	80%	N/A	20%	0.59%
Unicorn Wget	80%	N/A	20%	2.00%
DARPA E3 Trace	80%	N/A	20%	0.089%
	20%	N/A	20%	0.426%
	20%	20% FP	20%	0.272%
	20%	20% FP & TN	20%	0.220%
	20%	40% FP & TN	20%	0.173%

Table 6: Performance overhead of MAGIC on the E3-Trace sub-dataset.

Phase	Component	Time consumption (s)		Peak Memory consumption (MB)
		with GPU	CPU only	
Graph Construction	N/A	642		2,610
Training	Graph Representation	151	685	1,564
	Detection	78		1,320
Inference	Graph Representation	5	10	2,108
	Detection	825		1,667



Experimental results indicate that adapting the model to benign feedbacks consistently reduces false positives. A further reduction can be achieved by feeding both false positives and true negatives to the model. This is because the graph representation module can be retrained with any data to enhance its representation ability, as described in Sec 4.4.

6.4 Performance Overhead

MAGIC is designed to perform APT detection with minimum overhead, granting it applicability under various conditions. MAGIC completes its training and inference in logarithmic time and takes up linear space. We provide a detailed analysis of its time and space complexity in Appendix B. We further test MAGIC's run-time performance on sub-dataset E3-Trace and present its time and memory consumption in Table 6.

In real-world settings, GPUs may not be available at all. We also test MAGIC's efficiency without the GPU. With only CPUs available, the training phase becomes apparently slower. The efficiency of graph construction and outlier detection phase is not affected as they are implemented to perform on CPUs. We also measure the max memory consumption during training and inference. MAGIC's low memory consumption not only prevents OOM problems on huge datasets, but also makes MAGIC approachable under tight conditions.

Evaluation results on performance overhead manifest the claim that MAGIC is advantageous over other state-of-the-art APT detectors in efficiency. For instance, ATLAS [11] takes about an hour to train its model on 676MB of audit logs and ShadeWatcher [18] takes 1 day to train on the E3-Trace sub-dataset. Compared with ShadeWatcher, MAGIC is 51 times faster in training under the same train ratio setting (i.e. 80%

(a) FR, on Wget dataset (b) SR, on Wget dataset

Figure 7: Effect of different reconstruction components on MAGIC's performance and efficiency.

log entries for training on E3-Trace sub-dataset).

These evaluation results also illustrate that MAGIC is fully practicable in different conditions. Considering the fact that sub-dataset E3-Trace is collected in 2 weeks, 1.37GB of audit logs is produced per day. This means under CPU-only conditions, MAGIC takes only 2 minutes to detect APTs from those logs and complete model adaption every day. Such promising efficiency makes MAGIC an available choice for individuals and small-size enterprises. For larger enterprises and institutions, they produces audit logs in hundreds of GBs every day [23]. In this case, efficiency of MAGIC can be ensured by training and adapting itself with GPUs and parallelizing the detection module with distributed CPU cores.

6.5 Ablation Study

In this section, we first address the effectiveness of important individual components in MAGIC's graph representation module, then carry out a hyper-parameter analysis to evaluate the sensitivity of MAGIC. Analysis on individual components and most hyper-parameters are conducted on the most difficult Wget dataset and the hyper-parameter analysis on the detection threshold θ is conducted on all datasets.

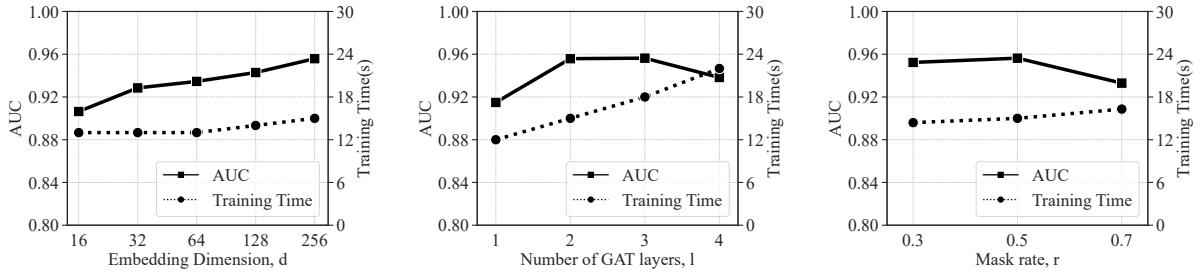
Individual Component Analysis. We study how feature reconstruction (FR) as well as structure reconstruction (SR) affect MAGIC's performance and Figure 7 presents the impact of these component to both detection result and performance overhead. Both FR and SR provide supervision for MAGIC's graph representation module. Compared with ordinary FR, Masked FR slightly boosts performance and significantly reduces training time. Sampled-based SR, however, is an effective complexity reduction component which accelerates training without losing performance, compared with full SR.

Hyper-parameter Analysis. The function of MAGIC is controlled by several hyper-parameters, including an embedding dimension d, number of GAT layers l, node mask rate r and the outlier detection threshold θ. Figure 8 illustrates how these hyper-parameters affect model performance in different situations. Hyper-parameters have little impact in most cases.

Generally speaking, relatively higher model performance is achieved with a larger embedding dimension and more GAT layers by collecting more information from more distant neighborhoods, as shown in Sub-figure 8(a) and 8(b). However, increasing d or l introduces heavier computation which leads to longer training and inference time.

The default mask rate of 0.5 yields best results. This is because MAGIC is unable to get sufficient training under a low mask rate. And under a high mask rate, node features are severely damaged which prevents MAGIC to learn node embeddings via feature reconstruction. Increasing mask rate slightly introduces more computation burden.

We further examine the anomaly scores of entities to assess the sensitive of θ. A lower θ naturally leads to a higher recall performance at the cost of more false positives and vice versa. As demonstrated in Figure 9, most malicious entities are given high anomaly scores compared with benign ones and are well-separated from them with little overlapping. The considerable spaces between benign and malicious anomaly scores support the claim that MAGIC does not depend on a precise threshold θ to perform accurate detection in practical situations. We quantify such spaces in Appendix D.



For an unsupervised detector as MAGIC, hyper-parameters are usually difficult to select. However, that is not the case for MAGIC. We provide a general guideline for hyper-parameter selection also in Appendix D.

7 Discussion and Limitations

Quality of Training Data. MAGIC models benign system behaviors and detects APTs with outlier detection. Similar to other anomaly-based APT detection approaches [7, 8, 10], we assume that all up-to-date benign system behaviors are observed during training log collection. However, if MAGIC is trained with low quality data that insufficiently covers system behaviors, many false positives can be generated. .

Outlier Detection. MAGIC implements a KNN-based outlier detection module for APT detection. While it completes training and inference in logarithmic time, its efficiency on large datasets is still unsatisfactory. To illustrate, our detection module takes 13.8 minutes to check 684,111 targets, making up 99% of total inference time. Other outlier detection methods, such as One-class SVM [43] and Isolation Forest [44], do not fit in our detection setting and cannot adapt to concept drift. Cluster-based methods and approximate KNN search may be more suitable to huge datasets. Meanwhile, KNN-based methods may be extended to GPU. We leave such improvements on our detection module to future research.

Adversarial Attacks. In Sec. 6.2, we show that MAGIC handles stealth attacks well, which avoid detection by behaving similar to the benign system. However, if attackers get to know how MAGIC works in details, they might conduct elaborately designed attacks to infiltrate our detector. We make a simple analysis on adversarial attacks and demonstrate MAGIC's robustness against them in Appendix A. As Graph-based

Figure 8: Effect of different hyper-parameters on MAGIC's performance and efficiency.

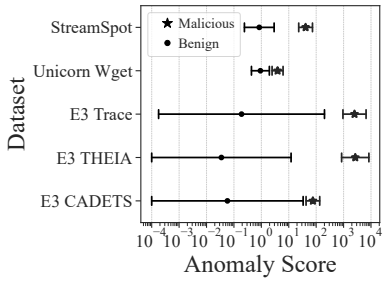

Figure 9: Anomaly scores of system entities. We exclude the highest and lowest 5% scores on each dataset.

approaches become increasingly popular and powerful in different detection applications, designing and avoiding these adversarial attacks on both the input graphs and the GNNs stands for an interesting research topic.

8 Related Work

MAGIC is mainly related to three fields of research, including the detection of APTs, graph representation learning and outlier detection methods.

APT Detection. The goal of APT detection is to detect APT signals, malicious entities and invalid interactions from audit logs. Recent works are mostly based on data provenance. As suggested by [18], provenance-based detectors can be categorized into rule-based, statistics-based and learning-based approaches. Rule-based approaches [2–6] utilize *a priori* knowledge about previous seen attacks and construct unique heuristic rules to detect them. Statistics-based approaches [7–9] construct statistics to measure the abnormality of provenance graph elements and perform anomaly detection on them. Learning-based approaches [10–18, 45] leverage deep learning to model either benign system behaviors [10, 12, 17] or attack patterns [11, 14–16, 18] and perform APT detection as classification [11, 15, 16] or anomaly detection [18, 45]. Among them, sequence-based methods [11, 14] detect APTs based on system execution/workflow patterns and graph-based methods [10, 12, 15–18, 45] model entities and interactions via GNNs and detect abnormal behaviors as APTs.

Graph Representation Learning. Embedding techniques on graphs start from the graph convolutional network (GCN) [46] and are further enhanced by the graph attention network (GAT) [30] and GraphSAGE [47]. Graph auto-encoders [19, 25–27] bring unsupervised solutions for graph representation learning. GAE, VGAE [25] and GATE [27] utilize feature reconstruction and structure reconstruction to learn output embeddings in a self-supervised way. However, they focus on link prediction and graph clustering tasks, irrelevant to our application. Recently, graph masked auto-encoders [19] leverage masked feature reconstruction and have achieved state-of-the-art performance on various applications.

Outlier Detection. Outlier detection methods view outliers (i.e. objects that may not belong to the ordinary distribution) as anomalies and aim to identify them. Traditional outlier detection methods include One-class SVMs [43], Isolation Forest [44] and Local Outlier Factor [48]. These traditional approaches are widely used in various detection scenarios, including credit card fraud detection [49] and malicious transaction detection [50]. This proves that outlier detection methods work well in anomaly detection. Meanwhile, auto-encoders themselves are effective tools for outlier detection. We explain why we do not use graph auto-encoders as anomaly detectors in Appendix F.

9 Conclusion

We have introduced MAGIC, an universally applicable APT detection approach that operates in utmost efficiency with little overhead. MAGIC leverages masked graph representation learning to model benign system behaviors from raw audit logs and performs multi-granularity APT detection via outlier detection methods. Evaluations on three widely-used datasets under various detection scenarios indicate that MAGIC achieves promising detection results with low false positive rate and minimum computation overhead.

A Analysis on Adversarial Attack

Adversarial attacks against MAGIC, such as evasion attacks and poison attacks, are tricky to implement but still possible to carry out. Two types of adversarial attacks are potentially practical against MAGIC, manipulating input audit logs or exploiting model architecture. The later approach is not an option for MAGIC's attackers, as they have no access to MAGIC's inner parameters. Similar to SIGL [45], we conduct a simple experiment concerning MAGIC's robustness against graph manipulations, which shows these attacks do not affect MAGIC's detection effectiveness.

In this experiment, we expect attackers have no knowledge of MAGIC's inner parameters and cannot get any feedback from MAGIC. However, attackers can freely manipulate the malicious entities within MAGIC's input audit logs, as well as a small proportion of benign entities. Consequently, we consider four types of attacks:

Malicious Feature Evasion (MFE). Attackers have altered the features of all malicious entities in the raw audit logs trying to evade detection. This affects the node initial embeddings of the input provenance graph and forces malicious entities to mimic benign ones in node features.

Malicious Structure Evasion (MSE). Attackers have adding new edges between malicious entities and benign ones, so that malicious entities behave more normally and tend to have local structures more similar to benign entities. This affects the graph representation module and pulls the embeddings of malicious nodes towards benign ones, making them more difficult to identify.

Combined Evasion (MCE). This type of attack is a combination of the MFE and MSE and causes malicious entities to approximate benign ones in both features and structures.

Table 7: Impact of different adversarial attack strategies on MAGIC's detection effectiveness.

Attack Type	None	MFE	MSE	MCE	BFP
AUC	0.9999	0.9999	0.9999	0.9994	0.9942

Benign Feature Poison (BFP). Attackers have manipulated the features of benign entities to poison MAGIC. Attackers have injected some benign entities with similar initial features as malicious entities, trying to convince MAGIC that the malicious entities behave normally. This shifts benign entities to mimic malicious ones in node features and gradually poisons MAGIC's detection module.

We evaluate MAGIC's robustness against the above four attack strategies on the E3-Trace sub-dataset and we present the results in Table 7. Experimental results confirm that MAGIC is robust enough against adversarial attacks. MFE has almost no impact on MAGIC's effectiveness. MAGIC is slightly more vulnerable facing the structure evasion attacks, because the graph structure is critical to unsupervised graph representation learning. However, the structure attacks are still weak against MAGIC's detection effectiveness. We believe that the feature and structure reconstruction involved in our graph representation module contributes to this robustness, as it learns a model to reconstruct both node features and its neighboring structure with the information from its neighbors. Consequently, adversarial attacks involving feature and structure altering of malicious entities will fail, and with MAGIC's model itself well-protected, attackers have to either extend their effort on searching and manipulating benign entities, or find other attack strategies against MAGIC. Meanwhile, BFP poses a relatively greater threat to MAGIC's performance. However, under BFP, only 0.057 AUC reduction is achieved by manipulating the input feature of an enormous 161,029 benign entities. This level of intervention in the benign system is beyond the capability of ordinary attackers and will definitely leave observable trace. Therefore, an effective BFP attack is also very difficult to carry out.

B Time and Space Complexity of MAGIC

Given number of system entities N, number of system interactions E, number of possible node/edge labels t, graph representation dimension d, number of GAT layers l and mask rate r the graph construction steps builds a featured provenance graph in $O((N+E)*t)$ time, masked feature reconstruction is completed in $O((N+E)*d^2*l*r)$ time and sample-based structure reconstruction takes only $O(N*d)$ time. Training of the detection module takes $O(N*logN*d)$ time to build a K-D Tree and memorize benign embeddings. Detection result of a single target is obtained in $O(logN*d*k)$ time. Thus, the overall time complexity of MAGIC during training and inference is $O(N*logN*d*k+E*d^2*l*r+(N+E)*t)$.

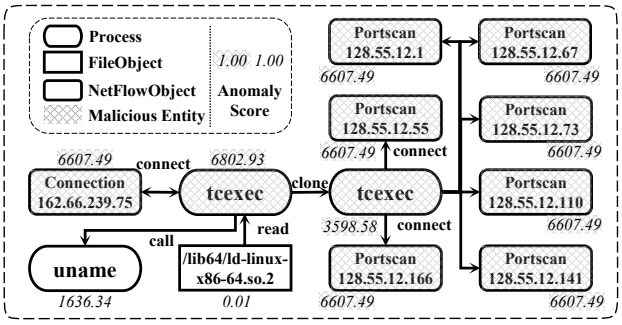

Figure 10: Another provenance graph of our motivating example (i.e. Pine Backdoor). Numbers assigned to nodes are the anomaly scores assessed by MAGIC's detection module.

MAGIC's memory consumption largely depends on d and t. The graph representation module takes up $O((N+E)*t)$ space to store a provenance graph and $O((N+E)*(t+d))$ space to generate output embeddings. The detection module takes $O(N*d)$ space to memorize benign embeddings. The overall space complexity of MAGIC is $O((N+E)*(t+d))$.

C Case Study

We use our motivating example described in Sec. 2.1 again to illustrate how MAGIC detects APTs from audit logs. Our motivating example involves an APT attack: Pine Backdoor, which implants an malicious executable to a host via phishing e-mail, aiming to perform internal reconnaissance and build a silent connection between the host and the attacker. We perform *system entity level detection* on it and obtain real detection results from MAGIC. First, MAGIC constructs a provenance graph from raw audit logs. We provide the example provenance graph in Figure 10 to illustrate. Among them, *tcexec*, *Connection-162.66.239.75* and the portscan *NetFlowObjects* which *tcexec* connects to are malicious entities while the others are benign ones. The graph representation module then obtains their embeddings via the graph masked auto-encoder. The embedding of *tcexec* is calculated by propagating and aggregating information from its multi-hop neighborhood to model its interaction behavior with other system entities. For instance, its 2-hop neighborhood is namely *Connection-162.66.239.75*, *tcexec*'s sub-process, *uname*, *ld-linux-x86-64.so.2* and other portscan *NetFlowObjects*. The detection module subsequently calculates distances between those embeddings and their k-nearest benign neighbors in the latent space and assigns anomaly scores to them. The malicious entities are given very high anomaly scores (3598.58~6802.93) that far exceed our detection threshold (3000) while others present low abnormality (0.01~1636.34). Thus, MAGIC successfully detects malicious system entities with no false alarm generated.

D Hyper-parameter Choice Guideline

The choice of detection threshold θ depends on the corresponding dataset MAGIC is operating on. However, finding a precise θ is not necessary on each individual dataset, according to Sec. 6.5. Even if there is only benign data available, users may adjust and choose the optimal θ according to the resulting false positive rate (i.e. use the first θ when false positive rate is below the desired value). Here we provide a simple analysis on how wide the threshold selection range is and what consequence selecting different θ may lead to.

Impact of Different θ Choices. Altering θ does not lead to drastic changes in detection results, especially for #FN. For example, on the E3-Trace sub-dataset, changing θ from 1000 to 5000 results in 2 more FNs and an 1% decrease in FPR. On E3-THEIA, altering θ from 100 to 500 provides 0.5% FPR decrease and does not change #FN. On E3-Cadets, setting θ as 100 instead of 10 leads to a 10% decreased FPR with only 30 new FNs generated.

Quantifing the Threshold Selection Range. By limiting FPR below 1% on entity level tasks, we get a minimum θ equals 1980 on E3-Trace, 180 on E3-THEIA dataset and 95 on E3-CADETS dataset. The resulting recalls are respectively 0.99985, 0.99996 and 0.99782. Meanwhile, the maximum θs that ensure recall > 99% are actually 6600, 1020 and 120 on the three different sub-datasets. The space between the minimum and maximum θ is big enough and the curves are flat. Consequently, MAGIC does not need a precise θ to obtain the desirable result and selecting threshold θ based on false positive rate is practical.

E Noise Reduction

Noise reduction is widely adopted by various recent works [11, 15, 17, 18] to reduce the complexity of provenance graphs and remove redundant and useless information. MAGIC applies a mild noise reduction approach as MAGIC is less sensitive to the scale of the provenance graph and more information is preserved in this way. Compared with noise reduction done in recent works [11, 18], we neither delete irrelevant nodes nor merge nodes with the same interaction behavior. This is because (1) attack-irrelevant nodes provide information for benign system behaviors and (2) multiple nodes with the same interaction behavior duplicate the information propagated to near-by nodes and impact on their embeddings.

F Auto-encoder Based Anomaly Detection

Among traditional applications of machine learning, anomaly detection via auto-encoders is common practice. Typically, auto-encoders are trained to reconstructing a target and minimize its reconstruction loss. Thus, the reconstruction loss of a newly-arrived sample indicates how similar it behaves

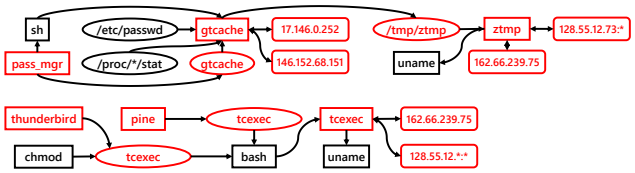

Figure 11: Attack graph of sub-dataset E3-Trace.

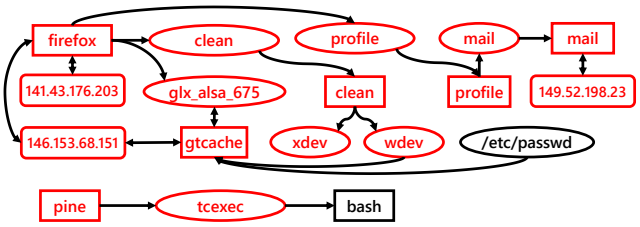

Figure 12: Attack graph of sub-dataset E3-THEIA.

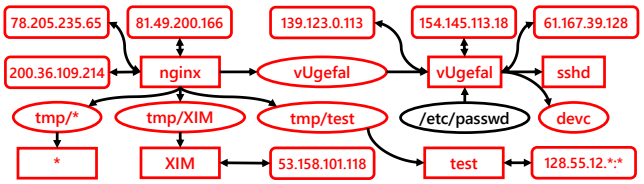

Figure 13: Attack graph of sub-dataset E3-CADETS.

to training samples and samples with high reconstruction errors are detected as outliers. However, we do not apply auto-encoder-based outlier detection because of two reasons: (1) our sample-based structure reconstruction produces high-variance reconstruction loss on single sample, which prevents stable threshold-based outlier detection and (2) MAGIC performs batched log level detection by detecting outliers in system state embeddings, which do not have a reconstruction target and cannot be compared in reconstruction error.

G Entity-level Data Labeling on DARPA TC datasets

A Feasible Labeling Methodology. Mining and labeling attack-relevant entities in DARPA TC datasets can be extremely effort-consuming, given the fact that the ground truth document they provide is practically unreadable. Recently, Watson [51] have carrited out a successful attempt to label the E3-Trace sub-dataset. We are able to repeat this labeling methodology on sub-datasets E3-Trace, E3-THEIA and E3-CADETS. The following is a detailed description on this labeling process:

• Traverse all log entries in the dataset. Among those records, we extract **process**, **file** and **netflow** entities.

• Extract entity names. Entities' semantic names are stored in different fields. For instance, *Subject.properties.map.name* stores **process** names in sub-dataset E3-Trace.

• Mine key attack-relevant entities from the ground truth document. Some attacks were not well-recorded but at least one of the attacks using the same strategy is well-recorded.

• Match the names of key attack entities with all extracted entities. The matching entities are labeled as positive. Explore the neighborhood of these entities and search for other entities that are involved in the attack. Newly-identified ones are also treated as positives.

The Resulting Ground Truth. We perform such labeling steps on sub-datasets E3-Trace, E3-THEIA and E3-CADETS and obtain the following ground truth, in the form of descriptive text and attack graphs.

• E3-Trace (Figure 11). Two successful attack attempts worked on Trace: Browser Extension and Pine Backdoor. During the Browser Extension attack, the user downloaded and executed *gtcache* via browser extension *pass_mgr*. **gtcache** communicated with the attacker, scaned sensitive information and created **ztmp** to portscan host *128.55.12.73*. In the Pine Backdoor attack, the user unfortunately launched the phishing executable *tcexec*. **tcexec** connected back to the attacker and performed a wide postscan on the local network.

• E3-THEIA (Figure 12). Three successful attack attempts worked on THEIA: Firefox Backdoor, Browser Extension and Pine Backdoor. The user was compromised by a malicious payload *clean* while browsing via *firefox*. **clean** acquired root privileges, connected back to the attacker and executed another payload *profile*. The Browser Extension attack aimed to resume the first attack by re-establishing the connection, grabbing root privileges and portscanning the local network via **gtcache** and **mail**. The Pine Backdoor attack is very similar to the one conducted on Trace but unexpectedly stopped due to missing library error.

• E3-CADETS (Figure 13). The attacker exploited the Nginx Backdoor and tried two attacks on CADETS. During the first attack, the attacker connected to a vulnerable Nginx server running on CADETS and injected process **vUgefal** with root privileges. It read sensitive information and tried to further infect the *sshd* process with malicious implants before the host crashed. The attacker then tried another attack on CADETS, resulting in a malicious process **XIM**. The attacker also created another process **test** to establish a long-lasting connection and portscan the local network.

CellularLint: A Systematic Approach to Identify Inconsistent Behavior in Cellular Network Specifications

Mirza Masfiqur Rahman*, Imtiaz Karim*, Elisa Bertino
Purdue University

Abstract

In recent years, there has been a growing focus on scrutinizing the security of cellular networks, often attributing security vulnerabilities to issues in the underlying protocol design descriptions. These protocol design specifications, typically extensive documents that are thousands of pages long, can harbor inaccuracies, underspecifications, implicit assumptions, and internal inconsistencies. In light of the evolving landscape, we introduce CellularLint–a semi-automatic framework for inconsistency detection within the standards of 4G and 5G, capitalizing on a suite of natural language processing techniques. Our proposed method uses a revamped few-shot learning mechanism on domain-adapted large language models. Pre-trained on a vast corpus of cellular network protocols, this method enables CellularLint to simultaneously detect inconsistencies at various levels of semantics and practical use cases. In doing so, CellularLint significantly advances the automated analysis of protocol specifications in a scalable fashion. In our investigation, we focused on the Non-Access Stratum (NAS) and the security specifications of 4G and 5G networks, ultimately uncovering 157 inconsistencies with 82.67% accuracy. After verification of these inconsistencies on 3 open-source implementations and 17 commercial devices, we confirm that they indeed have a substantial impact on design decisions, potentially leading to concerns related to privacy, integrity, availability, and interoperability.

1 Introduction

Cellular networks have emerged as the primary means of communication in the modern world, with 4G and 5G being the latest commercially available versions. Ranging from mobile communications to IoT devices to vehicular communications, cellular networks are a critical infrastructure for the digital world. With more than 1.4 billion subscribers, 5G is expected to exceed its much larger predecessor, 4G, and is forecast to gain more than 13 billion subscribers globally by the end of 2026 [4, 5]. These networks embody large infrastructure and support different features, including backward compatibility, interoperability, and heterogeneity.

> T_1: Whenever an ATTACH REJECT message with the EMM cause **#14 "EPS services not allowed in this PLMN"** is received by the UE ⋯ Additionally the attach attempt counter shall be reset when the UE is in substate **EMMDEREGISTERED.ATTEMPTING-TO-ATTACH**.
> T_2: **#14 (EPS services not allowed in this PLMN)**; The UE shall set the EPS update status to EU3 ROAMING NOT ALLOWED ⋯ the UE shall reset the attach attempt counter and enter the state **EMM-DEREGISTERED.PLMN-SEARCH**.

Figure 1: An example inconsistency identified by CellularLint-two different sub-state transitions for same precondition. T_1 is from section 5.5.1.1 and T_2 is from 5.5.1.3.5 of TS 24.301.

Like any large-scale, complex, layered system, cellular network designs are governed by protocol documentation. 3GPP, the 3rd Generation Partnership Project–a consortium of vendors, is the supervising body that handles the design and distribution of these protocol documents [2]. These documents are quite lengthy, developed by many stakeholders, and improved through releases and change requests over the years. Incorporating these changes and releases subsequently introduces diverging descriptions. Recently, few studies have shown, albeit through manual analysis during implementation testing, that protocol documents have inconsistent descriptions accounting for differing design possibilities and undefined behaviors in real-world devices, often with severe consequences [38, 54]. Fig. 1 shows an example scenario for diverging sub-state transitions on the same condition, found in the 4G Non-Access-Stratum (NAS) specification. Furthermore, in most cases, one of the inconsistent or conflicting behaviors is less secure than the other. For example, if one design suggests clearing some network identifier(s) after a connection has been lost while the other design suggests keeping it without specifying a clear motivation, the latter can make the user vulnerable to privacy violation attacks. Therefore, these diverging specifications defined in the standards can have severe security and privacy consequences.

Prior Research. Although prior research works [24–26, 35, 37, 38, 44, 46, 48, 54] have proposed approaches for detecting security and implementation flaws in cellular network protocols, they have at least one of the following limitations: (A) They are completely manual [26, 38, 44, 48] and inherently have limited scalability. (B) They employ formal verification [35, 37], foundationally relying on the quality of the properties, and do not primarily deal with inconsistent descriptions–subsequently choosing the most secure option when an inconsistent or confusing situation is encountered. (C) They focus on implementation testing [45, 54] and only report a few inconsistent descriptions on the way without proposing an approach to uncover them. (D) They use differential testing for noncompliance checking [38] without focusing on conflicting behavior detection in the standards. (E) They either analyze change requests or specifications through NLP techniques to understand security hazards [24, 25] without directly considering differing description analysis in specifications.

Problem. With the current state-of-the-art approaches having above-mentioned limitations, in this paper, we aim to take the first steps to answer the following research question- *Is it possible to develop a systematic, generalizable, and scalable specification analysis framework that can identify inconsistent descriptions from 4G and 5G specifications and associate them with differential design choices?*

A promising direction. Following the major advances in natural language processing (NLP) [20, 61], recent works have demonstrated the automated generation of Finite State Machine from both Request For Comments (RFC) documents and cellular network specifications [40, 53]. Such results indicate that a data-driven approach can be taken to discover inconsistencies in specifications as a root cause of design flaws and vulnerabilities as well.

Challenges. Detecting inconsistent behaviors systematically from the large and complex cellular network specifications using NLP requires tackling some very important research challenges. The first and foremost challenge is to quantize the specification into *segments*, which we can use for inconsistency detection. The specifications explain an event in a very large context; in some cases, an event is described in 5-6 pages. With such a large segment, any learning algorithm would fail to capture the finer details and attributes of the segment. Therefore, we need to devise a mechanism to create segments of reasonable size from the specifications. Second, the specifications are so large that in case all the segments are pairwise compared, the search space becomes intractable. For this, we need to devise an approach that reduces the search space substantially. Last, and most importantly, to the best of our knowledge, there are no datasets that could be utilized to detect inconsistent statements in cellular networks. In case there is a large number of inconsistencies that can be manually found, this trivially solves the problem and does not require a systematic framework. Fortunately or rather unfortunately, there are very few manually found conflicts in the specifications that can be used for closed-form solutions that we can use to train. This lack of ground truth creates a major hurdle for any learning-based solution.

Our Approach. In this paper, we introduce CellularLint–the first framework for uncovering inconsistencies from the upper layer of 4G and 5G specifications. For our method, we employ few-shot domain adaptation of language models.

To obtain a scalable solution, we initially cast the documents in sizeable segments based on domain-specific knowledge. These quantized segments preserve the context and event, which are essential before understanding inconsistencies. Second, based on this quantized pool of intra-document and inter-document test cases/segments, we produce *Pairs of Segments* (**PoS**). CellularLint compresses the search space of PoS into a manageable and informative dataset based on interpretable similarity measures. This guides our method to look into only relevant content–making the process highly scalable.

To address the lack of labeled examples, instead of heavily relying on expert annotations, CellularLint incorporates domain-aware annotations and ensemble decision mechanisms and takes only a fraction of labeled examples. We design seven domain-adapted, consistency-wise meaningful labels and map them to general-purpose natural language inference (NLI) annotations. CellularLint also utilizes human-in-the-loop active learning on multiple language models to finalize inconsistent descriptions in varying granularities.

To address the lack of supervision, we divide the learning objective into multiple phases- (1) initially converting the learning problem to a generalized setting of NLI and then (2) using multiple phases of active learning on a domain-specific dataset.

Findings. CellularLint discovered 157 conflicting descriptions from specifications. To evaluate the effectiveness of the discoveries, we investigate them on 3 open-source implementations and test them on 17 commercial UEs.

We uncover that implementations indeed take different design choices based on conflicting or inconsistent standards. Furthermore, in some cases, we have found that implementations choose the less secure option, and in some cases, tried to implement both options. For ease of discussion, we characterize a subset of our findings into four different categories–impacting security enforcement, privacy, interoperability, and causing denial-of-service. In these categories, we discuss a total of 11 issues that can have a severe impact on the privacy, integrity, availability, and interoperability of cellular network infrastructure.

Responsible disclosure and open-source. To further improve the cellular network standards, we have responsibly disclosed all our 157 findings to the 3GPP standardization body and the affected UE vendors. Furthermore, we will completely open-source CellularLint and all the detected inconsistencies to foster research in inconsistency detection in other

important protocol specifications [13] [1].

Contributions. To summarize, we make the following contributions:

- ***Framework.*** We design and implement CellularLint. To the best of our knowledge, this is the first systematic approach towards inconsistency detection for both 4G and 5G specifications.
- ***Few-shot learner.*** We demonstrate a novel few-shot approach with active multiphase learning for cellular network-specific pre-trained language models to subsidize insufficient labeled data effectively.
- ***New findings.*** We found 157 inconsistent descriptions and investigated the results on 3 open-source and 17 commercial device implementations.

2 Background

In this section, we introduce various preliminaries ranging from the 4G Long Term Evaluation (LTE) and 5G New Radio (NR) architectures to various NLP methods that are relevant to our work.

2.1 Cellular Network Preliminary

For cellular network preliminaries, here we discuss the most common components that are relevant to this paper.

2.1.1 Cellular Network Architecture

The network is composed of three main components: the user equipment (UE), the radio access network (RAN), and the core network. The architectural difference between 4G and 5G mostly lies on the RAN and Core Network side.

User Equipment (UE). The UE, a terminal device on the user end, is equipped with a Universal Subscriber Identity Module (USIM). The USIM contains the user identifier, master secret key, and session key for connectivity. These are essential for mutual Authentication and Key Agreement (AKA) between the user and the network. The most common UE are cell phones, tablet computers, and IoT devices with cellular connectivity.

eNodeB. eNodeBs or eNBs are base stations or, most commonly, mobile network towers in the 4G architecture. They stand as a middle entity in the connection establishment and maintenance for which the Radio Resource Control (RRC) protocol is implemented. eNodeB is replaced by gNodeB in the 5G network. eNodeB is responsible for transmitting and receiving signals to and from UEs.

gNodeB. The gNodeB or gNB–also called the Next-Generation NodeB–is used in 5G network. It is a significant upgrade from eNodeB. gNodeB supports Massive MIMO technology, has higher throughput, lower latency, and enables advanced network slicing.

4G-Core The core network in 4G LTE is called Evolved Packet Core (EPC). Two functional components–Mobility Management Entity (MME) and Home Subscriber Server (HSS) are relevant to our paper; hence we briefly discuss them in what follows.

- **Mobility Management Entity (MME).** The MME is responsible for handling signals between the UE and the core, as well as the eNodeB and the core. It is responsible for UE authentication, detach procedure, tracking area updates, etc.
- **Home Subscriber Server.** HSS works as a database to store subscriber information (IMEI and IMSI). It also provides relevant information for calls and IP sessions.

5G-Core. The 5G Core comprises many functional components such as the Access and Mobility Management Function (AMF), Session Management Function (SMF), User Plane Function (UPF), Authentication Server Function (AUSF), and so on. 5G leverages a large number of antennas on the core side to enhance signal quality.

2.2 ML Preliminaries

CellularLint detects inconsistencies from a natural language perspective, meaning that it focuses on the lexical and contextual analysis of the salient features of the protocol text documents to reveal inconsistencies from protocol specifications. Here, we discuss the NLP preliminaries required for CellularLint.

2.2.1 Few Shot Learning

Few-Shot Learning (FSL) [19,31] is a meta-learning approach that utilizes a pre-trained model to generalize over new categories of data using only a few labeled examples per class. For N-way-k-shot learning in NLP, given k labeled examples of each class from N classes for a new NLP task where k is generally very low, the pre-trained model has to learn efficiently to solve the new task.

2.2.2 Active Learning

Active learning [30, 52], especially human-in-the-loop active learning, is a machine learning paradigm that focuses on improving learning performance by minimizing the need to label large amounts of data. Often, domain-specific supervised learning is hindered by the insufficiency of ground truth data. Guiding the model by associating expert annotation with a subset of important data points can largely boost the performance of supervised training.

[1] https://cellularlint.github.io/

2.2.3 NLP Methods

Textual Entailment (TE). Textual entailment, or Natural Language Inference (NLI), is a binary relation where two text sequences can either form an agreement, a contradiction or be completely irrelevant to each other [17, 39]. From a NLP perspective, given two text sequences, where the first is a hypothesis and the second is a premise, the model has to find out whether the first text is in agreement with the second (or vice versa) or is in contradiction or has no logical relation.

Language Modeling. Recent years have seen revolutionary improvements in machine learning on textual data, much of which is due the use of transformers [28, 49, 62, 64, 66]. Transformers are widely used for sequence-to-sequence modeling, semantic parsing, machine translation, question-answering, and most recently for large language models. Transformers rely on the attention mechanism, which excels at learning complex linguistic patterns effectively through the understanding of each word's importance and its ability to identify its surrounding words, thereby characterizing the context.

3 Overview

In this section, we discuss the problem analysis scope and state the problem formally. Next, we discuss the challenges and corresponding approaches.

3.1 Scope of Analysis

The cellular network protocols (4G and 5G) comprise thousands of specifications–from the low layers to the link layer to the upper layers (Layer 3) of the protocols. Among all these specifications and related procedures, we focus on the NAS layer procedures. NAS layer procedures contain the mobility management and session management components, which in turn manage the most critical control plane procedures such as connection setup, initial authentication, mobility, hand-off, and service notifications. Previous works have shown several vulnerabilities in these components, resulting in severe security and privacy issues such as authentication-bypass [45], location exposure [36], impersonation [57], downgrading [41], to name a few. Keeping these in mind, in this work we focus on the NAS layer procedure. More specifically, we focus on four documents in two categories- the NAS technical specification TS (24.301, v17.6.0) [9] and the Security Architecture and Procedures specification (TS 33.401, v17.1.0) [7] for 4G, and the NAS specification (TS 24.501, v17.7.1) [8] and the Security Architecture and Procedures specification (TS 33.501, v17.5.0) [3] for 5G. All of them are available from the 3GPP archive. Release 17 is the latest complete version to have both NAS and its security specifications. Furthermore, having the same release ensures consistency and removes the possibility of unexpected inconsistency prediction (false positives) introduced by version mismatch. In fact, finding cross-version inconsistency is a different task that we leave as future work.

3.2 Problem Formulation

Here we define the problem formally: given a set of corpora $\mathcal{G} = \{\mathcal{C}^{4g}_{Nas}, \mathcal{C}^{4g}_{Sec}, \mathcal{C}^{5g}_{Nas}, \mathcal{C}^{5g}_{Sec}\}$ (where $\mathcal{C}^{4g}_{Nas}$ is the corpus produced from 4G NAS specification, $\mathcal{C}^{4g}_{Sec}$ is the corpus produced from 4G security architecture specification, similar notations are applicable for 5G), we need to quantize each corpus in text segments, that is, $\mathcal{C}_i = \{t_1, t_2, \cdots, t_n\}_i$ where t^i_a describes a-th meaningful event/sub-event/directive from corpus $\mathcal{C}_i$. Now our first objective is to construct intermediate sets, $\mathcal{S}_1 = (\mathcal{C}^{4g}_{Nas} \times \mathcal{C}^{4g}_{Nas}) \cup (\mathcal{C}^{4g}_{Nas} \times \mathcal{C}^{4g}_{Sec}) \cup (\mathcal{C}^{4g}_{Sec} \times \mathcal{C}^{4g}_{Sec})$ and $\mathcal{S}_2 = (\mathcal{C}^{5g}_{Nas} \times \mathcal{C}^{5g}_{Nas}) \cup (\mathcal{C}^{5g}_{Nas} \times \mathcal{C}^{5g}_{Sec}) \cup (\mathcal{C}^{5g}_{Sec} \times \mathcal{C}^{5g}_{Sec})$. Next, from each intermediate set $\mathcal{S}_m \in \{\mathcal{S}_1, \mathcal{S}_2\}$ containing tuples or pairs (t^i_a, t^j_b) of text Segments (PoS), our objective is to devise a model $\mathcal{M}$ which can determine all pairs that conflict between each other, that is, $\mathcal{M}(t^i_a, t^j_b) = k$. Here, k takes the value *consistent* or *inconsistent*.

3.3 Challenges & Solution Outline

We now discuss the main challenges and corresponding approaches that have driven the CellularLint's high-level design choices. We then present the key steps in our overall solution.

(C1) Segment quantization. In numerous scenarios, the specifications explain an event in a vast context. For example, in the 4G NAS specification, Section 5.5.1.2.4 describes "Attach accepted by the network", which is a six-page long description concerning one major event where the network accepts an attach request from the UE. If we consider this whole event as one complete and discrete, meaningful ***segment***, any learning algorithm will fail to capture the intricate details and attributes, causing differential and anomalous behaviors. Moreover, in the same section, there is a precondition *"If the UE indicates support for EMM-REGISTERED without PDN connection"*, which shall trigger an event on the MME side. A similar precondition is found for `tracking_are_update_request` message further away in the document. If the whole section is considered as a potential segment, one would not be able to match such sub-event triggers and may miss numerous possible interesting scenarios. An alternative choice can be selecting each sentence as an atomic unit governing a segment. However, this leads to a serious problem because, often, a single sentence from the specification is not sufficient to infer all the entities, states, or messages involved in a process. Also, due to the semi-structured nature of specifications, many sentences are repeated in different parts of the specifications. Thus, considering each sentence a meaningful segment would produce too many repeating units in the dataset, and if needed, it would be impossible to map back uniquely to the specification. Thus, this trivial solution is not applicable to

our case.

(A1) Sub-event driven segment quantization. As we have already established that considering a whole event as a segment likely affects the effectiveness and purpose of detected inconsistencies, we quantize such larger descriptions into smaller segments. However, in doing so, we preserve the completeness of the description of sub-events. We combine domain-specific understanding with standard NLP techniques to pinpoint sub-events. Specifically, we consider subsections and complete paragraphs as atomic units while constraining the sequence length and entity based on Parts-Of-Speech filtering. Details about the approach for segment quantization are given in §4.2.

(C2) Intractable search space. The protocol specifications are large documents defining and explaining all entities, events, state transitions, message structures, and so on in finer detail. Moreover, when we execute segment quantization to address **C1**, the resulting quantized dataset is even larger. Thus, traversing and matching texts directly using the entire dataset of quantized segments makes the finalized search space intractable with millions of potential segment pairs. For example, after the segment quantization, the brute-force traverse and match solution gives us more than ***12 million*** segment pairs for 5G-NAS specification alone. On top of that, to find inconsistencies, one may have to consider multiple related specifications rather than generating segments from just one. For instance, in our case, for 5G we consider the 5G NAS technical specifications and the security architecture and procedures specification. This, in turn, makes the search space tremendously larger and thereby causes a state-space explosion.

(A2) Finite segment filtration. To address **C2**, we reduce the segment sequence pair space by filtering the initial dataset based on similarity measures. The intuition behind this idea is that two completely different segments should not be considered inconsistent as they talk about totally different aspects of the protocol. Contrary to this, an inconsistent PoS would have at least the same pre-condition and hence would have a better similarity score. To achieve such a quantitative measure of texts, we first consider the vector embedding of texts. However, we observe that choosing an arbitrary embedding can severely affect the search space shrinkage and effectiveness of similarity scoring. We have thus carried out an extensive evaluation to determine the most reliable text vectorization technique for our problem. The details of the evaluation are discussed in §6.1. Thus we reduce the number of segments from millions to a few thousand–reducing the problem space to a tractable size.

(C3) Absence of ground truth. To the best of our knowledge, there are no datasets that could be utilized for NLP-based machine learning to detect conflicting statements from cellular protocols. Even if a processed, readily usable dataset existed, no closed-form solution would be able to trivially map text segments from multiple documents to specific inconsistencies. This is a novel problem–solving which is a key contribution of our work. Moreover, although state-of-the-art language models are very effective in learning contexts, they require a massive amount of labeled data due to the larger parameter landscape. Acquiring such a domain-specific dataset is often cumbersome and for this problem setup, even harder. Thus we have to design a technique that can work with only a handful of labeled examples.

(A3) Ground truth generation. We employ multi-phase supervision through human-in-the-loop active learning to subdue the insufficiency of ground truth. Our learning method neither requires a large amount of annotation nor suffers from too much uncertainty introduced by insufficient learning. In short, we first establish the learning landscape using a general-purpose dataset with some supervised data. Note that this general-purpose dataset is not from the cellular network domain but rather from image-crowdsourced caption writing and is publicly available. This intermediary model is utilized in consensus with human involvement alongside minimal synthesized data repeatedly to prepare the finalized model. The whole process never requires the complete ground truth of our problem. In fact, having a complete ground truth from the beginning is fundamentally contradictory here, as it would trivially solve the problem we have at hand. Indeed, if there were already a large number of inconsistent descriptions in specifications, then those could be directly reported to improve the protocol and would not require any additional analysis. Likewise, the lack of ground truth makes the problem both challenging and rewarding to some extent.

3.4 Approach Skeleton

Based on our discussion of challenges and approaches to the solution, we divide the inconsistency detection problem into multiple steps: (i) We employ domain-specific preprocessing alongside standard NLP techniques to quantize each $\mathcal{C}_i \in \mathcal{G}$. (ii) To produce each $\mathcal{S}_m$, we utilize an syntactic and contextual equivalence metric ψ to filter out irrelevant PoS. (iii) To address the absence of labeled examples, we use $\mathcal{M}'$ instead of $\mathcal{M}$ which first learns from a general dataset $\mathcal{P}$ to solve textual entailment task. In this task, for any two text sequences $t_x, t_y \in \mathcal{P}$, $\mathcal{M}'$ learns if t_y entails t_x or not. Formally, $\mathcal{M}'(t_x, t_y) = k'$ where k' takes the value of either entailment or contradiction or irrelevance (often called neutral). Subsequently we use $\mathcal{M}'$ with few domain-specific labeled data to generate our specialized model $\mathcal{M}$ with the learning objective of $\mathcal{M}(t_a^i, t_b^j) = k'$, where $t_a^i, t_b^j \in \mathcal{S}_m$.

4 Detailed Design

In this section, we discuss CellularLint in detail. Fig. 2 shows the main components of our framework.

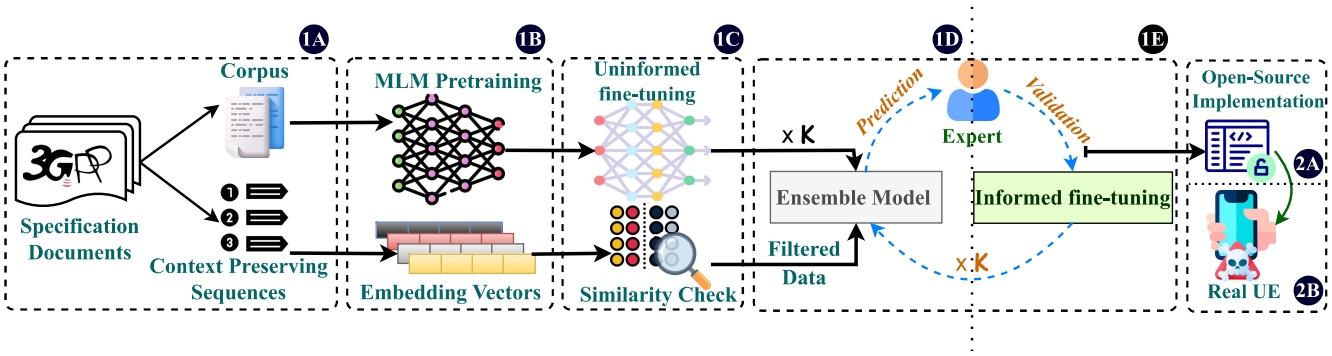

Figure 2: Architecture of CellularLint. The two-arrow process shown in 1A , 1B , and 1C represents independent and parallel processing.

4.1 Architecture

The overall framework is organized into two parts: 1 the Learner, and 2 the Dispatcher. Each of them has multiple submodules shown in Figure 2.

Learner. The learner consists of five sub-modules.

1A The ***first*** is preprocessing, which performs standard NLP preprocessing as well as domain-specific and task-specific preprocessing of all cellular network protocol specifications from the 3GPP archive. This generates a large corpus for our pre-training step. Here, a second-order preprocessing is also executed on the documents of our problem scope (NAS and Security of 4G and 5G), which produces the sub-event-oriented, context-preserving text segments. We call them context-preserving as when extracting them, our method makes sure that they do not describe multiple sections and the segments are not trimmed off halfway through an event description. For example, if a section is short and within our token limit (such as 5.3.10 in TS 24.301), we keep it as one segment. Alternatively, if a section contains multiple paragraphs (such as 5.5.3.2.3 from TS 24.301), each describing an independent event (they might be related when taken in a very large context), we consider each paragraph as a different segment. Details of the module can be found in §4.2.

1B The ***second*** sub-module is the pre-trainer. In this sub-module, we utilize the large corpus generated from the pre-processing module. This ensures that the model understands the domain with specific vocabularies and semantics. The detailed experimental setup is discussed in §5. In parallel to the training, we create embedding vectors for each segment. The embedding vectors are utilized for pairing and filtration of PoSs in the next sub-module.

1C In the ***third*** sub-module, we execute the uninformed fine-tuning. This is an important step for weak supervision and our first concrete endeavor toward task-specific learning. In short, we first fine-tune our candidate transformer models separately on the well-known Stanford Natural Language Inference (SNLI) corpus [18]. We call it uninformed supervision because the SNLI corpus contains examples that are not completely in accordance with our definition of consistency from a protocol perspective. For example, "*A group of people are ice skating in a big city.*" and "*The people are outside skating.*" are labeled as entailments in that corpus. Apparently, the second sequence is a vague representation of the first, i.e., a large and significant part of the first sequence is not expressed through the second sequence. Moreover, our main objective is to capture the protocol inconsistencies based on complex text patterns and intricate details of various cellular events for which fine-tuning on SNLI corpus is not solely sufficient. Thus, training on the SNLI corpus only gives us a loose estimate of our objective model. Nonetheless, this uninformed supervision is the first stepping stone in our analysis. In parallel, we complete the segment *pairing and filtration* based on the embedding vectors generated in the previous step. In short, we create all possible pairs of the segment vectors and filter them based on a similarity measure. Details of the method can be found in §4.3

1D At the ***fourth*** sub-module, we combine the predictions of k models on our dataset. Note that these k models are now fine-tuned on SNLI corpus from the previous step. It is known that different models have the ability to capture different semantics in varying capabilities. Therefore, combining their predictions through majority voting allows us to boost the prediction confidence. However, these models have not learned what consistency means from the perspective of cellular networks. Therefore, these predictions are not completely reliable as final output.

1E The most important sub-module for the learner is the multi-phase informed fine-tuning, which is the ***fifth*** and most crucial step. Here, we first take the ensemble prediction from the previous sub-module. Next, we sample a small subset of data from the predicted set, then validate and rectify the labels through domain-expert human annotators. This approach ensures ground truth addition while keeping the human involvement minimal. Also, rectifying annotations instead of annotating from scratch reduces the human effort even more. The models are again trained on the reconditioned examples in a supervised manner and used subsequently for predictions,

again on the whole dataset. In such a manner, we complete one phase of training. This method is followed k times (each defining a phase) before finalizing the prediction. Details on the experimental choices of this step can be found in §5.

Dispatcher. We take the high-confidence predictions as our results after multi-phase informed training and manually analyze them. To further show the impact of the inconsistent behaviors of the specifications, we use the dispatcher. The dispatcher has two sub-modules.

2A In the ***first*** one, we map the discovered inconsistent descriptions to the open-source implementations-srsRAN, open5GS, and OpenAirInterface [10–12]. Note that many boundary cases and uncommon events are not available (or available in non-granularity) in the open-source implementations. Even so, the predicted inconsistent sets are checked against these multiple sources to determine their design choices and security implications. Consequently, we create a subset of inconsistencies for the next sub-module.

2B In the ***second*** sub-module of the dispatcher, we consider each of the inconsistencies gathered from the previous step to determine whether they cause issues in real-world devices. Details of the setup can be found on our website [13].

4.2 Dataset Preparation

It has been shown that pre-training Large Language Models (LLM) can help understand domain-specific terminologies better than LLMs with no domain-specific pre-training (i.e., only pre-trained on general datasets such as Wikipedia corpus) [19, 22, 32, 55]. We first process the raw specifications from the 3GPP archive and pre-train language models on it to leverage the domain-specific learning in an enhanced capability. Our textual entailment task is a harness over the aforementioned pre-trained model. The details of the dataset preparation are discussed in what follows.

We remove the tables, figures, cross-document references, code segments, and additional ill-formed texts from the specifications to create the pre-training corpora. For the downstream fine-tuning, since we need semantically meaningful segments of texts to compare, we first extract section-wise texts. The sections usually comprise of many sub-descriptions based on cause values. Otherwise, each paragraph in a section is usually self-contained. Also, to conform to the sequence length limit of our candidate transformer models, we sometimes do finer fragmentation. In this case, sections 4 to 8 are considered for NAS in both 4G and 5G as the rest of the sections mostly contain definitions, abbreviations, glossary, scope, etc. For security, we consider section 4 to the annex for both 4G and 5G.

4.3 Pairing & Filtration

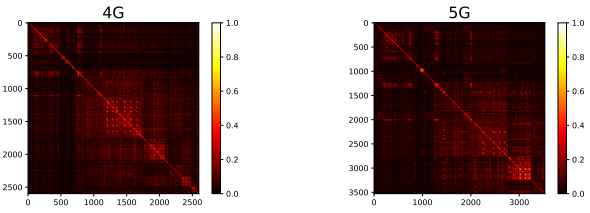
As discussed earlier, comparing all segments with each other for inconsistency will result in a massive search space, quantitatively, $\binom{N}{2}$ datapoints where N is the total number of extracted segments. To overcome this, first, we use the Term Frequency- Inverse Document Frequency (TF-IDF) to vectorize such segments (submodule 1B in Figure 2). To answer why TF-IDF is effective here, we compare five different embedding techniques–Sentence BERT (SBERT), Doc2Vec, Universal Sentence Encoder (USE), Word2Vec, and TF-IDF [21, 47, 51, 56, 60]. Among them, TF-IDF appears to be most effective (see details in §6.1).

Considering each segment to be a document, formally for a term t found in a document $d \in D$:

$$tf(t,d) = \frac{f_{t,d}}{\sum_{t' \in d} f_{t',d}}$$

$$idf(t,D) = -\log P(t|D) = \log \frac{n}{\sum \mathbb{1}_{(d \in D: t \in d)}}$$

$$tfidf(t,d,D) = tf(t,d) \cdot idf(t,D)$$



Here $f_{t,d}$ denotes the raw frequency of term t in document d. In our problem, d represents a text segment, and D represents the corpus. TF-IDF maps the text segments d in a k-dimensional latent space $\mathcal{X}$-

$$\phi : \mathcal{S} \rightarrow \mathcal{X} \quad d \in \mathcal{S}$$

In the next step, we use the cosine similarity score (ψ) to measure the similarity between each pair of TF-IDF vectors. For each vector $\mathbf{x}_1$ and $\mathbf{x}_2$:

$$\psi(\mathbf{x}_1, \mathbf{x}_2) = \frac{\mathbf{x}_1 \cdot \mathbf{x}_2}{\|\mathbf{x}_1\| \, \|\mathbf{x}_2\|} = \frac{\sum_{i=1}^{k} \mathbf{x}_{1i} \mathbf{x}_{2i}}{\sqrt{\sum_{i=1}^{k} \mathbf{x}_{1i}^2} \sqrt{\sum_{i=1}^{k} \mathbf{x}_{2i}^2}}$$

We generate the symmetric matrix of all pair similarity scores. Now, from this symmetric matrix (Figure 3), we take the lower triangular half and remove the datapoints that have $\psi < \psi_{min}$ and $\psi > \psi_{max}$. We consider the following cases when choosing values for ψ_{min} and ψ_{max}:

(a) (b)

Figure 3: Heatmap of the similarity matrices from 4G and 5G. The x and y axis represent the index of text segments extracted from the specifications. A brighter cell in the matrix represents more similarity.

- When ψ_{min} is too small, the segments are essentially describing two totally different events with a few words matched in the protocol specification. For a refined dataset, ψ_{min} should be kept relatively high.

- Using a ψ_{max} helps to filter out segments where two text segments have very small changes in vocabularies, i.e., synonymous words or changes of articles ("a" instead of "the", pronouns instead of proper noun phrases, etc.). These segment pairs state the same event with (almost) exact description.

Further evaluation and discussion for the choice of ψ are in section §6.

This gives us a very useful set of filtered PoS. For supervised training, we go through another round of filtering to remove a few common PoS that are generated from the most common sentences in the documents.

4.4 Protocol Language Entailment Annotation

We now discuss the hierarchical annotations of our dataset. The key challenge in finding inconsistencies in 4G/5G protocols is that there are no ground truth labels for model training. Thus, any supervised training task is hindered. We address this challenge by multi-phase training where the 0th phase ensures the general capability of the model in distinguishing what an entailment or contradiction is, and the next phases are to precisely capture what sort of disparity is present in our actual cellular dataset.

The Stanford Natural Language Inference (SNLI) dataset contains datapoints with 3 unique annotations, namely, *entailment, conflict*, and *neutral* [18]. Since our model is first fine-tuned on this dataset (submodule ⓭) as a 0th phase, we keep the same annotations to train the model(s) for subsequent phases. To characterize all scenarios, we consider 7 cases:

1: $t_1 = t_2$: t_1 is consistent with t_2

2: $t_1 \neq t_2$: t_1 is inconsistent with t_2

3: $t_1 \otimes t_2$: t_1 is not related to t_2

4: $t_1 \rightarrow t_2$: t_1 is related to t_2. t_1 happens before t_2

5: $t_1 \leftarrow t_2$: t_1 is related to t_2. t_2 happens before t_1

6: $t_1 \sqsupset t_2$: t_1 is related to t_2. t_1 contains more/detailed information than t_2

7: $t_1 \sqsubset t_2$: t_1 is related to t_2. t_2 contains more/detailed information than t_1

We argue that cases 1, 4, and 5 fall under entailment. Cases 2, 6, and 7 fall under contradiction. Case 3 maps onto the neutral label in the NLI task. For the contradiction class, cases 6 and 7 are difficult to perceive. We discuss this with a possible scenario. Suppose in a scenario both t_1 and t_2 independently describe the actions after an `attach_reject` is received by the UE with some specific EMM cause. Now, t_1 describes both the EPS status update and the security context clearing. In contrast, t_2 describes only the process of updating the EPS status but does not mention anything about security context clearing. This will fall under case 6. This is considered as an inconsistency because the missing security context clearing in t_2 might create confusion in the implementation design and later on cause serious security issues.

4.5 NLI Adaptation

At each phase, our annotated protocol dataset contains 150 PoS (in total 450 for three phases), whereas the SNLI dataset contains 570k English sentence pairs, which are ∼1266 times higher than the number of PoS in our dataset. Achieving even a reasonable performance is difficult if only this small dataset is used for transformer-based supervised learning, which contains millions of learnable parameters. Thus we first train transformer $\mathcal{T}$ on the SNLI dataset. This, in turn, produces a model $\mathcal{T}'$ that is ready to understand the difficult representation of conflicting statements. We then train $\mathcal{T}'$ on our 150 data points to obtain $\mathcal{T}_i''$ for each fine-tune phase i, and finally test it on the large test dataset containing 1881 PoS for 4G and 2541 for 5G. Formally, the classification task can be defined as follows. For input x,

$$h_{\mathcal{T}} = \mathcal{T}(x)$$
$$h_{fc} = W_{fc} * h_{\mathcal{T}} + b_{fc}$$
$$h_{drop} = \texttt{Dropout}(h_{fc}, p_d)$$
$$\hat{y} = \texttt{Softmax}(h_{drop})$$

where $\hat{y}$ denotes the predicted label. W_{f_c} denotes the weights of the fully connected layer with b_{f_c} being the bias. p_d is the dropout rate. The overall model can be represented as:

$$\hat{y} = \texttt{Softmax}(\texttt{Dropout}(W_{fc} * \mathcal{T}(x) + b_{fc}, p_d))$$

4.6 Few Shot Learning Optimization

We emphasize that the straightforward end-to-end training is less interpretable and not robust at all. Since we have no ground truth validation set, in order to ensure the correctness of the learning phase, we must ensure that the learning process is robust and interpretable as much as possible. Therefore, we leverage two key techniques here over the end-to-end training: ① **Transform & Ensemble.** In this method, we use majority voting of multiple transformer models. We take BERT, RoBERTa, and XLNet for this approach [28,49,66]. Note that we complete pre-training of these models before using them here. We call this ensemble model EnCell. In §6, we discuss how this approach improves the confidence of the framework. ② **Inconsistency-aware penalty.** As discussed earlier, we have a very small expert-annotated dataset, worse yet, with even fewer datapoints under the inconsistency class. In this method, we modify the standard cross entropy loss to penalize for wrong prediction on "inconsistent" labels. We use weighted cross-entropy loss:

$$\mathcal{L}_{wce} = \sum_{i=1}^{m} \hat{w}_y y_i \log \hat{y}_i, \quad \text{where } w_y = \frac{N}{n_i}, \hat{w}_y = \frac{w_i}{\sum_j^C w_j}$$

Here, N is the total number of training PoS, n_i is the number of training PoS for class i, and C is the total number of classes.

This assigns a higher penalty for misclassifying labels that have fewer PoS (in our case, the inconsistency class) than other classes.

5 Implementation

In this section, we discuss the implementation details of CellularLint.

Computational Hardware. For pre-training, we use about 2500 computing units from Google Colab pro+, which is equipped with Nvidia A100 GPUs. Multi-phase fine-tuning is performed on a computing server equipped with a 64-core CPU, 3x RTX 3090Tis, and 128GB RAM. Pre-training the base version of each model takes about 4 days in total. The uninformed fine-tuning on SNLI takes about 8-12 hours for each model, and for the informed multi-phase, each model requires different times, ranging between 10-15 minutes for each phase.

Pre-training. We use BERT-base, RoBERTa-base, and XLNET-base as our candidate models. Each of these models is first pre-trained on the specification corpus. BERT-base and RoBERTa-base work on the Masked Language Model (MLM) objective and XLNET works on the Permutation Language Model (PLM) objective. The first two are pre-trained for 5 epochs, and since XLNET-base is much larger in size, we pre-train it for 1 epoch.

Fine-tuning. We use $k = 3$ for the k-phase training. In the 0th phase with the SNLI dataset, we keep the learning rate to be 3×10^{-5} and batch size 32. The models are trained for 8 epochs. For all the consecutive fine-tuning phases, we observe that learning rate 2×10^{-5} and batch size 32 work better. The Adam optimizer with $\varepsilon = 10^{-8}$ has been used. To subsidize the low training data, we add $\frac{N}{10}$ synthetic PoS at each phase. We augment the dataset with Easy Data Augmentation (EDA) to gain these synthetic PoS [63]. For both pre-training and fine-tuning, Huggingface transformers standard pipeline based on PyTorch has been used [6].

To validate the inconsistencies in UE implementation, we prepared Software Defined Radio (SDR)-based testbeds. For details of the testbed preparation, we refer the reader to [13]. Table 5 lists the devices we tested.

6 Evaluation

In this section, we evaluate the performance of CellularLint from multiple perspectives–starting from ML training performance, identifying inconsistent descriptions of different levels, and ending with security implications. On a high level, we aim to answer the following research questions:

- *RQ1.* How does the choice of embedding affect the search space contraction?

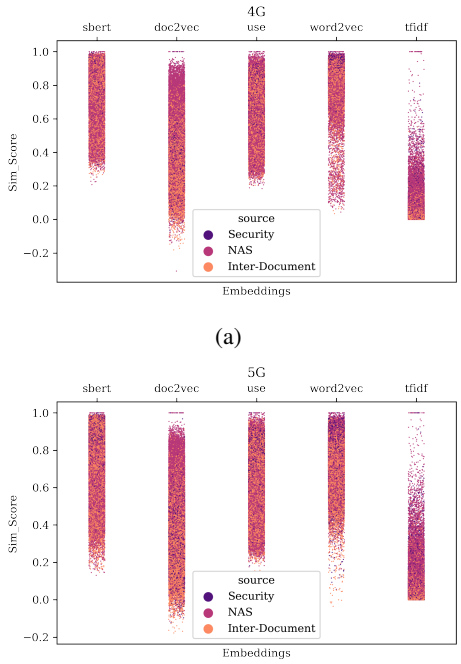


Figure 4: Embedding comparisons. Only 0.8% data were randomly sampled to generate the comparison for better visualization

- *RQ2.* What is the performance of EnCell for inconsistency classification and how do the optimization techniques affect the performance?
- *RQ3.* What are the issues found by CellularLint from specification documents and what are the security implications?
- *RQ4.* how does this methodology compare to other related approaches in terms of the final issues found?

6.1 RQ1. Effect of embedding choice

To benefit from the search space shrinkage through similarity measures, we identify the most effective embedding method for our dataset. Figure 4 presents the comparison of embeddings based on the distribution of ψ. For an embedding method ε, each point in the figure represents the ψ value of the PoS when ε is used. For better visualization, only 0.8% randomly sampled PoS are selected here. Recall that our method filters out irrelevant pairs and only considers the highly similar (syntactically) segments for further stages. Among the 5 different embeddings, namely SBERT, Doc2Vec, USE, Word2Vec, and TF-IDF, TF-IDF gives the most sparse representation on the high similarity span. It is evident from the comparison that SBERT, Word2Vec, and USE cannot be utilized to reduce the search space due to their very dense representation on the high similarity region. Doc2Vec shows

some sparsity above $\psi = 0.9$; however, the amount of PoS above that is very low. Following these results, we choose TF-IDF as our embedding technique for filtering.

6.1.1 PoS Filtration

For PoS filtering we set $\psi_{min} = 0.65$ for 4G and $\psi_{min} = 0.7$ for 5G, and $\psi_{max} = 0.99$ for both datasets. For 4G, we initially extracted 890 and 120 segments from NAS and security specifications, respectively. After sub-event driven quantization, we found 2599 unique segments for 4G. Considering all possible matches would give us ~ 6.75M datapoints, whereas our fine-grained approach limits the number of datapoints to only 1881, which is $\sim 3591x$ lower. For 5G, 846 and 329 segments were extracted from NAS and security. After sub-event realization, we found 3529 unique sequences for 5G. Considering all possible matches would give us ~ 12.45M datapoints whereas our fine-grained approach limits it to only 2541 datapoints, which is $\sim 4901x$ lower.

6.2 RQ2. EnCell performance

To evaluate how effectively the models and their ensemble EnCell adapt to the domain and classify inconsistencies, we evaluate them at each phase of the fine-tuning. Here, we show the precision, recall, F1-score, and accuracy of the models at each phase (Table 1 and Figure 5). Note that these are the $k = 0, \ldots, 3$ phases of training we mentioned in submodule ❶E of our method. Before the evaluation, all these models are pre-trained on the cellular network specification corpus and fine-tuned on the general-purpose SNLI dataset. Moreover, here all the models use weighted cross-entropy loss in all phases.

We observe that from phase 0 to phase 3, the F1 score improves about 29% for EnCell. RoBERTa performs better in the first two phases while EnCell does better in phase 3. This is expected as RoBERTa performs the best among the available pre-trained transformers on general NLI tasks. Once BERT and XLNet go through two phases of training, they start to perform in the vicinity of RoBERTa. This coherence of performance motivates the use of the ensemble approach in our task. Interestingly, although the accuracy of phase-3 RoBERTa (81.33%) and EnCell (82.67%) is similar, we observe approximately 2.9% improvement of EnCell over the F1 score of RoBERTa and 3.4% improvement over the best recall score provided by BERT. This emphasizes the need to use EnCell in an uncertain problem setting such as ours.

Effect of inconsistency-aware penalty. To understand the effectiveness of the data distribution-based weighted cross-entropy loss, we compare what happens when the general cross-entropy loss is used at phase 1 training and when the inconsistency-aware penalty is used. When general cross-entropy loss is used, we see only $3-5\%$ improvement on F1 score of our model. In contrast, the inconsistency-aware loss improves the F1 score of about $6-13\%$ at phase 1. This clearly indicates the usefulness of the penalty in our setting.

6.3 RQ3. Issues found by CellularLint

CellularLint found a total of 186 inconsistent PoS from 4G and 5G specifications. We observe that among them, there are certain scenarios that, if taken in a broader context, do not contradict. Yet the model predicts them as inconsistencies since it cannot always understand the large event at a single inference. Note that we do not consider them as false positives; provided only the context in the PoS, we can see that they are semantically conflicting. However, the additional context provided in the original specification shows that the larger context is different. In some cases, the larger context is defined 3-4 pages earlier than the original PoS.

This is a fundamental challenge for NLP-based conflict detection for cellular network protocol specifications. Therefore, we manually filter out such apparent inconsistencies and group the PoS into different categories. After filtering, we found a total of 157 PoS that may affect design choices. Table 2 shows the categorical breakdown of inconsistent pairs found by CellularLint. To do this manual filtration, we spent 6 human hours of time and found around 16% of issues detected by CellularLint had to be filtered out due to broader context.

Table 2: Conflicting statements breakdown by category

	Category	Count
4G	Integrity & ciphering	26
	Security context handling	2
	Bearer context	1
	GUTI related	41
	State transition	12
	Counters	6
	Misc	3
5G	Security key generation & handling	3
	Integrity & ciphering	3
	Timers	7
	State transition	2
	Paging	3
	PLMN handling	3
	GUTI related	3
	QoS rules	5
	PDU session establishment	30
	Counters	2
	Misc	5
	Total	157

6.3.1 Investigation of the issues

To further investigate how the discovered issues may impact design choices, we examine them against open-source 4G and 5G implementations from srsRAN (v23.04.1), Open5GS (v 2.6.6), and OpenAirInterface (v2.0.0) [10–12]. We look into both the UE and Core-Network implementations of these open-source implementations, which are widely used to analyze cellular network security [24, 25, 38]. Furthermore, in

Table 1: Precision, Recall, F1 Score, and Accuracy for the models at each phase. *Italic* represents the best performance in each phase. **Bold** represents the best overall. Model$_p$ denotes that the model has been *pretrained*.

Model	Phase 0				Phase 1			
	Precision	Recall	F1 Score	Accuracy	Precision	Recall	F1 Score	Accuracy

Table 3 and 4 report the result of our observation. Note that, even in open-source implementations a lot of functionalities are not implemented and scenarios related to protocol handovers could not be tested. To further validate the impact of the identified inconsistent descriptions, we perform end-to-end attacks in 17 COTS UE devices (Table 5). Note that here as well we could not confirm issues related to network states as it is not possible to confirm the specific substate of the commercial devices. Furthermore, we could not execute any attacks on the commercial carrier side as it is prohibited by law. Nonetheless, we have reported all our findings to 3GPP and the vendors. We want to emphasize the ultimate aim of

CellularLint is to find inconsistent statements in the specifications, and the implementation testing (both open-source and commercial UEs) is done to further validate the impact conflicting statements can have on implementation design. Though we are inherently bound by the issues we can test, we take a *best-effort* approach in validating the impacts. In the following sections, we go into our threat model and the details of the findings.

Threat model. We consider the communication channel between the core network, base station, and UE to be under the influence of a Dolev-Yao [29] attacker. In this threat model, an adversary can generate/parse messages from scratch or modify any intercepted message while not having any cryptographic capabilities. Concretely, we consider three scenarios commonly assumed in 4G and 5G: Man-in-the-Middle

(MitM), Fake Base Station (FBS), and signal injection attacks. The threat model is consistent with the existing approaches that consider real-world threats [38, 54, 65].

6.3.2 *Security Enforcement*

Finding 1. *NAS message ciphering.* After the completion of security mode procedures, the specifications suggest that, except for a few messages, all messages should be integrity-protected and ciphered. However, on two occasions (shown in Figure 6, it is emphasized that all messages after the security procedure should be integrity-protected and ciphered. Failure to enforce integrity and ciphering is a serious design flaw and can leave implementations subject to vulnerabilities and interoperability issues.

> T_1: From this time onward the UE shall cipher and integrity protect all NAS signalling messages with the selected NAS ciphering and NAS integrity algorithms.
> T_2: From this time onward, all NAS messages exchanged between the UE and the MME are sent integrity protected and **except for the messages** specified in clause 4.4.5, all NAS messages exchanged between the UE and the MME are sent ciphered

Figure 6: Ciphering exceptions. T_1 is from section 5.4.3.3 of TS 24.301 and T_2 is from section 4.4.2.5 of TS 24.301

Inconsistency to exploit. In the case of T_1, the specification states after the security context has been established, the UE shall cipher and integrity protect all NAS signaling messages with selected NAS ciphering and integrity algorithms. However, T_1 does not mention the scenarios where the UE accepts plain-text messages. On the contrary, T_2 is more lucid and explicitly mentions such scenarios. Due to this inconsistency of not explicitly mentioning exception cases, an implementation might accept unexpected plain-text messages even after the security context is established. Therefore, we design an attack based on this scenario.

Attack. For the attack, the adversary connects with a victim UE through a fake base station to send plain-text `identity_request` or `authentication_request` [54]. Similarly, the attacker can overshadow downlink packets to create plain-text messages. The affected UE accepts, processes and responds to the messages.

Investigation. In open-source implementations, we found all implementations accepting plain-text `authentication` and `identity` requests even after the security context has been established. On the other hand, on commercial UEs, we found 4 UEs accepting and responding to such plain-text messages (Table 6). Interestingly, for a very recent UE (Google Pixel 7a, 2023), plain-text `authentication_request` is accepted, whereas plain-text `identity_request` is not accepted. This is another interesting scenario where vendors try to implement different behaviors for different exception case messages.

Impact. The impact of accepting plain-text or integrity-failed NAS messages can be catastrophic and can be exploited by attackers to fingerprint users, traceability, and denial of service attacks. Note that DoLTEst [54] also reports several UEs accepting unprotected messages after the security context has been established, albeit from the implementation testing perspective. We, on the other hand, show that this issue in different implementations can be traced to the inconsistent behavior defined in the standards.

Finding 2. *Condition over integrity check.* On many occasions, the UE sets the counter for "SIM/USIM considered for GPRS/non-GPRS/5GS services" to implement a specific maximum value (Figure 7). While this flexibility is acceptable and standard practice, the precondition to check the integrity of the received message is often neglected.

> T_1: The UE shall consider the USIM as invalid for EPS services and non-EPS services until switching off or the UICC containing the USIM is removed or the timer T3245 expires as described in clause 5.3.7a. Additionally, the UE shall delete the list of equivalent PLMNs and enter state EMM-DEREGISTERED.NO-IMSI. **If the message has been successfully integrity checked** by the NAS and the UE maintains a counter for "SIM/USIM considered invalid for GPRS services", then the UE shall set this counter to UE implementation-specific maximum value.
> T_2: The UE shall consider the USIM as invalid for EPS services until switching off or the UICC containing the USIM is removed or the timer T3245 expires as described in clause 5.3.7a. The UE shall delete the list of equivalent PLMNs and shall enter the state EMM-DEREGISTERED.NO-IMSI. If the UE maintains a counter for "SIM/USIM considered invalid for GPRS services", then the UE shall set this counter to UE implementation-specific maximum value.

Figure 7: Condition over integrity check. T_1 is from section 5.5.1.2.5 and T_2 is from section 5.5.2.3.2 of TS 24.301.

Inconsistency to exploit. In the case of T_1, the protocol specifies successful integrity checking by the NAS. However, in T_2, this integrity checking is skipped. These PoS are related to `attach_reject` and `detach_request`. However, we have also found instances of network-initiated `detach_request`, where there are inconsistencies. As the inconsistency is related to the integrity checking of messages, the attack steps and impact are the same as finding 1.

