A Appendix

Table 5 lists the type and version for all applications we have evaluated, showing the broad range of our tested programs. For benchmark programs, we include the version number of the benchmark.

Table 6 shows the file size growth for all applications we have evaluated. Furthermore, the proportion of size growth that can be attributed to BINTSAN is given. The rest of the growth is caused by the rewriting process of ZIPR.

Table 7 contains a list of sanitization features included in UBSAN as defined in the clang documentation [41]. The table also contains a short explanation of why certain features are impossible at the binary level. Note that partially possible features are still marked as possible and that this assessment assumes the use of a heuristic to distinguish between signed and unsigned types. Other type inference heuristics have to be very precise for the sanitization checks to work as expected, and they appeared in our preliminary experiments as not sufficient. However, this might change in the future with new advancements in type inference research.

Table 7: Overview of UBSAN sanitization features [41], with a short assessment of whether these are portable to the binary level or not.

Sanitization	Description	Binary	Explanation
alignment	Use of a misaligned pointer or creation of a misaligned reference. Also sanitizes assume_aligned-like attributes.	✘	Type information is not accurate enough.
bool	Load of a bool value that is neither true nor false.	✘	Type information is not accurate enough.
builtin	Passing invalid values to compiler builtins.	✘	Information on compiler builtins is not available.
bounds	Out of bounds array indexing, in cases where the array bound can be statically determined.	✘	Static bound information is not available.
enum	Load of a value of an enumerated type that is not in the range of representable values for the enumerated type.	✘	Information on what values are representable is not available.
float-cast-overflow	Conversion to, from, or between floating-point types that would overflow the destination. Because the range of representable values for all floating-point types supported by Clang is [-inf, +inf], the only cases detected are conversions from floating point to integer types.	✓	
float-divide-by-zero	Floating point division by zero.	✓	
function	Indirect call of a function through a function pointer of the wrong type.	✘	Function type information is not accurate enough.
implicit-(un)signed-integer-truncation	Implicit conversion from integer of larger bit width to smaller bit width, if that results in data loss. That is, if the demoted value, after casting back to the original width, is not equal to the original value before the downcast.	✓	
implicit-integer-sign-change	Implicit conversion between integer types, if that changes the sign of the value. That is, if the original value was negative and the new value is positive (or zero), or the original value was positive and the new value is negative. Issues caught by this sanitizer are not undefined behavior but are often unintentional.	✓	
integer-divide-by-zero	Integer division by zero.	✓	
nonnull-attribute	Passing null pointer as a function parameter that is declared to never be null.	✘	Non-null type information is not accurate enough.
null	Use of a null pointer or creation of a null reference.	✘	Pointer type information is not accurate enough.
nullability-arg	Passing null as a function parameter that is annotated with _Nonnull.	✘	Non-null type information is not accurate enough.
nullability-assign	Assigning null to an lvalue that is annotated with _Nonnull.	✘	Non-null type information is not accurate enough.
nullability-return	Returning null from a function with a return type annotated with _Nonnull.	✘	Non-null type information is not accurate enough.
objc-cast	Invalid implicit cast of an ObjC object pointer to an incompatible type. This is often unintentional, but it is not undefined behavior; therefore, the check is not a part of the undefined group.	✘	Type information is not accurate enough.
object-size	An attempt to potentially use bytes for which the optimizer can determine that they are not part of the object being accessed.	✘	Struct type information is not accurate enough.
pointer-overflow	Performing pointer arithmetic that overflows or where either the old or new pointer value is a null pointer.	✓	
return	In C++, reaching the end of a value-returning function without returning a value.	✘	Function type information is not accurate enough.
return-nonnull-attribute	Returning null pointer from a function that is declared to never return null.	✘	Non-null type information is not accurate enough.
shift	Shift operators where the amount shifted is greater or equal to the promoted bit-width of the left-hand side or less than zero, or where the left-hand side is negative. For a signed left shift, also checks for signed overflow in C and for unsigned overflow in C++.	✓	
unsigned-shift-base	Check that an unsigned left-hand side of a left shift operation doesn't overflow.	✓	
signed-integer-overflow	Signed integer overflow, where the result of a signed integer computation cannot be represented in its type.	✓	
unreachable	If control flow reaches an unreachable program point.	✘	Compiler based reachability analysis is not available.
unsigned-integer-overflow	Unsigned integer overflow, where the result of an unsigned integer computation cannot be represented in its type.	✓	
vla-bound	A variable-length array whose bound does not evaluate to a positive value.	✘	Array bound information is not available.
vptr	Use of an object whose vptr indicates that it is of the wrong dynamic type or that its lifetime has not begun or has ended.	✘	Type information is not accurate enough.

ORANalyst: Systematic Testing Framework for Open RAN Implementations

Tianchang Yang, Syed Md Mukit Rashid, Ali Ranjbar, Gang Tan, Syed Rafiul Hussain

{tzy5088, szr5848, aranjbar, gtan, hussain1}@psu.edu

Abstract

We develop ORANalyst, the first systematic testing framework tailored for analyzing the robustness and operational integrity of Open RAN (O-RAN) implementations. O-RAN systems are composed of numerous microservice-based components. ORANalyst initially gains insights into these complex component dependencies by combining efficient static analysis with dynamic tracing. Applying these insights, ORANalyst crafts test inputs that effectively navigate these dependencies and thoroughly test each target component. We evaluate ORANalyst on two O-RAN implementations, O-RAN-SC and SD-RAN, and identify 19 previously undiscovered vulnerabilities. If exploited, these vulnerabilities could lead to various denial-of-service attacks, resulting from component crashes and disruptions in communication channels.

1 Introduction

The standard body for mobile telecommunications [1] has designed a new disaggregated architecture for 5G radio access network (RAN) to enable software-centric deployment on general-purpose hardware. This new architecture splits the RAN's network stack into multiple nodes, each capable of operating independently on geographically separated machines to form the RAN network. As 5G RAN evolves towards more diverse and adaptable deployments, the O-RAN Alliance [21], a worldwide community of mobile operators, vendors, and research institutions, proposes *Open RAN (O-RAN)*. It introduces *RAN intelligence controllers* to reshape RANs into smarter, open, virtualized, and interoperable multi-supplier solutions. These advanced controllers interact with different RAN nodes through standardized interfaces, enabling them to manage and optimize RANs in near real-time based on network metrics. O-RAN's software-centric intelligence controller also supports third-party applications to enhance the network's adaptive capabilities, thereby improving RAN performance and user experience. This new and complex RAN design, with its focus on flexibility, openness, and a software-centric architecture, unfortunately also greatly expands the attack surface of O-RAN. For instance, with nodes like radio units of base stations sourced from multiple vendors interfacing collectively with O-RAN, each interaction and dependency introduces a potential security risk. This heterogeneity and complex RAN architecture demand O-RAN's resilience against unexpected inputs, which could arise from malformed or potentially malicious data sent from its connected nodes.

Prior research has demonstrated that mobile RANs are susceptible to misconfigurations [45], implementation and dependency vulnerabilities [42], and can also be compromised by malicious user devices [5]. Consequently, adversaries exploiting a vulnerable RAN node may deliver unpredictable inputs to O-RAN components through its public-facing interfaces, leading to crashes that violate O-RAN's robustness and operational integrity. Such security lapses may lead to large-scale network collapses, substantial financial losses, and could even threaten national security. The active adoption of O-RAN technologies further amplifies these risks. More than 31 major operators from over 45 countries, including Deutsche Telekom and AT&T, are actively deploying or trailing commercial O-RAN [22, 53], with reports of these systems incorporating or are derived from open-source implementations [15, 24]. The urgency of these concerns underscores an in-depth security analysis of O-RAN implementations to certify the security and reliability of this next-generation network system. In this paper, we, therefore, aim to address the following research question: *can we develop an automated reasoning framework to analyze the robustness and operational integrity of O-RAN implementations, providing high-security assurances prior to their commercial deployments?*

Challenges. O-RAN's unique threat model and its service-based architecture (SBA) pose distinct challenges that existing software testing techniques [2, 4] struglle to address. Components in O-RAN are divided into separate microservice programs, such as the database, the subscription manager, and other applications. These components are deployed across different logical containers and communicate via network traffic. Functioning as independent, long-running programs, these microservices are continuously ready to process incoming re-

quests. They engage in complex network communications to fulfill O-RAN's functionalities. Each input originating from base stations or cellular devices traverses a complex path in the O-RAN, navigating through multiple components, undergoing numerous layers of sanitization checks and parsing processes, and engaging in a sequence of network request interactions before reaching components laying in deeper layers of O-RAN. The typical software testing approach of analyzing only a single component in isolation, without considering its dependencies on other components [18,50], would lead to a high number of false positive results. These false-positive vulnerabilities are not exploitable in a complete, i.e., end-to-end deployment of O-RAN, due to the sanity checks and preprocessings conducted by upstream components. Furthermore, unlike the well-defined protocols and messaging formats of O-RAN's public interfaces for communication with the RAN, the internal messaging systems between O-RAN's internal components lack standardization in technical specifications [68] and vary significantly across different implementations. Consequently, isolated testing further requires manually crafting messages that conform to the protocol and format each component expects to yield meaningful results.

Approach. To address these unique challenges, we introduce `ORANalyst`, a dynamic feedback-guided end-to-end testing methodology that intelligently identifies and navigates dependencies between O-RAN components to find threat-model-compliant problematic inputs. In our end-to-end testing method, testing inputs are sent to a component only through O-RAN's public-facing interfaces, e.g., the interface with RAN that is well-specified. By focusing on generating and testing the standardized messages that are interchanged between the RAN and the O-RAN, `ORANalyst` bypasses the need for detailed knowledge of each component's internal messaging implementations. Yet, developing such an end-to-end testing framework introduces its own set of challenges, most notably when testing and sending inputs to a deeply rooted component within O-RAN. Inputs targeting these components must navigate through several layers of decoding and validation conducted by upstream components. Test inputs may get discarded by these checks and never reach their intended targets unless the knowledge of the sequence and order of those upstream components (i.e., dependency among components) is strategically incorporated while crafting inputs.

To craft inputs that can effectively explore each component, `ORANalyst` first computes the dependencies among components involved in different O-RAN operations. It dynamically records the network and program execution traces of inputs during regular O-RAN operations, and combines both traces to identify each input's entry and exit points in each component. By leveraging this component-level reachability analysis, `ORANalyst` designs a dependency-aware incremental testing strategy. With this approach, `ORANalyst` starts testing with the components directly connected to the RAN (i.e., the root in the component-level dependency tree), and then progressively moves to those located deeper within the O-RAN's communication chain (i.e., subsequent successors). This gradual approach helps us resolve the dependencies and interactions of components while thoroughly analyzing each layer of the system. To ensure that the inputs generated by `ORANalyst` can effectively reach the component under test (CUT) and still provide enough variations to test the component, we design an inter-procedural static analysis to extract path constraints along each component's entry point to the exit point, while mitigating the well-known state explosion problem. Path constraints collected from components upstream of the CUT are combined to guide the generated inputs past those previous components to reach the CUT. At the same time, path constraints of the CUT enable `ORANalyst` to create inputs that probe into CUT's deeper logic.

Results. We have evaluated `ORANalyst` on the only two widely-used, commercially-adopted O-RAN open-source implementations. `ORANalyst` identified 19 issues in both the platforming components and the application programs running on both implementations. These issues can lead to component crashes and messaging channel disruptions.

Responsible disclosure and open-sourcing. We have reported all 19 issues to developers and received confirmation on 9 issues. 15 CVEs are assigned for all 19 reported issues. `ORANalyst` is publicly available on GitHub [29].

Contributions. In summary, our contributions include:

- We develop the first systematic analysis technique tailored for O-RAN systems dubbed `ORANalyst` that can compute the complex dependencies among components in O-RAN's service-based architecture.
- We design an effective test input generation mechanism that combines dynamic analysis with efficient static path constraint extraction, enabling the generated inputs to effectively probe and test deep O-RAN components.
- We evaluate `ORANalyst` on two O-RAN implementations and uncovered 19 critical issues that lead to component crashes and messaging channel disruptions.

2 Background

In Release 15, the mobile telecommunication standard body, the Third Generation Partnership Project (3GPP) [1], defined a flexible, disaggregated architecture for the 5G-RAN, splitting the base station into the Central Unit (CU), the Distributed Unit (DU), and the Radio Unit (RU), each designed to host different layers/functions of the 5G radio stack. To accommodate 5G RAN's transition towards diverse and software-centric deployment, the O-RAN Alliance [21] designs O-RAN (depicted in Figure 1) to create a multi-supplier solution where equipment from various vendors can be easily plugged and played to form the RAN. It incorporates a service-based architecture (SBA), where different functions and services are implemented as separate microservice programs, communicating over network traffic. Each microservice can be

independently developed, deployed, and scaled on general-purpose hardware. In addition to the disaggregation of the base station, O-RAN introduces two RAN Intelligent Controllers (RICs), the *Near-Real-Time RIC (Near-RT RIC)* and the *Non-Real-Time RIC (Non-RT RIC)*, for automated optimization and control of network operations and resources in response to real-time network conditions.

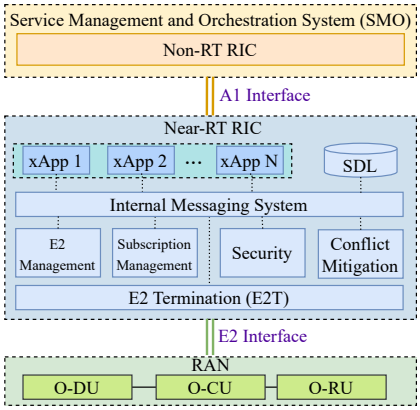

Figure 1: O-RAN RIC Architecture

❑ **Near-RT RIC and xApps.** Near-RT RIC's role is to dynamically manage and optimize the RAN by responding to network conditions in near real-time (10*ms* to 1*s* scale) [68]. Near-RT RIC's functionality is driven by modular applications known as *xApps*. These xApps can be sourced from third-party developers and may also be open-sourced, each designed to perform specific tasks, including load balancing, interference management, and Quality of Service (QoS) control. To support xApps' functionalities, Near-RT RIC provides various *platforming components*, such as a Shared Data Layer (SDL), Security, Conflict Mitigation, E2 Management, etc.

❑ **Non-RT RIC.** The Non-RT RIC operates on a timescale above 1 second and is part of the Service Management and Orchestration (SMO) framework. Its functions are typically strategic, e.g., policy control, network planning, and broader long-term RAN management tasks.

❑ **E2 open interface.** An O-RAN system can simultaneously govern multiple RAN nodes (i.e., CUs and DUs) from different operators. Each RAN node interfaces with the Near-RT RIC through the *E2 interface*. *E2 Termination (E2T)* is the end point of this interface in the Near-RT RIC, and *E2 Management* handles the setup, maintenance, and teardown of E2 sessions. The E2 interface runs over SCTP protocol [78] and is logically divided into two protocols: E2 Application Protocol (E2AP) [66] and E2 Service Model (E2SM) [67]. Both protocols are defined using ASN.1 formats [3] in the technical specifications. E2AP provides signaling procedures for the setup and modification of the E2 connection, error indication, and the reporting of general RAN status. E2SM supports service-level interactions between xApps and the RAN, e.g., reporting of various RAN-/cell-level metrics, control of RAN operations, etc.

❑ **Workflow between O-RAN RIC and RAN.** In a typical O-RAN RIC communication, after the SCTP connection between the Near-RT RIC and a RAN node is established, the RAN node first transmits an E2AP `E2SetupRequest` listing the service models it supports and the performance metrics it can report. The near-RT RIC processes this information and replies with an `E2SetupResponse` message. If the E2 setup is successful, xApps can send `subscription` messages to the connected RAN node specifying the E2SM used and the metrics they want to subscribe to. During this subscription negotiation, an xApp can specify trigger events or the periodicity with which the RAN node should send report metrics. Following a successful subscription, xApps continuously receive and process `indication` messages sent by the RAN, which contain the RAN's performance metrics, and optionally sending `control` messages to optimize RAN operations.

❑ **Open-source implementations.** Two commercially-adopted, widely-used O-RAN implementations are available as open-source projects: the O-RAN Software Community (O-RAN-SC) [23], which is developed through a collaboration between the O-RAN Alliance [21] and Linux Foundation [20]; and SD-RAN [32], developed by Open Networking Foundation (ONF) [27]. Both open-source projects are being utilized for commercial deployments. For example, O-RAN-SC's Near-RT RIC is being used by China Mobile in its private 5G network solution [15], whereas Deutsche Telekom is conducting a commercial field trial in Berlin using SD-RAN's RIC [24]. Both implementations are cloud-native where each component is shipped as a Docker image [6] and deployed in Kubernetes [17]. However, the two implementations differ in their approaches to handling logical components. For instance, the SD-RAN implementation consolidates the logical components of E2T, E2 management, and subscription management into a unified E2T microservice. In contrast, the O-RAN-SC implementation treats each of these components as distinct, individual microservices running in separate containers. Components in both implementations are developed using a variety of programming languages, with C/C++ and Go being the most predominant.

3 Threat Model & Motivation

In this section, we discuss our threat model and summarize the limitations of existing approaches when testing O-RAN RIC implementations, which motivates the design of `ORANalyst`.

3.1 Threat Model

O-RAN's interoperability [71], while offering significant benefits to network operators, also introduces substantial security challenges for the RIC. The RIC must manage interactions with RAN components from different vendors and network operators, each with distinct system implementations and differing security protocols. These variations not only exposes each individual RAN to potential security issues but

Category	Fuzzer	RT	NG	GA	NR	Notes on Requirements, Effectiveness and Efficiency
General Fuzzers	AFL [50]/LibFuzzer [18]	✗	✓	✗	✓	Requires complete control over the target program to fork, execute, and terminate for each testing run. Does not support long-running servers and can not explore the interactions between components.
Protocol Fuzzers	AFLNET [70]	✗	✓	✗	✗*	Similar to general fuzzers, requires complete control over the target server to fork, execute, and terminate for each testing run. *The stateful mode requires a response for each request.
Protocol Fuzzers	BooFuzz [4]/Peach [11]	✓	✗	✓	✓	Manual specification of message grammar is required. As generation fuzzers, no feedback is accepted, hence input generation is not guided by dynamic code exploration. Due to no feedback, a timeout mechanism is employed, which delays sending the next input, resulting in inefficiencies.
Protocol Fuzzers	Frizzer [9]	✓	✓	✗	✓	Dynamically instrument the code using Frida which is extremely slow. More importantly, Frida instrumentation is unstable and can lead to crashes of the target program, generating numerous false positives.
API Fuzzers	Restler [39]/EvoMaster [7]	✓	✓	✗*	✗	Requires a response with each request as feedback. *Can automatically generate Rest API-compliant messages, but does not work with the ASN.1 used in O-RAN.
Microservice Fuzzer	Evomaster RPC [83]	✓	✗	✓	✗	Requires manually developing a driver to send input and collect coverage for each testing component.
O-RAN Tester	`ORANalyst`	✓	✓	✓	✓	Can generate highly structured inputs automatically from the ASN.1 message definitions, while utilizing insights on the interactions of O-RAN components to test each target component efficiently.

Table 1: Comparison of Different Fuzzing Techniques. RT: support (R)emote (T)arget, NG: (N)o manual definition of (G)rammar is required, GA: (G)rammar-(A)ware input generation/mutation, NR: (N)o (R)esponse message required for each test case

also cumulatively heightens the overall network's susceptibility to breaches. Key security concerns include misconfigurations [45], vulnerabilities in implementation [45], dependency weaknesses [81], and potential compromises by malicious user devices, also known as User Equipments (UEs) [5]. Consequently, the RIC must be prepared for a variety of unexpected, malformed, or malicious inputs. Our threat model considers one misbehaving RAN transmitting unexpected or malicious inputs to the RIC. We do not consider vulnerabilities that require multiple misbehaving RANs collaborating to exploit in this work. We assume that RIC components are benign (but vulnerable) and do not attack each other as they are owned and deployed by the same party. This threat model aligns with the threat IDs T-O-RAN-05, T-E2-01, and T-E2-03 considered in O-RAN's official risk assessment [63]. O-RAN's study on security for Near-RT RIC and xApps [64] also identifies this threat as a critical issue and concludes that the Near-RT RIC should not assume that the data it received is valid or trusted. We align our work with the security assessments report by O-RAN. Under this threat model, our primary objective is to ensure the robustness and operational integrity of RIC against unpredictable and malicious inputs from RAN. This involves ensuring the RIC handles any unexpected data without crashing or hanging.

3.2 Limitations of Existing Testing Methods

Directly applying existing testing techniques for analyzing the O-RAN RIC encounters significant limitations, as summarized in Table 1. ($\mathbf{L_1}$): General program fuzzers, such as AFL [50], LibFuzzer [18], and Driller [77], are optimized for testing single monolithic command-line applications and struggle to navigate the intricate component-to-component interactions and diverse communication protocols inherent to O-RAN's distributed and service-based architecture. ($\mathbf{L_2}$): Protocol fuzzers like AFLNET [70] and BooFuzz [4] support sending testing inputs over network traffic, allowing them to target remote systems. However, they are generally tailored towards testing individual servers rather than an interconnected microservices environment. ($\mathbf{L_3}$): These fuzzers [4, 11] also often require the labor-intensive and error-prone task of manually constructing message grammars. ($\mathbf{L_4}$): Existing microservice fuzzers [83], though designed to address some aspects of service-based architectures, require the manual creation of driver code to feed inputs into test components and gather coverage feedback. ($\mathbf{L_5}$): API fuzzers like RESTler [39] and EvoMaster [7] primarily depend on analyzing response messages to guide their mutation strategies, whereas in O-RAN RIC, requests from the RAN often result in no observable responses. Besides, existing API fuzzers typically only support Rest APIs [28], instead of the ASN.1 messages on SCTP connections used by O-RAN's public interfaces.

3.3 Motivation for End-to-End Testing

`ORANalyst` employs an end-to-end design where all test inputs are sent through O-RAN's public-facing E2 interface. An alternative approach would be to adapt existing fuzzers [18, 50, 70, 77] to test individual components of the RIC in isolation. With this approach, the fuzzer abstracts away the interactions between the component under test (CUT) and other RIC components by using stubs, i.e., simplified components that perform no actual functionality. Upon finding a crash-inducing input, the fuzzer also needs to validate that the input can cause the crash in an end-to-end setup. However, O-RAN operations often involve complex inter-component communications, such as querying a database for cell configuration data of a RAN. Testing in isolation not only demands extensive effort to manually stub these interactions to produce realistic data [59] but also increases the risk of analysis errors from over-simplified stubbing. Furthermore, this isolated testing approach tends to generate many false positives, as many crash-inducing inputs detected under this approach would likely be filtered out by intermediate components in an end-to-end deployment, thus never reaching the CUT.

To illustrate this scenario, consider the high-level E2T processing logic presented in Listing 1. When it receives a new message from the RAN, it first decodes the message (line 2), validates the message content (line 6), and then processes the message or forwards it to other components based on the

```
1  func processE2AP(e2apByte []byte) error {
2    e2ap, err := decode(e2apByte)
3    if err != nil {
4      return err
5    }
6    if err = validateE2AP(e2ap); err != nil {
7      return err
8    }
9    switch e2ap.type{
10   case indication:
11     processIndication(e2ap)
12     // ... other cases
13   }
14 }
15
16 func processIndication(e2ap E2AP) {
17   indMsg := e2ap.IndicationMsg
18   if err := validateIndication(indMsg); err != nil {
19     return err
20   }
21   if stream, ok := getStream(indMsg); ok {
22     sendIndMsg(indMsg)
23   } else {
24     return errors.NewNotFound("stream not found")
25   }
26 }
```

Listing (1) Illustrative E2T Implementation

```
1  func GetUeID(ueID *e2sm_v2_ies.Ueid) (int64, error) {
2    switch ue := ueID.Ueid.(type) {
3    case *e2sm_v2_ies.Ueid_GNbUeid:
4      return ue.GNbUeid.GetAmfUeNgapId().GetValue(), nil
5    // ... other UE ID type cases
6  }
```

Listing (2) False Positive example, taken from SD-RAN's rimedo-ts xApp

```
1  struct encode_result encode_action_definition(const
       char *action_bytes){
2    // ... setup variables to be used for decoding
3    // decode action_bytes to e2smKpmRanFunctDescrip
4    asn_dec_rval_t rval =  asn_decode((void**)&
       e2smKpmRanFunctDescrip, action_bytes);
5    char **actionArr;
6    if(rval.code == RC_OK) {
7      // ... extract the action items from
         e2smKpmRanFunctDescrip to actionArr
8    }
9    // ... encode variables setup, setup buffer buf for
       encoding result
10   int encodeRes = encode_action_arr(&buf[0], &buf_size
       , actionArr);
11   int encoded[encodeRes]; // * vulnerable line *
12   // ... further processing using encoded
13 }
14
15 size_t encode_action_arr(unsigned char *buf, size_t *
       buf_size, char **actionArr) {
16   // allocate memory for actionDef, the structure to
       be encoded
17   for (int index = 0; index < actionDefCount; i++) {
18     // ... constructing the action definition list to
         actionDef for each index in actionArr
19   }
20   // ... constructing other fields of actionDef
21   asn_enc_rval_t encode_result = asn_encode_to_buffer(
       actionDef, buf, *buf_size);
22   if (encode_result.encoded == -1) {
23     return -1; // returns -1 when encounters an
         encoding error
24   }
25   // ... normal return of positive encoded size
26 }
```

Listing (3) Example of an unchecked return value issue, taken from O-RAN-SC's kpimon-go xApp, simplified for presentation

message type (lines 9 - 13). Therefore, all inputs must pass the initial checks and validations enforced by the E2T before reaching any other components. Now consider the simplified code in Listing 3, which demonstrates a crashing vulnerability found by `ORANalyst` from O-RAN-SC's kpimon-go xApp [16]. The vulnerability's root cause lies in lines 10 and 11, where the return value `encodeRes` can be negative in the event of an encoding error. This value is then used as the length for initializing an array without checking for negativity, leading to unexpected behavior when using the array and a program crash. At first glance, the issue might seem straightforward and detectable by certain existing static or dynamic analysis techniques [40, 41, 43, 46, 72, 74]. However, such detection results in numerous false positives. To illustrate, consider Listing 2 showing an SD-RAN's xApp [25]. Here, a pointer's field access in line 2 is not validated for nullity. A tool analyzing only the xApp would likely flag this as a crash-inducing bug. Yet, in an end-to-end setup where the input is sent from the RAN, we found that the E2T component enforces a non-null check on this field when validating the input (in a function represented by line 18 in Listing 1), leading to early rejection of the message. Consequently, such inputs can never reach the vulnerable xApp to trigger a crash.

Furthermore, testing any RIC component in isolation by directly interfacing the fuzzer with the CUT poses several additional challenges due to unspecified message formats for internal components and difficulties in triaging the results. O-RAN specifications do not define messaging protocols and formats used for communications between two *internal* RIC components. As a result, different RIC implementations employ different internal messaging infrastructures using custom APIs or formats, even for components performing similar functionalities. For instance, O-RAN-SC utilizes a customized routing system to relay indication messages from the E2T to the targeted xApps. However, SD-RAN's implementation uses gRPC's streams to complete the same task. Identifying these diverse messaging formats and crafting appropriate messages for each component demands manual and error-prone code scanning. On the other hand, verifying that the identified vulnerabilities in each component are exploitable from RAN inputs is also challenging. It requires complex and manual mapping of the tested internal message to the messages sent from RAN. In contrast, in an end-to-end testing setup, the protocols and messages accepted by the RIC from the RAN are well-defined in the E2AP and E2SM protocols by O-RAN specifications. In addition, any issues found by test inputs sent over the E2 interface are directly exploitable by a misbehaving RAN node. These reasons justify an end-to-end testing approach that aligns with our proposed threat model.

3.4 Scope of Testing

Our threat model specifically targets the E2 interface, the Near-RT RIC that is directly connected with E2, and the xApps that operate within the Near-RT RIC, due to their critical role in responding directly to RAN conditions. For the sake of exposition, we refer to the O-RAN RIC broadly as O-RAN occasionally in this paper. In this work, our main focus is on effectively reasoning about component dependencies and

interactions in O-RAN. We limit our scope to finding memory corruption issues that can cause O-RAN components to crash or become unresponsive, and do not consider logical or stateful bugs. Each of our testing runs is conducted in a stateless manner, which also reflects the RAN's limited control over the RIC's operational states. From the RAN's perspective, interactions with the RIC can be broadly categorized into two phases: *pre-connection* and *post-connection* with the RIC. The transition from the pre-connection to the post-connection is through RAN sending a successful `E2SetupRequest` message to the E2T. We test both scenarios by configuring the RIC to the corresponding state before starting testing. We only test individual inputs instead of sequences of inputs. While testing in the pre-connection state, if an `E2SetupReueqst` message sent from the RAN is accepted by the E2T, the state is transitioned to post-connection. `ORANalyst` terminates the established connection and initiates a new SCTP connection to the E2T, effectively resetting the state to pre-connection. O-RAN's technical specifications mandate SBA for implementing its RIC [61], so monolithic implementations are not specification-compliant. In this work, we focus on testing service-based implementations.

4 Challenges & Methodology

We first summarize the challenges in designing an end-to-end testing framework for O-RAN, then present `ORANalyst`'s design which aims to address these challenges.

4.1 Challenges of End-to-End O-RAN Testing

(C1) Generating targeted and meaningful test inputs. For end-to-end testing of an O-RAN RIC, inputs from the RAN are initially processed by the E2T (entry point in the RIC from RAN), where they undergo decoding and validation before being either routed to their target components or discarded. For testing components downstream of the E2T, e.g., xApps (as shown in Figure 1), it is essential to generate inputs that can successfully reach these targets to ensure effective testing. Moreover, without inputs reliably reaching the intended target, a timeout mechanism has to be employed to infer the inputs' failure to reach the target [51], resulting in more delays.

Motivating Example. To better explain this challenge, we illustrate it with the running example in Listing 3. Test inputs sent to the RIC from the fuzzer emulating as a RAN connecting to the RIC first pass through intermediate components (e.g., E2T) before reaching their target (i.e., the xApp in this example). To exploit the vulnerability in lines 10 and 11, the `encode_action_arr` function must return a negative value. We observe that the encoding process in line 21 may result in an error if the action definition list, constructed in the while loop from lines 17 to 19, is empty. The length and contents of this list are determined by the parameter `actionArr`, which is extracted in the `encode_action_definition` function from lines 6 to 8. Therefore, to uncover the vulnerability, the `action_bytes` variable, which contains the encoded information about supported RAN functions for RIC control, must either be decoded successfully but contain no action items or fail to decode. It is important to note that `action_bytes` are embedded within an `E2SetupRequest`, sent by the RAN during registration to the RIC. Should the entire `E2SetupRequest` message fail to decode or contain malformed information, it will be rejected by the E2T during the checks in lines 2 or 11 in Listing 1, preventing the message from reaching the affected xApp.

In summary, for a fuzzer to reveal the vulnerability, the test input it generates must satisfy the following criteria: **(i)** It must first navigate past decoding checks and validations of earlier components, such as the E2T, to reach the targeted component. **(ii)** Upon reaching the test component, the input must successfully pass initial decoding (syntactic correctness check) to prevent an early exit and ensure that it reaches the problematic code segment. **(iii)** Finally, the input must also contain some anomaly to trigger the vulnerability (e.g., an encoding error at line 22 in Listing 3 by providing an empty action definition list within `actionDef`.

(C2) Constantly evolving message formats. Existing general-purpose grammar-aware input generation tools like Peach [11] or BooFuzz [4] require manual extraction of message formats. No automated ASN.1 message generation tool currently exists. Libprotobuf-mutator-asn1 [19] can generate ASN.1 messages from protobuf [30] definitions but requires a manual ASN.1-to-protobuf translation. These manual efforts pose challenges for testing O-RAN protocols, i.e., E2AP [66] and E2SM [67], where hundreds of structures are used to define numerous message types. To make matters worse, both protocols are frequently updated by the standard body, rendering the manual construction and maintenance of grammar from the technical documents for each version impractical. Since O-RAN's initial release in 2020, both E2AP and E2SM protocols have undergone four major revision versions alongside numerous minor updates. Additionally, O-RAN implementations often utilize different versions of these protocols [23, 26, 32].

(C3) Identifying O-RAN's end-of-processing of an input. For efficient testing, a new test input should be dispatched as soon as the previous one finishes processing in the CUT. On the other hand, for accurate coverage collection and fault attribution, inputs must not overlap with previous processing ones. Precisely identifying the end-of-processing for input is often challenging in O-RAN RIC, as the RIC does not respond to certain types of inputs from the RAN (e.g., indication messages). This differs from the expectations of API fuzzers [7, 39], which depend on response messages to determine the end of a request. Moreover, unlike traditional fuzzing conventions, remote microservice targets in O-RAN do not signal input processing completion through function returns or control transfers back to the fuzzer.

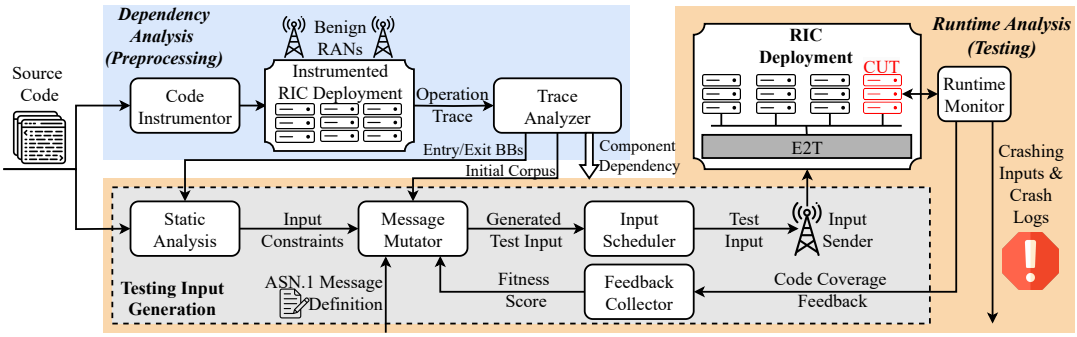

Figure 3: Architecture of ORANalyst. Details are discussed in §4.2

4.2 ORANalyst's Methodology

To address the challenges detailed in §4.1, we design ORANalyst, an end-to-end, grammar-guided, feedback-driven fuzzing framework for O-RAN. In this design, the fuzzer emulates a RAN node connected with the target O-RAN RIC system. To sidestep challenge (C1), ORANalyst takes an incremental testing approach, where it focuses on testing a singular O-RAN component at any time, while also considering the complex interactions among other components in the RIC without stubbing any components. Initially, ORANalyst focuses on the "shallow" components that are directly connected to the fuzzer. In this workflow, the first component tested is E2T, as it directly interfaces with the RAN, and is responsible for managing all message decoding and routing to other components of the RIC. During the testing of each component, ORANalyst also collects the path conditions required for the inputs to propagate to the next component through an efficient static analysis. We discuss in detail how we circumvent challenges in static analysis, such as the path explosion problem in §5. As the testing progresses, we move to components deeper in the system, aggregating path conditions collected from the previous components to constrain input mutation so that the generated message can reach the component under test (CUT) consistently. The architecture of ORANalyst is detailed in Figure 3. To achieve the proposed methodology, ORANalyst operates in two stages: a *preprocessing* stage, where it extracts component dependency information, and a *runtime testing* stage.