Investigation. In the case of open-source implementation, we see that all the open-source implementations in both 4G and 5G are vulnerable. However, in the case of commercial UEs, there were no instances of vulnerable behavior.

Finding 3. *Integrity check failure.* We found two conflicting PoS where different statements are found for failed integrity checks of the control plane messages (Figure 8). Following this PoS to 4G security specification, ultimately, we found three (one segment is common) instances of different statements. Two of them clearly suggest that messages that have faulty MAC should be discarded, whereas the third one directs to a slightly flexible strategy suggesting the processing of certain messages even if they fail integrity checks.

Inconsistency to exploit. In T_1, whenever there are some exceptional NAS messages that can trigger further MME actions, even with failed integrity, the specification mentions that. However, in T_2 for RRC, it does not specify such exceptional cases, though such exceptional cases exist, for instance, when `RRC_connection_resume` fails an integrity check, rather than just discarding, there are further steps. Through further

T_1: In case of failed integrity check (i.e. faulty or missing MAC-I) is detected after the start of integrity protection, the concerned message shall be discarded. This can happen on the UE side or on the eNB side
T_2: In case of failed integrity check (i.e. faulty or missing NAS-MAC) is detected after the start of NAS integrity protection the concerned message shall be discarded **except for some NAS messages** specified in TS 24.301 [9]. For those exceptions the MME shall take the actions ⋯ NAS message with faulty or missing NAS-MAC

Figure 8: Allowing exceptions for integrity failure. T_1 is from section 7.3.2 and T_2 is from section 8.1.1 of TS 33.401.

manual analysis, we find these cases are not mentioned in the TS 33.501 (Security architecture and procedures for 5G Systems) specification but in TS 38.331 (RRC specification), which were not included in the scope of CellularLint. In a practical scenario, an implementor would use the RRC specification first, which clearly states exceptional messages with failed integrity. But later on, when the security specifications would be taken into account, the implementor would find it confusing with a more strict description. There is a possibility that such inconsistency may not directly result in vulnerabilities. Still, it may cause differing implementations as both specifications cannot be logically taken into consideration at the same time. Hence, some implementations might not properly follow the integrity failing scenarios.

Investigation. In open-source implementations, we found 1 implementation accepting integrity-failed messages. On the contrary, in commercial UEs, none of the UEs accept control-plane messages with failed integrity. However, in our investigation, we found another interesting behavior: 16 UEs dropped the connection after receiving an RRC packet with failed integrity, whereas 1 UE did not (Table 6). These inconsistent UE behaviors can be traced back to T_2, which does not properly specify the exception cases and what to do in such scenarios.

Finding 4. *NCC reusage.* We found a conflicting PoS in the 5G Security specification where two different conditions are expressed for the validity of the Next hop Chaining Counter (NCC) (shown in Figure 9). NCC is used for cryptographic derivation of the AS security algorithms and, hence, is a very important identifier. One segment dictates that the NCC value has to be *fresh* and previously *unused* to be accepted. On the contrary, the other segment claims that the only condition for acceptance is that the NCC value has to be *different*.

T_1: If the sent NCC value is **fresh** and belongs to an **unused pair** of NCC, NH, the gNB shall save the pair of {NCC, NH} in the current UE AS security context and shall delete the current AS key K_{gNB}.
T_2: The UE shall take the received NCC value and save it as stored NCC ⋯ . If the stored NCC value is **different** from the NCC value associated with the current KgNB, the UE shall delete the current AS key K_{gNB}

Figure 9: Underspecified action for NCC. Both T_1 and T_2 are from section 6.8.2.1.2 of TS 33.501

Implication. NCC and NH are critical parameters that are used to establish AS security and derive K_{gnb}. These parameters are used during the `RRC_Reestablish` procedure to re-establish the RRC connection. This procedure is particularly important during handover. The expectation is that these

Table 5: List of devices tested

session key creation parameters (NCC and NH) would be fresh and unused to create diverse keys (precisely described in T_1). This is an important assumption ensuring forward and future secrecy guarantees of the keys. Forward and future secrecy ensures that the protocol defends the past and future sessions even if the current session is compromised [16]. These parameters are essentially used as nonces to ensure the diversification of the keys. However, if the fresh and unused NCC/NH value usage is not mandated, then the forward and future secrecy guarantees can be broken. Furthermore, as the `RRC_Reestablish` message (containing these parameters) is unencrypted, the attacker can easily detect the sessions where the same NCC/NH values are used for key derivation.

Investigation. We found that none of the open-source implementations properly check these parameters and just accept if they differ from the previously accepted ones.

6.3.3 Privacy

Finding 5. *GUTI deletion.* On many occasions, when a reject message is received from the network, the UE updates its EPS/5GS status, clears the context, and subsequently moves to a deregistered state. We observe that in many cases, a rejection cause $\mathcal{T}_C$ in a reject message $\mathcal{R}_M$ would suggest the UE to clear the context and move to deregistered state while the same cause $\mathcal{T}_C$ would keep the UE in registered state without clearing the security context (shown in Figure 10). For example, 5GM cause #13 received through `registration_reject` suggests the UE to delete

GUTI, TAI, ngKSI while the same cause received through `tau_reject` or `service_reject` message would keep the UE in a registered state without deleting the context. A cross-examination may suggest that since the messages are different, the same cause may trigger different behavior. However, other cause values such as #12 (tracking area not allowed) trigger similar behavior and state transition for different reject messages. Thus, it concretely verifies the conflicting suggestions about security context.

> T_1: #13 (Roaming not allowed in this tracking area) The UE shall set the 5GS update status to 5U3 ROAMING NOT ALLOWED (and shall store it according to subclause5.1.3.2.2) and shall **delete 5G-GUTI, last visited registered TAI, TAI list and ngKSI**
> T_2: #13 (Roaming not allowed in this tracking area) The UE shall set the 5GS update status to 5U3 ROAMING NOT ALLOWED (and shall store it according to subclause5.1.3.2.2) and shall delete the list of equivalent PLMNs (if available).

Figure 10: GUTI, TAI, eKSI deletion. T_1 is from section 5.5.1.2.5 and T_2 is from section 5.5.1.3.5 of TS 24.501.

Inconsistency to exploit. GUTI (Globally Unique Temporary ID) is a kind of temporary ID used to identify UEs. Each UE has a couple of different kinds of unique IDs, like IMSI, IMEI, etc. These sorts of temporary identifiers, like GUTI, are used to prevent attackers from tracking users. However, if these identifiers are not changed or reset, this can cause several privacy issues. An adversary can utilize old GUTI to track a UE through a linkability attack, violating privacy [33].

Investigation. In commercial UEs, we found a total of 16 devices not properly deleting GUTI for these reject messages (Table 6). One recent UE (Apple iPhone 12 Pro), however, deletes the security context with GUTI after receiving `service_reject`.

6.3.4 *Denial of Service*

Finding 6. *TAU and detach collision.* We found a PoS of conflicting directions when TAU and detach procedure collide (shown in Figure 11). The first one states that the `tracking_area_update` procedure shall be aborted and the `detach` procedure shall be progressed. On the other hand, the second segment states that the `detach` procedure shall be aborted and re-initiated while the `tracking_area_update` procedure is fully performed.

Inconsistency to exploit. An attacker can achieve downgrade/denial-of-service by injecting `detach_request` through fake-base-stations or signal-injection attacks [35]. In this case, an implementation that aims to implement both scenarios can exacerbate the situation by creating a deadlock state. As the statements are mutually exclusive either way,

T_1: Tracking area updating and detach procedure collision
EPS detach containing detach type "re-attach required" or "re-attach not required": If the UE receives a DETACH REQUEST message before the tracking area updating procedure has been completed, the **tracking area updating procedure shall be aborted** and the **detach procedure shall be progressed**.
T_2: If a cell change into a new tracking area that is not in the stored TAI list occurs before the UE initiated detach procedure is completed, the UE proceeds as follows: 1) If the detach procedure was initiated for reasons other than removal of the USIM or the UE is to be switched off, the **detach procedure shall be aborted** and re-initiated **after success- fully performing a tracking area updating procedure**.

Figure 11: TAU and Detach Procedure precedence conflicts. T_1 is from section 5.5.3.2.6 and T_2 is from section 5.5.2.2.4 of TS 24.301.

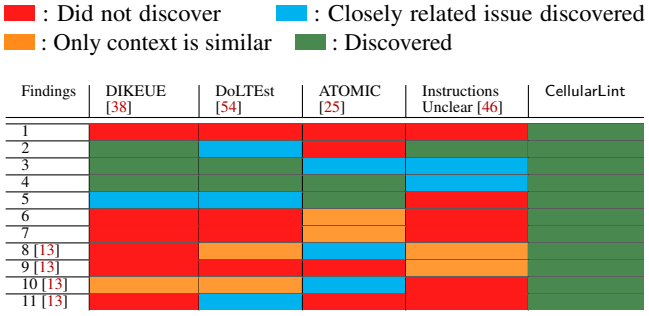
an implementation violates the specification. In our investigation of commercial implementation, we found all the UEs progress with the `tracking_area_update` procedure when such collision occurs (Table 6).

6.3.5 *Interoperability*

For this class of inconsistencies, we could not devise an attack scenario. However, these inconsistencies range from specifying different sub-state transitions for the same condition to missing timer expiration directives. The potential impact of these inconsistencies can cause interoperability issues between different implementations, i.e., one implementation following one directive and the other one following a different directive. For brevity, one of them is discussed here; we discuss the rest in [13].

Finding 7. *Sub-state transition confusion.* When `attach_reject` message is received with the emm cause #14, the 4G specification has differing state transition descriptions (shown in Figure 1). This certainly can cause confusion in implementation design.

Investigation. While looking further into open-source implementations, we found a very interesting scenario regarding this. In srsRAN, we see that the developers tried to implement both of them. We show the code snippet of srsRAN in Figure 12. Here, we can see that both of the conditional statements contain the same cause (lines 1 and 6) but have different sub-state transitions (lines 3 and 7). Of course, UE will go to the *EMM_DEREGISTERED.PLMN_SEARCH* substate due to the obscurity of the first "if". Such conflicts can potentially cause interoperability issues, leaving a possibility for further synchronization problems.



Finding 8 is about registration counter resetting, *finding 9* is about utilizing/not-utilizing timer expiry as a precondition, *finding 10* is about utilization of service attempt counter, *finding 11* is about PDCP counter resetting. We refer the interested reader to [13] for details.

6.4 RQ4. Comparison of other methodologies

```
1 if (...|| attach_rej.emm_cause ==
     LIBLTE_MME_EMM_CAUSE_EPS_SERVICES_NOT_
     ALLOWED_IN_THIS_PLMN ||...){
2    attach_attempt_counter = 0;
3    enter_emm_deregistered(emm_state_t::
     deregistered_substate_t::attempting_to_attach);
4 }
5 // TODO: handle other relevant reject causes
6 if (...|| attach_rej.emm_cause ==
     LIBLTE_MME_EMM_CAUSE_EPS_SERVICES_NOT_
     ALLOWED_IN_THIS_PLMN ||...) {
7    enter_emm_deregistered(emm_state_t::
     deregistered_substate_t::plmn_search);
 }
```

Figure 12: srsRAN implementation of emm cause #14

Table 7: Comparison with existing approaches.

Although to the best of our knowledge CellularLint is the first approach to detect inconsistencies from cellular specifications, we compare our methodology with the existing approaches based on the issues discovered. Table 7 shows comparison results based on the subset of findings presented in the paper. In terms of methodologies we compare with DIKEUE and DoLTEst that are implementation testing frameworks and, therefore, are not directly comparable to our methodology. The closest methods that deal with specification descriptions are [25] and [46]. We compare with respect to four characteristics: (1) if the issue was discovered, (2) if the context aligned to the issue has been discussed, (3) if a related root cause has been discussed, and (4) if the issue has not been discussed at all.

7 Related Works

We discuss the related works in three categories:

NLP efforts. Sequence classification tasks, especially supervised textual entailment, have largely been used recently in various domains and applications [18, 25, 34, 58, 59]. In contrast to those techniques, Andow et al. [14, 15] use Named Entity Recognition to leverage a rule-based approach for detecting privacy leaks in privacy policies of Android apps. The method, however, considers domain-specific assumptions for

ontology structuring and is not generalizable to cellular protocol documents.

NLP for cellular network. In recent days, NLP research in cellular networks has been gaining popularity due to the enormous information and the emergence of large language models. For instance, methodologies have been proposed to automatically analyze specification, RFC, and Change Request documents in various problem setting [23–25, 40, 42, 53]. Pacheco et al. [53] designed an approach that automatically builds state machines from RFC protocol documents using a data-driven zero-shot approach and synthesizes attacks based on that. Ishtiaq et al. [40] take a similar approach to synthesize FSM from 4G and 5G specifications. Chen et al. [25] discover Hazard Indicators (HI) from 4G specifications and verify implementations against them. Briefly, they input Risky Operation Description (ROD) and threat models in their framework and run a textual entailment model to find the HIs from which the test cases are generated. While they generate test cases from individual text descriptions, our method does a differential analysis on pairs of descriptions to generate test cases. A conformance testing approach has also been proposed based on NLP and causal relation extraction [23]. However, these methods do not primarily focus on inconsistencies in standards.

Vulnerability detection in cellular networks: Over the years a lot of work has focused on finding issues in various generations of cellular network design and implementation using formal verification [27, 37], dynamic analysis [45], differential testing [38], fuzzing, etc. Klischies et al. [46] consider underspecifications from protocol standards that are closely aligned with our goal. Baseband firmware analysis has also been effective in finding implementation issues [1,43,50]. However, these methods do not relate the root causes of implementation issues to the protocol standards.

8 Discussion

Manual efforts and limitations in CellularLint. Although CellularLint can discover conflicts under weakly supervised settings, there is still some manual labor involved. During the active learning phase, the annotators have to cross-examine the predictions from the model and refine them accordingly. This required approximately 16 human hours from domain experts. Furthermore, one of the critical limitations of CellularLint is that there are certain inconsistent PoS that, when taken into a broader specification context, are no longer inconsistent. This issue, with a larger context, requires manual efforts to parse through the results of CellularLint and filter out. This, in some sense, is the limitation of current NLP models that are unable to take into account this large context of cellular network specifications. To provide an example, in some cases, the context is defined 3-4 pages before the actual segment. It took about 6 human hours to detect the false positive from the final results.

Inconsistency-to-attack scenario. The aim of CellularLint is to find inconsistencies in the 4G and 5G specifications. As mentioned in §6.3.1, the design from inconsistent PoS to concrete attacks is a manual effort. We look into the POSs to uncover whether these design choices can lead to an attack. We want to emphasize that not all inconsistencies can lead to exploitable attacks. Similarly, as this part of the findings is manually designed, there can be other inconsistencies that lead to exploitable attacks but are not discussed in detail in the paper. Therefore, we open-source the list of major inconsistencies [13].

Implementation vs. specification issues. In terms of security issues in the 4G and 5G, they can be characterized in either one of the two categories: issues stemming from the specification design or from the implementation design. In this paper, we focus on the first category. For instance, the issues in findings 1 and 3 can be categorized as implementation issues where the UE accepts plain-text or integrity-failed messages. However, we focus on the specification consistency. The aim of our work is to clear scenarios in the standards that can cause inconsistencies in the implementation. We believe our work would inspire further specification-based textual analysis and ultimately realize the goal of machine-readable specifications.

Scalability and relevance to further security research. CellularLint is designed in a fashion that can be almost readily used for other cellular specifications and, with some training effort, can be utilized for other communication (non-cellular) protocols. For other cellular specifications, one can use the pre-trained+SNLI-fine-tuned state of EnCell. Only the last fine-tuning step with a low amount of data would be required. For completely different communication protocols, one can utilize the methodology of CellularLint to pre-train and fine-tune the models. Pairing and filtration, PoS selection, and optimization techniques would still follow the same methods. Furthermore, the impact of CellularLint is not limited to cellular network security, it can be applied to enhance the security of other communication protocols as well.

Impact of tables, figures and codes. While preprocessing, we removed tabular data, figures, and code snippets. These artifacts can potentially add more information to decide which of the text pairs are more secure. For example, CellularLint captured an inconsistent description regarding EAP-TLS authentication procedure, which we had to verify as a false positive manually. However, figure B.2.1.1-1 under Annex B.2 in TS 33.501 describes a timing diagram of that authentication procedure more clearly. Considering this could potentially help CellularLint capture the false positive in initial stage of analysis. Moreover, developers often focus on the finite state machines presented through the figures. Thus, learning from these artifacts alongside texts could strengthen the learning process, and we leave it as future work.

9 Conclusion and future work

In the paper, we propose CellularLint to detect inconsistencies in cellular protocol specifications in a scalable fashion. CellularLint uncovers 157 inconsistencies with 82.67% accuracy in the NAS and security specifications. After verification of these inconsistencies on open-source implementations and commercial devices, we confirm that they indeed have a substantial impact on design decisions, potentially leading to concerns related to privacy, integrity, availability, and interoperability.

Future work. In the future, we will work on improving CellularLint to include further context and improve the accuracy. Furthermore, we will aim to detect underspecifications with NLP techniques.

Abstract

On-device ML is increasingly used in different applications. It brings convenience to offline tasks and avoids sending user-private data through the network. On-device ML models are valuable and may suffer from model extraction attacks from different categories. Existing studies lack a deep understanding of on-device ML model security, which creates a gap between research and practice. This paper provides a systematization approach to classify existing model extraction attacks and defenses based on different threat models. We evaluated well known research projects from existing work with real-world ML models, and discussed their reproducibility, computation complexity, and power consumption. We identified the challenges for research projects in wide adoption in practice. We also provided directions for future research in ML model extraction security.

1 Introduction

Internet of Things (IoT) applications have seen a growing trend in adopting on-device machine learning (ML). This allows for the execution of ML models directly on the IoT devices, enhances user experiences, optimizes system performance, and enables intelligent decision-making at the edge. This trend is now boosted by new AI chips available in the latest devices such as Apple's Bionic neural engine, NVIDIA's Jetson series, Google's Coral Dev Board, and Qualcomm's AI-optimized SoCs [1]. Nowadays, modern smartphones come equipped with on-device ML capabilities, and some even have dedicated AI accelerators for tasks such as image recognition, language translation, and predictive text input. Even Large Language Models (LLM), such as The MLC Chat, can run locally on Android devices with the latest Snapdragon chip [12].

Although executing ML tasks in the cloud for IoT applications offers convenience to developers, it comes with security implications. First, user-private data are shared with the cloud and can be leaked to network attacks, or other users sharing the cloud. Second, cloud-based ML can cause latency, which decreases the performance of real-time applications such as intrusion detection [35, 114, 115]. Whereas, on-device ML avoids sending private user data to the cloud, and provides real-time responses. For example, autonomous vehicles utilize on-board ML models for real-time object detection, pedestrian recognition, and decision-making without constant reliance on cloud-based services. Smart speakers such as Amazon Echo or Google Home use on-device natural language processing (NLP) models to understand and respond to voice commands without relying entirely on cloud processing [127]. However, on-device ML introduces a new security challenge—the valuable, proprietary, and possibly security-critical ML models are now deployed on user-end devices, and adversaries may attempt to extract these models from devices, causing model stealing or extraction attacks [112].

The extraction of ML models from IoT applications can lead to both financial concerns and security implications. Intuitively, commercial ML models are the core intellectual property of model vendors. A leaked model gives away the research and development cost of the model owner, and may result in unethical business competition [112]. Further, IoT applications handle sensitive data, ranging from biometric information to personal preferences, and a leaked model poses a direct threat to compromise these sensitive data. This is because a leaked model can equip attackers with grey-box information (e.g., partial models, recovered models), or even white-box information (e.g., plaintext models), and allow attackers to perform further attacks more conveniently and accurately. For example, attackers can craft adversarial examples to deceive IoT users in decision-making, perform membership interference attacks to reveal sensitive training data or even data poisoning and model poisoning attacks [46, 74, 113] if the models need to be updated later. These attacks can lead to privacy violations and unauthorized use of the data collected by IoT devices [95]. In addition, ML models can be used for safety- and security-critical functions (e.g., climate forecasting, face authentication), and leaked models will allow attackers to bypass the safety or security check [133].

*The first two authors contributed equally to this work.

In performing and defending model extraction attacks, respectively, existing research has explored various techniques. From the attacker's perspective, existing works have explored decomposing [32] and decompiling techniques [42], runtime memory extraction [123], side-channel attacks [109], and data mining techniques [101] to extract valuable ML models. To defend against model extraction attacks, defenders have explored Advanced Encryption Standard (AES) [58], Homomorphic Encryption (HE) [132], Trusted Execution Environment (TEE) [45], data transformation [35], and various learning algorithm-based protection techniques [88]. While there have been advances in model extraction security, existing efforts have often been ad-hoc and fragmented. Together with the rapid advances in ML, it becomes challenging for researchers and practitioners to have a comprehensive understanding of all aspects of model extraction attacks. This gap hinders the development of robust security techniques, including issues related to privacy, optimization, and computation.

This research aims to contribute to building greater trust in IoT devices adopting on-device ML, and relieving privacy concerns in leaking sensitive user information. Specifically, we design a general framework to systematize existing studies in model extraction attacks and defenses. We define four categories of threat models, including app-based, device-based, communication-based, and model-based attacks and defenses. We focus on studies investigating Android-based applications and Arm-based devices, due to their popularity in serving on-device models [8]. Our investigation highlights a significant issue within the research community: many research projects, although innovative, may not be open source, or cannot be reproduced in practice, and the amount of effort in project deployment and maintenance prohibits the wide adoption of these projects. We further chose representative projects from each category of threat models and evaluated them with real-world ML models. We found that when research projects are applied to real-world ML models, they may not produce as good performance as reported in the paper. The computation complexity and power consumption can also be high. Our code in reproducing and evaluating existing projects is open-source[1]. Last, we point out the open challenges in applying these projects to practice, and future research directions for researchers and practitioners to enhance on-device ML security. Our investigation can be beneficial to myriad technologies ranging from ML training and inference, IoT and Android app development, IoT sensing, data communication, and secure memory design and development.

Note that although ML models can suffer from a range of attacks, including model pollution attacks [33], model stealing attacks [50], membership inference attacks [107], etc., ***this paper focuses on ML model extraction or stealing***.

2 Model Extraction: Security Design

This section provides context for later discussion. We give a high-level overview of the security design of model extraction techniques. Our goal is to describe the threat models, the security techniques, the methods, and the effective stages of model extraction. These factors will contribute to a general framework to analyze the challenges in preventing model extraction attacks.

2.1 Threat Models

We categorize existing works into four distinct types of threat models, from attacker's and defender's perspectives, respectively.

2.1.1 Attacker's perspective

App-based attacks: attackers assume they can gain access to the application files either through the public application marketplace, or through a vulnerability within the IoT devices. Attackers will perform application de-packaging or decompiling [112], and extract the model files [41, 80, 112, 129]. These model files can be either usable plaintext models or encrypted and obfuscated models. Attackers can directly utilize plaintext models or employ decryption and deobfuscation tools to reverse the plaintext model.

Device-based attacks: attackers assume they can access the IoT devices and gain access to the memory [112]. Attackers can either force a vulnerable application to launch and load ML models into memory or consistently scan the memory to wait for models to be loaded. Attackers assume that, no matter how many times the models have been encrypted/obfuscated, plaintext copies of ML models will eventually be loaded into memory so that the vulnerable application can actually use the models. Attackers also assume to have knowledge of the in-memory format of models. This is possible for well known frameworks, such as TensorFlow and PyTorch.

Communication-based attacks: attackers can intercept communication between various memory regions and hardware architectures on an IoT device. This communication data can encompass application runtime data, hardware usage records [59, 83], memory usage [67], electromagnetic [134] and power-related data [128]. Attackers assume to leverage these data to recover partial or complete details of ML models, including their structure and weights, or infer functionally equivalent models.

Model-based attacks: attackers assume to be able to send (selective) input queries to the models and observe the ML inference results. Attackers assume the ability to use the pairs of (sent data, and received inference results) to assess the functionality of models and fine-tune the data to send in subsequent steps. Attackers then go through the above process and train substitute models [96]. Attackers sometimes assume

to leverage pre-trained models to improve the accuracy of training substitute models or employ large-scale datasets or distributed methods to send query requests to the target models. Attackers can even use intelligent query agents and more advanced techniques to enhance query efficiency [86].

2.1.2 Defender's perspective

App-based defense: defenders assume that attackers can get access to an app package, and extract the model files from the app package. Defenders apply techniques, including encryption, obfuscation, or customized protection to model files in an app package. The files can contain model layers, weights, and other configurations.

Device-based defense: defenders assume that attackers can extract models from memory in plaintext. Defenders apply device-based protection, such as secure hardware, to prevent arbitrary memory access. Defenders can also customize hardware to support computation on encrypted data, so that memory extraction will not reveal plaintext models.

Communication-based defense: defenders assume that attackers cannot directly extract models from memory but can sniff the communication between two memory components. Defenders apply data transformation, encryption, and randomization techniques to prevent side-channel information leakage and enable further calculation based on the transformed data in the memory components.

Model-based defense: defenders assume that attackers can send crafted input to ML models and leverage the input and output pattern to train equivalent student models. Defenders apply weight obfuscation, misinformation and differential privacy to increase the effort of attackers in training equivalent student models.

2.1.3 Motivating Example

The threat models can exist alone or coexist with others. A powerful and motivated attacker can explore the four categories of threat models altogether. Now let us consider a real-world e-health application that runs on an Android phone and uses on-device ML in diagnosing skin cancer, diabetes, and hypomnesia [40]. The model takes input from sensors measuring human body data, including electrocardiography (ECG) data, Electroencephalogram (EEG) data, and polysomnography (PSG) recordings. The data are user-private and can be personal identifiable information (PII). Figure 1 describes the process of a powerful attacker (Alice) in extracting this ML model. A defender (Bob) tries to stop the model extraction attack throughout the process. Alice begins by downloading the e-health app from Google Play and using `apktool` to depackage the app. Alice expects to extract the plaintext model from the package (e.g., an App-based attack), but Bob has encrypted the model before shipping the app to Google Play (e.g., an App-based defense). Alice fails and continues in Step (1). Alice tries to run the app on a phone, invoke the ML task, and use the `Frida` tool to extract the model from memory (e.g., a Device-based attack). However, Bob has enforced the model to run only in the Trusted Execution Environment (TEE) (e.g., a Device-based defense). Alice fails again and continues in Step (2). Alice tries to sniff the communication between the secure and normal world to recover the model (e.g., a communication-based attack), but Bob has enabled random shuffling to avoid useful side-channel information (e.g., a communication-based defense). Alice fails again and continues in Step (3). Alice tries to query the model with specific input, obtain inference output, and use the input, output pattern to train a highly similar student model with less effort (e.g., a model-based attack). However, Bob has enabled adaptive misinformation to make the patterns misleading (e.g., a model-based defense), and the game continues in Step (4).

Alice and Bob's story can be executed across various IoT devices, encompassing smartphones, smart home devices, and wearable gadgets.

Privacy Concerns. The extraction of on-device ML can worsen privacy issues within IoT devices [22, 34], and bring new attacks including data poisoning attacks, model poisoning attacks, and membership inference attacks. Without the extracted models, attackers can only perform attacks based on black-box information. With the extracted models, under different threat models, attackers can obtain white-box, or grey-box information, with plaintext models, partial models, or surrogate models with high fidelity. The additional information makes it more convenient to perform attacks.

2.2 Security Techniques

Based on the threat models, attackers and defenders may explore different security techniques to perform or prevent ML model stealing attacks. The following describes the common techniques in different categories.

2.2.1 Attacker's perspective

Decomposing and Decompiling: these methods unpacks application packages to extract useful files (e.g., ML models) from the sources. Popular tools include apktool [2], Jadx [9], IDA Pro [7], and so on.

Memory analysis: these methods access device memory and obtain memory buffers containing model layers and weights. Popular tools include Frida [5], GDB [6], memfetch [11], and so on.

Side-channel attacks: these methods exploit indirect (side-channel) information that can be used to infer ML inference data. The side-channel information includes power consumption, electromagnetic (EM) radiation, cache accesses, timing, and so on. Popular tools include ChipWhisperer [4], SCALab [14], CacheAudit [3], etc.

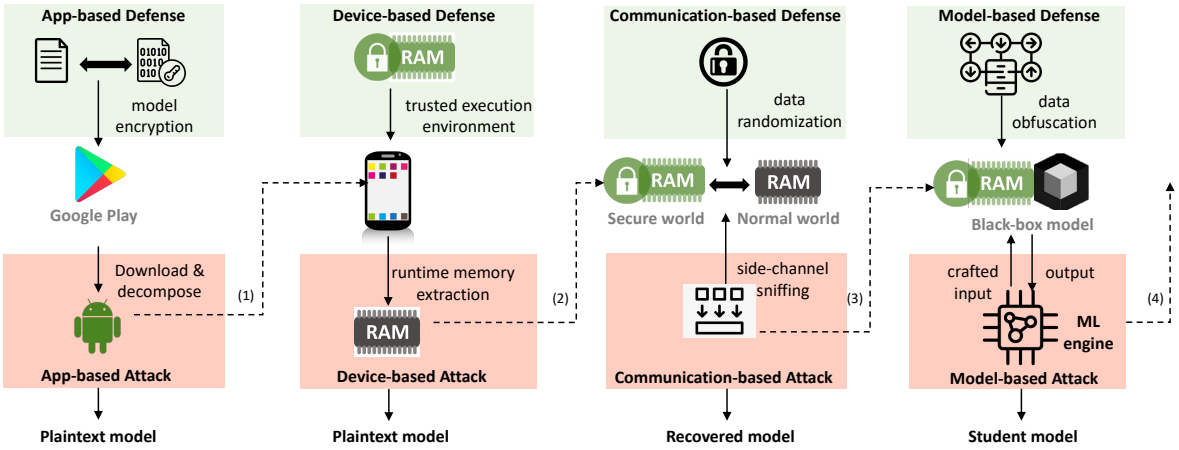

Figure 1: Example of threat models from attacker's perspective and defender's perspective. (*Note: (1) to (4) illustrates the cases when model extraction attacks fail in that category, respectively*).

Algorithm-based stealing: these methods monitor the input and output pairs of ML models, and apply statistical or ML-based algorithms to steal model parameters, or train highly similar substitute models. Popular methods include gradient-based techniques [49], active learning [119], generative techniques [62], and so on.

2.2.2 Defender's perspective

Encryption and obfuscation: these methods prevent unauthorized access or modification to ML models. Techniques include Advanced Encryption Standard (AES) [16], Homomorphic encryption (HE) [70], Multi-party computation (MPC) [29], Differential Privacy (DP) [18], Code obfuscation [63], multi-party computation (MPC) [29], string encryption, binary encoding, and so on.

Secure hardware: these methods allow the storing and execution of ML models in a secure environment. Popular secure hardware includes Trusted Execution Environment (TEE) [111], Secure Element (SE) [93], Physically Unclonable Function (PUF) [48, 57], and so on.

Pattern randomization: these methods reduce the chance for side-channel-based model extraction attacks by adding noises to ML inference or randomizing patterns that may coexist with ML inference. Popular techniques include oblivious shuffling, Address Space Layout Randomization, dummy memory access [82, 85], and so on.

Data and algorithm diversification: these methods increase the complexity of algorithm-based stealing, and prevent attackers from further model training. Popular techniques include model compression [56, 103, 116], adaptive misinformation [72], data augmentation [78, 84], adversarial training [23, 108, 137], ensemble learning [37, 47, 54], randomization [51] and so on.

3 Systematization

We systematize different categories of ML model extraction attacks and their corresponding defenses on IoT devices. Within each category, we delve into existing works, with their objectives, the security techniques involved, and challenges in adopting them in practice. Table 1 and Table 2 list all the papers discussed in this section.

3.1 App-based Attacks and Defenses

3.1.1 Attacker's perspective

App-based ML model extraction was introduced by Xu et al. in 2019 with the goal of understanding the usage trend of on-device ML [129]. Xu developed DL Sniffer to download and decompose app packages to extract ML models. With a collection of 16,500 mobile apps from Google Play, DL Sniffer successfully extracted 211 deep-learning models. This work unveiled that only 39.2% of the models were obfuscated and 19.2% were encrypted, while the rest of the models can be directly extracted in plaintext as a whole. Later, ModelXray [112] was created with the explicit aim of comprehensively examining the security aspects of on-device ML models. ModelXray investigates a larger app collection, with apps from three popular app stores. The results showed that the number of on-device models that are not protected at all can range from 34% to 76%, across the three stores. ModelXray also identified model reuse scenarios. Astonishingly, one model can be reused by over 80 apps, while such apps have been downloaded millions of times. ModelXray reveals that on-device model extraction attacks can be more severe than once thought. A few other works [41, 68] have explored app-based model extraction attacks in similar ways as used by DL Sniffer and ModelXray, while their goal is to perform

Table 1: Existing works on model extraction attacks.

Title	Category	Target	Method	Open-source	Reproduced	ML Framework

further attacks, such as adversarial attacks, to a portion of the extracted models.

In general, app-based model extraction attacks target the extraction of a whole model and can extract models on a large scale. Attackers leverage the weaknesses that (1) app packages are easily accessible and prone to reverse engineering, and (2) model files are not adequately protected through encryption or obfuscation measures. Next, we describe existing works that may potentially defend against the weaknesses.

3.1.2 Defender's perspectives

App-based model extraction defenses aim to obscure easily readable machine learning models into something highly complex and difficult to interpret. Thanks to advancements in computing power and model compression techniques, encrypting and decrypting model files on IoT devices has become increasingly feasible. For example, Samsung's Knox [106] employs AES encryption to secure various model formats. The models will be shipped in encrypted format with the app package. When ML inference starts, the models will be decrypted in the device memory, and start working as regular plaintext models. In IOS, Apple's CoreML [69] provides AES solutions to its models in a similar way. Outside of the industry community, researchers have developed specialized AES methods [16] that run faster with TensorFlow and provide bundling with app package. MMGuard [65] uses a secret token and inserts an extra input node to the model. This makes a stolen model to behave incorrectly without the secret token. It is worth noting that even traditional encryption algorithms are highly effective in preventing large-scale model extraction attacks.

Besides encrypting models into unreadable formats, obfuscation, and code conversion are investigated to produce models that are readable but difficult to interpret. For example, MindSpore [17] employs dynamic obfuscation to enable apps to perform regular ML inference, but will produce meaningless outputs unless the obfuscation scheme is known to the apps. MACE [10] opts for code conversion, turning models into C++ code representations. M2cgen [28] is capable of transforming a variety of machine learning models into more than ten types of code, including Java, C, Python, Go, and so on, with zero dependencies. NCNN [15] converts model files into binary formats and removes all text, creating a barrier against decomposing-based reverse engineering. Finally, MindsDB [90] converts model files into a database which facilitates easier model deployment. It also supports obfuscating models as a regular database file, making it less vulnerable to attacks targeting popular ML frameworks. In general, app-based defense solutions are effective in mitigating the weaknesses of app-based attacks, by preventing large-scale model extraction. However, as shown in Table 2, such solutions are often tied to an ML framework or a vendor-specific product, limiting the adoption to a broad range of apps and devices. Further, extra effort will be needed from the app/model vendors (e.g., in encrypting the models), the user/device (e.g., in decrypting the models), and key management between the two parties. The decryption process for the model may slow down app performance, depending on device settings.

3.1.3 Findings

We found that app-based model extraction defense solutions mostly come from the industry communities, which indicates that app-based model extraction attack is indeed a severe problem in practice.

We found that, from the attacker's perspective, attackers may not be able to directly use the extracted models for several reasons. First, attackers have to understand the input and output of the models. For example, the input is an image of a bird and the output (i.e., labels) is "bird". Attackers will need to understand the semantics of the app code to obtain such information. Second, the models can be black-box, so the model functionality is unknown to the attackers. The best chance for attackers is to hope the models come from popular ML frameworks (e.g., TensorFlow, PyTorch) and serve common functionalities (e.g., card recognition) so that the models are more likely to be understood and directly used. Last, the models may have been obfuscated or encrypted, so attackers will need to explore de-obfuscation or decrypt techniques to use the models.

We also found that app-based defense alone is not sufficient. For example, the key management mechanism can be vulnerable. Previous work [112] has found the key (or license) to be shipped together with the app package, and attackers can extract the key from the app and use that to decrypt the model. Even if the keys are not accessible, attackers can perform dynamic analysis of the app on a device, and bypass the encryption and obfuscation that have been described. Next, we introduce such cases as device-based attacks.

3.2 Device-based Attacks and Defenses

3.2.1 Attacker's perspective

Device-based ML model extraction attack is explored to bypass app-based model encryption. ModelXtractor [112] first demonstrated the case of extracting encrypted models from device memory in plaintext. The assumption is that for encrypted models to be used by the app, a plaintext model will eventually be loaded into memory. ModelXtractor uses app instrumentation with four types of instrumentation strategies to dynamically find the memory buffers where a (decrypted) model is loaded and accessed by the ML frameworks. ModelXtractor was able to extract models even though three layers of encryption had been applied.

Similar to ModelXtractor, Deng et al. developed AdvDroid [41] to hook API calls that relate to model loading

and extract models from memory. AdvDroid leverages program slicing to search the app code with relevant functions of model inference, and constructs a sequence of UI operations that are associated with the code. AdvDroid focuses on the models for image classification and object detection, with the assumption that the majority of the models are related to these two functions.

In general, device-based model extraction attacks cannot be performed on a large scale. Some apps are complicated and will require authentication and registration to start the ML model inference. Therefore, it depends on some “luck" to trigger a required ML model and extract it from memory.

3.2.2 Defender’s perspectives

Device-based model extraction protection aims at defending against in-memory model extraction and related attacks. Graviton’s architecture [120] was first proposed to support trusted execution environments on GPUs. Graviton enables applications to offload security- and performance-sensitive kernels and data to a GPU, and execute kernels in isolation from other code running on the GPU and all software on the host. Graviton requires hardware changes to integrate into existing GPUs. To relieve the hardware changes, SANCTUARY [31] presents the first security architecture that enables the execution of security-sensitive apps in TrustZone’s normal world with strongly isolated compartments. SANCTUARY is a generic Trusted Execution Environment (TEE) solution that paves the road for protecting on-device ML models. Based on SANCTUARY, OMG [27] provides a prototype implementation of user-space enclaves to protect both client data and model privacy for TensorFlow Lite models. OMG can protect the whole model while lacking support for GPU acceleration and easy adaptation. To solve the problem, LEAP [110] was developed to offer hardware-assisted secure IO and flexible resource management. LEAP also presents a developer-friendly TEE programming interface for app developers to enable memory-protected ML models. To protect partial models, DarkneTZ [91] allows selected layers (e.g., non-linear layers) to run inside the TEE to protect sensitive parts of the model from being stolen. DarknetTZ does not support secure GPU acceleration. ShadowNet [111] also runs sensitive layers inside TEE but extends the support to GPU, with a smaller TCB compared with DarknetTZ. In a different line of research, Mgx [66] introduces a memory protection unit (MPU) design through dynamically adjusting memory access permissions based on the execution context of the DNN model. MyTEE [55] introduced a TEE environment on embedded devices without assuming the existence of TrustZone hardware extensions.

In general, existing works in device-based defenses focused on TEE-based solutions. As Table 2 shows, the protection target ranges from a whole model, layers of the model, and model input/output. The deployment requires either changes to the hardware, or implementing the ML libraries in TEE. TEE-based solutions usually incur significant runtime inference overhead, which prohibits their wide adoption in protecting ML models in practice. The integration of GPU is promising while more research in this direction is warranted.

3.2.3 Findings

We found that attacks in this category are semi-automatic, and are hard to perform on large-scale. For attacks to be successful, attackers will need a deep understanding of the ML library, and the formats of ML models when they are stored in the memory. This excludes in-memory extraction of models from uncommon frameworks. Even after the models are extracted, the models may not be directly useful, as mentioned in the findings of app-based attacks and defenses.

We also found that device-based defense alone is not sufficient in preventing ML models from extraction. For example, TEE is usually limited in memory size and slow in ML inference speed, so large models cannot fit in TEE. When model partitions are needed, communication data between the secure world and the normal world will leak model information as well. Next, we describe attacks in this category.

3.3 Comm-based Attacks and Defenses

3.3.1 Attacker’s perspective

Communication-based attacks aim at stealing or recovering ML models by collecting data from or between different memory components during ML inference. The communication data can include direct model information or side-channel information. Direct model information leakage is only briefly mentioned in a few works [111, 117]. Most studies focus on side-channel data to extract ML models, including cache information, electromagnetic (EM) radiation, timing information, power consumption, and so on.

In cache and memory-based side-channel attacks, existing works have explored non-invasive and passive ways. For example, Hua et al. [67] designed the first attack to steal CNN architectures while it requires the attacker to monitor all of the memory addresses accessed by the victim. DeepRecon [60] reconstructs the architecture of a victim model by analyzing cache access times using Flush+Reload. It passively observes model-related function invocations, and reconstructs the victim’s entire network. Cache Telepathy [130] is similar but can obtain more detailed hyper-parameters, such as the number of neurons in fully connected layers and filter size in convolutional layers. DeepRecon and Cache Telepathy require a shared main memory segment between attacker and victim, while GANRED [83] relieves the requirement with cache timing side-channel. These works provide no direct evidence between the statistics and the attack’s effectiveness. To understand this issue, DeepSniffer [64] learns the relation between

extracted architectural hints (e.g., volumes of memory reads/writes obtained by side-channel or bus snooping attacks) and models internal architectures, to achieve more efficient attacks. Besides passive attacks, researchers have actively stimulated bit-flipping in the memory storing the models, and derive approximate models [104].

In timing-based side-channel attacks, Duddu et al. [44] aim to extract a black-box Neural Network and infer the depth of the network. They leveraged reinforcement learning-based optimization to reduce the search space and reconstruct a substitute architecture. These techniques do not work well when the model is sparse in either weights or activation layers, because off-chip transfers no longer correspond exactly to layer dimensions. To mitigate the sparsity problem, HuffDuff [131] leverages the boundary effect present in CONV layers, and the timing side channel of on-the-fly activation compression to extract black-box models.

With other side-channel information, CSI NN [26] uses timing and electromagnetic (EM) emanations to recover multilayer perceptron and convolutional neural networks. DeepEM [134] is similar but estimates the weights through margin-based adversarial active learning. Open DNN Box [128] derives the power signature of embedded AI devices, and employs machine learning techniques to discern the model architectures of embedded AI devices. It further utilizes the concept of model sparsity to deduce the model parameters.

Hermes Attack [140] uses plaintext Peripheral Component Interconnect Express (PCIe) traffic to leak the whole DNN model. The stolen DNN models have the same hyperparameters, parameters, and semantically identical architecture as the original ones. The methodology is supposed to be effective for all models. However, it depends on the buffer size of the snooping device. Leaky DNN [124] utilizes context-switching penalties to exploit GPU side channels and introduced the MosCons attack prototype, which enables a spy to obtain finer-grained information of DNN ops and hyperparameters. Scan chain attacks [100] reveal that course-grained scan-chain access to non-linear layer outputs is sufficient to steal ML models.

In general, the side-channel information to extract ML models can come from many sources, and be passive or active. These attacks can produce high accuracy and fidelity to the original models and are capable of recovering black-box models. As expected, such attacks cannot be performed to extract models on a large scale. In addition, the attacks may not always succeed because model information may have been transformed through encryption, obfuscation, and random shuffling, so the victim models do not serve as ground truth anymore. Next, we describe existing works with such defenses.

3.3.2 Defender's perspective

Communication-based model extraction defenses aim to mitigate model-related data or side-channel data leaked from TEE or hardware accelerators or between secure and normal worlds in TEE. To prevent communication data leakage between secure and normal worlds, existing works are based on the assumption that sensitive layers run in the secure world, while the rest of the layers run in the normal world. Based on this assumption, Slalom [117] first splits models into linear and nonlinear layers and secures nonlinear layers in SGX. Slalom uses masked input with encryption and randomization to the normal world layers and can protect partial model layers and user input to the models. To further protect the model weights from extraction, ShadowNet [111] applies linear transformation and random noises to secure the intermediate results transferred between the normal world and the secure world.

To prevent side-channel information leakage from hardware accelerators, NPUFort [122] protects general DNN accelerator from side-channel information leakage NeurObfuscator [77] prevents exact architecture extraction by obfuscating the dimension and number of the DNN layers. Liu et al. [82] proposed to prevent architecture extraction through memory access pattern analysis, including oblivious shuffle, address space layout randomization, and dummy memory accesses. Luo et al. [85] proposed to increase the difficulty of extracting DNN architectures through tensor execution scheduling, as a way to prevent EM based side-channel leakage. These methods require low-level modification and are limited by the execution environment. ObfuNAS [138], instead, obfuscates models via Neural Architecture Search (NAS) to defend against architecture extraction attacks without requiring specialized hardware.

Other secure ML systems use cryptographic primitives, such as E2DM [70], using HE for encrypted data and encrypted models. However, the performance overhead is significant and it is far from practical to apply these theoretical approaches to real-world applications.

In general, communication-based defense solutions can mitigate side-channel-based model extraction attacks. However, similar to device-based defenses, these approaches usually require low-level hardware changes or the development of a full-stack ML inference framework. This limits the protection to a certain type of hardware (e.g., TEE, GPU), or a certain ML framework (e.g., TensorFlow). The incurred deployment effort also prohibits the wide adoption of the existing solutions. Due to the ad-hoc nature of side-channel attacks, it is also challenging to propose a generic solution to prevent model extractions from different types of side-channel information.

3.3.3 Findings

We observed that the number of side-channel-based model extraction attacks exceeds the available defenses designed

to counter them. The extracted (or recovered) models can achieve high accuracy and fidelity. However, for the attacks to be successful, attackers will need to be co-located with the victim processes or share the same memory regions with the victim. The monitored data will need to be recorded in log files or be frequently transferred to the attackers. All of these increase the chance to expose the attacks and question the possibility of real-world attacks in practice. We are not aware of industry defense solutions in this category of threat model.

We also found that communication-based model extraction defense alone is not sufficient. For example, attackers do not need direct or side-channel model information to recover a model. Instead, attackers query the model with special input and obtain the inference result as output. but can. With the input, output pairs, attackers can train a substitute (or student) model of the victim model. Next, we introduce existing works with such attacks.

3.4 Model-based Attacks and Defenses

3.4.1 Attacker's perspective

Model-based extraction attacks assume that attackers use pairs of inputs, outputs to train substitute models that are highly similar with the victim models. Based on this assumption, existing works have explored to (1) achieve high model similarity with minimal accuracy loss, (2) eliminate the requirements of prior knowledge of the victim models, (3) optimize query efficiency and effectiveness, and (4) generate natural patterns to avoid extraction detection. Note that most of the attacks here are agnostic to the device setting. Even though some attacks were created in a cloud ML setting, we included them as they will be effective to on-device ML extraction as well. Due to the large number of papers within this category, we only describe the important ones.

Through API accesses, Tramer et al. [118] performed the first attack replicating ML model functionality to extract model parameters from popular model classes. It requires no prior knowledge of model parameters or training data. It also provides evidence that extraction attacks remain applicable even when the models only generate class labels. In a similar approach, Knockoff Nets [96] integrated reinforcement learning techniques to train a surrogate model to optimize query timing and effectiveness. Knockoff Nets aim to steal model functionality with black box internals. It does not require knowledge of model family or training data. Knockoff Nets could achieve remarkable accuracy and fidelity across a range of tasks. Simultaneously, Oh et al. [94] showed that model stealing attacks can extract different types of internal information from black-box models, such as activation types, optimization algorithms, and model hyperparameters, as have done by prior work [121]. ML-Stealer [79] presents a mere black-box access scenario. It incorporates VAE-based synthetic data generation and GAN-based replica model construction, so it does not require prior knowledge of the victim model nor the statistics of the training data. ML-Stealer has achieved a testing accuracy as high as 93.6%. To reduce the number of queries and the chance of exposure to possible defenses, Ma et al. [86] proposed a method to enhance the efficiency of model stealing using intelligent query agents. This approach employs highly accurate pre-trained models specialized for various tasks and strategically uses different categories of training data to probe the victim model. This allows intelligent query agents to achieve a near-identical accuracy to the victim model after a relatively small number of queries. Eventually, multiple intelligent agents collaborate locally to train an alternative model. In order to understand the factors that can impact the success rate of model stealing attacks, Liu et al. [81] conducted assessments of attacks under various conditions. They found that the complexity of the dataset used to train the victim model and the dataset used for the stealing attack can affect the attack's accuracy. S Pal et al. introduced an attack method [98] that employs active learning techniques to make model stealing attacks more effective. They used unannotated public data and made their attack follow a natural distribution that cannot be detected by a query distribution-based monitoring approach.

In general, model-based extraction attacks can achieve high accuracy. In generating the input queries, even though attackers may assume in-distribution datasets and out-of-distribution datasets [61], they mostly focus on image-based ML and datasets, and test on the common datasets, including CIFAR [73] and MNIST [39]. Even with different learning algorithms available, it is still hard to enable model stealing with generic types of input queries. In addition, model-based extraction attacks may fail, given the advances in different protection techniques, including adaptive misinformation, query distribution detection, and so on. Next, we describe existing works with such defenses.

3.4.2 Defender's perspective

Existing works in this category mostly focus on two directions: (1) minimizing prediction information leakage, and (2) adding cost and overhead to attacks.

In minimizing prediction information leakage, PRADA [71] serves as the first proactive defense method. PRADA's defense is based on the pattern of the attacker's query distribution, such as query proximity. It analyzes the distribution of consecutive queries and issues an alert when the query distribution is abnormal. Users can choose to return incorrect predictions, terminate queries, and so on. Since the data distribution generated in natural life is significantly different from the attacker's training set, PRADA has shown excellent identification and defense capabilities against abnormal queries, often achieving 100% accuracy. In a different approach, Prediction Poison [97] proposed a model-agnostic defense. It introduces targeted perturbations on posterior probabilities

and maximizes the angle deviation between the generated gradient signal and the original gradient signal. With a 1-2% accuracy loss, Prediction Poison reduces the accuracy of the substitute model by up to 65%, and query efficiency by 13.53%. GRAD2 [87] is also a perturbation-based defense. It uses gradient redirection to selectively alter the trajectory of model-stealing attacks. GRAD2 achieves small utility losses and low computational costs. In addition, adaptive misinformation [72] has been proposed to mislead model-stealing attackers. If a model input is outside of a pre-defined distribution, the predictions will be modified. Adaptive Misinformation maintains the high accuracy of the protected models while reducing the accuracy of the attacker's cloned model to 14.3%.

In adding cost and overhead to attacks, differential privacy [92, 99, 136] offers protection against model stealing attacks by introducing privacy-preserving noise into the training and inference processes of ML models. During ML training, controlled noise to the data and gradients makes it difficult for attackers to reconstruct a model. During ML inference, additional noise is introduced to the model's outputs, preventing attackers from learning specific internal parameters. In theory, this technique should significantly increase the complexity of stealing the model's architecture and parameters. However, empirical research conducted by Liu et al. [81] suggest that while DP and similar methods are effective at protecting the privacy of training data, their impact on model extraction attacks remains uncertain.

In general, the above defense solutions can help mitigate model-based extraction attacks. Through analyzing the distribution of input queries, these solutions can achieve a high accuracy. The challenges are (1) attackers may craft input queries that fit well into the pre-defined input categories, making adaptive misinformation and obfuscation techniques ineffective; (2) an unknown object from a pre-defined category may be incorrectly labeled as out-of-distribution category, and experience low-accuracy inference results. For example, attacks can query with unannotated public data [98] and do not demonstrate obvious patterns to bypass PRADA [71]. Therefore, it is hard for defenders to define a complete and accurate set of categories.

3.4.3 Findings

We have found that model-based extraction attacks have become more automated and with high fidelity, with the development of intelligent query agents [86]. However, the attacks may not be practical on IoT devices. Even with the optimized number of queries (e.g. 10k queries), the power consumption of devices will see an observable increase [20], and defenders may detect and terminate the attacker's querying processes.

For both attacks and defenses, the performance of the proposed solutions depends on the distribution of training data, the algorithm in generating the input, and output pairs, the number of queries, and the complexity of the victim models. It is hard for these solutions to be generalized, even with the large number of research papers available (we have only covered representative ones here). The effectiveness of the above solutions, therefore, can only apply to a small scale of models.

Since both attacks and defenses in this category are not specifically designed for IoT devices, we expect future research to identify unique challenges in IoT-specific model-based extraction security.

4 Evaluation

The goal of this section is to measure the gap between research and practice in defending model extraction attacks. Specifically, we aim to answer the following questions: (1) can research projects be reproduced in practice? (2) are proposed model extraction attacks and defenses effective in practice? and (3) what are their computation complexity and power consumption?

To obtain real-world ML models, we collected around 210K Android Application Packages (APKs) from AndroZoo [21]. The APKs were collected from popular Android stores spanning the period from 2020 to the current date. We used ModelXray [112] to filter out ML models from these APKs and obtained 16.5K models in total. Since different apps may use exactly the same models, we use hashes to identify the same models and obtain 3K **unique models** after de-duplication. The models come from different ML frameworks, and allow us to perform evaluation on existing projects described later.

4.1 Reproducibility.

We first use reproducibility as a criterion to measure the gap between research and practice in defending model extraction attacks. We will investigate (1) whether a research project is open source, (2) whether open-source projects can be reproduced with the results, and (3) what the challenges are in reproducing the projects.

Finding source code. We try three approaches: (1) go through the paper and search for the provided code link, (2) search paper title through Papers With Code [13], and (3) reach out to the author's team for code if the paper is newly published. If none of them produces a result, we consider the source code as not available.

The criteria for reproducibility. We consider a project as not reproducible if we experience system/hardware incompatibility while the system/hardware is not available anymore or has lost maintenance. In other cases, there might be erroneous code or documentation, or outdated library. We then allow two graduate students majoring in cybersecurity to test the code for a maximum of one week. If the code still fails to produce the paper-reported results, we consider the project as not reproducible.

Based on the above criteria, we statistically analyzed the existing papers, and summarized the results of open source and reproducible projects in Figure 2. As the figure shows, app-based attack and defense projects are the most reproducible ones, while device-based and communication-based projects have much lower percentages of being open source and reproducible. Projects that are not reproducible often lack core modules, have invalid links for downloading models or data, or face compatibility issues with older package versions or newer hardware requirements. The most challenging projects to reproduce are those released more than five years ago.

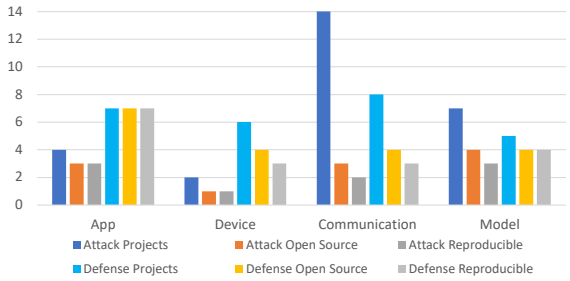

Figure 2: Open source and reproducible projects in attacks and defenses.

4.2 Effectiveness of Model Extraction Attacks.

To understand whether existing model extraction attacks are practical, for each threat model, we test and evaluate representative projects (from those reproducible) with real world applications. We consider a project representative if (i) it is popular on Github and its method is shared by most projects in the threat model, and (ii) it is the only reproducible project in the threat model. This criteria applies to defense projects as well.

4.2.1 App-based attack: ModelXray

ModelXray [105] is an app-based attack with diverse features, including package decomposing, ML model and library analysis, statistical data generation, and multi-task processing.

Results: We used our whole app collection to test ModelXray in extracting model files from app packages. We used the same criteria for plaintext model detection and obtained the results in Figure 3. Astonishingly, the attack success rate continues to rise even with heightened awareness and the availability of more defenses. Overall, the success rates is 33.83% for unique models (after we de-duplicate models with the same hashes), and 48.81% for all models, which are consistent with those reported by ModelXray (34% to 76%). It reveals that since the publication of ModelXray, the app-based attack is still a critical issue—a wide range of apps still do not protect their models at all.

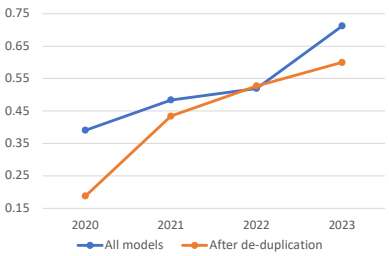

Figure 3: Success rate of ModelXray in the past four years.

Challenges: Relating this result to the app-based defenses in Table 2, we hypothesize the lack of protection to the following reasons: (1) the available protections are mostly vendor-specific [17, 106], (2) the few research solutions focus on TensorFlow [16], while our model collection shows only a small portion (e.g., 7%) of models are pure TensorFlow models. Even worse, we found that research popular frameworks (e.g., TensorFlow, PyTorch) have seen a decreased market portion in the last four years, while new ML frameworks are increasingly developed.

4.2.2 Device-based attack: ModelXtractor

ModelXtractor [105] uses Frida to extract ML models from memory, when applications are running and loading ML models. ModelXtractor can extract plaintext models even if the models have been encrypted several times before distributing to the app store.

Results: ModelXtractor is tailored to extract models in ProtoBuf (.pb, .pbtxt) and FlatBuffer (.tflite) formats. Despite the large number of models we collected, we found only 27 unique models that are encrypted and in these two formats. Since ModelXtractor requires a lot of manual effort in triggering the models, we opted to randomly select 10 models for our experiments.

Challenges: We were not able to extract useful and complete models due to the following reasons: apps cannot be instrumented, or do not trigger the ML functions; some apps require registration with phone numbers from certain countries that we could not obtain; banking apps require a local bank account to trigger ML functionalities. Additionally, ModelXtractor makes it hard to determine the start and end points of model buffers in memory. It relies on keyword searching, such as “TFL2" or “TFL3" as version numbers for TFLite models. With the fast development of new ML frameworks, ModelXtractor will see more difficulty in extracting models from memory. In fact, Deng’s work [41] with source code analysis on ML functions and program slicing can be a good complement to ModelXtractor. However, Deng’s work does not have open-source code available.

4.2.3 Comm-based attacks: DeepSniffer and DeepSteal

DeepSniffer [64] uses side-channel information, such as memory and bus monitoring, to snoop ML model structures. It functions during model executions and does not depend on specialized hardware. DeepSteal [104] leverages memory side-channel information to steal the model weight. It exploits hardware fault vulnerabilities using a rowhammer attack.

Results: DeepSniffer requires model checkpoints in *.ckpt* and *.pth.tar* formats, while DeepSteal requires PyTorch models in *.pt* format. With DeepSniffer, we successfully replicated the results reported by the paper. However, when testing with our real-world model checkpoints, DeepSniffer failed to infer layer sequences due to incompatible log files. With DeepSteal, we cannot run *.pt* models because only four types of hardware architectures (outdated) are available.

Challenges: Besides the log incompatibility issue, DeepSniffer requires retraining of predictors. The predictors may vary from one device to another and can be affected by factors such as obfuscation, trusted execution environments, model conversion, and other encryption methods. Also, the process of collecting memory access events, running the LSTM-CTC model for sequence identification, analyzing memory access patterns, and estimating layer dimensions could require non-trivial computational resources and energy demands.

4.2.4 Model-based attack: ML-Doctor

ML-Doctor [81] provides the newest and complete tool sets for model-based attacks. ML-Doctor assumes that (1) attackers have knowledge of training data and can use in-distribution data to perform attacks, and (2) target models are in black-box, but the inference function is accessible to attackers.

Results: ML-Doctor is designed to run Pytorch models in *.pt* format. We found only 8 unique models in our real-world model collection in this format. However, none of the 8 models could be loaded to ML-Doctor. We therefore repeated the same setting as reported in the paper, and achieved accuracy results ranging from 92% to 94%. However, the computational complexity of the model-stealing attack remains undetermined due to limited publicly available datasets. The study by Liu et al. (2022) [81] suggests that dataset complexity influences generalization, thereby affecting the computational cost of model-stealing techniques. Overall, the analysis indicates that the extraction attack is effective, and the results are consistent with those reported in the paper but it fails to cover broader validation across various ML models.

Challenges: ML-Doctor reveals that model-based defenses have been primarily theoretical rather than extending to real-world models. ML-Doctor may experience *false success* issues, meaning that the attack accuracy is not equal to the quality of capturing the utility or the specialized capabilities of the target models. This can happen when the target model randomly assigns labels to input data that are out of a pre-defined distribution.

While model extraction attacks offer ambiguous benefits, attackers face the growing sophistication of defensive strategies. Clues for identifying malicious queries, such as frequency, location, and data similarity, can be easily spotted and neutralized by defenders.

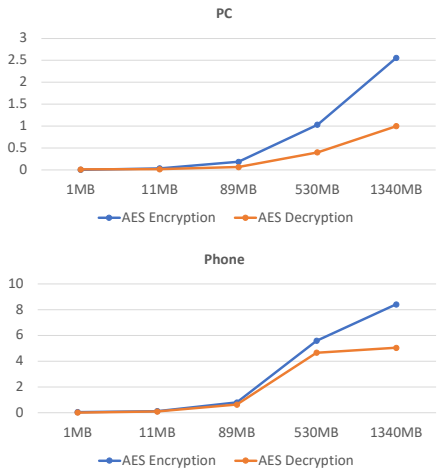

Figure 4: Execution time of encrypting and decrypting ML models with AES.

4.3 Effectiveness of Model Extraction Defenses

4.3.1 App-based defense: AES

App-based defenses, as reported in Table 2, use similar AES libraries. We select a lightweight package [16] using AES that allows us to quickly encrypt and decrypt TensorFlow model files.

Results: To assess the practicality of AES encryption, we compared performance on a desktop (Intel i5-12400, 64GB RAM) and a mobile device (Pixel 6) using various file sizes, as shown in Figure 4. We randomly selected five real-world model files in different sizes and recorded the encryption/decryption time. On Pixel 6, encrypting and decrypting a 1MB file took only 0.05 and 0.02 seconds, respectively. With the average APK size being around 2MB, encryption/decryption can be completed in approximately 0.1 seconds, demonstrating fast and practical AES implementation for on-device security.

Challenges: While encryption is effective in protecting ML models during distribution, it becomes limited when the model is loaded into memory for inference. Attackers who can access the system's memory may extract the model in decrypted format. To address this challenge, various new encryption techniques are continually emerging. The new methods aim to offer an additional layer of protection, even when the model is loaded into memory for operations [65].

4.3.2 Device and comm-based defense: ShadowNet

ShadowNet [111] is selected due to its support for Trusted Execution Environment (TEE) to protect model privacy and uses hardware acceleration to speed up the performance of on-device ML. ShadowNet secures non-linear layers in TEE and runs linear layers in GPU. It applies a linear transformation to the weight data sent between TEE and GPU. Other works use similar techniques but do not protect model weights [117], or lack the support for GPU acceleration.

Results: ShadowNet supports TFLite and Darknet frameworks to run in TEE-emulated mode. It also offers a model-transforming pipeline that transforms models into ShadowNet-enabled models. We were able to reproduce the results of ShadowNet using the same models as used in the paper, including MobileNet, AlexNet and MiniVGG. The amount of manual effort in setting up ShadowNet is huge, including (1) model preparation with Keras API, (2) choosing an obfuscation scheme on a model, (3) splitting model based on a set of rules, (4) generating model weights for the TEE part, and (5) writing the client application and trusted application for the model with ShadowNet libraries. We were not able to test our collected real-world models. According to the documentation, both CNN and RNN models in TFLite models from Android can be seamlessly integrated.

Challenges: The amount of effort in using ShadowNet is more than expected. The steps in transforming models to ShadowNet-enabled models prevent ShadowNet's wide adoption. In addition, ShadowNet's TEE-enabled mode is only supported on TFLite, while models from other ML frameworks will need to be transformed or even compressed, which will reduce the original models' accuracy. ShadowNet's prototype was tested on the Hikey board 960, while the other types of hardware may not be compatible.

4.3.3 Model-based defenses: Prediction-Poison and Adaptive Misinformation

Prediction-Poison(PP) [97] is selected due to its good performance on a variety of models and its effectiveness in poisoning the training objectives of the attacker by perturbing the predictions. Adaptive Misinformation (AM) [72] deliberately introduces inaccuracies for queries identified as Out-Of-Distribution (OOD) while ensuring that In-Distribution (ID) queries receive correct predictions. Because a significant portion of the adversary's queries fall into the OOD category, the mislabeled data leads the adversary to train low-quality student models with poor accuracy. Other defenses [71] will incur a slight delay of attack by increasing the number of queries and achieving low accuracy in protection.

Results: Both defenses aim to reduce the accuracy of the adversary's student model with a minimum impact on the defender's model accuracy. We used the Knockoff Nets attack strategy to evaluate the [96] Prediction-Poison (PP) [97] and Adaptive Misinformation (AM) [72]. Both defenses are limited to Pytorch models stored in .pth/.pt format. We examined the results on a surrogate dataset for undefended victim models provided by the author like MNIST, CIFAR10, ResNet-18, LeNET, and CUB200. Our investigation revealed that PP has overall lower clone accuracy whereas AM has lower computational overhead compared to PP. Additionally, both AM and PP have minimal defender accuracy loss (< 1% - 0.5%). However, we encountered errors while loading the other extracted models stored in .pt/.pth formats. The code will ask for an additional log file that was not available.

Challenges: Compared to previous works, PP and AM are effective techniques. But with an increase in the query budget and optimizing parameters, they may not scale well on resource-intensive devices or with large complex target models. The introduced computational overhead and the slowing down of model inference tasks could make them less practical in wide adoption. Additionally, an adaptive attacker may bypass the detection of misinformation.

In summary, the transition from open-source projects to practice requires a comprehensive examination of various factors. We have examined the effectiveness of attacks and defenses from several representative projects. Later work in evaluating the runtime performance, the required resources, and the deployment effort should be warranted.

4.4 Other Metrics

4.4.1 Computation complexity

Computation complexity is an important metric in determining attack feasibility in victim devices and defense performance. We analyze the computation complexity of the aforementioned projects which require access to victim devices.

DeepSniffer's complexity can be represented as $O(k + f(n) + b*n)$, where k is the number of kernel classes, $f(n)$ is the complexity function of the sequence model, and $(b*n)$ represents the search algorithm with the width (b) and the length of the sequence (n). DeepSteal reduces the search space of model weights W with a rowhammer attack and has an overall time complexity of $O(RowHammerAttacks)$ + $O(W + T*B)$, where (W) is the leaked weight bits, and $(T*B)$ is the number of training iterations and batches. ML-Doctor's complexity equals training a student model, which is $O(m*d*e)$, where m is the number of queries, d is the combined size of the network (total number of weights and biases), and e is the number of epochs.

The complexity of AES depends on key size, block size, number of rounds, and model size. The former three factors are usually fixed numbers (e.g., 128, 256), so the complexity becomes $O(m)$ where m is the model size. ShadowNet's complexity can be represented as $O(TEE + r*l)$, which depends on the TEE implementation, the number of linear layers l in target ML models, and a constant number r as the trans-

formation ratio. AM and PP train a process to minimize the worst-case loss over perturbations and the complexity equals $O(g*h)$, where $O(g)$ is the inner optimization in finding the worst-case perturbation, and $O(h)$ is the outer optimization in updating the model parameters.

4.4.2 Power consumption

Energy efficiency has been overlooked in existing model extraction attacks and defenses, although these efforts have considered efficient algorithms or code optimizations to accelerate execution or reduce computation overhead. We measure the power consumption of different ML model extraction attacks and defenses, using Intel PCM. Some methods are ignored because they do not need access to victim devices, such as ModelXray, or require a specific hardware architecture (e.g., DeepSteal) or device (e.g., ShadowNet) that are unavailable. Table 3 shows the power consumption in Joules before and after attacks or defenses. Specifically, AES consumes significantly less power compared with others. AM is more energy efficient compared to PP. The average consumption is around 30 Joules.

Table 3: Power consumption of different projects.

Project	Model	Before (J)	After (J)
DeepSniffer	ResNet-18	0.45	29.98
ML-Doctor	a simple CNN	0.70	33.81
AES	ResNet-18	0.41	3.28
PP	LeNet	0.42	33.47
AM	LeNet	0.77	29.24

5 Future Research Directions

Multi-user sharing on-device ML. In this paper, we focus on on-device ML models that are used by a single user. However, there are other cases where an IoT application with on-device ML is used by multiple users. For example, a smart home with different IoT devices can be shared by home residents [135]. Another example is a healthcare service using an IoT device that can be shared among multiple patients or staff in the hospital [76]. Sharing on-device ML may raise new security challenges which may lead to privacy violations for the app users if an attacker is one of the users who share the model. In this case, the attacker may try to attack the model to collect sensitive information about the model users (patients, for example). New defense techniques are needed if on-device ML is used in a multi-user environment to maintain the security and privacy of the users.

On-device ML in Federated Learning. In some on-device ML applications, the future updates for on-device ML models depend on locally trained models by different users to improve the accuracy of the model results. To make updating the ML model possible, federated learning (FL) is usually used to enable model training and inference to occur directly on the device [125]. FL regularly collects general information about all locally trained models to be used in the future update from the ML-provider server. Model extraction from the on-device ML apps by an untrusted user is still possible in a large number of IoT apps. More work is needed with the help of techniques like Multi-party Computation (MPC) to prevent such attacks on the on-device ML apps. We suggested using MPC since MPC plays an important role in privacy preserving when multiple-party involved in the system.

On-device models with early exit. Early exit policies and the architecture in ML allow large deep neural network (DNN) models to run on resource-constrained devices. This improves ML inference performance and data transmission efficiency. Existing works have partitioned ML models to introduce early exits across multiple systems [25, 52]. This includes transformer-based neural networks [24, 126, 139]. However, early exit models suffer from model extraction attacks as well. For example, model-based attacks can query the early-exit model with different types of input data and use the input, output pairs to infer the exit places and possible parameters. Existing efforts have been proposed to fingerprint early-exit models via inference time and have shown uniqueness and robustness on different model architectures [43]. In addition, because early exit policies are data-dependent, data patterns can be used to reveal model architecture or even model parameters. To defend against such attacks, we suggest future research to explore shuffling, randomization, and perturbation-based techniques [82], for example, exit point randomization, inference result perturbation, and inference with noises. We expect possible performance loss, including decreased inference speed and accuracy. We suggest following existing studies [43] to balance between model privacy and accuracy.

Cryptography-based defenses. Cryptography-based defenses provide a strong mathematical back-end to secure ML models from various attacks. For example, Homomorphic encryption (HE) [19, 30, 102] has been explored to ensure the privacy of both ML models and their input data. Even though the state-of-the-art HE and MPC algorithms are still too slow to use in practice, existing efforts have been explored to reduce the performance overhead. These include Partially Homomorphic Encryption (PHE) schemes for the reduced computation complexity, and optimized libraries to help mitigate the performance overhead. For example, Microsoft's SEAL (Simple Encrypted Arithmetic Library) [36] and IBM's HElib [53] provide optimized implementations for various applications. We suggest future research to explore more efficient Cryptography-based solutions to protect ML models from stealing, including AES, HE, and MPC.

ML models using on-device GPUs. GPUs are increasingly adopted by devices to accelerate ML tasks. With the advances in LLM, we expect to see more adoption of on-device GPUs in the future. However, modern GPUs lack memory protection support at the equivalent level of CPUs and can suffer

from a range of security attacks [38], including model data reconstruction from GPU dumps. We suggest future research to investigate securing on-device accelerators from model extraction attacks. For example, in general-purpose computers, GPUShield [75] provides a hardware-software cooperative region-based bounds-checking mechanism. It improves GPU memory safety by assigning a random unique ID to each buffer and storing individual bounds in the global memory. For embedded devices, D-Box [89] provides a compartmentalization solution to different tasks sharing access to DMA, allowing developers to create security policies flexibly. We believe both solutions would be interesting in isolating different ML tasks sharing the same on-device GPUs.

6 Conclusion

In this paper, we have provided a systematic review of knowledge concerning on-device ML model extraction attacks and defenses. To facilitate clear understanding, we have defined four types of threat models for both attacks and defenses. Our findings reveal that while certain attacks may not be practical or scalable, the corresponding defense solutions are often constrained in their deployment as well. Real-world ML implementation can be complex even in an on-device setting. Therefore, we have identified future research directions aimed at preventing complex model extraction attacks.

Abstract

Graph neural networks (GNNs) play a crucial role in various graph applications, such as social science, biology, and molecular chemistry. Despite their popularity, GNNs are still vulnerable to intellectual property threats. Previous studies have demonstrated the susceptibility of GNN models to model extraction attacks, where attackers steal the functionality of GNNs by sending queries and obtaining model responses. However, existing model extraction attacks often assume that the attacker has access to specific information about the victim model's training data, including node attributes, connections, and the shadow dataset. This assumption is impractical in real-world scenarios. To address this issue, we propose STEALGNN, the first data-free model extraction attack framework against GNNs. STEALGNN advances prior GNN extraction attacks in three key aspects: 1) It is completely *data-free*, as it does not require actual node features or graph structures to extract GNN models. 2) It constitutes a *full-rank attack* that can be applied to node classification and link prediction tasks, posing significant intellectual property threats across a wide range of graph applications. 3) It can handle the most challenging *hard-label* attack setting, where the attacker possesses no knowledge about the target GNN model and can only obtain predicted labels through querying the victim model. Our experimental results on four benchmark graph datasets demonstrate the effectiveness of STEALGNN in attacking representative GNN models.

1 Introduction

The success of GNNs heavily relies on large-scale datasets, similar to deep learning algorithms for images and texts. These datasets often contain sensitive information collected from users [38, 41], enabling the development of powerful GNN models in critical domains such as healthcare [18], banking systems [37], and bioinformatics [17]. For example, GNNs have been utilized to analyze brain networks using fMRI data [17]. Furthermore, GNN model owners may offer query API services, allowing others to access and benefit from the knowledge acquired by their GNN models. Pre-trained GNN models are also commonly shared with third parties for various downstream tasks [20, 22, 43, 44]. However, the availability of these pretrained models, combined with the sensitive data they were trained on, raises privacy concerns.

General model extraction attacks. Model extraction attacks are designed to steal information about a model's architecture and parameters. These attacks can either reconstruct the original model or create a substitute model that performs similarly [13, 33]. In these attacks, the attacker crafts multiple queries to be input into the victim model's API and captures the corresponding output. Subsequently, a local model is trained using this paired data (input, output). As real data for queries is often limited, recent studies [14, 35] have explored data-free model extraction attacks. These methods employ a generator to synthesize query examples as input to the victim model. The generator and surrogate model are trained in a competitive manner, similar to the principles of Generative Adversarial Networks (GANs) [1, 10]. The surrogate model aims to mimic the predictions of the victim model, while the generator maximizes the disagreement between the victim model's predictions and the surrogate model's predictions. It is important to note that most existing efforts on data-free model extraction attacks primarily focus on the Computer Vision (CV) domain [21]. However, developing efficient and effective data-free model extraction attacks for GNN models remains an open challenge, primarily due to the involvement of both graph structure and node attributes in GNN modeling.