4.2.1 Dependency Analysis Through Dynamic Tracing

When an input is sent to the RIC, it sequentially passes through several RIC components for processing. While static analysis allows ORANalyst to find execution paths of an input within a component, it cannot directly identify the subsequent component an input flows to. This inter-component information flow occurs via network traffic, such as API [28] or gRPC [13] calls, and the destination endpoint cannot be easily extracted through static methods. This is because endpoints from different components are connected through RIC's internal routing and messaging systems, which are managed dynamically during O-RAN's runtime. Additionally, extracting this information from O-RAN specifications is also not possible since implementations vary in their designs of the internal components. For example, SD-RAN merges the logical E2T, E2 management, and subscription management into a single E2T component, while O-RAN-SC separates each function into individual components. Manually scanning the code and compiling this information is an arduous and error-prone task. To address this, ORANalyst collects dynamic execution and network traces during the normal operation of O-RAN and constructs a *component dependency tree*.

The goal of dynamic tracing is to capture the flow of all message types in the O-RAN implementation to understand the implementation's components dependency. Specifically, for each message type, dynamic tracing provides three types of information: **(i)** A sequence of components the input passes through to guide ORANalyst's testing order from shallow- to deep-lying components during runtime analysis; **(ii)** Detailed information on the entry and exit points (basic blocks) of the input in each component, which the static analysis uses to generate path constraints for ORANalyst to create targeted inputs for testing the CUT (detailed in §5); and **(iii)** Raw packets collected over the E2 interface, used as initial corpus during runtime analysis. To extract these three pieces of information, we set up the target O-RAN implementation with all available xApps configured to communicate with unmodified benign RANs, recording naturally occurring traffic from O-RAN's regular operations for 24 hours. We collect two types of traces: **(i)** we use tcpdump [34] to record all raw packets sent and received by each RIC component, forming a network trace. **(ii)** We instrument each RIC component to assign unique identifiers to each edge and basic block in the source code, tracing code execution paths by collecting all executed basic blocks and edges during runtime to form an execution trace.

ORANalyst combines the collected network and execution traces using timing, order, and message type information to form a comprehensive operation trace. By aligning the order and timestamps of the network packets with the corresponding execution paths, it maps the sequence of components that each message type traverses. From the execution trace of each component, it extracts the entry and exit basic blocks

for the message traversed in a component. Although the execution path information is also available, we do not use it as the traces may not cover all execution paths from entry to exit, potentially over-restricting the input generation. Instead, we use static analysis to identify all potential execution paths and associated path constraints required for the input to flow from entry to exit, i.e., to the next component. We group the extracted information by message types and cross-validate to ensure consistency across the same message types. If messages of the same message type result in different extracted component dependencies or entry and exit points, it may indicate that the message type is not fine-grained enough. For example, indication messages of the same service model may have different reporting formats, resulting in different extracted dependencies. In case of any inconsistencies, we refine the message type distinctions to be more fine-grained if necessary, by sub-categorizing the message types.

As dynamic tracing only records messages that naturally occur during a 24-hour operation of O-RAN with benign RANs, it is possible that some rarely occurring messages are not captured. In that case, we do not test those messages. This is acceptable as this work aims for correctness, i.e., ensuring that all detected issues are true vulnerabilities exploitable by a misbehaving RAN node, rather than completeness, i.e., we do not claim to find all vulnerabilities. We provide an evaluation of our dynamic tracing in §7.2. Note that we did not encounter any circular dependencies, i.e., no single input traverses the same component more than once.

4.2.2 Runtime Analysis

The component dependency extracted during preprocessing guides `ORANalyst`'s runtime analysis. `ORANalyst` focuses on testing one component at a time, beginning with the first component the input encounters in the RIC (E2T), and progressively moves to deeper components. To ensure that test inputs can navigate past previous components to reach the deeper ones, input generation is refined iteratively during the testing of each CUT. `ORANalyst` extracts the necessary path constraints that ensure the input navigates past the CUT by designing an efficient *static analysis*, as detailed in §5. This allows `ORANalyst` to systematically explore and test each component in a dependency sequence. Below, we introduce other key components in the runtime analysis process.

❑ **Grammar-aware input generation.** Inputs sent to the RIC from RAN through the public-facing E2 interface follow the highly structured ASN.1 format, as specified by E2AP [66] and E2SM [67] protocols and detailed in the corresponding technical specifications. Traditional byte-level input generation and mutation methods [18, 50] view the entire input as bytes, ignoring its underlying structure and context. This approach leads to a significant proportion of test inputs being discarded by the RIC's decoding functions checking the syntactic correctness of the inputs. As a result, those inputs cannot reach the CUT's input processing logic, where the main functionalities of the component reside. Consequently, byte-level input generation and mutation methods miss the opportunity to uncover potentially more impactful vulnerabilities within the processing logic.

To address this, `ORANalyst` employs a grammar-aware mutation strategy that generates inputs conforming to the expected input structure but incorporating unexpected values. The grammar-aware generation strategy also allows us to control specific field values in the generated inputs to satisfy input constraints collected from static analysis. However, as mentioned in (C2), manually translating message formats from ASN.1 to fuzzer-specific formats [4, 11, 19] for various message types and versions in O-RAN protocols is not feasible. To overcome this, we leverage the limited number of datatypes in ASN.1 to directly implement mutation rules on ASN.1 formats without translating them into internal representations. By operating directly on ASN.1 formats, we can also support ASN.1-specific features like field constraints and encoding/decoding operations using existing ASN.1 compilers [35] to auto-generate information from ASN.1 grammars.

We implement a universal set of generation and mutation rules based on the *field datatypes* and the *constraints* each datatype may enforce, rather than on specific fields in a message. `ORANalyst` applies these universal rules across different message types and protocol versions during testing, eliminating the need for manual updates with each new revision. Raw packets collected over the E2 interface during dependency analysis are used as the initial corpus for the *message mutator*. The mutator decodes and mutates messages in the corpus, and can also generate missing message fields. Table 2 details the generation and mutation methods applied to each ASN.1 datatype. All inputs generated by the grammar-aware message mutator are in valid ASN.1 syntax. However, `ORANalyst` also selectively incorporates byte-level mutations into the generated and encoded test inputs to craft slightly malformed packets for testing the decoding logic of CUT. The motivating example in Listing 3 demonstrates that some encoding errors are required to trigger certain vulnerabilities, emphasizing the need to also test slightly malformed packets.

❑ **Identifying the end of input processing.** Test inputs generated by the message mutator are scheduled by the *input scheduler* and sent to the CUT by the *input sender*. However, as discussed in challenge (C3), it is difficult to determine when a test input has finished being processed by the CUT. To address this, we observe that like typical web server implementations, each component in the RIC operates in a continuously running loop that accepts new requests indefinitely. The return to the beginning of a new loop iteration, where a new request can be accepted, might indicate the completion of processing the previous input. However, in O-RAN, new threads are often spawned for parallel input processing. This means that even if the main loop is ready to accept new inputs, the processing of the previous input may still be ongoing in

Field Type	Constraints	Generation Method	Mutation Method
Boolean	-	Generate both True and False.	Change the boolean value to the alternative.
Integer	Value Constraint	Generate "interesting" values (e.g., 0, positive, negative, boundary values) within constraints.	Randomly select an integer value or assign boundary values within the given constraints.
Enumerated	Valid Enums	Generate all possible enumeration values.	Randomly change to a different enumeration option.
Bit String	Bit Size Constraint	Create bit strings of varying lengths, including boundary cases, within constraints.	Within size constraints, perform byte-level mutations, or generate a new random bit string.
Octet String	Octet Size Constraint	Generate random octet strings of diverse lengths, including edge cases.	Modify to a random octet sequence within size limits, or opt for boundary lengths.
Sequence / Sequence Of	Sequence Length	Produce sequences of varied lengths, including boundary lengths, randomly populating each entry according to its type.	Randomize length in constraints or set to lower/upper constraints, and randomly delete/add/mutate each element based on type.
Choice	-	Create instances of all available choice options using methods described in this table depending on the field type.	Mutate to an alternative choice option or modify the existing one while introducing random mutations in the subfields.
Optional	-	Populate the optional field although it is allowed to be empty.	Apply probabilistic mutations to the values of optional fields, randomly remove existing fields, or introduce previously absent ones.

Table 2: Generation and Mutation Methods for Each Field Type

different threads. To accurately determine the end of request processing, we establish two criteria: **(i)** the readiness of the main message-receiving loop to accept the next input, which `ORANalyst` monitors by instrumenting the start of the loop; and **(ii)** the termination of all threads initiated for processing the prior input, which `ORANalyst` tracks by instrumenting all thread creations and terminations. Existing O-RAN implementations we tested do not use thread pools to manage their threads. This is because, in Go, threads (goroutines) are lightweight and inexpensive to create and terminate, and there are simpler ways to limit concurrency than using thread pools. Consequently, `ORANalyst` only monitors thread creation and termination. However, support for thread pools can be added to `ORANalyst` by instrumenting the tasks submitted to the thread pool and monitoring the callbacks when tasks finish.

❑ **Feedback loop.** Leveraging components introduced above, we design `ORANalyst` to generate inputs that effectively reach any specific CUT in the O-RAN RIC. The *runtime monitor* oversees the processing of each input in the CUT and evaluates the outcome. Once input processing is complete, the runtime monitor first checks for and reports any crashes triggered by the input, and then restarts the crashed component. If no crash occurs, it collects code coverage data from the execution, which is then sent back to the *feedback collector* for fitness score calculation and subsequent test input scheduling. To handle scenarios where an input fails to reach the CUT, `ORANalyst` employs a timeout mechanism. If a series of consecutive inputs or a significant portion of inputs fail to reach the CUT, the runtime monitor raises an alert indicating a potential stall in the CUT or an issue with the input constraints. We detail this identification mechanism in §7.2.

5 Input Constraints Generation

To generate inputs that effectively reach and explore each component in the RIC, `ORANalyst` combines static analysis with dynamic tracing to generate path constraints that guide inputs from the E2 interface to the target component. Using dynamic tracing, as detailed in §4.2.1, `ORANalyst` extracts information about the specific components an input reaches, the sequence/order of traversal, and the entry and exit points (basic blocks) in each component. `ORANalyst` begins its testing of each component with an intra-component static dataflow analysis to collect path constraints required to reach the exit point (e.g., API or gRPC calls to another component) of the CUT from its entry point. Satisfying these path constraints ensures test inputs can reach the next component. These path conditions serve two critical purposes: First, they provide semantic guidance for the fuzzer when exploring the CUT, enabling it to produce inputs that are not only syntactically valid but also semantically interesting for exploring different branching paths of the CUT. In this setup, values satisfying and violating branch conditions are both tested. Second, in the context of testing subsequent components in the communication chain (based on the component dependency tree), these conditions are used to generate inputs that can navigate through the current component and reach the next one. In this scenario, `ORANalyst` specifically generates inputs that meet the branch conditions necessary to reach the exit point of the current component. Below we discuss details about the static analysis to ensure efficiency and accuracy.

5.1 Critical Path Conditions

When performing the static analysis on a CUT, we observe that enumerating all paths and branch conditions the input traverses from the entry to the exit quickly leads to path explosion issues. The problem arises from the need to exhaustively explore possible paths at each branch point, demanding significant memory and computing resources. This challenge is further exacerbated by the numerous checks and complex processing logic dependent on various message fields that are common in RIC components. We, however, observe that while many branch conditions evaluate different field processing routines, they usually do not alter the control flow leading to the exit. Moreover, we notice that certain errors in input processing or validation logic, despite triggering logging activities, do not result in input rejection, indicating these errors do not affect the message's progression to the exit.

For instance, consider the motivating example in Listing 3, where `action_bytes` undergo decoding in line 4. As these bytes are extracted from the input and are therefore tainted during the static analysis, an inter-procedural dataflow analysis would examine the `asn_decode` function's complex logic

and branches, resulting in path explosion. However, note that the return value `rval`, while used to guide input processing in line 6, does not lead to the early termination of the function even if the return value indicates an error, thereby not affecting the overall control flow. This observation allows us to bypass a detailed analysis of the decode function since the decoding result does not affect the control flow.

```
1 func AssociateRanToE2THandlerImpl(data models.
      RanE2tMap) error {
2   err := validateE2TAddressRANListData(data)
3   if err != nil {
4     xapp.Logger.Warn(" Association of RAN to E2T
       Instance data validation failed: " + err.Error()
      )
5     return err
6   }
7   // further processing
8   return sendRoutesToAll()
9 }
```

Listing 4: Critical Path Condition Example

Based on the above observation, we found that only a small portion of all path conditions checked along an execution path from the entry to the exit point need to be satisfied for the input to reach the exit. We denote such path conditions as *critical conditions*, and refer to the branches depending on these critical conditions as *critical branches*. Listing 4 illustrates an example of such critical path conditions, which depicts a simplified implementation for associating a RAN to an E2T instance in O-RAN-SC's routing manager. Here, if the validation check in line 2 fails, the input is discarded in line 5, preventing further processing or its acceptance. Thus, the condition in line 3 is deemed critical, and `ORANalyst` focuses on finding the input constraints that can fulfill this condition. This targeted focus on critical branches allows us to circumvent the common path explosion problem while computing path constraints using static analysis. This approach also ensures that identified critical conditions are enough to enable the input to traverse to the exit.

5.2 Extracting Path Conditions

To efficiently identify critical branches within a component whilst avoiding path explosion, we design an inter-procedural static analysis based on the Program Dependency Graph (PDG) [49] which comprises both the Control Dependency Graph (CDG) and the Data Dependency Graph (DDG). Using a function call graph, we first identify all sequences of function calls from an entry point to an exit point of the CUT, which we denote as function call paths. The task of identifying critical path conditions from entry to exit is then reduced to identifying the conditional branches that affect the execution of subsequent function calls along each function call path.

The algorithm `ORANalyst` uses to extract the critical path conditions is presented in Algorithm 1. It traces each function call in a function call path (lines 1-6) and identifies the basic blocks containing the call site that invokes the subsequent function in the call path (line 7). It then analyzes the callee

Algorithm 1 Critical Path Constraint Collection

Input:
$\mathcal{F}_{entry}$: Function Containing the Entry Point
$\mathcal{F}_{exit}$: Function Containing the Exit Point
Output: List of Boolean Expressions Representing the Critical Path Conditions Required to be Satisfied to Reach $\mathcal{F}_{exit}$ from $\mathcal{F}_{entry}$

1: **procedure** CollectPathConstraint
2: totalPathConstraint = { }
3: **for** each function call path P_i from $\mathcal{F}_{entry}$ to $\mathcal{F}_{exit}$ **do**
4: pathConstraint = { }
5: **for** each edge E_j in P_i **do**
// Get caller and callee of edge
6: f_{caller}, f_{callee} = getCallerAndCallee(E_j)
// Get target basic block in the caller containing call-site to callee
7: $b_{callsite}$ = getCallSiteBlock(f_{caller}, f_{callee})
// Get control blocks of $b_{callsite}$ in f_{caller}
8: $B_{control}$ = getControlDependentBlocks(CDG(f_{caller}), $b_{callsite}$)
// Append conditions in last instructions of control blocks
9: **for** each control block b_k in $B_{control}$ **do**
10: pathConstraint = pathConstraint ∪ getCondition(b_k)
11: **end for**
12: **end for**
13: totalPathConstraint = totalPathConstraint ∪ pathConstraint
14: **end for**
15: **return** totalPathConstraint
16: **end procedure**

function's CDG to determine the control dependency of these target basic blocks (line 8). Given a target basic block in a function, the CDG shows all basic blocks whose control decisions at the end of the block directly determine whether the target basic block is reachable. All these control decisions must be satisfied to reach the target basic block. These control decisions are collected as path conditions, and we extract all such conditions for all function calls in a function call path. By combining these conditions (lines 9-16), we obtain the path constraints required to follow all function call paths, i.e., the path constraints to reach the exit point from the entry point of a CUT. To handle indirect function calls, we use off-the-shelf points-to-analysis techniques [79] available for Go-SSA IR for Go programs and LLVM-IR for C/C++ programs. We observe that the use of pointers and function pointers (i.e., indirect calls) in existing O-RAN source code is very limited. Therefore, existing points-to-analysis tools are adequate for our analysis. This observation may not be true for all future O-RAN implementations, but it is a common trait of most protocol implementations.

We illustrate the above idea with the example presented in Listing 4. In this example, the target line to reach is line 8, and the critical branch is the `if` branch in line 3. If the branch condition `err` $!=$ `nil` is evaluated to be true, line 8 would not be reachable. Hence, we collect the condition `err` $!=$ `nil` as well as its required value `False` as the critical condition. Since we only focus on extracting critical path conditions utilizing CDG, our methodology can effectively disregard non-critical branches, such as those pertaining to error logging that do not result in early function termination. Furthermore, this approach also sidesteps the exponential increase in

enumerating paths that typically results in path explosion.

5.3 Selective Function Processing

Some conditions collected during the previous step may depend on the return values of function calls. For example, the collected condition `err!=nil` in Listing 4 depends on the result of the `validateE2TAddressRANListData` function. To determine what inputs can satisfy this condition, `ORANalyst` needs to further analyze the `validateE2TAddressRANListData` function. However, some functions, such as library functions, typically do not contain meaningful constraints on the input. To alleviate path explosion, we selectively analyze only functions that yield meaningful constraints on the input. To this end, we first discern functions that contain meaningful input constraints, which we call *validating functions*, as they typically apply validation checks that inputs must satisfy to reach the exit point. We call other functions *generic*.

The `validateE2TAddressRANListData` function is an example of a validating function, as it validates the input and contains critical conditions on inputs. Inputs containing values that fail this validating function get discarded by the component. Conversely, *generic* functions can generate errors in case of failure and can also affect control flows, but they do not yield meaningful constraints on the inputs. For example, in Listing 5, the database retrieval function SDL.Get is a generic function. We would skip analyzing the implementation details of this function since it would not result in meaningful constraints over the input. Instead, our static analysis would only record the function itself as a condition, i.e., that the data retrieval corresponding to the key is successful.

```
data, err := SDL.Get(key)
if err != nil {
  return err
}
// further processing using data
```

Listing 5: Generic Function Example

Based on this insight and the following observation, we design a heuristic approach to distinguish between generic and validating functions. We observe that generic functions are typically called multiple times in different contexts due to their broad use cases, while validating functions are used in more specific contexts. We use the following criteria to identify the functions we want to process: **(i)** The function should not be from a library or an imported open-source shared project, as these functions are often generic and involved in data management, logging, or networking (e.g., `SDL.Get` in Listing 5). **(ii)** The function should not be invoked by more than a threshold number of functions across more than a number of packages of the CUT. This criterion helps identify and exclude generic functions that are likely to be invoked in different contexts due to their broad applicability. In practice, we use empirical observations to set the threshold. During testing, if a function is invoked by more than three functions in the CUT or by functions from more than two different packages, we label it as generic and do not analyze it. We provide some assessments of the classification accuracy in §7.2.

Finally, for the functions we decide to analyze, we apply a similar methodology as described in §5.2 to collect conditions. We identify the basic blocks generating the required return value and utilize the function's CDG to determine the conditions for reaching these blocks. For example, in the `validateE2TAddressRANListData` function in Listing 4, we examine the basic blocks returning no errors and use the CDG to identify the conditions for reaching these blocks. This process is recursive, continuing until all conditions are resolved without dependencies on other validating functions.

5.4 Path Conditions To Input Constraints

After extracting the path conditions of each function call path, we map the collected conditions as constraints to specific fields in the generated test inputs. Each extracted path condition is represented as a boolean variable, along with its requisite value (True/False) for reaching the target block. For example, Listing 4 produces the boolean variable condition err != nil, and the required value False, as explained in §5.2. To generate constraints on inputs based on each condition, we employ a *backward dataflow analysis*. This analysis traces the variable involved in the condition back to a field access operation from the input through a backward taint analysis. `ORANalyst` then maps the condition on the boolean variable to constraints of specific fields in the input. The extracted constraints are used as additional rules for the input generator.

Loops. Performing backward analysis on loops can create scalability issues and potentially unsound results. However, due to the characteristics of protocol implementations, we observe that the majority of loops in O-RAN's RIC components iterate over a list of items in the message. In such scenarios, each iteration functions independently of the others, and the execution results from each iteration do not carry over to other iterations. We identify these scenarios by confirming that in the loop body, there are no cross-iteration dependencies (e.g., in SSA form, no variables defined inside the loop are used outside of their defined iteration, and no *phi* instructions are used to select a value from previous iterations). For such cases, we only analyze the loop once, treating the loop index as a symbolic value representing the list index. For other generic loops performing calculations where results are carried over iterations, we limit the number of loop iterations we process by capping the number of loop unrollings `ORANalyst` performs.

6 Implementation

We implement `ORANalyst` with five main components: (i) automated instrumentation for feedback collection from CUT, (ii) inter-component input tracing, (iii) static analysis for in-

put constraints, (iv) grammar-aware input generator, and (v) fuzzing engine to compute fitness score and schedule inputs.

Feedback instrumentation. For C/C++ components, we use AFL++ [50]'s afl-clang as our instrumentation tool. For Go, we extend go-fuzz [12]'s AST-based basic block coverage tool to include edge coverage by instrumenting branching statements for comprehensive path tracking. A universal customized runtime monitor is injected in each CUT to monitor the runtime information, manage shared memory for coverage data, and collect and relay coverage feedback to the fuzzer.

Dynamic tracing. We employ tcpdump [34] to capture network traces for each RIC component. Using our instrumentation tool, we assign unique identifiers to each edge and basic block to track code execution and collect execution traces.

Static analysis. We construct PDG using the LT algorithm [54] and the algorithm by Ferrante et al. [49]. For Go programs, we perform the static analysis on SSA intermediate representation (IR), while for C/C++ programs, we utilize SVF [79] to work with LLVM IR.

Grammar-aware input generation. The input generation utilizes datatype definitions, constraint specifications, and encoding/decoding routines from code generated by the ASN.1 C compiler [35] using E2AP and E2SM ASN.1 grammars [66, 67]. Additionally, we incorporate input constraints identified through static analysis to input generation by applying special rules on the specific messages and fields involved.

Fuzzing engine. We build our fuzzing engine by extending go-fuzz [12] to support remote coverage data reception, static analysis, and grammar-aware input generation.

7 Evaluation

❏ **Experiment setup.** For our experiments, we use a laptop with Intel i7-9750H CPU and 16GB DDR4 RAM. Only two matured and commercially-adopted open-source O-RAN RIC implementations exist: O-RAN-SC [21] and SD-RAN [32]. We evaluated both implementations. Specifically, we tested on SD-RAN's latest 1.4 release and O-RAN-SC's most recent I-release. Both O-RAN implementations offer a Kubernetes-based deployment for their RIC, wherein each microservice component is separately compiled into a Docker image and then deployed as a pod within the Kubernetes deployment, communicating with other components via network traffic.

To prepare an O-RAN implementation for testing, we first instrument the source code of the CUT and recompile it following the original Dockerfile into an instrumented Docker image. We then replace the original CUT's Docker image with the instrumented image in the Kubernetes deployment. For each vulnerability identified by `ORANalyst`, we conduct manual validation to ensure that the vulnerability can be reproduced in the original deployment, thereby confirming that the instrumentation does not introduce any false-positive issues. We have not encountered any false positives caused by our instrumentation. When we discover a crash that is triggered continuously and hinders the deeper testing of the component, we manually devise and apply a patch to suppress the crash.

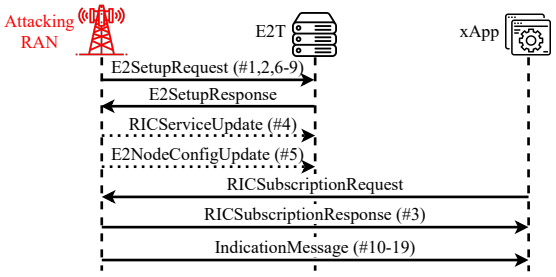

Figure 4: Flow of exploitable messages between the attacking RAN, E2T, and xApp. Other RIC components are omitted for conciseness. Dotted lines represent optional messages, while solid lines represent required messages in the procedure. # denotes the vulnerability IDs corresponding to the message.

7.1 Identified Issues & Potential Exploits

We deploy `ORANalyst` to test 4 xApps and 6 platform components across two O-RAN RIC implementations. These components vary in size, with each one's lines of code (LoC) typically ranging from several thousand to 100,000. The testing is conducted in both the pre-connection and post-connection state, each for a 24-hour period for each component. We identify 19 distinct issues across 7 components. Among these, 17 issues led to crashes, and 2 resulted in the blockage of communication channels, thereby obstructing all subsequent messages, as detailed in Table 3. Notably, only 7 of the 19 issues (#1, 6, 7, 8, 9, 13, 14) were triggered by malformed packets, which either caused segmentation faults or index out-of-bounds panics during decoding. Conversely, the remaining 12 issues were exploitable through well-formed inputs. The discovery of these issues underscores `ORANalyst`'s efficacy in reaching and exploring the processing logic, while findings through malformed inputs demonstrate that `ORANalyst` is also capable of discovering issues in the decoding logic. Figure 4 illustrates the flow of messages within the O-RAN procedures and highlights the messages that trigger vulnerabilities listed in Table 3. The figure shows the sequence in which these messages interact with the E2T and an xApp within the RIC. For simplicity, this diagram does not include other components involved in the RIC, such as E2 Management.

❏ **Memory issues.** The most common problems we identified are memory-related, such as crashes caused by index out-of-bounds panics. For example, the Key Performance Measurement (KPM) E2SM indication message type includes a field for an array of measurement items and an integer count of the number of items in the array. In SD-RAN's kpimon xApp, we observed that the count value is used to iterate over the array items without validating the array's boundaries. Consequently, when the actual number of items is less than the reported count, an index out-of-bounds panic is triggered, leading to the xApp's crash (issue #19). Attackers can cause

	Component	#	Cause	Vulnerability Description	Exploit Message	Impact of Vulnerability	Location
ORAN-SC	e2t	1	**IA**	Unexpected input causes 'std::invalid_argument' exception, leading to termination of E2T. This can be exploited to cause a DoS of all RIC components and RANs managed by the E2T.	E2SetupRequest	Crash & DoS	sctpThread-.cpp:1941
		2	**SF**	Unexpected input leads to segmentation fault. This can be exploited to crash the service, causing a DoS.	E2SetupRequest	Crash & DoS	sctpThread-.cpp:2180
		3	**SF**	Similar to above, leading to service crash and potential DoS.	RICSubscription-Response	Crash & DoS	sctpThread-.cpp:2451
	e2mgr	4	**OR**	Runtime panic due to array index out of range. This can be exploited to disrupt the service by causing unexpected crashes.	RICServiceUpdate	Crash & DoS	ric_service_update_-handler.go:107
		5	**OR**	Runtime panic due to index out of range, leading to service disruption.	E2NodeConfigur-ationUpdate	Crash & DoS	e2_node_config-uration_update_-ack.go:279
	kpimon-go	6	**UR**	Return value used as size to initialize array without checks. This may lead to a negative-sized array, which can be exploited to cause memory corruption or execute arbitrary code.	E2SetupRequest	Crash, DoS, & Memory Corruption	wrapper.c:L246
		7	**UR**	Similar to above, leading to crashes and memory corruptions.	E2SetupRequest	Crash, DoS, & Memory Corruption	wrapper.c:266
		8	**UR**	Similar to above, leading to crashes and memory corruptions..	E2SetupRequest	Crash, DoS, & Memory Corruption	wrapper.c:277
		9	**UR**	Similar to above, leading to crashes and memory corruptions.	E2SetupRequest	Crash, DoS, & Memory Corruption	wrapper.c:288
		10	**OR**	Index out of range error, which can be exploited to cause unexpected crashes and disrupt the service.	IndicationHeader	Crash & DoS	control.go:485
		11	**OR**	Index out of range error, similar to above, leading to DoS.	IndicationMessage	Crash & DoS	control.go:530
		12	**SF**	Exploit message cause unexpected signal during runtime execution. This can crash the service, causing a DoS.	IndicationMessage	Crash & DoS	Not yet identified
SD-RAN	onos-e2t	13	**OR**	Runtime panic due to index out of range. This can be exploited to cause crashes and disrupt the service.	IndicationMessage	Crash & DoS	marshal.go:57
		14	**OR**	Slice bounds out of range, which can be exploited to corrupt data and cause crashes.	IndicationMessage	Crash & DoS	aper.go:140
	ric-sdk-go	15	**EH**	Errors not handled properly, which can be exploited to crash the entire stream and block communication channels.	IndicationMessage	Communication Channel Blockage	node.go:223
	rimedo-ts	16	**OR**	Slice bounds out of range, which can lead to DoS.	IndicationMessage	Crash & DoS	reader.go:36
		17	**OR**	Slice bounds out of range, similar to above, DoS.	IndicationMessage	Crash & DoS	reader.go:18
	onos-kpimon	18	**EH**	Error channel blocking due to unhandled errors. This can be exploited to block subsequent messages and disrupt service.	IndicationMessage	Communication Channel Blockage	monitor.go:207
		19	**OR**	Index out of range error, which can lead to DoS.	IndicationMessage	Crash & DoS	monitor.go:133

Table 3: Summary of Discovered Vulnerabilities

All vulnerabilities are exploitable by malicious RAN nodes. Vulnerability Causes: **SF**: (S)egmentation (F)ault; **OR**: index/slice bounds (O)ut of (R)ange; **EH**: improper (E)rror (H)andling; **UR**: (U)nhandled (R)eturn value; **IA**: (I)nvalid (A)rgument error (due to unexpected input formats).

the affected components to crash by sending carefully crafted requests that exploit these memory issues in memory-safe languages like Go, leading to service disruptions. For components implemented in C/C++, which are not memory-safe, an attacker may exploit memory issues to trigger component crashes or even remote code execution.

❏ **Improper error handling.** Our evaluation uncovers two error-handling issues (#15, 18) that lead to the disruption of communication channels. Specifically, `ORANalyst` identified a flaw (#15) within the error handling of indication message streams of onos-sdk-go, an SDK used by xApps in SD-RAN. xApps employ this SDK to receive indication messages over gRPC streams. According to the usage of gRPC streams, any error in the stream requires the abortion of the current stream and the re-initialization of a new one. However, when `ORANalyst` generates inputs that trigger an error in the stream, the SDK tries to read repeatedly from the same stream. The read operation is enclosed in an infinite loop, and continuously trying to read from the aborted stream traps the process in an endless loop of reprocessing the same error, rendering the xApp incapable of processing any new messages. All SD-RAN xApps using onos-sdk-go are vulnerable to this issue.

❏ **Attacks and impacts.** As shown in Figure 4, an adversary exploiting the identified vulnerabilities can craft malicious inputs and send those to the target components from the malicious RAN to trigger crashes. Crashes within the O-RAN's RIC components can further lead to substantial DoS impacts on other RANs connected to the same RIC. Restarting the crashed component and re-establishing communication with other components and RANs could take several minutes. An adversary can also repeatedly crash the component after each restart. E2T is particularly vulnerable, as it serves as the primary conduit for message distribution from and to RANs, and its failure could deny all O-RAN services for the connected RANs. For example, a malicious RAN could send carefully crafted `E2Setup` messages to exploit vulnerability #2, triggering segmentation-fault to crash E2T, disrupting all communications between O-RAN-RIC and connected RANs. Moreover, the communication channel blockage issues (#15, 18) are undetectable from the RAN, as the affected RAN does not receive any error messages and can continue transmitting to the blocked channel. This effectively disables communication between the xApp and the RAN indefinitely.

7.2 Evaluation of Intermediate Components

Below, we present an evaluation of the correctness and completeness of `ORANalyst`'s intermediate components against manually constructed baselines to provide insights into the efficacy of these components. Additionally, we conducted ablation studies of components in `ORANalyst` in §7.3.

❏ **Dynamic tracing (§4.2.1).** We instrumented four xApps and six platform components across two O-RAN RIC implementations and collected traces of messages that occurred

during a 24-hour operation of O-RAN with benign RANs. We collected 14 GB of execution traces, containing sequences of executed basic block and edge identifiers, and 23 GB of network traces in pcap format. From the collected traces, we extracted 15 types of messages across the two RICs, including `E2SetupRequest`, `E2ConfigurationUpdate`, `E2ConnectionUpdate`, and `indication` messages of different service models. However, we did not collect any traces of `resetRequest` in SD-RAN as this message only occurs to reset the connection from an abnormal failure. Similarly, we did not collect any `errorIndication` message trace in O-RAN-SC as this message is only used to report errors not reportable by other appropriate response messages.

❏ **Generic/validating functions classification (§5.3).** Mislabeling generic functions as validating (i.e., false-positives) overloads static analysis to process unnecessary functions, wasting time and resources and risking path explosion if the false-positive rate is high. Conversely, false-negative cases might result in missing path conditions, preventing some generated test inputs from reaching the CUT. Calculating the false-negative rate is challenging due to the large code base size of O-RAN implementations. For example, SD-RAN's E2T alone contains over 6,000 functions and over 100,000 LoC, excluding imported libraries. However, the results of static analysis are used to construct input constraints that ensure the test inputs generated by `ORANalyst` can effectively reach and explore the CUT. Instead of directly finding the false-negative cases, we monitor the percentage of test inputs that successfully reach the CUT. If this success rate falls below a threshold (99% in our testing), we manually analyze rejected inputs to identify any missed validating functions. We have not experienced the percentage dropping below the threshold during testing. On the other hand, manually verifying false-positive cases is manageable because, for each entry/exit pair, only around 30 functions are labeled as validating in each CUT. During our testing, we identified only 4 false-positive cases. Including these false-positive functions would not cause path explosion during static analysis.

❏ **Generated input constraints (§5.4).** To provide insights into the accuracy of the extracted input constraints, we manually validated the constraints for the `E2SetupRequest` and `indication` messages in SD-RAN's E2T component. For an `E2SetupRequest` to pass through the E2T, `ORANalyst` extracts 13 constraints on input fields, which are enforced to confirm the message type and validate field types and contents. Although the static analysis encountered a loop iterating over a list of information elements in the message, this loop was correctly resolved using the approach discussed in §5.4, as there were no dependencies between loop iterations. We confirmed that all 13 extracted constraints were accurate. For an `indication` message to pass through the E2T, `ORANalyst` collected three input constraints, which we validated to be accurate. These constraints specify that the input is of the correct type (indication message) and that the specified stream for forwarding the indication message exists. To further complement this evaluation, we evaluate the overall impact of the input constraints on the efficacy of `ORANalyst` by conducting ablation studies testing `ORANalyst` without using the extracted input constraints in §7.3.

7.3 Benchmark with State-of-the-Art

❏ **Benchmark tools adaptions.** We test state-of-the-art tools to benchmark against `ORANalyst`. However, none of these tools can support O-RAN implementations off-the-shelf. We discuss the adaptations made to these tools below.

(a) AFLNET [70]. AFLNET, an adaptation of AFL [2] for network protocol fuzzing, uses response messages to extract state information that guides mutations. It requires complete control over the server binary for forking, execution, and termination. To use it with O-RAN, we developed an intermediate program to manage remote coverage feedback and forward it to AFLNET. Since inputs sent to the RIC often yield no response messages, AFLNET infers incorrect state transitions for these messages, which negatively impacts its performance. Hence, we disabled AFLNET's stateful testing.