*corresponding author

Limitations of current model extraction attacks against GNNs. Current model extraction attacks on GNNs are designed based on different levels of background knowledge available to the attackers [4,33,34,39]. For instance, attackers who have access to the node attributes of a set of adversarial nodes can generate queries from these adversarial nodes and utilize the responses to train a substitute GNN. One example of such an attack is presented in [39], where discrete graph structure learning methods (e.g., LDS [8]) are employed to construct a connected substitute graph using these node attributes. Another approach, as described in [33], involves initializing the graph structure using K-nearest neighbors (KNN) based on the node attributes and then updating it using a graph structure learning framework [2].

The availability of information about the real training data is crucial for launching a successful model extraction attack in all these scenarios. However, it is important to note that most real-world graphs, such as social and economic networks, involve human-related activities. Due to privacy concerns, these graphs are typically highly protected and not accessible to potential attackers. For example, in a social network, user-related information like friend lists, profiles, likes, comments, and other details are considered highly sensitive and private. As a result, existing attacks become ineffective without access to the actual training dataset.

Moreover, prior research has predominantly concentrated on validating the effectiveness of these attacks within the context of node classification tasks, largely overlooking the critical evaluation of their applicability to another crucial real-world scenario: link prediction tasks. Node classification tasks involve predicting labels or attributes for individual nodes within a graph, whereas link prediction tasks revolve around forecasting the presence or absence of edges between pairs of nodes. Both of these tasks play pivotal roles in various domains such as social sciences, biology, and molecular chemistry. Hence, it becomes imperative to ascertain whether model extraction attacks can effectively compromise GNNs when deployed for link prediction tasks. Tab. 1 provides a comparative overview of StealGNN in comparison to existing methods, shedding light on the specific scenarios and experimental tasks for which they were designed. StealGNN conducted experiments to assess the performance of both node classification and link prediction tasks. This comprehensive evaluation enables us to offer a more holistic understanding of the attack's potential impact across a broad spectrum of graph applications. Notably, the studies by [4] and [39] primarily focused on experimentation with transductive GNNs, which are designed to make predictions exclusively for nodes present during training, while [33] concentrated on inductive GNNs, which possess the capability to predict previously unseen nodes during inference.

Challenges of conducting data-free model extraction attacks on GNNs. Data-free model extraction attacks against GNNs present unique challenges when compared to data-free attacks on other neural networks: (1) Graphs exhibit diverse levels of connectivity and hierarchical organization, making it difficult to generate graphs with specific structural properties such as connectivity patterns, node degrees, or community structures. (2) Graphs often include attributes associated with nodes and edges in addition to structural information. Generating meaningful attributes while ensuring their consistency with the graph structure adds an additional layer of complexity. This complexity arises from the need to create attributes that not only carry relevant information but also align seamlessly with the underlying graph topology and relationships, maintaining coherence and relevance throughout the entire graph analysis process. (3) Unlike pixel-level image data that allows for smooth spatial transformations, graph structures are discrete. This discrete nature poses challenges when applying traditional gradient-based optimization methods like backpropagation.

Our contribution. This paper focuses on data-free model extraction attacks, which is considered the most challenging and widely deployed setting for such attacks on GNNs. Importantly, StealGNN does not require access to real-world data. Instead, it utilizes a generative model to generate synthetic graphs for launching the attack. A key innovation of StealGNN lies in its ability to conduct model extraction without the need for access to real-world graph data. It leverages a powerful graph generator during the training process to create synthetic graphs for launching the attack. As illustrated in Fig. 1, the attacker employs this innovative generator to produce synthetic graphs specifically crafted for querying the victim model. The surrogate model is trained to imitate the victim model based on the input-output pair.

To address the challenge of lacking access to actual gradients of the victim model for updating the generator's parameters, we categorize the attacks based on the training scheme of the generator into three types: **(1) Type I Attack:** In this type of attack, gradients are propagated back through a surrogate model and the gradient approximation of the victim model. By leveraging the estimated gradients of the victim model and the surrogate model's gradients, the generator optimizes its parameters to capture knowledge from both models. **(2) Type II Attack:** This type of attack involves propagating gradients back through only one surrogate model. While this strategy simplifies the gradient flow, it still allows the generator to learn from the surrogate model. **(3) Type III Attack:** In this type of attack, gradients are passed back through two surrogate models. By utilizing the gradients derived from both surrogate models, the generator benefits from diverse perspectives and insights, enhancing the learning and knowledge extraction process. Extensive experimentation has consistently demonstrated the exceptional performance of StealGNN across all three attack scenarios. Our contributions can be summarized as follows:

(1) StealGNN: We introduce StealGNN, a pioneering research endeavor that addresses data-free model extraction

attacks on Graph Neural Networks (GNNs). By developing a trainable graph generator, STEALGNN demonstrates its ability to train a high-quality surrogate model from black-box GNN models, even when only hard labels are available.

(2) Systematic Study: We conduct a comprehensive investigation and propose three extraction attack scenarios based on the updating scheme of the graph generator parameters. These scenarios provide a systematic understanding of different approaches within the STEALGNN framework.

(3) Task Flexibility: STEALGNN is highly adaptable and robust, capable of effectively handling various tasks. It can be applied to both node classification and link prediction tasks, showcasing its versatility. The results obtained from our experiments provide compelling evidence for the superior performance of STEALGNN in these tasks.

2 Background

2.1 Notations

We define an undirected, unweighted, and attributed graph as $\mathbf{G} = (\mathbf{V}, \mathbf{E})$, where $\mathbf{V}$ represents the set of nodes, and $\mathbf{E}$ represents the set of edges. The adjacency matrix $\mathbf{A}$ is defined as follows: $\mathbf{A}_{u,v} = 1$ if the edge $(u,v) \in \mathbf{E}$, and 0 otherwise. In this notation, n denotes the total number of nodes, d represents the dimension of the node features, and c indicates the number of node classes. We use $\mathbf{F} \in \mathbb{R}^{n \times d}$ to denote the node feature matrix, and $\mathbf{Y} \in \mathbb{R}^{n \times c}$ represents the node label matrix. Furthermore, we refer to the graph generator as $\mathcal{M}_G$, the feature generator as $\mathcal{M}_{G_F}$, the structure generator as $\mathcal{M}_{G_A}$, the victim GNN model as $\mathcal{M}_V$, and the surrogate GNN model as $\mathcal{M}_S$.

2.2 Graph Neural Networks

Graph Neural Networks (GNNs) have garnered significant attention in the field of graph-structured data learning for a variety of tasks [40]. In general, most GNN models follow a paradigm that includes neighborhood aggregation and message passing [9]. At the k-th layer, the representation $\mathbf{h}_v^k$ of each node v is learned by iteratively aggregating the embeddings $\mathbf{h}_u^{k-1}$ of its neighboring nodes $u \in \mathcal{N}(v)$:

$$\mathbf{h}_v^k = \text{AGG}\left(\mathbf{h}_v^{k-1}, \text{MSG}\left(\mathbf{h}_v^{k-1}, \mathbf{h}_u^{k-1}\right)\right), u \in \mathcal{N}(v), \quad (1)$$

where $\mathbf{h}_v^0 = \mathbf{X}_v$ represents the node feature of node v. MSG stands for message aggregation. It calculates the messages exchanged between a node v and its neighbors u at layer $k-1$. These messages typically encapsulate information about local structural patterns and features. AGG is referred to as the aggregation function. It combines information from the previous layer's representation $\mathbf{h}_v^{k-1}$ and the messages generated by the MSG function, which involves interactions between the node of interest v and its neighboring nodes $u \in \mathcal{N}(v)$. After K iterations of aggregation, a node representation, denoted as $\mathbf{h}_v^K$, captures the structural information within its K-hop network neighborhood.

3 Threat Model

3.1 Attacker's Setting

Generally, the knowledge of an attacker regarding the threat model in GNN-based attacks can be classified into two settings: black-box attack and gray-box attack. (1) Black-Box Attack: The attacker lacks access to the target GNN's parameters, architecture details, and hyperparameters. They can query the model for predictions. (2) Gray-Box Attack: In this scenario, the attacker has partial knowledge about the target model, like its structure, but no access to parameters.

In this paper, we address the most challenging adversarial setting: black-box attacks. Our attack methodology fundamentally differs from previous black-box attacks on GNNs [33, 39]. These attacks assume that the adversary has access to the victim model's original training data, such as node features, structure, or shadow datasets. However, this assumption often misaligns with real-world scenarios, where training data is frequently treated as private and diligently protected from potential attackers. For instance, a real-world deployment of a GNN in a financial institution for fraud detection. The GNN is trained on a vast dataset containing transaction histories, user profiles, and behavioral patterns. In this context, the training data is highly confidential and sensitive, as it may contain personal information and proprietary insights. Allowing external access to this training data would not only violate privacy regulations but also pose substantial security risks. Given such real-world example and the broader context of privacy concerns, the assumption that adversaries have access to the victim model's training data becomes increasingly unrealistic. Therefore, our work addresses a more realistic scenario wherein attackers are constrained to rely on synthetic datasets to query the victim model and extract valuable information.

3.2 Attacker's Goal

The objective of this attack is to extract information from the target model by training a model that exhibits similar behavior. The attack may focus on different aspects of the target model's information, leading to two primary goals in model extraction: (1) The attacker aims to obtain a model that achieves comparable accuracy to the target model. (2) The attacker attempts to replicate the decision boundary of the target model. Model extraction attacks pose a threat to the security of models used in API services [26] and can serve as a foundation for various privacy attacks and adversarial attacks.

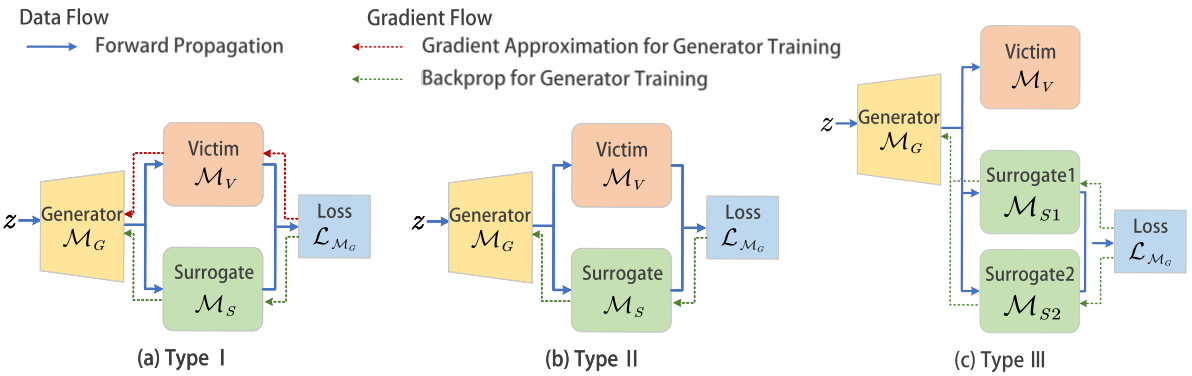

Figure 1: Generator update strategies: (a) Gradients are propagated through both a surrogate model and an approximation of the victim model. This approach aims to capture a broader understanding of the victim model's decision-making process. (b) Gradients are passed back through a single surrogate model. This simplifies the update process by relying on the knowledge learned by a single surrogate model, potentially sacrificing some diversity in the learned knowledge. (c) Gradients are passed back through two surrogate models. This allows the generator to benefit from the diverse perspectives captured by both surrogate models, enhancing its ability to emulate the victim model more effectively.

3.3 Attacker's Taxonomy

The computation of the model extraction loss is essential for updating the parameters of the local graph generator through backpropagation. In typical scenarios, gradients can be backpropagated to the generator by utilizing both a victim model and a surrogate model. However, in black-box scenarios, the parameters of the victim model are inaccessible, rendering it impossible to backpropagate gradients through the victim model. Due to this constraint, we have developed three types of attacks based on different sources of gradients for updating the generator's parameters.

Type I Attack: As illustrated in Fig. 1(a), in this type of attack, the gradient is propagated back through the surrogate model and estimated using a gradient approximation method for the victim model. The zeroth-order gradient estimate, introduced by Polyak and Juditsky [28], is a technique used to approximate gradients when the analytical form of the model is unavailable. Instead, it relies on querying the model at various input points and observing the corresponding output values to estimate the gradient. This approach is particularly valuable in the context of black-box optimization problems. By iteratively sampling and comparing model predictions, the zeroth-order gradient estimate enables derivative-free optimization and exploration of the model's behavior.

By leveraging the estimated gradient of the knowledge-rich victim model, the generator can enhance its graph generation process to capture and incorporate the valuable knowledge from the victim model into the agent model. This optimization allows the generator to produce graphs that effectively encapsulate the desired knowledge and transfer it to the agent model, thereby improving the performance and capabilities of the agent model.

Type II Attack: As illustrated in Fig. 1(b), in this type of attack, the generator is trained exclusively using gradients propagated back through the surrogate model. As the model extraction process progresses, the surrogate model refines its behavior, gradually aligning with that of the victim model. This alignment enables the gradients derived from the surrogate model to serve as a reasonable approximation of the gradients of the victim model. Leveraging this approximation, the generator can effectively train and optimize itself, facilitating the extraction of knowledge from the victim model and its subsequent incorporation into the agent model.

Type III Attack: When the graph generated by the generator passes through both the victim model and the surrogate model, two possible outcomes can occur: consistent predicted categories between the victim and surrogate models or inconsistent predicted categories. If the generated graph yields consistent predicted categories, it does not contribute to the imitation of the surrogate model from the victim model. As a result, the surrogate model fails to gain additional information that can improve its emulation of the victim model. However, if the generated graph results in inconsistent predictions between the two models, the surrogate model can acquire deeper and more complex knowledge from the victim model, gradually approaching the decision-making process of the victim model.

As illustrated in Fig. 1(c), in this attack, we simultaneously train two surrogate models and introduce a loss function that enforces inconsistency in their predictions. When the same graph is inputted to both surrogate models and the victim model, the inconsistent predictions of the surrogate models indicate that at least one of them has learned valuable information inconsistent with the victim model. This approach prevents the generator from solely generating simple graphs to minimize the model extraction loss, as the surrogate model would fail to learn any meaningful information.

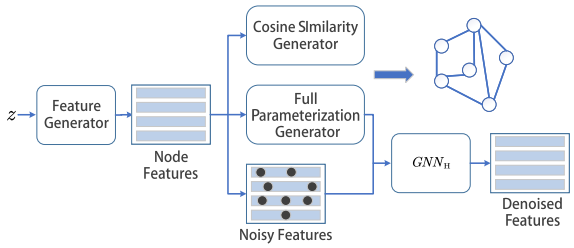

Figure 2: The framework for graph generators. It consists of two types of graph structure generators: the cosine similarity generator and the full parameterization generator.

Advantages, Disadvantages, and Real-World Applicability of Attack Types: In practical scenarios, the choice of attack type hinges on various factors, including the attacker's constraints on querying the victim model, available computational resources, and the depth and complexity of knowledge extraction objectives. For a more detailed connection with real-world scenarios, please refer to the appendix A.4.

(1) Type I Attack: This method effectively harnesses gradient estimation techniques, making it well-suited for intricate proprietary models. However, it may introduce noise and consume substantial computational resources, especially when numerous queries are required to obtain accurate gradient estimates. Type I attacks excel when multiple queries to the victim model are feasible. (2) Type II Attack: These attacks solely rely on surrogate model gradients, simplifying their implementation. However, compared to Type I attacks, Type II knowledge transfer may be slower, given the initial disparity between surrogate and victim model gradients. This approach proves advantageous when query access to the victim model is limited (e.g., due to API rate restrictions) or when the victim model's behavior evolves gradually. Type II attacks are computationally less intensive than Type I but remain effective in accumulating knowledge over time. (3) Type III Attack: Type III attacks aim to capture intricate and profound knowledge from victim models. However, their implementation involves the complexity of deploying and training two surrogate models, along with a loss function to enforce inconsistency. Simultaneously running and monitoring these two surrogate models can be computationally demanding. This approach is suitable when attackers seek to ensure that surrogate models acquire in-depth knowledge from the victim model, particularly in scenarios where simplistic attacks may prove insufficient or when the victim model resists direct extraction attempts.

4 StealGNN

4.1 Attack Framework

Given a victim model $\mathcal{M}_V(\mathbf{G};\theta_V)$, the objective of StealGNN is to learn a surrogate model $\mathcal{M}_S(\mathbf{G};\theta_S)$ that closely resembles the victim model in terms of its behavior and predictions. To achieve this, a graph generator $\mathcal{M}_G(z;\theta_G)$ is employed to generate synthetic graphs $\mathbf{G}$. The generator is updated based on the loss function $\mathcal{L}_{\mathcal{M}_G}$. The surrogate model $\mathcal{M}_S(\mathbf{G};\theta_S)$ is trained using input-output pairs $(\mathbf{G}, \mathcal{M}_V(\mathbf{G}))$, where $\mathcal{M}_V(\mathbf{G})$ represents the output of the victim model for a given input graph $\mathbf{G}$. By training the surrogate model based on these pairs, the surrogate model learns to approximate the behavior and predictions of the victim model.

The proposed StealGNN attack follows a specific data flow, as shown in Fig. 1(a) with a blue arrow. It begins by sampling a random noise vector z from a standard normal distribution. The graph generator $\mathcal{M}_G$ takes this noise vector as input and generates a graph $\mathbf{G}$. This generated graph is then used as input for both the victim model $\mathcal{M}_V$ and the surrogate model $\mathcal{M}_S$, which perform their respective inferences and produce output predictions. The loss function is computed based on the outputs of the victim model $\mathcal{M}_V$ and the surrogate model $\mathcal{M}_S$, measuring the discrepancy between their predictions. This loss function serves as a measure of how well the surrogate model can emulate the victim model.

We will now provide a detailed description of the graph generator's architecture and explain the training process for both the generator and surrogate model.

4.2 Graph Generator

4.2.1 Feature Generator

The feature generator $\mathcal{M}_{G_F}(z)$ is a function defined as $\mathcal{M}_{G_F}: \mathbb{R}^{1\times z} \to \mathbb{R}^{n\times d}$. It transforms a one-dimensional noise vector z into a two-dimensional node feature matrix $\mathbf{F}$ with n rows (representing the number of nodes in the graph) and d columns (representing the dimension of the node features). The purpose of this transformation is to ensure that the generated graph's node features align with the expected input feature dimension of the victim model. It is worth noting that since the victim model is fixed, the required input feature dimension can be determined from the specifications of the victim model. Additionally, the number of nodes is a hyperparameter of the generator, allowing the attacker to choose the desired size for the generated number of nodes. In Fig. 6, we provide experimental results illustrating the outcomes of different choices for this hyperparameter.

4.2.2 Structure Generator

The structure generator $\mathcal{M}_{G_A}(\mathbf{F})$ is a function $\mathcal{M}_{G_A}: \mathbb{R}^{n\times d} \to \mathbb{R}^{n\times n}$ with parameters θ_A which takes the node features $\mathbf{F} \in \mathbb{R}^{n\times d}$ as input and produces a matrix $\mathbf{A} \in [0,1]^{n\times n}$ as output. Specifically, $\mathbf{A}_{ij} \in [0,1]$ indicates the presence of an edge between nodes $\mathbf{x}_i$ and $\mathbf{x}_j$. In order to conduct a comprehensive analysis and promote flexibility and diversity during the graph structure generation process, we have designed two distinct graph structure generators. These generators are as follows:

Cosine similarity graph structure generator: One approach to infer a graph structure is to utilize a similarity metric and assign the edge weight between two nodes based on their similarity [30]. In order to achieve sparsity in the graph structure, we construct a similarity graph using the cosine similarity of the node features. This approach only connects pairs of nodes whose similarity exceeds a predefined threshold. To be more specific, given the node features $\mathbf{F}$, the element of the adjacency matrix $\mathbf{A}_{cos}$ can be computed as follows:

$$\mathbf{A}_{cos_{ij}} = \text{Cosine}(\mathbf{F}_i, \mathbf{F}_j) = \frac{\mathbf{F}_i \cdot \mathbf{F}_j}{\max\left(\|\mathbf{F}_i\|_2 \cdot \|\mathbf{F}_j\|_2\right)}. \quad (2)$$

To promote sparsity in the learned adjacency matrix $\mathbf{A}_{cos}$ and reduce the impact of small values on the aggregation process in GNNs, we adopt a thresholding mechanism. Entries in $\mathbf{A}_{cos}$ with values smaller than a given threshold τ are removed. Specifically, we set a threshold value τ, and if $\mathbf{A}_{cos_{ij}}$ is larger than τ, it is set to 1, indicating the presence of an edge between nodes $\mathbf{x}_i$ and $\mathbf{x}_j$. Otherwise, it is set to 0, indicating the absence of an edge between the corresponding nodes.

Full parameterization graph structure generator: In this generator, we employ the Full parameterization method [8], which is also utilized in the SLAPS framework [7]. Given the parameter matrix $\theta_A \in \mathbb{R}^{n\times n}$, the generator function is defined as $\tilde{\mathbf{A}}_{fp} = \mathcal{M}_{G_A}(\mathbf{F};\theta_A) = \theta_A$. In other words, the generator disregards the input node features and directly optimizes the adjacency matrix. The full parameterization in this generator is simple and flexible, enabling the learning of any adjacency matrix. Once the parameterized adjacency matrix is generated, it undergoes additional processing to obtain a well-defined symmetric adjacency matrix. Subsequently, self-supervised learning is employed to train the learnable parameters within the structure generator.

(1) Adjacency processor: To address the issues of non-symmetry, non-normalization, and potential negative values in the generated adjacency matrix $\tilde{\mathbf{A}}_{fp}$, we apply a series of transformations to obtain the final adjacency matrix $\mathbf{A}_{fp}$. Specifically, we define $\mathbf{A}_{fp}$ as follows: $\mathbf{A}_{fp} = \frac{1}{2}\boldsymbol{D}^{-\frac{1}{2}}\left(\text{P}(\tilde{\mathbf{A}}_{fp}) + \text{P}(\tilde{\mathbf{A}}_{fp})^T\right)\boldsymbol{D}^{-\frac{1}{2}}$. In this formulation, P represents an activation function that is applied element-wise to its input, ensuring non-negativity. The sub-expression $\frac{1}{2}\left(\text{P}(\tilde{\mathbf{A}}_{fp}) + \text{P}(\tilde{\mathbf{A}}_{fp})^T\right)$ guarantees that the resulting matrix $\text{P}(\tilde{\mathbf{A}}_{fp})$ is symmetric. Finally, to normalize the resulting symmetric adjacency matrix, we compute its degree matrix $\boldsymbol{D}$ and multiply it from the left and right with $\boldsymbol{D}^{-\frac{1}{2}}$. By applying these transformations, we obtain a symmetric, non-negative, and normalized adjacency matrix $\mathbf{A}_{fp}$. This ensures the compatibility and suitability of the generated adjacency matrix for further processing and utilization in the model extraction process.

(2) Self-supervision: This self-supervised task is inspired by denoising autoencoders [36]. We define $\text{H} : \mathbb{R}^{n\times f} \times \mathbb{R}^{n\times n} \to \mathbb{R}^{n\times f}$ as a GNN with parameters θ_H. It takes the node features and the generated adjacency matrix as input and produces updated node features of the same dimension as output. We train H to denoise the input features by feeding it a noisy version $\tilde{\mathbf{F}}$ of the original features $\mathbf{F}$ and expecting it to generate the denoised features $\mathbf{F}$. During training, we minimize the following loss function:

$$\mathcal{L}_\text{denoise} = \frac{1}{|\mathbf{F}_{idx}|}\sum_{i\in\mathbf{F}_{idx}} \mathcal{L}_\text{reconstruction}\left(\mathbf{F}_i, \text{H}\left(\tilde{\mathbf{F}}, \mathbf{A}_{fp}; \boldsymbol{\theta}_\text{H}\right)_i\right), \quad (3)$$

where idx represents the indices corresponding to the elements of $\mathbf{F}$ to which we introduce noise. Similarly, $\mathbf{F}_{idx}$ refers to the values at these selected indices. In each epoch, idx consists of a random uniform selection of r percent of the indices from $\mathbf{F}$. The noise is introduced by replacing the values at the indices specified by idx with 0. $\mathcal{L}_\text{reconstruction}$ denotes the reconstruction loss between the denoised features $\mathbf{F}_i$ and the corresponding predicted features $\text{H}(\tilde{\mathbf{F}}, \mathbf{A}_{fp})_i$. We use the mean-squared error loss. In this attack, the generator initially optimizes the feature generator and structure generator parameters using $\mathcal{L}_\text{denoise}$. This optimization aims to minimize the denoising loss, which encourages the GNN H to learn meaningful representations capable of reconstructing the original features accurately, even in the presence of noise. This self-supervised training process plays a crucial role in capturing informative and meaningful graph structures. Subsequently, the resulting graph is fed into both the victim and agent models, facilitating the extraction of knowledge from the victim model.

4.3 Training Surrogate Model

The surrogate model $\mathcal{M}_S$ is trained using the responses obtained from the victim model $\mathcal{M}_V$ when provided with a query graph $\mathbf{G}$. Due to the unavailability of the victim model, the attacker encounters different types of outputs when querying the victim model, which can range from probability outputs (referred to as soft labels) to one-hot label predictions (hard labels). This paper specifically focuses on studying the most challenging scenario, where the victim model exclusively provides hard labels as output.

The generator $\mathcal{M}_G$ takes a noise vector z as input and generates a graph $\mathbf{G}$ (as described in Equation 4). This generated graph $\mathbf{G}$ is then used to query both $\mathcal{M}_V$ and $\mathcal{M}_S$, resulting in the outputs $\overrightarrow{\mathbf{Y}_V}$ and $\overrightarrow{\mathbf{P}_S}$ respectively (as shown in Equation 5). It is important to note that $\overrightarrow{\mathbf{Y}_V}$ represents hard labels obtained from the victim model, while $\overrightarrow{\mathbf{P}_S}$ represents soft labels derived from the surrogate model.

$$\mathbf{G} = \mathcal{M}_G(z;\theta_G); \quad z \sim \mathcal{N}(0, I), \quad (4)$$

$$\overrightarrow{\mathbf{Y}_V} = \mathcal{M}_V(\mathbf{G},\theta_V); \quad \overrightarrow{\mathbf{P}_S} = \mathcal{M}_S(\mathbf{G};\theta_S). \quad (5)$$

The surrogate model parameters θ_S are updated using the cross-entropy loss function [3] to minimize the discrepancy between $\overrightarrow{\mathbf{P}_S}$ and $\overrightarrow{\mathbf{Y}_V}$:

$$\mathcal{L}_{\mathcal{M}_S} = CE(\mathcal{M}_S(\mathbf{G};\theta_S), \mathcal{M}_V(\mathbf{G};\theta_V)) = -\sum_{i=1}^{n}\overrightarrow{\mathbf{Y}_{V_i}}\log\overrightarrow{\mathbf{P}_{S_i}}. \quad (6)$$

By training the surrogate model $\mathcal{M}_S$ using the graph $\mathbf{G}$ and the ground truth labels $\overrightarrow{\mathbf{Y}_V}$ of the victim model $\mathcal{M}_V$, we can extract the knowledge embedded in $\mathcal{M}_V$. This is achieved by guiding $\mathcal{M}_S$ to learn the exact mapping of $\mathcal{M}_V$, thereby capturing its knowledge and replicating its behavior.

4.4 Training Graph Generator

To mitigate the issue of simplistic or duplicate graphs generated by the generator, we introduce a mechanism to encourage the production of more complex and diverse graphs. This mechanism aims to increase the discrepancy between the surrogate and victim models. Specifically, the generator model $\mathcal{M}_G$ is trained to maximize the disagreement between the predictions of the victim model $\mathcal{M}_V$ and the surrogate model $\mathcal{M}_S$. In other words, the loss function for the generator in the Type I Attack and Type II Attack is defined as $\mathcal{L}_{\mathcal{M}_G} = -\mathcal{L}_{\mathcal{M}_S}$. This formulation incentivizes the generator to produce diverse and complex graphs, thereby amplifying the discrepancy between the two models.

4.4.1 Type I Attack

Since the output of the victim model consists of hard labels, which are discrete and non-probabilistic predictions, it cannot be directly utilized to compute approximate gradients. To address this, we employ a label-smoothing regularization technique [23], which aims to soften the hard-label outputs of the victim model into soft labels. This soft label output is then utilized to approximate the gradient of the victim model, enabling us to perform gradient-based optimization. As shown in Fig. 1(a), our objective is to update the parameters θ_G of the generator model using gradient descent in order to minimize the loss function $\mathcal{L}_{\mathcal{M}_G}$ as depicted in Equation 7:

$$\theta_G^{t+1} = \theta_G^t - \eta \nabla_{\theta_G} \mathcal{L}_{\mathcal{M}_G}. \tag{7}$$

To update θ_G, we need to compute the derivative of the loss function $\nabla_{\theta_G} \mathcal{L}_{\mathcal{M}_G}$. This derivative can be decomposed into two components, as shown in Equation 8.

$$\nabla_{\theta_G} \mathcal{L}_{\mathcal{M}_G} = \frac{\partial \mathcal{L}_{\mathcal{M}_G}}{\partial \theta_G} = \frac{\partial \mathcal{L}_{\mathcal{M}_G}}{\partial \mathbf{G}} \times \frac{\partial \mathbf{G}}{\partial \theta_G}. \tag{8}$$

The second component corresponds to the derivative of the generator's output with respect to its parameters, which can be easily computed by performing backpropagation through $\mathcal{M}_G$. However, the first component, which represents the derivative of the loss function with respect to the generator's output, poses a challenge. It requires access to the model parameters of the victim model θ_V. Since the victim model $\mathcal{M}_V$ is considered a black-box model from the attacker's perspective, we do not have direct access to θ_V. As a result, backpropagation cannot be applied to compute this derivative.

To overcome this limitation, we resort to an alternative approach that involves performing additional queries to approximate the gradient. Specifically, we employ zeroth-order gradient estimation techniques [25, 28] to estimate the gradient without explicitly accessing the victim model's parameters:

$$\hat{\nabla}_{\mathbf{G}} \mathcal{L}_{\mathcal{M}_G}(\mathbf{G}; u_i) = \frac{d \cdot \left(\mathcal{L}_{\mathcal{M}_G}(\mathbf{G} + \varepsilon u_i) - \mathcal{L}_{\mathcal{M}_G}(\mathbf{G}) \right)}{\varepsilon} u_i, \tag{9}$$

where u_i represents a random variable drawn from a d-dimensional unit sphere, with each component being uniformly distributed. Additionally, ε denotes a small positive constant. To estimate the gradient, we adopt an averaged version of the random gradient estimate, as proposed in previous works [6, 14, 19]. This involves computing the forward difference using m random directions, denoted as $\{u_1, u_2, ..u_m\}$. In our experiments, we set m to 2, utilizing two random directions to estimate the gradient. This choice is based on a trade-off between computational efficiency and gradient estimation accuracy. While increasing the value of m could potentially provide a more accurate gradient estimate, it also incurs a higher computational cost. Our experiments demonstrated that using two random directions already yielded sufficiently accurate gradient estimates for our specific application, striking a balance between accuracy and computational efficiency.

$$\hat{\nabla}_{\mathbf{G}} \mathcal{L}_{\mathcal{M}_G}(\mathbf{G}) = \frac{1}{m} \sum_{i=1}^{m} \hat{\nabla}_{\mathbf{G}} \mathcal{L}_{\mathcal{M}_G}(\mathbf{G}; u_i). \tag{10}$$

The expression $\hat{\nabla}_{\mathbf{G}} \mathcal{L}_{\mathcal{M}_G}$ represents an estimate of the true gradient $\nabla_{\mathbf{G}} \mathcal{L}_{\mathcal{M}_G}$. By substituting this gradient estimate into Equation 8, we obtain an approximation for the gradient of the generator's loss function, denoted as $\hat{\nabla}_{\theta_G} \mathcal{L}_{\mathcal{M}_G}$. This estimated gradient can be utilized to perform gradient descent, enabling the update of the generator model's parameters θ_G according to Equation 7. Through this parameter update, the generator model $\mathcal{M}_G$ is trained to generate synthetic graphs that facilitate the process of model extraction.

4.4.2 Type II Attack

As shown in Fig. 1(b), in this type of attack, the attacker solely relies on the gradient computed through surrogate $\mathcal{M}_S$. During the training process, the surrogate model learns to mimic the victim model, serving as an appropriate proxy to encourage the generator in generating diverse and informative graphs.

4.4.3 Type III Attack

Fig. 1(c) illustrates an overview of this attack type. When provided with a black-box Victim model, two surrogate models, surrogate 1 and surrogate 2, are generated. The final extracted model is an ensemble that consists of these two surrogate models. The model output is obtained through an equal-weight

soft voting mechanism, combining the predictions of the two surrogates. In accordance with a previous study by Rosenthal et al. [29], the generator training in this work incorporates disagreement losses to update the generator model. The disagreement loss measures the disparity between the predictions of a pair of surrogate models. In cases where two clones exhibit inconsistent predictions on specific samples, two scenarios arise: 1) If one of the clones aligns with the victim model's prediction, this sample assists the other clone in learning from the victim model. 2) If both clones' predictions do not match the victim model's prediction, they can both learn from this sample. Mathematically, the disagreement loss quantifies this difference by leveraging the standard deviation of the surrogate models' outputs for each corresponding node.

$$\mathcal{L}_{\mathcal{M}_G} = -\frac{1}{N}\sum_{i=1}^{N}\left[\mathrm{Std}\left(\mathbf{P}_{S1_i}, \mathbf{P}_{S2_i}\right)\right], \tag{11}$$

where Std denotes the standard deviation across the surrogate models. $\mathbf{P}_{S1_i}$ and $\mathbf{P}_{S2_i}$ represent the predictions of the two surrogate models, respectively. This loss function encourages the generator to produce data that prompts disagreement between two surrogate models when making predictions. The standard deviation quantifies this disagreement between the surrogates on generated data. By minimizing this loss, the training process aims to create data that exposes differences between the surrogates, allowing one of them to adapt and align better with the behavior of the victim model. This approach helps improve surrogate model accuracy by leveraging discrepancies in their predictions on generated data.

4.4.4 Training Procedure

Given the loss functions $\mathcal{L}_{\mathcal{M}_G}$ and $\mathcal{L}_{\mathcal{M}_S}$, similar to the training approach used in Generative Adversarial Networks (GAN) [10], we adopt an alternating training strategy for the generator and surrogate model, resembling a two-player game. The training process can be formulated as:

$$\min_{\mathcal{M}_S}\max_{\mathcal{M}_G}\mathbb{E}_{z\sim\mathcal{N}(0,1)}[\mathcal{D}(\mathcal{M}_V(\mathcal{M}_G(z)), \mathcal{M}_S(\mathcal{M}_G(z)))], \tag{12}$$

where $\mathcal{D}(\cdot)$ represents the discrepancy between the victim and surrogate models. The loss function used to update the generator $\mathcal{M}_G$ is identical to that of the surrogate model $\mathcal{M}_S$, with the exception that the objective is to maximize it.

We provide a concise summary of the StealGNN algorithm in Algorithm 1 (available in the appendix A.1). Our objective is to acquire a surrogate model $\mathcal{M}_S$ from a black-box victim model $\mathcal{M}_V$. Initially, both the surrogate model and generator are randomly initialized. During the generator optimization, the surrogate model parameters remain static, while the generator parameters θ_G are updated based on the chosen attack type. This procedure enables the generator to produce synthetic graphs for efficient knowledge extraction from the victim model. Conversely, in the surrogate training phase, the generator remains fixed, and the surrogate model parameters θ_S are updated. This training phase centers on replicating the victim model's behavior, ensuring the surrogate model captures the targeted knowledge. To maintain balanced training for both the generator and surrogate model, each training phase repeats n_G and n_S times, respectively, before advancing to the next epoch. This repetition enhances the learning and convergence of both models. Training iterations persist until the query budget Q is depleted, indicating that the attacker has exhausted the allotted number of queries for knowledge extraction from the victim model.

Table 2: Summary of datasets.

Dataset	#Nodes	#Edges	#Features	#Classes
Cora [31]	2,485	5,069	1,433	7
Pubmed [24]	19,717	44,324	500	3
A-Computers [32]	13,381	245,778	767	10
OGB-Arxiv [11]	169,343	1,166,243	128	40

5 Evaluation

In this section, we conduct experiments to evaluate the effectiveness of StealGNN. We present the experimental setup and provide evaluation results for node classification tasks, including both transductive and inductive scenarios. Additionally, we evaluate the performance of StealGNN on the link prediction task. Finally, we provide a detailed analysis of the model and parameters used in our experiments. For experimental results on the transductive scenario, please refer to the appendix A.3.

5.1 Experimental Setup

5.1.1 Datasets

To assess the effectiveness of our proposed framework, we conduct experiments using four publicly available benchmark datasets. The dataset statistics are summarized in Tab. 2. For Cora, Pubmed, and A-Computers, we follow the splitting strategy employed in previous work [32], where 20 nodes from each class are randomly sampled as labeled nodes, 30 nodes are used for validation, and the remaining nodes are assigned to the test set. For OGB-Arxiv, we adopt the random split configuration of 90K/29K/48K as established in prior research [12].

Using the same or similar data splits as previous research enables researchers to compare their results directly with existing literature. It ensures consistency in evaluation, making it easier to gauge the effectiveness of new methods or compare them with established approaches. We also explored alternative splits for these datasets, utilizing a 60%/20%/20% division for training, validation, and testing sets. This partitioning strategy allocated a larger proportion of nodes to the

training dataset, resulting in higher accuracy for the victim model when evaluated on the test set. Detailed results of these experiments can be found in the Tab. 5.

5.1.2 Victim Model ($\mathcal{M}_V$) and Surrogate Model ($\mathcal{M}_S$)

To evaluate the performance of the StealGNN framework, we employ widely used GNN models, namely GCN, GAT, and GraphSAGE. The victim model is also trained using the data partitioning scheme described above. Various architectures of the victim model, including different numbers of layers and hidden units, are trained and tested. The model with the highest test accuracy is then selected as the final victim model. Therefore, for different datasets and different models, their model architectures may vary. The architecture and accuracy of the victim model selected for the final experiment can be seen in Tab. 7 in the appendix A.2.

Experiments involving different types of surrogate models and architectures are presented in the Model Analysis and Parameter Analysis sections. In the main experiment, we have chosen to utilize a GCN model with 2 layers and 256 hidden units as the default surrogate model because it consistently performed well across different datasets, as shown in Fig. 4 and Fig. 5.

5.1.3 Generator ($\mathcal{M}_G$)

In our experiments, the choice of hyperparameters for the generator was motivated by their effectiveness in achieving our objectives. For the feature generator, we adopted a design inspired by [35], known for generating informative features. The hyperbolic tangent function was chosen as the final activation to ensure generated features fall within the range [-1, 1]. Regarding the structure generator, we used cosine similarity, which does not require additional training parameters to generate the adjacency matrix, simplifying the model. For the self-supervised training of the full parameter generator, a GCN model with 2 layers and 512 hidden units was selected to strike a balance between complexity and efficiency.

5.1.4 Implementation

For the node classification task, we perform comprehensive experiments on both inductive and transductive graph neural networks (GNNs). However, due to space limitations, the model experiments presented below default to the inductive scenario, where the learned GNN model is capable of generalizing to previously unseen graphs during training. Experiments conducted on transductive scenarios can be found in the appendix A.3. Our experiments are trained using the Adam optimizer [15]. During training, each query consists of the generator being trained $n_G = 2$ times with a learning rate of $1e-6$, while the surrogate model is trained $n_S = 5$ times with a learning rate of 0.001. The total number of queries Q is set to 100. By training the models for a maximum of 100 epochs, we ensure that the models have ample opportunities to converge and achieve satisfactory performance on our experimental dataset.

5.1.5 Evaluation Metric

In model extraction attacks, the objective is to closely align the behavior of the surrogate model with that of the victim model. To evaluate the performance of our attack, we employ two metrics: (1) Accuracy: We measure the accuracy of the attacker's surrogate model on the test dataset. The accuracy is computed as the ratio of correct predictions to the total number of predictions made by the surrogate model. This metric provides an assessment of the attack's effectiveness in replicating the victim model's behavior. (2) Fidelity: The fidelity metric quantifies the agreement between the predictions made by the surrogate model and the victim model. Fidelity serves as a complementary evaluation metric, capturing the similarity in prediction outcomes between the surrogate and target models. To mitigate the impact of randomness during training, we conduct multiple runs of each experiment with different random seeds. Specifically, we perform 5 runs for each experiment and report the average and standard deviation of both accuracy and fidelity across these runs. This approach allows us to capture the overall performance and the degree of variability in the results, providing a more robust evaluation of the attack method.

5.1.6 Baselines

StealGNN is the first study to address data-free model extraction specifically for GNNs. While there have been related methods in the past, they differ in important aspects. Firstly, methods like GNN model extraction or stealing [33, 39], although related, are not data-free techniques as they require access to some original data information. Secondly, there exist techniques such as GNN's data-free knowledge distillation [5, 44], but they are primarily designed for graph classification tasks and operate in white-box scenarios where gradient information of the teacher model is accessible. For each dataset, we conducted several experiments to compare the performance of our model:

- Real Data: We used real training data for model extraction. This allowed us to assess the impact of using artificial graphs for the extraction process.
- Random Graph: We generated random graphs using random noise without updating the parameters of the generator during the training process.
- Graph Structure Experiments: For each type of attack, we conducted experiments using three different graph structures:

Table 3: Experimental Results on the Induction Scenario for Node Classification Task. The table presents the mean and variance of 5 training runs. The brackets indicate the difference between the accuracy of the surrogate model and the accuracy of the victim model. Entries displayed in red font indicate that the surrogate model outperforms the victim model.

(a) Self-Loop Graph Structure ($\mathbf{E}$): In this case, the graph structure consisted of only self-loops, and the adjacency matrix was represented by matrix $\mathbf{E}$.

(b) Cosine Similarity Graph Structure ($\mathbf{A}_{cos}$): The graph structure was generated based on cosine similarity, and the adjacency matrix was represented by matrix $\mathbf{A}_{cos}$.

(c) Full Parameterization Graph Structure ($\mathbf{A}_{fp}$): The graph structure was generated using a parametric approach, and the adjacency matrix was represented by matrix $\mathbf{A}_{fp}$.

By conducting these experiments with different graph structures and utilizing both real data and random graphs, we aimed to evaluate the effectiveness and performance of our model extraction approach.

5.2 Performance Evaluation

Based on the node classification results presented in Tab. 3 and the link prediction results in Tab. 4, it can be observed that all three types of model extraction attacks yield promising results. The Real Data approach, which utilizes real training datasets for extraction, demonstrates a high level of effectiveness. This method resembles traditional knowledge distillation techniques, resulting in a surrogate model that closely approximates the behavior of the victim model. The surrogate model's performance is very similar to that of the victim model, indicating successful extraction of knowledge. On the other hand, the results obtained from the Random Graph approach are noticeably inferior. This can be attributed to the randomly generated graph, which lacks any form of training. Consequently, the distribution of the real training data significantly differs from that of the randomly generated graph,

Table 4: Experimental Results on Link Prediction Tasks. The table displays the accuracy results of the experiments. Note that the OGB-Arxiv dataset is excluded from the analysis due to OOM issues.

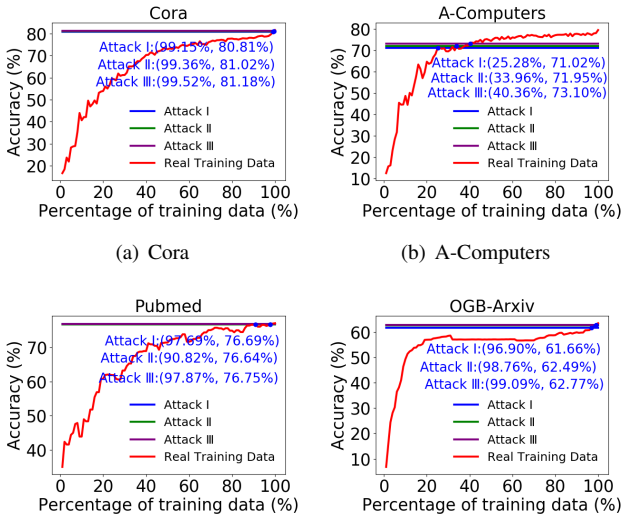
making it challenging to extract knowledge from the victim model into the surrogate model. As a result, the surrogate model's performance suffers.

The experimental results demonstrate that all three types of attacks have achieved notable performance. Attack Type I and Attack Type II exhibit comparable results, while Attack Type III outperforms the other two and consistently achieves the highest accuracy in several datasets. Attack Type III leverages the prediction inconsistency between the two surrogate models to train the generator. This approach ensures that the training process continuously generates informative graphs, facilitating the surrogate model's improved learning from the victim model. As a result, Attack Type 3 exhibits superior performance, achieving optimal accuracy in multiple experimental settings.



Among the three graph structure generation methods, the full-parameter approach stands out as the most effective. It excels due to its capability to generate a diverse range of graph structures through self-supervised training. With a full-parameter model, the generator has access to a larger parameter set, allowing it to capture a broader spectrum of graph structures during training. This flexibility enables the generator to produce diverse graph structures, contributing to more effective knowledge transfer from the victim model to the surrogate models. In contrast, the Self-Loop and cosine similarity methods may be limited in generating diverse graph structures. Self-Loop lacks a specific training process, and cosine similarity structure generation doesn't require training parameters, potentially restricting their ability to generate a wide range of graph structures compared to the full-parameter method. The superior performance of the full-parameter approach underscores the significance of diverse graph structures in facilitating effective knowledge transfer during model extraction attacks.

Table 5: Experimental Results for a 60%/20%/20% Data Splitting Scheme. Values within parentheses indicate improvements compared to another data partitioning scheme. $\mathcal{M}_S$ is also GCN.

Dataset	Cora	Pubmed	A-Computers	OGB-Arxiv
$\mathcal{M}_V$ (GCN)	88.72±0.32 (+8.11)	89.59±0.16 (+12.83)	85.46±0.64 (+4.83)	69.58±0.48 (+2.83)

Tab. 5 presents the results of using an alternative data partitioning scheme. Employing a 60%/20%/20% data split increases the number of nodes in the training dataset, resulting in improved accuracy for the victim model. Correspondingly, the surrogate model, which extracts model information from a better victim model, also exhibits enhanced accuracy. This underscores the effectiveness of STEALGNN - as the victim model's accuracy improves, it imparts richer knowledge to the surrogate model, showcasing the knowledge transfer capabilities of the framework.

The experimental results reveal a noteworthy trend where the surrogate model's accuracy often exceeds that of Real Data and occasionally surpasses the victim model's performance (highlighted in red). One plausible explanation, supported by prior research [33], revolves around the presence of noise in real training data. Real-world data can inherently contain noise, including inconsistencies and inaccuracies. To mitigate this, various data denoising techniques have been proposed [42]. In our approach, a unique feature is the use of a graph generator explicitly trained for model extraction. This generator produces synthetic data tailored for the extraction process, resulting in cleaner and more suitable training data for surrogate models. As a result, we obtain surrogate models that not only replicate the victim model's behavior but, in some cases, even outperform it.

Figure 3: Training with Different Percentages of Real Data. The red curve represents the results as the percentage of real data used for model extraction gradually increases.The intersection point in the graph indicates the required rate of real training data to achieve the same performance as our data-free Attack.

5.3 Model Analysis

In order to gain a deeper understanding of the effectiveness of our data-free attack model, we conducted further analysis to evaluate the role of the generated graphs. Specifically, we compared the performance of the generated data with varying percentages of real data to quantify its impact. Furthermore, we also examined how the structure of the victim model and the surrogate model impacts the performance of the attack. By varying the architecture and parameters of these models, we can assess their influence on the effectiveness of the extraction attack. This analysis provides insights into the sensitivity of the attack to different model structures and can help identify optimal configurations for achieving higher performance.

5.3.1 Comparison with Existing Methods

Directly comparing with existing GNN model extraction methods is challenging due to differing setups. They assume access to original node features or structures, while ours are generated. We held StealGNN's node features or adjacency matrix fixed as real data, while the other was generated (w/ A w/o X: real adjacency matrix, generated node features). From Tab. 6, it is evident that our model consistently outperforms existing works. This highlights that our framework not only addresses scenarios with no access to any real data but also exhibits superior performance in scenarios where partial real data information is available.

Table 6: Comparison between the work by Wu et al. [39] and StealGNN. "w/ A w/o X" denotes that the adjacency matrix of the generated graph is based on real data, while node features are synthetic. Conversely, "w/ X w/o A" indicates that node features are real data, while the adjacency matrix is synthetic.

	w/ A w/o X		w/ X w/o A

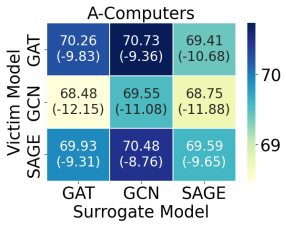
5.3.2 Quantitative Analysis: Role of the Generated Graph

We conduct a detailed analysis of the impact of both the generated graphs and the real data on the performance of the surrogate model. To perform this analysis, we vary the percentages of real data from 0% to 100% and observe the corresponding attack results presented in Fig. 3. In the figure, the x-axis represents the percentage of real training data required, while the y-axis denotes the accuracy rate. The intersection point between the attack's straight line and the curve representing the real data corresponds to the percentage of real data needed to attain our performance. The results reveal an interesting finding: a substantial proportion of real data is required to achieve accuracy levels comparable to our data-free attacks. This implies that the generated graphs play a crucial role in the knowledge transfer process. As the percentage of real data decreases, the attack accuracy decreases as well, indicating that the generated graphs become increasingly essential in compensating for the lack of real data. They demonstrate that the generated graphs effectively capture and transfer valuable information from the victim model, enabling the surrogate model to achieve high accuracy even in the absence of real data.



5.3.3 Impact of Different Combinations of Surrogate and Victim Models

In real-world scenarios, attackers do not have access to the architecture of the victim models. To assess the reliability of our attacker in extracting victim models under such circumstances, we conducted experiments using different combinations of surrogate and victim models for Attack I-$\mathbf{A}_{cos}$. With our experimental setup, which includes three victim models and three surrogate models, we explored nine different combinations for each dataset. Fig. 4 demonstrates that our attacker is capable of constructing viable surrogate models across various combinations. This observation confirms the effectiveness of our attack in successfully extracting useful knowledge from victim models, regardless of the specific combination of surrogate and victim models.

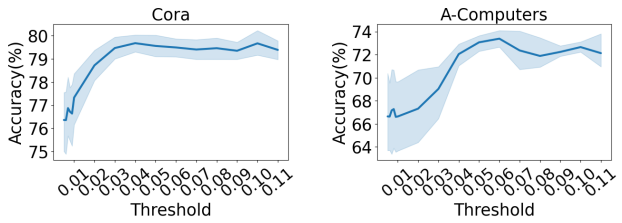
5.3.4 Impact of Different Surrogate Model Structures

To assess the robustness of our attack in different scenarios, we perform ablation experiments to examine the influence of different surrogate model architectures on the attack's effectiveness. Fig. 4 demonstrates that using GCN as a surrogate model consistently leads to more reliable model extraction. We further investigate the impact of various GCN architectures on the performance of our attack I-$\mathbf{A}_{cos}$. From the observations in Fig. 5, we draw the following conclusions: (1) Accuracy tends to be higher when the surrogate model employs a two-layer structure with 256 hidden units. (2) In contrast, the effect is significantly poorer when the number of hidden units is only 16. These findings indicate that the number of hidden units in the surrogatemodel has a substantial impact on the success of model extraction. Surrogate models with a higher number of parameters are more effective in extracting the unknown architecture of the victim model.



5.4 Parameter Analysis

5.4.1 Impact of the Size of Generated Graph

We investigate how the size of the generated graph, specifically the number of nodes, affects the performance of our attack. We conduct experiments on the Cora and Pubmed datasets, varying the node number of the generated graph from 5 to 400, as shown in Fig. 6: (1) Even with a generated graph containing only 50 nodes, our data-free model extraction attacks still achieve satisfactory accuracy. This highlights the effectiveness of our approach, as even a relatively small graph can capture and transfer valuable model information. (2) In Fig. 6 (b), we observe that the attack's performance tends to improve as the number of nodes in the generated graph increases. This suggests that a larger generated graph is more effective in capturing the complex and rich information of the victim model. In all of our experiments, we set the number of generated nodes to 250, which yields favorable results.

5.4.2 Impact of the Threshold τ

The threshold τ of the generated structures plays a crucial role in controlling the sparsity of the adjacency matrix. When the threshold exceeds 0.11, the model extraction performance significantly decreases due to the sparse nature of the generated graph, where there are almost no edges present. To understand the impact of threshold τ on the attack performance, we conducted experiments by varying τ from 0.005 to 0.11 on the Cora and A-Computers datasets. The results are shown in Fig. 7. From the figure, we observe that smaller thresholds, corresponding to denser graphs, lead to lower accuracy in the attack. This can be attributed to the fact that overly dense graph structures introduce significant disparities between the distribution of real data and generated data,

(a) Cora (b) A-Computers

Figure 7: Impact of Threshold τ.

hindering the learning process of the surrogate model. In our experiments, we set τ to 0.1 as it achieved satisfactory results.

6 Discussion

Limitation. An inherent limitation is its reliance on query access to the target GNN model. In practical scenarios, unrestricted query access may not always be feasible due to factors like access restrictions, cost considerations, or privacy concerns. These limitations can hinder the attacker's ability to execute a sufficient number of queries. Additionally, query-based attacks may not be suitable for all applications, where the cost or impact of querying the target model might be prohibitive. Future research should explore alternative attack strategies that reduce reliance on query access, thereby expanding the practical scope of GNN model extraction attacks and addressing scenarios with limited query access.

Defense. Prior defense strategies against model extraction attacks have often focused on adding noise to the output probabilities while maintaining the label outputs, effectively perturbing the probability distribution while preserving the top-1 label [16, 27]. However, it is crucial to note that this type of defense approach prove ineffective against StealGNN due to its inherent hard-label setting. In StealGNN, the attacker solely relies on the data's label information for model extraction, making it impervious to perturbations in output probabilities that do not alter the top-1 label. Therefore, traditional noise injection defenses that preserve label accuracy might not deter StealGNN effectively. Moreover, employing a defense strategy that deliberately introduces incorrect labels to the victim model's output can be detrimental to its performance. While this approach may disrupt model extraction attempts, it comes at the cost of degrading the accuracy and reliability of the GNN model's predictions, which is undesirable in practical applications.

To address the vulnerability of GNN models to StealGNN and similar model extraction attacks, it is imperative to explore alternative countermeasures that strike a balance between security and model performance. Some potential countermeasures and research directions include: (1) Adaptive Defenses: Developing adaptive defense mechanisms that dynamically adjust the model's behavior in response to potential model extraction threats. Such defenses could selectively introduce perturbations or noise when they detect suspicious querying patterns while maintaining performance in normal use cases. (2) Privacy-Preserving Techniques: Incorporating privacy-preserving techniques, such as differential privacy, into GNN models can add an additional layer of protection against model extraction attacks. These techniques can help obscure sensitive information in model responses.

7 Related Work

Model extraction attacks against GNNs. Graph learning models are indeed vulnerable to model extraction attacks, which aim to construct a surrogate model that closely matches the performance or prediction distributions of the target model. Our proposed extraction attack approach differs from existing methods in the context of Graph Neural Networks (GNNs). Prior model extraction attacks against GNNs, such as the work by Defazio et al. [4] and Wu et al. [39], typically assume that the attacker has access to information about the victim model's original training data, including node features, graph structure, or subgraphs. These attacks involve perturbing subgraphs or reconstructing missing attributes/edges based on auxiliary information to train a surrogate model that mimics the target model's behavior. These approaches primarily focus on transductive GNNs, and the problem of predicting unseen nodes has not been extensively explored. While Shen et al. [33] consider model stealing attacks against inductive GNNs and perform security risk assessments, their assumption of having access to node features from the same graph distribution used to train the victim model is also unrealistic in many real-world scenarios.

8 Conclusion

In this study, we explored data-free model extraction attacks on GNNs to assess their vulnerability without access to original training data. Through extensive experiments and analysis, we uncovered the effectiveness and limitations of these attacks. Our findings reveal that data-free model extraction can achieve high success rates in extracting knowledge from victim GNN models. These attacks employ synthetic graph generation and surrogate models to approximate the victim model, resulting in accurate proxies that capture its behavior.

A Appendix

A.1 Algorithm

Algorithm 1 iteratively improves the surrogate model's performance by leveraging the generated synthetic data and optimizing both the generator and surrogate model parameters.

A.2 Victim Model Selection

Our framework is designed to extract knowledge from message-passing-based GNN models. In our experiments, we consider three representative GNN models: GCN, GAT, and GraphSAGE, which serve as the victim models. To select the most suitable pre-trained victim model, we conduct experiments with various architectures for each of these three models. We explore different combinations of the number of layers and hidden units, ranging from 1 to 5 and 16 to 256, respectively. The goal is to find the architecture that achieves the highest accuracy. After thorough experimentation, we determine the final architecture and accuracy of the chosen victim models, which are presented in Tab. 7. These models serve as the targets for our data-free model extraction attacks.

A.3 Tranductive Node Classification

Tab. 8 presents the results of node classification experiments in transductive scenarios. The table compares the performance of the three attacks using Real data and Random Graph. The results demonstrate that our framework achieves excellent performance even in the transductive scenario. This finding further confirms the versatility of our model, which can be successfully applied in various scenarios, including both transductive and inductive settings for node classification and link prediction tasks.

A.4 Connection with Real-World Cases

Type I Attack: Knowledge Transfer through Estimation:
(1) Real-World Scenario: Imagine a scenario in which a company has developed a highly effective recommendation system using a proprietary graph neural network for personalized content recommendations to users. Competing companies may want to extract knowledge from this system without direct access to the model's parameters or training data.
(2) Application: In this case, attackers can use a surrogate model to estimate gradients of the victim model's behavior by querying it with various inputs (e.g., user profiles, content features). They use these gradients to improve their own recommendation system, effectively transferring the valuable knowledge from the victim model.

Type II Attack: Gradual Alignment with Surrogate Model:
(1) Real-World Scenario: Consider a situation where a pharmaceutical company has developed a GNN-based model to predict the effectiveness of drug compounds for specific diseases. Competing research groups want to emulate this model's predictions without having access to its internals.
(2) Application: Attackers can train a graph generator that is only based on surrogate model's predictions. As surrogate model gains more data and refines its predictions, it gradually aligns with the victim model's behavior. Over time, the surrogate model becomes a closer approximation of the victim model, and the attacker can extract valuable drug compound prediction knowledge.

Type III Attack: Exploiting Inconsistent Predictions:
(1) Real-World Scenario: Suppose there is a financial institution using a GNN for credit risk assessment. A competitor may be interested in understanding the decision-making process of this model to improve risk assessment strategy.
(2) Application: Attackers can simultaneously train two surrogate models, each of which attempts to mimic the victim model's behavior. If these surrogate models make inconsistent predictions for certain credit applications (e.g., one surrogate approves while the other rejects), it indicates that they have

Table 7: Architecture selection and accuracy of the victim model in two tasks.

Jasper Stang
University of Würzburg

Alexandra Dmitrienko
University of Würzburg

Abstract

Due to costly efforts during data acquisition and model training, Deep Neural Networks (DNNs) belong to the intellectual property of the model creator. Hence, unauthorized use, theft, or modification may lead to legal repercussions. Existing DNN watermarking methods for ownership proof are often non-intuitive, embed human-invisible marks, require trust in algorithmic assessment that lacks human-understandable attributes, and rely on rigid thresholds, making it susceptible to failure in cases of partial watermark erasure.

This paper introduces ClearStamp, the first DNN watermarking method designed for intuitive human assessment. ClearStamp embeds visible watermarks, enabling human decision-making without rigid value thresholds while allowing technology-assisted evaluations. ClearStamp defines a transposed model architecture allowing to use of the model in a backward fashion to interwove the watermark with the main task within all model parameters. Compared to existing watermarking methods, ClearStamp produces visual watermarks that are easy for humans to understand without requiring complex verification algorithms or strict thresholds. The watermark is embedded within all model parameters and entangled with the main task, exhibiting superior robustness. It shows an 8,544-bit watermark capacity comparable to the strongest existing work. Crucially, ClearStamp's effectiveness is model and dataset-agnostic, and resilient against adversarial model manipulations, as demonstrated in a comprehensive study performed with four datasets and seven architectures.

1 Introduction

In the realm of rapidly advancing technologies, machine learning stands out for many advantages, primarily revolving around automation, informed decision-making, and insightful recommendations drawn from historical data. This transformative technology finds extensive application in diverse real-world scenarios, ranging from critical tasks such as medical image classification [5] to facilitating processes like natural language processing [12], and extends further into domains like autonomous driving [7] and translation services [50]. At its core, a machine learning system consists of a model, often a Deep Neural Network (DNN), and data. Acquiring this data, especially in large quantities necessary for robust machine learning, can be both challenging and costly. Furthermore, the data can be inherently sensitive, such as in the case of medical images, warranting strict protection under the umbrella of intellectual property (IP) rights belonging to its owner. Once data becomes available, significant computational resources are utilized for model training, which entails substantial effort and, consequently, costs. The resulting model, infused with knowledge distilled from underlying training algorithms and exhaustive data, represents a culmination of innovation and expertise in the field DNNs and embodies the IP of its creator.

However, in case a model is made available to the public or sold to third parties, the matter of safeguarding IP rights becomes a challenge. In the face of potential adversarial entities, these models are vulnerable to theft, unauthorized resale, unwarranted modification, or illicit utilization. Such circumstances, recognized as copyright infringements, have the potential to escalate into legal proceedings, underscoring the significance of robust and comprehensive protective measures.

The state-of-the-art approach to safeguarding the IP of trained models is model watermarking [3, 35]. Existing DNN watermarking methods commonly require a key as input to an algorithm for watermark extraction. This process generates an output that is subsequently verified against the secret ground truth of the watermark. Watermarking methods can be categorized based on two main properties: whether they operate by accessing the model's internals (white-box) [15, 15, 34, 54, 57, 61, 63], such as the weights, or by analyzing only prediction outputs (black-box) [1, 21, 28, 36, 40, 70, 71]. Moreover, a watermark is either 1-bit [28, 40, 54] or multi-bit [1, 15, 15, 21, 28, 34, 36, 57, 61, 63, 70, 71]. A 1-bit watermark merely indicates the presence or absence of a watermark, whereas a multi-bit watermark incorporates details like the name of the copyright holder.

Problem Statement. However, the watermarking techniques

proposed so far can be considered non-intuitive, as they embed human-invisible watermarks. Consequently, for watermark verification, the evaluator must place trust in the algorithm, which typically extracts data from the DNN that lack human-understandable attributes. This data is then distilled into a single value, and then compared to a rigid threshold, where values above it confirm watermark's existence and values below it deem the watermark invalid. In cases of partial watermark erasure algorithmic assessment might fall short, while humans with a clear understanding of its prior presence might be able to easily verify a copyright infringement. In the context of an image, for instance, it is imaginable that a watermark, depicted as a stamp, could be erased, for instance, up to 70%; nevertheless, even with this level of reduction, it may still remain conspicuously apparent that the watermark was once embedded into the image.

This paper addresses these challenges and introduces ClearStamp, the first multi-bit, white-box DNN watermarking method that follows an intuitive approach. ClearStamp embeds a visible watermark that can be assessed through human inspection, empowering humans to make decisions based on common sense and reasoning while retaining the option for technology-assisted evaluations. In addition, the method is generic and can be applied to various datasets and model architectures, and is robust against a wide range of watermark erasure techniques, including manipulation attempts by adaptive attackers who know the details of the protection method and even of underlying keys.

Contributions. This paper makes the following contributions:

- We propose ClearStamp, the first DNN watermarking mechanism that yields human-visible and understandable outputs, bypassing the need for rigid value thresholds and enabling more coherent and defensible jurisdiction, especially in cases where portions of the watermark remain obviously discernible. As a consequence, ClearStamp provides more security for the model creators' intellectual property.

- We have pioneered the utilization of transposed model training inspired by deconvolutions [18,20,26,48,67,69] as a novel approach for integrating a visible and human-comprehensible watermark into a DNN. In this method, we define a transposed model architecture specifically tailored to the existing model's structure, which shares weights with the original model. This enables model training in a reverse fashion, focusing on embedding the watermark, while the effects on conventional forward training for the model's primary task are negligible.

- We entangle the watermark and the main task within all model layers to create a robust watermark that can withstand adversarial model manipulations, such as fine-tuning on third-party datasets, pruning of model parameters, or adaptive adversaries attempting to remove or overwrite the watermark. Inspired by Siamese Networks [30], we achieve this by sharing weights between the model's primary task and the watermark and by enforcing that the watermark does not cause abnormal model parameters. Any malicious modification necessitates sacrifices in the model's main task performance, rendering the model less useful.

- We conduct a systematic large-scale study to analyze factors influencing ClearStamp, demonstrating its independence from application-specific factors by leveraging different datasets (MNIST [16], CIFAR-10 [32], GTSRB [51], and CIFAR-100 [32]) and model architectures (CNNs, ResNet-18, ResNet-34 [25], ViT [17], and VGG11 [46]) during evaluation. Additionally, we test the watermark's robustness under various fine-tuning and pruning scenarios and showcase a substantial watermark capacity of 8,544 bits that can be embedded with a low error rate of 4.45%, which is comparable to the strongest existing work in terms of capacity with 8,400 bits [34].

In summary, this work introduces a highly intuitive and easy-to-understand white-box multi-bit DNN watermarking method, offering a robust defense against various attack scenarios. The embedded watermark is human-understandable, addressing the limitations of existing solutions, which often lack intuitive design and human-friendliness in the final decision-making process, a task that can be seamlessly undertaken by a human evaluator when employing ClearStamp.

2 Background

Watermarking Watermarking [14, 19, 24, 29, 39, 43, 59] is a technique to embed a digital mark or identifier into digital media, e.g., images or audio, without significantly altering the content's appearance or functionality, with the purpose of embedding a discernible sign of ownership, authenticity, or other relevant information. Those signs can then be used for various scenarios, e.g., copyright protection, authenticity verification, ownership attribution, digital rights management, tamper detection, or metadata embedding. Watermarks come in various forms, with visible and concealed watermarks being notable categories. 1-bit watermarks make explicit ownership claims through their mere presence, while multi-bit watermarks convey additional information. The choice of watermarking method depends on the specific use case and the desired level of security. Extracting the watermark, which is a *secret value*, relies on knowing the *extraction method* and is often accompanied by a specific *secret key*.

In DNNs the watermark is embedded typically within the model's parameters [3, 35]. This can transpire either directly, necessitating white-box access to the parameters for extraction and verification, or indirectly through a learning process that configures the parameters to produce outputs containing the watermark when subjected to specific inputs. In such a

case, black-box access is necessary for watermark verification. Both methods are achieved by introducing an additional regularization term to the loss function during model training. This regularization term orchestrates parameter adjustments in alignment with the intended watermarking objectives.

For watermark extraction and verification, the DNN and the watermark's secret key are fed into an extraction algorithm which yields some data. Those data are then verified against the watermarks ground truth secret by an algorithm that relies on a rigid threshold.

Transposed Model Functionality The transposed functionality of a machine-learning model is the reverse of the original model's task. We leverage the concept of transposed models to embed a watermark into the model. For instance, consider a model that classifies image inputs into a feature vector indicating detected objects within the image. The transposed functionality would involve inputting such a feature vector into the model to generate an image that embodies the characteristics encoded within that feature vector. This concept extends to the more granular level of model layers, where transposed layers reverse the functionality of their corresponding original layers. A transposed model consists of multiple transposed layers in the reverse order of the original model's architecture. Below, we discuss common model layers and existing or straightforward methods for transposing their functionality. However, certain layers may not be capable of precisely recovering the original input, especially when input data have undergone compression, resulting in information loss.

Linear Layer. A linear layer performs a calculation such as $y = x \cdot w^T + b$, where w and b denote weights and bias matrices, and x and y represent input and output, respectively. Here, T denotes the transposed operation such that the matrix is flipped over its diagonal, e.g., A_{ij} becomes A_{ji}. Linear layers can be accurately reversed by computing $x = (y-b) \cdot w$, effectively retrieving the original input from the output.

Batch Normalization. Batch normalization layers [27] are used to keep the data flowing through a model in a specific range. Such layers perform a computation akin to $y = \frac{x-E(x)}{\sqrt{Var(x)+\varepsilon}} \cdot \gamma + \beta$, where $E(x)$ and $Var(x)$ are the feature-wise mean and variance of the input data, ε is a small constant, and γ and β are learnable parameters. As mean and variance are dependent on x, the operation cannot be reversed straightforwardly when only provided with y. To address this, one can set default values for $E(x) = 0$ and $Var(x) = 1$, resulting in $x = \frac{(y-\beta)\cdot\sqrt{1+\varepsilon}}{\gamma}$, which provides a good approximation.

Pooling Layer. Pooling layers [68] reduce the dimensionality of data by selecting representative values among multiple data points based on specific rules, such as computing the average or selecting the maximum value. As this process fundamentally involves downsampling, the transposed functionality is centered around upsampling. Consequently, the exact transposition of such downsampling computations can only be approximated, as new data points must be inferred. One common approach to upsample data is through interpolation, with several interpolation methods available, such as the nearest-neighbor algorithm [44] or the bilinear algorithm [45].

Convolutional Layer. A convolution [33] transforms the input to extract relevant features. This transformation applies a filter or kernel to the input to produce output data points. Multiple input data points are convolved with the filter to generate a single output data point. Hence, similar to downsampling, the computation cannot be exactly reversed. However, a method proposed in [69] offers a reasonably effective approximation[1].

Dropout Layer. Dropout layers [49] are designed to distribute knowledge across various parameters. They implement a regularization technique that simulates training numerous neural networks with varied architectures concurrently. During training, random layer outputs are ignored, altering the layer's appearance and connectivity. Each training update reflects a distinct "view" of the layer. They exert influence during training, have no learnable parameters, and remain inconsequential during inference. Therefore, dropout layers are utilized identically to the forward pass during transposed training.

Activation Functions. Activation functions, e.g., ReLU [2], introduce non-linearity in a model and play a significant role in the model's ability to generalize learned knowledge. Some activation functions introduce lossiness, like ReLU, which maps all negative input values to zero while the positive input values remain the same. Naturally, such operations are irreversible, and thus, activation functions can not be transposed.

Transformer Blocks. Transformer models, like Vision Transformer [17], deviate from convolution-based models and are constructed by so-called transformer blocks, which consist of an encoder and an attention module, both featuring linear layers, dropout layers, and activation functions. Vision Transformer divides the image into patches and embeddings are generated for each patch. The transposed functionality of these linear layers, dropout layers and activation functions was already elaborated in the previous paragraphs, indicating that transposing a Vision Transformer is straightforward.

In summary, the transposition of model functionalities can be applied to a variety of common machine learning architectures. While some layers allow for a straightforward reversal, others necessitate approximation methods due to inherent complexities and information loss.

Image Similarity Human discernment of whether two images share identical content is typically straightforward. Nevertheless, conventional machine-based methods for quantifying errors, such as the computation of Mean Squared Error (MSE) across all pixels in an image, can yield substantial error values, particularly when the images possess matching structural elements but differ in aspects like color. Human visual perception excels at extracting structural information from images,

[1] The method of [69] is also used in PyTorch as transposed convolution modules and can be seen as the gradient of the respective convolution.

and in this context, Wang *et al.* [64] introduced the Structural Similarity Index (SSIM). Within this paper, we employ SSIM as part of a loss function to embed a watermark into a DNN, as well as for post-extraction verification of the watermark's presence and integrity. The SSIM has a value range of $[-1, 1]$, where 1 indicates perfect similarity, 0 indicates no similarity, and -1 indicates perfect anti-correlation.

SSIM addresses the limitations of other metrics by providing a quantifiable measure of image dissimilarity considering luminance, contrast, and structure, aligning more closely with human perception. As exemplified in Tab. 1, MSE calculations often highlight substantial disparities from the original image, whereas SSIM reliably identifies high levels of structural similarity of the content. As visualized in the fifth column of Tab. 1, even SSIM values of, e.g., 0.18, are sufficient, such that a human can claim similarity between two images.

Image						
SSIM	1	-1	0	-0.02	0.18	0.75
MSE	0	64,322	31,642	32,856	19,764	5,909

Table 1: A reference image (first column) compared to images (first to sixth column) regarding SSIM and MSE values.

3 Problem Setting

Considered Scenario. We consider a classical watermarking scenario: The model owner trains a Deep Neural Network (DNN) by utilizing a proprietary dataset and costly resources making it critical to protect the resulting model, which is the intellectual property of the owner. Thereby, a maximally effective watermark should be embedded that allows ownership claim. The produced model is then legally or illegally distributed, e.g., sold or stolen, and placed into production. If the owner suspects a copyright infringement of their model, an inspection of the suspected model can be conducted. Precisely, it should be possible to extract and verify the watermark, even if benign or adversarial modifications have been performed on the copy of the original model. In the following, we first define the objectives (Sect. 3.1) and the threat model (Sect. 3.2).

3.1 Watermark Objectives

Inspired by related works [6, 9, 10, 15, 21, 36, 65, 66], we define several objectives, that should be fulfilled by an effective watermark: 1) *Understandability*: The evaluation of the watermark should be easily possible by human inspection. We add this objective to the commonly used ones, as the final decision in common DNN watermarking methods typically relies on a rigid threshold that may not detect leftovers after watermark erasure attempts, but those could be obvious to detect for human observers. Such situations occur for example for partly erased watermarks, that are interpreted as removed by a machine but are still recognizable by human inspection. We visualize a respective toy example in App. 7.1. Further, decisions that can be made by humans are more intuitive and easily comprehensible than empirically determined thresholds. 2) *Fidelity*: Watermark embedding should preserve the model performance on the primary task. 3) *Reliability*: It must be reliably possible to extract the watermark from previously watermarked models[2]. 4) *Robustness*: The embedded watermark must withstand model modifications, which we describe in Sect. 3.2. 5) *Integrity*: The watermark method should uniquely identify the watermark's secret value respective to the watermark's key and should not extract a valid watermark from unwatermarked models. 6) *Capacity*: The amount of information embedded into the watermark should be maximized to strengthen ownership claims. 7) *Efficiency*: Embedding the watermark should introduce negligible computational overhead. 8) *Security*: The watermark should not introduce obvious footprints allowing for easy detection and removal. 9) *Generalizability*: The approach should be independent of the dataset or model architecture.

3.2 Threat Model

Our threat model specifies DNN model modification scenarios the attacker can undertake with the goal of removing the watermark from the trained and watermarked model.