(b) BooFuzz [4]. As a successor to Sulley [33], BooFuzz is a generation-based, extensible network protocol fuzzer used in several recent protocol fuzzing research [76, 82]. Unlike feedback-driven fuzzers, BooFuzz relies on predefined message grammars to generate test inputs. Constructing these grammars is manual and error-prone, especially for complex protocols like E2AP and E2SM. For our analysis, we simplify this by allowing BooFuzz to directly generate test inputs from the initial corpus by treating each message as a byte array. The corpus column for BooFuzz in Table 4 represents the number of total test inputs generated by BooFuzz. In addition, BooFuzz does not accept any feedback. To prevent input overlap, a brief delay between tests is introduced for BooFuzz, which highlights its inefficiency. Completing the testing of all BooFuzz-generated inputs required just under 22 hours out of the allocated 24 hours of testing budget.

(c) Frizzer [9]. Frizzer is a coverage-guided black-box fuzzer based on the Frida [8] instrumentation toolkit. It can remotely connect to the Frida instance running on the target program's host, making it suitable for testing remote targets like O-RAN components directly. However, it requires manual identification of the address of the main network protocol handler function in the target server. We manually identified this address by inspecting the CUT binary. During testing, we found that Frizzer's Frida injections frequently caused segmentation faults in the E2T, resulting in crashes unrelated to the test inputs and generating numerous false positives. These crashes also triggered E2T restarts, with each restart taking considerable time, significantly reducing testing efficiency. After reviewing all crashes discovered by Frizzer, we confirmed that they were all false positives. Consequently, we have not included Frizzer's results in Table 4.

O-RAN-SC Component	E2T				Kpimon					
Fuzzer	crashes	corpus	cover	% decoded	crashes	corpus	bb cover	edge cover	% reaching xApp	% decoded
`ORANalyst`	3	2149	4326	72.35	3	73	1838	910	100/100	55.64
`ORANalyst` w/o input constraints	3	2149	4326	72.35	1	47	1828	907	47.27/59.01	53.50
`ORANalyst` w/o grammar	0	1433	4647	3.9	1	59	1831	906	40.64/80.81	16.76
AFLNET	0	245	3663	21.78	0	41	1824	901	32.81/97.83	12.37
BooFuzz	1	427033*	3655	81.96	1	427033*	1824	899	10.71/11.65	33.40
Radamsa	0	1323	3916	3.76	0	66	1827	901	11.39/78.20	4.40
Radamsa-filter	0	137	3467	100	1	35	1820	896	62.54/62.54	86.13

Table 4: Comparative Testing Results

(d) Radamsa [31]. Radamsa is used by Frizzer for message mutation. To avoid the instability caused by Frizzer's Frida instrumentation, we replace Frida with our coverage collection mechanism and evaluate Radamsa's effectiveness.

(e) Radamsa with filter. Our evaluation shows that most inputs generated by Radamsa fail to pass the initial decoding checks, and Radamsa struggles to generate meaningful test inputs that can thoroughly explore the CUT. To address this, we implement a pre-filter to examine the format of generated messages. Only those messages that successfully passed the decoding checks were forwarded to the target in this mode.

❏ **Benchmark CUTs.** To evaluate `ORANalyst`'s performance under O-RAN's multi-language environment, we selected two components as benchmark targets: (i) the ORAN-SC's E2T component, developed in C++, and (ii) the kpimon-go xApp, implemented in Go. We perform the testing in the post-connection to the RIC state, i.e., after RIC's acceptance of a successful `E2SetupRequest` as part of the testing setup. In this testing state, `ORANalyst` identifies 3 crashes for kpimon-go (i.e., #10-12 in Table 3), as opposed to 7 discovered in both states. For fairness, we evaluated all benchmark tools, along with `ORANalyst` on the same hardware setup, using identical initial corpus sets for a 24-hour period on each target. We conducted the testing of two targets separately by accepting code coverage feedback from the corresponding target component. Inputs aimed at testing E2T may also flow to the xApp, and any inputs targeting the xApp must first pass through and be routed by E2T. Since BooFuzz [4] is a generation fuzzer and does not accept feedback to guide its input generation during test-time, testings of both E2T and the xApp use the same set of test inputs generated by BooFuzz from the provided initial corpus set.

❏ **Metrics.** We collect the following statistics for each test, summarized in Table 4: **(i)** The number of issues found by each tool. **(ii)** The number of interesting corpora generated. In mutation fuzzers, an input is saved as a corpus if it explores previously uncovered code regions, so this metric roughly represents the fuzzer's ability to generate diverse inputs exploring different code regions. For BooFuzz, the corpus column reflects the total test cases generated. **(iii)** The number of basic blocks and edges covered by test inputs. Given that the aflclang tool used for instrumenting C++ components is limited to edge coverage, for E2T, we only collect the edge coverage. **(iv)** The percentage of inputs successfully decoded by the CUT and thus reaching its processing logic is also computed. We manually identify the start point of the input processing logic and record the number of inputs reaching this point. In this testing setup, E2T decodes the E2AP layer, while the xApp decodes the E2SM layer of inputs. **(v)** For the kpimon xApp, which is not directly connected to the fuzzer, we record the percentage of all test cases that can reach the xApp. The first value represents the percentage of all inputs that reach the xApp, and the second value represents the percentage of inputs successfully decoded by E2T that reach the xApp.

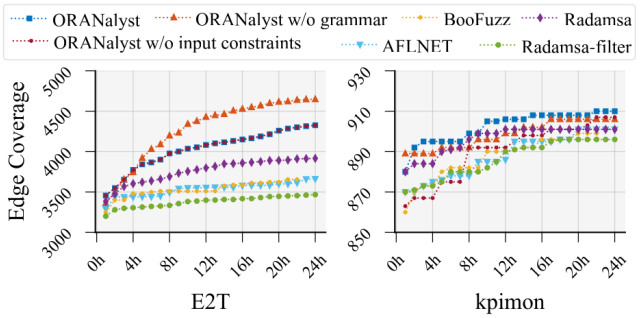

Figure 5: Discovered Edges Over Time by Evaluated Fuzzers

❏ **Ablation study.** We conduct an ablation study and present the results in Table 4. This study evaluates `ORANalyst` without extracted input constraints but still employing message grammar, as well as disabling the grammar-aware mutation entirely (also no input constraints). Since all inputs sent by `ORANalyst` through the E2 interface reach E2T, no input constraints are required to test E2T. Therefore, we directly use the evaluation results for `ORANalyst` to demonstrate the outcome of testing the E2T without input constraints. While `ORANalyst` without grammar-aware mutation achieves higher coverage for E2T, most of the test cases fail the decoding checks, indicating that the increased coverage likely comes from exploring the decoding logic. `ORANalyst` without grammar also cannot find any issues in E2T, and only finds one crash in the xApp. When testing the xApp, `ORANalyst` without input constraints performs only slightly better than `ORANalyst` with no grammar at all in terms of test inputs reaching the xApp or decoded by the xApp. This demonstrates that `ORANalyst` without input constraints struggles to generate inputs that efficiently reach and explore the xApp.

❏ **Benchmark results.** Comparative evaluation results of other tools is also presented in Table 4. All identified issues

are crashes. Figure 5 visualizes the number of covered unique edges by the benchmark tools. ORANalyst significantly outperforms all other tools, achieving both the highest coverage and the most discovered crashes. As discussed in §4.2.2, ORANalyst probabilistically applies byte-level mutations on well-formed inputs generated by the grammar-aware mutator to produce slightly malformed inputs, to test the decoding logic in addition to the processing logic. These malformed inputs that reach previously unexplored code regions are then added to the corpus for further mutations. As illustrated in Listing 3, carefully mutated malformed inputs can uncover vulnerabilities that strictly valid inputs cannot expose. During the evaluation, we configured the probability for a byte-level mutation at 10%, which explains why a subset of inputs generated by ORANalyst fails to be decoded. Setting this byte-level mutation probability to 0% would ensure all inputs generated by ORANalyst pass the decoding checks.

Although Radamsa with filter results in less coverage than Radamsa without filter in both components, it finds more issues due to its focus on input processing logic rather than decoding logic. Not all inputs generated by Radamsa-filter are decoded by the xApp because the E2SM layer contains some byte fields with encoded data that the filter does not validate, leading to possible decoding errors when the xApp tries to decode those bytes. BooFuzz identifies issues #1 in the E2T and #12 in the xApp. Both ORANalyst without grammar and Radamsa-filter identify issue #10 in the xApp. ORANalyst without input constraints is the same as ORANalyst when testing the E2T, and it finds issue #12 in the xApp.

8 Discussion and Limitations

Manual efforts. To prepare an O-RAN implementation for testing, we manually modify the original Dockerfile for each component to incorporate the instrumentation tool during the build process. We then build the instrumented Docker image and replace the original one in the O-RAN deployment. To collect network traces for dynamic tracing, communications between components must be unencrypted, or the encryption key must be saved to decode the collected traffic. We opt for saving the encryption key to decrypt the network traffic. While ORANalyst's components are mostly automated, some steps involve manual intervention. For example, transferring outputs from one component to another, such as inserting identified input constraints from static analysis into input generation, is currently manual. Automating these steps through scripting is primarily an engineering effort. Furthermore, we manually triage and diagnose the root cause of each issue.

Generalizability of ORANalyst. There are only two widely-used, commercially-adopted O-RAN implementations available, and we demonstrate ORANalyst's generalizability by testing both. While our input generation currently supports only ASN.1-specified messages, ORANalyst's testing methodology can be extended to other protocol implementations and microservice systems. Our observations about the limited use of complex loops and pointers discussed in §5 are based on common characteristics typical of protocol implementations in general, not just O-RAN.

ORANalyst assumes the availability of source code or intermediate representation (IR) for two reasons: **(i)** to instrument the components and collect execution traces to understand component dependencies, and **(ii)** to dynamically monitor test input execution and collect coverage data as testing feedback. For scenarios where only program binaries are available, additional methodologies and toolkits are required to perform these tasks. This can be achieved through reverse engineering [10, 14], binary instrumentation [55], or runtime analysis [36]. When even the binaries are unavailable, dependency analysis and feedback collection can be conducted through network traffic analysis [34, 37] or log analysis [38].

Monitoring multiple components simultaneously. Although our approach utilizes insights about component dependencies and the complex communication traversal of inputs, the testing focuses on a single component at a time, while also taking into account components' inter-dependencies and interactions. Extending our monitoring to multiple components simultaneously could uncover more complex vulnerabilities stemming from the interplay of components.

9 Related Work

Protocol testing. Several protocol fuzzers focus on performing state-aware testing from response codes [70], state tracking graphs [56] and dynamic queries to server [52, 60], but they cannot be applied to testing service-based systems. Also, many approaches use grammar-guided fuzzing to generate semantically valid inputs, either through manually constructed state and input message models [4, 11, 80] or through information extracted from source code [57, 75]. However, they either require manual work or assume specific source code formats, and cannot be applied to O-RAN.

Testing leveraging source code analysis. Several approaches leverage lightweight static analysis or concolic execution to guide fuzzers in generating interesting inputs [44, 48, 58, 69, 77]. Driller [77] leverages concolic execution to solve path constraints to reach deeper code branches and unexplored compartments. However, its concolic execution cannot avoid path explosions nor guarantee comprehensive component coverage. ORANalyst's dynamic and static analysis combination sidesteps path explosion and guarantees test input's reachability to all components. Peng et al. [69] adopt lightweight static analysis to extract an abstract state machine of the implementation and guide the fuzzer to generate inputs exploring new states and transitions. However, all of the previous works focus on monolithic programs and cannot handle inter-program communications between components in O-RAN RIC.

O-RAN security. The O-RAN Security Work Group has conducted several threat models, risk assessment, and security

studies of O-RAN components [62–65], but they only offer broad guidelines. Polese et al. [71] outline general research directions for O-RAN, including its security aspects. Shen et al. [73] explores the possibility of authentication and authorization attacks in the O1 interface of O-RAN, and Dik et al. [47] assess security threats at the transport layer of O-RAN's open fronthaul interface. Existing research on the emerging O-RAN technology has been concentrated on theoretical security issues or potential research avenues. This study is the first effort aiming at identifying actual security vulnerabilities within O-RAN implementations.

10 Conclusion

We propose the first systematic testing framework designed for O-RAN implementations, `ORANalyst`. By integrating efficient static analysis with dynamic trace analysis, `ORANalyst` resolves complex component dependencies in O-RAN RIC. It applies these insights to generate test inputs that can pass the initial decoding and validation checks to effectively explore deeply rooted components. Evaluation of `ORANalyst` on two major open-source O-RAN implementations yields the discovery of 19 previously uncovered vulnerabilities.

Abstract

In this paper, we present a novel and scalable multi-party computation (MPC) protocol tailored for privacy-preserving machine learning (PPML) with semi-honest security in the honest-majority setting. Our protocol utilizes the Damgård-Nielsen (Crypto'07) protocol with Mersenne prime fields. By leveraging the special properties of Mersenne primes, we are able to design highly efficient protocols for securely computing operations such as truncation and comparison. Additionally, we extend the two-layer multiplication protocol in ATLAS (Crypto'21) to further reduce the round complexity of operations commonly used in neural networks.

Our protocol is very scalable in terms of the number of parties involved. For instance, our protocol completes the online oblivious inference of a 4-layer convolutional neural network with 63 parties in 0.1 seconds and 4.6 seconds in the LAN and WAN settings, respectively. To the best of our knowledge, this is the first fully implemented protocol in the field of PPML that can successfully run with such a large number of parties. Notably, even in the three-party case, the online phase of our protocol is more than 1.4× faster than the Falcon (PETS'21) protocol.

1 Introduction

In recent years, machine learning (ML) has gained immense popularity across various domains, including medicine, banking, recommendation systems, and biometric authentication. However, the widespread use of ML models has raised significant privacy concerns. Moreover, many companies offer pre-trained ML models, and performing inference operations on sensitive data introduces additional privacy considerations. Regulations like HIPAA and GDPR impose significant constraints on institutions aggregating personal data from individuals. To enable effective machine learning while preserving privacy, the ideal approach is for individuals to retain their personal information locally while collaborating to train models in a secure multi-party manner.

Secure Multi-Party Computation (MPC) [3, 21, 47] enables a group of n parties to collectively compute a function on their private inputs while preserving the privacy of the inputs. MPC offers a promising approach to address these privacy challenges in ML. It enables privacy-preserving machine learning (PPML) by performing secure computations on distributed datasets without exposing the individual data points or the model itself. This allows multiple parties to collaborate on training or inference tasks while keeping their data private. By leveraging cryptographic techniques and secure protocols, MPC-based PPML ensures that sensitive information remains protected throughout the computation process.

In the context of PPML, there have been significant research efforts to enhance secure multi-party computation protocols in different settings. In the dishonest-majority setting, the majority of PPML protocols concentrate on the two-party scenario [7, 12, 24, 31, 33, 35, 38, 40, 41, 42]. On the other hand, in the honest-majority setting, existing PPML protocols only consider the three-party [8, 12, 29, 34, 39, 44, 45] and four-party cases [4, 9, 13, 28], where the protocols tolerate one corrupted party. However, many applications like federated learning involve large numbers of participants, yet existing privacy-preserving machine learning protocols focus on 2-4 parties only, falling short of real-world needs. There is a pressing need to develop scalable protocols that can accommodate machine learning with many distributed data owners.

In theory, there are general-purpose MPC protocols, such as those mentioned in [10, 17, 18, 26], that can support an arbitrary number of parties. However, these protocols lack efficient methods for securely computing non-linear functions like truncation and comparison. This limitation is the primary reason why they do not report specific performance results when applied to a large number of parties in PPML.

Previous protocols often utilize power-of-two rings $\mathbb{Z}_{2^\ell}$ and prime fields $\mathbb{F}_p$. Power-of-two rings, specifically those with $\ell = 32$ or 64, are particularly favored due to their superior computation efficiency. This efficiency stems from the compatibility of the ring operations with native datatypes. Prime fields offer significant advantages when it comes to leveraging

the fast protocol proposed by Damgård and Nielsen [17], hereafter known as the DN protocol, which is based on Shamir Secret Sharing.

In PPML, the secure computation of truncation and comparison functions plays a vital role. Practical truncation protocols are based on the approaches (and their extensions) proposed in [35] and [6] in the power-of-two rings and prime fields setting, respectively. However, these methods result in a significant gap between the shares and the secret, necessitating the use of either a large modulus or low precision to mitigate truncation errors. For the secure computation of the comparison function, protocols (such as [15, 34]) typically rely on the computation of boolean circuits with bit shares. These methods also introduce a large gap between the shares and secrets. Moreover, the online round complexity can be as high as $O(\log \ell)$. Note that [12, 20] show how to reduce the gap of the truncation protocol in the power-of-two rings setting, but the round complexity of their comparison protocols is still high. Additionally, [32] shows how to mitigate the gap in the comparison protocol in the prime fields setting. But the gap in the truncation protocol still persists.

1.1 Our Contribution

We design and implement a general framework of scalable multi-party computation protocols for privacy-preserving inference, where the model is secret-shared among all data owners, with semi-honest security in the honest majority setting. This establishes a foundation for realizing practical large-scale privacy-preserving collaborative training in the future. Our schemes leverage the DN [17] protocol with Mersenne prime fields. I.e., the prime is in the form $p = 2^\ell - 1$. It is worth noting that we are the first to take advantage of the unique properties of Mersenne primes to optimize truncation and comparison from a theoretical standpoint. The key contributions of this paper are as follows.

1. We propose a novel protocol to securely compute the truncation function in the setting of prime fields with Mersenne primes. This new protocol reduces the gap between shares and the secret to just 1 bit. As a result, It allows us to use a smaller modulus or achieve higher precision, thereby directly improving both computation and communication efficiency. We further combine it with the DN multiplication protocol, resulting in an efficient protocol for fixed-point multiplication with 1 round online complexity.
2. We propose an efficient protocol to securely compute the bitwise comparison function in the setting of Mersenne prime fields. It eliminates the gap between shares and the secret with 1 round online complexity. To achieve this, besides utilizing the special properties of Mersenne primes, we also present an optimized Prefix-OR protocol with only 1 round online complexity. This new Prefix-OR protocol works for any prime field, which is of independent interest.
3. We simplify and extend the techniques of evaluating two-layer multiplication in [22], to securely compute ReLU (Maxpool) operations in neural networks, resulting in efficient protocols with 3 rounds ($3\log m$ rounds) online complexity.
4. We implement our framework with C++ and conduct experiments of oblivious inference for neural networks with varying numbers of parties, ranging from 3 to 63. For example, when performing inference on a 4-layer convolutional neural network with 63 parties, the online (preprocessing) time is 0.4 s (2.4 s) and 4.3 s (12.3 s) in the LAN and WAN setting, respectively. To the best of our knowledge, this is the first fully implemented protocol in the field of PPML that can successfully run with such a large number of parties. Even in the three-party case, our protocol outperforms the Falcon protocol [45] in terms of online phase speed, being more than $1.4\times$ faster.

An overview of the different protocols considered in this work is provided in Appendix A

1.2 Overview of Techniques

Let p be a Mersenne prime, which is in the form of $p = 2^\ell - 1$ for some prime ℓ. It is well known that the distribution of Mersenne primes is quite sparse. However, for practical purposes in privacy-preserving machine learning, it is fortunate that values of ℓ such as 31, 61, and 127 are often sufficient. These specific values of ℓ are typically suitable for most use cases in PPML, allowing for efficient computations within the domain.

Advantages of Mersenne Primes. A key observation in this paper is that Mersenne primes are very close to power-of-two numbers. Mersenne primes exhibit similar properties to power-of-two numbers, which leads to several advantages in computations. In particular, modular operations performed over Mersenne primes involve simple operations such as bit shifts and additions, making them highly efficient. When encoding a signed integer $a \in [-(p-1)/2, (p-1)/2]$ into a representation $\bar{a}$ within the range of $[0, p-1]$ in $\mathbb{F}_p$, the most significant bit (MSB) of $\bar{a}$ effectively indicates the sign bit of a. This is due to the fact that $(p-1)/2 = 2^{\ell-1} - 1$. The plain truncation protocol in $\mathbb{F}_p$ is quite simple when p is a Mersenne prime. Truncating $\bar{a} \in \mathbb{F}_p$ by d bits is just shifting the bits of $\bar{a}$ down by d positions and filling the top d bits with the MSB of $\bar{a}$.

Probabilistic Truncation with Only 1-Bit Gap. Let $\text{Trunc}_d(x)$ denote the truncation of $x \in \mathbb{F}_p$ with d bits. The starting point is the method presented in ABY3 [34]. In a nutshell, they utilize the property that $\text{Trunc}_d(z) =$

$\text{Trunc}_d(x = z + r) - \text{Trunc}_d(r) + e$ for small z with high probability for uniformly random $r \in \mathbb{F}_p$, where $|e| \leq 1$ is some rounding error. The constraints on z and the probability mentioned in the previous statement are imposed due to certain cases where the equation does not hold. This deviation from the equation occurs when there is a "wapping around" event.

The "wapping around" event happens in two cases. 1) z, r represent two postive integers, but $x = z + r$ represents a negative integer. 2) z, r represent two negative integers, but $x = z + r$ represents a positive integer. This is due to the implicit modulo operation involved in operations within the prime field $\mathbb{F}_p$. The constraints on z and r make this bad case occur only with a small probability. In conclusion, for $z \in [0, 2^{\ell_z}] \cup [p - 2^{\ell_z}, p)$, the equation holds with probability $1 - \frac{2^{\ell_z+1}}{p}$ for some $\ell_z > 0$.

It is easy to see that the gap between z and p should be large enough to make the equation hold. In this paper, we fully leverage the properties of Mersenne primes to narrow the gap between z and p to just 1 bit.

We consider $z \in [0, (p-1)/2]$ representing a positive integer. Under this condition, only one specific case will trigger the "wrapping around" event. I.e., r represents a positive integer, but x represents a negative integer. In other words, $r_{\text{msb}} = 0 \wedge x_{\text{msb}} = 1$. In this case, let us look into the result of $\text{Trunc}_d(x = z + r)$. As described before, $\text{Trunc}_d(x = z + r)$ shifts down x by d bits and fills the first d bits with the MSB of x, which is bit 1. Surprisingly, the deviation in the equation is caused by the "misfilled" first d bits, and we simply remove this term to make the equation hold again in this case!

Removing the first d bits with all 1's is equivalent to substract $(2^d - 1) \cdot 2^{\ell-d} = (2^\ell - 2^{\ell-d}) = p - (2^{\ell-d} - 1)$. This is equivalent to adding $2^{\ell-d} - 1$ in the field. In the MPC setting, we remain to compute the share of $(1 - r_{\text{msb}}) \cdot x_{\text{msb}}$ to obliviously indicate whether the "wrapping around" event occurs or not. Fortunately, $x = z + r$ will be revealed in the protocol because r is uniformly random, and x_{msb} can be computed locally. Further, in the preprocessing phase, we will prepare the share of r_{msb}. Therefore the share of $(1 - r_{\text{msb}}) \cdot x_{\text{msb}}$ can be computed locally!

Note that our truncation protocol can be simply modified to support elements that represent negative integers as well. Let $\bar{z} \in [0, 2^{\ell-2}) \cap [p - 2^{\ell-2}, p)$, set $z = \bar{z} + 2^{\ell-2} \in [0, (p-1)/2]$. Then, we can easily obtain $\text{Trunc}_d(\bar{z})$ by applying our protocol on z. This is because $\text{Trunc}_d(z) \approx \text{Trunc}_d(\bar{z}) + 2^{\ell-d-2}$.

In PPML, the secure truncation protocol typically follows a secure multiplication protocol. Specifically, there is a need to securely compute the truncation of the product of two values, denoted as $\text{Trunc}_d(a \cdot b)$. This operation is often referred to as a secure fixed-point multiplication protocol. In the DN [17] multiplication protocol, $ab + r$ will be revealed anyway. This enables us to further reduce the online round complexity of secure fixed-point multiplication protocol to 1 round.

Round-Efficient Comparison. Our secure bitwise comparison protocol follows from [15]. The core and bottleneck of this protocol are to compute all the Prefix-ORs of a bit vector. Specifically, given a bit vector $(a_1, \ldots, a_\ell)$, compute $b_i = \bigvee_{j=1}^{i} a_j$ for $1 \leq j \leq \ell$. Several works [15, 36] of secure Prefix-OR protocols are proposed to optimize the online round complexity. These protocols have achieved constant online round complexity, but the actual number of rounds involved can still be relatively large. [6] proposed a small constant-round version that requires a large gap.

A key observation of this paper is that instead of computing all Prefix-ORs, we compute its dual problem Prefix-ANDs. This is because computing $b_i = \bigvee_{j=1}^{i} a_j$ is identical to compute $\bar{b}_i = \bigwedge_{j=1}^{i} \bar{a}_j$, where $\bar{b}_i = 1 - b_i$ and $\bar{a}_i = 1 - a_i$. The Prefix-ANDs problem is indeed to compute all prefix products $\bar{b}_i = \prod_{j=1}^{i} \bar{a}_j$ for $1 \leq j \leq \ell$, which could be securely computed with 1 round online complexity using the unbounded fan-in multiplication protocol from [1, 6, 15, 36].

With this efficient secure comparison protocol, we could design a fast secure DReLU protocol. DReLU is the derivative of the non-linear activation ReLU function. It serves as a core building block in PPML. Given a number a, $\text{DReLU}(a) = 0$ if $a < 0$, and $\text{DReLU}(a) = 1$ otherwise. In other words, $\text{DReLU}(a) = 1 - a_{\text{msb}}$. Follow the idea from SecureNN [44], we have $a_{\text{msb}} = t_{\text{lsb}}$, where $t = 2a \in \mathbb{F}_p$, because p is odd.

In the preprocessing phase, we generate the shares of a random value r, denoted as $[r]_p$, and the shares of the bits of r, denoted as $[r]_{\text{B}}$. In the online phase, $[y]_p = [t + r]_p$ is revealed, and one can compute $[t_{\text{lsb}}]_p = y_{\text{lsb}} \oplus [r_{\text{lsb}}]_p \oplus [(t + r \geq p)]_p$. Note that $t + r \geq p$ if and only if $y < r$. Since we already have $[r]_{\text{B}}$, using the secure bitwise comparison protocol on bits results in an efficient secure DReLU protocol.

Vertorized Secure Two-Layer Multiplication. Many operations in neural networks can be derived from DReLU. For example, the ReLU functions can be represented as $\text{ReLU}(a) = \text{DReLU}(a) \cdot a$, and $\text{Max}(a, b) = \text{DReLU}(a - b) \cdot (a - b) + b$. We observe that the last step of secure DReLU involves securely XORing two shares of bits, which is essentially a secure multiplication. Therefore the ReLU and Max functions can be seen as two-layer multiplications. We adopt a vectorized version of the optimized two-layer multiplication protocol proposed in the recent work [22]. This approach allows us to further reduce the online round complexity associated with these operations.

1.3 Other Related Work

Truncation. The protocol of truncation over fields in the recent work from Escudero et al. [20] indeed originates from the previous works presented by Catrina and de Hoogh [6], which entails a large gap between the secrets and the actual modular in the field to assure the correctness with statistical security.

Authors in ABY3 [34] and [14] propose alternative methods for truncation over rings, but unfortunately their methods require a large gap or involve complex bitwise subprotocols in logarithmic rounds. The current state-of-the-art for truncation in the ring case [12, 20] uses the fact that the input is positive to reduce the gap to 1-bit without any bitwise subprotocols. Our method for truncation over fields is similar to this idea yet with a more intuitive and simple way of detecting and correcting the error caused by the "wrap around" event. Moreover, we seamlessly combine the truncation and DN multiplication to instantiate the fixed-point multiplication.

Comparison. Catrina and de Hoogh [6] proposed a (small) constant-round comparison protocol that requires a large gap for correctness. The most recent work for comparison is Rabbit [32], which removes the need for a large gap but depends on several logarithmic bitwise subprotocols. The comparison with no gap requirement was first studied in [15], and optimized by [36], with non-negligible constant cost, in which the main bottleneck is the bitwise less-than protocol involved a very costly circuit for evaluating prefix-OR. In our work, we propose a naive approach to compute the prefix-OR in the field setting, directly optimizing the bitwise less-than protocol in [15]. Various protocols for complex computations, e.g. deterministic truncation and DReLU, can benefit from this efficient bitwise less-than primitive.

1.4 Paper Organization

We organize the paper as follows: In Section 2, we provide an overview of the known techniques used in Damgård-Nielsen protocols [19]. In Section 3, we discuss our secure truncation protocol with only a 1-bit gap and propose a detailed protocol for fixed-point multiplication. Then, in Section 4, we introduce the optimized bitwise primitives that we have developed. Section 5, presents our efficient building blocks, including DReLU, ReLU, and Maxpool, which are essential for neural networks. Finally, in Section 6, we analyze the efficiency of our frameworks based on the results obtained from our implementation.

2 Preliminary

2.1 Model.

We use $P_1, \ldots, P_n$ to denote n parties, respectively, which are to do the secure computation. We assume that each pair of parties share an authenticated channel and the parties have an authenticated broadcast channel, and the corrupted parties are assumed to be poly-time bounded. We describe our protocols in the so-called "honest-but-curious" model with passive security in the honest-majority setting, but standard techniques will be applicable to make our protocols robust with malicious security.

2.2 The Field over Mersenne Primes.

A Mersenne prime is a prime number that can be expressed in the form $M_\ell = 2^\ell - 1$, where ℓ is a prime number. Examples of Mersenne primes include $\ell = 31, 61, 127$. Throughout the rest of the paper, we will work with a fixed Mersenne prime $p = 2^\ell - 1$ to establish a finite field $\mathbb{F}_p$ on which most of our computations will be performed. The size of an element in $\mathbb{F}_p$ is denoted by ℓ. Let E be the set $\{-1, 0, 1\}$ and $2E$ be the set $\{0, \pm 1, \pm 2\}$ for brevity.

2.3 Secret Sharing.

This work is based on Shamir's (t, n)-threshold scheme [43] where n is the number of parties and t denotes the number of corrupted parties. For ease of simplicity, we let $n \geq 2t + 1$. Each party is assigned a unique element $\alpha_i \in \mathbb{F}_p$ as the identity. For notational convenience, we index P_i by the identity $\alpha_i = i$.

By a t-polynomial we mean a polynomial $f(X) \in \mathbb{F}_p[X]$ of degree at most t. To share a secret $x \in \mathbb{F}_p$ with degree t, a uniformly random t-polynomial with $f(0) = x$ is chosen, and P_i is given the share $x_i = f(\alpha_i)$. We use $[x]_p$ to denote a degree-t sharing, such that $[x]_p = (x_1, \ldots, x_n)$ where party P_i is holding x_i. The scheme is t-`privacy` and $(t+1)$-`reconstruction` such that any $\leq t$ shares jointly leak no information about the secret and any $\geq t + 1$ shares can uniquely reconstruct the secret. Let $P_{\texttt{pking}}$ be the party that all parties agree on in the beginning. We write $x \leftarrow \Pi_{\text{Reveal}}([x]_p)$ during which each party sends its share to $P_{\texttt{pking}}$, and $P_{\texttt{pking}}$ reconstructs x and sends it back to other parties. This procedure is a dominant factor of the complexity, so we measure the round complexity of a protocol by the number of rounds of parallel invocations of Π_{Reveal}.[1] And the communication complexity is measured by the number of field elements sent by each party.

If $[a]_p$ and $[b]_p$ are degree-t sharings, multiplying directly yields a degree-$2t$ sharing. We use $\langle y \rangle_p$ to denote a degree-$2t$ sharing, which requires at least $2t + 1$ shares for interpolation. In the honest-majority setting, the honest parties could recover y since $2t + 1 < n$. Similarly, we write $y \leftarrow \Pi_{\text{Reveal}}(\langle y \rangle_p)$.

The Shamir's scheme allows to compute $[a + b \mod p]_p$ and $\langle a \cdot b \mod p \rangle_p$ from $[a]_p$ and $[b]_p$ with no communication. For simplicity, we write $[a + b]_p = [a]_p + [b]_p$ and $\langle ab \rangle_p = [a]_p \cdot [b]_p$.

2.4 Review: DN Multiplication.

Damgård and Nielsen proposed the most renowned DN protocol [17] in the honest majority setting for semi-honest security. The protocol consists of 4 phases: Preprocessing Phase, Input Phase, Online Phase, and Output Phase. Here we give a brief description of the Preprocessing Phase and the Online Phase.

[1] When measuring the round complexity in the preprocessing phase, we roughly measure a parallel unit broadcast as one round, which is common in the generation of randomness.

Offline Phase. In the offline phase, all parties need to prepare enough shared random numbers. Specifically, there are two kinds of random sharings in DN multiplication. The first kind is the degree-t sharing $[r]_p$. The second kind is a pair of random sharings $([r]_p, \langle r \rangle_p)$ of the same secret r, which is referred to as the random double sharings. We write the generation of random sharings as $[r]_p \leftarrow \Pi_{\text{Rand}}$ and $([r]_p, \langle r \rangle_p) \leftarrow \Pi_{\text{DoubleRand}}$.

In the original DN protocol, preparing a pair of double sharings requires the communication of $\frac{2n}{t+1} \approx 4$ field elements per party and $\frac{n}{t+1} \approx 2$ field elements per party for a random sharing $[r]_p$.

Online Phase. In the online phase, all parties need to evaluate addition and multiplication gates layer by layer. The addition gate can be locally computed. For a multiplication gate with input sharings $[x]_p$ and $[y]_p$, directly multiplying two degree-t sharings yields a degree-$2t$ sharing. After that, a pair of double sharings $([r]_p, \langle r \rangle_p)$ is consumed to securely reduce the degree. All parties execute the following steps.

1. All parties compute $\langle xy + r \rangle_p = [x]_p \cdot [y]_p + \langle r \rangle_p$.
2. $P_{\texttt{pking}}$ collects shares of $\langle xy + r \rangle_p$ and reconstructs the value $xy + r$. Then $P_{\texttt{pking}}$ sends it back to other parties.
3. All parties locally compute $[xy]_p = (xy + r) - [r]_p$.

We write the above DN multiplication protocol as $[xy]_p \leftarrow \Pi_{\text{Mult}}([x]_p, [y]_p)$. The online complexity of this protocol is 1 round with 2 field elements per party.

Reduce Communication Complexity with PRG. The communication complexity of distributing sharings can be reduced by utilizing pseudo-random generators (PRG). This trick has been used in previous works such as [22, 30, 37]. With PRG, the communication cost of distributing a degree-t sharing can be reduced by a factor of 2 and the cost of distributing a degree-$2t$ sharing is free. As a result, preparing a random sharing and a pair of double sharing both require the communication of 1 field element per party. And the improved DN multiplication protocol with PRG has communication complexity of 3 field elements per party.

2.5 Useful Techniques

Multiplication with Public Output by PRZS. DN multiplication protocol allows us to securely compute $[xy]_p$ from input $[x]_p$ and $[y]_p$ in one round. But using the pseudo-random sharing of zero (PRZS [11]) technique, we can securely compute the product of two sharings $[x]_p, [y]_p$ with public output xy in one round rather than invoking the original DN multiplication protocol that computes $[xy]_p$ and reveals the degree-t sharing. It works as follows: The parties generate a pseudo-random degree-$2t$ sharing $\langle 0 \rangle_p$ that can be done without interactions; each party computes $\langle z \rangle_p = [x]_p \cdot [y]_p + \langle 0 \rangle_p$; then reveals the degree-$2t$ sharing $\langle z \rangle_p$ to obtain xy. We write $xy \leftarrow \Pi_{\text{MultPub}}([x]_p, [y]_p)$ that can be done in 1 round with communication of 2 field elements per party (in the online phase).