Fine-Tuning. In fine-tuning [47, 53], the adversary continues training with a dataset akin to the original training dataset in the hope of removing watermarks that are added on top of the main task. Here we assume, that the adversary is aware of the training procedure including hyperparameters, and hence can adopt the settings for model modifications. Specifically, the learning rate is either kept at parity with the original training or, alternatively, can be decreased from the original value. In most benign fine-tuning scenarios, such a reduction of the learning rate is a typical approach to preserve the already trained meaningful features and only provoke small changes caused by the new dataset. Alternatively, the adversary can fine-tune the model on a different dataset, which may necessitate the substitution of the last model layer with an untrained counterpart due to a different number of label classes.

Pruning. Pruning [23] is normally used to reduce the DNN size to facilitate deployment in smaller setups like embedded devices. As the adversary can arbitrarily modify model weights, parameters can be pruned in the hope of removing the watermark while keeping a reasonable main task performance. This entails the elimination of a specific proportion of parameters, called pruning level, characterized by the lowest absolute values within the model, as those parameters are deemed to have the most marginal influence on the model's

[2]Note that watermarks from models that have been significantly manipulated to the extent that the original main task is severely compromised do not require detection, as the model no longer retains the creator's IP rights.

overall performance. Such pruning methods can be combined with fine-tuning, which is called fine-pruning [37, 56].

Adaptive Adversary. An informed adversary, possessing knowledge of the watermarking methodology, may attempt to manipulate the existing watermark [29, 57] leveraging the same embedding technique. Thereby, the adversary can invent a new watermark that can either contain meaningful or random data and embed the watermark in the hope of removing or replacing the original one. Removing the watermark would prevent ownership claims by the model creator. A replacement would transfer the possibility of claiming model ownership to the adversary. Usually, the watermark is kept secret and the adversary is not aware of the watermark's data.

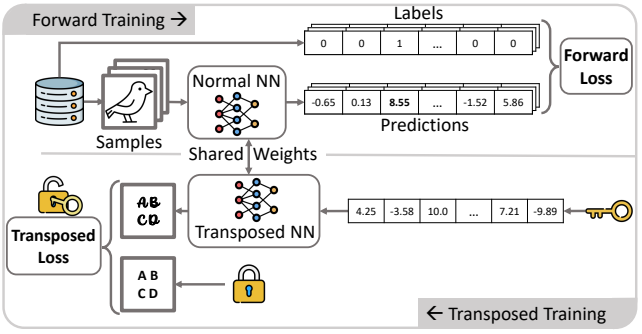

Figure 1: Visualization of main task forward training and watermark (key & lock) embedding in transposed training.

4 Approach

In this section, we present our general concept in Sect. 4.1, followed by details about the generation of transposed models in Sect. 4.2, the composition of the watermark in Sect. 4.3, and details on the training procedure in Sect. 4.4.

4.1 Overview

We propose *ClearStamp*, a white-box and multi-bit DNN watermarking method, that embeds a watermark secret matching to a specific watermark key within the complete set of model parameters. The watermark key has the form of a regular output vector of the DNN and the watermark secret is represented by an input-like sample of the DNN, that can contain arbitrary information, e.g., random text superimposed on an image, without necessitating visual or context-wise similarity to actual dataset samples. After legal or illegal model distribution of the trained and watermarked model, ClearStamp's verification process can use the key to extract the embedded secret from the DNN and, thus, claim ownership and potentially copyright infringement. Below, we describe ClearStamp's principle and outline the successive steps of ClearStamp during the model life-cycle.

Principle of ClearStamp. In the process of embedding a watermark into the model, ClearStamp employs transposed model training, as visualized in Fig. 1. Therefore, we construct a transposed model architecture that is constructed using the method presented in Sect. 4.2 and establish weight sharing (similar to Siamese Networks [30]) between the standard model and transposed model by assigning the parameters of each layer to the respective transposed layer. Consequently, these shared weights can be subject to regular training for the main task via conventional (forward) training with respect to the forward loss, e.g., cross-entropy, as illustrated in the upper portion of Fig. 1. Simultaneously, we perform the transposed training with the predefined watermark key and secret visualized as key and lock in Fig. 1, representing the training data. The key, a prediction-like vector, is fed into the transposed model, generating an output akin to the input data of the regular DNN, e.g., an image, as visualized in the lower part of Fig. 1. During transposed training, the shared model weights are optimized with respect to a transposed loss, that is calculated by comparing the output of the transposed model with the watermark's secret. By applying both, forward and backward training, ClearStamp can entangle the main task and the watermark within all model layers of the DNN.

ClearStamp Life Cycle. During a model's life-cycle, ClearStamp follows the four steps visualized in Fig. 2. The untrained model is initialized with random parameters, that neither performs well on the main task for forward model inference nor on the watermark for transposed inference. 1) In the watermark hardening phase, we initialize the parameters of the model by transposed training on the watermark until a self-defined sufficient enough watermark quality is reached, which essentially means, that the model is overfitted on the watermark[3]. Thereby, the watermark builds the basis for the main task in the consecutive forward training within the model parameters. 2) During the constraint training phase, normal forward model training is equipped such that the already embedded watermark from step 1 persists. Thereby, we alternate between optimizing the two tasks, which is described in detail in Sect. 4.4. The training can mainly focus on optimizing the main task, as the effect of the watermark task during optimization is minimal, due to the foregone watermark hardening step. The parameters are prepared during step 1 such that the watermarking task yields a negligible loss compared to the main task and essentially functions as a constraint during normal model training. 3) After model distribution, the model is manipulated by a third party, e.g., fine-tuned[4]. As long as the main task performance is preserved, the watermark should remain embedded. 4) Finally, a transposed inference on the

[3] We suggest an SSIM value above 0.95 as watermark quality threshold, as such values can be achieved fast in transposed-only training since the watermark consists of a limited small amount of key-value pairs. In our experiments, we combine this threshold with a maximum of 10,000 epochs.

[4] Step 3 can differ depending on the scenario/attack. We describe various scenarios in Sect. 3.2 and provide evaluations in Sect. 5.2 and Sect. 5.4.

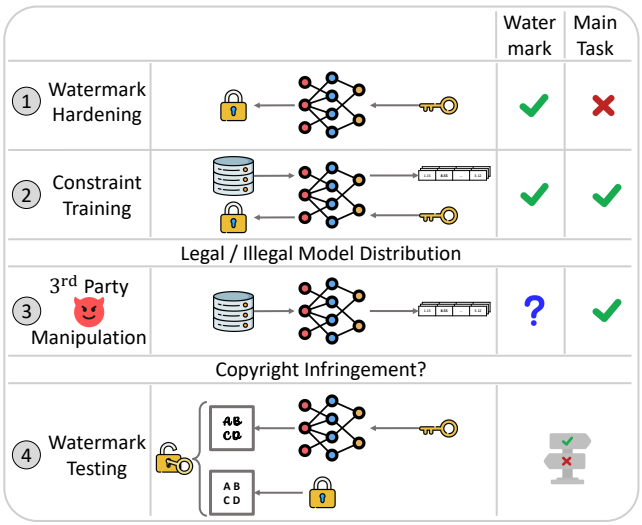

Figure 2: Overview of ClearStamp's life cycle steps.

watermark key is conducted to extract the watermark data, which is verified against the ground truth watermark secret by human-only inspection or machines. Since the main task relies on the fortified parameters established in step 1, creating an inherent interconnection between the tasks, substantial modifications made to the watermark in step 3 directly influence the main task. This direct impact enhances the overall robustness of the watermark.

To enable ClearStamp, we must define several components: First, in Sect. 4.2, we define rules for the creation of a transposed model from a given model architecture. Second, we specify how the key and the secret of the watermark are composed in Sect. 4.3. Third, in Sect. 4.4, we determine how to train while maintaining the watermark.

4.2 Transposed Model Generation

To ensure fulfillment of the generalizability requirement from Sect. 3.1, we establish guidelines for the generation of transposed models. Thereby, we define how model layers and connections are translated to the transposed version[5]. Linear layers and batch normalization layers [27] are straightforward mathematical operations and easy to transpose, as discussed in Sect. 2. For pooling layers [68], we leverage interpolation based on the nearest-neighbor algorithm [44]. Convolutional layers [33] are transposed with deconvolutions[6] as in [69]. Dropout layers [49] and activation functions, e.g., ReLU [2], are used likewise to their untransposed functionality.

Skip Connections. Skip connections fork the data processing within the model architecture and merge the data from both branches at a later stage, alleviating the vanishing gradient problem and improving the accuracy of DNNs. Skip connections effectively perform an operation akin to $a+b=c$ during the merging process within the forward path. Hence, they are difficult or impossible to reverse as only the output c is provided during transposed training, rendering a and b indistinct. To transpose the skip connection, we freeze one part of the connection, such as b, during transposed training. Thus, by the inverse of the mathematical operation between a and b the skip connection can be transposed utilizing c and the frozen b. This effectively adds b to the watermark's key. To get a reasonable estimation of a realistic value for b, we start training an unwatermarked model for a few initial epochs.

Additional Dropout Layers. To ensure the robustness requirement from Sect. 3.1, ClearStamp strives for a robust entanglement between the watermark and the main task. Therefore, the watermark needs to be embedded within all model layers during the watermark hardening step. To facilitate the entanglement between the watermark and the main task, spreading the watermark across multiple parameters must be enforced. Such a behavior can be achieved within model architectures by utilizing dropout layers [49]. For model architectures that lack inherent dropout layers, we artificially add such layers into the transposed architecture. Specifically, dropout layers are incorporated after each convolutional and linear layer, with the exception of the final layer responsible for producing the ultimate output of the transposed model. The dropout rate is an insensitive parameter, that must be set to some reasonable value, which can be quickly identified by analyzing the first few update steps during watermark hardening. Higher dropout rates extend the duration of the hardening process but do not compromise ClearStamp's functionality.

4.3 Watermark Composition

Watermark Key. The key's structure must align with the dimensions of a regular output vector of the (forward) model. Generally, there are no constraints on the values within this vector, allowing for arbitrary and extreme values, that are usually not encountered in forward prediction vectors. However, we need to enforce an overlap of the model's forward output value range and the watermark key's value range. Otherwise, e.g., if the key only consists of positive values, the model will most likely group the outputs of the main tasks to different value ranges, e.g., negative values. Such a separation prevents tight entanglement of the two tasks and encourages the model to handle the tasks in a multi-task instead of a constraint-task manner. As a result of separated value ranges, the watermark can be removed from the model with minimal effects on the main task, contrary to scenarios where the value ranges overlap. To address this, we generate random key vectors with values between a predefined range from -10 to 10, as visualized in Fig. 1, given that most random initialized models

[5]Please note that the transposed model can be generated solely from the weights of the original model and does not require any additional parameters.

[6]We adapt the settings, e.g., kernel size and stride, from the convolution with potential adjustments to padding to ensure the output of the deconvolution matches the original input.

predominantly generate values around zero.

Watermark Secret. The watermark's secret, adaptable to regular input sample dimensions like images, can be 1-bit using a random image or multi-bit with additional content like text. Similar to the watermark key values, the values of the watermark secret should fall within the range of typical input data. This ensures an intertwined relationship between the watermark and the main task parameters, ultimately enhancing the robustness of the watermark. When employing a loss function solely based on structural similarity between images, there might be challenges in producing outputs within the desired range. To address output range challenges, we employ a dual-loss strategy in transposed training. SSIM ensures structural similarity with the watermark secret, while MSE maintains exact secret values in the output.

Multi-Key. Employing not just one, but multiple unique key-secret pairs within a single watermark significantly increases the capacity of the multi-bit watermark addressing the capacity requirement from Sect. 3.1. This approach allows for the embedding of a greater volume of information. Furthermore, it enhances the robustness of the watermark as multiple keys influence a larger portion of the model's parameters, complicating erasure attempts by third parties. These distinct key-secret pairs are inputted into the transposed model as a unified batch. This method compels the model to grasp the underlying structure of the secrets and integrate the watermark throughout all layers. Additionally, this approach offers the advantage of preventing the parameters in the transposed model from memorizing specific key-secret pairs. Instead, the model generalizes the functionality underlying the samples, reinforcing learned capabilities across various layers. To optimize this approach, it is advisable to ensure that the different key-secret pairs share a consistent structure, such as all containing textual information within images. This uniformity enhances the model's ability to learn and embed diverse information effectively.

4.4 Constraint Training

Watermarking the model in the proposed way (cf. Fig. 1) essentially corresponds to simultaneously learning two separate tasks within one model, resulting in a multi-objective optimization problem consisting of the model's general functionality as task one and the watermark in the transposed model as the second task. After overfitting the transposed model to the watermark in the watermark hardening phase (step 1 of Fig. 2), the watermarking task can be considered as a constraint to the main task in step 2 in Fig. 2. This entails, that we optimize the main task while keeping the watermark functionality. To execute this optimization, we leverage sequential optimization, essentially alternating between optimizing the model parameters for the main task and the watermark. Alternatives to this optimization approach are discussed in App. 7.4.

5 Evaluation

Hardware & Experimental Setup. Experiments are implemented in PyTorch, a prominent Python-based machine learning library [55], on a server featuring an AMD EPYC 7413 24-Core Processor (64-bit) with 96 processing units and 128GB main memory. An NVIDIA A16 GPU with 4 virtual GPUs (each 16GB GDDR6 memory), is used via CUDA [42].

Datasets & Model Architectures. We use common datasets mainly focusing on image classification with MNIST [16], CIFAR-10 [32], GTSRB [51], and CIFAR-100 [32] trained on models of different types and sizes, namely CNNs (with and without batch normalization), ResNet-18, ResNet-34 [25], ViT [17], and VGG11 [46].[7]

Default Scenario. Throughout our experiments, we systematically vary model architecture, dataset, and hyperparameters to illustrate the versatility of our approach. Unless otherwise specified, our default scenario uses MNIST [16] trained on a CNN consisting of two convolution layers both followed by a ReLU and a 2D max pooling layer and followed by three fully connected layers of decreasing output sizes (512, 256, 10). For training purposes, we employ separate Adam optimizers with a learning rate of 0.0001, both for the primary task and transposed training. We trained the model for five epochs.

5.1 General Functionality

Watermark Definition. A watermark for ClearStamp consists of one or multiple watermark keys and secrets, which are kept confidential. In our experiments, the keys are vectors consisting of ten randomly chosen values between -10 and 10[8]. The chosen secrets are images containing four letters like "ABCD", as visualized in Fig. 3a and App. Fig. 11a.

Baseline - No Watermark. First, we trained a model without a watermark, which serves as a baseline for model performance. As can be seen in (1) in Tab. 2, we reached a model accuracy of 89.88%. When trying to extract a watermark before and after training, we get images as in Fig. 3b and Fig. 3c, respectively. The images clearly show no relation or similarity to Fig. 3a, indicating the absence of the watermark essentially fulfilling the integrity requirement from Sect. 3.1. Additionally, the two pictures yield an SSIM of 0.00 and -0.06 when being compared to Fig. 3a, confirming that watermarked and unwatermarked models are clearly distinguishable. However, human perception instead of a low SSIM should be the main criterion for the decision, as even for small SSIMs close to zero human observers can still recognize similarities between images (cf. Tab. 1 in Sect. 2).

Watermark Hardening. Next, in step 1 of ClearStamp

[7] We use PyTorch model instances for predefined model architectures.

[8] The precise random key vector for the experiments with one key is provided in App. 7.3. There, we also provide experiments with key ranges -5 to 5 and -50 to 50 to show that the range is an insensitive parameter.

Table 2: In these experiments MNIST [16] was trained on a CNN with a learning rate of 0.001 for five epochs.

	Number of keys	Untrained Model		Watermark Hardening			Training			Extracted Watermark Figure	Watermark Considered Valid	4 epochs fine-tuning with 1/10 of training learning rate	
		Accuracy	SSIM	Steps	Accuracy	SSIM	Constraint	Accuracy	SSIM			Accuracy	SSIM

(a) (b) (c) (d) (e) (f) (g)

Figure 3: Visualization of (a) the watermark secret and (b-g) extracted watermarks for the experiments listed in Tab. 2.

(cf. Fig. 2) we perform transposed training as described in Sect. 4.1 to embedded a watermark consisting of one key-secret pair into an untrained model. As transposed loss, we combine SSIM and MSE between the transposed model output and the watermarks ground truth secret. We name each adjustment of the transposed model parameters by the optimizer as a hardening step. As presented in (2) in Tab. 2 we reached an SSIM of 0.95 after 7,000 hardening steps. The resulting image after watermark extraction depicted in Fig. 3d clearly shows the content of the ground truth secret Fig. 3a and an existing watermark can be attested. As expected, the accuracy on the main task remained naïve with 10.22% and 8.57% accuracy before and after training, respectively.

Constraint Training. In ClearStamp's second step, we train the model's main task while keeping the watermark embedded as described in Sect. 4.4. As reported in (3) in Tab. 2, the watermark remains embedded, while the main task accuracy of 88.37% is achieved, fulfilling the reliability requirement from Sect. 3.1. Hence, we observe a negligible accuracy drop compared to the unwatermarked model ((2) in Tab. 2) satisfying the fidelity requirement from Sect. 3.1. To emphasize this important fact, we visualize the main task loss for unwatermarked and watermarked training in App. Fig. 13c showing minimal differences. These results could be reproduced independently of the optimizer used for the different tasks, which we elaborate on in App. 7.3.

Multi-Key. Next, we investigate multiple watermark key-secret pairs, as explained in Sect. 4.3. We employed ten and eleven keys to show the independence from the number of classes in the dataset, ten for MNIST [16].[9] The secrets are distinct four-character images[10], as visualized in App. Fig. 11a. The results for ten and eleven keys are shown in (4) and (5) in Tab. 2, respectively, and show that ClearStamp embeds the watermark successfully. Thus, we can increase the watermark capacity without a significant negative impact on the watermark's or the model's performance[11]. Notably, we stopped hardening after 10,000 hardening steps but it would be possible to continue training until a 0.99 SSIM is reached[12]. While it is possible to increase the number of keys and thus the capacity, which we discuss in Sect. 5.5, we proceed with eleven keys to showcase the functionality of ClearStamp. To show the independence from the concrete secret images, we conducted the same experiments with other images, visualized in App. Fig. 12a and App. Fig. 12b, yielding similar results.

5.2 Model Manipulations

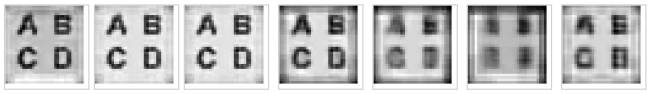
Next, we evaluate illegal and legal third-party model manipulations, that are applied in step 3 of Fig. 2.

Fine-Tuning. To evaluate ClearStamp's robustness against fine-tuning, as described in Sect. 3.2, we continued training on the MNIST train set after executing our default scenario for another two epochs (half of the original five epochs rounded down) with the same learning rate, as well as with 1/10 of the original learning rate (similar to [1,9,34,40,57,65]). After fine-tuning for two epochs, we continued for another two epochs with identical settings to showcase ClearStamp's behavior under excessive fine-tuning conditions. To evaluate the watermark robustness against unseen data, we executed the same fine-tuning process but employed the MNIST [16] test set. As Tab. 3 shows, ClearStamp shows strong robustness against fine-tuning as the watermark remained embedded yielding high SSIM values and clear images (Fig. 4a to Fig. 4c)[13]. Later, in Sect. 5.3, we also evaluate cross-dataset fine-tuning. In scenario (2) in Tab. 3 we can observe a slight increase in SSIM after 4 epochs compared to 2 epochs, which is counter-intuitive. We believe that caused by the overlapping value ranges of our watermark and the entanglement of parameters, weight changes for the forward path can have small positive effects on the watermark's similarity score.

[9] We provide results for another experiment leveraging 20 keys in App. 7.3, which yields similar results as for eleven keys.

[10] During visualizations, we stick to the first image containing "ABCD".

[11] We observe a slight increase in main-task accuracy for (5) in Tab. 2, indicating, that the watermarking is tightly enmeshed with the main task and serves as regularization in this experiment. However, the general observation is a minimal drop in accuracy due to watermark embedding.



[12] We report the mean SSIM values for multiple keys. If not specifically mentioned, the means do not contain extreme outliers.

[13] The accuracies show, that fine-tuning with 1/10 of the original learning rate is a better setting if an adversary wants to increase the model accuracy on a third-party dataset.

Table 3: Fine-tuning experiments for a CNN trained using MNIST [16] test set with a learning rate of 0.001 for five epochs with eleven watermark keys.

Fine-Tuning Scenario	2 Epochs		4 Epochs		Wateermark	
	ACC	SSIM	ACC	SSIM	Figure	Valid
(1)	88.64%	0.90	87.42%	0.88	Fig. 4a	✓
(2)	88.56%	0.92	89.86%	0.93	Fig. 4b	✓
(3)	96.31%	0.92	97.02%	0.92	Fig. 4c	✓

(1) Same as training learning rate (0.001) & same data
(2) 1/10 of training learning rate (0.0001) & same data
(2) 1/10 of training learning rate (0.0001) & unseen data

(a) (b) (c) (d) (e) (f) (g)

Figure 4: Visualization of extracted watermarks for the fine-tuning experiments listed in Tab. 3 in (a-c). Figures (d-f) visualize pruning with 60%, 80%, and 90% respectively, while (g) shows fine-pruning with 40%.

Pruning. Besides fine-tuning, we investigate model pruning (cf. Sect. 3.2) similar to [9, 15, 34, 40, 57, 65]. As depicted in Fig. 5, the watermarking withstands pruning and is coupled to the main task accuracy, as for low pruning levels, which maintain the accuracy, the SSIM remains high. For example, for 60% pruning with an accuracy drop from 89.1% to 78.56%, the SSIM is still 0.69, yielding Fig. 4d. Even for 80% pruning, which already suffers in accuracy with 50.1% we obtain an SSIM of 0.47 resulting in Fig. 4e, which is still sufficient for a human observer to identify the watermark when being aware of the ground truth secret Fig. 3a. Starting from 90% pruning (cf. Fig. 4f), the watermark cannot be clearly identified, but the model already decreased to 26.76% accuracy essentially being useless. Fig. 4g shows the result with an SSIM of 0.62 and an accuracy of 89.79% after two fine-tuning epochs followed by pruning with 40%, typically called fine-pruning [28, 56]. As the images prior to 90% pruning in Fig. 4f are clearly distinguishable from Fig. 3c while Fig. 4f suffers low accuracy, we can conclude that ClearStamp is robust against model pruning essentially addressing the security requirement from Sect. 3.1.

5.3 Generalizability

Below, we explore different scenarios showing that ClearStamp can fulfill the generalizability requirement from Sect. 3.1. Essentially we demonstrate the independence from datasets and model architectures. During these experiments, we use fine-tuning with 1/10 of the original learning rate as the default model modification approach.

Dataset. First, we changed the dataset to CIFAR-10 [32], essentially changing the input layer to match the three color channels of the CIFAR-10 input samples. Then, we conducted

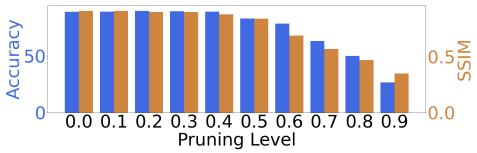


Figure 5: Model accuracy on the main task and corresponding watermark SSIM for different pruning levels between 0 (unpruned) and 90%.

the same experiment for GTSRB [51], which has 43 label classes. The results reported in (1) and (2) in Tab. 4 show, that the watermark was successfully embedded and survived fine-tuning yielding Fig. 6a and Fig. 6b. As the images clearly show the expected letters, we observe the dataset independence of ClearStamp.

Small Model Architectures. Next, to show that ClearStamp is also applicable to very simple model architectures, we trained MNIST [16] on a CNN with only three fully connected layers each of size 1024 and report the result in (3) in Tab. 4. Further, to show ClearStamp's independence of added batch normalization layers when embedding the watermark, we enhanced our default setting by adding such a layer after each convolutional layer and report the results in (4) in Tab. 4. The extracted images Fig. 6c and Fig. 6d, as well as the high SSIM values above 0.85 after raining and fine-tuning reported in Tab. 4 confirm ClearStamp's good performance for small models. However, even if the images yield clear watermark evidence, the presence of batch normalization layers seems to diminish the robustness of the watermark resulting in a lower SSIM of 0.85 after fine-tuning. This effect might be caused by the circumstance, that for batch normalization layers, the mean and variance of the input data are unknown during transposed training and fixated to $E(x) = 0$ and $Var(x) = 1$, essentially causing information loss.

Medium-Size Model Architectures. To address bigger model architectures, we evaluate CIFAR-10 [32] and GTSRB [51] on a ResNet-18 [25] model trained for ten epochs[14], whereas both datasets yielded similar results reported in (5) and (6) in Tab. 4. As retractable in Fig. 6e and Fig. 6f, the watermark is still clearly visible after ten epochs.

Further, we evaluate CIFAR-10 [32] on ResNet-34 [25] and use the same setup as in the ResNet-18 experiment. The results in (7) in Tab. 4 yield a bigger drop in SSIM to 0.55 after fine-tuning, probably introduced by the size of the model and the amount of transposed convolution layers, which introduce uncertainty due to their upsampling nature. Nevertheless, the resulting image Fig. 6g leaves no doubt that the watermark is still strongly embedded.

Inspired by [1, 57], we also evaluate cross-model fine-tuning scenarios. We used our medium-size model setups and

[14] As ResNet-18 [25] contains skip connections, we first trained for three epochs, to get valid values for skip connections fixating (cf. Sect. 4.2).

Table 4: Experiments showing the independence of ClearStamp from datasets and model architectures. Tests were conducted with eleven watermark keys and fine-tuning was performed for the same number of epochs as training epochs.

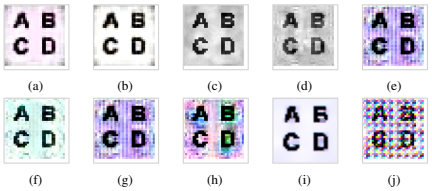

Figure 6: Visualization of extracted watermarks for the experiments listed in Tab. 4.

trained CIFAR-100 [32] on ResNet-18 [25] but fine-tuned the model on CIFAR-10 [32], which necessitates changing the last layer due to ten instead of 100 output classes. As the watermark is embedded based on CIFAR-100, the last layer needs to be replaced with the original layer during watermark extraction, thus rendering this layer as part of the key. We report positive results with 0.51 SSIM in (8) in Tab. 4. The watermark extraction yielded Fig. 6h, which clearly contains the watermark. We also conducted an experiment where we added the watermarked last layer to an unwatermarked model, resulting in an SSIM of 0.06 and watermark images that do not yield any perceptible content. These experiments combined demonstrate that the watermark is embedded within all network parameters and not only resides within the last layer, contributing to the robustness requirement from Sect. 3.1.

Large Model Architectures. To address even larger model architectures, we trained CIFAR-100 [32] on VGG11 [46] for 200 epochs and 100 epochs of fine-tuning. As the results in (9) in Tab. 4 show, ClearStamp could successfully embed a robust watermark even in a large model architecture.

To evaluate ClearStamp on transformer blocks, we trained CIFAR-10 [32] on a Vision Transformer [17]. The extracted watermark after fine-tuning is visualized in Fig. 6j. It has a colorful background, but the watermark text is clearly visible, indicating that ClearStamp can also handle such architectures.

Summarized, we showed, that ClearStamp is independent of the model architecture and, combined with the dataset independence, applicable in arbitrary application scenarios.

5.4 Adaptive Adversary

Watermark Erasure. An adversary with knowledge of ClearStamp's functionality could try to erase an embedded watermark as defined in Sect. 3.2. Thereby, a random watermark key in the predefined value range could be used in combination with a secret image consisting of random noise. An even stronger adversary with the knowledge of embedded watermark keys (which exceeds usual assumptions as in Sect. 3.2 could also use such an image. As both scenarios yield the same effects, we depict the results for a stronger adversary (using an already embedded watermark key) in the main body of the paper and append the random key experiment results in App. 7.3.

We use the same mechanism as in step 1 in Fig. 2 to embed the adversarial key-secret pair, with the intention of erasing the existing secret for the respective watermark key and potentially for other existing keys that are part of the watermark. Our experiment revealed, that the erasure of the watermark involves a significant loss in main task accuracy as both tasks are entangled within the model parameters by design. During watermark erasure attempts, the adversary sacrifices usually more than 10% accuracy in our setup compared to the initial 89.10%, whereas some other existing works consider 3.5% accuracy drop as acceptable in related works [40]. In Fig. 7, we show seven out of eleven watermark images[15] after five, seven, and eleven adversarial hardening steps with respective remaining accuracy values of 82.89%, 78.60%, and 74.30%. Even the third row with an accuracy drop of 14.8% shows clear evidence, as one should keep in mind, that an unwatermarked model yields an image similar to Fig. 3c. In the first and second rows of Fig. 7, the watermark existence can still be attested by a human observer even though the SSIMs are

[15]We show only seven images due to space limitations in the paper.

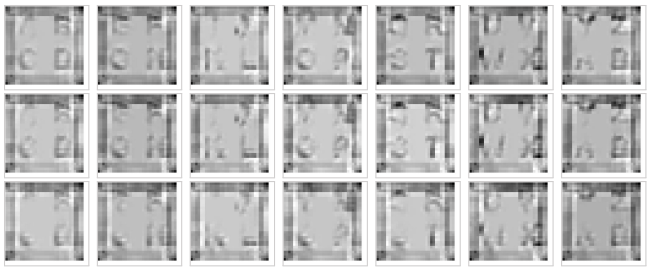

Figure 7: Extracted watermark images after five, seven, and eleven adversarial hardening steps during watermark removal. The corresponding main task accuracies to the lines are 82.89%, 78.60%, and 74.30% originating from 89.10% with SSIMs of 0.13, 0.11, and 0.01.

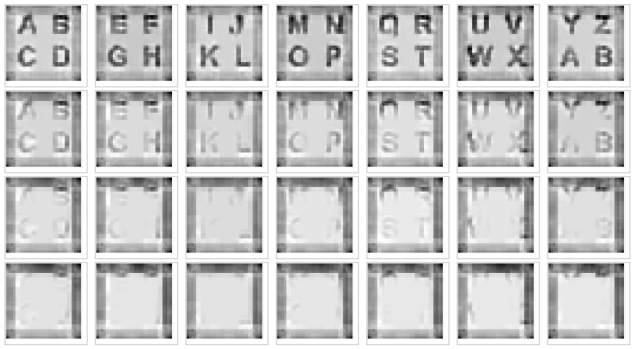

Figure 8: Watermarks after watermark overwriting with eleven keys. The lines correspond to the first four hardening steps with accuracy drops from 89.10% to 83.89%, 70.38%, 56.39%, and 46.52%, and SSIMs of 0.52, 0.17, 0.05, 0.01.

low with 0.13, 0.11, and 0.01. This shows that the definition of rigid thresholds is challenging as in the case of SSIMs such low values could also stem from content-wise unrelated images. Therefore, a threshold needs to be set higher to avoid false positives. Hence, ClearStamp improves the decision-making in such situations, essentially increasing the security for the model owner while fulfilling the understandability requirement from Sect. 3.1. We got similar results when using a completely black image as a key and when using an image that an unwatermarked model yields for the adversarial key after a transposed inference, which is reported in App. 7.3.

Further, we can report, that we observed the same effect when increasing the number of keys embedded by the adversary from one to eleven. We experimented with eleven already embedded or eleven random keys combined with secret images containing random noise, only black pixels, and yielded images from an unwatermarked model like Fig. 3c.[16] For example, for the latter, we measured accuracy drops from 89.10% to 83.89%, 70.38%, 56.39%, and 46.52% after one

[16] Due to space limitations in the paper we only report one scenario, as all scenarios yield similar results.

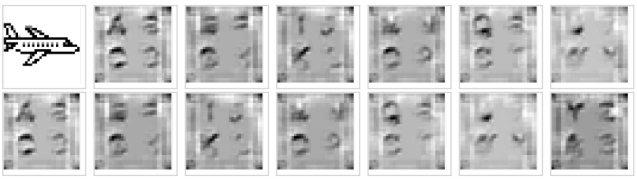

Figure 9: An adversarial watermark secret (first image) and extracted watermarks after six (line one) and seven (line two) hardening steps corresponding to 79.25% and 78.25% remaining main task accuracy originating from 89.10% and SSIMs of 0.24 and 0.23.

to four hardening steps resulting in the four lines of Fig. 8, where the watermark is still completely identifiable in the second line, and partially even in the third line. To achieve a removal degree as showcased in the fourth line, the adversary would need to sacrifice 42.58% in main task accuracy.

To validate that our findings are not intrinsic to our specific application scenario, we also conducted the experiment for CIFAR-10 [32] trained on ResNet-18 [25] yielding similar results that we report in App. 7.3.

Watermark Overwriting. Besides removing the watermark, an adversary could also try to overwrite the watermark with a second watermark. When embedding one new watermark image, in our case an airplane icon as visible in the first image in the first line of Fig. 9 with a random key, the adversary provoked an accuracy drop from 89.10% to 79.25% and 78.25% after six and seven hardening steps. While evidence for the original watermark is still visible after six steps, it starts to be vague after seven steps, as can be seen in the first and second lines in Fig. 9, respectively.

Summarized, we can conclude, that ClearStamp is robust against adaptive adversaries with the knowledge of ClearStamp's functionality, that try to remove or overwrite the watermark or embed an additional watermark, even if the adversary is equipped with knowledge about the keys. If the adversary erases the watermark, he sacrifices a minimum of 10% of accuracy, whereas usually around 3.5% accuracy drop is considered as acceptable [40].

5.5 Capacity

To evaluate the capacity and generalizability to arbitrary watermark locks, we generated random bit strings and converted them into images using dot code [58]. The image is initially divided into square patches that correspond to the number of bits in the string. Based on the bit value, the patch is colored black for zero or white for one. An example of this is shown in App. Fig. 11b. Multiple watermarks were injected into the model, with the same capacity and randomly generated keys. Likewise, the extracted watermark was again divided into patches to extract the bit sequence. Values less than 0.53

in each channel were set to 0, while others were set to 1. To determine the bit of the patch, black and white pixels were counted and the majority was used as a decoding result. To evaluate the outcome, the Binary Error Rate (BER) was utilized, which is the number of incorrect bits divided by the total number of bits. We first generated images with 36-bit capacity and injected those into the CNN model. The evaluation has shown that the BER is consistently low at roughly 3.43% and 2.96% after fine-tuning. For larger bit lengths of 100 bits per image we injected the MiT license text [17] (8,544 bits) into a ResNet-18 [25] model. We compared the results for applied (7,4) Hamming code [22] error correction (14,952 bits) and without. ClearStamp achieves average BERs after training of as little as approximately 5.92% and 3.62% with and without error correction, respectively. After fine-tuning the BER increased to 6.46% without error correction and 4.45% with error correction. ClearStamp is capable of injecting large payloads such as licenses or images and, as the limit of keys is not yet exhausted, even larger files could be injected.

5.6 Runtime

Regarding ClearStamp's runtime, we measured the individual steps, namely hardening, constraint training, and watermark testing for our default scenario with eleven random keys.[18] We report averages over ten experimental runs. Hardening with 10,000 steps took 53.48 seconds and is a one-time effort. The evaluation only takes 0.02 seconds. The training time increased from 67.62 to 94.39 seconds for the five epochs, introducing a one-time overhead of 39.58%, which is expected, as an additional loss needs to be computed and a second optimization step is executed during training. Therefore, we consider the efficiency requirement from Sect. 3.1 as fulfilled. Summarized, we can show that ClearStamp is a robust watermarking mechanism that withstands adversarial watermark-removing attempts and barely influences the DNN's main task performance while providing high watermark robustness. Most importantly, no non-intuitive algorithm based on a riding threshold needs to be applied to evaluate the watermark.

6 Related Work

Our approach, ClearStamp, stands out as the pioneer in the field of model watermarking by incorporating transposed model training, making it unique and unparalleled in comparison to existing methodologies. This novel technique sets it apart from related research, rendering direct comparisons challenging. The distinctive advantage of our method lies in its departure from conventional approaches that rely on fixed thresholds for decision-making during watermark verification. Instead, ClearStamp produces a discernible image with interpretable content. This output can be easily scrutinized by human evaluators, enabling intuitive decision-making when compared to the authentic ground truth image.

In the following sections, we present an overview of contemporary techniques in model watermarking and fingerprinting. Despite employing diverse methods, these existing approaches share common objectives with ours. Typically, watermarking methods seek to embed a distinctive signature into the model, ensuring its uniqueness to the model owner. On the other hand, fingerprinting methods are geared toward copyright protection, embedding a unique signature into the model that is specific to the authorized user. Additionally, we overview the related works that, while not strictly falling under watermarking or fingerprinting categories share relevance due to their underlying methodologies or the goals they aim to accomplish.

Watermarking. Uchida *et al.* [57] proposed a white-box, multi-bit watermarking approach, which embeds the watermark into weights of convolutional layers by introducing an additional loss term, referred to as parameter regularization. However, the method relies on a rigid threshold for watermark verification and is not robust against watermark overwriting attacks. ST-DM *et al.* [34] improves this approach in such scenarios by using modulation techniques. The capacity of the watermark was thereby shown for up to 8,400 bits but naturally is limited by the model architecture.

Frontier Stitching [40] is a 1-bit, black-box methodology rooted in adversarial examples. This technique modifies the decision boundaries between classes for specific input samples positioned at the interface of two classes, serving as essential keys. However, identifying such samples is contingent upon the specific application context and proves to be a challenging task, making this approach less universally applicable and user-friendly. For verification, a hard threshold of prediction matches is used.

Adi *et al.* [1] propose a multi-bit, black-box method, which embeds backdoors into the DNN that serve as a watermark. Within the paper, eight backdoors acting as watermarks were implanted, whereas randomly generated input samples were used to produce specific output classes. Similarly, Zhang *et al.* [70] and Zhang *et al.* [71] follow the same approach varying the backdoor types, whereas Li *et al.* [36] produces an imperceptible backdoor trigger with a second generative model. A method that also leverages backdoor-like behavior is Guo *et al.* [21], where a black-box watermarking technique is proposed specially crafted for embedded devices. The method trains the DNN to behave significantly differently on a portion of training samples, that are modified using a specific perturbation. Naturally, these approaches embed additional behavior besides the model's main task, providing the potential for side effects during normal inference. Further, the decision-making relies on a threshold for the number of occurred backdoor-based mispredictions. Contrary to these

[17] MiT License available at https://opensource.org/license/mit/.

[18] For estimating the skip connections, we trained an unwatermarked model for a few initial epochs (three in this case). This is a one-time effort, that is only necessary for models with skip connections in the model architecture.

works, WILD [38] removes backdoor-based watermarks.

Tartaglione *et al.* [54] propose a white-box, 1-bit watermark that fixates model parameters as watermarks and applies a modified loss function for increased robustness. As the approach fixates parameters, the watermark capacity is limited by the number of parameters in the model and hence depends on the model architecture.

DeepJudge [10] is a testing framework that can be used for copyright protection as a non-invasive alternative to watermarking techniques. The method compares how similar a DNN and a second suspected DNN under test behave based on six metrics and hard thresholds. The metrics are derived via inference of carefully chosen samples that are able to characterize the models.

Wang *et al.* [61] presents a white-box approach for incorporating a multi-bit watermark into weights by leveraging a second secret independent model for watermark embedding and verification. Similarly, RIGA [63] is an algorithm that embeds a multi-bit, white-box watermark using adversarial training with two additional models. Thereby, the first model is responsible for embedding the watermark, while the second enhances the stealthiness. However, the verification of both approaches is based on the black-box functionality of additional models. Hence, the decision-making is not comprehensible, as the model's functionality does not follow an understandable algorithmic pattern, but delivers outputs utilizing optimized parameters tuned with regard to training data.

EWE [28] is a method based on a special loss function, which enforces the entanglement of the watermark and the main task (similar to ClearStamp), such that removing the watermark negatively affects the main task. However, the watermark is embedded in the forward path, thus leaving the possibility of unexpected side-effects during inference.

DeepSigns [15] proposes a white-box, multi-bit approach that embeds a watermark within the probability density function of activations in multiple DNN layers by fine-tuning the model parameters. When verifying the watermark, an algorithm uses the extracted activations to compute the watermark which is then evaluated against the ground truth utilizing bit error rate combined with a rigid threshold. Further, a black-box approach is suggested, that verifies model ownership by a hard threshold applied to the number of matches when comparing the prediction outputs of specific secret input-prediction pairs.

Fingerprinting. A consecutive work to DeepSigns [15] leveraging the same principle and inheriting the same shortcomings is DeepMarks [9], but embeds information in the model weights instead of the activations and is designed as a fingerprinting approach. Based on this fingerprinting technique, DeepAttest [8] offers hardware-level IP protection and usage control for DNNs. With the help of a Trusted Execution Environment, the fingerprint is validated to ensure that only validated DNNs are allowed to run on specific devices, a method that is also leveraged in DeepMark [65].

IPGuard [6] searches for adversarial examples that are close to the decision boundary of a DNN, leveraging that a model is characterized by its decision boundary. The method does not tamper with the training process at all, but can run after training even on legacy models and, hence, does not affect the model performance at all. However, humans who do not understand the decision boundaries of DNNs might have problems understanding the approach. Further, the ownership verification is based on a hard threshold, which is difficult to determine. The decision boundary is also leveraged by MetaFinger [66], a black-box fingerprinting method that identifies samples by meta-training that are close to the decision boundary, which can later be used to identify a specific model.

Orthogonal Works. Further, there are some works, that are close but also orthogonal to ClearStamp. TamperNN [41] is a method designed to recognize if a model was tampered, e.g., fine-tuned, by analyzing inputs, that tend to change the prediction class easily. Chen *et al.* [11] suggest a method to infer the origin of a student model in the domain of transfer learning by embedding a fingerprint in the teacher model that is passed on to the derived student model. Venugopal *et al.* [60] propose a method to watermark the model output instead of the model itself by selecting a specific result out of the selection of possible results in a machine translation task. DAWN [52] is a technique used to prevent model extraction attacks by changing the prediction on the model inference API for a small set of samples to embed a watermark into models trained on these predictions. BOP [13] modifies the Adam optimizer to prevent so-called heavily spiked weights during watermark embedding and, hence, increase covertness while simultaneously increasing the robustness. Wang *et al.* [62] demonstrated that statistical analysis of model weights can detect a watermark. Once identified, the watermark can be overwritten using the original embedding technique, effectively removing it.

Deconvolutions [20,69] are the inspiration and basis for our work and are used to approximately reverse convolutional operations that are often leveraged in machine learning. Such deconvolutions are used in scenarios that require up-sampling of feature maps, such as generative models [18,67] and encoder-decoder architectures [26,48], which generate images from an embedding. However, the deconvolutions mostly possess their own trainable weights independent of the convolutions. Weight sharing is used in Siamese Networks [30], which provides the motivation to share the weights between convolutions and deconvolutions and, thus, for transposed training.

7 Conclusion

Machine learning models can be considered as the model creator's intellectual property that needs to be protected from unauthorized use. DNN watermarking techniques offer a solution to this problem by embedding a secret watermark into the model parameters. Obviously, these watermarks must be robust against erasure attempts, while simultaneously a minimal

effect on the model's main task is expected.

Existing watermarking approaches rely on rigid thresholds in the final decision-making process after the watermarking data is extracted from the model during watermark verification. Thereby, such a threshold can fail to detect remaining fractions of embedded watermarks that were attacked with an erasure attempt, even if a human observer would clearly identify the remaining watermark.

To address this problem we proposed ClearStamp, the first human-understandable and intuitive DNN watermarking approach that allows human decision-making directly on the extracted watermark data without relying on a threshold. We show that ClearStamp's effect on the model's performance is negligible and that ClearStamp is independent from specific application scenarios. Further, ClearStamp withstands adversarial model manipulations and offers a capacity of 8,544 bits with a low error rate of 4.45%.

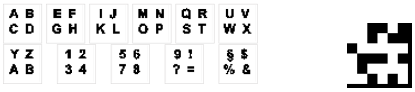
Appendix



7.1 Additional Visualizations

Partly Removed Watermarks. To understand the necessity of the understandability property proposed in Sect. 3.1, a partly removed watermark is a concrete example. An adversary could remove most of a watermark, e.g., 70%, which would result in a negative watermark verification conducted by a machine. However, the rest of the watermark could potentially be recognizable, if the watermark is visible to human inspection. An example of two partly erased watermarks is depicted in Fig. 10b. The watermark is the "ABCD" text in

(a) (b)

Figure 10: Visualization of (a) the default eleven watermark secrets and (b) partly erased watermarks. The first image contains the unaltered "ABCD" watermark.

(a) (b)

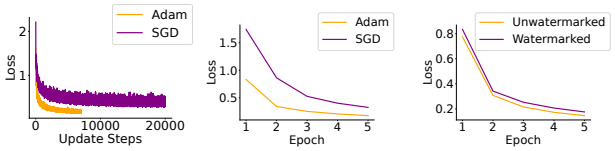
the lower right corner of the first image. The second and the third image are two versions of partly removed watermarks, which still yield enough information to a human, but might not be recognized by a machine.

7.2 Additional Experimental Details

Random Key Vectors. The key vectors are randomly chosen between -10 and 10. It is not imperative, that -10 and 10 need to be part of the vector. The key vector from the single watermark experiments reported within this paper consists of the following values: -0.0748, 5.3644, -8.2304, -7.3593, -3.8515, 2.6815, -0.1981, 7.9288, -0.8874, 2.6461.

Watermark Secrets. During the evaluation, we use eleven distinct secrets. The secrets are images with black text on a white background (cf. Fig. 11a). Further, we experimented with different watermark images, which yielded the same experimental outcomes. Thereby, we used only one letter on each image (cf. Fig. 12a) as well as the icons of the ten CIFAR-10 [32] label classes and added an extra icon (cf. Fig. 12b).



Fidelity. To show ClearStamp's fidelity we provide a plot of the main task loss during training of an unwatermarked and a watermarked model yielding minimal differences in Fig. 13c.

Capacity. We showcase one of the capacity images (cf. Sect. 5.5) which are embedded into a model in Fig. 11b.

(a) (b) (c)

Figure 14: Visualization of the watermark for different key ranges (a) -5 to 5 (b) -10 to 10, and (c) -50 to 50.

7.3 Additional Experiments

Different Optimizer. To show ClearStamp's optimizer independence, we experimented using SGD with a learning rate of 0.01. We terminated the watermark hardening after 20,000 update steps at an SSIM of 0.89 SSIM. We achieved a main-task accuracy of 83.22% after training while the SSIM remained high at 0.83. This result (cf. Fig. 13) shows, that ClearStamp functions for different optimizers with Adam outperforming SGD in both main-task and watermark embedding.

Different Key Range. In Fig. 14, we provide the results for eleven embedded keys with different key ranges. Thereby, we follow the same experimental setup as in the multi-key paragraph of Sect. 5.1. Especially, we use -5 to 5, -10 to 10, and -50 to 50 as key ranges, where -10 to 10 is already reported in Sect. 5.1. The watermark images in Fig. 14 visualize the watermark after fine-tuning, and yield results that look similar. The experiments yield comparable SSIMs of 0.9272, 0.9305, and 0.9249. Hence, we can claim, that the range parameter is an insensitive value and can be fixed at -10 to 10.

Multi-Keys with 20 Keys. To ensure independence from the number of keys, we expand the experiments to 20 simultaneously embedded keys. The results show that the quality of the watermark does not decrease yielding images similar to Fig. 3g with SSIM. Hence, we can claim, that the performance does not decrease significantly when utilizing more keys.

Adaptive Adversary. An adversary could try to erase an embedded watermark. Thereby, an existing and embedded key could be used in combination with the image that an unwatermarked model yields for that key for a transposed inference. We got similar results when using a completely black image. Then, an adversary adapts ClearStamp's training procedure and tries to erase the watermark. However, the entangled parameters force the adversary to sacrifice main task accuracy. After removing the watermark completely, the

(a) (b)

Figure 15: Adaptive attack with (a) existing / (b) random key.

adversary sacrificed approximately 10% accuracy in our setup compared to the original 89.10%. In Fig. 15a, we show seven out of eleven watermark images after three to six adversarial update steps with respective remaining accuracy values of 85.96%, 83.07%, 79.67%, and 76.32% (SSIMs of 0.16, 0.08, 0.04, and 0.02). For the first two lines, the watermark can be identified. In the third row, the it can be assumed, but it is already hard to discern, while in the fourth line, it is mostly removed. Thereby, one should keep in mind, that an unwatermarked model yields an image similar to Fig. 3c.

When using a random key and an inferred image from an unwatermarked model as a lock, we get similar results. Within the first four update steps, the main task accuracy is reduced from 89.10% to 88.61%, 85.31%, 81.00%, and 74.81% (SSIMs of 0.60, 0.26, 0.11, and 0.04), essentially sacrificing more than 10%. The watermarks can be seen in the four rows of Fig. 15b, showing that the watermark is still clearly visible in the third row. Even in row four, one can see them slightly. The results for a random key combined with a black image or a random image show the same effect.

To validate the independence from our application scenario, we experimented with an already embedded watermark key and an inferred image from an unwatermarked model similar to Fig. 3c for CIFAR-10 [32] trained on ResNet-18 [25]. We could observe the same effect of steadily decreasing main task accuracy with increasing watermark erasure. We report the watermarks after eleven and 22 hardening steps with accuracy drops of 10.12% and 18.62% (SSIMs of 0.38 and 0.24) in Fig. 16, showing that the watermark is still partially embedded while sacrificing lots of main task accuracy.

7.4 Further Considerations

Ownership Claim Automation Ideally, a human evaluator should determine the ownership claim and the presence of a watermark by comparing it to the ground truth. However, in situations where a large volume of images needs validation, automation becomes essential. One potential automated approach involves employing similarity metrics to assess whether a watermark matches the ground truth watermark. However, relying solely on the SSIM metric may not be optimal. The evaluation demonstrates that the watermark remains visually detectable even at low SSIM values.

A more effective method could involve automating the decision-making process through machine learning (ML). This could be achieved by training an ML model to serve as a feature extractor, responsible for generating embeddings from both the watermark image and the ground truth watermark. By comparing these embeddings using a decision layer within the network, the system can make a final determination about the presence of a copyright infringement. This automated approach could ensure accurate and efficient validation, especially when dealing with a large number of images.

Figure 16: Watermarks after an erasure attack on ResNet-18 [25] trained on CIFAR-10 [32].

Other Constraint Optimization Methods As an alternative to the sequential optimization (cf. Sect. 4.4), one could use a weighted sum method, which adds up the two losses while assigning corresponding weights, essentially introducing an additional hyperparameter. Usually, such weights indicate the task importance. However, this method necessitates extensive hyperparameter tuning if the loss values are at different scales. The loss values then need to be weighted such that both loss terms receive equal importance, since otherwise the smaller one is deemed already sufficiently optimized.

Constraint optimization methods, e.g., Augmented Lagrangian optimization [31] or the Alternating Direction Method of Multipliers [4] are highly effective in enforcing hard constraints. However, it is important to note that our approach, ClearStamp, does not impose strict thresholds for valid SSIM values. Introducing these methods would necessitate adding thresholds and hyperparameters to ClearStamp, which would then need optimization. It's worth emphasizing that a rigid SSIM threshold isn't essential in our context; we aim for high SSIM values around 0.9, but the similarity between an extracted watermark and the secret can already be claimed for very low SSIMs. Implementing such constraint optimization methods would shift the focus toward optimizing the watermarking task to meet the defined threshold. This could potentially detract attention from the primary task and lead to suboptimal performance in both tasks. Moreover, after the constraint is met, there's a risk of diminishing the importance of the watermarking task, potentially hindering the achievement of superior quality.

However, in real-world applications where a hard threshold is desired, we suggest considering [31], as it is a method capable of reliably enforcing inequality constraints.

DeepEclipse: How to Break White-Box DNN-Watermarking Schemes

Abstract

Deep Learning (DL) models have become crucial in digital transformation, thus raising concerns about their intellectual property rights. Different watermarking techniques have been developed to protect Deep Neural Networks (DNNs) from IP infringement, creating a competitive field for DNN watermarking and removal methods.

The predominant watermarking schemes use white-box techniques, which involve modifying weights by adding a unique signature to specific DNN layers. On the other hand, existing attacks on white-box watermarking usually require knowledge of the specific deployed watermarking scheme or access to the underlying data for further training and fine-tuning.

We propose *DeepEclipse*, a novel and unified framework designed to remove white-box watermarks. We present obfuscation techniques that significantly differ from the existing white-box watermarking removal schemes. *DeepEclipse* can evade watermark detection without prior knowledge of the underlying watermarking scheme, additional data, or training and fine-tuning. Our evaluation reveals that *DeepEclipse* excels in breaking multiple white-box watermarking schemes, reducing watermark detection to random guessing while maintaining a similar model accuracy as the original one. Our framework showcases a promising solution to address the ongoing DNN watermark protection and removal challenges.

1 Introduction

The rising cost of computational and engineering expenditures associated with training massive Deep Neural Networks (DNN) models has reached unprecedented levels [17, 53, 55, 56]. Given that well-trained DNNs are invaluable assets for AI corporations, they face a growing threat from model embezzlement and unauthorized usage [15, 24, 65]. Consequently, model copyright protection has become increasingly vital and studied, also by large corporations such as IBM [76], Google [1], and Microsoft [9, 12]. Hence, recently, several approaches known as DNN watermarking have emerged [1, 4–6, 8–11, 13, 14, 16, 18–21, 27–29, 31–34, 36–42, 44, 47, 48, 50–52, 57, 58, 61, 66, 69–73, 75–79, 81], aimed at tracking down illicit duplicates in the open domain [45, 63].

DNN Watermarking Schemes. DNN watermarking methods can be categorized into two primary types: black-box and white-box watermarking. While the former requires only API access for model predictions, the latter demands access to the model's internal architecture. Both watermarking categories follow two essential phases: injection and verification. During training, a secret signature (i.e., the watermark) is incorporated into the target model. Subsequently, the verification is performed by extracting the signature from the model and then comparing it with the original one kept by its owner. The positive verification of the watermark's presence and authenticity shall prove the model's ownership. This verification can further prove to a third independent party, e.g., a court jury or a government agency, the reliability of the ownership's claim [63].

In this paper, our focus is on white-box watermarking schemes. Since white-box watermarks embed a signature into the model's parameters, they require access to the suspect model when verifying the ownership [16, 66, 70]. The watermark is, therefore, tied intricately to the model's internal structure and architecture. One distinguishing feature of the white-box watermarking is that, given the high dimensionality of neural networks, the probability of collision for two honest model owners is highly improbable since their models should have the same weight initialization and the same watermark parameters initialization to end up with the same extracted signature [16]. This unique property has directed significant research attention towards white-box model watermarking, highlighting its prominence in the field [45, 63].

Attack on White-Box Watermarking. The recent emergence of DNN watermarking schemes has given rise to watermark removal attacks, which can be classified into three subcategories [45]: (i) input preprocessing, (ii) model modification, and (iii) model extraction. However, as we elaborate in detail in Section 6, these attacks have various limitations because they typically require access to (i) data for re-training,

(ii) hardware capabilities, or (iii) knowledge of the embedded watermark.

Our Goals and Contributions. We address the limitations of existing white-box watermark removal methods by proposing a novel unified white-box watermark obfuscation framework *DeepEclipse*. Our attacks target the most studied types of white-box watermarking schemes, namely, weights-based [9, 10, 13, 19, 31, 42, 66, 70, 73] and activation-based [6, 16, 20, 58]. In a weight-based watermarking scheme, the model owner embeds a secret message into the weights of one or multiple layers during training. In contrast, in activation-based schemes, watermarks are characterized by embedding the message into the activation maps of layers for selected samples.

We present two white-box watermark obfuscation methods, basic and advanced, associated with different adversarial settings. The basic attack assumes a setting where a passive verifier checks the credibility of the model provided by the owner. Passive verifiers receive the position of the watermarked layer(s) from the original model owner and strictly follow the protocol of the watermarking scheme to extract the message. For this setting, we introduce a novel obfuscation technique to neutralize common white-box watermarking defenses by altering the structure and weights of the model's layers through layer splitting and reshaping while preserving the model's utility. Thus, this restructuring of the model layers hinders the passive verifier from correctly extracting the watermark. In some instances (e.g., a trial), the disputing parties may be required to disclose more information about their models to the verifier. Thus, a more active verifier that has access to more information, such as the whole model, can be present for the watermark verification. As a result, this verifier can perform a set of computations on the model's parameters to effectively undo any possible obfuscation an adversary may have employed. The advanced obfuscation attack addresses this setting and is the most robust adversarial setting, where a third-party verifier typically requires access to data and parameters for watermark verification. For the advanced obfuscation attack, we first identify possible watermarked layers using frequency analysis and then apply more substantial model modifications to make the identified layers noisy. In frequency analysis, we extract the frequency components of the weight matrix to study the patterns that help us discriminate the watermarked layers from the non-watermarked layers, as detailed in Section 5.2.1. The rationale behind employing frequency analysis is to minimize the potential impact on the model's effectiveness. Thus, once we determine the watermarked layers, we do not have to apply advanced obfuscation techniques to all the layers. Our extensive evaluations show that even in the worst-case scenario, we reduce the accuracy by only 4%.

Our attacks are designed to work for DNNs that incorporate linear or convolutional layers, or a combination of both, and operate effectively without prior knowledge of the specific watermarking scheme used.

In summary, our key contributions are as follows:

- We propose a novel framework, *DeepEclipse*, for obfuscating DNN watermarks. Our approach significantly differs from the existing white-box watermarking removal schemes since it can evade watermark detection without prior knowledge of the underlying watermarking scheme, additional data, and/or training or fine-tuning.
- We introduce two obfuscation attacks within our framework, each tailored to different adversarial settings. The basic obfuscation involves splitting and reshaping the layers within a DNN, while the second one builds noisy layers on top of the first, specifically designed to counter active verifiers who possess access to more information than is typically required for watermark verification (cf. §4).
- To aid in identifying potential layers that white-box watermarking schemes may have modified, we employ a frequency-based analysis of the model weights using Discrete Fourier Transform (DFT). This analysis not only identifies potential alterations but also helps minimize the loss in utility when applying our advanced obfuscation attack (cf. §4).
- We extensively evaluate our approach against a diverse range of well-known white-box watermarking methods. The results demonstrate that *DeepEclipse* effectively breaks multiple white-box watermarking schemes, reducing watermark detection to the level of random guessing while maintaining a similar accuracy to the original model (cf. §5).
- Finally, we conduct a comprehensive evaluation of the applicability of *DeepEclipse* across various model architectures and benchmark datasets. Our findings indicate that the base obfuscation algorithm has no discernible impact on the behaviour of stolen models. Additionally, our more advanced obfuscation attack, even in the worst-case scenario, only minimally impacts the accuracy of the targeted models (cf. §5).

2 Background

Deep Neural Networks (DNNs). A DNN can be expressed as a mathematical function denoted as $F(X;W)$, with X representing the input data samples and W denoting the network's parameters (comprising weights and biases). This network is structured into several layers, denoted as F_i (where i ranges from 1 to L). The first layer, known as the input layer, is labeled as F_1, while the final layer, termed the output layer, is designated as F_L. The intermediate layers are commonly referred to as hidden layers. In a feed-forward neural network, data moves in a unidirectional path, starting from the input layer, traversing through the hidden layers, and ultimately

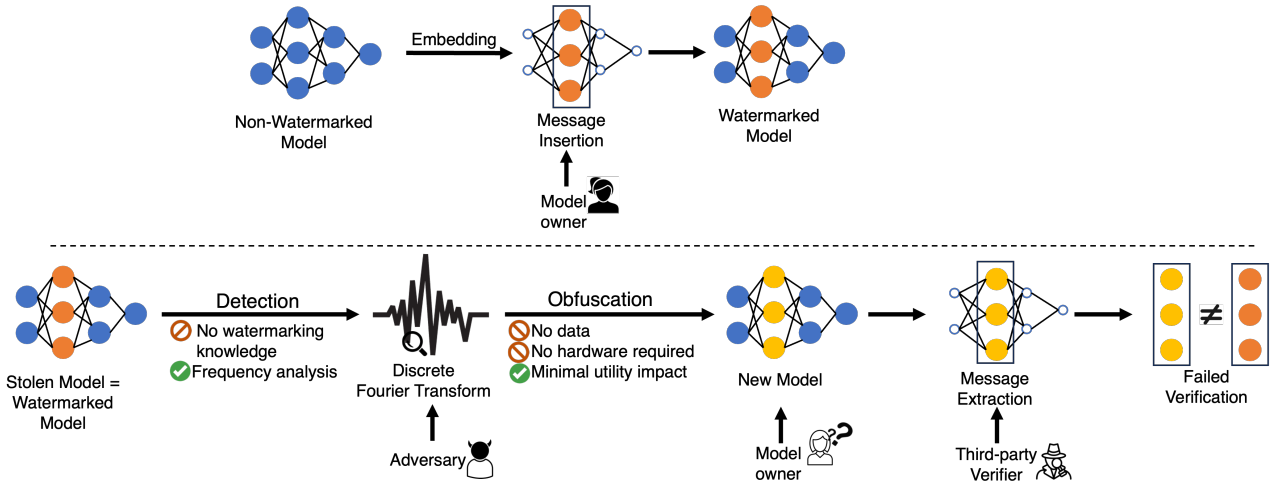

Figure 1: *DeepEclipse* overview. Top: Represents the expected behavior of the model owner, i.e., watermark insertion. Bottom: Analyzed detection and proposed obfuscation pipeline, followed by the verification process. We have assumed an adversary who has acquired an unauthorized copy of the watermarked model (Stolen Model) and is trying to hinder the model's verification (done by a third-party verifier: passive or active) by executing the obfuscation techniques (base or advanced).

reaching the output layer. While this architecture is conventional for tasks like classification [62], it is not unusual to encounter alternative architectural arrangements with different data flows [23]. Below, we briefly describe layers that have been extensively investigated in watermarking literature as the common choices for embedding watermarks.

- **Linear Layer.** A linear layer, often a fully connected or dense layer, is a fundamental element within a neural network responsible for executing a linear transformation on its input. This transformation involves taking an input vector $\overrightarrow{x} \in \mathbb{R}^m$, a weight matrix $A \in \mathbb{R}^{m \times n}$, and a bias vector $b \in \mathbb{R}^n$. The activation of the linear layer returns the output vector $\overrightarrow{x}'$ with dimension n. In the training process, the values of A and b are modified/updated using backpropagation according to the patterns learned from the data. The linear transformation can be mathematically represented as:

$$F_i(\overrightarrow{x}) = \overrightarrow{x} A_i + b_i \tag{1}$$

  White-box watermarks can extract the message from linear layers' matrix A, either by checking the values of the weights itself [70], by calculating statistical values such as its mean [9], Mean Square Error [19], Discrete Cosine Transform [31] or by evaluating the output fo the layer on specific values [16]. Therefore, in this paper, we change the shape and values of matrix A and vector b to change the output and statistical values of the layer without incurring catastrophic results for the model, as detailed in Section 4.

- **Convolutional Layer.** The convolutional layer is the base building block of convolutional neural networks (CNNs) utilized for feature extraction in image processing tasks. It performs a convolution operation on the input data to produce feature maps. Given an input signal X composed of several input channels C (for an input image, the channels are the 3 RGB colors), a learnable filter that is usually a square kernel K of dimension $k_h \times k_w$ for each input planes, the convolution operation for a single new element at position (υ, ι) of a singular feature map $p \in P$ is defined as follows:

$$\begin{aligned} Conv_i(X, P, \upsilon, \iota) &= b_i^P + (X \star K^P)(\upsilon, \iota) \\ &= b_i^P + \sum_{\tau=0}^{C-1} \sum_{\varkappa=0}^{k_h-1} \sum_{j=0}^{k_w-1} X_{\upsilon+\varkappa, \iota+j}^{\tau} \cdot K_{\varkappa, j}^{P} \end{aligned} \tag{2}$$

  Each element in the output feature maps undergoes iterations in the convolutional process. Convolutional layers typically consist of multiple kernels, each responsible for generating P individual feature maps. These individual feature maps are then combined to form the layer's output. Thus, the convolutional layer's weights are represented as $Conv \in \mathbb{R}^{P \times C \times k_h \times k_w}$, where p depends on the number of output feature maps, and the shape $\mathbb{R}^{k_h \times k_w}$ (same for all kernels). Watermarking aims to insert a signature message into the kernels of specific channels within convolutional layers, as seen in the previous [13, 66, 78]. When extracting this signature message, it is crucial to maintain the positions of the altered weights and the statistical values of the kernel matrix. Therefore, in this work, our objective is to modify the shape and values of kernels K without causing significant changes to the model, as discussed in Section 4.

Activation Functions. An activation function is a mathematical operation used in various machine learning and

computational models to introduce non-linearity to the output of a neuron or unit, allowing it to capture complex patterns and relationships in the data. One standard activation function of the hidden layers is the Rectified Linear Unit [2], which truncates all negative values to zero. Another standard activation function that is used for the output layer is the Softmax [7], which transforms the output vector of F_L into a probability distribution over multiple classes.

Discrete Fourier Transform. The Fourier Transform is a mathematical technique that converts a function into a representation highlighting the frequencies present in the original function. It achieves this by extracting the sine and cosine basis functions that comprise the function. The Fourier Transform can be used in both continuous (Continuous Fourier Transform, CFT) and discrete (Discrete Fourier Transform, DFT) scenarios. DFT, which includes information on both amplitude and phase. In this study, we employ the DFT [67] to break down the model's weights to analyze the pattern in the variance of changes in frequency values to distinguish the watermark from non-watermark layers, as detailed in Section 4.

White-box Watermarking. A white-box watermarking scheme for DNNs is designed to transparently mark and distinguish a specific neural network model or its elements. Thus, allowing one to easily evaluate the model ownership by detecting the mark (signature message). Unlike black-box watermarks, which usually add marks to the model's output or predictions, white-box watermarks incorporate the signature message directly into the model's structure or parameters. This integration makes them more conspicuous and verifiable when interacting with the model. The white-box watermark process can be divided into multiple phases: 1) *Integration into Model*, where the owner often adds the watermark into the model during its training process. The approaches (studied in this work) typically select convolutional layers [13, 66, 78] or linear layers [6, 16] to add the watermark. 2) *Message extraction*, where the third-party verifier obtains a secret message from the model following the instruction of the model owner, and 3) *Watermarking verification*, where the extracted signature is compared with the signature provided by the model owner claiming the theft. The owner's message and the extracted message ($M_o, M_e \in \{0,1\}$), each of length N, are compared using similarity metrics computed by adding the matching bits and normalizing the count relative to the message length.

$$\mathrm{Sim}(M_o, M_e) = \frac{1}{N}\sum_{i=0}^{N}\begin{cases}1, & \text{if } M_{o_i} = M_{e_i},\\ 0, & \text{if } M_{o_i} \neq M_{e_i}.\end{cases} \tag{3}$$

A watermark is considered retained in a model if it is possible to successfully extract the same message from the model with a similarity score exceeding a certain threshold specified by the watermarking scheme. If the success rate falls below this threshold, we consider the watermark as removed. Importantly, watermarks should remain in surrogate models created based on the source model.

In this paper, we focus on attacking these white-box watermark schemes by introducing obfuscation techniques to demonstrate how easily these defenses can be evaded. Thus effectively illustrating the urgent need to develop better watermark schemes to prevent the theft of intellectual property (IP) from DNN models.

3 Threat Model

Adversary's Goals and Constraints. We consider a distinct threat model concerning adversaries seeking to prevent watermark verification. Figure 1 presents an overview that outlines the watermark obfuscation setup and the associated threat model. As illustrated in Figure 1, we consider an adversary who has acquired an unauthorized copy of the watermarked model and is trying to hinder the model's verification by executing the obfuscation techniques (base or advanced, as detailed in Section 1). The verification is implemented by a third-party verifier who can be classified as passive or active. Importantly, we assume that the adversary does not require (i) prior knowledge about injected watermarks, (ii) data availability for training and fine-tuning, or (iii) hardware capability for training and fine-tuning. Note that, as mentioned in Section 6, existing attacks require access to an entire dataset for training or incur significant reductions in the model utility.

As mentioned earlier, the adversary has acquired an unauthorized copy of a watermarked model, possessing complete knowledge of its model structure and parameters. Thus, to conceal any traces of model infringement, the adversary's objective is to obstruct the watermarking verification.

Defense's Goal and Constraints. To ensure a trustworthy ownership verification, a model watermark scheme should satisfy a minimum set of fundamental requirements, which are: (i) **Fidelity** ensure no degradation in neural network function due to watermarking, (ii) **Reliability** minimize false negatives in watermark detection, (iii) **Robustness** withstand model modifications without compromising watermark integrity, (iv) **Integrity** minimize false positive in watermark detection, (v) **Capacity** embed large information while meeting fidelity and reliability criteria, (vi) **Efficiency** keep overhead minimal for embedding and detection, (vii) **Security** ensure undetectable watermark presence in the network, (viii) **Generalizability** applicable in both white-box and black-box scenarios. *DeepEclipse* focuses against **Reliability**, **Robustness** and **Security**, since the approach will maximize the false negative by modifying layers in which the watermark presence was detected.

The watermarking scheme fails: (i) if the verifier, following the procedure outlined by the watermarking scheme, is unable to extract the secret message (M_e) from the stolen model, or

(ii) the computed similarity (Equation Eq. 3) between the extracted secret message (M_e) and the owner's message (M_o) is less than a specified threshold (δ), or it falls into the scenario of a random guess: $Sim(M_o, M_e) \leq 0.5 + \delta$.

Verifier's Goal and Constraints. We consider two types of verifiers: a passive verifier and an active verifier. A passive verifier receives the position of the watermarked layer(s) from the original model owner and strictly follows the protocol of the watermarking scheme to extract the message. When encountering a verification failure or not correctly extracting the watermark signature, the passive verifier halts the verification process. In this case, the attacker's goal is achieved, and the watermarking is broken.

An active verifier can access more information beyond what is needed for standard verification protocol (passive verifier). In this setting, the verifier can inspect the layers' parameters, trying to undo any possible obfuscation the adversary may have deployed. We analyze how *DeepEclipse*'s advanced obfuscation technique (used on top of the base obfuscation) can effectively prevent any detection while causing a minimal drop in the model utility (Section 4).

4 Design

This section explains *DeepEclipse* design, which provides a detailed execution overview, highlighting the insights that enhance its effectiveness in bypassing an active verifier.

4.1 High-Level Idea

We propose two obfuscation techniques: (1) The Base obfuscation attack and (2) The Advanced obfuscation attack. Since we focus on the most prevalent architectures to implement our attack scheme (discussed in Section 1), we concentrate on the *Linear* and *Convolutional* layers, which are the primary targets for white-box watermarking schemes to embed a watermark. Thus, this approach is applicable to the classes of watermarking where the defense embeds the watermarks into layers involving matrix multiplication, and the signature of the watermark is present on referential transparent layers.

Linear Layers. The Base obfuscation attack alters the structure and weights ($A \in \mathbb{R}^{m \times n}$) of a model's layers ($F_i$) through layer splitting (using the Identity matrix, $I_{n \times n}$, as shown in Figure 2), thus expanding the architecture, while preserving the model's utility. Consequently, we construct two new layers with weights and shapes incompatible with the original watermarked layer while maintaining the same behavior of the stolen model's architecture. We still consider the possibility of an active verifier checking whether the output of the aggregated layers is the same as the original watermarked one [9, 16]. To falsify this verification, we apply further modifications. Specifically, we split the watermarked layer into two new layers as before, and combine the second one with the following layer (i.e., the first layer after the watermarked one in the original architecture), as depicted in Figure 3. This way, we implement both base and advanced obfuscation attacks for linear layers.

Convolutional Layers. In the Base obfuscation attack for the *Convolutional* layer, our goal is to manipulate the filters' shape ($k_h \times k_w$) of the *Convolutional* layer ($Conv_i$) and its values without modifying its outputs. Hence evading detection from a passive verifier. In the Advanced Obfuscation Attack, we first identify the possible watermarked layers using frequency analysis of the model weights to limit the potential drop in the model's utility. To accomplish this, we employ the Discrete Fourier Transform (Section 2) to extract the frequency components present in the model weights. Our analysis reveals that the average change in the frequency values of the watermarked layers is less volatile (or less fluctuations in the values) than the weights of the non-watermarked layers. Section 4.2 and 5.2.1 provides a more detailed explanation. After identifying the potential watermarked layers, we aim to apply additional perturbation to the kernel's frame after implementing the base scheme. Thus, we first draw a random noise from normal distributions (details in Section 4.2) and incorporate it into the values of the kernel's outer border, as portrayed in Figure 5.

In summary, to obfuscate the watermarked layers, we perform splitting and reshaping for the *Linear* layers and perform splitting and noising for the *Convolutional* layers.

4.2 Detailed Design

To simplify the analysis, we first provide details of the detection phase and then describe the operation of the two obfuscation techniques for both the linear and the convolutional layers.

Detecting Watermarked Layers. As detailed in Section 2, we use DFT of the weight matrix (A) to extract the frequency components consisting R_r^r and R_r^i, where R_r^r denotes the real part and R_r^i denotes the imaginary part of the frequency amplitude. Our goal is to examine these frequency components' average rate of change, enabling us to differentiate between watermark and non-watermark layers. Upon analysis of either R_r^r or R_r^i, we observed that the rate of change in the frequency values for watermarked layers is notably different from non-watermarked ones, as shown in Section 5.

Thus, we employ Simple Moving Average (SMA), a well-established technique for identifying trends or patterns in data. SMA calculates the average value of a data series within a specified moving window of data points and shifts this window across the data to create a new set of averaged values. Our approach begins by considering the input frequency vector, either R_r^r or R_r^i, of length f. Then, we apply the SMA formula to assess the average rate of change in these frequency components within a window of size r, as described below:

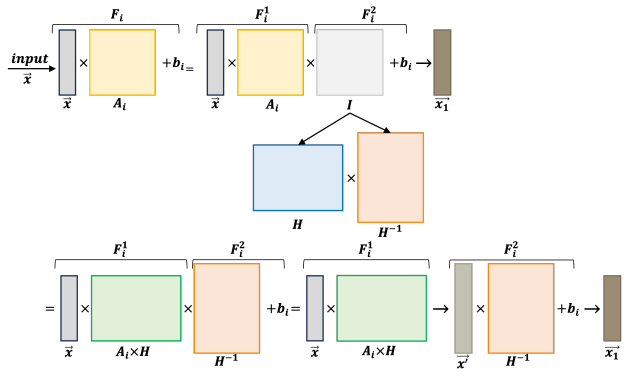

Figure 2: Basic *Linear* Layers obfuscation. The original layer is split into two, with the first layer being the matrix multiplication between the original layer and a random matrix, and the second layer being the inverse of the random matrix.

$$SMA(l) = \frac{R_r^i(l) + R_r^i(l-1) + \ldots + R_r^i(l-r+1)}{r} \quad (4)$$

where $R_r^i(l)$ represents it's value at index l.