Unbounded Fan-in Prefix-products. [1] proposed a technique to do unbounded fan-in multiplication in constant rounds. We follow the protocols in [6, 15, 36] to compute all prefix-products $b_i = \Pi_{j=1}^{i} a_j$ for $i = 1, \ldots, t$ as follows: In the preprocessing phase, parties prepare t correlated pairs of random sharings $([r_i]_p, [r'_i]_p)$ where $r'_1 = r_1^{-1}$ and $r'_i = r_{i-1} r_i^{-1}$ for $i > 1$ such that $r_i \Pi_{j=1}^{i} r'_i = 1$, with communication of $7t$ field elements per party. In the online phase:

1. For $i = 1, \ldots, t$: Compute $c_i \leftarrow \Pi_{\text{MultPub}}([a_i]_p, [r'_i]_p)$.
2. For $i = 1, \ldots, t$: Compute locally $[b_i]_p = [r_i]_p \cdot \prod_{j=1}^{i} c_j$.

We write it as $[b_1]_p, \ldots, [b_t]_p \leftarrow \Pi_{\text{PreMult}}([a_1]_p, \ldots, [a_t]_p)$ which can be done in 1 round with $2t$ field elements per party. The generation of random values can be done in 2 rounds with $7t$ field elements per party ([36], [6]).

Random Bitwise-Sharings. [15] proposed a protocol to securely generate the shares of a uniformly random element along with the shares of its decomposed bits. Let r be an unknown uniform number such that $0 \le r = \sum_{i=0}^{t-1} 2^i r_i < p$ where each $r_i \in \{0, 1\}$, the parties generate each $[r_i]_p$ by computing $S(a) = \frac{\frac{a}{\sqrt{a^2}}+1}{2}$ on a random sharing $[a]_p \leftarrow \Pi_{\text{Rand}}$, in which $\sqrt{a^2}$ is formulated to equal the unique element in $[1, (p-1)/2]$ so $a/\sqrt{a^2}$ is 1 or -1 in half chance when a is uniformly random in $\mathbb{F}_p^*$. Then the parties generate $[r]_p$ locally. We use $[r]_{\text{B}}$ to denote the generated $([r_0]_p, \ldots, [r_{t-1}]_p)$, and write the above process as $([r]_p, [r]_{\text{B}}) \leftarrow \Pi_{\text{SolvedBits}}$. Note that the original protocol in [15] invokes a bitwise less-than circuit and aborts if $r \ge p$ to guarantee the generated r lies in the field. Under the condition that it does not abort, r is uniformly random from $\mathbb{F}_p$ as desired. In this work, $p = 2^\ell - 1$ is a Mersenne prime, thus the probability that $r \ge p$ is $2^{-\ell}$. Hence, we omit the less-than circuit for larger primes, which can be done in 2 rounds with communication of $3t$ field elements per party in the preprocessing phase.

Beaver Triples. A Beaver triple [2] consists of three degree-t sharings $([a]_p, [b]_p, [c]_p)$ such that $c = a \cdot b$. Given two sharings $[x]_p, [y]_p$, one can compute $[xy]_p$ locally after revealing $u = x + a$ and $v = y + b$ as follows.

$$[xy]_p = u \cdot v - u \cdot [b]_p - v \cdot [a]_p + [c]_p$$

2.6 Security Model

We use $\mathcal{P} = \{P_1, \ldots, P_n\}$ to denote a set of n parties.We consider the honest-majority setting in the presence of static semi-honest adversaries. Such an adversary controls $t < n/2$ parties at the beginning of the protocol and follows the protocol specification exactly. However, it may try to learn more information than allowed by looking at the transcript of messages that the corrupted parties received and their internal

state. We model and prove the security of our protocols under the universal composition (UC) framework [5]. Due to space constraints, we formally describe the functionalities mentioned in this work in Appendix B.

3 Our Fixed-Point Multiplication

3.1 Truncation in the Field

In this section, we consider signed integers in the interval $(-2^{\ell-1}, 2^{\ell-1})$ where ℓ is the length of the Mersenne prime p. Given an interger $x \in (-2^{\ell-1}, 2^{\ell-1})$, we can represent x with a corresponding integer in $\mathbb{F}_p$ by computing $(x \mod p) \in [0, p-1]$.

In Definition 3.1, we define the truncation operation (represented in the field) of integers. It is worth noting that the truncation operation is indeed a special division, in which the divisor is in the form 2^d. Intuitively, given some integer $d > 0$, let x be an integer with $|x| = x_1 \cdot 2^d + x_2$ and $0 \le x_2 < 2^d$, the truncation of x is x_1 if $x \ge 0$, and $p - x_1$ if $x < 0$.

Definition 3.1 (Truncation of Represented Integers)**.** *Given an element $x \in \mathbb{F}_p$, the truncation of x, denoted by* $\mathrm{Trunc}_d(x) \in \mathbb{F}_p$*, is defined as follows.*

$$\mathrm{Trunc}_d(x) = \begin{cases} \lfloor x/2^d \rfloor, & 0 \le x \le (p-1)/2 \\ p - \lfloor (p-x)/2^d \rfloor, & (p-1)/2 < x \le p-1 \end{cases}$$

Note that when $0 \le x \le (p-1)/2$, x represents a non-negative number, the truncation operation just removes the d least significant bits. x represents a negative number when $(p-1)/2 < x \le p-1$, and $p-x$ is the absolute value. The truncation operation first removes the d least significant bits of the absolute value and then represents the resulting negative integer in the field. It is easy to check that $\mathrm{Trunc}_d(x) = p - \mathrm{Trunc}_d(-x) = -\mathrm{Trunc}_d(-x) \in \mathbb{F}_p$.

In applications such as privacy-preserving machine learning, the truncation operation needs to be performed under MPC protocols. A common approach involves initially running a comparison circuit to determine the specific case, followed by executing the rounding operations. Running a comparison circuit with MPC is often a bottleneck in the process.

A key observation of this article is that when considering a Mersenne prime p in the form of $p = 2^\ell - 1$, the sign is entirely dependent on the most significant bit. This is because $(p-1)/2 = 2^{\ell-1} - 1$. x represents a negative integer if and only if the $(\ell-1)$-th bit is 1. Based on this, we present a more efficient truncation procedure as described in Theorem 3.1.

Intuitively, instead of running a comparison circuit with MPC, we simply shift the bits of x down by d positions and fill the top d bits with the MSB of x.

Theorem 3.1. *Let p be a Mersenne prime in the form of $p = 2^\ell - 1$. Let $x \in \mathbb{F}_p$ and $x_0, x_1, \ldots x_{\ell-1}$ be the bit decomposition such that $x = \sum_{i=0}^{\ell-1} x_i \cdot 2^i$. We have:* $\mathrm{Trunc}_d(x) = \sum_{i=d}^{\ell-1} x_i \cdot 2^{i-d} + \sum_{i=\ell-d}^{\ell-1} x_{\ell-1} \cdot 2^i$.

Proof. If $0 \le x \le (p-1)/2$, then $x_{\ell-1} = 0$. We have $\mathrm{Trunc}_d(x) = \sum_{i=d}^{\ell-1} x_i \cdot 2^{i-d}$ as desired.

If $(p-1)/2 < x \le p-1$, due to the definition, we have

$$\mathrm{Trunc}_d(x) = 2^\ell - 1 - \lfloor (2^\ell - 1 - x)/2^d \rfloor$$

The $2^\ell - 1 - x$ term can be viewed as:

$$\begin{aligned} 2^\ell - 1 - x &= (2^\ell - 1 - \sum_{i=0}^{d-1} x_i \cdot 2^i - \sum_{i=d}^{\ell-1} x_i \cdot 2^i) \\ &= (2^\ell - \sum_{i=d}^{\ell-1} x_i \cdot 2^i - 2^d) + (2^d - 1 - \sum_{i=0}^{d-1} x_i \cdot 2^i) \end{aligned}$$

Note that $0 \le 2^d - 1 - \sum_{i=0}^{d-1} x_i \cdot 2^i \le 2^d - 1$, we have

$$\lfloor (2^\ell - 1 - x)/2^d \rfloor = 2^{\ell-d} - \sum_{i=d}^{\ell-1} x_i \cdot 2^{i-d} - 1.$$

Therefore, along with $x_{\ell-1} = 1$, we have

$$\begin{aligned} \mathrm{Trunc}_d(x) &= 2^\ell - 2^{\ell-d} + \sum_{i=d}^{\ell-1} x_i \cdot 2^{i-d} \\ &= \sum_{i=\ell-d}^{\ell-1} x_{\ell-1} \cdot 2^i + \sum_{i=d}^{\ell-1} x_i \cdot 2^{i-d} \end{aligned}$$

□

A Big Gap when Truncating. The SecureML paper [35] presents a truncation method in the 2PC setting. This technique, along with its extensions, is utilized by many other works [34, 44, 45] to perform secure truncation operations. For instance, the truncation technique in ABY3 [34], which can be extended to any number of parties, involves computing $\mathrm{Trunc}_d(z) \approx \mathrm{Trunc}_d(z = x + r) - \mathrm{Trunc}_d(r)$, where r is uniform. However, using this method, the above equation only holds for elements within the range of $[0, 2^{\ell_z}] \cup [p - 2^{\ell_z}, p)$ with probability $1 - \frac{2^{\ell_z+1}}{p}$ for some ℓ_z. Consequently, the size of the truncated value should be much smaller than p. In practice, we have to choose large p (say with 64-bit length) to avoid truncation errors of large magnitude. Essentially, we impose constraints on z to avoid a "wrapping around" event triggered by two cases. 1) z, r represent two positive integers, but $x = z + r$ represents a negative integer. 2) z, r represent two negative integers, but $x = z + r$ represents a positive integer due to the implicit modular operation within $\mathbb{F}_p$.

In the following subsection, we propose a novel truncation protocol that narrows the gap to just 1 bit. Concretely, the modified constraint $z \in [0, (p-1)/2]$ eliminates the "wrap around" event triggered by the first case, facilitating the detection and correction of the truncation errors of large magnitude. Further the truncation equation holds for any r (not just for uniform r with high probability). This enables us to choose smaller p (say with 32-bit length), thereby improving computation and communication efficiency.

3.2 Truncation with Only 1-Bit Gap

We introduce a novel truncation method in Theorem 3.2, which effectively reduces the size of the gap between the secret value and the actual modulus to just 1 bit. Notably, this gap size remains fixed and is independent of the correctness of the truncation result.

Theorem 3.2. *In the field $\mathbb{F}_p$ where $p = 2^\ell - 1$, let $z \in [0,(p-1)/2]$ and z can be divided into two field numbers $x = z + r \mod p$ and $y = p - r$ such that $x + y = z \mod p$ where $r \in \mathbb{F}_p$ can be any field element. Then we have $\mathrm{Trunc}_d(x) + \mathrm{Trunc}_d(y) + \delta(r,x) \cdot (2^{\ell-d} - 1) \in \mathrm{Trunc}_d(z) + E$, where $\delta(r,x) = 1$ if $r_{msb} = 0 \wedge x_{msb} = 1$, and 0 otherwise.*

Proof. For $z, r \in \mathbb{F}_p$, define $z = z_1 \cdot 2^d + z_2$, we have $\mathrm{Trunc}_d(z) = \lfloor z/2^d \rfloor = z_1$. Consider the following cases.

Case 1: $0 \le r \le (p-1)/2$, which means $r_{\mathrm{msb}} = 0$. In this case, we define $r = r_1 \cdot 2^d + r_2$, where $0 \le r_2 < 2^d$. It is easy to know that, there exists some integers $c \in \{0,1\}$ and $0 \le \varepsilon \le 2^d - 1$ such that $r_2 + z_2 = c \cdot 2^d + \varepsilon$. By definition, $\mathrm{Trunc}_d(y) = p - \lfloor r/2^d \rfloor = p - r_1$ because $(p-1)/2 < y < p$.

Since $0 \le z \le (p-1)/2$, we have $x = z + r = (z_1 + r_1) \cdot 2^d + (z_2 + r_2) \in \mathbb{F}_p$. We further discuss the following two subcases.

1. $0 \le x \le (p-1)/2$, which means $x_{\mathrm{msb}} = 0$. In this case, we have

$$\begin{aligned}\mathrm{Trunc}_d(x) &= \lfloor (z+r)/2^d \rfloor \\ &= \lfloor r_1 + z_1 + (r_2 + z_2)/2^d \rfloor \\ &= r_1 + z_1 + \lfloor (r_2 + z_2)/2^d \rfloor = r_1 + z_1 + c\end{aligned}$$

   Therefore, we have $\mathrm{Trunc}_d(x) + \mathrm{Trunc}_d(y) = r_1 + z_1 + c + (p - r_1) = z_1 + c = \mathrm{Trunc}_d(z) + c \in \mathbb{F}_p$.

2. $(p-1)/2 < x \le p-1$, which means $x_{\mathrm{msb}} = 1$. In this case, we have

$$\begin{aligned}&\mathrm{Trunc}_d(x) \\ &= p - \lfloor (p - (z+r))/2^d \rfloor \\ &= p - \lfloor (p - (z_1 \cdot 2^d + r_1 \cdot 2^d + z_2 + r_2))/2^d \rfloor \\ &= p - \lfloor (2^\ell - 1 - (z_1 + r_1) \cdot 2^d - (z_2 + r_2))/2^d \rfloor \\ &= p - \left\lfloor \frac{2^\ell - (z_1 + r_1 + c + 1) \cdot 2^d + (2^d - 1 - \varepsilon)}{2^d} \right\rfloor \\ &= p - (2^{\ell-d} - 1 - (z_1 + r_1 + c)) - \left\lfloor \frac{2^d - 1 - \varepsilon}{2^d} \right\rfloor \\ &= p - (2^{\ell-d} - 1) + (z_1 + r_1 + c)\end{aligned}$$

   The last equation holds because $0 \le 2^d - 1 - \varepsilon < 2^d$. Therefore, we have $\mathrm{Trunc}_d(x) + \mathrm{Trunc}_d(y) + (2^{\ell-d} - 1) = p + (z_1 + r_1 + c) + p - r_1 = z_1 + c = \mathrm{Trunc}_d(z) + c \in \mathbb{F}_p$.

Case 2: $(p-1)/2 < r \le p-1$, which means $r_{\mathrm{msb}} = 1$. In this case, we have $0 < p - r \le (p-1)/2$. Define $p - r = \tilde{r}_1 \cdot 2^d + \tilde{r}_2$, where $0 \le \tilde{r}_2 < 2^d$. Therefore, $\mathrm{Trunc}_d(y) = \lfloor (p - r)/2^d \rfloor = \tilde{r}_1$. We further discuss the following two subcases.

1. $0 \le x \le (p-1)/2$, which means $x_{\mathrm{msb}} = 0$. In this case, define $\tilde{c} \in \{0,1\}$ such that $\tilde{c} = 0$ if $\tilde{r}_2 \le z_2$, and $\tilde{c} = 1$ otherwise. We have $x = z + r - p \in \mathbb{F}_p$, and

$$\begin{aligned}\mathrm{Trunc}_d(x) &= \lfloor (z + r - p)/2^d \rfloor \\ &= \lfloor ((z_1 - \tilde{r}_1) \cdot 2^d + (z_2 - \tilde{r}_2))/2^d \rfloor \\ &= \lfloor ((z_1 - \tilde{r}_1 - \tilde{c}) \cdot 2^d + (z_2 - \tilde{r}_2 + \tilde{c} \cdot 2^d))/2^d \rfloor \\ &= z_1 - \tilde{r}_1 - \tilde{c}\end{aligned}$$

   The last equation holds because $0 \le z_2 - \tilde{r}_2 + \tilde{c} \cdot 2^d < 2^d$. Therefore, we have $\mathrm{Trunc}_d(x) + \mathrm{Trunc}_d(y) = z_1 - \tilde{r}_1 - \tilde{c} + \tilde{r}_1 = \mathrm{Trunc}_d(z) - \tilde{c}$.

2. $(p-1)/2 < x \le p-1$, which means $x_{\mathrm{msb}} = 1$. In this case, define $\hat{c} \in \{0,1\}$ such that $\hat{c} = 0$ if $z_2 \le \tilde{r}_2$, and $\hat{c} = 1$ otherwise. We have $x = z + r \in \mathbb{F}_p$, and

$$\begin{aligned}\mathrm{Trunc}_d(x) &= p - \lfloor (p - z - r)/2^d \rfloor \\ &= p - \lfloor (\tilde{r}_1 \cdot 2^d + \tilde{r}_2 - z_1 \cdot 2^d - z_2)/2^d \rfloor \\ &= p - \lfloor ((\tilde{r}_1 - z_1 - \hat{c}) \cdot 2^d + (\tilde{r}_2 - z_2 + \hat{c} \cdot 2^d))/2^d \rfloor \\ &= p - \tilde{r}_1 + z_1 + \hat{c}\end{aligned}$$

   The last equation holds because $0 \le \tilde{r}_2 - z_2 + \hat{c} \cdot 2^d < 2^d$. Therefore, we have $\mathrm{Trunc}_d(x) + \mathrm{Trunc}_d(y) = p - \tilde{r}_1 + z_1 + \hat{c} + \tilde{r}_1 = \mathrm{Trunc}_d(z) + \hat{c} \in \mathbb{F}_p$.

This concludes the proof. □

It is worth noting that Theorem 3.2 can be extended to a power-of-two ring $\mathbb{Z}_{2^\ell}$ in a natural way by replacing the Mersenne prime p with 2^ℓ. It allows the truncation protocol of [12, 20] in $\mathbb{Z}_{2^\ell}$ to be realized in a simpler manner.

Dealing with Negative Integers. Theorem 3.2 imposes the contraint $z \in [0,(p-1)/2]$ on the truncated value z. In fact, it is possible to support truncation on negative integers. The following Corollary 3.3 shows how to handle field elements that represent negative integers.