Next, we analyze the core assumptions or working of the watermarking schemes (discussed in Section 1) regarding the embedding and extracting of secret messages. The motivation here is to decide on different attack strategies to help remove the watermark from the models. We do this analysis for both the *Linear* and *Convolutional* layers.

Linear layers. A generic watermark defense framework needs to keep track of the original layer's weight values and their position in the $\mathbb{R}^{m \times n}$ matrix [6, 10, 19, 31, 42, 73] during the embedding and extracting of a message in one or multiple *Linear* layers. Hence, some defenses work to address this limitation by taking an alternative approach. Such as, they employ one of two strategies: either train an extra deep neural network (DNN) to extract the hidden message from the layer's weights [58] or analyze the activation maps of the layer for specific input instances [9, 16]. Hence, it becomes apparent that the attack on these defenses can be divided into three categories: (i) attacks targeting the model weights, (ii) attacks targeting the DNN-based approaches, and (iii) attacks targeting the activation maps. Consequently, the principle method to remove the watermark can also be divided into three categories: first, modify the weight's matrix; second, impede the DNN-based approaches to change the shape of the weight's matrix (such that the DNN is no longer able to take them as input), and lastly, replace the output shape of the layer. Below, we propose a scheme encompassing all the above categories to fool the active verifier.

Base Linear Layer Obfuscation. Given the input vector $\overrightarrow{x}$ to the watermarked layer F_i with weights matrix A_i, we conduct the following transformation and execute the obfuscation techniques on it to evade watermark verification by the passive verifier. Figure 2 illustrates the Base obfuscation attack for the *Linear* layer F_i. Our motivation for executing this obfuscation is to introduce an Identity matrix ($I_{n \times n} = HH^{-1}$) to transform the characteristic Equation (Equation 1) of *Linear* layer F_i into two new layers: F_i^1 and F_i^2, as shown in Figure 2. For a passive verifier, both will appear as random layers with no relation to the original F_i. Therefore, any signature M_e extracted from either of them will not be similar or comparable with the owner secret message M_o. The new layers are given by:

$$\begin{aligned} F_i^1(\overrightarrow{x}) &= \overrightarrow{x} \times A_i \\ F_i^2(F_i^1) &= F_i^1(\overrightarrow{x}) \times I_{n \times n} + b_i \end{aligned} \quad (5)$$

Notably, this does not change the behaviour of the whole model, as the aggregated behaviour of the two layers is identical to the original one, $F_i(\overrightarrow{x}) = F_i^2(F_i^1(\overrightarrow{x}))$. For example, the original vector $\overrightarrow{x}$ is first computed with layer F_i^1. Then, the result is given as input to layer F_i^2, as shown in Equation 1. Due to the introduction of H and H^{-1}, which can be of any size and content, F_i^1 and F_i^2 have custom shapes and parameters that appear random to a third-party passive verifier.

However, finding an H of any shape such that $HH^{-1} = I_{n \times n}$ can appear challenging, as it does not consider the case for a non-square (or rectangular) matrix A_i. The reason is that it is not prevalent in the literature that the multiplication of a rectangular matrix with its inverse is equal to an identity matrix (rectangularity problem).

Hence, to tackle the problem of changing the values and shape of the layer's weights while accounting for the problem of rectangularity, we proceed as follows: first, we construct two rectangular matrices H and its inverse H^{-1} such that: (i) $H \times H^{-1} = I_{n \times n}$ and (ii) A_i is dimensionally compatible with H (i.e., we can multiply A_i with H). Then, we can assign the product $A_i \times H$ to F_i^1 and H^{-1} to F_i^2. Consequently, as per the modification depicted in Figure 2, from F_i we obtain two new layers F_i^1 and F_i^2, with weights and shapes incompatible with the original F_i. These two layers maintain the same behaviour of F_i when substituted in sequence to the architecture of the stolen model.

Now, the problem reduces to proving that H and H^{-1} exist, such that the size of H becomes irrelevant, and we can obtain infinitely many different such matrices with the desired characteristics. Below, we provide a formal proof that multiplying a rectangular matrix with its inverse can result in an identity matrix.

Theorem 1. *$H \times H^{-1} = I_{n \times n}$ and A_i is dimensionally compatible with $H \in \mathbb{R}^{n \times h}$, when $h > n$ and $rank(H) = n$.*

Proof. Given an arbitrary rectangular matrix $H \in \mathbb{R}^{n \times h}$ with $h > n$ and it's transpose H^T, such that $HH^T = I_{n \times n}$. We assume that the matrix H has the nullity zero property [49]. This

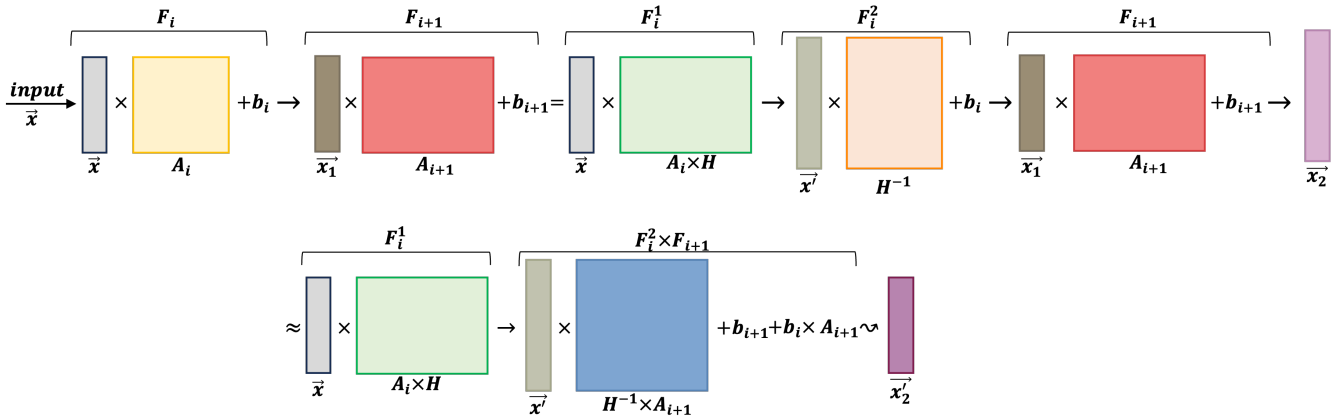

Figure 3: Advanced *Linear* Layers obfuscation. The watermarked layer is multiplied by a random matrix, and the subsequent layer is multiplied by the inverse of the random matrix. The subsequent Bias is updated with the original watermarked Bias.

property of a matrix is associated with matrices that have "full rank" or are "invertible". The "full rank" property of a matrix is a characteristic that indicates that the matrix has linearly independent columns ($rank(H) = n$), and "invertible" means that a square matrix has an inverse matrix. Under these conditions, the square matrix HH^T, of shape $n \times n$, is invertible, such that,

$$(HH^T) \times (HH^T)^{-1} = I_{n \times n} \tag{6}$$

Then, due to the associative property of matrix multiplication, we can modify Equation 6 and replace it by:

$$H[H^T \times (HH^T)^{-1}] = I_{n \times n} \tag{7}$$

Thus, $H^T \times (HH^T)^{-1}$ can be replaced by H^{-1}. Consequently, we have found two matrices $H \in \mathbb{R}^{n \times h}$ and $H^{-1} \in \mathbb{R}^{h \times n}$ such that $H \times H^{-1} = I_{n \times n}$ with the only constrain of (i) choosing h such that $h > n$ and (ii) the square matrix HH^T must be invertible. □

In summary, the constraints for finding H and H^{-1} becomes: (i) $h > n$ and (ii) $rank(H) = n$. It allows us to generate infinitely many random matrices, and, as shown in Figure 2, finally updating Equation 5 into:

$$\begin{aligned} F_i^1(\overrightarrow{x}) &= \overrightarrow{x} \times (A_i \times H) \\ F_i^2(F_i^1) &= F_i^1(\overrightarrow{x}) \times H^{-1} + b_i \end{aligned} \tag{8}$$

Finally, we can substitute $F_i(\overrightarrow{x})$ with the sequence of the transformed two new layers, F_i^1 and F_i^2. F_i^1 can either have no bias or a bias with an imperceptible value because it adds no perturbations to the output. Further, if we choose a matrix H such that $A_i \times H$ has only positive values, and F_{i-1} uses an activation function such as ReLU, we can further make F_i^1 inconspicuous to a passive verifier by applying $\text{ReLU}(F_i^1(\overrightarrow{x}))$ after F_i^1. However, an active verifier (see Section 3) may undo the obfuscation if H^{-1} is multiplied with F_i^2, as showcased in Figure 2. Hence, we propose an advanced layer obfuscation technique for the linear layers to evade the active verifier. We apply further modifications to the base method by keeping the first constructed layer F_i^1 and aggregating the second one F_i^2 with the subsequent *Linear* layer F_{i+1} if it exists. Otherwise, we can easily generate a new one using H and H^{-1}. This way, the perceived outputs will only be the one from F_i^1 and $F_i^2 \times F_{i+1}$, as shown in Figure 3.

Advanced Linear Layer Obfuscation. To deceive the active watermark verifier that examines the output of the *Linear* layers and is more robust in other adversarial scenarios, where it can employ complex computations (Section 3), which includes using multiplication to reverse the splitting of F_i into F_i^1, F_i^2 presented above. To deceive such an active verifier, it is imperative to devise an advanced obfuscation method. To do so, as shown in Figure 3, *DeepEclipse* aims to conceal F_i^2 within the *Linear* layer following F_i, denoted as F_{i+1}. Thus, we keep the first layer from the base obfuscation: F_i^1, and we substitute F_{i+1} with $F_{i+1} \times F_i^2$, as shown in Equation 9. As we have shown before for the passive verifier, the active verifier extracts a signature M_e from F_{i+1} that is incompatible with the M_o (that the owner extracts from A_i), further, even the signature extracted from $F_{i+1} \times F_i^2$ is of no use to the active verifier. Based on the structural properties of DNNs, it is guaranteed that A_i must be dimensionally compatible with A_{i+1}. We also update the bias b_{i+1} by appending the bias b_i from the now hidden layer F_i^2. If the original layer F_i made use of any activation function such as ReLU, then the new layer F'_{i+1} does not maintain the soundness that we guarantee in our base obfuscation approach, because the intermediate activation function is skipped. Nonetheless, as we will show in Section 5, our obfuscation incurs minimal utility loss.

$$\begin{aligned} F'_{i+1}(\overrightarrow{x}) &= \overrightarrow{x} \times A_{i+1} + b_{i+1} \\ F'_{i+1}(\overrightarrow{x}) &= \overrightarrow{x} \times (H^{-1} \times A_{i+1}) + (b_i \times A_{i+1}) + b_{i+1} \end{aligned} \tag{9}$$

Convolutional Layers. After examining the defenses for DNN watermarking, it becomes apparent that a generic wa-

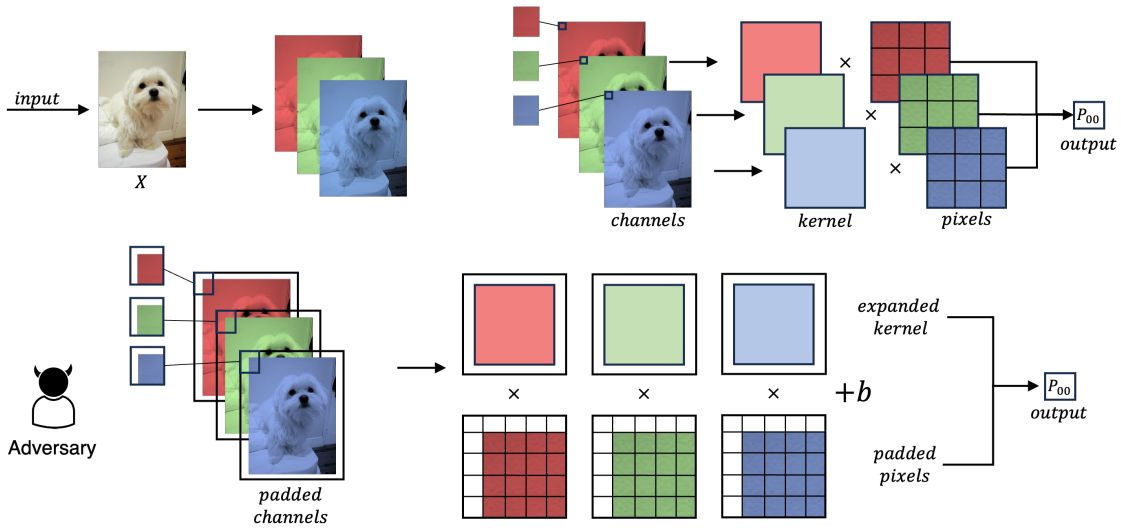

Figure 4: Basic *Convolutional* Layers obfuscation. Each feature maps of the Kernel is expanded with zeros padding.

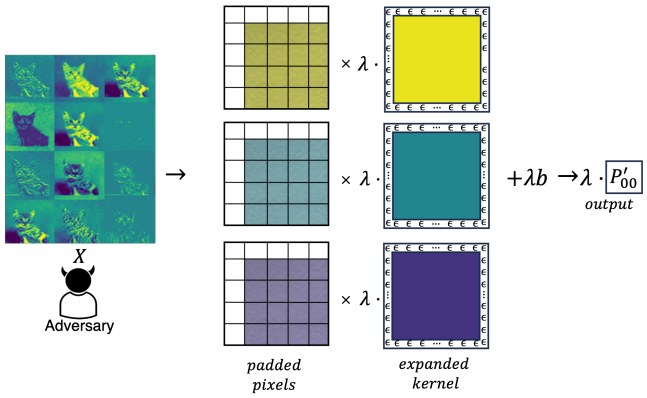

Figure 5: Advanced *Convolutional* Layers obfuscation. Each feature maps of the Kernel is expanded with padding using an ε value, then the whole layer is multiplied by a random constant λ, and the subsequent layer is also multiplied by $\frac{1}{\lambda}$.

termark defense framework aiming to embed and extract a message within one or multiple convolutional layers should consider various factors. These factors include the number of channels and the shape of the kernel ($\mathbb{R}^{C\times k_h\times k_w}$) [6, 10, 13, 42, 66, 73], the location of the selected weights within the filters [19], and the statistical values extracted from the filter's weights [6, 13, 73]. Specific approaches address these vulnerabilities differently. Instead of directly encoding the message into the weights, they opt for either training an additional DNN to extract the hidden message from the layer's weights [70] or evaluate the values of the output feature maps p (Section 2) for particular input signals [9, 20]. Hence, the attack on these defenses can be divided into three categories: (i) attacks targeting the kernel parameters (shape, location, and values), (ii) attacks targeting the DNN-based approaches, and (iii) attacks targeting the output feature maps. Consequently, the principle method to remove the watermark can also be divided into three categories: first, modify the kernel; second, impede the DNN-based approaches; and lastly, replace the output feature map. Below, we propose a scheme encompassing all the above categories to fool the active verifier.

Base Convolutional Layer Obfuscation. In this passage, we target watermarking methods that embed their signature within the *Convolutional* layers denoted as $Conv_i$. We formally prove how to manipulate the filters' shape of the *Convolutional* layer and values without modifying its outputs, evading detection from passive verifiers.

Theorem 2. *Convolutional layer, $Conv_i$, filters' shape $(k_h \times k_w)$, and values (at location (υ,ι)) can be manipulated without modifying their outputs.*

Proof. In this proof, we aim to extend the kernel filter (Equation 2). As illustrated in Figure 4, one can observe that this extension is achieved by padding the initial kernel ($Conv_i$) with a frame of zeros (or values that vanish imperceptibly) with no impact on the layer's output. Although the frame's dimensions can vary, we will assume a frame of -1 on all sides for this design explanation. Still, any value, even rectangular frames, is acceptable, as non-regular shapes further help hide the obfuscation from an active verifier.

Then, given input matrix X, input channels C, output feature map P, we ensure that the behaviour of the obfuscated $Conv_i^{'}$ remains the same for all output feature map P elements. Hence, we also consider additional padding for the input channels C, which must follow the same frame as the one put on the kernel (Figure 4). After applying these modifications, Equation 2 for a single element at position (υ, ι) becomes:

$$Conv_i^{'}(X,P,\upsilon,\iota) = b_i^P + \sum_{\tau=0}^{C-1}\sum_{\varkappa=-1}^{k_h+1}\sum_{j=-1}^{k_w+1} X_{\upsilon+\varkappa,\iota+j}^{\tau}\cdot K_{\varkappa,j}^{P} \quad (10)$$

$$= b_i^P + \sum_{\tau=0}^{C-1} X_{\upsilon-1,\iota-1}^{\tau}\cdot K_{-1,-1}^{P} + ... + X_{\upsilon,\iota}^{\tau}\cdot K_{0,0}^{P} + ...$$
$$... + X_{\upsilon+k_h-1,\iota+k_w-1}^{\tau}\cdot K_{k_h-1,k_w-1}^{P} + ... + X_{\upsilon+k_h,\iota+k_w}^{\tau}\cdot K_{k_h,k_w}^{P}$$

$$= b_i^P + \sum_{\tau=0}^{C-1} X_{\upsilon-1,\iota-1}^{\tau}\cdot 0 + ... + X_{\upsilon,\iota}^{\tau}\cdot K_{0,0}^{P} + ...$$
$$... + X_{\upsilon+k_h-1,\iota+k_w-1}^{\tau}\cdot K_{k_h-1,k_w-1}^{P} + ... + X_{\upsilon+k_h,\iota+k_w}^{\tau}\cdot 0$$
$$= b_i^P + \sum_{\tau=0}^{C-1} X_{\upsilon,\iota}^{\tau}\cdot K_{0,0}^{P} + ... + X_{\upsilon+k_h-1,\iota+k_w-1}^{\tau}\cdot K_{k_h-1,k_w-1}^{P}$$
$$= b_i^P + \sum_{\tau=0}^{C-1}\sum_{\varkappa=0}^{k_h}\sum_{j=0}^{k_w} X_{\upsilon+\varkappa,\iota+j}^{\tau}\cdot K_{\varkappa,j}^{P} = Conv_i(X,P,\upsilon,\iota)$$

Thus, proving that it is possible to change the filters' shape and values of a *Convolutional* layer without modifying its outputs. □

However, an active verifier could notice the padding added to the filters, choosing to apply the verification on the non-padded kernel, undoing the obfuscation. Hence, below, we provide advanced layer obfuscation techniques for the *Convolutional* layers to fool the active verifier.

Advanced Convolutional Layer Obfuscation. While introducing padding to the input channels of a *Convolutional* layer would not typically raise suspicion of passive verifiers, as it is common practice in model architectures [23]. However, an active verifier may detect the presence of a zero border (or imperceptibly vanishing values) within the kernel. To counteract this potential detection, we develop a new formulation that introduces an additional perturbation to the kernel's border as depicted in Figure 5. The idea is to incorporate random noise into the values of the kernel's border, as shown in Figure 5. As a result, we dynamically calculate distinct random noise, denoted as ε, for each filter K^p $\forall p \in P$, and add it to the kernel's border.

$$\begin{aligned} \forall p \in P,\ \varepsilon^p &= \beta * median(|K^p|) * \mathcal{N}(\mu,\sigma^2) \\ \forall p \in P,\ \varepsilon^p &= \beta * min(|K^p|) * \mathcal{N}(\mu,\sigma^2) \end{aligned} \quad (11)$$

We present two potential formulations for computing ε, one using the absolute median and the other using the absolute minimum. When the absolute median is chosen, it results in a greater decrease in utility compared to using the absolute minimum. Consequently, employing the absolute median leads to more pronounced changes in the statistical characteristics of the *Convolutional* layer than when using the absolute minimum. In our evaluation we employed $\mu = 0.33$, $\sigma = 0.1$, and fixed scaling of $\beta = 10$. Furthermore, to blend and integrate the values of ε with the original filters K, we introduce an additional random factor λ that multiplies the matrices of the new kernel as well as the bias. This adjustment elevates the values of the border, exceeding the extremely subtle vanishing values that an active verifier might erroneously perceive as zeros. Following these supplementary obfuscation steps, Equation 10 transforms into:

$$\begin{aligned} Conv_i^{'}(X,P,\upsilon,\iota) &= \lambda b_i^P + \sum_{\tau=0}^{C-1}\sum_{\varkappa=-1}^{k_h+1}\sum_{j=-1}^{k_w+1} X_{\upsilon+\varkappa,\iota+j}^{\tau}\cdot \lambda K_{\varkappa,j}^{P} \\ &= \lambda b_i^P + \lambda\sum_{\tau=0}^{C-1}\sum_{\varkappa=-1}^{k_h+1}\sum_{j=-1}^{k_w+1} X_{\upsilon+\varkappa,\iota+j}^{\tau}\cdot K_{\varkappa,j}^{P} \end{aligned} \quad (12)$$

To prevent model fluctuations that can occur due to the random boosting of λ in $Conv_i^{'}$, we divide the subsequent $Conv_{i+1}$ kernel's matrices by λ again. Thus, following the flow of the new obfuscated model, $Conv_i^{'}$ and $Conv_{i+1}$ becomes:

$$\begin{aligned} Conv_i^{'}(X,P,\upsilon,\iota) &= \lambda b_i^P + \lambda\sum_{\tau=0}^{C-1}\sum_{\varkappa=-1}^{k_h+1}\sum_{j=-1}^{k_w+1} X_{\upsilon+\varkappa,\iota+j}^{\tau}\cdot K_{\varkappa,j}^{P} \\ Conv_{i+1}(X,P,\upsilon,\iota) &= b_{i+1}^P + \frac{1}{\lambda}\sum_{\tau=0}^{C-1}\sum_{\varkappa=0}^{k_h}\sum_{j=0}^{k_w} X_{\upsilon+\varkappa,\iota+j}^{\tau}\cdot K_{\varkappa,j}^{P} \end{aligned} \quad (13)$$

If the subsequent layer is *Linear*, we can employ the base obfuscation technique as shown above to obtain $HH^{-1} = \frac{1}{\lambda}\cdot I$. As the random noise ε is added to the layers, we cannot guarantee the soundness of this advanced obfuscation approach. Nonetheless, as shown in Section 5, while the obfuscation incurs some utility loss, the verification of all watermarking is compromised.

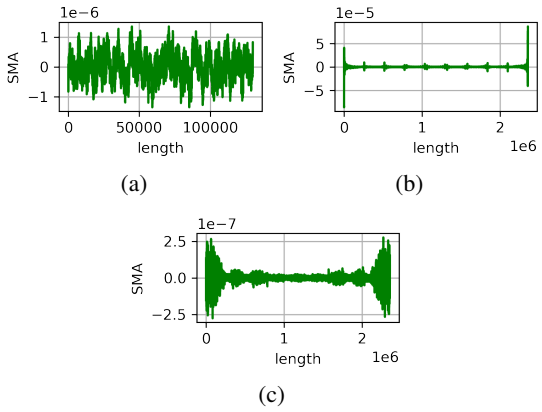
5 Evaluation

In this section, we demonstrate that our detection and evaluation can prevent the verification of watermarking signatures without impairing the performance of the original NN.

5.1 Experimental Setup

All the experiments were conducted on a server running Debian 11, with 1 TB of memory, an AMD EPYC 7742 processor with 64 physical cores and 128 threads, and 4 NVIDIA Quadro RTX 8000. We leveraged Pytorch [54] to implement the attack. For the defenses, the environment used was suggested by their authors when available.

Datasets. For conducting the experiments, we used the well-known CIFAR-10 [30] and MNIST [35] dataset. The CIFAR-10 dataset consists of small images (32×32) of objects or



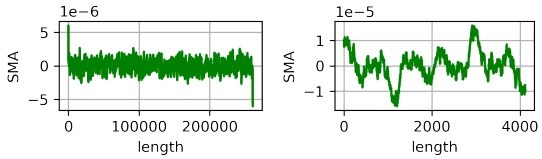


Figure 6: SMA analysis of *Convolutional* watermarked Layer belonging to the ResNet-18 (b). Subfigures (a) and (c) represent the SMA analysis of the non-watermarked layers before and after (b).

(a) non-watermarked (b) watermarked

Figure 7: SMA analysis of *Linear* watermarked and non-watermarked Layers.

animals. It includes 50k images for training and 10k for testing, depicting objects from 10 categories. The MNIST dataset is a collection of 70k grayscale images, each (28×28) pixels in size, representing handwritten digits $(0-9)$.

Models. The considered models for the evaluation include ResNet-18 [22] for the CIFAR-10 dataset and a Convolutional Neural Network (CNN) for MNIST. The CNN starts with two Convolutional layers, with a 3x3 filter and padding of 1, each followed by one Max-Pooling layer of size 2×2 and stride of 1. Then, two Convolutional layers, with a 5x5 filter and padding of 0, each followed by one Max-Pooling layer of size 2×2 and stride of 1. Lastly, we added four fully connected layers with ReLU activation and another fully connected layer with Softmax activation for the classification task. The choice of datasets and models used for our evaluation is based on the existing and available watermarking defenses presented in the following Section.

5.2 Evaluation Results

In this section, we demonstrate how *DeepEclipse* performs in defending against watermarking mechanisms, considering both the passive verifier (basic obfuscation) and the active verifier (advanced obfuscation). Our approach takes into account potential model modifications. We provide a detailed account of the frequency detection results, which play a pivotal role in distinguishing layers that may have been watermarked from those that have not. Then, we present the results of our approach when applied to each linear and convolutional layer under both obfuscation schemes. Finally, we delve into the discussion of how the utility of our approach may be impacted when we employ advanced obfuscation on the entire model.

5.2.1 Frequency Detection

This section demonstrates how the frequency components differ between watermarked and non-watermarked layer weights, as shown in Figure 7 for the *Linear* layers and Figure 6 for the *Convolutional* layers. Each point on the plots represents the average of the model weight's frequency within a 1000-point window. For *Convolutional* layer analysis, we watermarked different layers of ResNet-18 and analyzed the average (SMA) frequency patterns of the *Convolutional* layers.

For *Linear* layer analysis, we tested watermarking on one or more *Linear* layers in the CNN. We concluded that, for the *Linear* (Figure 7), the watermarked layers exhibit a higher degree of stability in the average change of frequency values, with fewer fluctuations compared to the weights of the non-watermarked layers. Similarly, we observed less volatility for the SMA values for the *Convolutional* layers, except for the sudden high jumps in values at the extreme points. Thus, we were able to discriminate the watermarked layers from the non-watermarked layers.

5.2.2 *DeepEclipse* Attack on Linear Layers

To evaluate our approach against watermark defenses that embed their signature in the *Linear* layers, we will consider a CNN trained on MNIST [35]. Following Table 1, we outline the drop in watermarking verification's accuracy using *DeepEclipse*'s base and advanced obfuscations, or if the signature extraction is completely prevented, e.g., due to incompatible matrix multiplication, the verifier cannot proceed (marked as no signature, *N.S.*). To simplify the evaluation process, we categorize the evaluated watermark frameworks on how their approaches extract the secret signature during the passive verification and how they attempt to bypass the obfuscation during active verification.

Weight-Based Watermarks. This category of watermarks [6, 9, 10] embeds the secret message into the weights of F_i (Section 2 and 4.2). During passive verification, they use a secret matrix $S \in \mathbb{R}^{n \times n}$ (or a secret vector $\overrightarrow{w} \in \mathbb{R}^n$), kept by the model owner, to obtain the secret message by multiplying the selected layer weights A_i (or statistical features of A_i) with this secret: $A_i \times S$ or $A_i \times \overrightarrow{w}$. However, as shown in Figure 2, *DeepEclipse* transforms F_i into F_i^1. Therefore, when the passive verifier tries to multiply $(A_i(m \times n) \times H(n \times h))$ by S (or $\overrightarrow{w}$), the dimensions will be incompatible $(h \neq n)$, failing the

extraction. In the active verifier setting, as illustrated in Figure 3 and in Section 4.2, we assume that the active verifier tries to reshape the weights of F_i^1 or $F_i^2 \times F_{i+1}$ to match the dimensions of S (or $\overrightarrow{w}$). While it is possible, however, the content of both layers has no relation to the original A_i (as well as different statistical features). Therefore, as shown in Table 1, the resulting watermarking confidence will be akin to a random guess.

Weight-Selection Watermarks. This category of watermarks [19,31] chooses values at specific positions in the layer F_i. Thus, during verification, the passive verifier searches for those values in the same positions as in A_i and calculates the secret message from the vector composed of those values. Since *DeepEclipse* transforms the layer F_i into F_i^1 with dimension $\mathbb{R}^{m \times h}$ and also updated its weight matrix with random values, which has no direct relation to the original A_i; therefore, when the passive verifier tries to locate the watermarked elements, it will extract random weights, obtaining low watermarking confidence that disproves the model ownership. When we assume an active verifier who try to multiply F_i^1 with F_i^2 to obtain the original F_i, we show that *DeepEclipse* advanced obfuscation can counteract this reversing by replacing F_i^2 with $F_i^2 \times F_{i+1}$, as detailed in Section 4.2. When the active verifier extracts the signature weights again, they will observe that it has no relation to the original A_i (as well as different statistical features). Therefore, as shown in Table 1, the resulting watermarking confidence drops to a random guess.

Activation-Based Watermarks. This category of watermarks [16, 58, 73] evaluates the activation maps of selected layer F_i for a hidden dataset of selected inputs. To extract the signature from the output of F_i, the passive verifier generates a secret transformation matrix $S \in \mathbb{R}^{n \times n}$ that is dimensionally compatible with A_i ($\mathbb{R}^{m \times n}$). But as shown in Figure 2, *DeepEclipse* transforms F_i into F_i^1 into a new layer with weights $A_i \times H \in \mathbb{R}^{m \times h}$, leading the secret matrix S to be dimensionally incompatible with F_i^1 ($h \neq n$). Consequently, the passive verifier fails to extract the signature from the model.

In the advanced scenario, we assume that the active verifier tries to reverse back F_i from F_i^1 and F_i^2, but *DeepEclipse*'s advanced obfuscation preventively merges F_i^2 with F_{i+1} into $F_i^2 \times F_{i+1}$. Thus, even if the active verifier tries to reshape the outputs to match S, the activation maps of both layers will still contain enough noise, lowering the watermark confidence, as shown in Table 1.

5.2.3 *DeepEclipse* Attack on Convolutional Layers

To evaluate our approach against watermark defenses that embed their signature in the *Convolutional* layers, we consider a ResNet-18 [22] trained on CIFAR-10 [30]. In Table 2, we outline the drop in watermarking verification's accuracy with the use of *DeepEclipse*'s base and advanced obfuscations, or if the signature extraction is completely prevented (*N.S.*). Again, we categorize the evaluated watermarks based on how their approaches extract the secret signature from the *Convolutional* layers during the passive verification and how an active verifier would attempt to bypass the obfuscation during verification.

Weight-Based Watermarks. This category of watermarks [6, 9, 10, 13, 66, 70] embeds the secret message into the weights of one or more *Convolutional* layers. At verification time, the passive verifier extracts a vector $\overrightarrow{w} \in \mathbb{R}^{C \cdot k_h \cdot k_w}$ that is the flattened average of one or more $Conv_i \in \mathbb{R}^{P \times C \times k_h \times k_w}$ for each feature maps $p \in P$. Then, a signature is obtained by computing a similarity (Equation 3) between $\overrightarrow{w}$ (in some cases using trained DNN [70]), and the owner's secret signature M_o. Since, we expand the kernel, as illustrated in Figure 4, *DeepEclipse* forces the extraction of a signature of incorrect size $C \cdot k_h^{'} \cdot k_w^{'}$ that cannot be compared with the owner's signature, halting the verification. An active verifier could detect the padding in the kernel, but by carefully adding noise, as explained in Equation 13, *DeepEclipse* prevents the verifier from determining the position of the original kernel to extract. The only option left for an active verifier, in order to obtain a

functional M_e, is to reshape the kernels to match them with the owner's signature size. However, this operation does not help the active verifier, given that, as shown in Table 2, the computed watermarking confidence with the reshaped kernels is still too low to justify a claim of ownership.

Activation-Based Watermark. This category of watermarks [20, 42, 73] evaluates the resulting feature maps for a hidden dataset of selected inputs given to the selected *Convolutional* layers $Conv_i$. To extract the signature, the passive verifier generates a secret matrix S that is dimensionally compatible with the feature map of the *Convolutional* layer. During the verification, *DeepEclipse* base obfuscation changes the statistical values that the defense is expected to obtain, reaching watermark confidence that cannot support the claim of ownership. In the active verifier scenario, the original kernels remain hidden during the inspection, producing again a lower watermark confidence than the base obfuscation case, as shown in Table 1.

5.2.4 Runtime Evaluation

To evaluate the applicability of *DeepEclipse* in real-case scenarios, we evaluated the increase in complexity and runtime execution of obfuscated models with regard to the original stolen models. Table 4 shows that our approach does not increase significantly the execution time after the injection of the watermarking. Instead, for the advanced obfuscation, the multiplication of layers by a smaller H reduces the execution time.

6 Related Works

This section provides an overview of the removal attacks on white-box watermarking schemes. The attacks can be subdivided into the following categories (Lukas N. *et al.* [45]): (i) input preprocessing, (ii) model modification, and (iii) model extraction. We will present only watermarking schemes that check the model composition.

Model Modification. In this category, the adversary first transforms a model to introduce vulnerabilities that can be further exploited using various techniques such as fine-tuning, pruning and more [3, 26, 43, 45, 46, 60, 64, 66, 68, 74, 80].

In [46], they first select a subset of the dataset, which they modify using Projected Gradient Descent (PGD), causing disruption to the watermark. Subsequently, they fine-tuned the model, utilizing the true labels for the adversarial examples, to ensure that the model's predictions aligned more closely with the underlying data.

In the case of the regularization attack [60], the authors initially applied a regularization technique, such as L2, to the model. They then fine-tuned the model to discover a new optimal local minimum, aiming to reduce the drop in accuracy caused by the initial regularization step. Due to the modifications made to the model's weights, the watermark has been removed. Szegedy *et al.* [64] introduced Label Smoothing, a method where uncertainty was introduced during training. This was achieved by combining one-hot encoded or predicted labels with a uniform distribution over all possible labels. This approach served to regularize the model, treating the ground-truth class label and other potential labels equally likely. Because the regularization process influenced the model's layers, the resultant modifications rendered the watermark less detectable.

In [66], the authors employed fine-tuning to modify the model's weights and introduced various fine-tuning approaches aimed at removing the watermark from the model. These approaches include (i) fine-tuning all layers, (ii) fine-tuning only the last layer after freezing the preceding layers, (iii) retraining all layers by re-initializing the weights of the last layers and then fine-tuning all weights, and (iv) retraining only the last layer. Through the fine-tuning process, the layers containing the watermark are updated, resulting in a failure during the watermark verification. They also presented another approach, which embeds a watermark using the same watermarking scheme but a different watermarking key, thus overwriting the previous one.

In [43], the authors introduced the fine-pruning method for removing the watermark, which involves a combination of fine-tuning and pruning to reduce the effectiveness of the watermarking, thus eliminating it. Initially, the pruning step entailed setting the activation of neurons with low activation for benign samples to zero. Then, the model was fine-tuned to mitigate the drop in test accuracy. Considering the impact of these two approaches independently on watermark removal,

their combination also led to the failure of the watermark.

Another set of methods focuses on altering model weights to eliminate or obscure watermarked layers. For instance, Zhu M. *et al*. [80] employ the weight pruning technique, which involves randomly pruning weights in the model until a specific sparsity level is achieved within each layer. In another study [45], authors introduced the weight shifting technique, where they apply minor perturbations to the filters of convolutional networks. Subsequently, the model is fine-tuned to enhance test accuracy.

In the Weight Quantization approach [26], the authors utilize b bits to quantize the model's weights. These weights are then divided into 2^b equally spaced segments, with each weight parameter approximated by the central value of its respective segment. All of these aforementioned approaches, [26,45,80] operate on the assumption that, in typical scenarios, watermarks are embedded within the model weights or architecture. Therefore, modifying these components weakens the watermarking. Moreover, Lukas N. *et al*. [45] presented the feature permutation technique, where neurons in a hidden layer are randomly rearranged without affecting the model's functionality. This is possible due to the feature invariance of deep neural networks. Altering the positions of the weights within the neural network also has an impact on the watermark, as it directly affects the layer(s) containing it.

Neural Cleanse [68] and Neural Laundering [3] are approaches based on reverse engineering. Firstly, the watermarking is removed by reverse-engineering the watermarking trigger from the model, eliminating the trigger. After this process, the trigger can be unlearned by fine-tuning it on different labels or by iteratively pruning the most active neurons in some layers. The distinction between Neural Cleanse and Neural Laundering is that the first was developed for removing backdoors, while the latter used the same approach to remove the watermark.

Yifan Y. *et al*. [74], presented a Neural Structural Obfuscation approach, which uses dummy neurons to perform neural structural obfuscation, automatically generating and injecting dummy neurons inside the target model to reduce the success of watermark verification. While this approach works against the passive verifier, this approach will not work against an active verifier as described in Section 3. This active verifier could easily detect the added dummy neuron by comparing the weights of the original model and the obfuscated one, as described in Section 4.

Model Extraction. In this watermark removal scheme, the knowledge from the source model is transferred into a surrogate model. However, this category lies in the black-box domain except for the Distillation [25], which introduces model compression by transferring knowledge from a larger teacher neural network to a smaller student network.

All the approaches discussed above have certain limitations, primarily based on their demands for data and resources to facilitate training, fine-tuning, or modification to remove the watermark embedded in the image or the model. For instance, in the case of Model Modification, the model needs to be modified to perform the necessary modification, leading to a need for input data and resources to perform the fine-tuning to compensate for the drop in accuracy. Lastly, Model Extraction employs a distillation process wherein the teacher model must be reduced to a student model during the training. This, again, requires the availability of suitable data and computational resources. Table 3 outlines these reported watermark removal attacks, detailing the limitations regarding the prior information they need (data and fine-tuning or retraining) to function effectively.

7 Security Considerations

This section considers the effectiveness of our obfuscation techniques, corroborating that *DeepEclipse* can neutralize both the passive and active verifiers without requiring prior knowledge of the underlying watermarking schemes, additional data or training, and fine-tuning. To bypass our attack scheme, an active verifier has to ensure that they can either undo the obfuscation schemes or compute a different set of operations that can help them identify the modifications done on the stolen model. Thus succeeding in verifying the watermark. Below, we present the schemes through which a verifier can determine that the given model is indeed a stolen copy of the original model: i) Keep track of the original layer's weight values and their positions in the $\mathbb{R}^{m\times n}$ matrix, ii) Train and deploy an extra deep neural network (DNN) to extract the hidden message from the layer's weights [70], iii) Analyze the activation maps of the layer for specific input instances [16, 20], or iv) Perform an extra set of computations to compare the original and the assumed stolen model. Thus, an advanced verifier with knowledge of the stolen model architecture, an attempt to compute H from $A_i \times H$ using A_i and then obtain the identity matrix from the subsequent H^{-1}.

Thus, the adversary, when attacking the watermarking approaches, can alter the weight matrix or alter the layer's output. *DeepEclipse* encompasses these attack methods through two obfuscation schemes presented in Section 4. These schemes reshape the entire watermarked area of the model by splitting and expanding using $I_{n\times n}$ for Base Linear Layer Obfuscation, merging $F^2 i$ with layer $F^1 i+1$ for Advanced Linear Layer Obfuscation, modifying the kernel shape ($k_h \times k_w$) and size using padding for Base Convolutional Layer Obfuscation, and introducing noise λ, ε for further alteration in the Advanced Convolutional Layer Obfuscation. Against an advanced verifier that tries to obtain H from $A_i \times H$, the adversary can expand the model architecture by incorporating new layers between $A_i \times H$ and H^{-1} using the obfuscation schemes presented in Section 4, and, if the adversary does not want to introduce noise, by cleverly introducing another H^{-1} in the middle of the expansion it can deceive the verifier into thinking it has obtained the identity matrix before the expected

position.
We also empirically verified the effectiveness of *DeepEclipse* in Section 5. The results reveal that *DeepEclipse* effectively disrupts multiple such schemes, reducing watermark detection to the level of random guessing while maintaining model accuracy. Therefore, *DeepEclipse* is robust against both passive and active verifiers.

8 Conclusion

This paper presents *DeepEclipse*, a unified white-box watermark obfuscation framework. Unlike existing methods, it offers both basic and advanced obfuscation techniques, catering to different scenarios. The basic method targets passive verifiers adhering to standard protocols, while the advanced method addresses situations where active verifiers have access to the entire model and can perform additional computations. Extensive evaluations were conducted, testing *DeepEclipse* against various white-box watermarking methods. The results reveal that *DeepEclipse* effectively disrupts multiple schemes discussed in the paper, reducing watermark detection to the level of random guessing while maintaining model accuracy.

A Algorithmic Implementation

Algorithmic implementation of *DeepEclipse*: starting from Algorithm 5, if the SMA detection algorithm has not found any potential layer, we apply the obfuscation to the whole model (line 2); otherwise, for each watermarked detected layer, we apply the specific obfuscation based on its type and accordingly to the kind of verification that is expected. The function AdvConvObfuscation (Algorithm 3) calculates an ε value for each feature of the layer's feature map and uses it for padding; it then multiplies the whole layer by a random value and divides the subsequent one by the same value. The function BaseConvObfuscation (Algorithm 4) pads each feature map of the kernel with zeros. The function AdvLinearObfuscation (Algorithm 1) calculates the matrices H and H^{-1} based on the dimension of the watermarked layer and the subsequent one; it then multiplies the original layer's weight by H and the subsequent layer by H^{-1}. Lastly, function BaseLinearObfuscation (Algorithm 2) calculates the matrices H and H^{-1} based on the dimension of the watermarked layer; it then expands the model on that specific layer while keeping the previous and subsequent layers untouched.

Algorithm 1 AdvLinearObfuscation(M, *layer*)
Input:
M Model to obfuscate
layer position of the Linear layer
Output:
M Model with advanced obfuscation of Linear layer

1: $H, H^{-1} \leftarrow RandomMatrix(M[layer], M[layer+1])$
2: $M[layer] \leftarrow M[layer] \times H$
3: $M[layer+1] \leftarrow M[layer+1] \times H^{-1}$
4: **return** M

Algorithm 2 BaseLinearObfuscation(M, *layer*)
Input:
M Model to obfuscate
layer position of the Linear layer
Output:
M' Model with base obfuscation of Linear layer

1: $H, H^{-1} \leftarrow RandomMatrix(M[layer])$
2: $M', newLayer \leftarrow expandModel(M, layer)$
3: $M'[layer] \leftarrow M'[layer] \times H$
4: $M'[newLayer] \leftarrow H^{-1}$
5: **return** M'

Algorithm 3 AdvConvObfuscation(M, *layer*)
Input:
M Model to obfuscate
layer position of the Conv. layer
Output:
M Model with advanced obfuscation of Conv. layer

1: **for** p in $FeatureMap(M[layer])$ **do**
2: $\varepsilon \leftarrow \beta * min(|M[layer][p]|) * \mathcal{N}(\mu, \sigma^2)$
3: $M[layer][p] \leftarrow PadKernel(M[layer][p], \varepsilon)$
4: **end for**
5: $\lambda \leftarrow random()$
6: $M[layer] \leftarrow M[layer] * \lambda$
7: $M[layer+1] \leftarrow M[layer+1]/\lambda$
8: **return** M

Algorithm 4 BaseConvObfuscation(M, *layer*)
Input:

Abstract

Malicious utilization of a query interface can compromise the confidentiality of ML-as-a-Service (MLaaS) systems via model extraction attacks. Previous studies have proposed to perturb the predictions of the MLaaS system as a defense against model extraction attacks. However, existing prediction perturbation methods suffer from a poor privacy-utility balance and cannot effectively defend against the latest adaptive model extraction attacks. In this paper, we propose a novel prediction perturbation defense named MODELGUARD, which aims at defending against adaptive model extraction attacks while maintaining a high utility of the protected system. We develop a general optimization problem that considers different kinds of model extraction attacks, and MODELGUARD provides an information-theoretic defense to efficiently solve the optimization problem and achieve resistance against adaptive attacks. Experiments show that MODELGUARD attains significantly better defensive performance against adaptive attacks with less loss of utility compared to previous defenses.

1 Introduction

With the rapid development of machine learning, more and more organizations have begun deploying well-trained machine learning models as black-box capabilities that provide services for customers, i.e. Machine-Learning-as-a-Service (MLaaS) systems. While easy access to well-trained models brings convenience to users and creates wealth for the model owner, it also leads to potential threats to the ownership and security of the confidential models deployed in MLaaS systems. Recent studies show that MLaaS systems are vulnerable to model extraction attacks, where the attacker can replicate the parameters or functionality from the deployed confidential (target) model to an extracted substitute model by querying the system and learning from the query result [21, 35, 43]. Model extraction attacks allow attackers to retain access to the service through the extracted substitute model while avoiding any subscription or access costs imposed by the model provider. Furthermore, the extracted substitute model can expose the weakness of the target model and makes it vulnerable to downstream attacks, such as evasion attacks and membership inference attacks [23, 38, 40, 41].

There have been many works discussing the defense against model extraction attacks, and the proposed defense methods mainly fall into four types: (a) Model extraction detection tries to distinguish the attacker from other benign users according to the distribution of the query data [23, 25]. (b) Model information monitoring tries to evaluate how much information of the target model has been exposed to a specific user, and adjust the response strategy according to the information gained by the user [13, 25]. (c) Model watermarking forces the target model to learn a non-removable "watermark" (a specific input-output pair) so that the owner can claim ownership with it [1, 22]. (d) Prediction perturbation perturbs the output (prediction) of the target model so that the attacker cannot extract the model correctly [28, 36].

On one hand, none of model extraction detection, model information monitoring, and model watermarking are general to all kinds of model extraction attacks. Model extraction detection is effective only when the query data of an attacker distributes differently from the query data of a benign user, which is a strong assumption in practice [35]. Model information monitoring is not able to defend against collaborative attackers who divide the query data among multiple users to avoid querying with a single user. And model watermarking cannot prevent attackers from stealing the model for private use or for subsequent attacks. On the other hand, although prediction perturbation makes the minimum assumption and is universal to all kinds of attacks, previous prediction perturbation methods usually suffer from a bad privacy-utility balance because of heuristic perturbation mechanisms. Additionally, recent studies have shown that there exist strong adaptive attacks that can significantly weaken the defensive performance of previous prediction perturbation methods [8].

In this paper, we propose a novel prediction perturbation method, MODELGUARD, which aims at attaining a better privacy-utility balance under the presence of adaptive model

extraction attacks. MODELGUARD investigates a general optimization formulation that considers both parameter-stealing and functionality-stealing attacks. The optimization formulation aims at attaining the optimal defensive performance while maximally preserving the utility of the target model with the utility constraints. Since the adaptive attack method is arbitrary and unknown to the defender, we explore two different ways to deal with the adaptive attack when solving the optimization problem, resulting in two variants of MODELGUARD: MODELGUARD-W and MODELGUARD-S. Our contributions are:

1. We propose the first general formulation for the defense against adaptive model extraction attacks. We unify the parameter-stealing attack and the functionality-stealing attack in our formulation such that we can defend against both kinds of attacks in one objective.

2. We develop a constrained optimization problem that aims at defending against adaptive model extraction attacks while maintaining the utility of the target model. We propose MODELGUARD to solve the optimization problem with two variants: MODELGUARD-W and MODELGUARD-S. Especially, MODELGUARD-S attains an information-theoretic defense against strong adaptive attacks and outperforms the other defenses.

3. We evaluate MODELGUARD against a wide range of attacks, including a strong adaptive attack we propose based on the Bayesian estimator. We empirically show that compared with previous defenses, MODELGUARD attains a significantly better privacy-utility balance when defending against adaptive model extraction attacks[1].

This paper is organized as follows: We define the threat model in Section 2 and we present our defense MODELGUARD in Section 3. The experimental results are given in Section 4. We leave the discussion on related works to Section 5 and we conclude this paper in Section 6.

2 Threat Model

Attacker's goal Query-based model extraction attacks aim at learning a substitute model with the predictions returned by a black-box target model, as shown in Figure 1. We denote $f_t(\cdot;\boldsymbol{w}_t)$ as the target model with parameters $\boldsymbol{w}_t$ trained on a confidential dataset (X_t, Y_t). When performing the model extraction attack, the attacker uses the unlabeled query dataset $X_q = [\boldsymbol{x}_{q,1}, \boldsymbol{x}_{q,2}, \cdots, \boldsymbol{x}_{q,N}] \in \mathbb{R}^{N\times d}$ (with N samples in d dimensions) to query the target model and get its predictions. If there is no prediction perturbation defense, the clean prediction set $Y_q = [\boldsymbol{y}_{q,1}, \boldsymbol{y}_{q,2}, \cdots, \boldsymbol{y}_{q,N}] = f_t(X_q;\boldsymbol{w}_t)$ will be returned to the attacker from the target model, where $\boldsymbol{y}_{q,i} \in \mathbb{R}^C$ is the prediction result (i.e., the confidence score vector over C classes) of the i-th query $\boldsymbol{x}_{q,i}$. Otherwise, the attacker will receive the perturbed prediction set $\hat{Y}_q = [\hat{\boldsymbol{y}}_{q,1}, \hat{\boldsymbol{y}}_{q,2}, \cdots, \hat{\boldsymbol{y}}_{q,N}] = p(Y_q)$ where p is a perturbation mechanism. With the query data and the prediction returned from the target model, the model extraction attacker can train a substitute model $\boldsymbol{w}_s$ to attain two different goals: parameter-stealing and functionality-stealing.

[1] Get our codes at https://github.com/Yoruko-Tang/ModelGuard.

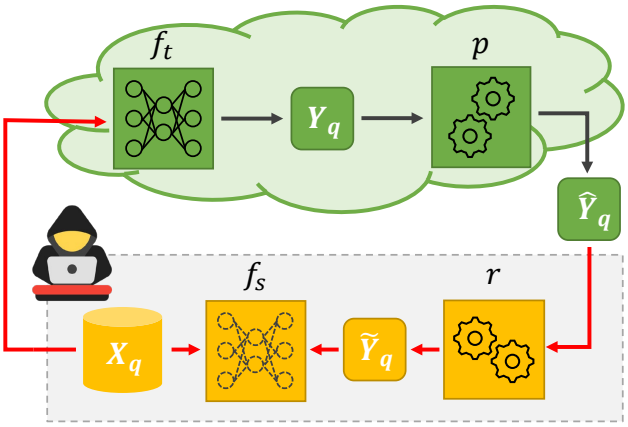

Figure 1: A general framework of a model extraction attack against a prediction perturbation defense. The clean predictions Y_q of the query data X_q outputted by the target model f_t are perturbed to $\hat{Y}_q = p(Y_q)$ by a mechanism p, and the perturbed predictions are returned to the user. The adaptive attacker first tries to recover the clean predictions from the perturbed predictions with $\tilde{Y}_q = r(\hat{Y}_q)$. Then the attacker trains the substitute model f_s with the recovered predictions.

For the parameter-stealing attack, the goal is to learn a substitute model with the same architecture and the same parameters as the target model, i.e., $\boldsymbol{w}_s^* = \boldsymbol{w}_t$. For the functionality-stealing attack, the goal is to learn the substitute model that can attain the maximum similarity with the target model in the clean predictions, namely,

$$\min_{\boldsymbol{w}_s} \quad L(X_q, Y_q; \boldsymbol{w}_s) = \mathcal{L}(f_s(X_q;\boldsymbol{w}_s), Y_q), \tag{1}$$

where $f_s(\cdot;\boldsymbol{w}_s)$ is the prediction of the substitute model $\boldsymbol{w}_s$, and $\mathcal{L}(Y_{\text{pred}}, Y_{\text{targ}})$ is a supervised loss that can measure how similar the predictions Y_{pred} and the target labels Y_{targ} are, e.g., cross-entropy (CE) loss or mean squared error (MSE) loss.

Attacker's background knowledge We assume that the attacker is not able to access the exact training dataset (X_t, Y_t) of the target model. However, the attacker knows the domain of X_t and can use any query data X_q from a similar domain. Moreover, we consider a strong attacker who knows the model architecture of the target model so that the attacker is able to use the same model architecture in the substitute model when conducting the model extraction attack [8, 35].

In this paper, we assume that the attacker is adaptive, namely, the attacker knows about the prediction perturbation defense. In this case, the attacker first tries to recover the

clean predictions $\tilde{Y}_q = r(\hat{Y}_q)$ from the perturbed predictions $\hat{Y}_q$ with a prediction recovery mechanism r. And then they use $\tilde{Y}_q$ to train the substitute model. We allow the adaptive attackers to know the details of the perturbation such that they can reproduce the same perturbation given a clean prediction [8].

Remark 1. Our adaptive attack model can cover the non-adaptive attack by simply setting r to be an identity function. Additionally, an adaptive model extraction attack without an explicit prediction recovery can also be covered by our threat model. An arbitrary model extraction attack algorithm that results in a substitute model $\tilde{\boldsymbol{w}}_s^*$ satisfying $f_s(X_q;\tilde{\boldsymbol{w}}_s^*) = \tilde{Y}_q$ is equivalent to recovering the predictions to $\tilde{Y}_q = r(\hat{Y}_q)$ first and then training the substitute model with $(X_q, \tilde{Y}_q)$.

Attacker's capability We assume that the attacker can only interact with the target model by query, namely, there are no side channels providing extra information about the target model. The attacker can use any query data as long as it is a valid input of the target model, i.e., the attacker can use natural data or generate synthetic data for queries. And the attacker has unlimited query budgets, namely, the attacker can repeat querying with the same data arbitrarily many times. The attacker has sufficient computing power to implement any training and prediction recovery algorithms, and to implement the same perturbation mechanism as the defender.

3 MODELGUARD Design

In this section, we introduce our defense framework, MODELGUARD. We will first give a brief overview of MODELGUARD in Section 3.1. We formulate our defense goal as a constrained optimization problem in Section 3.2, and then we introduce two variants of MODELGUARD to solve the optimization problem from Section 3.3 to Section 3.5.

3.1 Overview

MODELGUARD aims at defending both parameters and functionality of the target model against adaptive attacks while maintaining a high utility of the protected system. Our method is derived from a constrained optimization problem that tries to find the perturbed prediction set $\hat{Y}_q$ to maximize the loss $\mathcal{L}(\tilde{Y}_q, Y_q)$ under some utility constraints. However, since we are not aware of how the attacker recovers the prediction, it is intractable to directly solve the optimization problem. Instead, we explore two different ways to deal with the unknown recovery mechanism r when solving the optimization problem, leading to two variant defense methods, MODELGUARD-W and MODELGUARD-S: MODELGUARD-W assumes a weak adaptive attack and solves the optimization problem with the approximation $\tilde{Y}_q = r(\hat{Y}_q) \approx \hat{Y}_q$; MODELGUARD-S considers the optimal recovery mechanism r^* (i.e., the Bayes estimator) that leads to the lowest recovery loss, and we try to maximize an information-theoretic lower bound of the objective function against the attack with the optimal recovery mechanism.

3.2 Objective and Constraints

The goal of prediction perturbation is using the perturbed prediction set $\hat{Y}_q$ to prevent the attacker from replicating the target model parameters $\boldsymbol{w}_t$ or learning the functionality. To defend against parameter-stealing and functionality-stealing attacks discussed in Section 2, we can formulate two different optimization objectives respectively:

$$\max_{\hat{Y}_q} \quad \|\tilde{\boldsymbol{w}}_s^* - \boldsymbol{w}_t\|_2^2, \tag{2}$$

$$\max_{\hat{Y}_q} \quad L(X_q, Y_q; \tilde{\boldsymbol{w}}_s^*) = \mathcal{L}(\tilde{Y}_q, Y_q). \tag{3}$$

A unified objective for defending against both attacks Directly defending against parameter-stealing attacks is intractable since the defender does not know about the training details of the substitute model, such as the training hyperparameters and the training algorithms. The following lemma shows that maximizing $L(X_q, Y_q; \tilde{\boldsymbol{w}}_s^*)$ can also maximize the lower bound of $\|\tilde{\boldsymbol{w}}_s^* - \boldsymbol{w}_t\|_2^2$ under a smoothness assumption commonly used by optimization literature [5]. Therefore, we can use Equation (3) as a unified objective for defending against both kinds of attacks.

Lemma 1. *Assuming that $L(X_q, Y_q; \boldsymbol{w}) = \mathcal{L}(f_t(X_q; \boldsymbol{w}); Y_q)$ is M-smooth in $\boldsymbol{w}$. Given two models $\boldsymbol{w}_t$ and $\tilde{\boldsymbol{w}}_s^*$ with the same architecture such that $f_t(X_q; \boldsymbol{w}_t) = Y_q$ and $f_s(X_q; \tilde{\boldsymbol{w}}_s^*) = \tilde{Y}_q$, we have:*

$$\|\tilde{\boldsymbol{w}}_s^* - \boldsymbol{w}_t\|_2^2 \geq \frac{2}{M}\left[\mathcal{L}(\tilde{Y}_q, Y_q) - \mathcal{L}(Y_q, Y_q)\right]. \tag{4}$$

We prove Lemma 1 in Appendix A.1.

Utility and validity constraints We consider the scenarios where the users care about not only the top-1 label but also the confidence scores in the predictions, which can be used for downstream tasks such as out-of-distribution detection [18]. This leads to the following two utility constraints:

(Distortion constraint) As different downstream tasks may have different utility metrics, we adopt the ℓ_1 norm of the perturbation as a generic metric of the utility loss [36]. And we constrain the distortion magnitude as follows:

$$\|\hat{\boldsymbol{y}}_{q,i} - \boldsymbol{y}_{q,i}\|_1 \leq \varepsilon, \quad i = 1, 2, \cdots, N. \tag{5}$$

(Top-1 accuracy preserving constraint) The top-1 label cannot be changed by the perturbation:

$$\arg\max_k \hat{y}_{q,i}^{(k)} = \arg\max_k y_{q,i}^{(k)} \quad i = 1, 2, \cdots, N, \tag{6}$$

where $\hat{y}_{q,i}^{(k)}$ is the k-th dimension of $\hat{\boldsymbol{y}}_{q,i}$.

In addition to the utility constraints, we also need to guarantee that the perturbed predictions are valid predictions. Thus we have the following validity constraint:

(Simplex constraint) The perturbed predictions must be valid confidence score vectors:

$$\sum_{k=1}^{C} \hat{y}_{q,i}^{(k)} = 1, \text{ and } \hat{\boldsymbol{y}}_{q,i} \succeq 0, \quad i = 1, 2, \cdots, N. \tag{7}$$

Namely, for each perturbed prediction, the sum of all dimensions is 1 and each dimension is non-negative. The ℓ_1 distortion on $\hat{\boldsymbol{y}}_{q,i}$ cannot be larger than 2.0 under this constraint.

Challenges in solving the optimization problem It is still intractable to solve Equation (3) directly because we are not aware of what recovery mechanism r is used to calculate $\tilde{Y}_q$. We explore two options to bypass this difficulty: (a) Assuming a weak adaptive attack and approximating $\tilde{Y}_q = r(\hat{Y}_q) \approx \hat{Y}_q$ when solving Equation (3); (b) Defending against the strongest adaptive attack where r leads to the lowest $\mathcal{L}(\tilde{Y}_q, Y_q)$. In the following sections, we will introduce how to solve Equation (3) with these two options respectively.

3.3 MODELGUARD-W

In this section, we introduce the first variant MODELGUARD-W which adopts the first option, i.e., treats $\tilde{Y}_q \approx \hat{Y}_q$.

As we are focusing on classification tasks in this paper, we set $\mathcal{L}$ to be the CE loss $\mathcal{L}_{\text{CE}}$, which is one of the most popular loss functions in classification tasks. With this specific loss and the simplification $\tilde{Y}_q = \hat{Y}_q$, we can reformulate Equation (3) for each $i = 1, \cdots, N$ respectively as follows.

$$\begin{aligned} \min_{\hat{\boldsymbol{y}}_{q,i}} \quad & \sum_{k=1}^{C} y_{q,i}^{(k)} \log \hat{y}_{q,i}^{(k)} \\ \text{subject to} \quad & \|\hat{\boldsymbol{y}}_{q,i} - \boldsymbol{y}_{q,i}\|_1 \le \varepsilon, \\ & \arg\max_k \hat{y}_{q,i}^{(k)} = \arg\max_k y_{q,i}^{(k)}, \\ & \sum_{k=1}^{C} \hat{y}_{q,i}^{(k)} = 1, \text{ and } \hat{\boldsymbol{y}}_{q,i} \succeq 0. \end{aligned} \tag{8}$$

Because of the logarithm in the objective function, it is difficult to solve this constrained non-convex optimization problem directly. A good convex approximation to this non-convex objective function is to swap Y_q and $\hat{Y}_q$ in the loss function, which instead maximizes $\mathcal{L}_{\text{CE}}(Y_q, \hat{Y}_q)$ as follows:

$$\begin{aligned} \min_{\hat{\boldsymbol{y}}_{q,i}} \quad & \sum_{k=1}^{C} \hat{y}_{q,i}^{(k)} \log y_{q,i}^{(k)} \\ \text{subject to} \quad & \|\hat{\boldsymbol{y}}_{q,i} - \boldsymbol{y}_{q,i}\|_1 \le \varepsilon, \\ & \arg\max_k \hat{y}_{q,i}^{(k)} = \arg\max_k y_{q,i}^{(k)}, \\ & \sum_{k=1}^{C} \hat{y}_{q,i}^{(k)} = 1, \text{ and } \hat{\boldsymbol{y}}_{q,i} \succeq 0. \end{aligned} \tag{9}$$

In this formulation, the objective function becomes linear w.r.t $\hat{\boldsymbol{y}}_{q,i}$, and thus this optimization problem becomes Linear Programming, which can be solved efficiently by existing algorithms [5]. We call this defense MODELGUARD-W.

Remark 2. As justified in Appendix A.2, the solution $\hat{\boldsymbol{y}}_{q,i}$ of Equation (9) assigns a small confidence score $\hat{y}_{q,i}^{(k)}$ to the class k where $y_{q,i}^{(k)}$ is large, which can also lead to a small objective value in Equation (8). Thus, minimizing Equation (9) is an effective approximation of minimizing Equation (8).

MODELGUARD-W is effective against the attack that satisfies $\tilde{Y}_q \approx \hat{Y}_q$, but it may fail to defend against strong adaptive attacks where $\tilde{Y}_q$ significantly deviates from $\hat{Y}_q$. We will see how we are able to derive a defense against strong adaptive attacks with the optimal r in the following sections.

3.4 Bayes Attack

Now we consider the second option, where we treat r as the optimal prediction recovery that leads to the lowest loss $\mathcal{L}(\tilde{Y}_q, Y_q)$. We begin with the introduction to the optimal prediction recovery, i.e., the Bayes estimator, in this section. And we introduce the second variant, MODELGUARD-S, which defends the information-theoretic lower bound of the objective function in Section 3.5.

Objective of the prediction recovery The goal of the attacker is contrary to the goal of the defender given in Equation (3): the attacker tries to find a recovery function r against the perturbation function p that minimizes $\mathcal{L}(\tilde{Y}_q, Y_q)$. As the clean predictions are unknown to the attacker, Y_q becomes a random variable in the perspective of the attacker, and the attacker tries to minimize the following posterior expected loss conditioned on the returned prediction set $\hat{Y}_q$:

$$\min_r \quad \mathbb{E}\left[\mathcal{L}(r(\hat{Y}_q), Y_q) | \hat{Y}_q\right], \tag{10}$$

where $\mathbb{E}$ stands for the expectation w.r.t Y_q.

For analysis simplicity, we adopt the most popular squared loss $\mathcal{L}(\boldsymbol{x}, \boldsymbol{y}) = \|\boldsymbol{x} - \boldsymbol{y}\|_2^2$ as the recovery loss[2], whose Bayes estimator (i.e., the minimizer r^*) is given by the posterior mean of Y_q given $\hat{Y}_q$:

$$\tilde{Y}_q^* = r^*(\hat{Y}_q) = \mathbb{E}[Y_q | \hat{Y}_q]. \tag{11}$$

Namely, the optimal recovered prediction $\tilde{Y}_q^*$ is the average of all the clean predictions that can result in the same perturbed prediction $\hat{Y}_q$ returned to the attacker.

Bayes Attack: a brute-force Bayes estimator As the attacker does not know about the true distribution of Y_q, it is non-trivial to calculate the posterior mean $\mathbb{E}[Y_q | \hat{Y}_q]$ even though the

[2] Lemma 2 shows that our analysis can also adapt to CE loss.

attacker knows the defense mechanism. Previous adaptive attack methods use some approximate estimators as the solution to Equation (10), e.g., a trained neural network as an approximation of the Bayes estimator r^* [8,28]. As an alternative, we propose a brute-force method which we call Bayes Attack, to find the Bayes estimator in Equation (11) under the assumption that the attacker has sufficient computing power. Since we allow the attacker to perform the same perturbation $p(Y)$ given any clean prediction set $Y = [\boldsymbol{y}_1, \boldsymbol{y}_2, \cdots, \boldsymbol{y}_N] \in \mathbb{R}^{N\times C}$, the attacker can build a lookup table that contains $(Y, p(Y))$ pairs of all possible valid Y. When given the perturbed prediction set $\hat{Y}_q$, the attacker finds all the Y that satisfy $p(Y) = \hat{Y}_q$ in the table, then the mean of these Y will be used as the recovered prediction set $\tilde{Y}_q$. We can summarize it as follows:

$$\begin{aligned}
&\mathbb{T} = \{(Y, p(Y)) : \exists X \in \mathbb{R}^{N\times d}, \exists \boldsymbol{w}, Y = f_t(X; \boldsymbol{w})\},\\
&\mathbb{M}(\hat{Y}_q) = \{Y : (Y, p(Y)) \in \mathbb{T}, \|p(Y) - \hat{Y}_q\| \le \delta\},\\
&\tilde{Y}_q = \frac{1}{|\mathbb{M}(\hat{Y}_q)|} \sum_{Y\in\mathbb{M}(\hat{Y}_q)} Y,
\end{aligned} \tag{12}$$

where $\mathbb{T}$ is the lookup table, and $\mathbb{M}(\hat{Y}_q)$ contains all matching clean prediction sets within a small error tolerance δ.

Remark 3. Bayes Attack is proposed against the deterministic defense mechanism. For a randomized perturbation mechanism $p(Y)$, as we allow an unlimited query budget of the attacker, the attacker can repeat querying the target model with the same query data and obtain the mean of the perturbations. This makes it equivalent to attacking against a deterministic perturbation mechanism $p'(Y) = \mathbb{E}[p(Y)]$. Therefore, we exclude randomized perturbation from the discussion.

Partial Bayes Attack: shrinking the sampling space In practice, we are not able to implement the perfect Bayes Attack, because we do not have an infinite computing power to traverse all possible clean prediction sets Y, especially when we need to recover the prediction set Y_q as a whole in a very high dimension ($Y_q \in \mathbb{R}^{N\times C}$). We can approximate the perfect Bayes Attack based on the fact that most defense mechanisms perturb each clean prediction $\boldsymbol{y}_{q,i}$ independently, i.e., $\hat{\boldsymbol{y}}_{q,i} = p(\boldsymbol{y}_{q,i})$ is only dependent on $\boldsymbol{y}_{q,i}$. Therefore, we can build a lookup table that contains $(\boldsymbol{y}, p(\boldsymbol{y}))$ pairs in a much lower dimension ($\boldsymbol{y} \in \mathbb{R}^C$) instead of $(Y, p(Y))$ pairs in a high dimension ($Y \in \mathbb{R}^{N\times C}$), namely,

$$\mathbb{T} = \{(\boldsymbol{y}, p(\boldsymbol{y})) : \exists \boldsymbol{x} \in \mathbb{R}^d, \exists \boldsymbol{w}, \boldsymbol{y} = f_t(\boldsymbol{x}; \boldsymbol{w})\}. \tag{13}$$

Even with the independent sampling, the sampling space of $\boldsymbol{y}$ is still huge when the number of classes is large (e.g., up to 256 in our experiment). Based on the observation that the prediction $\boldsymbol{y}$ in the neighborhood of each $\boldsymbol{y}_{q,i}$ is more likely to be perturbed to a result close to $\hat{\boldsymbol{y}}_{q,i}$, we further shrink the sampling space by only sampling clean predictions from the neighborhood of each true clean prediction $\boldsymbol{y}_{q,i}$ as elaborated in Appendix B.1. We obtain Partial Bayes Attack with the independent sampling and the neighborhood sampling.

3.5 MODELGUARD-S

Now we introduce our second variant MODELGUARD-S, which is an information-theoretic defense against strong adaptive attacks such as Bayes Attack. We target maximizing the expectation of the loss in Equation (3), i.e., $\mathbb{E}[\mathcal{L}(\tilde{Y}_q, Y_q)]$, against the prediction recovery with a statistical estimator. Given any recovery mechanism r, the expectation of the loss can be lower bounded by the following lemma derived from Information Theory:

Lemma 2. *Given a prediction perturbation mechanism p such that $\hat{Y}_q = p(Y_q)$, an adaptive model extraction attack with an arbitrary recovery function r cannot attain a smaller gap between recovered predictions $\tilde{Y} = r(\hat{Y}_q) = r(p(Y_q))$ and clean predictions Y_q than the following lower bound:*

$$\mathbb{E}\left[\|\tilde{Y}_q - Y_q\|_2^2\right] \ge \frac{NC}{2\pi e} \exp\left(\frac{2}{NC} h(Y_q|\hat{Y}_q)\right), \tag{14}$$

where $h(Y_q|\hat{Y}_q)$ is the conditional entropy. Subsequently,

$$\mathbb{E}\left[\mathcal{L}(\tilde{Y}_q, Y_q) - \mathcal{L}(Y_q, Y_q)\right] \ge \frac{Cl}{2\pi e} \exp\left(\frac{2}{NC} h(Y_q|\hat{Y}_q)\right), \tag{15}$$

where l is a constant related to the loss function $\mathcal{L}$, e.g., $l = 0.5$ for CE loss and $l = 1$ for MSE loss.

We prove Lemma 2 in Appendix A.3.

Lemma 2 reveals that no adaptive attack can precisely recover the clean predictions when the uncertainty (i.e., the conditional entropy $h(Y_q|\hat{Y}_q)$) is still large given the perturbed predictions. Therefore, maximizing the conditional entropy can maximize the lower bound of the expected loss $\mathbb{E}[\mathcal{L}(\tilde{Y}_q, Y_q)]$ and defend against the adaptive attacks with any recovery mechanisms. Maximizing the conditional entropy is equivalent to minimizing the mutual information $I(Y_q; \hat{Y}_q)$ since $h(Y_q|\hat{Y}_q) = h(Y_q) - I(Y_q; \hat{Y}_q)$, so we can formulate our defense objective as follows:

$$\begin{aligned}
\min_{\hat{Y}_q} \quad & I(Y_q; \hat{Y}_q) \\
\text{subject to} \quad & \|\hat{\boldsymbol{y}}_{q,i} - \boldsymbol{y}_{q,i}\|_1 \le \varepsilon, \\
& \arg\max_k \hat{y}_{q,i}^{(k)} = \arg\max_k y_{q,i}^{(k)}, \\
& \sum_{k=1}^{C} \hat{y}_{q,i}^{(k)} = 1, \text{ and } \hat{\boldsymbol{y}}_{q,i} \succeq 0, \\
& \text{for } i = 1, 2, \cdots, N.
\end{aligned} \tag{16}$$

Online prediction quantization We notice that without the top-1 accuracy preserving constraint and the simplex constraint, Equation (16) is a rate-distortion problem in information theory. Since minimizing the mutual information in the rate-distortion problem is equivalent to finding the optimal

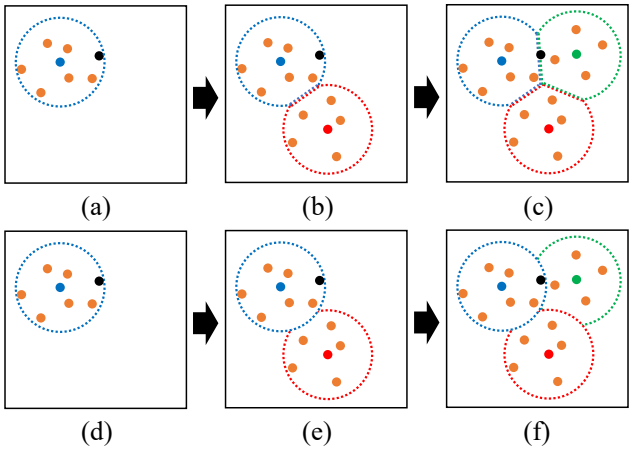

Figure 2: An illustration of non-ordered (upper) and ordered (lower) incremental prediction quantization. The order of the centroids is blue -> red -> green. The quantization result of the black point changes from the blue centroid in Figure (a) to the green centroid in Figure (c) in non-ordered incremental quantization, while it is always quantized to the blue centroid from Figure (d) to (f) in ordered incremental quantization.

compression method for the source data Y_q under the distortion constraint [11], we can adopt a classical compression method, vector quantization, to solve this problem.[3] However, we are not able to use a standard vector quantization to compress the whole clean prediction set Y_q because of the sequential characteristics of the query data and the requirement for a timely response. Namely, we have to perturb each prediction one by one as soon as it arrives instead of perturbing all predictions together after getting all the query data.

A naive solution to this problem is to quantize each clean prediction $\boldsymbol{y}_{q,i}$ independently with predefined static quantization centroids. Because static quantization does not utilize the distribution information of the source data, it usually either introduces a large distortion with a small number of centroids or attains a low compression rate (large mutual information) with a large number of centroids. Therefore, we turn to seek an online (dynamic) quantization method that can automatically increase the number of centroids to achieve a better balance between utility and defensive performance.

Information leakage in online prediction quantization A simple online quantization method is that we add a new centroid if no existing centroids are close enough to the incoming clean prediction. Otherwise, we quantize the incoming clean prediction to the closest centroid that satisfies the distortion constraint. However, we will see that this online quantization method may cause potential information leakage to the attacker, which may weaken the defensive performance.

[3] We do not consider randomized compression methods as discussed in Remark 3.

Algorithm 1 MODELGUARD-S

Initialize centroids $\mathbb{C}_i = \emptyset$ for each label $i = \{1, 2, \cdots, C\}$.
while getting new input $\boldsymbol{x}_s$ from the user **do**
  Get clean prediction $\boldsymbol{y}_q = f_t(\boldsymbol{x}_s)$ with top-1 label t.
  if $\mathbb{C}_t == \emptyset$ or $\min_{\boldsymbol{c} \in \mathbb{C}_t} \|\boldsymbol{c} - \boldsymbol{y}_q\|_1 > \varepsilon$ **then**
    Append $\boldsymbol{y}_q$ to the end of $\mathbb{C}_t$.
  end if
  $\hat{\boldsymbol{y}}_q \leftarrow$ the first element in $\{\boldsymbol{c} \in \mathbb{C}_t : \|\boldsymbol{c} - \boldsymbol{y}_q\|_1 \le \varepsilon\}$.
  Return $\hat{\boldsymbol{y}}_q$ to the user.
end while

We consider quantizing the t-th clean prediction $\boldsymbol{y}_{q,t}$. We denote $Y_{q,t-1} = [\boldsymbol{y}_{q,1}, \boldsymbol{y}_{q,2}, \cdots, \boldsymbol{y}_{q,t-1}]$ as the historical clean perturbations, together with their perturbations $\hat{Y}_{q,t-1} = [\hat{\boldsymbol{y}}_{q,1}, \hat{\boldsymbol{y}}_{q,2}, \cdots, \hat{\boldsymbol{y}}_{q,t-1}]$ that have been returned to the user. We can decompose $h(Y_{q,t}|\hat{Y}_{q,t})$ as:

$$\begin{aligned} h(Y_{q,t}|\hat{Y}_{q,t}) =& h(Y_{q,t-1}, \boldsymbol{y}_{q,t}|\hat{Y}_{q,t-1}, \hat{\boldsymbol{y}}_{q,t}) \\ =& h(Y_{q,t-1}|\hat{Y}_{q,t-1}) + h(\boldsymbol{y}_{q,t}|Y_{q,t-1}, \hat{Y}_{q,t-1}) \\ & - I(Y_{q,t-1}; \hat{\boldsymbol{y}}_{q,t}|\hat{Y}_{q,t-1}) \\ & - I(\boldsymbol{y}_{q,t}; \hat{\boldsymbol{y}}_{q,t}|Y_{q,t-1}, \hat{Y}_{q,t-1}). \end{aligned} \tag{17}$$

Therefore, we need to minimize the last two terms to maximize the conditional entropy:

$$\min_{\hat{\boldsymbol{y}}_{q,t}} \quad I(\boldsymbol{y}_{q,t}; \hat{\boldsymbol{y}}_{q,t}|Y_{q,t-1}, \hat{Y}_{q,t-1}) + I(Y_{q,t-1}; \hat{\boldsymbol{y}}_{q,t}|\hat{Y}_{q,t-1}). \tag{18}$$

While the first term in Equation (18) can be minimized by an online quantization method that quantizes each clean prediction $\boldsymbol{y}_{q,t}$ one by one, the second term introduces an additional requirement that the new quantization result $\hat{\boldsymbol{y}}_{q,t}$ should not provide extra information about historical clean predictions $Y_{q,t-1}$ given previous quantization results $\hat{Y}_{q,t-1}$. For instance, given the same query data $\boldsymbol{x}$ with the same clean prediction $\boldsymbol{y}_{q,t_1} = \boldsymbol{y}_{q,t_2} = f_t(\boldsymbol{x})$, the quantization results at different times t_1 and t_2 should be consistent: $p(\boldsymbol{y}_{q,t_1}) = p(\boldsymbol{y}_{q,t_2}) = p(f_t(\boldsymbol{x}))$. Otherwise, the attacker can obtain new information about the clean prediction from the difference. While the online quantization increases the centroids over time to satisfy the distortion constraint, it may also introduce inconsistency in the quantization result. An example of such information leakage in online quantization is shown in the upper three figures of Figure 2, where we always quantize the new clean prediction to the nearest centroid. After the online quantization adds a new centroid (the green point) to satisfy the distortion constraint for new inputs coming in Figure (c), the quantization result of the black point changes from the blue point to the green point. This change allows the attacker to know that the green point is near the boundary of the blue and green areas in Figure (c) since the quantization result can be changed only when the point is near the boundary.

MODELGUARD-S: an ordered incremental prediction quantization Based on the analysis above, we propose the second variant, MODELGUARD-S, which is described in Algorithm 1 and illustrated in Figure 2 (d) - (f). The key idea of MODELGUARD-S is to automatically increase the number of centroids while maintaining the order of the centroids. For each class, MODELGUARD-S maintains one set of centroids for quantizing the predictions with the top-1 label of this class, such that MODELGUARD-S does not change the top-1 label after quantization (Line 1 in Algorithm 1). Given a new clean prediction for perturbing, if none of the existing centroids in the set are close enough to satisfy the distortion constraint, we append this clean prediction as a new centroid to the end of the set (Lines 4-5 in Algorithm 1). Each clean prediction is always quantized to the first centroid that satisfies the distortion constraint (Line 7 in Algorithm 1), such that we avoid the information leakage in different quantization results for the same data queried at different times.

An intuitive explanation of why prediction quantization can defend against adaptive attacks is that quantization maps all clean predictions in a cluster to the same perturbed prediction, i.e., the quantization centroid. Therefore, the attacker cannot distinguish between different clean predictions in the same cluster and the Bayes estimator becomes the mean of the cluster, which makes it unable to recover the clean prediction precisely given a perturbed prediction.

4 Experiments

In this section, we evaluate MODELGUARD and compare it with previous defense methods with extended experiments. We first introduce the common experiment settings in Section 4.1, then we show the defensive performance of different defense methods against a wide range of attack methods in Section 4.2. We will also give ablation studies to further explore and understand our MODELGUARD in Section 4.3

4.1 Experiment Setup

Training datasets and model architectures of target models In Table 1, we summarize the training datasets and the architectures of the target models. We conduct experiments with four target models trained on four different image classification datasets respectively: Caltech256 [15], CUB200 [45], CIFAR100, and CIFAR10 [26]. Since one of the baselines, Adaptive Misinformation [24], requires using Outlier Exposure (OE) [19] that trains the model with an additional OE dataset, we train all the target models used in our experiments with OE, adopting Indoor67 [39] and SVHN [33] as the OE dataset. We adopt two different models as the target models: ResNet50 [17] for Caltech256 and CUB200, and VGG16-BN [42] for CIFAR100 and CIFAR10. We also report the top-1 accuracy of each target model in Table 1.

Query datasets and model architectures of substitute models The query datasets and architectures of the substitute models are also summarized in Table 1. When conducting model extraction attacks, We use ImageNet1k [12] as the query dataset for target models trained on Caltech256 and CUB200, while we use TinyImageNet200 [32] as the query dataset for target models trained on CIFAR100 and CIFAR10. Following Orekondy et al. [36], we use the same model architecture of the target model for each substitute model.

Evaluation metric Following previous literature [24, 36], we mainly use the extraction accuracy, i.e., the top-1 accuracy of the substitute model tested on the test set of the target model, as the metric of defensive performance. We also use fidelity, i.e., the top-1 label agreement between the target model and the substitute model [28], as an auxiliary metric in a part of our experiments. The lower extraction accuracy and fidelity, the better defensive performance.

Attack algorithms Each model extraction attack algorithm can be decomposed into two parts: the query strategy and the attack strategy, and each query strategy can be combined with different attack strategies.

We consider two query strategies: KnockoffNet [35] and JBDA-TR [23]. The query dataset of KnockoffNet consists of only natural data, while JBDA-TR generates synthetic data from a small amount of natural data (called seed set) by using Jacobian-based data augmentation. We sample $50,000$ images as the query dataset for KnockoffNet and $1,000$ images as the seed set for JBDA-TR. We fix the random seed to sample the same images for all attack strategies and defense methods.

We consider the following attack strategies, including both weak adaptive attacks (Top-1 Attack, S4L Attack, and Smoothing Attack) and strong adaptive attacks (D-DAE Attack, D-DAE+ Attack, and Partial Bayes Attack):

1. Naive Attack: No prediction recovery is performed, and standard CE loss is used for training the substitute model.
2. Top-1 Attack: Only the hard top-1 label in the perturbed prediction is used for training the substitute model.
3. S4L Attack [21]: A self-supervised rotation loss is added to the CE loss for training the substitute model. S4L attack can be viewed as an adaptive attack without an explicit prediction recovery.
4. Smoothing Attack [29]: The query image is augmented by random affine augmentations. The predictions of several augmented images are averaged as the recovered prediction of the original image.
5. D-DAE [8]: A generative model is trained to recover the clean prediction. The training data (i.e.,(perturbed prediction, clean prediction) pairs) of this generative model is generated by small shadow models.

Table 1: Overview of experiment settings. The dataset and model architecture selections are partly following Orekondy et al. [36].

Defender	Training Dataset X_t	Caltech256	CUB200	CIFAR100	CIFAR10
	OE Dataset X_{OE}	Indoor67	Indoor67	SVHN	SVHN
	Target Model $\boldsymbol{w}_t$	ResNet50	ResNet50	VGG16-BN	VGG16-BN
	Top-1 Accuracy of $\boldsymbol{w}_t$	85.67%	82.19%	75.11%	93.70%
Attacker	Query Dataset X_q	ImageNet1k	ImageNet1k	TinyImageNet200	TinyImageNet200
	Substitute Model $\boldsymbol{w}_s$	ResNet50	ResNet50	VGG16-BN	VGG16-BN

6. D-DAE+: D-DAE+ amends the original D-DAE method by using the lookup table generated for Partial Bayes Attack as the training data of the generative model.

7. Partial Bayes (pBayes) Attack: The independent sampling and the neighborhood sampling are used to establish the Bayes estimator as we proposed in Section 3.4.

Defense methods We evaluate the following defense methods in our experiments:

1. No defense (None): No perturbation is added to the prediction, and the clean prediction is always returned to the user.

2. Reverse Sigmoid Defense (RevSig) [28]: A reverse sigmoid function is used to perturb the clean prediction to attain large CE loss $\mathcal{L}_{\text{CE}}(Y_q, \hat{Y}_q)$.

3. Maximizing Angular Deviation (MAD) [36]: The perturbation is obtained by maximizing the angular deviation between the gradient of the CE loss calculated with clean predictions Y_q and the gradient of the CE loss calculated with perturbed predictions $\hat{Y}_q$.

4. Adaptive Misinformation (AM) [24]: An out-of-distribution (OOD) detection mechanism is combined with the prediction perturbation, and only the prediction of an OOD query data is perturbed to a wrong prediction generated from another misinformation function $\hat{f}_s$.

5. Top-1 Defense (Top-1): Only the hard top-1 label is returned to the user. Top-1 Defense can be viewed as a static quantization method that quantizes all the predictions with the same top-1 label to one centroid. Thus, Top-1 defense may introduce large distortions in the perturbed predictions with too few centroids.

6. Rounding Defense (Rounding): Only one decimal place is kept in each dimension of the prediction vector. Rounding defense can be viewed as another static quantization method that quantizes each dimension of the prediction independently. For example, $\boldsymbol{y} = [0.12, 0.31, 0.26, 0.31]$ is quantized as $\hat{\boldsymbol{y}} = [0.1, 0.3, 0.3, 0.3]$.

7. MODELGUARD-W: The perturbations are calculated by solving Equation (9) as introduced in Section 3.3.

8. MODELGUARD-S: The predictions are quantized as introduced in Section 3.5.

We provide more details of the above-mentioned attack and defense methods, as well as the model training hyperparameters in Appendix B.

4.2 Experimental Results

In this section, we conduct two groups of experiments. In the first group, we evaluate the performance of each defense method under fixed utility constraints to show that our method outperforms other baselines under the same utility constraint. In the second group, we show the privacy-utility trade-off of different defense methods with different distortion budgets, and we will see that our method attains a better balance between the defensive performance and the model utility compared with other methods.

Defensive performance with fixed utility constraints We first evaluate all the defenses under fixed utility constraints that keep ℓ_1 distortion not more than 1.0 and top-1 accuracy not changed. More specifically, we fix $\varepsilon = 1.0$ for MAD, MODELGUARD-W, and MODELGUARD-S, and we fix $\gamma = 0.2$ and β (0.008, 0.011, 0.02, 0.21 for Caltech256, CUB200, CIFAR100, and CIFAR10 respectively) for RevSig to make the maximal distortion (i.e., the largest distortion imposed by each defense in all perturbed predictions $\hat{\boldsymbol{y}}_{q,i} \in \hat{Y}_q$) at around 1.0 [4]. For AM, we fix τ (0.25, 0.3, 0.4, 0.7 for Caltech256, CUB200, CIFAR100, and CIFAR10 respectively) such that the protected accuracy (i.e., the accuracy of the target model $\boldsymbol{w}_t$ on the test set when adding perturbations to the predictions) does not drop significantly.

The attack and defense results on target models trained on Caltech256, CUB200, CIFAR100 and CIFAR10 are reported in Table 2, Table 3, Table 4 and Table 5 respectively. Each row reports the extraction accuracy of the substitute model using the specific attack method against the specific defense method given in each column. We report the maximal extraction accuracy and fidelity among all the attacks against each defense since we hope to verify each defense against the strongest attack. We also report the maximal ℓ_1 distortion and the protected accuracy as the measurements of utility loss.

[4] We are not able to control the distortion of AM, Top-1 and Rounding Defense, thus we report their vanilla ℓ_1 distortions.

Table 2: Defensive performance of different defense methods against different attacks on the target model trained on Caltech256.

Query Method	Attack Method	None	RevSig	MAD	AM	Top-1	Rounding	MODELGUARD-W	MODELGUARD-S

Protected Accuracy of $\boldsymbol{w}_t$		82.19%	82.19%	82.19%	81.22%	82.19%	82.19%	82.19%	82.19%

pBayes Attack outperforms other attacks Since we hope to verify our defense against the strongest adaptive attack, we first compare the results of different attacks. Among all the attacks, we can see that KnockoffNet + pBayes Attack attains the highest extraction accuracy in most cases. Previous studies have shown that when attacking against prediction perturbation defenses, model extraction attacks with natural data attain better results than attacks with synthetic data [8, 36]. And the superiority of pBayes Attack aligns with our analysis in Section 3.4 that pBayes Attack utilizes the Bayes estimator which can minimize the squared posterior expected loss. Some exceptions where pBayes Attack is not the best attack method could be attributed to the imperfect lookup table. Since we do not have the infinite computing power to generate the complete lookup table, a finite number of (perturbed predictions, clean predictions) pairs in the lookup table may introduce bias into the derived Bayes estimator.

MODELGUARD outperforms existing defenses When defending against the strongest attack, Top-1 Defense and MODELGUARD-S with strong prediction quantization always attain lower maximal extraction accuracy than the other defenses. While pBayes Attack can penetrate the other defenses and achieve a comparable extraction accuracy as attacking against no defense, none of the attacks can weaken the defensive performance of Top-1 Defense or MODELGUARD-S to attain a significantly higher extraction accuracy than Naive Attack. This result is consistent with our analysis in Section 3.5 that no attacker can exactly recover the clean predictions from the quantized predictions because the quantization is not invertible. While Top-1 Defense achieves a little lower extraction accuracy compared with MODELGUARD-S in some cases, it introduces a much larger ℓ_1 distortion that exceeds the distortion constraint. Thus, MODELGUARD-S should be chosen among all defenses we discuss since it is the strongest defense against strong adaptive attacks under utility constraints.

Although Rounding Defense also contains prediction quantization in its perturbation mechanism, it fails to achieve strong defensive performance because of static quantization. Namely, Rounding Defense introduces too many centroids

and fails to reduce the mutual information $I(Y_q;\hat{Y}_q)$.

We notice that when defending the target model trained on CIFAR10, there is only a small difference between different defense methods against strong adaptive attacks. Because of the small number of classes, the attacker can easily extract the target model even with only the hard label (i.e., Top-1 Attack). As a result, no defense method can defend against the model extraction attack effectively under the top-1 accuracy preserving constraint. In our result, MODELGUARD-S attains the best defensive performance with the lowest maximal extraction accuracy and fidelity among all defenses, which verifies the effectiveness of MODELGUARD-S in this extreme case.

MODELGUARD-W vs. MODELGUARD-S When defending against Naive Attack, Smoothing Attack and S4L Attack, MODELGUARD-W attains the lowest extraction accuracy while satisfying both top-1 accuracy preserving constraint and distortion constraint. However, adaptive attacks with strong prediction recovery mechanisms, e.g., D-DAE+ and pBayes Attack, can significantly weaken the defensive performance of MODELGUARD-W. We can see that pBayes Attack can penetrate MODELGUARD-W and achieve a comparable extraction accuracy as attacking against no defense. This is because D-DAE+ and pBayes Attack significantly deviate from the assumption of MODELGUARD-W that the attack is nearly non-adaptive, i.e., $\tilde{Y}_q \approx \hat{Y}_q$. In contrast, MODELGUARD-S considers the strongest adaptive attack that can lead to the worst defensive performance, thus no attacks including D-DAE+ and pBayes Attack can attain significantly higher extraction accuracy than Naive Attack against MODELGUARD-S. Since strong attacks should be considered by the defender, MODELGUARD-S should be chosen among the two variants.

Impact of the distortion budget To evaluate the privacy-utility balance of different defenses, we now change the distortion budget in a range of $[0,2.0]$, which covers all possible ℓ_1 distortion values under the validity constraint. We set $\varepsilon \in \{0.25,0.5,0.75,1.0,1.25,1.5,1.75,2.0\}$ for MAD, MODELGUARD-W and MODELGUARD-S, and we vary $\beta \in [0,1.0]$ with fixed $\beta = 0.2$ for RevSig to allow different distortions.

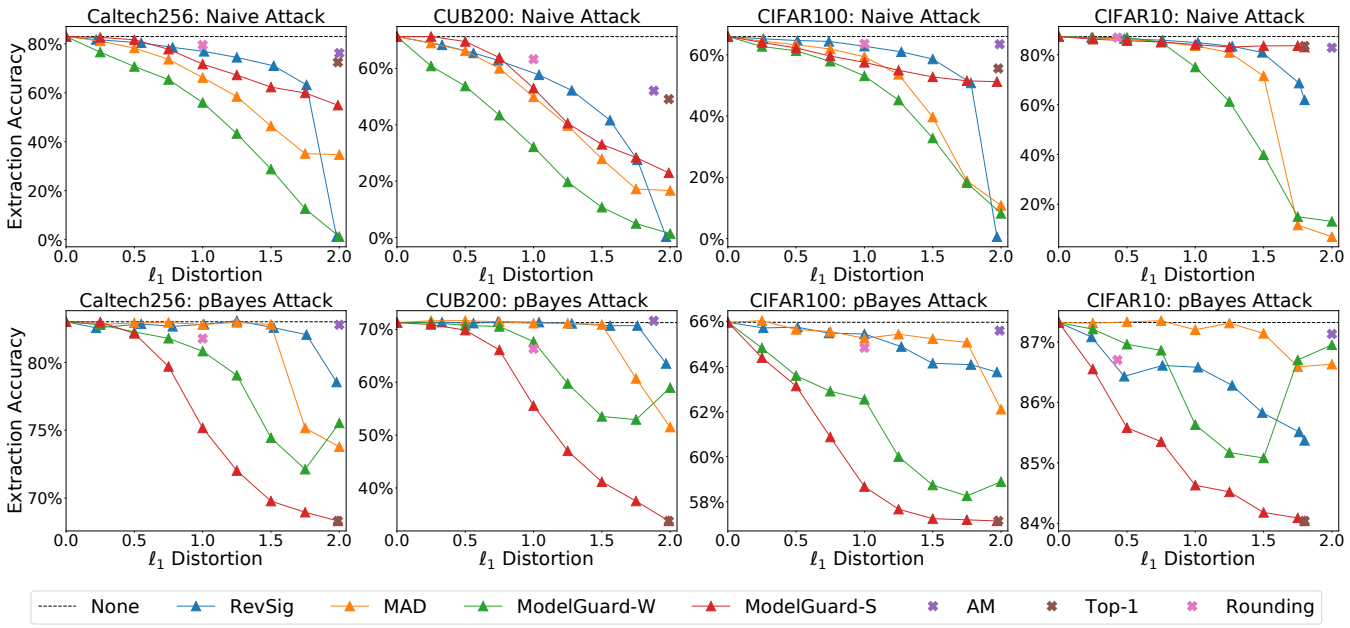

Figure 3: The extraction accuracy of Naive Attack (upper) and Partial Bayes Attack (lower) against defenses with different ℓ_1 distortion budgets for the perturbation.

We show the extraction accuracy of Naive Attack and pBayes Attack against each defense in Figure 3.

As shown in the upper four figures, MODELGUARD-W can attain the lowest extraction accuracy given different ℓ_1 distortion budgets when defending against Naive Attack in most cases. MAD and RevSig can attain similar results with MODELGUARD-W only when the distortion budget is very large (e.g., 2.0). The superiority of MODELGUARD-W against Naive Attack is guaranteed by the optimality of Linear Programming when solving Equation (9), while previous methods are not able to guarantee the optimal defensive performance because of heuristic perturbation mechanisms.

Although MODELGUARD-S does not attain a strong defense against Naive Attack because MODELGUARD-S is maximizing the pessimistic lower bound of the objective function in Equation (3), it shows excellent resistance to pBayes Attack which utilizes a strong prediction recovery. MODELGUARD-S consistently attains the lowest extraction accuracy among all the defenses under any distortion budget, and other defenses fail to defend against pBayes Attack until a large distortion budget (e.g., larger than 1.5). While Top-1 Defense lacks flexibility, MODELGUARD-S can easily adapt to different distortion budgets and attain the best privacy-utility trade-off.

We notice that there are some fluctuations in the extraction accuracy of pBayes Attack when attacking against some defenses, which makes the extraction accuracy not monotonically decrease w.r.t the increase of the distortion budget. This is because the lookup table we use in pBayes Attack is randomly sampled, which inevitably introduces some variance in the recovery.

4.3 Ablation Studies

How does conditional entropy influence defensive performance? Since the conditional entropy $h(Y_a|\hat{Y}_a)$ generally decreases with the increasing number of centroids used for quantization, we plot how the extraction accuracy and the mean recovery distance $\mathbb{E}\|\tilde{\mathbf{y}}_q - \mathbf{y}_q\|_2$ of pBayes Attack change with respect to the number of centroids. We can see in Figure 4 that with more centroids used in quantization, i.e., smaller conditional entropy, the extraction accuracy increases while the recovery distance decreases. This result aligns with our theory that the adaptive attack can recover the prediction more precisely and attain higher extraction accuracy when the conditional entropy is smaller.

How may a non-ordered incremental prediction quantization leak information? As we discussed in Section 3.5, an online quantization that does not output consistent results given the same clean prediction may leak information to the attacker. We now show how this information leakage can happen in practice. We consider a simple attack strategy called m Queries Per Image (m-QPI), where the attacker repeats querying the target model with the same query dataset for m times and use the average of the query results as $\tilde{Y}_q$ to train the substitute model. For example, in 1-QPI, the attacker conducts only one query through the whole query dataset, which is the same as Naive Attack. In 2-QPI, the attacker conducts the second query after querying through the whole query dataset for the first time, and then the attacker averages the query results of the first query and the second query.

We consider the non-ordered incremental quantization that

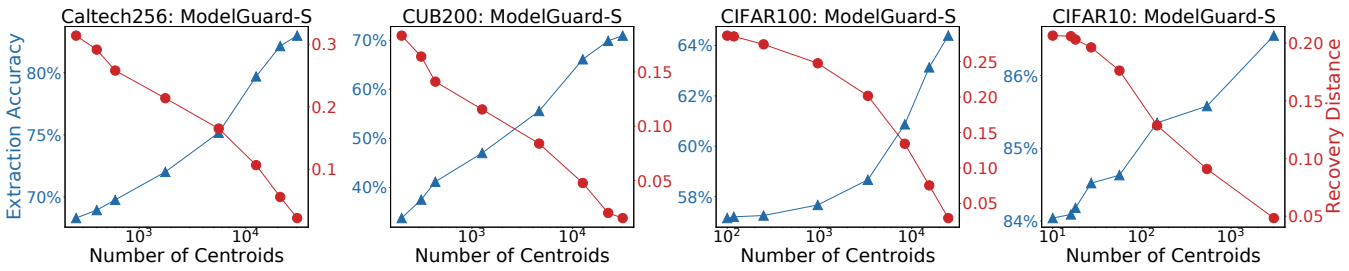

Figure 4: The extraction accuracy (blue line) and the mean recovery distance (red line) of Partial Bayes Attack against MODELGUARD-S with different numbers of centroids.

Table 6: The mean recovery distance of 1-QPI (1st column) and 2-QPI (2nd column) on the changed predictions. The 3rd column gives the number of predictions changed in the second query of 2-QPI.

X_t	1-QPI	2-QPI	Changed Predictions
Caltech256	0.300	0.193	2335
CUB200	0.205	0.142	2443
CIFAR100	0.372	0.239	2071
CIFAR10	0.463	0.252	393

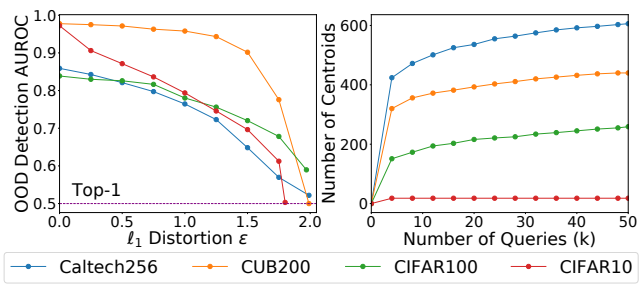

Figure 5: Left: AUROC of the OOD detector given predictions perturbed by MODELGUARD-S with different ℓ_1 distortion budgets ε. Right: Number of centroids created by MODELGUARD-S along the query procedure.

always quantizes the clean prediction to the closest centroid. In Table 6, we report how many quantization results among total $50,000$ queries are changed in the second query of 2-QPI, together with the mean recovery distance $\mathbb{E}\|\tilde{\mathbf{y}}_q - \mathbf{y}_q\|_2$ of 1-QPI and 2-QPI on these changed predictions. We can see that the recovery distance can be significantly decreased by 2-QPI, which verifies that the non-consistent quantization results in a non-ordered incremental quantization may cause information leakage to the attacker.

We do not report the extraction accuracy here because the proportion of changed quantization results is too small (less than 5%) to cause a significant extraction accuracy change in our experiments. However, there still exists a potential risk of more significant information leakage in a larger system by using a non-ordered quantization. MODELGUARD-S with ordered quantization can completely eliminate such potential risk with consistent quantization results.

How does MODELGUARD influence the utility in the downstream task? While ℓ_1 distortion in the prediction is a generic metric for measuring the utility loss of the perturbation, a specific utility metric may be considered for a specific downstream task when determining the distortion budget ε used by MODELGUARD. We consider a specific downstream task, out-of-distribution (OOD) detection, and we show how the ℓ_1 distortion influences the AUROC of the OOD detector in Figure 5. Following [19], we use the Maximum Softmax Probability $\max_k y^{(k)}$ as the in-distribution (ID) score. We use X_t as the ID set, and we use DTD [9] as the OOD set for Caltech256 and CUB200, while GTSRB [20] for CIFAR100 and CIFAR10. We can see that MODELGUARD-S can maintain a good detection performance (AUROC ≥ 0.8) with $\varepsilon \leq 0.75$, while the detection performance is still acceptable (AUROC ≥ 0.7 is acceptable according to [18]) until $\varepsilon = 1.5$ in most cases. Notice that Top-1 Defense always has AUROC $= 0.5$ because it only returns one-hot vectors for both ID and OOD queries.

How does the independent sampling influence the performance of Partial Bayes Attack against MODELGUARD? Since MODELGUARD-S utilizes dynamic quantization, the perturbation result depends on the historical queries that increase the number of centroids. However, we observe that MODELGUARD-S will behave like a static quantization method with almost invariant centroids after a short "warm-up" phase. Figure 5 shows the number of centroids used in MODELGUARD-S with $\varepsilon = 1.5$, and we can see that the centroids increase slowly after the first $4,000$ queries. This makes Partial Bayes Attack with independent sampling in Equation (13) attain similar performance with the perfect Bayes Attack that samples the whole prediction sequence in Equation (12) against MODELGUARD-S, while avoiding huge sampling cost for sampling in a high dimension.

How efficient is MODELGUARD? Since the real-time nature of an MLaaS system is usually important in many scenarios, the computational overhead introduced by the defense mechanism should be as little as possible. We compare the response time for returning the prediction of a single query to the user with different defenses in Figure 6. Among all de-

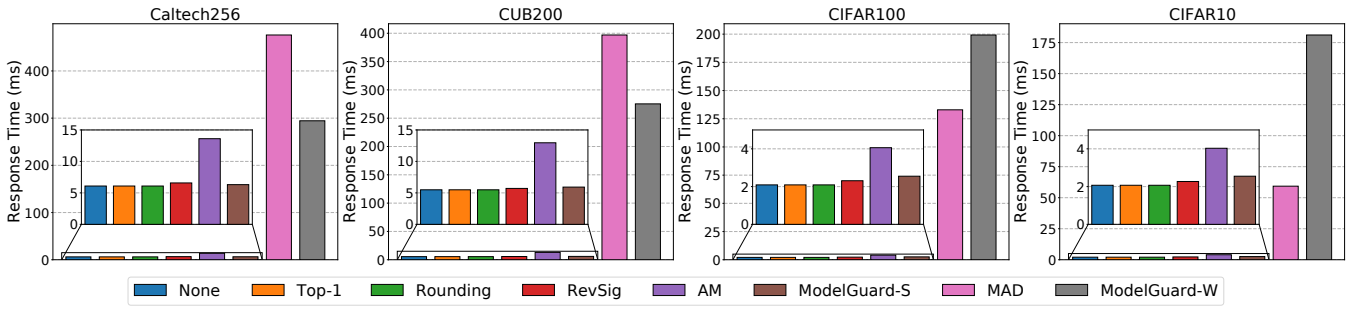

Figure 6: Response time of different defenses.

fenses, only MAD and MODELGUARD-W introduce a significant computational overhead when perturbing the prediction. MODELGUARD-S requires only marginal extra computation compared with None Defense since we only need to calculate the distance between the incoming clean prediction and the existing centroids when quantizing each prediction. Moreover, MODELGUARD-S only needs a small extra memory to store the quantization centroids. To summarize, MODELGUARD-S attains both high computation and memory efficiency.

5 Related Works

Model extraction attacks Machine Learning (ML) systems have been shown to be vulnerable to various kinds of attacks, such as evasion attacks [14], data poisoning attacks [3], backdoor attacks [16] and so on. In this paper, we focus on a specific attack called model extraction attack that aims at compromising the confidentiality of ML models. Model extraction attack aims at stealing the parameters or functionality of the target model deployed in the ML-as-a-Service (MLaaS) system such that the attacker can retain access to the service without paying [43]. Furthermore, the extracted substitute model can expose the vulnerability of the target model to the attacker such that the attacker can conduct powerful downstream attacks on the target model, such as white-box model evasion attacks [38], hyperparameter stealing attacks [46], and model inversion attacks [41]. Model extraction attacks can be conducted in different ways, e.g., via the power side channel [2] or via the query interactions [34], while we focus on query-based model extraction attacks in this paper.

Previous studies have shown that the attacker can use a small number of queries to attain high-fidelity model extraction, with either natural data [10,35] or synthetic data [23,44]. In addition, active learning [7] and semi-supervised learning [21] can also be applied in model extraction attacks to further improve query efficiency and attain higher extracted accuracy, which makes these attacks even more practical and threatening in realistic settings.

Recently, as more defenses against the model extraction attack have been proposed, adaptive model extraction attacks that can penetrate the defenses are getting more attention. Lee et al. [28] explore using a DNN model to recover the clean predictions given perturbed predictions from the target defended by a known defense mechanism. Chen et al. [8] complement this idea with a defense detector so that the attacker can detect an unknown defense and recover the clean predictions accordingly. In this work, we additionally propose a strong adaptive model extraction attack method based on the Bayesian estimator. We evaluate MODELGUARD and show its resistance against these adaptive attacks.

Defenses against model extraction attacks A wealth of works strive to defend the target against model extraction attacks and many different defense methods have been proposed. There are mainly four types of defenses:

(a) **Model extraction detection** detects the model extraction attacker based on the assumption that the query data from the attacker is distributed differently from the benign users [23,37]. Such detection can be bypassed by using query data that is similar to the data of benign users, e.g., natural data from a domain similar to the task domain of the target.

(b) **Model information monitoring** monitors the information of the model exposed to each user such that the system can reject to respond [25], add more noise in the response [47], or increase the query cost [13], for a user that may obtain too much information for model extraction. This kind of defense cannot defend against collaborative attacks, where each individual attacker queries the system with only a small amount of data, and all the attackers share the query results to collaboratively train a single substitute model.

(c) **Model watermarking** forces the target model to learn a specific input-output pair (i.e., watermark), such that the attacker cannot remove this "backdoor" when extracting the model, and the owner can claim the ownership with this non-removable watermark [1,4,6,22]. Model watermarking cannot prevent "stealth attackers" who only use the substitute model in private or for subsequent attacks.

(d) **Prediction perturbation** perturbs the prediction returned to the user to enlarge the loss [24,28] or change the gradient direction [30,36] calculated with the perturbed prediction, such that the attacker cannot extract the target correctly. Although prediction perturbation makes the least assumptions about the attacker, previous perturbation methods either achieve marginal defensive performance or impose a large

utility loss because of heuristic perturbation mechanisms. In addition, there is little discussion about the prediction perturbation against adaptive attacks. In this work, we try to develop a novel prediction perturbation framework, MODELGUARD, to attain a better privacy-utility trade-off. MODELGUARD also provides the first information-theoretic prediction perturbation defense against adaptive model extraction attacks.

6 Conclusion, Limitations, and Future Work

In this paper, we propose MODELGUARD, a novel prediction perturbation defense against adaptive model extraction attacks. MODELGUARD investigates a general optimization problem that aims at defending against different kinds of model extraction attacks while maintaining a high utility of the protected system. We explore two different variants, MODELGUARD-W and MODELGUARD-S, to efficiently solve the optimization problem. Especially, MODELGUARD-S utilizes an information-theoretic method that can defend against the adaptive attack with the optimal prediction recovery. Our experimental results show that MODELGUARD-S attains a significantly better defensive performance than other baselines against adaptive attacks while maintaining a high utility.

Although MODELGUARD-S is theoretically resistant to the perfect Bayes Attack, because of our limited computing power, we are not able to evaluate the defensive performance of MODELGUARD-S against the perfect Bayes Attack with a complete lookup table. Our proposed Partial Bayes Attack samples a partial lookup table from the complete lookup table, which may cause a biased Bayes estimator and a suboptimal attack performance. It is a meaningful future work to derive a better estimation method for the perfect Bayes Attack.

Another important future direction is extending the defenses against model extraction attacks to domains beyond classification. While we only evaluate our defenses on image classification tasks following previous works [24, 36], our theory and methodology can adapt to different tasks by modifying the utility and validity constraints, as well as the loss function $\mathcal{L}$ in the objective function.

A Proofs

A.1 Proof of Lemma 1

Lemma 1. *Assuming that $L(X_q, Y_q; \boldsymbol{w}) = \mathcal{L}(f_t(X_q; \boldsymbol{w}); Y_q)$ is M-smooth in $\boldsymbol{w}$. Given two models $\boldsymbol{w}_t$ and $\tilde{\boldsymbol{w}}_s^*$ with the same architecture such that $f_t(X_q; \boldsymbol{w}_t) = Y_q$ and $f_s(X_q; \tilde{\boldsymbol{w}}_s^*) = \tilde{Y}_q$, we have:*

$$\|\tilde{\boldsymbol{w}}_s^* - \boldsymbol{w}_t\|_2^2 \geq \frac{2}{M}\left[\mathcal{L}(\tilde{Y}_q, Y_q) - \mathcal{L}(Y_q, Y_q)\right].$$

Proof. With the M-smoothness of $L(X_q, Y_q; \boldsymbol{w})$ and the fact that $\nabla L(X_q, Y_q; \boldsymbol{w}_t) = 0$, we have

$$\begin{aligned}\|\tilde{\boldsymbol{w}}_s^* - \boldsymbol{w}_t\|_2^2 &\geq \frac{2}{M}\left[L(X_q, Y_q; \tilde{\boldsymbol{w}}_s^*) - L(X_q, Y_q; \boldsymbol{w}_t)\right] \\ &= \frac{2}{M}\left[\mathcal{L}(\tilde{Y}_q, Y_q) - \mathcal{L}(Y_q, Y_q)\right],\end{aligned}$$

where the last equation comes from the definition that $f_t(X_q; \boldsymbol{w}_t) = Y_q$ and $f_t(X_q; \tilde{\boldsymbol{w}}_s^*) = f_s(X_q; \tilde{\boldsymbol{w}}_s^*) = \tilde{Y}_q$ since f_t and f_s has the same architecture. □

Remark 4. The smoothness assumption provides the relationship between the model parameters $\boldsymbol{w}$ and the loss L such that we can unify the parameter-stealing attack and the functionality-stealing attack in one framework. However, MODELGUARD is still an effective defense against the functionality-stealing attack without the assumption, as justified by our experiments on neural networks that may not satisfy the smoothness assumption.

A.2 Theoretical Justification of Approximating Equation (8) with Equation (9)

We will show that the solution $\hat{\boldsymbol{y}}$ of Equation (9) has a low confidence score $\hat{\boldsymbol{y}}^{(k)}$ at the class with large $\boldsymbol{y}^{(k)}$, which leads to a small objective value in Equation (8). To make the solution interpretable, we analyze the optimization problem given in Equation (9) with a distortion relaxation (i.e., $\varepsilon = 2.0$). Without loss of generality, we consider $y^{(1)} = \max_k y^{(k)}$.

$$\begin{aligned}\min_{\hat{\boldsymbol{y}}} \quad & \sum_{k=1}^{C} \hat{y}^{(k)} \log y^{(k)} \\ \text{subject to} \quad & \hat{y}^{(1)} \geq y^{(j)}, j = 2, 3, \cdots, C \\ & \sum_{k=1}^{C} \hat{y}^{(k)} = 1, \text{ and } \hat{\boldsymbol{y}} \succeq 0.\end{aligned}$$

The Lagrangian of this problem is given by:

$$\begin{aligned}&L(\hat{\boldsymbol{y}}, \mu_1, \cdots, \mu_C, \nu_2, \cdots, \nu_C, \lambda) = \\ &\sum_{k=1}^{C} (\log y^{(k)} - \mu_k + \lambda)\hat{y}^{(k)} - \sum_{j=2}^{C} \nu_j (\hat{y}^{(1)} - \hat{y}^{(j)}) - \lambda.\end{aligned}$$

The Karush-Kuhn-Tucker (KKT) condition for the optimal solution $(\hat{\boldsymbol{y}}, \mu_1, \cdots, \mu_C, \nu_2, \cdots, \nu_C, \lambda)$ of this problem is

$$\begin{cases}\hat{y}^{(1)} \geq \hat{y}^{(j)}, j = 2, \cdots, C; \sum_{k=1}^{C} \hat{y}^{(k)} = 1, \text{ and } \hat{\boldsymbol{y}} \succeq 0; \\ \mu_k \geq 0, k = 1, 2, \cdots, C; \nu_j \geq 0, j = 2, \cdots, C; \\ \partial L / \partial \hat{y}^{(1)} = \log y^{(1)} - \mu_1 + \lambda - \sum_{j=2}^{C} \nu_j = 0; \\ \partial L / \partial \hat{y}^{(j)} = \log y^{(j)} - \mu_j + \lambda + \nu_j = 0, j = 2, \cdots, C; \\ \mu_k \hat{y}^{(k)} = 0, k = 1, \cdots, C; \nu_j (\hat{y}^{(1)} - \hat{y}^{(j)}) = 0, j = 2, \cdots, C.\end{cases}$$

We first assume that $\nu_j = 0$, we get from the fourth condition:

$$\nu_j = 0 \Rightarrow \mu_j = \lambda + \log y^{(j)} \geq 0 \Rightarrow \lambda \geq -\log y^{(j)}.$$

Equivalently, with the last condition and the fact that $\hat{y}^{(1)} = \max_k \hat{y}^{(k)} > 0$, we have

$$\lambda < -\log y^{(j)} \Rightarrow \nu_j > 0 \Rightarrow \hat{y}^{(j)} = \hat{y}^{(1)} > 0.$$

On the other hand, if $\lambda > -\log y^{(j)}$, we know that

$$\lambda > -\log y^{(j)} \Rightarrow \mu_j - \nu_j = \lambda + \log y^{(j)} > 0 \Rightarrow \mu_j > \nu_j \geq 0,$$

which means that $\hat{y}^{(j)} = 0$ according to the last condition.

In the last case $\lambda = -\log y^{(j)}$, we have $\mu_j = \nu_j$. If $\mu_j = \nu_j > 0$, we have $\hat{y}^{(1)} = \hat{y}^{(j)} = 0$, which is impossible. Thus we have $\mu_j = \nu_j = 0$ and $0 \leq \hat{y}^{(j)} \leq \hat{y}^{(1)}$. In conclusion, for $j = 2, \cdots, C$, we have

$$\begin{cases}y^{(j)} < e^{-\lambda} \Rightarrow \hat{y}^{(j)} = \hat{y}^{(1)}; \\ y^{(j)} = e^{-\lambda} \Rightarrow 0 \leq \hat{y}^{(j)} \leq \hat{y}^{(1)}; \\ y^{(j)} > e^{-\lambda} \Rightarrow \hat{y}^{(j)} = 0.\end{cases}$$

This result shows that except for the top-1 class, all classes with $y^{(k)}$ larger than the threshold $e^{-\lambda}$ will be reduced to 0 in the solution $\hat{\boldsymbol{y}}$.

A.3 Proof of Lemma 2

Lemma 2. *Given a prediction perturbation mechanism p such that $\hat{Y}_q = p(Y_q)$, an adaptive model extraction attack with an arbitrary recovery function r cannot attain a smaller gap between recovered predictions $\tilde{Y} = r(\hat{Y}_q) = r(p(Y_q))$ and clean predictions Y_q than the following lower bound:*

$$\mathbb{E}\left[\|\tilde{Y}_q - Y_q\|_2^2\right] \geq \frac{NC}{2\pi e} \exp\left(\frac{2}{NC} h(Y_q | \hat{Y}_q)\right),$$

where $h(Y_q|\hat{Y}_q)$ is the conditional entropy. Subsequently,

$$\mathbb{E}\left[\mathcal{L}(\tilde{Y}_q, Y_q) - \mathcal{L}(Y_q, Y_q)\right] \geq \frac{Cl}{2\pi e} \exp\left(\frac{2}{NC} h(Y_q | \hat{Y}_q)\right),$$

where l is a constant related to the loss function $\mathcal{L}$, e.g., $l = 0.5$ for CE loss and $l = 1$ for MSE loss.

Proof. The following inequality holds for Y_q with an arbitrary distribution conditioned on the event $\{\hat{Y}_q = \hat{Y}\}$ [11]:

$$h(Y_q|\hat{Y}_q=\hat{Y}) \le \frac{1}{2}\log\left((2\pi e)^{NC}\det(\mathrm{Cov}(Y_q|\hat{Y}_q=\hat{Y}))\right)$$
$$\Rightarrow \det\left(\mathrm{Cov}(Y_q|\hat{Y}_q=\hat{Y})\right) \ge \frac{1}{(2\pi e)^{NC}}\exp\left(2h(Y_q|\hat{Y}_q=\hat{Y})\right),$$

where the equality holds with Gaussian $Y_q|\{\hat{Y}_q=\hat{Y}\}$. Now we consider an arbitrary recovery function r such that $\tilde{Y}_q = r(\hat{Y}_q)$. With the fact that the Bayesian estimator $\tilde{Y}_q^* = r^*(\hat{Y}_q) = \mathbb{E}[Y_q|\hat{Y}_q]$ minimizes $\mathbb{E}\left[\|\tilde{Y}_q - Y_q\|_2^2|\hat{Y}_q\right]$, we get:

$$\begin{aligned}
&\mathbb{E}\left[\|\tilde{Y}_q - Y_q\|_2^2|\hat{Y}_q=\hat{Y}\right] \ge \mathbb{E}\left[\|Y_q - \mathbb{E}[Y_q|\hat{Y}_q=\hat{Y}]\|_2^2|\hat{Y}_q=\hat{Y}\right]\\
=&\mathrm{tr}\left(\mathbb{E}\left[(Y_q-\mathbb{E}[Y_q|\hat{Y}_q=\hat{Y}])(Y_q-\mathbb{E}[Y_q|\hat{Y}_q=\hat{Y}])^T|\hat{Y}_q=\hat{Y}\right]\right)\\
=&\mathrm{tr}\left(\mathrm{Cov}(Y_q|\hat{Y}_q=\hat{Y})\right)\\
\ge& NC\left[\det\left(\mathrm{Cov}(Y_q|\hat{Y}_q=\hat{Y})\right)\right]^{1/NC} \qquad (19)\\
\ge&\frac{NC}{2\pi e}\exp\left(\frac{2}{NC}h(Y_q|\hat{Y}_q=\hat{Y})\right).
\end{aligned}$$

Inequality (19) uses the inequality of arithmetic and geometric means: $\forall \boldsymbol{A} \in \mathbb{S}_{++}^{n\times n}$,

$$\mathrm{tr}(\boldsymbol{A}) = \sum_i \lambda_i(\boldsymbol{A}) \ge n(\prod_i \lambda_i(\boldsymbol{A}))^{1/n} = n\left[\det(\boldsymbol{A})\right]^{1/n},$$

where $\lambda_i(\boldsymbol{A})$ is the i-th eigenvalue of $\boldsymbol{A}$. Taking expectation over $\hat{Y}_q$ at both sides yields the first part of the lemma with Jensen's Inequality.

Now we prove the second part of this lemma. For MSE loss, we notice that

$$\mathcal{L}_{\mathrm{MSE}}(\tilde{Y}_q, Y_q) = \frac{1}{N}\sum_{i=1}^{N}\|\tilde{\boldsymbol{y}}_{q,i} - \boldsymbol{y}_{q,i}\|_2^2 = \frac{1}{N}\|\tilde{Y}_q - Y_q\|_2^2$$

and $\mathcal{L}_{\mathrm{MSE}}(Y_q, Y_q) = 0$, thus we get $l = 1$ immediately.

For CE loss, We have

$$\mathcal{L}_{\mathrm{CE}}(\tilde{Y}_q, Y_q) - \mathcal{L}_{\mathrm{CE}}(Y_q, Y_q) = \frac{1}{N}\sum_{i=1}^{N} D_{\mathrm{KL}}(\boldsymbol{y}_{q,i}||\tilde{\boldsymbol{y}}_{q,i}).$$

$D_{\mathrm{KL}}(\boldsymbol{p}||\boldsymbol{q})$ is 1-strongly convex because

$$H_{\boldsymbol{p}} = \nabla_p^2 D_{\mathrm{KL}}(\boldsymbol{p}||\boldsymbol{q}) = \mathrm{diag}([1/p^{(1)}, 1/p^{(2)}, \cdots, 1/p^{(C)}]),$$

and $1/p^{(k)} \ge 1$ given $p^{(k)} \in [0,1]$. With $D_{\mathrm{KL}}(\boldsymbol{q}||\boldsymbol{q}) = 0$,

$$\begin{aligned}
D_{\mathrm{KL}}(\boldsymbol{p}||\boldsymbol{q}) &= D_{\mathrm{KL}}(\boldsymbol{p}||\boldsymbol{q}) - D_{\mathrm{KL}}(\boldsymbol{q}||\boldsymbol{q})\\
&\ge \left(\nabla_{\boldsymbol{p}} D_{\mathrm{KL}}(\boldsymbol{p}||\boldsymbol{q})\big|_{\boldsymbol{p}=\boldsymbol{q}}\right)^T(\boldsymbol{p}-\boldsymbol{q}) + \frac{1}{2}\|\boldsymbol{p}-\boldsymbol{q}\|_2^2\\
&= \sum_{k=1}^{C}(p^{(k)} - q^{(k)}) + \frac{1}{2}\|\boldsymbol{p}-\boldsymbol{q}\|_2^2 \qquad (20)\\
&= \frac{1}{2}\|\boldsymbol{p}-\boldsymbol{q}\|_2^2,
\end{aligned}$$

where Equation (20) uses the result that $\nabla_{\boldsymbol{p}} D_{\mathrm{KL}}(\boldsymbol{p}||\boldsymbol{q})\big|_{\boldsymbol{p}=\boldsymbol{q}} = [1,1,\cdots,1]$. Accordingly, we will get

$$\mathcal{L}_{\mathrm{CE}}(\tilde{Y}_q, Y_q) - \mathcal{L}_{\mathrm{CE}}(Y_q, Y_q) \ge \frac{1}{2N}\|\tilde{Y}_q - Y_q\|_2^2,$$

and $l = \frac{1}{2}$ for CE loss. □

B Experiment Details

Our experiments are conducted on a server with one NVIDIA TITAN RTX GPU and one Intel Xeon Gold 6254 CPU.

B.1 Attack Methods

Query Strategies We consider two query strategies:

KnockoffNet [35]: Following Orekondy et al. [36], we consider the KnockoffNet with a random strategy. The attacker randomly selects unlabeled natural data X_q to query the target model and obtain the predictions $\hat{Y}_q$. $(X_q, \hat{Y}_q)$ then is used for training a substitute model with an attack strategy.

JBDA-TR [23]: JBDA-TR starts from a small query dataset (with 1,000 natural images in our setting) and repeatedly conducts two steps: (a) querying the target model and training a substitute model with the current query dataset; (b) augmenting the query dataset with a randomly targeted iterative Fast Gradient Sign Method (I-FGSM) [14, 27]:

$$X_{q,t} = X_{q,t-1} + \alpha\mathrm{sign}(\nabla f_s(X_{q,t-1}, Y_{q,t})), \quad t = 1,2,\cdots,T$$

where α is the step size and T is the number of iterations in I-FGSM. $Y_{q,t}$ is randomly selected targeted labels in each iteration. The augmentation stops when the size of the query dataset reaches the targeted size ().

Attack Strategies Details of some attack strategies:

S4L Attack [21]: S4L Attack appends a self-supervised rotation loss to the CE loss, as given by:

$$\begin{aligned}
L_{\mathrm{S4L}}(X_q, \hat{Y}_q) =& \frac{1}{|X_q|}\sum_{\boldsymbol{x}_q \in X_q}\mathcal{L}_{\mathrm{CE}}(f_s(\boldsymbol{x}_q;\boldsymbol{w}_s), \hat{\boldsymbol{y}}_q)\\
&+ \frac{1}{4|X_q|}\sum_{\boldsymbol{x}_q \in X_q}\sum_{j=0}^{3}\mathcal{L}_{\mathrm{CE}}(f_r(R_j(\boldsymbol{x}_q);\theta_s), j),
\end{aligned}$$

where $R_j(\boldsymbol{x})$ rotates $\boldsymbol{x}$ by $j \times 90°$. $f_r(\cdot;\theta_s)$ shares the model with $f_s(\cdot;\boldsymbol{w}_s)$ except for the last layer.

Smoothing Attack [29]: Following Lukas et al. [29], we use random cropping and random horizontal flipping to generate $n = 3$ augmented images for each original image in the query dataset, and we average their query results as the recovered prediction of the original image.

D-DAE [8] and D-DAE+: We implement D-DAE without the defense detector since we assume that that attacker knows the details of the defense. D-DAE trains a three-layer neural

network as the restorer to recover the clean predictions given the perturbed predictions. The training dataset of the restorer is $\{(p(f_i(\boldsymbol{x})), f_i(\boldsymbol{x})) : \boldsymbol{x} \in X_q, i = 1, \cdots, S\}$ where f_i is a small shadow model trained on a public dataset (we use a randomly sampled subset of the query dataset with original labels as the public dataset). We generate a total of $1,000,000$ training samples with $S = 20$ shadow models in our experiments. D-DAE+ amends D-DAE by replacing its training dataset with the lookup table generated for Bayes Attack.

Partial Bayes Attack: Considering the limited computing resources we can use when evaluating our defenses, in addition to the independent sampling introduced in Equation (13), we further shrink the sampling space for the lookup table by only sampling possible clean predictions from the neighborhood of true clean predictions $\boldsymbol{y}_{q,i} \in Y_q$ as follows:

$$\mathbb{T} = \bigcup_{i=1}^{|Y_q|} \{(\boldsymbol{y}_j, p(\boldsymbol{y}_j)) : \boldsymbol{y}_j \sim \mathrm{Dir}(\boldsymbol{y}_{q,i}, s), j = 1, \cdots, K\}. \quad (21)$$

$\mathrm{Dir}(\boldsymbol{m}, s)$ is a Dirichlet distribution with mean $\boldsymbol{m}$, and the precision s controls how concentrated the samples are [31]. We set $s = 8C$ and $K = 20$ in our experiments where C is the number of classes, resulting in a lookup table with $1,000,000$ samples in total.

Remark 5. Notice that even the attacker uses $\boldsymbol{y}_{q,i} \in Y_q$ as the means, they do not know which one corresponds to a specific $\boldsymbol{x}_{q,i} \in X_q$. Therefore, the attacker is not able to use the means of the samples to train the substitute model directly. In addition, we set a relatively small precision s in order to prevent the samples from becoming too close to the true clean prediction $\boldsymbol{y}_{q,i}$, which simulates the situation that the attacker does not know the clean predictions exactly.

B.2 Defense Baselines

Details of some defense baselines are given as follows.

Reverse Sigmoid (RevSig) [28]: Lee et al. propose to use a Reverse Sigmoid function to perturb the prediction:

$$\hat{y}_{q,i}^{(k)} = \alpha_i \left[y_{q,i}^{(k)} - \beta \left(s\left(\gamma s^{-1}(y_{q,i}^{(k)}) \right) - \frac{1}{2} \right) \right], \quad k = 1, \cdots, C.$$

$s(x) = \frac{1}{1+e^{-x}}$ is the sigmoid function, and $s^{-1}(\cdot)$ is its inverse function. α_i is a factor that normalizes $\hat{\boldsymbol{y}}_{q,i}$ such that $\sum_{k=1}^{C} \hat{y}_{q,i}^{(k)} = 1$. β and γ are hyperparameters that can control the perturbation magnitude.

Maximizing Angular Deviation (MAD) [36]: MAD maximizes the angle between the gradient calculated with $\hat{\boldsymbol{y}}_q$ and the gradient calculated with $\boldsymbol{y}_q$ as follows:

$$\max_{\hat{\boldsymbol{y}}_{q,i}} \quad \left\| \frac{\boldsymbol{G}^T \hat{\boldsymbol{y}}_{q,i}}{\|\boldsymbol{G}^T \hat{\boldsymbol{y}}_{q,i}\|_2} - \frac{\boldsymbol{G}^T \boldsymbol{y}_{q,i}}{\|\boldsymbol{G}^T \boldsymbol{y}_{q,i}\|_2} \right\|_2^2$$
$$\text{subject to} \quad \text{(utility and validity constraints in Section 3.2)}$$

$\boldsymbol{G}$ is the Jacobian of the substitute model: $\boldsymbol{G} = \nabla_{\boldsymbol{w}_s} \log f_s(\boldsymbol{x}_{q,i}; \boldsymbol{w}_s)$. As the defender is not aware of the substitute model $f_s(\cdot; \boldsymbol{w}_s)$, Orekondy et al. [36] propose to use a randomly initialized model $f_{s,\mathrm{sur}}(\cdot; \boldsymbol{w}_{s,\mathrm{sur}})$ as the surrogate model for the substitute model and calculate the Jacobian with this surrogate model during the defense.

Adaptive Misinformation (AM) [24]: AM is a selective prediction perturbation mechanism that relies on an out-of-distribution (OOD) detector. Their perturbation mechanism can be formulated as follows:

$$\hat{\boldsymbol{y}}_{q,i} = (1 - \alpha_i)\boldsymbol{y}_{q,i} + \alpha_i \hat{f}_t(\boldsymbol{x}_{q,i}; \boldsymbol{w}_p),$$
$$\text{where} \quad \alpha_i = \frac{1}{1 + \exp\left(\nu(y_{q,i}^{(\max)} - \tau)\right)}.$$

ν is a large constant (we set $\nu = 1000$ following Kariyappa et al. [24]) and $\hat{f}_t(\cdot; \boldsymbol{w}_p)$ is a misinformation model that is trained to minimize the reverse CE loss as follows:

$$\min_{\boldsymbol{w}_p} \quad \mathcal{L}_{\mathrm{CE}}(\boldsymbol{1} - \hat{f}_t(X_q; \boldsymbol{w}_p), Y_q),$$

where $\boldsymbol{1} = [1, 1, \cdots, 1]$ is a vector with all 1 elements.

B.3 Training Hyperparameters

Hyperparameters for training target models We train the target models with Outlier Exposure (OE), which uses the following loss function:

$$L_{\mathrm{OE}}(X_{\mathrm{ID}}, Y_{\mathrm{ID}}, X_{\mathrm{OOD}}; \boldsymbol{w}_t) = \mathcal{L}_{\mathrm{CE}}(f_t(X_{\mathrm{ID}}; \boldsymbol{w}_t), Y_{\mathrm{ID}}) + \lambda \mathcal{L}_{\mathrm{CE}}(f_t(X_{\mathrm{OOD}}; \boldsymbol{w}_t), \mathcal{U}),$$

where $(X_{\mathrm{ID}}, Y_{\mathrm{ID}})$ is equivalent to the in-distribution training dataset (X_t, Y_t) (i.e., Caltech256, CUB200, CIFAR100 and CIFAR10), while X_{OOD} is the out-of-distribution dataset (i.e., Indoor67 and SVHN). $\mathcal{U}$ is a uniform label that has the same value at all dimensions. We set $\lambda = 1.0$ in our experiments following Kariyappa et al. [24].

We use models pretrained on ImageNet1k to initialize the target models in all our experiments. We train each model for 100 epochs. We use an SGD optimizer with an initial learning rate of 0.01, a batch size of 64, and a momentum of 0.5 for all the models, while we halve the learning rate every 30 epochs.

Hyperparameters for training substitute models We use the same pretrained model to initialize the substitute models as what we do for the target models. The number of training epochs is set to 30 for all the experiments as we find the substitute models can always converge within 30 epochs. We use an SGD optimizer with an initial learning rate of 0.01 and a batch size of 32 for Caltech256 and CUB200, and an initial learning rate of 0.1 and a batch size of 128 for CIFAR100 and CIFAR10. The momentum is also set to be 0.5. We halve the learning rate every 10 epochs.

SHiFT: Semi-hosted Fuzz Testing for Embedded Applications

Northeastern University

Abstract

Modern microcontrollers (MCU)s are ubiquitous on critical embedded applications in the IoT era. Therefore, securing MCU firmware is fundamental. To analyze MCU firmware security, existing works mostly adopt re-hosting based techniques. These techniques transplant firmware to an engineered platform and require tailored hardware or emulation of different parts of the MCU. As a result, security practitioners have observed low-fidelity, false positives, and reduced compatibility with real and complex hardware.

This paper presents SHiFT, a framework that leverages the industry semihosting philosophy to provide a brand-new method that analyzes firmware natively in MCUs. This novel method provides high fidelity, reduces false positives, and grants compatibility with complex peripherals, asynchronous events, real-time operations, and direct memory access (DMA). We verified compatibility of SHiFT with thirteen popular embedded architectures, and fully evaluated prototypes for ARMv7-M, ARMv8-M and Xtensa architectures. Our evaluation shows that SHiFT can detect a wide range of firmware faults with instrumentation running natively in the MCU. In terms of performance, SHiFT is up to two orders of magnitude faster (i.e., $\times 100$) than software-based emulation, and even comparable to fuzz testing native applications in a workstation. Thanks to SHiFT's unique characteristics, we discovered five previously unknown vulnerabilities, including a zero-day on the popular FreeRTOS kernel, with no false positives. Our prototypes and source code are publicly available at https://github.com/RiS3-Lab/SHiFT.

1 Introduction

Embedded devices are of paramount importance for the modern world. They control critical systems in many domains with real-time responsiveness and low power consumption (e.g., Internet-of-Things, Cyber-Physical Systems, etc.). Microcontrollers, the primary functional component of deeply embedded devices, are becoming increasingly powerful, and rich in network connectivity [20], thus facing threats that pullulate in the cyberspace [40]. MCU security, therefore, is critical to users and the operators of these devices.

In recent years, we have seen a significant rise in attacks targeting embedded and IoT devices [27, 40], where attackers can steal private and critical information of the infected devices, or even manipulate the behavior of the connected physical infrastructure. Such attacks have been studied [68] and reported in smart homes [21], connected vehicles [24, 56], intelligent factories [49], power grids [45], and more.

The attacks usually result from bugs and vulnerabilities rooted in the MCU firmware in production environments. Therefore, detecting and eliminating MCU firmware bugs before deployment is critical because vendors may fail to patch firmware once a vulnerability is known, and is being exploited. A *notable example* is the unfixable firmware bug affecting a DMA buffer in the first generation of the Nintendo Switch. This bug compromises an early boot stage of the console's system on a chip (SoC) and the whole system security [60]. Even when patching after deployment is possible, a complete shutdown and reboot of the physical infrastructure might be needed, hence leading to high financial and operative costs. Thus, firmware developers must find bugs as early as possible at the source code level, leveraging in-house testing [46].

Researchers have explored various approaches to improve the security of embedded devices, including remote attestation [69], compartmentalization [38, 53], and dynamic and static firmware analysis [6, 34, 58]. Notably, dynamic analysis has elicited the interest of security practitioners because it is less prone to producing false positives, adds no runtime overhead, and it is more practical in identifying bugs before deployment. However, contrary to software running in a workstation, firmware is not directly compatible with the majority of traditional security approaches because of various hardware and software constraints of the MCU platform [18, 46, 62].

To solve these limitations and specifically enable dynamic analysis, previous works have explored several *re-hosting* techniques, such as pure software-based emulation [25, 26], hardware-in-the-loop (HiL) [43, 44], and symbolic abstrac-

tions [23,30]. Despite these efforts, these solutions are limited in terms of *fidelity*, which describes how well the behavior of an emulation system mirrors its physical counterpart (i.e., the real hardware [33,71]). Low fidelity reflects many issues in firmware analysis, such as limited compatibility with complex peripherals, asynchronous events, real-time operations and DMA. As a result, critical bugs may not be found, or bugs that are reported may not be easy to reproduce nor observed on real hardware (i.e., false positives).

In this work, we propose SHiFT, a fuzz testing framework that introduces "semihosting" as a new re-hosting technique. SHiFT allows the firmware running natively in an MCU to consume fuzzing services in a workstation. SHiFT is novel in the sense that it runs most of the fuzzer's infrastructure and the target firmware entirely in the MCU, without requiring software-based emulation of peripherals, and providing high fidelity.

SHiFT maintains flexibility and practicality in detecting bugs and vulnerabilities early in firmware development. This characteristics benefits first-party developers that have access to source code and functional testing tools, but do not have automated methods to test firmware–from a security perspective–directly on hardware. Consequently, developers can integrate SHiFT in existing development pipelines that embrace continuous integration and continuous delivery (CI/CD) maintaining short development cycles with speed, reliability and security.

SHiFT's implementation involves two components: an MCU fuzzing cluster running FreeRTOS-MPU tailored to support coverage-guided fuzzing and sanitizer instrumentation, and a workstation running a mutation engine. SHiFT's implementation is vendor-agnostic, and portable to many MCU development platforms. We evaluated SHiFT's compatibility with relevant embedded architectures, its fuzzing performance, and fault detection capabilities. The results show that SHiFT is compatible with popular embedded architectures. Its performance is vastly superior to the software-based state-of-the-art emulation, and even comparable to native fuzzing in a workstation. In our work, the unique characteristics of SHiFT allowed the detection of previously-unknown bugs (that we reported responsibly to the vendors) that are easily verifiable in real hardware.

In summary, this work makes the following contributions:

- We propose a novel re-hosting technique based on the *semihosting* philosophy that, contrary to software-based emulation or HIL, executes the firmware under test entirely in an MCU with high fidelity.
- We implement, evaluate and will make public SHiFT prototypes for various popular embedded architectures.
- We demonstrate that by systematically lifting specific limitations of an MCU, it is possible to use MCU devices to build practical security tools, which helped to identify five previously-unknown vulnerabilities.

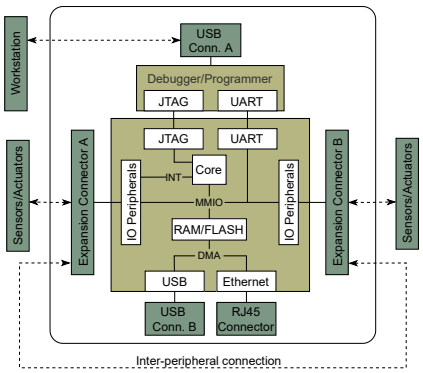

Figure 1: Reference MCU development board architecture. Dashed lines denote external wiring connections, sensors, actuators, and off-chip peripherals added by developers for developing and testing. Adapted from [55].

2 Background

Previous work [59] has classified embedded systems according to the type of OS that they run, and their specific hardware requirements. Our work focuses on devices based on MCUs that implement a specialized RTOS, or a bare-metal design (i.e., Type II, and III, respectively). Devices that have a memory management unit (MMU), and that support a general OS such as Linux (i.e, Type I) are not considered in this work because of their similarity to traditional computers, and the vast availability of security tools.

2.1 The MCU ecosystem

MCUs are tiny self-contained[1] computers that are constrained in computing power, hardware features and data storage. Nevertheless, these devices are unique in undertaking mission-critical tasks, satisfying real-time constraints, and being energy-efficient for battery-powered scenarios [53]. MCUs usually implement a single address space with specific physical addresses mapped to RAM, FLASH and peripherals. The core processor accesses and interacts with these components using three main methods: memory-mapped IO (MMIO), DMA and interrupts (INT) as depicted in Figure 1.

The software executed by an MCU is a monolithic binary (i.e., firmware) that contains the complete software stack including drivers, communication protocols, user applications, and optionally, a scheduler library or RTOS. Firmware is usually developed on workstations equipped with a cross-compiler that generates a binary file. The binary file is then flashed and debugged on a development board. Figure 1 depicts a generic MCU development board that includes a target MCU, expansion connectors to access on-chip peripherals, a terminal connection (USART), and a debugger/programmer.

[1] Processor core, RAM, FLASH and I/O hardware are integrated in a single die.

2.2 Firmware security analysis

Firmware analysis is a challenging endeavor because the security tools and methods—used on standard software and computers—are not directly compatible with firmware and the operative conditions of MCUs. This incompatibility is a consequence of the following embedded devices' characteristics: 1) strong coupling among firmware, sensors and peripherals that requires non-standardized inputs interfaces [34]; 2) diversity of software and hardware that precludes generalization of methods that either rely on specific instruction set architecture (ISA) tooling, or assume the existence of specific software abstractions provided by a common OS [33]; 3) the absence of specialized instrumentation and run-times that can work in bare-metal, or RTOS designs [18,46,59]; and 4) MCU hardware limitations, or minimalistic firmware designs that simply hide crashes and memory corruptions without proper exception management [46, 59, 62].

Security practitioners have embraced *re-hosting* as the mainstream technique to iron the incompatibility issues of firmware security analysis. "Re-hosting specifies that a binary that would run on a specific hardware is instead run on a host system using system emulation" [71]. Conceptually, re-hosting aims to enable dynamic firmware testing by transplanting firmware from the actual device into an engineered environment that model the original hardware behavior, and executes firmware with visibility and control.

Fasano, et al. [33] classified re-hosting techniques into three non-exclusive categories: *pure software-based emulation*[2] that emulates or replaces all necessary components to run a particular firmware; *HiL* that partially emulates the MCU components and forwards interactions to the actual device when the emulator lacks component models that firmware needs to interact with; and *symbolic abstraction* that replaces interactions between firmware and hardware with symbolic values.

2.3 Open challenges and limitations

Despite the efforts made by the re-hosting community to enable firmware analysis, developers face challenges and limitations when using their SoTA solutions. In the following subsections we systematically describe these issues and how they affect dynamic firmware analysis.

2.3.1 Reduced Fidelity

Re-hosting based on soft-emulation inevitably approximates the behavior of real hardware at its best. This approximation compromises the fidelity of the firmware-hardware interactions and precludes the identification of firmware issues that are closely associated with hardware behavior [51, 76]. A non-exhaustive categorization of these bugs that are hardly observable on soft-emulation platforms includes:

- **Post-silicon and peripheral interfacing bugs:** these bugs are rooted in the silicon implementation [57] or in the integration of an MCU with peripherals due to faulty designs or electrical connections. While impossible to observe on emulators, these issues can compromise firmware execution on the actual device and require vendor-specific firmware "work-arounds" or silicon revisions to be solved [67].
- **Timing and synchronization issues:** this category is related to race conditions, time drifting, time constraint violations, RTOS priority inversions, and wrong handling of interrupts. Current solutions use the number of executed basic blocks as a heuristic to trigger interrupts in a round-robin fashion [34, 63]. This method lacks granularity and does not reflect the concatenation of asynchronous events observed on an actual device.
- **Multi-master violations:** these issues are associated with DMA operations performed by dedicated controllers and peripherals with DMA capabilities. Besides the notable effort made by the authors of DICE [54], most re-hosting works do not support DMA or require non-scalable manual assistance to provide limited support for these operations. Thus, current solutions cannot exercise and analyze several code sections that depend on DMA.

2.3.2 Reduced observability

The fault detection techniques of current re-hosted solutions are based on experimental-only methods [35, 50], require considerable engineering effort [26, 46], or only provide coarse-grained detection capabilities [17, 34]. This last method is widely adopted and relies on major memory segment violations (i.e., when reading or writing operations occur on reserved memory areas). Unfortunately, these major violations usually do not occur, or they occur later during firmware execution [59]. Potentially observing a fault later during execution is still valuable for firmware analysis, but it demonstrates the re-hosting limitations on detecting specific faults when they occur.

2.3.3 Limited compatibility

This limitation has two dimensions: First, for soft-emulation approaches the current solutions are not compatible with complex peripherals since these solutions can only model simple peripheral-processor interactions [76]; and second, the methods used by re-hosting under the HiL category, with exception of GDBFuzz [31], usually require custom hardware only available for academic use [28, 44], or proprietary commercial libraries and expensive debugging dongles [47]. These

[2] In the following sections, we will refer to "pure software-based emulation" as soft-emulation for clarity and brevity.

exclusive requirements make these methods far from being used in practice due to hardware and software unavailability, cost and complexity.

3 System Design

SHiFT addresses the aforementioned challenges based on a novel re-hosting technique that borrows the *semihosting*[3] industry philosophy. Semihosting enables firmware, running natively in an MCU, to use facilities available in a workstation [2]. In the context of dynamic firmware analysis, SHiFT is a fuzz testing framework running on MCUs that uses fuzzing facilities provided by a workstation (i.e., a semi-hosted fuzz testing framework).

3.1 Design assumptions and scope

Our design uses the popular ARM Cortex-M architecture and the FreeRTOS-MPU [7] as a basis. However, the principles and design considerations are non-exclusive, and are applicable to other RTOS, bare-metal designs and architectures as shown in §5.

We assume the tester is a *first-party developer* of embedded devices who has access to a development board, and the source code of the complete firmware, or at least the software components that will be dynamically analyzed. Having access to the development board and source code is a realistic assumption considering that our method is meant to be integrated as part of the development, and in-house testing of an embedded device. It is worth noting that having access to source code does not solve various challenges associated with the MCU constraints and re-hosting that we summarized earlier. Further, previous works [18,46,59,63] have also identified and discussed these remaining challenges, and have agreed with our observation.

We also assume the tester has access to a GCC compiler that supports coverage-guided fuzzing (SANCOV), Address Sanitizer (ASAN) [65], and optionally Undefined Behavior Sanitizer (UBSAN) instrumentation. We assume the run-time of the instrumentation is not available. These assumptions are reasonable and realistic because GCC mainstream supports ASAN and UBSAN since version 4.8 and SANCOV since version 6.3 [5,8]. Further, the instrumentation run-time is OS-specific, and unavailable for Type II and III devices [18,46]. We validate our assumptions and extend the compatibility analysis of our solution in §5.

3.2 SHiFT overview and workflow

SHiFT is delivered as a framework that includes ready-to-use components to implement a semihosted fuzzer in an MCU.

[3] Originally termed by ARM [15], semihosting has been used in embedded devices for decades [12].

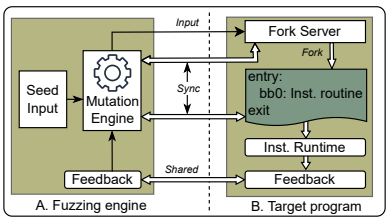

Figure 2: Canonical fuzzer. A. and B. are processes of the same host.

This framework is accompanied by exemplary templates (i.e., projects that integrate all SHiFT's components in a compilable firmware), a tailored compiler, and a proxy running in a workstation.

SHiFT's workflow can be summarized in four steps done by the tester: integration, configuration, compilation, and fuzz testing.

Integration: the tester combines all the source code to build a semihosted fuzzer and a target application in a single binary. For a given firmware codebase, the tester can choose between porting the complete target firmware to any of the exemplary templates, adding the SHiFT framework components to the existing firmware codebase, or porting only specific functions or libraries to the exemplary templates.

Configuration: the tester configures SHiFT components to deliver the fuzzing input to the target application according to the integration method and the portions of the target application to be tested.

Compilation: the tester adds the corresponding compilation flags to instrument the files that will be tested and compile the firmware into a single binary using our tailored compiler.

Fuzz testing: the tester flashes the binary into the development board, or a cluster of them, and launches the fuzzing campaign using the proxy provided by our framework.

3.3 Decoupling a canonical fuzzer

A canonical fuzzer contains a fuzzing engine and a target program running in the same host as mutually-isolated processes (A and B in Figure 2, respectively). The fuzzing engine uses communication primitives (e.g., pipes or shared memory) to synchronize execution, feed input, and retrieve feedback from the target. The target program leverages OS facilities (e.g., syscalls, vitual memory, and error handling), compiler instrumentation, and runtimes to fork, execute, and record feedback of instrumented routines. We call collectively these OS facilities the *fuzzer's infrastructure*.

SHiFT instantiates a semi-hosted fuzzer design by decoupling a canonical fuzzer, and defining two major components: a fuzzing workstation, and an MCU fuzzing cluster (A and B in Figure 3, respectively). In the following sections, we describe our design considerations for each of these major components, and describe how we tackle the unique challenges that the MCU platform pose in terms of constrained

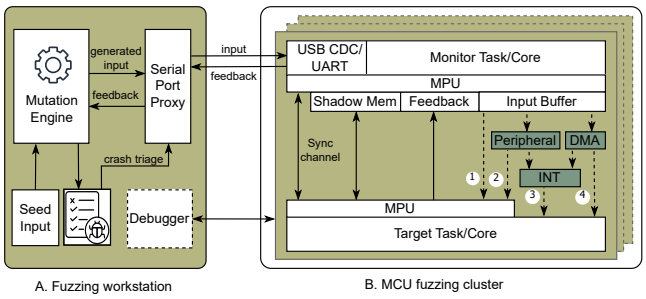

Figure 3: SHiFT framework architecture. Dashed line denotes optional component not needed during the fuzzing campaign.

computing power and memory, lack of OS and hardware facilities, and lack of specialized sanitizer runtimes.

3.4 The fuzzing workstation

We designed the workstation to generate the fuzzing input because it has enough computing power and storage capacity to execute SoTA genetic algorithms and mutation strategies. Thus, the fuzzing workstation integrates a classic feedback-based fuzzing engine as a drop-in component. It also includes a proxy that mimics the target program of the canonical fuzzer. This proxy abstracts the same communication primitives of the original target. However, the proxy merely delivers input, and awaits feedback. It does not control any of the aspects of the target firmware execution and fuzzer's infrastructure.

This independence of the firmware execution has two consequences: first, it instantiates the semihosting philosophy by implementing the fuzzer's infrastructure in the MCU and consuming the fuzzing input from the workstation; and second, it drastically reduces the communication bandwidth between the workstation and the MCU cluster. This last point is a significant advantage of our design compared with classic HiL approaches. HiL, such as Avatar [58] or uAFL [47], uses a debugging dongle to control the MCU from the workstation to mimic the functionality of the fuzzer's infrastructure. This synchronization is complex and requires huge bandwidth, which is mitigated by proprietary debugging dongles. Nonetheless, it reduces the throughput of the fuzzing campaign [59].

3.5 The MCU fuzzing cluster

The MCU fuzzing cluster component implements a fully-functional fuzzer (i.e., the fuzzer's infrastructure) except for the input generator, which we deemed better fits the characteristics of a workstation, as we described earlier. The fuzzing cluster consumes the mutated input from the fuzzing workstation, controls and executes the target program (i.e., firmware), collects coverage, manages errors or faults, and provides feedback to the mutation engine. The cluster's elements (MCUs) are mutually-independent. That is, they do not share any information of the fuzzing process. The fuzzing engine in the workstation, however, can leverage the feedback from the cluster in its own way, taking advantage of the workstation's plentiful computing resources.

Next, we describe how SHiFT supports the fuzz testing process, and our reasoning to solve specific challenges that the MCU platform poses for this novel approach.

3.5.1 Architecting firmware for fuzzing

SHiFT supports single (*S-C*) and dual-core (*D-C*) configurations to take advantage of modern MCUs' heterogeneous architectures. For each configuration, our design defines two mutually-isolated components in the MCU to provide high flexibility, and maintain a robust fuzzing platform.

The first component (Monitor in Figure 3) is the entry point of the semihosted fuzzer. This component manages the communication channel (input and feedback), MPU configuration, fault exceptions, and the initialization of the target. The second component (Target in Figure 3) executes the code under test, and collects coverage information. Monitor and Target are either tasks or cores. That is, they depend on SHiFT's configuration—whether it operates in *S-C* or *D-C*, respectively.

In *S-C* configuration, SHiFT uses RTOS primitives to create a monitor task, which in turn manages the target task. This target task can be deleted and recreated by the monitor task to exercise every testing input (standard mode), or can be reused for a configurable number of input tests, and later refreshed to improve performance (persistent mode) [14]. The *S-C* configuration is meant to test specific parts of the firmware, for example, user applications, libraries and drivers. This configuration is restricted in that the tested code must be compatible, or ported to run in a RTOS task (i.e., the target task).

In dual-core configuration, SHiFT maintains the same roles for the Monitor and the Target, but each one runs on a distinct core. This configuration is compatible exclusively with MCUs that implement two or more cores. This is a more flexible configuration in terms of testing because the Monitor and the Target are independent firmware running different libraries, RTOS, or even bare-metal designs. This configuration also supports the standard and persistent modes, but instead of deleting and recreating the target task, SHiFT reboots the target core to refresh it.

3.5.2 Delivering fuzzing input

SHiFT is highly-flexible in supporting various methods to deliver the fuzzing input to the target. The specific method is defined configuring small harness functions that extend the monitor and the target (i.e., configuration in §3.2). The simplest method, which resembles AFL running in a workstation, is by sharing the monitor's input buffer with the target (i.e.,

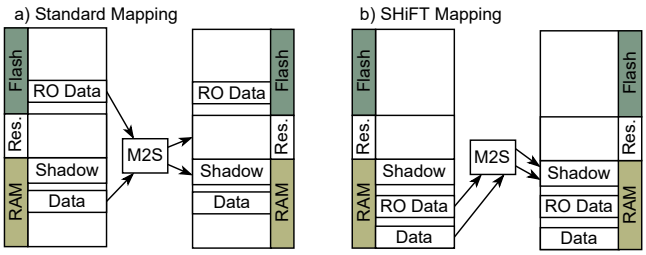

Figure 4: ASAN Mem-to-Shadow (M2S) computation in a MCU, a) shows an illegal mapping to a reserved memory area (Res.), and b) shows a valid mapping compatible with MCUs.

① in Figure 3). The most complex method, and key aspect of SHiFT's contributions, is by using real peripherals to send the fuzzing input from the monitor, and receive the fuzzing input in the target. This method supports and executes all the peripheral's MMIO, interrupts and DMA (i.e., ②, ③, and ④ in Figure 3) handled directly by the MCU hardware with high fidelity. For this method, the harness function in the monitor includes peripheral drivers to write the fuzzing input, and the target includes the original application's drivers and routines to read data from peripherals. Also, the tester needs to physically interconnect peripherals leveraging the development board (Figures 1 and 10). The reader is referred to our case study in §5.6.3 for a practical example.

3.5.3 Detecting and managing faults

SHiFT leverages the FreeRTOS-MPU kernel to detect out-of-bounds accesses and privilege mismatches. SHiFT also controls the Cortex-M traps for integer division-by-zero and unaligned accesses. For MCUs that integrate a floating-point unit (FPU), our design also handles exceptions derived from division-by-zero and invalid floating-point operations. SHiFT detects hangs by using RTOS primitives or watchdog timers, for *S-C* and *D-C* configurations, respectively.

Our design masters the Cortex-M exception model by defining specialized RTOS-independent handlers to systematically manage faults. This model differentiates exception conditions from usage faults (division-by-zero, unaligned accesses, and undefined instructions), hangs or timeouts, memory faults (MPU mismatches) and bus faults (e.g., illegal fetches) [48]. SHiFT uses the exception handlers to stop the target, and notify the monitor with the corresponding exit code using RTOS primitives. Notice that this exception model is a commodity on standard computers, but non-existing in embedded devices [59].

3.5.4 Supporting compiler instrumentation

SHiFT supports SANCOV, ASAN and optionally UBSAN run-time libraries for bare-metal and RTOS-based firmware. From a high-level perspective, the run-time library constitutes the implementation of callbacks that the compiler inserts into the code to trace the program counter on every basic block (BB), or to add memory checks on load and store operations to detect memory errors. To support the run-time libraries, our design tackles two fundamental constraints of the MCU: limited memory RAM, and the lack of MMU.

For SANCOV, our run-time design is inspired, but not limited, by AFL [1] with two particular optimizations in coping with the limited RAM, and returning the coverage feedback to the fuzzing workstation.

The first optimization reduces the size of the bitmap (i.e., RAM) that holds the number of hits of every edge[4]. We reduce it up to 1/8 of the original bitmap size (i.e., 64kB/8). This is feasible since MCU firmware is typically much smaller than regular software.

The second optimization adds an extra level of indirection into the bitmap to build the feedback dynamically. This is due to the observation that the bitmap hits are very sparse, making it highly inefficient to send the entire bitmap back for every fuzzing input. Thus, we only send back to the workstation the exercised edges and their hit counts instead of the entire bitmap.

For ASAN, the original algorithm assumes it is running on a Type I device, or a regular computer that supports virtual memory. Concretely, ASAN uses 1/8 of the virtual space for shadow memory, which is used to check whether a byte is safe to access [65]. This method is *incompatible* with MCUs, because these devices do not have an MMU to translate arbitrary addresses from the virtual space into the physical location of the shadow in RAM. Figure 4 explains this issue. This figure shows that the computation M2S for the Data segment is correct pointing to the shadow in RAM. However, for the Read-Only (RO) Data segment, the computation M2S points to a reserved area.

In our design, we solve this issue by relocating the RO Data segment into RAM (i.e., Figure 4.b), reserving 1/8 of the available RAM for shadow, and systematically choosing an `Offset` value for ASAN M2S. Without the assistance of an MMU, the modified instrumentation computes valid physical addresses for the shadow of Data and RO Data segments.

The addition of ASAN extends MPU protections to allow SHiFT to detect errors, including out-of-bounds on the heap and in global variables, use after free, illegal free, and double free. In the case of the stack, ASAN increases MPU protection granularity by adding checks for internal structures allocated in the stack region.

3.5.5 Selecting a communication channel

We analyzed multiple commodity interfaces of commercial MCUs. Table 1 summarizes the results of writing and reading operations for various interfaces. We also conducted a survey (Appendix §A) and determined that USART and USB are the most popular interfaces in commercial MCUS. Upon our

[4]We omit and adapt some AFL details to simplify our description.

Interface	Native Speed	Write [MB/s]	Read [MB/s]
Ethernet	100 Mbps	11.71	5.86
USB ST-Link	12 Mbps	0.57	0.49
USB-CDC	12 Mbps	1.06	0.97
UART	7.5 Mbaud	0.72	0.74

Table 1: Average speed for read and write operations on different interfaces of the NUCLEO-H743 development board

analysis, we selected the serial communication USB-CDC because it assures a trade-off between throughput and availability. Also, it is universally-accessible by the fuzzing workstation because drivers for serial ports are already available in every major OS.

4 Implementation

SHiFT's implementation includes, FreeRTOS-MPU extensions, run-times for SANCOV, ASAN and UBSAN, GCC compiler modifications, templates for *S-C* and *D-C* configurations including harness prototypes, a communication protocol and a customized serial proxy. The changes for GCC compiler are 2 LoC. The rest of our implementation constitutes of 2,140 LoC distributed on different SHiFT's components, which does not take into account the target firmware code. The proxy includes 600 lines of code (LoC) that we implemented exclusively on the fuzzing workstation.

4.1 FreeRTOS-MPU and kernel extensions

We selected FreeRTOS-MPU (V10.4.2) because it is arguably the most popular RTOS for Type II devices [20]. However, we used exclusively primitives available on any RTOS to make SHiFT easily portable. These primitives include methods to spawn and stop tasks, semaphores and notifications. Further, supporting the Cortex-M MPU is not mandatory, but highly desirable for better fault detection and robustness.

We extended the FreeRTOS-MPU kernel using the `application_defined_privileged_functions.h` file. This header file is used to define functions that the application writer wants to execute in privileged mode (i.e., syscalls). Thus, we defined wrappers for *malloc*, *free*, and *watchdog* handlers, which are used by the ASAN run-time and fuzzing templates. If the RTOS does not support the MPU, all the firmware is executed in the privileged mode and these wrappers are not necessary.

4.2 SANCOV and ASAN run-times

We used the GNU ARM Embedded Toolchain 10.3-2021.10 release [9], including the source code of the GCC compiler, libraries and run-times in the same package.

Our SANCOV run-time implements coverage measurements based on a modified version of AFL's edge tracking algorithm [36]. Our modifications account for the optimizations described in §3.5.4, which are mostly implemented in the `__sanitizer_cov_trace_pc` callback inserted by SANCOV to trace the program counter.

Configuration	Mem. area	Base Addr.	Size [kB]	Offset
Single-Core Monitor & Target	RAM	0x24000000	512	
	SHADOW	0x20000000	64	0x1B800000
	FLASH	0x08000000	1024	
Dual-Core Target	RAM	0x24000000	256	
	SHADOW	0x10000000	32	0x0B800000
	FLASH	0x08100000	512	
Dual-Core Monitor	RAM	0x24060000	128	
	FLASH	0x08000000	512	

Table 2: Memory layout to support ASAN instrumentation for the STM32H74x MCU family.

Our ASAN run-time is based on the `libsanitizer` source code. We make it compatible with RTOS-based and bare-metal designs by refactoring the run-time callbacks and removing the support for thread details and advanced memory allocators, which are OS-specific. The refactored callbacks include functions for (de-)initialization of the run-time and poisoned areas, reporting `load` and `store` violations, and memory (de-)allocators helpers. To support ASAN instrumentation, we re-compiled GCC with a custom `Offset` defined in `asan_mapping.h` and `arm.c` of GCC source code[5]. We also modified the firmware linker script, as described in Table 2, to accommodate the shadow, and relocate the data segments, according to the details in §3.5.4.

4.3 Communication protocol

We implemented a robust 2-message protocol to send the fuzzing input to the MCU, and to send back the feedback from the MCU. This protocol also includes a cyclic redundancy check (CRC) for error detection. On the MCU side, we built the protocol on top of a generic USB communication device class (CDC) example provided by the MCU vendor.

4.4 Serial proxy

The serial proxy abstracts the communication between the fuzzing engine and the MCU connected through a serial port (Figure 3). It acts as the target program maintaining compatibility with AFL, AFL++, and any other SoTA fuzzing engine that uses the same communication primitives (i.e., pipes and shared memory). We use libserialport [16], a cross-platform library, for communication between the proxy and the serial port in the fuzzing workstation.

5 Evaluation

We evaluated SHiFT to answer the following questions:

[5] GCC supports `Offset` as a command line option for KASAN, but not for ASAN. [22]

1. What is the compatibility of SHiFT with relevant embedded architectures? What are the requirements of SHiFT in terms of FLASH and RAM?

2. How does SHiFT's observability and fault detection capabilities compare to the SoTA?

3. How does SHiFT's fidelity compare to other solutions?, and How does reduced fidelity affect fuzz testing?

4. What is the fuzzing performance of SHiFT?, and how does SHiFT's unique characteristics support fuzz testing of complex hardware settings?

To answer 1), we empirically evaluated the compatibility of thirteen embedded architectures in §5.1, and analyzed the memory footprint of SHiFT in §5.2. To answer 2), we performed a fault detection analysis and compared to the SoTA in §5.3. To answer 3), we conducted a qualitative analysis of SHiFT fidelity comparing to the SoTA, and empirically analyzed the effects of low fidelity in fuzz testing in §5.4.1 and §5.4.2, respectively. Finally, to answer 4) we conducted a performance analysis in §5.5, and describe case studies in §5.6.

The default setting for our experiments includes a workstation equipped with an AMD Ryzen 3700x CPU, 32 GB of RAM, and Ubuntu 22.04. We used a wide range of development boards from ST-Microelectronics, Adafruit Industries, NXP, Microchip Semiconductors, Gigadevice, and Espressif Systems. Collectively, we evaluated 13 embedded architectures, including complete fuzzing campaigns on 6 different development boards from different vendors, and three architectures (i.e., ARMv7-M, ARMv8-M and Xtensa). Please refer to Table 3.

5.1 Compatibility analysis

For this analysis, we selected 13 popular embedded architectures according to market studies [4, 20]. Then, we verified their characteristics, toolchain and documentation considering SHiFT's design assumptions detailed in §3.1. Finally, we obtained the latest public toolchain, ported, compiled and tested SHiFT prototypes (eleven in total) considering the characteristics of each architecture, and the hardware that we have for validation.

The results in Table 3 demonstrate that our design has excellent compatibility since 100% (13) of the architectures support SANCOV, 92% (12) support software-based error detectors, and 77% (10) support hardware-based protections. The only exception is the 8bit AVR architecture which does not support software or hardware methods to detect faults. We estimate that porting SHiFT to another architecture requires on average 4 hours of effort for a single engineer, which includes the recompilation of GCC (about 90 minutes).

Table 4: Flash and RAM requirements for different fractions of the original (64k) AFL bitmap (bmp). % represents the usage of available Flash and RAM for the STM32H74x MCU.

5.2 Footprint analysis

In this section, we analyze the sizes of RAM and FLASH needed by SHiFT under single-core (*S-C*) and dual-core (*D-C*) configurations as well as different AFL bitmap size settings. The results in Table 4 demonstrate that SHiFT's footprint is moderate. It uses at most 23.2% and 17.5% of RAM and FLASH, respectively, out of the 1024kB provided by the MCU for each section. The moderate requirements make SHiFT compatible with actual embedded (i.e., constrained), or even more memory-limited scenarios. Also, note that the bitmap size is highly-adjustable to fit various characteristics of the fuzzing target.

5.3 Fault detection analysis

For this experiment, we configured SHiFT in S-C mode using the synthetic benchmark detailed in Appendix C as the target program. This benchmark contains artificial errors (detailed in Table 5) that the target executes upon a simple verification of conditional statements evaluated on a testing input. The goal of this test is to verify that SHiFT's hardware and software-based protections can detect, and report the firmware errors detailed in Table 5 according to our design. Simultaneously, we compared these results and notable SHiFT's testing features with re-hosting SoTA works according to their respective conceptual designs. For this particular analysis, we did not run our synthetic benchmark on each tool to avoid biased results due to wrong configurations, or assumptions not fulfilled by our benchmark.

Table 5 demonstrates that SHiFT provides comprehensive fault detection features, which collectively, cannot be sup-

ported by any SoTA tool. Note that the fault detection capabilities of each tool are not directly related to the vulnerabilities reported by them. This is because some reported vulnerabilities were identified and interpreted upon manually debugging general crashes that are observed later during firmware execution, but not when the actual fault happened.

5.4 Fidelity analysis

Fidelity is arguably the most important and difficult property to quantify in re-hosting and emulation-based scenarios [51, 52, 71]. There are works that propose tailored fidelity metrics to favor particular designs [76], or benchmarks meant to evaluate how well the soft-emulation technique mimics the real hardware (e.g., the unit test of P2IM [34]). However, all of those metrics or benchmarks are not applicable to SHiFT because we use the real hardware, thus comparing to soft-emulation would be unfair. Instead, we present a qualitative analysis inspired by Wright et al. [71], and we empirically explain the effects of low fidelity on dynamic firmware analysis.

5.4.1 Qualitative analysis

The qualitative analysis defines a 2-dimensional plane for the conceptual axes of memory and execution fidelity. The memory axis represents the state of any addressable resource of the MCU (i.e., RAM, FLASH, and peripherals). This axis increases granularity from black box to register. For black box, granularity is coarse, and the memory state is only verifiable externally. On the other hand, register means that the state of both, internal memory and registers, is similar to the real device. Execution fidelity axis denotes how close the emulated execution mirrors the behavior when firmware runs on the actual device. In black box, the external behavior is similar to the real device, but internally, there is no warranty of the functions or instructions that are executed. On the other end, cycle means that the emulated platform mimics the behavior of the real device at the CPU cycle level. For both axes, the perfect level is only achieved by the real device. Also, there is a blur between classification points since specific parts of the firmware can be executed at different levels of fidelity due to particular design considerations of each tool [71].

SHiFT achieves higher fidelity than emulation-based approaches, and slightly lower fidelity than GDBFuzz and uAFL. These tools, similar to SHiFT, use real hardware, and do not require instrumentation that can affect execution fidelity (Figure 5). We also consider that a perfect solution does not exist yet because, for example, GDBFuzz halts the processor continuously, and uAFL adds harnesses in the firmware to hold and provide fuzzing input. Thus, both tools cannot achieve cycle execution accuracy. [6]

[6]We updated Wright's work [71], with the SoTA and corrected a miss. The author confused the fuzzing phase of P2IM with its model instantiation.

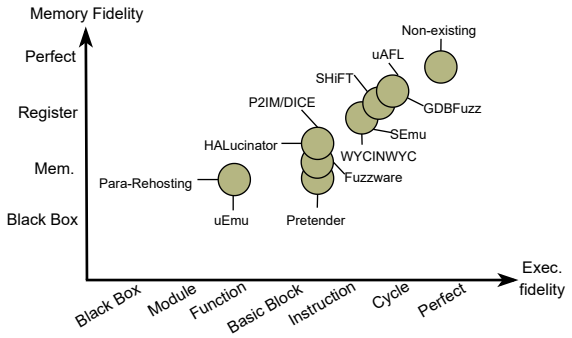

Figure 5: SHiFT's fidelity compared with the SoTA.

5.4.2 Impact of fidelity on dynamic analysis

For this analysis, we selected P2IM and Fuzzware, two prominent re-hosting solutions, to explain the fidelity effects on dynamic analysis when compared to hardware-based solutions such as SHiFT. We used the synthetic benchmark as a control test, and we specifically concentrate on the coverage tracking and false path exploration effects.

We observed that fuzzing engines struggle in tracking code coverage when the firmware is forced to consume input with sophisticated, but low-fidelity, methods. For example, for the synthetic benchmark, SHiFT identified all the bugs in less than 6 minutes, whereas P2IM identified only three in 24 hours (Table 8). We verified this effect by coverage, and not by fault detection capability. A similar effect was observed by the authors of Fuzzware. They found their sophisticated "bit-granular input overhead reduction" ineffective because it "conflicts with the byte-level heuristics that drive the fuzzer's input mutation process" [63].

We also observed that aggressive strategies to increase code coverage can violate hardware invariants, increase false positives, and put additional burden on the tester. For example, Fuzzware is optimized for code coverage by providing "optimized" fuzzing input when firmware reads from peripheral's registers that are determined to affect firmware state. On the other hand, P2IM maps primitive models that mimics the peripheral's register behavior, and exclusively provide fuzzing input for Data Register (DR) read operations.

We observed that the conservative P2IM approach–in this particular case–honors the expected hardware invariant by returning a previously written value on a Configuration Register (CR), which is evaluated in a critical conditional statement. Fuzzware, however, violates this hardware invariant by assigning a "Bitextract" model (i.e., a masked fuzzing input) to mutate specific bits of the CR and increase coverage factitiously. This violation makes Fuzzware perform poorly by majorly exploring false paths, reporting false positives and not reaching the target function of the synthetic benchmark. Nevertheless, we need to mention that for different firmware images and conditions, P2IM heuristic approach can also mis-

Persistent With ASAN	22.7	5.7	4.1

Table 6: End-to-end fuzzing performance in [kRun/s] of (1) vanilla AFL++ running in the workstation, a single instance of SHiFT for (2) single-core (S-C) and (3) dual-core (D-C) configurations.

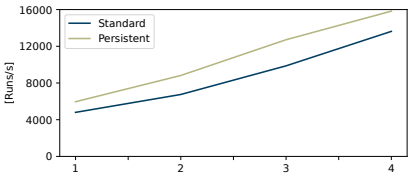

Figure 6: SHiFT's cluster test for *S-C* configuration.

classify peripheral registers, violate hardware invariants, and reflect similar issues as Fuzzware. These limitations has been already acknowledged by P2IM's authors [34].

5.5 Performance analysis

For this analysis, we used the same synthetic benchmark running on SHiFT as an end-to-end fuzzing framework to measure its raw performance in terms of runs/sec on different configurations, including the cluster setup.

Despite the huge computing power advantage of the workstation, the results show that SHiFT performance is comparable and, in some cases, superior to our workstation running AFL++ natively (i.e., without emulation). Specifically, SHiFT is 2.42 times faster than the workstation in standard mode (i.e., creating a new target for every fuzzing input) when running with ASAN instrumentation, as detailed in Table 6. This impressive result is obtained mainly thanks to the FreeRTOS spawning process, and our MCU-specific ASAN run-time. These two components are leaner and lighter than their workstation counterparts without sacrificing equivalent functionality for real embedded applications.

In the case of the *D-C* operation, the results are merely informative since there is no equivalent operation mode of AFL++ in a workstation. Nevertheless, note that in this mode, SHiFT's performance is still significant since it can fuzz and reboot a complete core more than 410 times per second. Also, note that performance decreases significantly in this mode compared with the *S-C* mode because the target runs in the slower CM4 core of our MCU.

For the cluster performance, we analyzed the *S-C* in the standard and persistent mode for the settings of one to four development boards connected simultaneously. SHiFT boosts performance linearly with two or more MCUs, whereas a single board performs relatively better when working alone, as depicted in Figure 6. We attribute this result to the nature of the USB protocol whose low-level analysis we considered out-of-the-scope of this work.

5.6 Case studies

This section presents case studies of SHiFT performing fuzz testing campaigns on firmware used in industrial and commercial devices. The tested firmware includes samples previously tested by other works, and new firmware collected from open-source projects. Each firmware was tested 10 times for 24 hours using a fixed seed input[7], and a single development board for the hardware-based solutions, i.e., SHiFT and GDBFuzz. We used the AFL++ mutation engine for all tools, except for P2IM because it is tightly-coupled with a customized AFL. Porting P2IM to AFL++ is a non-trivial task, thus we consider it out of the scope of this work. Thanks to SHiFT's unique characteristics, we identified five previously unknown vulnerabilities as shown in Table 7.

[7]We used the UTF-8 encoded string "testinput".

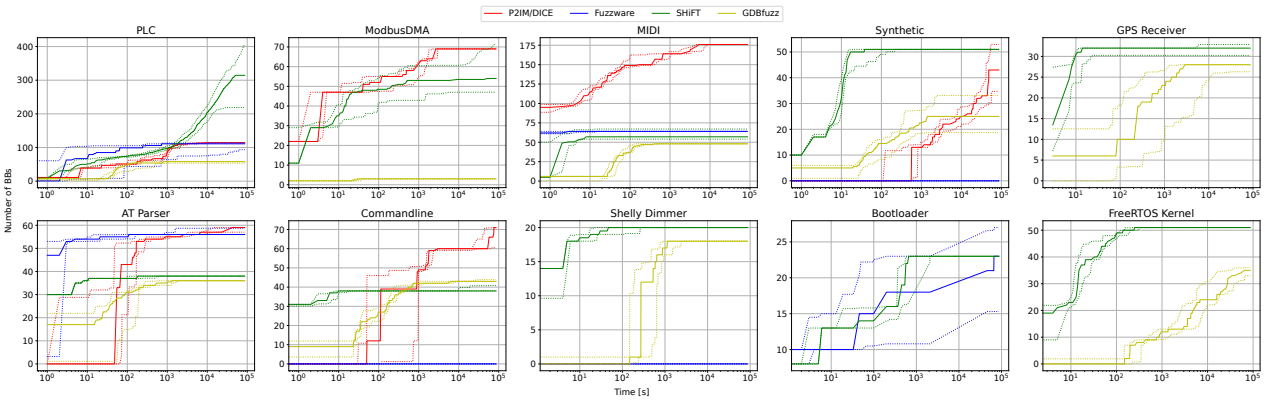

Figure 7: Basic block (BB) coverage over 24-hour campaigns for SHiFT compared to P2IM/DICE, Fuzzware and GDBFuzz. Shown are the median and 95% confidence intervals.

Firmware	Vulnerability	CWE	Instances
Shelly Dimmer	Divide by zero	369	3
Bootloader	Buffer overflow	120	1
FreeRTOS K.	Improper handling of insufficient privileges	274	1

Table 7: Vulnerabilities identified by SHiFT. Each instance is categorized according to the Common Weakness Enumeration (CWE).

5.6.1 Fuzzing libraries and full-stack firmware

SHiFT is highly flexible in that it allows exercising specific functions of the firmware (i.e., cases #1, and #4 to #7 in Table 8) by delivering the fuzzing input through a shared memory area. SHiFT can also exercise the complete software stack including, drivers, ISR, and the user application, which uses DMA operations to get data from peripherals (i.e., cases #2 and #3).

For the aforementioned test cases, SHiFT outperforms the SoTA[8] by up to two orders of magnitude in speed, while detecting all the previously reported vulnerabilities (i.e., nine in total on firmware #1, #2 and #3) with no false positives.

In terms of basic blocks coverage, SHiFT outperforms GDBFuzz in all cases, except underperforming slightly for the CommandLine firmware. In comparison, the performance of soft-emulation solutions widely fluctuate between outperforming (e.g., case #7 for P2IM) and totally falling short (e.g., cases #4 and 7 for Fuzzware), when compared with SHiFT. We consider this result as expected because of different design choices of soft-emulation approaches that affect fidelity and the fuzzing performance. The reader is also referred to §5.4 for more details about this phenomenon.

Note that all our observations demonstrated statistical significance through the Mann-Whitney U test ($p<0.05$). Also, the reported basic blocks were filtered according to the target functions instrumented by SHiFT. This procedure can slightly benefit SHiFT and GDBFuzz, but allows comparability by "normalizing" the code sections under analysis. This is necessary due to the slightly different targets under analysis for hardware-based and soft-emulation approaches (i.e., soft-emulation usually consider the whole binary, while GDBFuzz relies on a user-specified entry function, and SHiFT is based on source-code instrumentation).

[8]We exclude from the SoTA High-level emulation (HLE) approaches [26, 64] because they require considerable engineering effort and do not execute the whole firmware.

5.6.2 Finding insecure conditions and post-silicon bugs

We fuzz tested the full-stack of the dimmer depicted in Figure 8. This firmware (#8 in Table 8) uses communication peripherals, GPIOs, real-time events and interrupts. Under this configuration, SHiFT identified three previously unknown vulnerabilities that can be *realistically observed in a deployed device*. The three vulnerabilities are similar in nature to the code in Listing 1. Specifically, function `get_active_power`, which is accessible remotely, is vulnerable to a division-by-zero in line #7, under these specific conditions: 1) the dimmer receives a command to report the active power, 2) condition in line #3 is `false` because of ADC operation, and 3) `voltage_max_period` is zero.

```
1  static uint32_t get_active_power(void)
2  {
3      if ((adc_data[0] == 0) || (adc_data[1] == 0))
4          return 0;
5      else
6          return (880373 * 15.5 * 556) /
7          voltage_max_period *
8          current_total_mag_period;
9  }
```

Listing 1: Vulnerable code fragment of the dimmer firmware

Conditions 1) and 2) are easily satisfied by SHiFT features because it supports firmware reading the ADC through DMA, receiving a remote command through the USART, and triggering the corresponding interrupt service routine. Condition 3) occurs only when the dimmer receives a command before the zero crossing routine is executed at least once. We verified this condition is met only on the actual device on two scenarios: a) when a command is received on the first 8.3 [ms] of operation of the dimmer (i.e., a time sensitive operation), or b) when the zero-crossing module is disconnected or fails

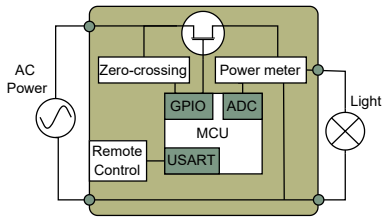

Figure 8: Simplified architecture of an IoT dimmer fuzz tested with SHiFT.

(i.e., a peripheral interface issue). Thanks to SHiFT unique characteristics a tester can fuzz test firmware combined with specific hardware scenarios (e.g., a disconnected cable), and reason about unsafe/insecure conditions that can happen in a deployed device, but cannot be observed in an emulator.

Also, further analysis demonstrated that SHiFT helped to identify a documented post-silicon bug that we were not aware of beforehand. In particular, we observed that the division by zero is only caught by SHiFT's UBSAN instrumentation, but not by the real FPU when configured to trigger exceptions on this type of errors. Thus, GDBFuzz and SHiFT, this last configured without UBSAN, were not able to identify the division by zero. The reason for this unexpected behavior is that the FPU's interrupt line is not present on the NVIC silicon of the MCUs STM32h743 and 745 [67]. Notice, that post-silicon issues like this cannot be identified by emulated platforms either, because this issue only affects the real FPU of a particular MCU family.

5.6.3 Fuzzing bare-metal firmware

The bootloader firmware (#9 in Table 8) demonstrates the flexibility of SHiFT for testing firmware that implement baremetal designs and uses complex peripherals. The bootloader implements a full-state protocol that remotely manages the flashing and execution of the main MCU's application through the CAN bus.

We used the *D-C* configuration of SHiFT to test the bootloader. We interconnected the monitor (Cortex-M7) and the target (Cortex-M4) using two on-chip CAN bus peripherals and external CAN bus transceivers as detailed in Appendix B. The fuzzing setup operates strictly under the CAN bus specifications (i.e., frame format, payload size, and speed), and supports all the asynchronous events derived from this bus operation. We commented out the bootloader's operations that write into the MCU's flash to avoid wearing out this memory during the fuzzing campaign.

Thanks to SHiFT unique setup, we discovered a vulnerability with security implications in the communication protocol of the bootloader. Specifically, this protocol temporarily accumulates in RAM chunks of data up to the size of a flash page before writing it into the MCU's flash. Unfortunately, this routine uses the data length code (DLC) embedded into the CAN bus frame to weakly verify the length of the received data chunks (i.e., the routine assumes the DLC is always a submultiple of the flash page's size). If the DLC is not a submultiple of the flash page's size, the bootloader routine keeps storing the incoming chunks of data overflowing the temporal buffer, and potentially compromising critical memory sections of the firmware.

5.6.4 Finding a zero-day in the FreeRTOS kernel

This bug was identified when we ported SHiFT to the NUCLEO-L552 board, which implements a Cortex-M33 MCU (#10 in Table 8). We used our synthetic benchmark as a control test on this board and observed that the FreeRTOS `TaskYield` syscall triggered a systematic MPU violation. This syscall is used by SHiFT's monitor to switch context when fuzzing a target. Upon analysis, we identified that the FreeRTOS port for the entire ARMv8-M architecture, including the Cortex-M33, fails to obtain privileged execution level before writing the ARM `Interrupt Control and State Register` [3]. This register is only writable on privileged mode, and is used to trigger a `PendSV` interrupt that handles a request to switch context. We consider that this vulnerability has security implications because when triggered causes a denial-of-service. We responsibly reported this issue to the FreeRTOS developers, who acknowledged and patched it.

This zero-day highlights the benefits of automated testing on real hardware even when (FreeRTOS-)developers have access to source code and traditional debugging tools. Notice that soft-emulated platforms can potentially help to detect this bug as well. However, until the time of this writing, P2IM,

Fuzzware and other tools based on QEMU or the Unicorn engine do not fully support the Cortex-M33 or the Xtensa architectures, just to mention a few. This issue can be considered only an engineering limitation, but in reality, it exposes a fundamental challenge (i.e., hardware diversity) of embedded platforms that is not easily addressed by soft-emulation.

6 Discussion

Can SHiFT replace soft-emulation? The answer to this question is no. Soft-emulation is well-known for its independence from the physical platform, which in turn facilitates advanced analysis with much flexibility and scalability. For instance, SHiFT provides high fidelity in exchange for a relatively less scalable cluster-based design. Soft-emulation, on the other hand, can leverage multiple instances (e.g., taking advantage of cloud computing) to reduce the time needed to explore the input space. However, it cannot improve fidelity. Consequently, we argue that soft-emulation and hardware-based solutions like SHiFT are rather complementary than competing approaches.

Testing on hardware caveats: Fuzz testing on embedded development boards needs extra precaution. This process stresses the hardware, can damage the system, or force it into unsafe states. Therefore, the tester has to implement mitigations to, for example, prevent wearing-out the MCU's FLASH by repetitive writing operations or avoid testing devices connected to physical actuators that can behave unsafely.

Binary-only scenarios: SHiFT's design assumes access to the firmware's source code. However, testing firmware in a binary-only form is always valuable when the embedded application cannot tolerate instrumentation, when developers link first-party source code with third-party blobs, or simply when source code is not available. In this scenario, SHiFT can borrow design ideas from previous works (e.g., [31], and [47]) to acquire coverage information from blobs using debugging or tracing components provided by the Cortex-M architecture (e.g., the ARM-embedded trace macrocell (ETM), or the embedded trace buffer (ETB) [19]). We consider supporting these hardware facilities out of the scope for this work.

Semihosting beyond fuzz testing: SHiFT provides strong evidence and a reference design that future work can leverage to perform dynamic analysis in MCUs. We envision applications where semihosting catalyzes other verification techniques that benefit from high fidelity (e.g., concolic execution). In this scenario, executing the firmware in an actual device provides accurate concrete values to mitigate state explosion and false positives (i.e., two common pitfalls of concolic techniques). Meanwhile, workstations can perform computing-intensive, but generic, operations (e.g., constraint solvers) on behalf of the MCU.

7 Related Work

Soft-emulation and HLE: These approaches eliminate the hardware and physical layers through using emulated models or High-level Emulation (HLE). For example, Firmadyne [25] uses QEMU to emulate a generic kernel with the filesystem of the firmware to perform user space analysis. FirmAE [73], FIRM-AFL [74] and Costin's work [29] adopted a similar approach. These works are only applicable to firmware using a specific kernel or filesystem since they rely on the Linux kernel abstractions. To analyze monolithic firmware, other works leverage emulated models of peripheral behavior at different abstraction layers [26, 29, 34, 54].

HALucinator [26] hooks calls into vendor-specific Hardware Abstraction Layer functions to implement the HLE paradigm within a generic emulator. Safirefuzz [64] proposes a similar approach but removes emulation by near-native execution of binaries as Linux user space processes in an ARM exclusive design. Para-rehosting [46] also executes firmware natively in Linux using HLE principles and source code. This last approach supports instrumentation-based sanitizers, but contrary to SHiFT that executes the entire firmware in the MCU, Para-rehosting executes sections of the firmware in a workstation with reduced fidelity.

P2IM [34] and µEMU [75] model MMIO access patterns. DICE [54] extends emulators to support basic DMA operations, and SEmu [76] uses NLP to process documentation and improve models. Unlike SHiFT, soft-emulation analysis suffers from false positives during the emulation. It is also limited in real-time analysis, precise interrupt handling, and advanced DMA support. Except DICE [54], and partially HALucinator [26], DMA support is considered orthogonal, or out of scope by most of the re-hosting works.

HiL: These approaches avoid the need for hardware abstractions by forwarding hardware accesses to a physical device during the emulation. In particular, AVATAR [72] orchestrates the execution of an emulator and implements an expensive synchronization to forward the I/O accesses from the emulator to the real device. SURROGATES [44] improves the forwarding performance through an FPGA-based interface and enables near-real-time analysis. PROSPECT [43] adopts a similar design with AVATAR and SURROGATES, but extends to Linux-based systems. It forwards system calls that are likely to access peripherals to the physical device to achieve a partial emulation during the fuzzing process.

Compared with SHiFT, HiL approaches are limited in flexibility. Specific debugging interface, or tailored hardware might be needed. It is also difficult to synchronize asynchronous or real-time events between the device and the emulation environment because these solutions halt the processor while synchronizing.

To improve performance and reduce the I/O forwarding latency, later works adopt similar design with different optimizations [32, 37, 58, 61, 70]. Charm [70] uses USB 3.0

to forward MMIO to a physical device to analyze Android device drivers for ARM in a virtualized environment. PRETENDER [32] records hardware behavior to automate the modeling of MMIO and interrupt-driven hardware peripherals. Kammerstetter [42] caches peripheral device communication and provides run-time program state approximation. Frankenstein [61] captures live snapshots of the physical hardware states during normal operation and integrates them to the emulated environment to analyze Bluetooth firmware. FIRMCORN [37] optimizes the virtual execution environment by hooking hardware-specific functions to avoid program halts and crashes.

These works sacrifice a complete real-time analysis, and can only support a specific type of hardware and software. Alternatively, SHiFT solves these problems executing the firmware entirely in an MCU, removing complex synchronization and dependencies on tailored hardware.

Similar to SHiFT, GDBFuzz and uAFL [31,47] are fuzzing frameworks that execute the code on the MCU. However, for collecting coverage SHiFT uses SANCOV instrumentation, whereas GDBFuzz uses breakpoints, and uAFL uses the ARM ETM. Their dependency on specific debugging facilities limits their applicability (e.g., uAFL only works for ARM). Also, GDBFuzz and uAFL do not support software sanitizers as SHiFT does, and they implement the fuzzing "manager" (i.e., SHiFT's Monitor in Figure 3) in the workstation. Thus, uAFL and GDBFuzz are classic HiL with reduced fault detection capabilities and slower performance.

Symbolic abstraction: These approaches emulate software layers and consider all the values from hardware to be symbolic. For example, FIE [30] uses KLEE to symbolically execute the firmware. It assumes every peripheral is capable of returning the full range of possible values, which over-approximates the hardware capabilities. This leads to false positive and can cause state explosion even for a small firmware.

To increase scalability, later works explored different techniques [39, 66]. Firmalice [66] leverages program slicing and aims at automatic analysis of binary firmware. FirmUSB [39] develops targeting algorithms and uses domain knowledge to speed up the unconstrained symbolic execution for USB firmware. Fuzzware [63] uses symbolic execution to determine the meaningful parts of the hardware-generated value. Lealaps [23] calculates the expected values for peripheral registers using symbolic execution, and steers the concrete execution on the fly. Jetset [41] uses guided symbolic execution to create peripheral models that make firmware to boot and execute till a particular point of interest.

Symbolic abstraction based analysis may also involve hardware-in-the-loop. Inception [28] performs symbolic execution to handle different levels of memory abstractions, interaction with peripherals, and interrupts. It then uses a JTAG debugger to redirect memory accesses to the real hardware. While this design reduces differences with real execution, collecting the interrupts from the real hardware suffers from inconsistencies. Compared to SHiFT, the above analysis is computation intensive and limited to small size firmware.

8 Conclusion

In this paper, we presented SHiFT, a semi-hosted fuzz testing framework to enable dynamic analysis of MCU firmware with high fidelity and support for complex peripherals, interrupts, real-time operations, and DMA. SHiFT can detect faults that previous rehosting approaches have overlooked or lack support. We demonstrated empirically that boosting coverage without maintaining fidelity is not enough, or even worse for firmware fuzzing. Our evaluation shows that SHiFT is compatible with multiple embedded architectures, and requires only moderate memory resources. SHiFT achieved a high-speed performance comparable with a workstation running AFL++ natively, and superior to that in some cases. When testing real firmware, our framework exposed five previously-unknown vulnerabilities. We deeply discussed SHiFT's novel characteristics, and fairly compared to soft-emulation approaches. Finally, this work lifted the constraints of running security analysis natively in MCUs, and provided a reference design for future dynamic analysis in resource-constrained devices.

Cascade: CPU Fuzzing via Intricate Program Generation

Flavien Solt
ETH Zurich

Katharina Ceesay-Seitz

Kaveh Razavi
ETH Zurich

Abstract

Generating interesting test cases for CPU fuzzing is akin to generating programs that exercise unusual states inside the CPU. The performance of CPU fuzzing is heavily influenced by the quality of these programs and by the overhead of bug detection. Our analysis of existing state-of-the-art CPU fuzzers shows that they generate programs that are either overly simple or execute a small fraction of their instructions due to invalid control flows. Combined with expensive instruction-granular bug detection mechanisms, this leads to inefficient fuzzing campaigns. We present Cascade, a new approach for generating *valid* RISC-V programs of arbitrary length with highly *randomized* and *interdependent* control and data flows. Cascade relies on a new technique called asymmetric ISA pre-simulation for entangling control flows with data flows when generating programs. This entanglement results in non-termination when a program triggers a bug in the target CPU, enabling Cascade to detect a CPU bug at program granularity without introducing any runtime overhead. Our evaluation shows that long Cascade programs are more effective in exercising the CPU's internal design. Cascade achieves 28.2x to 97x more coverage than the state-of-the-art CPU fuzzers and uncovers 37 new bugs (28 new CVEs) in 5 RISC-V CPUs with varying degrees of complexity. The programs that trigger these bugs are long and intricate, impeding triaging. To address this challenge, Cascade features an automated pruning method that reduces a program to a minimal number of instructions that trigger the bug.

1 Introduction

With the increasing popularity of open-source RISC-V CPUs and the high cost of formal verification, CPU fuzzing is gaining momentum [8, 9, 14, 30, 32, 34, 35]. The effectiveness of CPU fuzzing strongly depends on the quality of the test cases and efficient bug detection. State-of-the-art CPU fuzzers fail at both: they execute only a small fraction of the intended instructions per test case, and rely on incomplete or expensive instruction-granular bug detection mechanisms at runtime.

This paper presents Cascade, a new CPU fuzzer that explicitly generates *valid* RISC-V programs of arbitrary length with highly randomized and interdependent data and control flows. Executing many instructions per program enables Cascade to efficiently trigger bugs. When a bug is triggered, the interdependence of the data and control flows results in program non-termination, enabling Cascade to detect bugs at program granularity without any runtime overhead. Our evaluation shows that Cascade achieves significantly more coverage than the state-of-the-art fuzzers and discovers a large number of new bugs in RISC-V CPUs of various complexities.

Programs for CPU fuzzing. To investigate properties of the programs generated by state-of-the-art CPU fuzzers [32, 35, 36], we defined two metrics measuring 1) *completion*: the proportion of the instructions in a program that actually execute, 2) *prevalence*: the overhead due to non-randomized initial and final sequences. We find that for each generated program, only a small fraction of the instructions gets a chance to actually execute on the target CPU and that most executed instructions perform non-randomized initialization. These findings hint at low instruction throughput in existing state-of-the-art CPU fuzzers. Furthermore, detecting a bug triggered by these programs introduces its own set of challenges.

Bug detection. Generally, the most obvious way to check whether a program triggered a bug is by checking the CPU's architectural state (i.e., registers and memory) instruction by instruction against a golden model [8, 9, 30, 34, 35]. Apart from performance implications, this approach has practical limitations; as an example, the registers are not always easy to identify in a given CPU's RTL design. In particular, out-of-order CPUs may keep multiple versions of the registers at the same time and identifying the correct ones for monitoring introduces a non-trivial effort when porting a fuzzer to a new CPU [4]. It is also possible to force termination by handling uncontrolled exceptions in the programs [32]. While this technique reduces the problem to only checking the architectural state at the end, it can miss bugs that happen in the middle of the program. An ideal solution generates programs that

execute to completion without the need for checking the state during program execution

Cascade. We rely on the idea that finding a bug-triggering program in a CPU is equivalent to finding a program for which the CPU behaves incorrectly. We propose a new fuzzer called Cascade that constructs complex and random RISC-V programs that exert the CPU's architectural and microarchitectural features without requiring time-consuming and error-prone expert effort specific to each CPU. The programs generated by Cascade mix a highly randomized data flow with the control flow, while steering the control flow at all times. To efficiently predict some necessary register values, we introduce the novel notion of asymmetric ISA pre-simulation, where instead of using the Instruction Set Architecture (ISA) simulator to compare the CPU under test with a golden reference model, we use it to construct programs with valid and predictable architectural control flows. Constructing valid programs with highly interdependent control and data flows provides us with three interesting properties. First, the programs can be long, which significantly boost fuzzing performance. Second, with highly randomized data and control flows, we explore unusual operand values and control flows. Lastly, the highly entangled data and control flows enables the non-pervasive detection of bugs amidst long programs by transforming bug expressions into program non-terminations, enabling Cascade to detect bugs without any runtime overhead.

The programs generated by Cascade exercise a rich set of functionalities provided by the RISC-V ISA; they support exceptions without (necessarily) causing termination, data flow-dependent privilege transitions, complex FPU (Floating-Point Unit) operations, and operations under randomized Control and Status Registers (CSRs) exploring different operational states of the CPU. We evaluate Cascade on 6 real-world RISC-V CPUs of different complexities and ISA extensions: VexRiscv, PicoRV32, Kronos, CVA6, Rocket and BOOM. Compared to the state-of-the-art fuzzers such as TheHuzz and DifuzzRTL, Cascade achieves the same coverage 28.2 and 97 times faster, respectively. Cascade discovers 37 new bugs (29 new CVEs) in 5 of these 6 designs which is more than all the state-of-the-art CPU fuzzers combined [10, 14, 32, 35, 36]. We additionally found a critical bug in the popular Yosys synthesizer that results in a wrong netlist.

Automated program reduction. Cascade-generated programs that trigger these new bugs can be long and highly complex, making the analysis of the non-termination intractable by humans. To tackle this challenge, Cascade relies on a new automated program reduction technique that creates minor in-place modifications to a bug-triggering program. These modifications iteratively reduce the program to a minimal bug-triggering form while preserving the sufficient bug-triggering CPU state. Using this technique, we find that these bugs result in hangs, wrong values and exceptions, decode issues and quantifiable performance counter inaccuracies. Furthermore, we find that Cascade's program reduction is significantly helpful when reporting the bugs to the respective CPU maintainers.

Contributions. Our contributions are as follows:

- We design and implement Cascade for generating valid RISC-V programs with highly complex and entangled data and control flows for finding CPU bugs. Cascade correct-by-construction programs achieve high fuzzing performance without introducing any overhead for bug detection.
- We design and implement a new analysis method to efficiently reduce Cascade-generated programs to a minimal form, while preserving the bug-triggering behavior.
- We evaluate the performance of Cascade in terms of speed and coverage and compare it with state-of-the-art CPU fuzzers [32, 35, 36]. We report a total of 37 new bugs found in 5 of the 6 considered RISC-V CPU designs. We further report a bug in the popular open-source Yosys synthesizer.

Open sourcing. For the benefit of the research and CPU design and testing communities, we publish the source code and experiments of Cascade at this URL: https://comsec.ethz.ch/cascade.

2 Background

In this section, we provide background on formal verification, fuzzing software and hardware, and finally on RISC-V.

2.1 Formal verification of hardware

Assertion-based formal verification aims to prove that a hardware design satisfies certain properties, for all possible input values that it may receive and for infinite depth in time. Usually, formal verification engineers manually write properties that target specific verification goals, often taking design-specific knowledge into account. Tools for automated property generation either generate a certain kind of properties, like information flow properties [19], require a (semi-)formal model of the specification [21, 38], or use novel languages [18]. Furthermore, exhaustively verifying complex properties on real world designs does not always scale and requires semi-manual abstraction techniques such as black-boxing or initial value abstraction [20, 25]. Given the high computational and manual cost of formal verification, alternative fuzzing techniques are starting to gain popularity.

2.2 Software fuzzing

Fuzzing consists in applying random inputs to a unit under test and observing whether the unit behaves as expected and

whether the output is correct. The goal is to find unknown bugs by covering as much state space as possible by iteratively mutating the input data. While fuzzing usually does not provide formal guarantees of correctness, it has been shown to be a very effective technique to find bugs [23].

Every fuzzer needs a strategy to *generate test cases* and to *detect bugs* when they happen. Software fuzzers may rely on some form of coverage feedback [15, 26, 29, 58], static or dynamic taint analysis [16, 27, 40, 42] or grammars [6, 24, 28, 44, 51, 57] to incrementally find test cases that better exercise the software's functionality. Software fuzzers mainly rely on two techniques to detect when bugs are triggered: crashes [29] and sanitizers [45]. Sanitziers provide, for example, address related checks like buffer overflows [45], checks for undefined behavior such as division by zero [22] or floating-point numerical issues [17].

2.3 Hardware fuzzing

Due to the high cost of formal verification, CPUs are an interesting target for fuzzing. Hardware fuzzers for CPUs differ from software fuzzers on both aspects of test-case generation and bug detection. While software fuzzers often generate random input data streams with little or no input format considerations, hardware fuzzers need to prioritize generation of inputs that follow certain protocols, like bus or ISA specifications, in order to be effective [55]. Inspired by software fuzzing, state-of-the-art hardware fuzzers generate new test cases by generating random instruction sequences and mutating the test case [8–10, 14, 30, 32, 34–36]. Every new CPU fuzzer finds new bugs, but often fewer [8, 9, 14, 30, 32, 34, 35].

Since processors hang only in rare cases, crash detection is not sufficient for bug detection, and sanitizers are currently limited to handwritten SystemVerilog assertions [36]. Therefore, hardware fuzzing needs new methods for bug detection. Most hardware fuzzers apply differential fuzzing by comparing register values of the CPU under test with the results from a purely software-based Instruction Set Simulator (ISS) that serves as a golden model [32]. Comparing the result of every instruction is expensive in terms of runtime, and only feasible for simple CPUs where a direct mapping from RTL design signals to registers is possible. Some CPU fuzzers [32] dump the register values via storage instructions at the end of a test case and compare the results with the ones from the ISS. Such a comparison is only possible if a test case completes and intermediate deviations between the ISS and the CPU under test are propagated through time until the end of the test case.

2.4 RISC-V

RISC-V [59] is a free and open ISA, consisting of an unprivileged and a privileged specification. RISC-V targets a large diversity of CPUs, and therefore provides a set of options. First, CPUs may comply with the 32-bit or the 64-bit

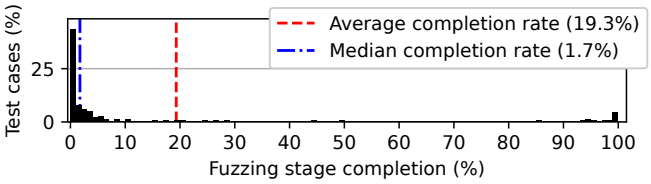

Figure 1: Completion rates of DifuzzRTL executions.

specification, which share most features. Second, CPUs may implement ISA extensions. In addition to the base ISA, common extensions are F (floating-point), D (double-precision support), M (integer multiplication and division), A (atomic operations), and C (compressed instructions). Compared with other established ISAs, RISC-V ISA features a small number of instructions. In particular, RISC-V requires two instructions to load an immediate 32-bit value into a register (`lui` followed `addi`). Furthermore, the only operations that influence the program control flow are `jal` (direct jump), `jalr` (indirect jump), branches, exceptions and privilege level changes. Note that in RISC-V, the targets of branches are immediates. In the case of self-modifying code, the `fence.i` instruction must be executed before executing newly-stored instructions.

RISC-V, in its common implementation in open source CPUs, supports up to three privilege levels which are machine mode (M), supervisor mode (S) and user mode (U), in decreasing order of privilege. The M mode is the only mandatory privilege level. Upward privilege transitions are done through interrupts or exceptions, and downward transitions happen through specific instructions (`mret` and `sret`). Depending on the target privilege level, the architectural fetch address following an exception is pre-set in the `mtvec` or `stvec` Control and Status Registers (CSRs). CSRs are further used to configure how the CPU should operate in certain conditions, such as whether exceptions should be delegated to another privilege level, or if the floating-point unit is enabled. Spike [47] is a widely used open-source ISS for RISC-V.

3 Motivation and Challenges

In this section, we first analyze important aspects of the recently-published CPU fuzzers DifuzzRTL [32] and TheHuzz [35]. From these observations, we describe challenges which will guide the design of Cascade.

3.1 Observations

We collected 500 CPU inputs generated by DifuzzRTL [32] for the Rocket core to understand key aspects of test cases generated by a state-of-the-art CPU fuzzer. We also analyze the test cases generated by TheHuzz [35] based on the description in their paper since TheHuzz is not open source at the time of this writing.

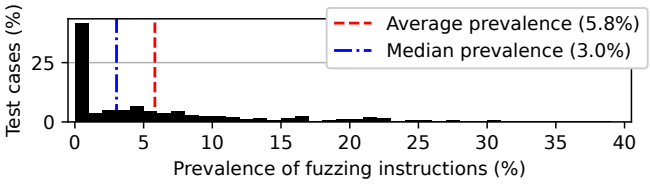

Figure 2: Prevalence of fuzzing instructions in DifuzzRTL.

Completion. Figure 1 shows the percentage of the fuzzing instructions that execute at least once in each test case produced by DifuzzRTL. We measure completion on the ISS, assumed bug-free. We observe that these programs do not generally complete the execution of their fuzzing sections, mostly because of the difficulty to predict intermediate values that affect the control flow, such as operands of branch instructions. Similarly, TheHuzz limits its test cases to 20 instructions, (10 of the first being non-control-flow instructions), again, because it is difficult to control the behavior of control-flow instructions when fuzzing.

Observation 1. Completion: CPU fuzzers struggle with fully executing their test cases.

Prevalence. In the programs generated by DifuzzRTL, we separate the instructions in two categories: *overhead* and *fuzzing* instructions. *Overhead* instructions are generic, non-randomized instructions such as setup routines or hard-coded exception handlers, while *fuzzing* instructions are the ones actually randomized. We define *prevalence* as the proportion of executed instructions that are *fuzzing* instructions. Figure 2 shows the prevalence in the programs generated by DifuzzRTL. Strikingly, only a small proportion of the executed instructions are fuzzing instructions. Similarly, the very short fuzzing sequences of TheHuzz are preceded by an overwhelming amount of configuration (overhead) instructions [35, 46].

Observation 2. Prevalence: most executed instructions correspond to overhead and are not fuzzing.

Conclusion. The existing coverage-guided approaches are insufficient. They produce malformed non-completing programs dominated by overhead instructions.

3.2 Overview of challenges

Our analysis suggests that we might significantly improve fuzzing results by constructing programs that address these limitations. We provide an overview of the challenges based on our previous observations and how we address them in the rest of this paper. The first challenge concerns completion and prevalence of the generated programs.

Challenge 1. How to generate programs that complete and have a high fuzzing prevalence?

Section 4 discusses a new design for program construction. Longer programs have a higher prevalence, but only if they complete. We propose to build *valid* programs that are expected to complete, by pre-defining a control flow ahead of execution. This is in contrast with existing CPU fuzzers that rely on mutation-based test-case generation strategies. The result of this step is a set of *intermediate* programs that have instructions with complex data flows, but control flows that are not dependent on the (complex) data flows. Our next challenge is to make the control flows dependent on the complex data flows while ensuring completion. Entangling data flows into control flows has two major benefits. First, it helps finding bugs related to (speculative) control flows. Second, it enables transforming a data-flow bug symptom into a program non-termination, effectively providing a non-pervasive design-agnostic way of detecting data-flow bugs in arbitrarily long and complex programs without any runtime overhead.

Challenge 2. How to generate valid programs with a high degree of dependence between data and control flows?

Section 5 proposes a novel method for efficiently constructing a complex data-dependent control flow for test cases, called asymmetric ISA pre-simulation. Asymmetric ISA pre-simulation mixes a highly randomized data flow with the control flow of the intermediate programs. This method is based on the new insight that instead of using an ISS for differential fuzzing, we can use it for generating a *valid* program. Repeated usage of the ISS for the ultimate program generation, however, would introduce a large performance penalty. We design a new scheme that allows us to reduce the number of ISS calls to only one per generated program.

Our prototype fuzzer implementation of the ideas presented in Sections 4 and 5, called Cascade, generates programs that trigger a large number of new bugs, more than any CPU fuzzer so far. The programs leading to these bugs, however, may be long and complex by construction, to an extent that makes it inconceivable to interpret them manually from logic waveforms, like it may have been done so far. This leads us to our last challenge.

Challenge 3. How to extract and interpret the bug from a complex program?

Section 6 discusses a new algorithm for iterative program reduction to find a minimal number of instructions inside program triggering CPU bugs. We successfully applied it for all the bugs found by Cascade, which significantly helped us when reporting the issues to the respective CPU maintainers.

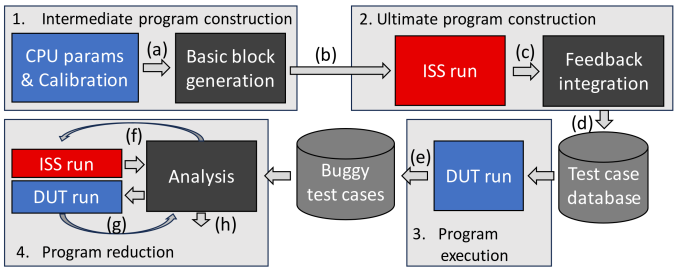

Figure 3: Overview of Cascade.

Listing 1: Example basic block.

```
xor         x3,x4,x9
csrrwi      x9,mcause,15

fld         f8,(x3)
feq.s       x4,f9, f8
jalr        x9,(x7)
```

4 Design

We outline Cascade, before explaining the intermediate program construction. In Section 5, we explain how Cascade uses ISS feedback to entangle data and control flow.

4.1 Cascade overview

Figure 3 provides an overview of the fuzzing process and its components. Cascade proceeds in four steps: (1) intermediate program construction, (2) ultimate program construction, (3) program execution and (4) program reduction. The program construction (steps 1 and 2) is decoupled from the other steps, so the same program can be executed on multiple versions of the same CPU, or on CPUs with compatible extensions.

Intermediate program construction. Cascade takes as an input the supported ISA extensions, addresses for dumping registers and stopping the RTL simulation, and descriptions of known bugs to circumvent, and starts with a brief calibration stage (taking less than a second) to evaluate some CPU parameters, such as supported CSR bits (a). Generating programs is then a parallel task. Cascade first generates the *intermediate* program as a sequence of basic blocks, where control flow is isolated from the data flow (b).

Ultimate program construction. An ISS then executes the whole *intermediate* program once to collect the data-flow dependent values of registers (c). Cascade uses this information to entangle the data flow with the control flow, as explained in Section 5 to produce the *ultimate* program (d). It is defined as a triple (ELF file, descriptor, and the expected final register values (optional)), where the descriptor is a short identifier that permits re-generating the same program.

Program execution. The program execution is also a parallel task. Each ultimate program is executed independently on a simulated design under test. The output (e) is a pair (descriptor, success). The descriptor is the same as in (d). The success flag is raised if the program terminated successfully, and optionally if the dumped register values match.

Program reduction. The program reduction phase takes as input a test descriptor that leads to an execution failure and produces a reduced program that preserves the buggy behavior while reducing the program complexity as described in Section 6. The analysis consists in iteratively reducing the program (f) and re-running it to check if the bug is still triggered (g), and to produce a minimal program that is easy to understand (h), as explained in Section 6.

4.2 Intermediate program construction

We first explain the structure of the programs generated by Cascade. We then show how Cascade selects instructions to form basic blocks. We finally discuss the memory management mechanism for ensuring sound program construction.

4.2.1 High-level program structure

Basic blocks. A program is a sequence of instructions within basic blocks. Basic blocks are made of zero or more instructions that do not affect the control flow, followed by a single instruction that affects the control flow. Accordingly, Cascade constructs programs as sequences of basic blocks, where the last instruction of a basic block steers to the next basic block. Each basic block is placed at a random location in memory (see Section 4.2.3). The order of basic blocks' execution is not necessarily identical with their placement in memory. The memory outside of basic blocks and of their data is left uninitialized, defaulting to zeros in simulation.

Initial and final basic blocks. All programs start with an initial basic block that sets up an initial state and random register values before jumping to the first fuzzing basic block, which eventually jumps to the next, and so on. The program ends with a final basic block that optionally dumps register values, and sends a signal indicating that the program's end was reached. No overhead instruction, as defined in Section 3, is executed between the initial and final basic blocks.

4.2.2 Basic block generation

Control-flow behaviors. We call instructions that do not change the control flow of a given program *still* instructions, and others *hopping* instructions. For example, a branch can be taken (still) or non-taken (hopping). Similarly, a memory load instruction such as `lw` can succeed (still) or raise an exception (hopping). We define the instructions that may be still or hopping depending on register values, or that are unconditionally hopping but whose destination depends on register values, as *cf-ambiguous*. For example, `beq` and `lw`

are *cf-ambiguous*, but `add` and illegal instructions are not. Listing 1 shows an example basic block, where cf-ambiguous instructions are represented in red.

Picking instructions. Instructions are grouped in categories, which are listed in Appendix A. Some groups of instructions will behave in the same context-dependent way, for example all floating-point instructions will be conditioned by whether an FPU is present and activated. Hence, Cascade picks instructions hierarchically, by first choosing a category, and then a specific instruction. Both are chosen randomly with certain probabilities, which are varied between programs. When picking a cf-ambiguous instruction, Cascade chooses immediately whether it must be still or hopping. Cascade biases the choice of operands by granting higher probabilities to registers recently used as outputs.

In particular, Cascade supports complex FPU operations and CSR interactions. It additionally supports exceptions and privilege switches as simple hopping instructions, which can only be picked under certain architectural conditions that are generated by the mechanism explained in Section 5. Ultimately, the complex data flow originates from combining initial static data with a diverse stream of random instructions.

Circumventing known bugs. Ideally, discovered bugs should be fixed immediately. In reality, however, this may take time and effort. Due to limited human resources, some bugs may remain unfixed for a long time, polluting bug reports and potentially restrain test case continuation. Known bugs may be ignored after triaging the causes of bug reports. However, known CPU bugs can influence the control flow of Cascade programs early, shadowing the rest of the program. Furthermore, triaging is an expensive operation that must then be repeated many times for the instances of the same bug. Instead, Cascade allows circumventing known bugs by constructing programs that will not trigger them. By increasing the completion rate, Cascade is able to progress and find more bugs faster. As an example, in the Rocket core, the retired instruction performance counter ignores `ecall` and `ebreak` instructions (R1) [1]. The circumvention configures Cascade to avoid that generated programs read this counter after these instructions until it has been written again, hence it covers exactly the bug.

Note that Cascade's approach of circumventing certain bugs may result in the under-exploration of the components in which the bugs exist. Automatically circumventing bugs via automated RTL patching is an interesting future direction that can address this issue altogether.

4.2.3 Memory management

To produce sound programs, Cascade imposes some constraints on the memory layout of the generated programs. In particular, Cascade ensures that (a) instructions do not overlap, (b) store operations do not overwrite instructions, and (c) later transformations of the program (discussed in Sections 5 and 6) do not have unintended effects. Intuitively, the constraint (b) would prevent from detecting some potential bugs related to self-modifying code. RISC-V requires self-modifying code to use `fence.i`, which means that such bugs are limited in scope. We leave the exploration of such bugs as future work and instead focus on non-self-modifying code.

Progressive memory allocation. Cascade allocates memory on the fly for each new instruction. Whenever a hopping instruction is generated, space is allocated for the first instruction in the next basic block, at a reachable random new address that offers enough space for a new basic block. Initially, space is allocated (at random locations) for the initial and final basic blocks, which have known upper bounds in length. Additionally, to anticipate program reduction, Cascade allocates space for a *context setter* block used for program reduction and leaves it empty (details are discussed in Section 6).

Strong memory allocation. The memory allocator can *strongly* allocate memory areas, i.e., forbid loads from there. Reading from a memory location could entangle its data with the data and control flows. Strong allocations prevent reading from a memory location that stores very specific parts of the program where some instructions differ between the *intermediate* and *ultimate* programs as described in Section 5.

Memory operations. Memory stores, randomized in number and size, can only target some specific memory areas, allocated at the start of the program's creation. Memory loads can target any address, except for the strong allocations. Heuristically, we bias memory loads to target more often memory areas that have been recently written, although so far, this specific heuristic has not been critical in finding bugs.

5 Ultimate Program Construction

The fundamental idea behind asymmetric ISA pre-simulation is to execute an *intermediate* program on the ISS to collect feedback for constructing the *ultimate* program with a control flow that is identical but dependent on the data flow.

Steering the control flow. There are three schemes for generating an arbitrary, but controlled, control flow. The first scheme is not to control the values used by cf-ambiguous instructions such as `jalr` but to place the next basic block accordingly. This scheme is not viable because most addresses are inaccessible or already allocated. The second scheme is not to involve the random data flow and rely on direct branches or registers loaded with fixed values. This is how the control flow of the *intermediate* program is constructed. The third scheme entangles data and control flow by observing the data flow and applying an offset to a register used by a cf-ambiguous instruction. We rely on the third scheme to construct the control flow of the *ultimate* program.

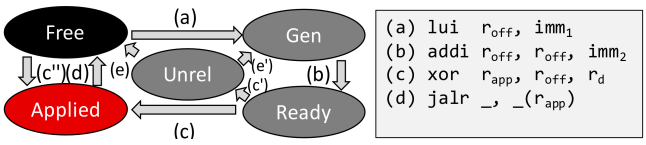

Figure 4: Life cycle of registers regarding offset construction. The instructions can be separated by other (unrelated) instructions.

5.1 Offset construction and register lifecycle

Some cf-ambiguous instructions such as indirect jumps (`jalr`) require a specific operand value `val` that Cascade intends to impose. Following the principle of dependency preservation, we let `val` depend on a randomly picked *dependent register* r_d. Since we do not want to constrain r_d's value, r_d is generated by the random data flow and its value is unknown when we pick the cf-ambiguous instruction. Hence, to calculate `val` we propose to generate an *offset register* value to be eventually combined with r_d's value. The combination of r_d and r_{off} is performed by an *offset applier* instruction, for instance `xor`, whose output is defined as the *applied register* r_{app} and holds the intended value `val`.

Branches. Because *applied registers* are a somehow precious resource, Cascade does not use this method for branches. Instead, it uses the ISS feedback to obtain the operand values and selects a suitable branch opcode, depending on whether the branch should be still or hopping.

Registers involved. In total, this construction involves two registers (r_d, whose value is randomized by the program's data flow, and r_{off} to offset its value). Since there is no reason to specifically reuse r_d or r_{off} as an output of the offset applier, a third register could be used as r_{app}, in accordance with the principle of maximizing the degrees of freedom.

Offset state machines. This scheme implies that 1) r_{app} must be available for use when the cf-ambiguous instruction is picked, 2) r_{app}'s calculation requires that r_{off} is ready before the offset applier instruction, and 3) r_d must be available when the offset applier instruction is executed. To comply with these requirements, we maintain a simple state machine for each architectural integer register. The state machine is composed of five states: *free*, *under generation (gen)*, *ready*, *unreliable (unrel)* and *applied*, as illustrated in Figure 4. All registers initially start in the *free* state. Cascade can create instruction (a) to move a *free* register to state *gen*, or (b) to move a register from *gen* to *ready*. When there is at least one register, r_{off}, in the *ready* state, then Cascade can pick an offset applier instruction. If Cascade chooses to define $r_{app} = r_{off}$, then r_{off} is moved to the *applied* state (c). Else, r_{off} is moved to the *unrel* state (c') and r_{app} is moved to the *applied* state (c''). Once r_{app} is used by a cf-ambiguous instruction (d), it returns to the *free* state. An *unrel* register must not be used as an input to any instruction and may be overwritten by an instruction to become *gen* (e'), or by an ordinary instruction to become *free* (e).

Pre-simulation. Cascade relies on an ISS to determine the value of dependent registers when encountering a cf-ambiguous instruction. So far, the state of the art [8, 9, 14, 30, 32, 34, 35] always submits the same program that is given to the CPU to the ISS. If we imitated the state of the art, the ISS should be called every time a cf-ambiguous instruction is encountered because r_{app} would be random until the correct r_{off} can be computed from r_d. The ISS could not proceed to the next basic block (or complete a correct memory operation) without running at least once per cf-ambiguous instruction.

We introduce the *asymmetric* ISA pre-simulation method to address this critical performance bottleneck by requiring a single ISS execution. The fundamental insight is to provide to the ISS not the *ultimate* program that the CPU under test will execute, but an *intermediate* program such that (a) the values of all *dependent registers* (in the constructions of *applied registers*) are identical between the two programs and (b) the programs' control flows are identical and (c) in the *intermediate* program, no applied register depends on the randomized data flow.

Concretely, the *intermediate* program differs from the intended *ultimate* program in three aspects. When generating the *intermediate* program: 1) we choose the immediates `imm1` and `imm2` to set the value of r_{off} to `val`, 2) we substitute of the offset-applying instruction with a `mv` instruction, which copies r_{off} into r_{app}, and 3) we transform non-taken branches into NOPs, because the value of the operands are not yet known. Given these transformations, the *intermediate* program complies with the aforementioned requirements.

Intermediate register states. This scheme for offset construction guarantees by design that at any point in the program, all *free* and *applied* registers have the same value in the *intermediate* and *ultimate* program. This invariant does not hold for registers in the *gen*, *ready* and *unrel* states. Therefore, they should never be used as the input for any instruction other than the next instruction in the offset construction cycle, respectively steps (b) and (c) in Figure 4. Note that state machine transitions are a specific instruction category in Cascade, as enumerated in Appendix A.

5.2 Privilege transitions

Exceptions are a particular case of hopping instructions. They require some basic bookkeeping in the fuzzer to maintain the privilege state and delegation flags, which indicate the target privilege level active when some exception occurs.

We use one to two offset/dependent/applied register triples per exception. The first is used to populate the trap vector, either `mtvec` or `stvec`, depending on the current privilege state and whether the exception will be delegated. The second is used when an exception depends on a register value, e.g., in

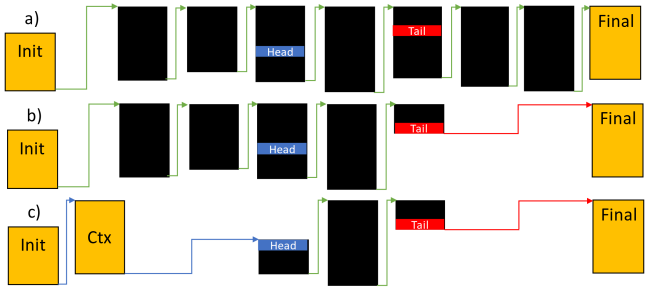

Figure 5: (a) Original, (b) tail-reduced and (c) fully reduced program. Black rectangles and arrows represent basic blocks and control flow. Ctx is the context setter block.

a misaligned memory load exception. It is populated similarly as an indirect jump or a load would be. Note that since basic blocks are generated on the fly, the value to be inserted into the trap vector is only known when the exception-triggering instruction is generated, which may be many basic blocks later; while this adds some necessary complexity to the fuzzer, it does not negatively affect the program's degrees of freedom in any way. The implementation of downward privilege transitions is in all respects comparable with exceptions.

6 Program Reduction

Cascade generates potentially long test cases, and CPU bugs are revealed by programs not terminating, thanks to the entanglement of the data and control flows. To understand the underlying CPU bug, it is necessary to reduce the programs to a minimal form, while preserving the instructions and states that trigger the CPU bug. We first show how to find the last instruction (*tail*) involved in triggering the bug, then the first (*head*). Figure 5 illustrates the program reduction process.

6.1 Identifying the bug's tail

We propose to reduce the program progressively by transforming some instructions into direct jumps that skip some of the last basic blocks and observing whether the bug is still triggered. The result is illustrated in Figure 5 (b).

Identifying the tail basic block and instruction. Cascade finds via a binary search the last basic block which, when omitted along with its successors, erases the buggy behavior. To remove such a final sequence, Cascade replaces its predecessor's hopping instruction with a direct jump toward the final block. Cascade then searches the bug's tail instruction in the converse way.

Failing control-flow instructions. If the tail instruction is a hopping instruction, the algorithm above will find a tail basic block B_n, but no tail instruction. This is because for skipping the basic block B_n but not B_{n-1}, a direct jump instruction toward the final block will replace the (bug-triggering) hopping instruction of B_{n-1}, hence removing B_n erases the buggy behavior. The tail instruction being a hopping instruction is hence the necessary and sufficient condition for failing.

6.2 Identifying the bug's head

Most often, a single instruction, provided with the correct architectural context, is sufficient to trigger the bug reliably. In such cases, finding the tail instruction is enough to understand the bug. However, some bugs required a sequence of instructions (up to 2), possibly far apart, to be triggered, such as the bugs V1-V9 and V14 that we describe in Section 7, because they rely on a specific microarchitectural context. Hence, for these bugs, identifying the head is necessary. The result of this step is illustrated in Figure 5 (c).

Maintaining the architectural context. Identifying the tail instruction can be done by exclusively inserting direct jump instructions in the right places iteratively, but identifying the head instruction is more challenging because removing predecessor instructions ahead may influence the architectural state. We leverage the following insight to identify the bug's head: we find the head by preserving the architectural state but simplifying the microarchitectural state. Concretely, only for this step, a *context setter* basic block is inserted, by replacing the initial block's hopping instruction. Once a candidate head basic block and instruction is chosen, the context setter uses the ISS to infer the architectural context, including for instance register values, privilege level and some performance counter values. It then loads the architectural state of the CPU, using simple instructions such as wide loads for register values, and basic instruction sequences for populating CSRs and setting the proper privilege. The detection of the bug's head is then performed similarly to the tail, following the converse algorithm where the head instruction is the first instruction that, when omitted, erases the buggy behavior.

Sandwich instructions. For all bugs found by Cascade so far, identifying the tail and head instructions has always been sufficient for understanding and reproducing the bugs. However, Cascade includes facilities to flatten the remaining instructions (in black in Figure 5 (c)) and removing them iteratively. Such transformations are not guaranteed to work on a given specific program, for example if the hopping instruction was an exception and some following instruction checks the exception cause. In practice, finding another program that reveals the same bug in case of failure of advanced transformations is sufficient, notably because finding new programs that trigger the same bug is fast, as we show in Section 7.6.3.

7 Evaluation

In this section, we evaluate Cascade in terms of performance, program metrics, coverage, and the discovered bugs. We

use microbenchmarks to quantify the performance of program construction and compare it with previous work (Section 7.1). We evaluate the impact of program lengths on fuzzing throughput (Section 7.2). We then evaluate the program metrics for Cascade (Section 7.3) as we did for DifuzzRTL in Section 3.1. We compare the coverage achieved by Cascade according to multiple coverage metrics and compare it with the state-of-the-art fuzzers that specifically target these metrics (Section 7.4). We then show the bug discovery efficacy of programs of different lengths (Section 7.5). We also describe the 37 new bugs found in 5 of the 6 evaluated RISC-V CPUs and in Yosys, evaluate the time to detection (Section 7.6) and provide a full list in Appendix D. Finally, we evaluate the performance of program reduction (Section 7.7).

Evaluation setting. The performance results were obtained on a machine equipped with two AMD EPYC 7H12 processors at 2.6 GHz containing 256 logical cores and 1 TB of DRAM. We use Verilator 5.005 to simulate the CPUs' RTL. As an ISS, we use spike (version 1.1.1-dev, commit `fcbdbe79`). We use a recent version of a widely-used commercial simulator to collect simulator-based coverage similar to previous work [35]. We use the most recent versions of each CPU, where bugs are fixed or circumvented by Cascade. Appendix B provides detailed information about these designs. Notably, we tested Cascade on a variety of CPU complexities, from a simple minimal 32-bit integer core (PicoRV32) to an application-class Linux-capable out-of-order core (BOOM). We implemented Cascade as 6 k lines of Python code.

Baselines. We compare with the existing open-source generic CPU fuzzers, which are RFUZZ [36] and DifuzzRTL [32]. Despite the claim made in the original paper [35], TheHuzz is not open source at the time of this writing, and its authors were reluctant to answer any question or share their code over a period of a year, hence we rely on the results reported in their paper [35]. We re-implemented RFUZZ to support Verilog, and relied on the Docker image provided by DifuzzRTL [31].

7.1 Program generation performance

To quantify the performance of program construction, we measure the amount of time spent in intermediate program construction, asymmetric ISA pre-simulation and RTL simulation, for each CPU under test, over 24 hours of fuzzing. Figure 6 shows the results.

Results. While by construction, the duration of the instruction generation and asymmetric ISA pre-simulation is identical across designs, the RTL simulation time increases with the complexity of the design, hence the proportion of time spent generating programs largely decreases with the complexity of the designs. When generating the programs in real time, the program generation takes between 26.5% and 78.9% of the total fuzzing time.

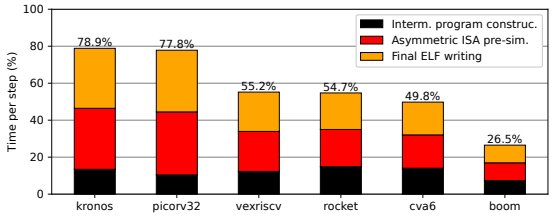

Figure 6: Performance of program construction. The rest of the time is spent in the RTL simulation.

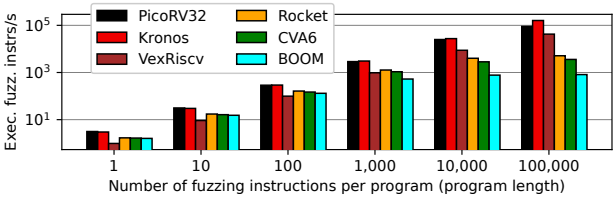

Figure 7: CPU-under-test execution throughput given program length. Note the logarithmic Y axis.

Input reuse. To make Cascade's evaluation as pessimistic as possible, we systematically dynamically generate new inputs by default. Note that by construction, Cascade's inputs are reusable across designs that share compatible ISA extensions, and across CPU generations. Hence the input generation is, in fact, a one-time cost that can further be amortized.

Runtime overhead. DifuzzRTL reports a runtime overhead of 6.1% to 6.9% for control register coverage, and 97% for multiplexer select coverage. TheHuzz reports a runtime overhead of 71% These slowdowns do not include input generation. Cascade incurs no runtime overhead by design.

7.2 Throughput of long programs

To understand the throughput boost provided by long programs, we measure the number of fuzzing instructions executed per second when controlling the number of instructions per program generated by Cascade, including program generation time. The experiment was run for 1 core-hour per bar. Figure 7 shows the throughputs of program execution, while Figure 8 details the average duration of a single program generation. Constructing very long programs requires managing a wider memory range, resulting in longer program generation times. Consequently, the overhead of generating longer programs counteracts the improvements in terms of fuzzing throughput when programs become too large.

To find the sweet spot for the length of programs, Figure 9 shows that the effective fuzzing throughput when considering both the raw fuzzing throughput and the overhead of program generation at the same time. These results show that programs of 10 k instructions generally provide the best effective fuzzing throughput, and that the fuzzing throughput is improved by three orders of magnitude between single-instruction and 10 k-instruction programs.

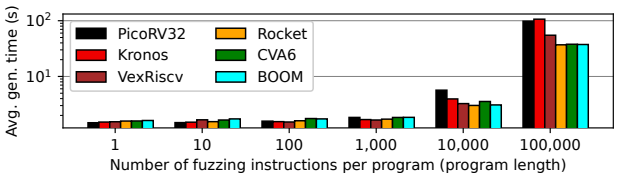

Figure 8: Program generation performance given program length. Note the logarithmic Y axis.

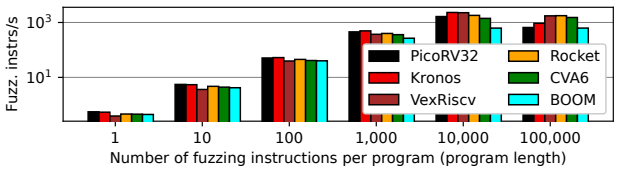

Figure 9: Effective fuzzing throughput given program length. Note the logarithmic Y axis.

7.3 Program metrics

As part of our initial observations in Section 3, we exposed the completion and prevalence program properties. We evaluate these metrics for Cascade. We additionally evaluate the length of dependency chains between fuzzing instructions, which matters for non-termination when a bug is triggered.

Prevalence and completion for Cascade. Since Cascade always completes except when finding a CPU bug, we observe the expected completion rate of 100%. Figure 10 shows the prevalence of fuzzing instructions for Cascade. The high prevalence is because programs are relatively long and fully randomized except the initial and final basic blocks.

Dependencies. We analyze dependency chains between fuzzing instructions. On top of entangling the data flow with the control flow to force non-termination when a bug is triggered, these dependencies can further exercise corner cases inside a CPU's design. For this analysis, we calculate the length of instruction dependency chains. Each register starts with a dependency number of -1, which gets reset when it is a destination of a CSR read or of an instruction that only takes immediates. We calculate an instruction's dependency number as the maximum of the dependency numbers of the source registers, plus one, which also becomes the new dependency number of the destination register.

Figure 11 and Figure 12 show the distribution of the length of the dependency chains for DifuzzRTL and Cascade, respectively. The fuzzing instructions with zero dependencies here are instructions in the form of `xor rd, rd, rd`. The programs generated by DifuzzRTL have very few interdependencies. Similarly, TheHuzz does not explicitly generate or favor programs with dependencies [35], hence we expect even lower numbers. In contrast, Cascade generates programs with longer dependency chains, which could further be improved if needed by lowering the probabilities of picking dependency-resetting instructions such as CSR reads.

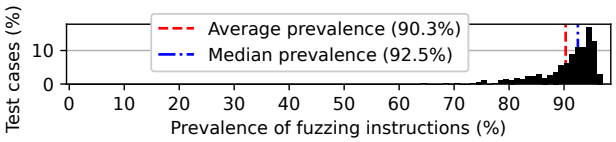

Figure 10: Prevalence of fuzzing instructions for Cascade.

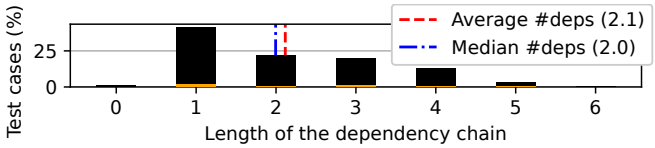

Figure 11: Length of the dependency chains for DifuzzRTL. Control-flow instructions are represented in orange.

7.4 Coverage evaluation

We show that Cascade is faster in increasing coverage compared to the state-of-the-art fuzzers with their own coverage metrics. We consider the open-source coverage metrics used for fuzzing (i.e., multiplexer select and control register coverage). To compare with the results reported by TheHuzz [35], we additionally consider the coverage metrics provided by the commercial simulator (branches, conditions, expressions, FSM states and transitions, statements, and toggles).

7.4.1 Control register coverage (DifuzzRTL)

We first compare the control register coverage of Cascade with the one achieved by DifuzzRTL, which explicitly aims at maximizing this coverage. DifuzzRTL supports legacy versions of Rocket and BOOM. Running Cascade on this BOOM version leads to quasi-systematic timeouts, revealing old bugs in the obsolete BOOM RTL. Hence, we executed all test cases on the legacy Rocket core provided in the Docker image [31], which was already exempt of unexpected bugs.

Results. Figure 13 shows the control register coverage achieved by Cascade and DifuzzRTL. Cascade achieves more coverage than DifuzzRTL, in a shorter time. In particular, Cascade achieves the same coverage in 30 minutes (15 minutes when using a pre-generated corpus) as DifuzzRTL in 48 hours, which is a speedup of 97x (respectively 186x).

7.4.2 Multiplexer select coverage (RFUZZ)

We now compare the multiplexer select coverage achieved by Cascade with the one achieved by RFUZZ. We adapted RFUZZ as a sequence of Yosys [60] passes to support Verilog, more general than FIRRTL [33], and ensured that the results match with the original open-source implementation. We will open-source the instrumentation code to foster further research. We execute Cascade on the RFUZZ-instrumented versions of the designs as well. We execute the RFUZZ experiments until completion, i.e., as implemented in the original RFUZZ fuzzer, when all input sequences in the adherence

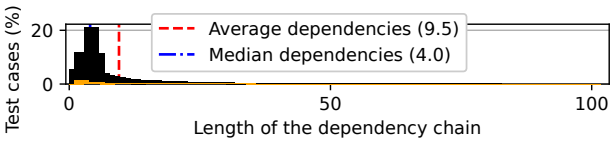

Figure 12: Length of the dependency chains for Cascade. Control-flow instructions are represented in orange. Fuzzing instructions depended on up to 270 other fuzzing instructions.

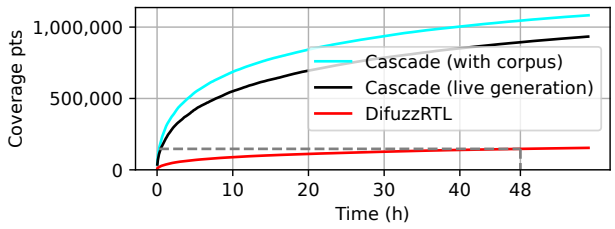

Figure 13: Achieved control register coverage.

to the corpus cease to increase coverage. We had to exclude CVA6 because of the Yosys bug found by Cascade.

Results. Figure 14 shows the multiplexer select coverage achieved by Cascade and RFUZZ. First, in terms of coverage, for the two simpler designs, RFUZZ is a bit slower than Cascade (note that in this experiment, Cascade also suffers from the runtime overhead due to the instrumentation), but eventually achieves a superior coverage. Since RFUZZ is a lower-level fuzzer, it is expected to be able to toggle some more multiplexer signals eventually, for example by fuzzing the bus protocol, whereas an ISA-level fuzzer like Cascade and many others [8, 9, 14, 30, 32, 34, 35] will not explore these state machines. However, as soon as CPUs become more complex, RFUZZ is unable to make any progress.

Second, regarding delay, the order of magnitude to saturate coverage for Cascade is approximately 100 seconds, which corresponds to its order of magnitude for finding bugs as we show later. This suggests that, although a naive RFUZZ implementation seems inadequate to finding bugs in CPUs, especially when they are complex, its coverage metric seems relevant to evaluating the quality of a fuzzing campaign.

7.4.3 Simulator-based coverage (TheHuzz)

We compare the simulator-based coverage achieved by Cascade with the one reported by TheHuzz. We reproduce the experiment from TheHuzz that led to their Figure 5 [35]. We compare the simulator coverages of Cascade and DifuzzRTL, and use DifuzzRTL as a pivot to compare with TheHuzz. Note that to fit the methodology of TheHuzz, both DifuzzRTL and Cascade rely on pre-generated corpuses in this experiment.

Results. Figure 15 shows a per-instruction speedup of Cascade over DifuzzRTL of 27x for the simulator-collected coverage, while TheHuzz reports a speedup of 3.33x. Since TheHuzz reports a runtime slowdown of 71%, Cascade is 28.2x faster than TheHuzz on TheHuzz's target coverage metric.

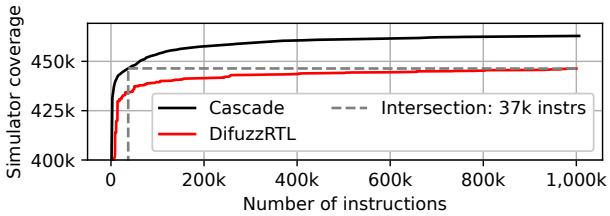

Figure 15: Simulator-collected coverage per instruction of Cascade and DifuzzRTL. Note that the y-axis starts at 400k.

7.5 Efficacy of long programs

To better understand the influence of program length on the efficacy of finding bugs, we enforce the number of fuzzing instructions per program, fuzz on 64 cores and report the bug discovery times in Figure 16. Even limited to a single fuzzing instruction, Cascade discovers C8-C9 in a core-hour, undetected by TheHuzz [35] and HypFuzz [14]. Yet clearly, longer programs are more efficient at finding bugs. Also note that some bugs are hard to separate for this measurement, in particular C2-C7 and C10, and may overlap. The bug found only by the longest programs in 24 core-hours is K3.

7.6 Bug discoveries

Cascade discovered 37 new bugs in 5 CPUs and 1 bug in the Yosys synthesizer. Figure 17 classifies the new bugs in six categories, and Appendix D provides more information in terms of description, CWEs and CVEs. We first analyze the discovered bugs and their security implications, and then evaluate the bug detection performance of Cascade.

7.6.1 Bug descriptions

Exceptions. Cascade discovered 11 exception-related bugs in 4 designs, which we define as missing or spurious exceptions. For example, in VexRiscv, interactions with a disabled

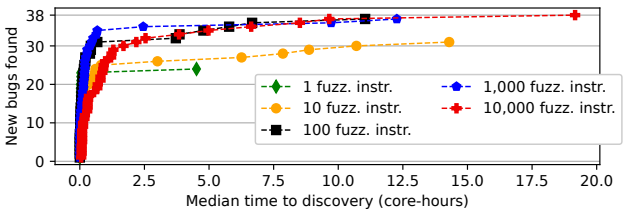

Figure 16: Time to reveal each bug when fuzzing with fixed numbers of instructions on 64 cores.

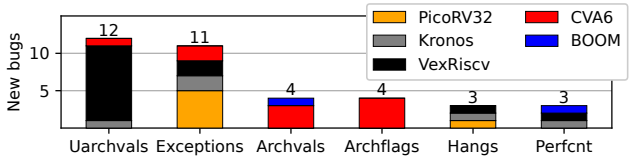

Figure 17: Discovered CPU bugs. Exceptions: missing or spurious exceptions. Uarchvals: wrong computations under microarchitectural conditions. Archvals: systematic wrong computations. Archflags: wrong status flags. Hangs: CPU hangs. Perfcnt: wrong performance counter values

FPU are wrongly permitted (V10, V11). In Kronos, writes to a non-existent CSR fail to trigger an exception (K3). In PicoRV32, Kronos and CVA6, spurious exceptions may be triggered by some CSR accesses (P2-P5, C8-C9) or incorrectly decoded valid instructions (P6, K5).

Microarchitectural-state-dependent wrong computations. Cascade discovered 12 bugs that produce wrong computations under certain microarchitectural conditions (*Uarchvals*) in Kronos and VexRiscv. In Kronos, a bug in the hazard detection unit (K1) causes, under some conditions, wrong register forwarding in a read-after-write-after-write double-hazard, where it forwards the first written value instead of the second. In VexRiscv and CVA6, wrong calculations occur under some microarchitectural FPU conditions (V1-V9, V14, C10). Such bugs are often hard to fix. Indeed, the VexRiscv maintainers proposed a fix, which solved most of the occurrences, but Cascade discovered a way to tamper with the FPU's microarchitectural state again with a different approach (V8, V9, V14), which has ultimately been fixed by the maintainers.

Systematic wrong computations. Cascade discovered 4 bugs in BOOM and CVA6 that produce wrong output values regardless of the microarchitectural state (*Archvals*). In BOOM, double-precision divisions and square roots ignore the (immediate) static rounding mode (B1). In CVA6, we found two wrong output sign bugs (C1, C6), and one unexpected infinity bug (C7).

Systematic wrong flags. Cascade discovered 4 incorrect flag bugs in CVA6 (*Archflags*) (C2-C5). Since flags are typically used to guide a control flow, emitting FPU operations that will set flags incorrectly may provide an illegitimate control flow influence. Such bugs are difficult to fix. The CVA6 maintainers contacted us to test a fix, which we found to fix some bug (C2), but preserving another (C3).

Hangs. Cascade discovered 3 bugs that cause hangs in Kronos, PicoRV32 and VexRiscv (V12, P1, K2). In PicoRV32, the hang is systematic for accessing some CSR addresses. The hang in Kronos, also related to CSR access, depends on the microarchitectural state. The hang in VexRiscv is achievable when speculatively executing an illegal compressed floating-point instruction and later executing a legitimate floating-point instruction: microarchitectural resources are reserved but are never released, which results in a deadlock. The latter bug is similar to the recently-discovered Zenbleed bug [39], where an architectural bug leaves traces after speculation.

Performance counter inaccuracies. Cascade discovered 3 inaccurate performance counter bugs (*Perfcnts*) in Kronos, VexRiscv and BOOM (K4, V13, B2). They incur an offset in the retired instruction counters when written by software.

Yosys logic synthesizer bug. Yosys [60] is a popular open-source logic synthesizer, which is typically used for instrumenting a CPU [32, 36, 48, 54]. It may also be used to part of an emulation or ASIC flow. Cascade found a bug (Y1) that leads to incorrect logic synthesis of CVA6's FPU.

Other findings. Besides discovering new bugs in CPUs and in Yosys, Cascade found known bugs in CVA6, and the performance counter inaccuracy in Rocket discovered by DifuzzRTL and reported by TheHuzz and HypFuzz [14, 32, 35].

Additionally, Cascade found two issues related to X over-propagation in VexRiscv (shadowing of RTL logical signals by undefined values [33, 56]), which may happen under some conditions. First, some uninitialized instruction cache lines can enter the pipeline and pollute signals. Second, in case of FPU underflow, a hardware table is accessed with a too large index. HypFuzz [14] discusses the implications of such vulnerabilities when describing their third vulnerability [14].

7.6.2 Security implications

We classify the security implications of the discovered bugs into six categories, as presented in Figure 19. The same bug may belong to more than one category.

Data-flow integrity. We define data-flow integrity bugs as allowing a malicious time-shared user to cause a victim entity to execute computations with a wrong result. Cascade found 12 such bugs, where preparing the (micro)architectural state can cause wrong computations (V1-V9, V14, K1, B1). For example, exploiting the BOOM dynamic rounding bug (B1), an attacker process can force a victim process to take a different floating-point rounding mode than expected.

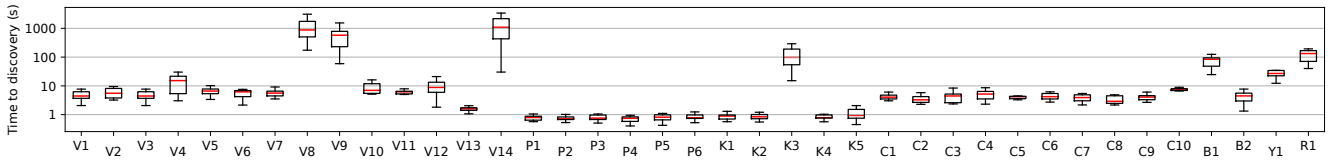

Figure 18: Time to reveal each bug when fuzzing on 64 processes. R1 is the known instruction counting bug in Rocket. Note the logarithmic scale. Bugs are labeled as follows: B (BOOM), C (CVA6), K (Kronos), P (PicoRV32), V (VexRiscv), and Y (Yosys).

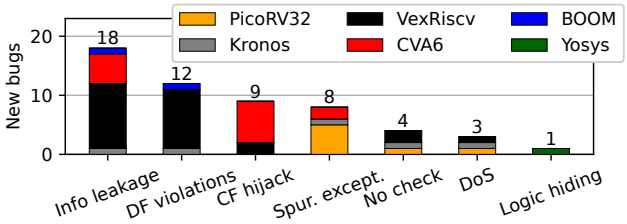

Figure 19: Security implications of discovered bugs. Note that some bugs belong to more than one category.

Information leakage. Sources of information leakage are many. For example, data-flow integrity bugs may also enable information leakage in the opposite direction, from the victim to an attacker running on the same core. So do bugs that illegally set some flags (C2-C5), and some unauthorized accesses (V10, V11), creating core-local side channels.

Control-flow hijack. Cascade found 9 bugs that let an attacker process influence the control flow of a victim process (C1-C7, V5, V6). For example, CVA6 sets wrong flags in diverse situations (C2-C5) and produces wrong finitude or sign results (C1, C6, C7), which typically influence the control flow. Concretely, we found that the inexact flag is not set in some cases of underflow or overflow (C4), preventing some potential security checks. On VexRiscv, the microarchitecture can be prepared to corrupt comparisons, for example making two equal registers be considered distinct (V5, V6). This preparation must be done by a process on the same core.

Spurious exceptions. Cascade found 8 spurious exception bugs (P2-P6, K5, C8, C9), which break isolation boundaries from higher privilege levels, for example, in the context of trusted execution environments. For example, in PicoRV32, reading some mandatory CSRs causes exceptions (P2), hence, a malicious machine could give the illusion that they are accessible, but actually the machine solely emulates the interactions, providing arbitrary values.

Missing checks. Cascade found 4 missing checks, with several implications. First, they may permit to bypass security checks (V10, V11), problematic, for example, if the FPU is time-shared with other cores. Second, they can deceive a victim to believe that a feature is supported (K3, P5). They can additionally be exploited to escape program analysis, where supposedly dead code is shadowed by an exception.

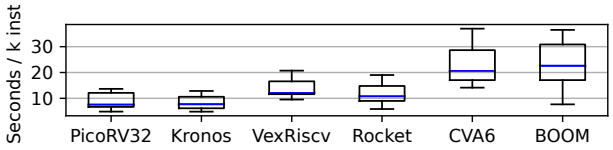

Figure 20: Program reduction performance.

Denial of service. All the hangs that we found (V12, P1, K2) can happen at any privilege level, leading to DoS attacks.

Logic hiding. Using the discovered Yosys bug (Y1), a malicious contributor can inject bugs into a design while submitting an apparently innocuous RTL design, by transforming the RTL into an equivalent one that will trigger Y1 accordingly.

7.6.3 Bug detection performance

We fuzz on 64 processes for 24 hours and summarize the time to discover each bug in Figure 18, where we repeated the discovery 10 times with different seeds. Note that some bugs are hard to separate for this experiment, in particular C2-C7 and C10, and may overlap. In most runs, bugs are discovered in less than 18 core-hours (17 minutes). Design and bug complexities influence the discovery time.

7.7 Program reduction performance

We evaluate the performance of Cascade's program reduction. Since all designs still have at least one non-fixed bug (V14, P6, K4, C9, B2 and R1), we focus on them for this analysis. We run the fuzzer to collect 100 programs that trigger the bug in each design. Then, we perform the program reduction on these programs, and measure the time required to reduce each program and normalize it by the number of instructions in the program, including the initial and final blocks.

Results. Some program reductions could fail, e.g., because a load instruction would target the hopping instruction of a basic block preceding a candidate tail block during the reduction phase and its result would propagate to the control flow. Experimentally, we did not observe such failures. Figure 20 shows the time to reduce each program, normalized by the length of the program. program lengths varied between 193 and 62,870 instructions. The timeout upper bound, conservatively set to $30 \times n_{instructions} + 1000$ cycles, influences program reduction performance. In this specific experiment, all programs were reduced to a single instruction.

8 Discussion

We discuss porting Cascade to other ISAs and limitations of coverage metrics used by the state-of-the-art CPU fuzzers.

Adaptations to other ISAs. While the fundamentals of Cascade's approach comply with most widespread ISAs, its current implementation is RISC-V-specific. Adaptation to RISC ISAs such as ARM and MIPS requires ISS and instruction generator adaptations. We expect porting Cascade to CISC ISAs to be more challenging due to more instructions.

Coverage metrics. The coverage metrics used by the state-of-the-art CPU fuzzers such as TheHuzz [35] and DifuzzRTL [32] are dominated by ineffective terms while introducing runtime overhead. For TheHuzz, toggle coverage represents around a million points and 89% of the achievable points on Rocket. Given that TheHuzz considers the sum of all coverage points of all types, any mutation that would produce such a single new toggle would be considered as discovering new coverage. Limitations of such simple metrics are well-known [53], yet the more powerful alternative, functional coverage, requires significantly more effort [7]. This explains why HypFuzz, building on the same metric as TheHuzz, found a single new bug (see Appendix C). DifuzzRTL defines control registers as registers which control a multiplexer inside the same HDL module. This coverage metric continues to increase when exploring registers whose fanout multiplexers already took all values. Ultimately, DifuzzRTL optimizes for exploring an immense number of combinations of values for registers that are mainly arbitrarily selected [12].

9 Related Work

In the recent years, hardware fuzzing has flourished. We first cover generic hardware fuzzers, then CPU fuzzers.

Generic hardware fuzzers. RFUZZ [36] is a generic hardware fuzzer that relies on multiplexer control signals to generate inputs based on AFL [29]. DirectFuzz [10] targets RFUZZ toward specific modules. Trippel et al. [55] proposed to fuzz the hardware simulation binary itself, using software fuzzing methods. Ruep et al. [43] proposed a fuzzer for SpinalHDL designs. Li et al. [37] proposed a new coverage metric for fuzzing. Ragab et al. [41] proposed a distance-to-target feedback metric to direct fuzzers towards specific targets. None of these publications reported the discovery of any bugs.

CPU fuzzers. Many active open-source repositories rely on testing tools, such as the RISC-V compliance suite [46], which generates basic unit tests, and RISCV-DV, a UVM-based testing framework based on commercial simulators [2]. To address their insufficiencies, several projects proposed fuzzing CPUs. DifuzzRTL [32] generates instructions and collects control register coverage to guide the fuzzing process and discovered 16 new bugs. Its source code, while relying on obsolete languages, is available for fuzzing legacy versions of Rocket and BOOM [31]. ProcessorFuzz [12] is a concurrent work that generates instructions and collects coverage of control and status registers on the ISS and reported the discovery of 9 new bugs (see Appendix C), including 7 on BlackParrot, maintained by certain authors of ProcessorFuzz. Kabylkas et al. present Dromajo and Logic Fuzzer [34] and report the discovery of 13 new bugs, including 4 with the help of Logic Fuzzer. Bruns et al. [8] exploited ISS coverage to find new VexRiscv bugs. Similarly, Herdt et al. [30] exploited ISS coverage to find 10 new bugs in their own core. N. Bruns et al. [9] generate an infinite instruction stream on the memory channel to find a bug in their own core. Such an infinite instruction stream is known to cause compatibility issues due to strong microarchitectural assumptions [8]. Kande et al. [35] proposed TheHuzz, based on commercial RTL simulator coverage feedback, and fond 7 new bugs. Chen et al. [14] proposed a technique to speed up the coverage obtained by TheHuzz and found one new bug (see Appendix C). Cascade is the first fuzzer to take a constructive approach to tackle the observations and challenges exposed in Section 3.

10 Conclusion

We presented Cascade, a CPU fuzzer based on the explicit construction of intricate RISC-V programs. Cascade is effective: it finds 37 new bugs on 5 RISC-V CPUs with varying degrees of complexity and vastly outperforms the state-of-the-art coverage-guided CPU fuzzers. What sets Cascade apart from the state of the art is its ability to efficiently construct long complex programs that enable high-throughput CPU fuzzing while terminating by design. Any non-termination signifies the discovery of a bug in the target CPU. We described how Cascade generates its programs using a new technique, asymmetric ISA pre-simulation, which enables Cascade to efficiently entangle an arbitrarily-complex control flow with an arbitrarily-complex data flow. Since the bug-triggering programs generated by Cascade may be long and complex, we introduced a new technique for program reduction transforming a program to the only few instructions that trigger the CPU bug.

Ethical considerations. We reported all bugs to their respective maintainers, and proposed fixes when our understanding of the language and design was sufficient.

Acknowledgements

The authors would like to thank the anonymous reviewers for their valuable feedback, Tobias Kovats for his contribution to RFUZZ re-implementation, and the maintainers of the designs we tested for their support in understanding and fixing some of the bugs. This work was supported in part by a Microsoft Swiss JRC grant and by the Swiss State Secretariat for Education, Research and Innovation under contract number MB22.00057 (ERC-StG PROMISE).

A Instruction Categories

The instruction categories used in Cascade are the following: REGFSM (Register lifecycle), FPUFSM (Update the FPU state), ALU (rv32 ALU operations), ALU64 (rv64 ALU operations), MULDIV (rv32 multiplications and divisions), MULDIV64 (rv64 multiplications and divisions), AMO (rv32 atomics), AMO64 (rv64 atomics), JAL (Direct jumps), JALR (Indirect jumps), BRANCH (Branches), MEM (rv32 integer memory operations), MEM64 (rv64 integer memory operations), MEMFPU (rv32 floating memory operations), FPU (rv32 floating-point operations), FPU64 (rv64 floating-point operations), MEMFPUD (rv32 double memory operations), FPUD (rv32 double operations), FPUD64 (rv64 double operations), TVECFSM (Update trap vector), PPFSM (Update previous privileges), EPCFSM (Update trap previous PC), MEDELEG (Update exception delegation), EXCEPTION (Trigger an exception), RDWRCSR (Read/write some CSRs), DWNPRV (Transition privileges downward), FENCES (Fences or `wfi`).

B CPUs under Test

Our testbench consists of 6 RISC-V CPUs of varying complexities and ISA extensions. VexRiscv [50] (`e142e12`, Linux, AHB-L, FPU, rv32imfd) is a highly parametrable CPU written in SpinalHDL, supporting Linux. PicoRV32 [61] (`f00a88c`, Default, rv32im) is a size-optimized CPU written in Verilog (IEEE 1364-2005). Kronos [49] (`13678d4`, Default, rv32i) is a CPU optimized for FPGA applications, written in SystemVerilog (IEEE 1800-2017). CVA6 [62] (`109f9e9`, 4-way 8 kB caches, rv64imafd) is an application-class CPU with Linux support supported by the OpenHW Group organization, and written in SystemVerilog (IEEE 1800-2017). Rocket [3] (`004297b`, BigCore, rv64imafd) is a reference application-class CPU with Linux support, maintained by the Chips Alliance, written in Chisel. BOOM [5] (`004297b`, MediumBoom, rv64imafd) is an out-of-order application-class CPU with Linux support, maintained by the Chips Alliance, written in Chisel.

C Considerations of Previous Fuzzing Claims

In this appendix, we correct some claims from previous work and underline that an ISS-CPU mismatch is not always a bug. In TheHuzz [35], it is considered as a bug (B4) that CVA6 does not throw an exception when executing self-modifying code without `fence.i`. RISC-V does not specify any behavior in this case, hence this is a feature request and not a bug. In HyPFuzz [14], their vulnerability V2 was later denied by the CVA6 maintainers [13], and V3 is not a bug [52]. Since V3 is not a bug, we naturally did not count similar occurrences as bugs in the evaluation of Cascade (see Section 7.6.1). Conclusively, HypFuzz only describes a single new bug. In the archived version of ProcessorFuzz [11], Bug 10 is not a bug but a feature request, because the described behavior is explicitly permitted by the RISC-V specification.

D Enumeration of Discovered Bugs

Table 1 shows the bugs we found in the three designs, the corresponding CWEs and CVEs.

Concurrent findings. After a first bug report campaign, we submitted some new bug reports that were, in the meanwhile, concurrently found by the VexRiscv maintainer. These bugs are V10 and V11. From existing github issues, it cannot be excluded that symptoms of C1 had been noticed in the past. However, the root cause was clearly not understood, until Cascade and its analysis facilities allowed us to propose a fix, that has been approved and merged by the maintainers.

Table 1: Bug Report Table.

Design	Id	Bug Description	CWE	CVE	Sev.
VexRiscv	V1	Non-deterministic conversion from single-precision float to int	681	2023-34885	4.9
	V2	`fmin` with one NaN does not always return the other operand	193	2023-34885	4.9
	V3	Conversion from double to float may pollute the mantissa	681	2023-34885	4.9
	V4	Dependent arithmetic/muldiv FPU operations may yield incorrect results	193	2023-34885	4.9
	V5	Equal registers may be considered distinct by `fle.s` and `feq.s`	697	2023-34885	4.9
	V6	`flt.s` may return 1 when operands are equal	697	2023-34885	4.9
	V7	Under some microarchitectural conditions, square root may be imprecise	1339	2023-34885	4.9
	V8	Single-precision muldiv followed by conversion may pollute the mantissa	681	2023-34891	4.9
	V9	Dependent arithmetic/muldiv operations may cause largely wrong output	682	2023-34891	4.9
	V10	Operations on floating-point registers are authorized when FPU is disabled	1189	2023-34885	4.9
	V11	Wrong access control to the FPU flags leaks information	1189	2023-34892	4.9
	V12	Hang on speculatively executed compressed FPU instructions	1342	2023-34896	7.7
	V13	Inaccurate instruction count when `minstret` is written by software	684	2023-40063	3.6
	V14	Some register comparisons are still incorrect despite a partial fix	697	2023-34885	4.9
PicoRV32	P1	Accessing a non-implemented CSR causes the CPU to hang	1281	2023-34898	4.6
	P2	Spurious exceptions when reading mandatory CSRs	1281	2023-34897	2.6
	P3	Performance counters are not writable	284	2023-34900	2.6
	P4	Performance counters can only be read using some opcodes	284	2023-34914	2.6
	P5	Performance counter addresses are incorrect	684	2023-34913	2.6
	P6	Spurious exception when decoding `fence` instructions	705	2023-34899	5.0
Kronos	K1	RaWaW double-hazard may cause a wrong register value to be forwarded	226	2023-34902	6.6
	K2	Reading existing CSRs causes the CPU to hang in some uarch conditions	1281	2023-34901	7.1
	K3	In some uarch conditions, no exception when writing inexistent CSRs	1281	2023-42310	2.6
	K4	Inaccurate instruction count when `minstret` is written by software	684	2023-40066	3.6
	K5	Incorrect decode logic for `fence` and `fence.i`	684	2023-34903 2023-40064	5.0 5.0
CVA6	C1	Double-precision multiplications yield wrong sign when rounding down	682	2023-34904	4.4
	C2	Single-precision floating-point operations may treat NaNs as zeros	684	2023-34906	5.1
	C3	Division by NAN incorrectly sets NX and NV fflags	684	2023-34905	5.1
	C4	The inexact (NX) flag not set in case of overflow or underflow	684	2023-34907	5.1
	C5	Division of zero by zero incorrectly sets the DZ flag	684	2023-34909	5.1
	C6	Plus and Minus infinity microarchitectural structures are inverted	1221	2023-34910	4.4
	C7	Infinities are not rounded properly and stick to infinity	1339	2023-34911	4.4
	C8	Spurious exceptions when reading some performance counters	684	2023-34911	5.0
	C9	Wrong supervisor performance counter access control	684	2023-42311	5.0
	C10	Under some microarchitectural circumstances, wrong NAN conversion	682	2023-34908	5.1
BOOM	B1	Static rounding is ignored for `fdiv.s` and `fsqrt.s`	1339	2023-34882	6.5
	B2	Inaccurate instruction count when `minstret` is written by software	684	2023-40065	3.6

Abstract

Rapid embedded device proliferation is creating new targets and opportunities for adversaries. However, the complex interactions between firmware and hardware pose challenges to applying automated testing, such as fuzzing. State-of-the-art methods re-host firmware in emulators and facilitate complex interactions with hardware by provisioning for inputs from a diversity of methods (such as interrupts) from a plethora of devices (such as modems). We recognize a significant disconnect between how a fuzzer generates inputs (as a monolithic file) and how the inputs are consumed during re-hosted execution (as a stream, in slices, per peripheral). We demonstrate the disconnect to significantly impact a fuzzer's effectiveness at discovering inputs that explore deeper code and bugs.

We *rethink* the input generation process for fuzzing monolithic firmware and propose a new approach—*multi-stream input generation and representation*; inputs are now a collection of independent streams, one for each peripheral. We demonstrate the versatility and effectiveness of our approach by implementing: i) stream specific mutation strategies; ii) efficient methods for generating useful values for peripherals; iii) enhancing the use of information learned during fuzzing; and iv) improving a fuzzer's ability to handle roadblocks. We design and build a new fuzzer, MULTIFUZZ, for testing monolithic firmware and evaluate our approach on synthetic and real-world targets. MULTIFUZZ passes all 66 unit tests from a benchmark consisting of 46 synthetic binaries targeting a diverse set of microcontrollers. On an evaluation with 23 real-world firmware targets, MULTIFUZZ *outperforms* the state-of-the-art fuzzers Fuzzware and Ember-IO. MULTIFUZZ reaches significantly more code on 14 out of the 23 firmware targets and similar coverage on the remainder. Further, MULTIFUZZ discovered 18 *new* bugs on real-world targets, many thoroughly tested by previous fuzzers.

1 Introduction

With the availability of lower cost, lower power and smaller computing devices, we are witnessing a proliferation in *smart* devices. Now, microcontrollers running firmware are becoming integral components of safety and security critical systems. Firmware on embedded systems integrates and interacts with a diverse set of peripheral devices, such as modems or serial ports, while managing communications with the user, often without any supervisory control from an operating system. *Importantly*, the lack of supervisory control reduces the ability to detect faults and abort in a controlled manner [38] with potential safety and security implications. So, a scalable and automated method to identify software bugs and vulnerabilities before public release is a research and societal imperative.

Fuzzing is a de-facto industry standard for software testing and can play a crucial role in developing secure connected devices through scalable and automated testing of firmware. To test software, fuzzers automatically generate and execute inputs to uncover unusual program behavior. However, the unique characteristics of embedded devices and their firmware present challenges for adopting fuzzing tools [38]. To overcome these challenges, it is becoming increasingly common to execute firmware in an emulated environment in a process known as re-hosting [15].

When firmware runs on top of a standard operating system, re-hosting is possible by emulating operating system abstractions [6,30,48,52,53]. Unfortunately, this approach cannot be applied to fuzz monolithic firmware, which directly interacts with a large number of peripherals through memory-mapped Input/Output (MMIO) as shown in Figure 1. Fuzzing this type of firmware effectively requires supplying values for each peripheral register whenever accessed [1]

Handling MMIO Accesses. One solution for dealing with MMIO accesses is to perform hardware-in-the-loop testing, where each access is forwarded to physical hardware [11,12,37,38]. However, interacting with physical hardware can be complex and slow, introduces restrictions on how inputs can be manipulated, and inhibits the fuzzer's scalability. Alternatively, high-level emulation approaches enable hardware-

[1] Our work focuses strictly on monolithic firmware, for simplicity, the term 'firmware' refers to 'monolithic firmware' in the remainder of the paper.

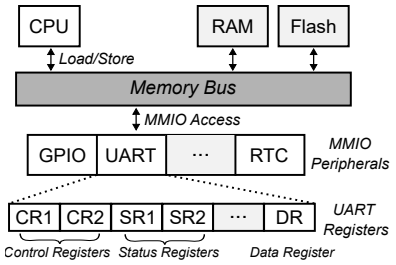

Figure 1: An overview of how the CPU of a microcontroller (MCU) interacts with memory-mapped (MMIO) peripherals. Monolithic firmware fuzzing requires supplying values for each of the peripheral registers whenever they are accessed.

free firmware re-hosting by abstracting away the hardware. These approaches avoid MMIO accesses either by emulating hardware-abstraction layers (HALs) [10, 47] or by building target-specific fuzzing harnesses [34, 44]. However, these approaches require significant engineering effort and can miss bugs in low-level code that is not executed because of the high-level emulation.

Instead, recent approaches [13, 16, 42, 54] have shown it is possible to fully automate firmware re-hosting by using a fuzzer to generate inputs for MMIO accesses to unknown peripherals. These approaches exploit the fact that *approximate* emulation of peripheral values is sufficient for the execution of most firmware. In fact, unusual values can be desirable for fuzzing, as they allow error handling code to be more thoroughly tested, which is often a source of bugs [28]. To improve the effectiveness of fuzzers based on this idea, prior work has investigated several approaches, including building peripheral models by observing MMIO access patterns [16, 35], utilizing a symbolic solver to guide execution [5, 29, 54], performing local symbolic execution to obtain precise access models that focus mutations only on the relevant bits of the input [42], and exploiting commonalities in hardware behavior to make better use of input data [13].

Input Generation and Representation. Existing re-hosting approaches use off-the-shelf fuzzing frameworks such as AFL [51] and AFL++ [18] for input generation. However, these frameworks are primarily designed to test programs that take files as inputs. The input representation used by a fuzzer can significantly impact on its ability to generate effective inputs [1, 19, 33, 45, 46]. We observe this to be the case for firmware fuzzing.

A file-based input representation is ineffective for fuzzing firmware because there is a significant disconnect between the way the input is generated and how the input is consumed during execution. Values for peripheral accesses are derived by consuming bytes from the input file. However, firmware usually interacts with multiple peripherals in an order that depends on the specific execution path. This results in data consumed by each peripheral being scattered, in an unknown manner, throughout the input file.

Consequently, mutation strategies and instrumentation techniques that assume values are accessed in contiguous blocks are less effective as even a tiny change in a sequential file input can lead to significant changes in the execution path and the subsequent mapping of bytes to peripherals. Our key insight is to recognize the inputs behave more like *streams* than files and current file-like representation limits the fuzzer's ability to take advantage of stream or peripheral specific mutations and prevents the fuzzer from effectively employing techniques that rely on inferring relationships between inputs and the state of the program during execution to solve fuzzing roadblocks.

Our Approach. Driven by these observations, we propose a multi-stream input representation for firmware fuzzing. This representation splits the input into multiple independent streams, one for each MMIO peripheral register. This is a more *natural* input representation, as it more closely reflects how firmware consumes data during execution. A multi-stream representation makes mutation operations that rely on manipulating contiguous bytes in the input, such as splicing and input-to-state replacement strategies, more effective. Additionally, by detecting when streams run out of data and employing one of three stream-specific length extension strategies, we avoid cases where the firmware gets stuck waiting for data. Further, by ensuring that streams are mutated independently, the fuzzer no longer spends a disproportionate amount of effort mutating values for MMIO peripherals that are frequently read but are uninteresting.

We implemented our approach in a new fuzzing framework, MULTIFUZZ, which we evaluate with 66 unit-tests developed by P^{2}IM [16], the 20 firmware binaries used for benchmarking in existing state-of-the-art firmware fuzzers, and 3 new real-world firmware targets. Compared to existing fuzzers, Fuzzware and Ember-IO, MULTIFUZZ achieves higher code-coverage, and uncovers 18 previously *undiscovered* bugs.

Our Contributions. In summary, we make the following contributions:

- We share limitations associated with using existing input representation methods for fuzzing firmware.
- We re-think input generation and propose a new approach—*multi-stream input generation and representation*. We design strategies for generating and mutating multi-stream inputs to solve fuzzing roadblocks and reach deeper code faster.
- We design and implement a new fuzzer, MULTIFUZZ, specifically tailored to improving firmware fuzzing by taking advantage of a multi-stream input representation. We open-source[2] our fuzzer to facilitate further research in firmware fuzzing.
- We demonstrate MULTIFUZZ outperforms existing state-

[2]Repo: https://github.com/MultiFuzz/MultiFuzz

of-the-art firmware fuzzers, Fuzzware and Ember-IO, in code coverage and bug discovery with real-world targets.

Responsible Disclosure. We disclosed the bugs found in our work in accordance with the security policies listed for the associated projects (see Appendix A.3).

2 Input Representation for MMIO Accesses

Prior to delving into the technical details of our approach, we re-visit the implications of using a file-based input representation for fuzzing re-hosted firmware to understand the limitations with existing approaches.

A Perspective on Mutational File Fuzzing for Firmware. The fuzzing frontends, AFL [51] and AFL++ [18], utilized by existing state-of-the-art firmware fuzzers [13, 16, 42, 54] are designed to test applications that take a single file as input. Therefore, to test firmware, individual MMIO accesses must be mapped back to the generated file at execution time. To do so, firmware fuzzers keep track of the position within the input to read the next value from, irrespective of the peripheral being accessed by the firmware. If there is no data left, then execution stops. Since the fuzzing frontend is unaware of this mapping, it introduces issues when mutating inputs that reduce the fuzzer's effectiveness. In this section, we describe three critical issues associated with using a file-based input representation for firmware fuzzing: Input stability, data scattering and ineffective input extensions.

Input stability. A small mutation to a file-based input can lead to highly non-local changes throughout input due to the manner in which the firmware receives input data from the fuzzer. Consider the example in Figure 2, when the value

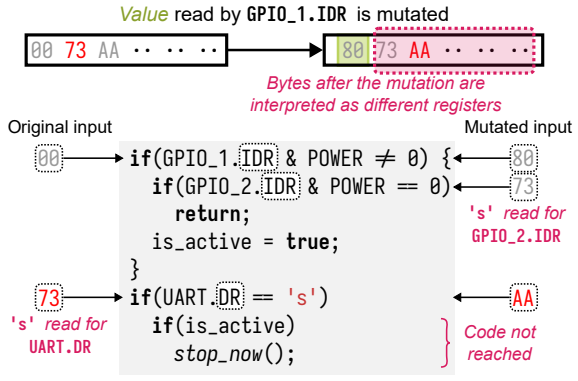

Figure 2: An example of input stability issues manifesting with file-based input representation. The byte mutation in the *mutated input* changes the value read by `GPIO_1.IDR` (`0x00` to `0x80`) and causes the execution path to change. Consequently, the value originally used for the `UART.DR` (`0x73` or `s`), is now consumed by an access from a different peripheral.

(`0x00`) read from the first GPIO peripheral (`GPIO_1.IDR`) undergoes mutation, it results in the input taking a different path through the program. Consequently, the value originally read for `UART` data register (`0x73` representing an ASCII 's' character) is instead consumed when a different peripheral is accessed (the second GPIO peripheral `GPIO_2.IDR`). This leads to the firmware reading a different value (`0xAA`) for the data register, causing a later comparison that expects the value to be 's', to suddenly be false. In fact, this not only impacts the `UART` data register but potentially changes the values read for *all* future MMIO accesses. These input stability issues make it difficult for a fuzzer to make a small mutation to one part of the input without inadvertently breaking seemingly unrelated other parts of the input. Notably, the presence of interrupts further exacerbates this problem. Interrupts typically access multiple peripherals, and the scheduling of these interrupts depends on the execution path, increasing the likelihood of a significant divergence from a small change.

Data Scattering. Firmware intersperses accesses to different peripherals during execution. Using a file-based input can cause data accessed by a particular peripheral to be scattered across a large portion of the input. This can significantly hinder mutation strategies that rely on data being contiguous in the input. For example, a value is inserted from a dictionary, different bytes of the inserted value may be read by *multiple* peripherals. This also poses challenges for mutation strategies that rely on identifying associations between input bytes and values observed during executions, such as Redqueen [2]. Additionally, mutations that involve copying sub-slices of inputs, such as the *splice* operation in AFL, are also likely to be less effective, as the copied data can be consumed by different peripherals.

Ineffective input extensions. Firmware often executes continuously in a loop, waiting for data or events to occur before performing other actions. Consequently, during fuzzing, it is imperative for the fuzzer to provide *adequate* and *valid* data to the multiple registers associated with each MMIO peripheral. Existing firmware fuzzers, relying on file-based mutation strategies, do not attempt to discover effective input extensions that provide sufficient data for peripherals. Instead, these fuzzers rely *entirely* on mutation operations that only indirectly increase the size of inputs [7]. As a result, existing fuzzers experience roadblocks when firmware requires large amounts of data to be read from peripherals. Consider the function shown in Listing 1, which is used to print startup messages to a serial port. This function writes characters to the serial device one byte at a time, first checking whether the device is ready by reading a 32-bit value from the status register, then writing the byte to the data register. Some firmware may try to print large messages (e.g., exceeding 100 characters). Therefore, to make progress, the fuzzer must also extend inputs by a large number of bytes, *all* of which must indicate that the peripheral is ready to receive. In practice even

larger extensions are required due to the presence of interrupts and other MMIO accesses that can occur while the print function is executing. Further, since existing input generation strategies cannot differentiate between MMIO peripherals, they are unable to inform future input extensions based on prior accesses.

```
void serialprintPGM(char* buf) {
    while (*buf != NULL) {
        while ((UART.SR & READY) != READY);
        UART.DR = *buf;
        ++buf;
    }
}
```

Listing 1: A simplified version of the function used to printing startup messages to the console in the *3D Printer* firmware.

3 MULTIFUZZ Design

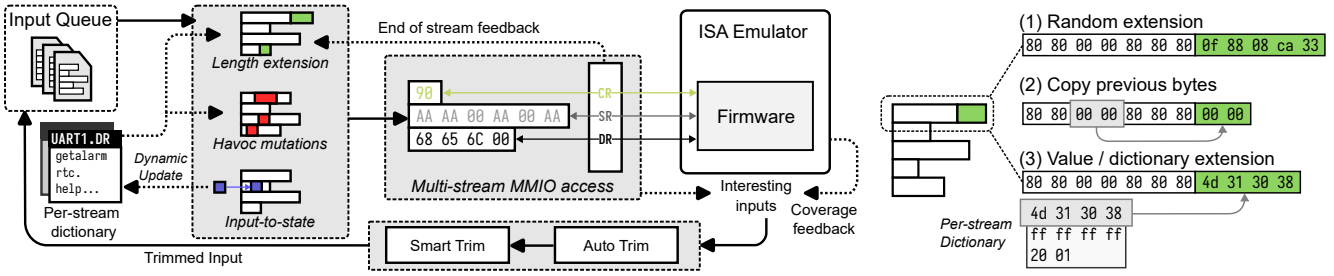
As discussed in the previous section, executing firmware relies on managing inputs for multiple MMIO peripherals. However, the normal approach to input generation based on mutating file-like inputs leads to fuzzing roadblocks and ineffective mutations, inhibiting progress. Generating and providing *effective* values for MMIO accesses is critical to building an efficient and effective fuzzer. In the following section, we introduce the design of MULTIFUZZ, a generic firmware fuzzer that removes the disconnect between the generation-time and execution-time usage of inputs to enable more effective exploration of firmware binaries.

Instead of relying on a normal file-based input representation, we propose representing inputs as a collection of *independent* streams, with each stream corresponding to an MMIO peripheral register. To make effective use of the proposed representation, we design strategies for generating and mutating multi-stream inputs. These strategies address the challenges presented in Section 2, allowing the fuzzer to reach deeper code faster. In particular:

- We develop a strategy for initializing and extending each stream within the input driven by feedback from stream exhaustion (see Section 3.1).
- We develop a series of stream-specific mutation operations: stream-to-stream splicing, mutations using a dynamic dictionary, and colorization and input-to-state replacement by adopting Redqueen for multiple-streams (see Section 3.2 and Section 3.3).
- To improve *efficiency*, we develop a strategy to prevent a disproportionate amount of mutation effort from being spent on peripheral registers with a large number of accesses and automatically reduce the effort spent mutating streams with no influence on program control flow (see Section 3.3.1).

A high-level overview of MULTIFUZZ is shown in Figure 3a. With this approach, the fuzzer can mutate and extend data for individual MMIO peripherals independently by employing a set of multi-stream specific strategies. This intuitive approach solves the problems posed by input stability, peripheral data scattering, and the ineffectiveness of input extensions in normal mutational file fuzzing, as discussed in Section 2.

3.1 Effective Input Extension



Determining the appropriate sizes for fuzzing inputs is challenging, even in normal mutational file fuzzing [2, 7, 20]. Inputs that are too short may fail early validation checks, while overly long inputs slow down execution and reduce the likelihood of byte-orientated mutations affecting critical bytes. One solution is to start with a *good* initial input corpus [26]. However, accomplishing this is extremely difficult for firmware since the fuzzer needs to manage MMIO accesses to a variable number of unknown peripherals. In fact, obtaining even a *single* effective starting input is challenging [29, 42, 54]. Consequently, firmware fuzzers typically start with a simple, generic input seed and heavily rely on mutations to reach deeper into the code.

As we discussed in Section 2, the file-based input representation used in existing approaches inhibits the fuzzer's ability to extend inputs effectively, reducing fuzzing performance. However, a multi-stream representation introduces new challenges, as the fuzzer must now initialize multiple streams. To address the complexity in initializing multi-stream inputs, we employ two techniques we: i) extend inputs using stream-specific length extension strategies; and ii) then utilize an improved trimming strategy to eliminate uninteresting bytes from each stream. We discuss these methods in detail, next.

3.1.1 Multi-stream Length Extension

The core of MULTIFUZZ's approach to generating multi-stream inputs is an efficient length extension strategy. Starting with an initial value for every stream would be impractical, as it is common for a large, mostly unused, region of memory to be reserved for MMIO[3]. Instead, our approach is to start with an empty input and develop techniques for dynamically initializing streams. MULTIFUZZ first executes the firmware until it accesses a MMIO peripheral for the first time, then captures a snapshot of the emulator's state at that point. Using this snapshot, the fuzzer rapidly tests new inputs by extending the stream that the firmware failed to read, creating a new empty stream if one does not already exist. A similar approach is used to extend non-empty seed inputs, except the snapshot is taken when all the data for a stream has been consumed. When extending a stream, one of, or a combination of, the following three strategies is selected: (1) random extension, (2) copying previous bytes within the input, and

[3] For example, ARM Cortex-M reserves a 0.5 GB region for peripherals.

(a) An overview of the core components of MULTIFUZZ.

(b) An overview of the three length extension strategies utilized by MULTIFUZZ.

(3) utilizing interesting values and values from a dynamic dictionary. Figure 3b contains a visual example of each of these strategies.

Random extension. The simplest length extension strategy used by MULTIFUZZ is to generate random bytes and append them to the end of the target stream. This strategy is effective at extending streams for MMIO peripherals that the firmware does not expect to return exact values. As an example, firmware typically expects to read data from an Analog-to-Digital Converter (ADC) peripheral that lies within a range of outputs, so generating any value within the expected range allows the fuzzer to make progress.

Copy previous bytes. We propose extending streams by copying bytes from earlier slices within the same stream. As shown in Figure 3b (2), the fuzzer first selects a slice of bytes (`[00 00]`) from a previous location in the stream and then appends them to the end of the stream. This strategy leverages the observation [13] that peripheral registers are often interacted with in similar ways at different points during execution. Values that enable progress to be made for earlier reads are often useful to use for subsequent reads. For example, in the code presented in Listing 2, the firmware waits for the USART peripheral to finish synchronization, monitoring the SYNCBUSY register until it reads zero. To make progress, every time the firmware calls the `usart_is_syncing` function, the fuzzer must generate a value of '`0`' for the stream. By using a length extension strategy that duplicates previous values within the stream, subsequent calls to this function are solved more easily, improving fuzzing performance.

```
void usart_is_syncing() {
  while (USART.SYNCBUSY != 0) {
    // Wait until synchronization is complete.
  }
}
```

Listing 2: Example of a function that waits until the value read from USART sync register is non-zero prior to continuing.

Value and dictionary extension. Streams can also be extended using a predefined set of *interesting* values or values collected into a stream-specific dictionary that is *dynamically* updated as part of the input-to-state stage (Section 3.2). For interesting values, we use a reduced set of values used by existing fuzzers [18, 19, 51]. We observed that values with a bit pattern of all ones or all zeros (i.e., the bytes `0xff` and `0x00`) are effective. This effectiveness arises from how firmware interacts with certain MMIO registers. For example, it is common for actions the firmware takes to depend on whether a specific bit within a status register is set or cleared. By extending the input with values consisting of all zeros or all ones, both possibilities can be tested without knowing the exact bit checked. In the code shown in Listing 3, the firmware only reads data from the UART peripheral after checking whether the receive ready bit is set in the status register (`UART.SR`). By extending the input with a value consisting of all ones, the fuzzer successfully progresses through this check, as the necessary bit is set. These values are also good starting points for additional mutation strategies such as bit-flipping, which are incorporated within the Havoc stage (see Section 3.3).

```
void UARTClass::IrqHandler(void) {
  // Check if new data is available.
  uint32_t status = UART.SR;
  if ((status & RXRDY) == RXRDY) {
    // Read new data.
    store_char(UART.RHR);
  }
 // ...
}
```

Listing 3: Firmware code snippet checking a ready bit in a status register (`UART.SR`) prior to accessing the data register.

Inspired by the effectiveness of mutation stacking in AFL [20], MULTIFUZZ may choose to apply multiple extension strategies to a single stream. Each time MULTIFUZZ attempts to extend an input, it chooses a random number of extensions to apply and chooses a random strategy for each extension. Like mutation stacking in AFL, if the fuzzer fails to make any progress after many attempts, we allow the amount of stacking to increase.

After applying one or more extension strategies and exe-

cuting the modified input, the fuzzer then evaluates the code-coverage for the input. Whenever an extension causes the input to reach new code, we save the mutated input for future mutations; otherwise, we revert the extension and make a new attempt from the saved snapshot.

In the code shown in Listing 3, for a new data byte to be read from the UART peripheral, *both* the `UART.SR` stream and the `UART.RHR` stream must be extended. However, if the fuzzer has found other inputs that already cover the code, then an extension just to `UART.SR` is 'uninteresting' and discarded. To address this issue, whenever execution halts due to reaching the end of a stream that was not extended, in subsequent extension attempts the fuzzer also extends this stream. As an additional optimization, if a stream is consistently exhausted, then larger extensions to this stream are used in future attempts.

3.1.2 Input Trimming

Since the length extension stage always increases the size of inputs, the fuzzer may generate inputs that are longer than necessary. Given two different inputs that cover the same code, the shorter input is often preferable for fuzzing. Shorter inputs have several advantages: they can generally be executed more quickly, enabling the fuzzer to attempt a greater number of mutations within the same amount of time. Performing mutations on shorter inputs is more likely to yield a meaningful change to the program's behavior. Additionally, shorter inputs tend to be simpler and thus easier to understand, which aids in the analysis and triaging of crashes.

To address this, MULTIFUZZ utilizes a smart trimming strategy, which consists of two steps: first, the fuzzer automatically removes any unused bytes at the end of a stream (*Auto Trim*), then the fuzzer repeatedly attempts to remove slices within each stream, while ignoring *uninteresting* changes to control flow (*Smart Trim*).

Auto Trim. After execution halts due to reaching the end of one of the input streams, it is possible that there are bytes at the end of other streams that were never accessed. By maintaining a cursor for each stream that tracks bytes read, Auto Trim can efficiently truncate input streams, removing all unread data that can never impact the execution path. This is particularly effective later in the fuzzing campaign when a greater number of extensions are attempted.

Smart Trim. It is also desirable for the fuzzer to remove bytes *within* a stream. For example, consider the control-flow graph (CFG) depicted in Figure 4. This CFG corresponds to a function where the firmware repeatedly reads from the UART status register (`dev->SR`) until a ready bit is set. If the status register stream is filled with bytes where the ready bit is not set, then the fuzzer will execute unnecessary iterations of the loop. However, the trimming strategies employed by traditional fuzzers such as AFL [51] and AFL++ [18] are incapable of removing these bytes primarily because of the

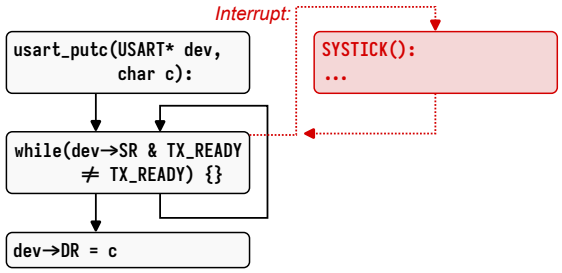


Figure 4: The control-flow graph associated with a function for writing a character to a USART peripheral. In the example, while waiting for the peripheral to be ready, an interrupt occurs, resulting in additional control flow.

criteria they employ to determine valid removals. Traditional fuzzers only consider a removal to be valid if the execution path is unaltered after the removal. Changes in the execution path are detected by monitoring whether different bits are set in the coverage bitmap. For the example in Figure 4, removing bytes without the ready bit set leads to the removal of the loop back-edge and any interrupt handlers that were triggered during the loop. This change to the execution path causes existing trimming strategies to reject the removal.

To improve MULTIFUZZ's ability to trim input streams, we developed an alternative heuristic for rejecting inputs modified during the trim stage, which we call *Smart Trim*. In contrast to the approach used by AFL and AFL++, our approach only rejects removals that prevent *newly* covered code from being reached. This approach is based on the observation that the newly covered code is the only part of the execution path that we care about keeping. In other words, if the trimmed input was found first, the untrimmed input would never have been saved. In Figure 4 for example, if the fuzzer has saved at least one prior input that covers the loop edge and any interrupt handlers, the trim stage can fully remove all non-ready values from the status register (`SR`) stream. Smart Trim can remove bytes from both within and at the end of streams, but it carries a runtime cost proportional to the size of the input. Auto Trim reduces the overhead of Smart Trim by enabling it to start with an already reduced input.

3.2 Multi-stream Input-to-State Replacement

A fuzzer's ability to reach deeper parts of the code in a target can be hindered by complex comparison operations, such as multi-byte integer and string comparisons. This challenge has led to the development of various techniques targeted at addressing this issue [7, 9, 17, 21, 27]. Notably, the input-to-state (I2S) replacement technique introduced by Redqueen [2] has proven highly effective at directly solving many complex comparisons and has been incorporated into several fuzzing frameworks [8, 18, 19, 31]. I2S replacement operates in two stages: first, the fuzzer adds instrumentation to record compar-

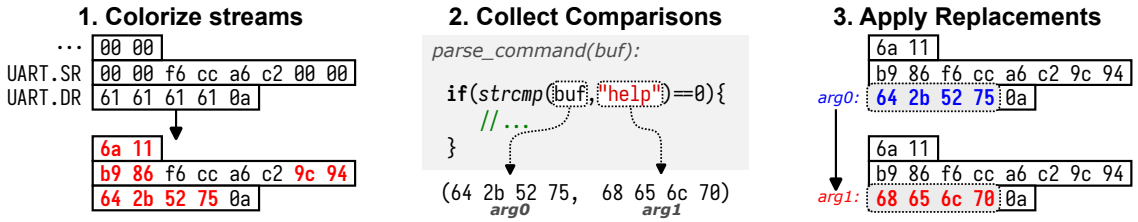

Figure 5: An overview of the multi-stream input-to-state replacement strategy employed by MULTIFUZZ. (**1**) The fuzzer first attempts to *colorize* each stream individually. (**2**) Next the colorized input is executed with instrumentation that logs the operands comparison operations and functions. (**3**) The fuzzer then searches and replaces matching operands within each stream.

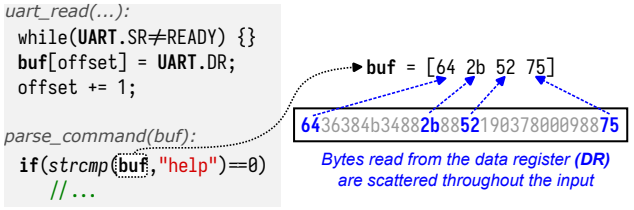

Figure 6: With a file-based input representation, bytes read from the data register of the UART peripheral and stored into the buffer `buf` become scattered throughout the input.

ison operands during program execution, and then the fuzzer searches for bytes in the input that match one of the operands. When a match is found, the fuzzer attempts to replace the input bytes with the correct value (i.e., the matched operand).

In firmware, most complex comparisons involve bytes read from data registers. However, between reading each byte of data, firmware typically waits for new data to become available, either by *polling* the associated status register or by waiting for an interrupt to be triggered. This is problematic when using a file-based input representation as the interspersed accesses between data registers and other peripherals makes it difficult to identify complete multi-byte values within the original input, as shown in Figure 6. In contrast, our multi-stream input representation inherently solves this issue. By separating each peripheral into individual streams, we ensure that the data associated with each stream remains contiguous. This enables MULTIFUZZ to solve complex comparisons by performing I2S-style replacements on individual streams with minimal changes, as shown in Figure 5.

Similar to the original implementation in Redqueen [2], we first attempt to replace non-critical bytes (i.e., bytes that do not affect control flow) with randomly generated values in a process called *colorization*. This increases the entropy of the input, which decreases the likelihood of a spurious match for a comparison. Colorization is performed on a per-stream basis, and we also keep track of streams where every byte has been replaced with a random value (fully colorized) for later use in stream selection (Section 3.3.1).

After colorization, MULTIFUZZ executes the firmware with the modified input and records the operands of each comparison that is encountered. After execution, the fuzzer searches each stream for a match with one of the recorded operands, and if a match is identified, the fuzzer replaces the operand with the other recorded value. To evaluate each replacement, MULTIFUZZ re-executes the firmware with the modified input and checks for changes to the execution path. The replacements are tested individually, with the bytes that were replaced in the input restored to their original values after each attempt. The fuzzer saves any input that reaches new code for future mutations and records any replacement value that changes the execution path into a *per-stream* dictionary. This dictionary is later employed by the length extension stage (Section 3.1.1) and for havoc-style mutations discussed in the next section.

3.3 Multi-stream Mutations

By construction, length extension only modifies values that appear at the end of input streams. However, it is also often beneficial to mutate earlier bytes within the input. To achieve this, MULTIFUZZ includes a havoc stage that randomly applies one or more mutations to any part of the input stream. We then enhance the standard havoc operations by introducing several modifications aimed at improving their effectiveness in mutating multi-stream inputs. We describe these modifications in the remainder of this section.

Stream-to-stream splicing. Splicing involves combining parts of existing inputs to generate new inputs, enabling a fuzzer to repurpose useful sections of previous inputs in different ways. However, data that is useful for one MMIO register is often less relevant for other registers, particularly if they differ in type. For example, Figure 7 shows the streams associated with a UART peripheral from an input discovered while fuzzing the *CNC* target. In the stream for the status register, nearly all bytes have either the transmit ready bit or the receive ready bit set (bits 5 & 6). Conversely, the stream for the data register consists almost entirely of printable ASCII characters. Therefore, using bytes from one stream as part of a splice operation on a stream of a different type is unlikely to be effective. A multi-stream representation enables us to implement a more targeted splicing operation and prevent

inter-mixing of data across streams. Whenever a stream is selected for a splice operation, the fuzzer ensures that the operation uses data from streams associated with the same MMIO register (see Section 4). For example, in Figure 7, data from the `UART.DR` stream of one input will be spliced with data from the `UART.DR` stream of another input.

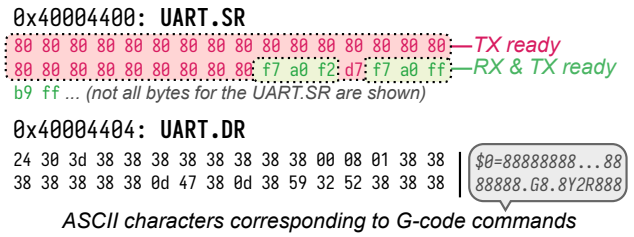

Figure 7: A fragment of an input generated while fuzzing the *CNC* target. This fragment demonstrates the difference between data generated for a status register (`UART.SR`), favouring repetition of bytes for signalling TX/RX ready, compared to a data register (`UART.DR`), favoring ASCII characters.

Per-stream dictionary replacement. As part of the input-to-state stage, the fuzzer collects values found in comparison operations into a per-stream dictionary. During the mutational stage, the fuzzer may mutate an input by copying values from the dictionary into the associated stream. Like stream-to-stream splicing, the per-stream nature of the dictionary ensures that it contains a higher proportion of values relevant to the target stream. In Figure 8, the fuzzer inserts a value of "getalarm" into the UART data register stream using the associated per-stream dictionary.

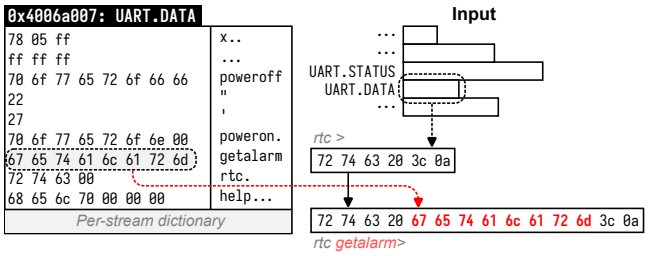

Figure 8: An example of a dictionary mutation when fuzzing the *Console* binary. The fuzzer inserts the dictionary value "getalarm" into the stream for the `UART.DATA` register.

3.3.1 Stream Selection

MULTIFUZZ utilizes a stream selection strategy that avoids excess mutations to uninteresting input streams. When performing havoc-style mutations, first the fuzzer randomly chooses a stream, then the fuzzer selects a random number of mutations to apply to the stream. The fuzzer selects short streams just as frequently as long streams. Given that longer streams contain more bytes, this effectively biases mutations such that an individual byte within a longer stream is *less* likely to be mutated than an individual byte within a shorter stream. This bias is both *intentional* and *desirable*. Status registers are almost always read before accessing data registers, usually to ensure that the peripheral is ready before performing an action or to check for errors. Consequently, significantly more data is read from status registers compared to data registers. If each byte was given equal weight for mutation, it would result in a disproportionate amount of mutation effort being devoted to status registers, which are typically significantly less interesting from a security perspective. By selecting the stream for mutation *independently* to the location within the stream to mutate, we ensure that the fuzzer better balances its mutational effort.

One issue with this approach is that firmware may access peripheral registers during initialization, which have no impact on the behavior of the firmware. For instance, interactions with configuration registers during initialization have no impact on the behavior of the firmware since the configuration is ignored by the emulator. To reduce the number of mutations performed on these streams, MULTIFUZZ employs a simple heuristic based on information collected during the colorization (see Section 3.2). During colorization, we track how much of the stream can be replaced by random bytes without changing the execution path, which we refer to as the colorization rate. If a stream has a colorization rate of 100%, then it was never observed to change the execution path, making it unlikely that mutating the stream is useful. However, in rare cases, this heuristic may fail, such as when the value is used in a single comparison with a hard-to-solve value. Therefore, we still occasionally mutate fully colorized streams (with a probability of 0.1× that of mutating other streams).

4 Implementation

To execute the ARM firmware targets, we utilize the timer and NVIC implementation from Fuzzware [42], and ICICLE [8] for emulation and instrumentation. Additionally, we adopt the same three hang detection heuristics as Fuzzware: i) an upper limit on the number of interrupts triggered (excluding SysTick), ii) a limit on the number of blocks executed without any MMIO access, and iii) an overall limit on the total blocks executed. While MULTIFUZZ is compatible with additional features from Fuzzware (such as MMIO models), the additional features are not used in our evaluation.

For input generation, MULTIFUZZ's core fuzzing loop follows a similar design to AFL and AFL++ [18, 51], then incorporates the new mutation and extension operations described in Section 3. Additional implementation details are discussed in the following section.

MMIO dispatching. Each multi-stream input is represented

as a mapping from a memory address to a stream (an array of bytes with a cursor). Like other firmware fuzzers, MULTIFUZZ assumes that the emulator is aware of the location of the memory region corresponding to memory-mapped Input/Output (MMIO). Whenever firmware accesses memory within the MMIO region, the emulator uses the target address of the access as a key in the map maintained for the input. If no mapping exists for the address, execution is terminated. Otherwise, the emulator returns the next value from the stream to the firmware and updates the cursor. The fuzzer dispatches MMIO accesses of different sizes that target the same address to the same stream. Overlapping accesses that start at *different* addresses are treated as different streams. This typically only occurs as part of APIs that end up discarding the overlap using a bit mask. As a concrete example, when the firmware attempts to read a value from the address `0x40004404`, the emulator checks that `0x40004404` is within the ARM MMIO region (it is) and resolves the value by looking up the address `0x40004404` in the map for the multi-stream input.

Input-to-state (I2S) replacement. I2S replacement consists of three parts: colorization, comparison logging, and replacement. We re-implemented colorization by adapting the algorithm described in Redqueen [2] to be performed one stream at a time. To capture comparison operands, we use the implementation of CmpLog from Icicle, which injects code at translation time to record the operands of comparison-like instructions and function calls. The operands are stored in a region of memory shared with the fuzzer and used as part of the replacement step. We implement a per-stream replacement process, which includes a restriction on the number of attempts per stream, to avoid excess overhead in the presence of large streams, along with an additional enhancement to address oversized reads, described below.

It is common for firmware to perform oversized reads of MMIO registers and either truncate or mask the value before using it. This causes the values in the original input stream to be padded with the bits removed during truncation, resulting in the interesting bytes being strided within the stream. In cases where the firmware immediately truncates the value after it is read, as shown in Figure 9, we can detect and replace the oversized read with a smaller read when the pattern is encountered by the emulator. To handle cases where truncation is not performed immediately, we also search each stream for strided matches of operands whenever multi-byte reads to a peripheral register are detected. When performing a replacement on a strided match, we repeat the character up to the stride amount, which addresses any alignment issues. An example of a strided replacement being applied is shown in Figure 10.

Hangs from length extension. During testing, we observed that the length extension mutation strategy can *overshoot* and cause the input to reach (and become stuck in) an error handler or another kind of loop. For example, in the *GPS*

```
char usart_getc(void) {
  int value = UART.DR;
  return (char)value;
}
```

```
ldr   r3, [->UART]
ldr   r0, [r3, #0x4]