Corollary 3.3. *In the field $\mathbb{F}_p$ where $p = 2^\ell - 1$, let $a \in [0, 2^{\ell-2}) \cup [p - 2^{\ell-2}, p)$ and $b = a + 2^{\ell-2}$ such that $b \in [0,(p-1)/2]$. We have $\mathrm{Trunc}_d(b) - 2^{\ell-d-2} \in \mathrm{Trunc}_d(a) + E$.*

Proof. Let $z = b$, $r = -2^{\ell-2}$ and $x = z + r = a$. According to Theorem 3.2, we have $\mathrm{Trunc}_d(a) + \mathrm{Trunc}_d(2^{\ell-2}) \in \mathrm{Trunc}_d(b) + E$, because $r_{\mathrm{msb}} = 1$. The proof follows since $\mathrm{Trunc}_d(2^{\ell-2}) = 2^{\ell-d-2}$. □

Protocol 3.1. Π_{Trunc} *(Newly added!)*

Input: $[a]_p$ where $a \in [-2^{\ell-2}, 2^{\ell-2})$.
Output: $[f]_p \in [\text{Trunc}_d(a)]_p + 2E$.
Common Randomness: $([r]_p, [r]_B) \leftarrow \mathcal{F}_{\text{SolvedBits}}$.

1. $[r_{\text{msb}}]_p \leftarrow [r_{\ell-1}]_p$
2. $[r']_p \leftarrow \sum_{i=d}^{\ell-1} 2^{i-d} \cdot [r_i]_p + \sum_{i=\ell-d}^{\ell-1} 2^i \cdot [r_{\text{msb}}]_p$
3. $[b]_p \leftarrow [a]_p + 2^{\ell-2}$ such that $b \in [0, (p-1)/2]$
4. $\langle c \rangle_p \leftarrow [b]_p + [r]_p$
5. $c \leftarrow \Pi_{\text{Reveal}}([c]_p)$, and compute $\text{Trunc}_d(c)$ and c_{msb}
6. $[e]_p \leftarrow (1 - [r_{\text{msb}}]_p) \cdot c_{\text{msb}}$
7. $[f]_p \leftarrow \text{Trunc}_d(c) - [r']_p + [e]_p \cdot (2^{\ell-d} - 1)$
8. Output $[f]_p - 2^{\ell-d-2}$

As a result, we are able to perform truncation operation over a signed integer $a \in [0, 2^{\ell-2}) \cup [p - 2^{\ell-2}, p)$, described in Protocol Π_{Trunc}. Note that $[r_{\text{msb}}]_p$ and $[r']_p$ computed in Step 1 and Step 2 can be generated in the preprocessing phase. More generally, we can think of $([r']_p, [r]_p, [r_{\text{msb}}]_p)$ as a random truncation triple consumed for every pure truncation operation over secret integers.

Theorem 3.4. Π_{Trunc} *securely realizes* $\mathcal{F}_{\text{Trunc}}$ *in the* $\mathcal{F}_{\text{SolvedBits}}$*-hybrid model with abort, in the presence of a fully semi-honest adversary controlling* t *corrupted parties.*

Proof. The correctness follows immediately from Theorem 3.2 and Corollary 3.3. Step 3 and Step 8 are applying Corollary 3.3 to a, then one gets $\text{Trunc}_d(a) \in \text{Trunc}_d(b) - 2^{\ell-d-2} + E$. Steps 4 - 7 are applying Theorem 3.2 to b under the condition of $b = a + 2^{\ell-2} \in [0, (p-1)/2]$, then it holds that $\text{Trunc}_d(b) \in \text{Trunc}_d(b+r) - \text{Trunc}_d(r) + \delta(r, b+r) \cdot (2^{\ell-d} - 1) + E$ for some random r, where $b+r$ can be revealed as c in Step 5 and $\delta(r, b+r)$ can be evaluated locally as e in Step 6.

As for privacy, note that the only leaked information is $c = b + r$ in Step 5, where b is relevant to a. Since r is assumed to be a uniformly random, unknown value from $\mathbb{F}_p$, independent of a and b, it follows that c is uniformly random in $\mathbb{F}_p$ and leaks no information about a. □

3.3 Fixed-Point Multiplication

We further extend the truncation process above to build a 1-round fixed-point multiplication protocol, as described in Protocol $\Pi_{\text{Fixed-Mult}}$. Assuming we have another kind of random truncation triple $([r']_p, \langle r \rangle_p, [r_{\text{msb}}]_p)$ where r is assumed a uniformly random value in $\mathbb{F}_p$ and $r' = \text{Trunc}_d(r)$, we can realize it with the same online complexity as DN multiplication. Note that the second component is a degree-$2t$ sharing. We defer the detailed protocol $\Pi_{\text{Trunc-Triple}}$ of generating such a random truncation triple to Section 3.4.

Protocol 3.2. $\Pi_{\text{Fixed-Mult}}$

Input: $[a]_p$ and $[b]_p$.
Output: $[y]_p \in [\text{Trunc}_d(a \cdot b)]_p + 2E$.
Common Randomness: A random truncation triple $([r']_p, \langle r \rangle_p, [r_{\text{msb}}]_p) \leftarrow \mathcal{F}_{\text{Trunc-Triple}}$ such that $r' = \text{Trunc}_d(r) \in \mathbb{F}_p$ and $r_{\text{msb}} \in \{0, 1\}$ is the MSB of r.

1. $\langle c \rangle_p \leftarrow [a]_p \cdot [b]_p + \langle r \rangle_p + 2^{\ell-2}$
2. $c \leftarrow \Pi_{\text{Reveal}}(\langle c \rangle_p)$, and compute $\text{Trunc}_d(c)$ and c_{msb}
3. $[e]_p \leftarrow (1 - [r_{\text{msb}}]_p) \cdot c_{\text{msb}}$
4. $[f]_p \leftarrow \text{Trunc}_d(c) - [r']_p + [e]_p \cdot (2^{\ell-d} - 1) - 2^{\ell-d-2}$
5. Output $[f]_p$

Before digging into the fixed-point multiplication protocol, it is necessary to discuss the translation from a fixed-point number to a field element. Considering a fixed-point number x in which the bit length is ℓ and the size of the fractioanl part is d such that $x = \sum_{i=0}^{\ell-1} x_i \cdot 2^{i-d}$ where x_i is the i-th bit of x, we can represent x with a corresponding field element by computing $a = x \cdot 2^d \in \mathbb{F}_p$. Similarly, we can represent a fixed-point number y with $b = y \cdot 2^d \in \mathbb{F}_p$. Then multiplying a and b yields $ab = xy \cdot 2^{2d}$ after which a truncation operation is required to obtain $\text{Trunc}_d(ab) = xy \cdot 2^d$ which preserves the original fractional precision.

Back to our fixed-point multiplication protocol described in Protocol $\Pi_{\text{Fixed-Mult}}$, the inputs are $[a]_p$ and $[b]_p$ representing two fixed-point numbers. In the online phase, only Step 2 requires communication of 2 field elements per party, which is the same as DN multiplication. Hence, the online complexity is exactly 1 round with 2 field elements per party. The random truncation triple can be generated in the preprocessing phase, with complexity of 2 rounds and 3ℓ field elements per party (deferred to be described in Section 3.4).

Theorem 3.5. $\Pi_{\text{Fixed-Mult}}$ *securely realizes* $\mathcal{F}_{\text{Fixed-Mult}}$ *in the* $\mathcal{F}_{\text{Trunc-Triple}}$*-hybrid model with abort, in the presence of a fully semi-honest adversary controlling* t *corrupted parties.*

Proof. The correctness can be proved similarly as Theorem 3.4 where ab is the value to be truncated. As for privacy, the value c revealed in Step 2 leaks no information about a or b. The sharings $[a]_p$ and $[b]_p$ are degree-t sharings, so $[a]_p[b]_p$ is a degree-$2t$ sharing of ab. Therefore, $\langle c \rangle_p = [a]_p[b]_p + \langle r \rangle_p + 2^{\ell-2}$ is a uniformly random degree-$2t$ sharing of $ab + r + 2^{\ell-2}$, as r is assumed to be uniformly random. □

3.4 Generation of Random Truncation Triple

In this section, we introduce a simple method to generate the random truncation triple $([r']_p, \langle r \rangle_p, [r_{\text{msb}}]_p)$ consumed in the fixed-point multiplication protocol, where $r \in \mathbb{F}_p$ is uniformly random, $r' = \text{Trunc}_d(r) \in \mathbb{F}_p$ and r_{msb} is the MSB of r.

Protocol 3.3. $\Pi_{\text{Trunc-Triple}}$

Input: None.
Output: $([r']_p, \langle r\rangle_p, [r_{\text{msb}}]_p)$, where $r' = \text{Trunc}_d(r)$.

1. $([r]_p, [r]_{\text{B}}) \leftarrow \mathcal{F}_{\text{SolvedBits}}$
2. $[r_{\text{msb}}]_p \leftarrow [r_{\ell-1}]_p$.
3. $[r']_p \leftarrow \sum_{i=d}^{\ell-1} 2^{i-d} \cdot [r_i]_p + \sum_{i=\ell-d}^{\ell-1} 2^i \cdot [r_{\text{msb}}]_p$
4. $\langle r\rangle_p \leftarrow \sum_{i=0}^{\ell-1} 2^i \cdot [r_i]_p \cdot [r_i]_p + \langle 0\rangle_p$

As described in Protocol $\Pi_{\text{Trunc-Triple}}$, we utilize the functionality $\mathcal{F}_{\text{SolvedBits}}$ to generate ℓ random bits $\{r_i\}_{i=0}^{\ell-1}$ and the corresponding random element $r = \sum_{i=0}^{\ell-1} 2^i \cdot r_i$ as the raw material of such a random truncation triple. Note that all the steps can be done in the preprocessing phase and the complexity of this protocol depends on the generation of the solved bits, that is 2 rounds and 3ℓ field elements per party.

Theorem 3.6. $\Pi_{\text{Trunc-Triple}}$ *securely realizes* $\mathcal{F}_{\text{Trunc-Triple}}$ *in the* $\mathcal{F}_{\text{SolvedBits}}$*- hybrid model with abort, in the presence of a fully semi-honest adversary controlling t corrupted parties.*

Proof. The correctness of Step 3 follows directly from Theorem 3.1 which tells us that the truncation operation can be done at bit-level, i.e. shift the bits of r down by d positions and fill the top d bits with the MSB of r. In Step 4, it holds that $r = \sum_{i=0}^{\ell-1} 2^i \cdot r_i \cdot r_i$ since $r_i \in \{0,1\}$. Note that we use the pseudo-random sharing of zero (PRZS [11]) technique to randomize the polynomial coefficients of $\langle r\rangle_p$ where the pseudo-random degree-$2t$ sharing $\langle 0\rangle_p$ can be generated by PRG without communication.

The privacy follows from the fact that we only invoke the private ideal functionality $\mathcal{F}_{\text{SolvedBits}}$. □

4 Improved Bitwise Primitives

Before introducing the protocols of building blocks in privacy-preserving machine learning, we first propose our novel method to compute the prefix-ORs, which is the core and bottleneck to realizing the bitwise less-than functionality.

4.1 Prefix-ORs Protocol

In this section, we consider prefix-ORs, which computes $b_j = \bigvee_{i=1}^{j} a_i$ for $j = 1,\ldots,\ell$ where $a_i \in \{0,1\}$. We propose a simple and efficient method to securely compute prefix-OR, as described in Protocol Π_{PreOR}. Intuitively, instead of computing prefix-ORs, we compute a dual problem. I.e., $\overline{b}_j = \bigwedge_{i=1}^{j} \overline{a}_i$ for $j = 1,\ldots,\ell$.

Note that this protocol only composes one invocation of Π_{PreMult} while other steps can be done locally. Hence, the online complexity is 1 round with 2ℓ field elements per party and the preprocessing complexity is 2 rounds with 7ℓ field elements per party.

Protocol 4.1. Π_{PreOR}

Input: $[a_1]_p, [a_2]_p, \ldots, [a_\ell]_p$ where $a_i \in \{0,1\}$.
Output: All prefix ORs $[a_1]_p, [a_1 \vee a_2]_p, \ldots, [\vee_{i=1}^{\ell} a_i]_p$.

1. For $i = 1,\ldots,\ell$: compute $[b_i]_p \leftarrow 1 - [a_i]_p$.
2. $([c_1]_p, \ldots, [c_\ell]_p) \leftarrow \mathcal{F}_{\text{PreMult}}\ ([b_1]_p, \ldots, [b_\ell]_p)$
3. Output $(1 - [c_1]_p, \ldots, 1 - [c_\ell]_p)$.

Protocol 4.2. $\Pi_{\text{Bitwise-LT}}$

Input: a and $[b]_{\text{B}}$ where $a, b \in \mathbb{F}_p$ and $b = \sum_{i=0}^{\ell-1} 2^i b_i$
Output: $[a < b]_p$

1. Let $a_0, ..., a_{\ell-1}$ be the decomposed bits of a.
2. Set $\overline{a}_i = 1 - a_i$ and $\overline{b}_i = 1 - [b_i]_p$ for $0 \le i \le \ell - 1$.
3. For $i = 0,\ldots,\ell-1$: compute $[c_i]_p = \overline{a}_i \oplus [\overline{b}_i]_p$.
4. Run $([d_{\ell-1}]_p, \ldots, [d_0]_p) \leftarrow \mathcal{F}_{\text{PreOR}}\ ([c_{\ell-1}]_p, \ldots, [c_0]_p)$
5. Set $[e_i]_p = [d_i - d_{i+1}]_p$ where $[e_{\ell-1}]_p = [d_{\ell-1}]_p$
6. Output $[a < b]_p = \sum_{i=0}^{\ell-1} \overline{a}_i \cdot [e_i]_p$.

Theorem 4.1. Π_{PreOR} *securely realizes* $\mathcal{F}_{\text{PreOR}}$ *in the* $\mathcal{F}_{\text{PreMult}}$*-hybrid model with abort, in the presence of a fully semi-honest adversary controlling t corrupted parties.*

Proof. The correctness holds because computing $b_j = \bigvee_{i=1}^{j} a_i$ is equivalent to copmute $\overline{b}_j = \bigwedge_{i=1}^{j} \overline{a}_i$ where $\overline{a}_i$ denote the opposite bit of a_i and so is $\overline{b}_j$. The privacy follows from the fact that this protocol only invokes the private ideal functionality $\mathcal{F}_{\text{PreMult}}$. □

4.2 Bitwise Less Than Protocol

Based on the above optimized Prefix-ORs protocol, we propose a round-efficient protocol to securely compute the bitwise less-than circuit. Specifically, given a public value a and shared bits $[b]_B$, it outputs the share of $(a < b)$. Thanks to the special form of Mersenne prime, in the online phase, the round complexity of the resulting protocol is just 1 round and the communication complexity is 2ℓ field elements per party. The preprocessing complexity is 2 rounds and 7ℓ field elements per party.

Our protocol described in Protocol $\Pi_{\text{Bitwise-LT}}$ follows the method in [15], with the substitution of our optimized prefix-OR subprotocol. In order to further reduce round complexity, we equivalently compute $p - b < p - a$, because $p - a$ is public. A key observation is that given the bit representation of $b = (b_0, \ldots, b_{\ell-1})$, the bit representation of $p - b$ is simply $(1 - b_0, \ldots, 1 - b_{\ell-1})$. This is because p is a Mersenne prime, and its bit representation is $(1, \ldots, 1)$.

Theorem 4.2. $\Pi_{\text{Bitwise-LT}}$ *securely realizes in the* $\mathcal{F}_{\text{PreOR}}$*-hybrid model with abort, in the presence of a fully semi-honest adversary controlling* t *corrupted parties.*

Proof. Note that a, b are in the range of $[0, p-1]$. Considering $\overline{a}, \overline{b} \in \mathbb{Z}_{2^\ell}$ where ℓ is the bit-length of p, define $\overline{a} = p - a$ and $\overline{b} = p - b$. Observe that $a < b$ if and only if $\overline{b} < \overline{a}$. One can compute $[\overline{b}]_{\text{B}} = (1 - [b_0]_p, \ldots, 1 - [b_{\ell-1}]_p)$ as described in Step 2. This is because $p = 2^\ell - 1$ is in the form of all 1s.

In the following steps, we compare $\overline{b} < \overline{a}$. We start from the most significant bit and look for the first bit where $\overline{b}$ and $\overline{a}$ differ. The XOR in Step 3 computes a bitwise sharing $[c]_{\text{B}}$ with ones on all positions where the bits differ. In Step 4, we invoke $\mathcal{F}_{\text{PreOR}}$ to compute all prefix-ORs starting from MSB. This results in a string $(d_{\ell-1}, \ldots, d_0)$ which contains a series of 0's followed by 1's starting at the first location where $\overline{b}$ and $\overline{a}$ differ, denoted by k. As computed in Step 5, we have $e_i = 1$ if $i = k$, and $e_i = 0$ otherwise. In the special case $\overline{b} = \overline{a}$, all $e_i = 0$ so the output is clear 0 as it should be. Otherwise, the output is $\overline{a}_k$ that can be extracted with $e_k = 1$.

The privacy follows from the fact that the protocol only invokes the private ideal functionality $\mathcal{F}_{\text{PreOR}}$. □

5 Building Blocks in Neural Network

In this section, we first describe an efficient way to realize DReLU in a field over Mersenne prime. Then we use the state-of-the-art technique in [22] (CRYPTO 2021) to realize ReLU and Max (the unit operation in Maxpool) with the same round complexity as DReLU.

5.1 DReLU

ReLU is a non-linear activation function that is commonly used in neural networks, which can solve the vanishing gradient problem. It can be represented as $\text{ReLU}(x) = \text{Max}(0, x)$ and the derivative of ReLU (DReLU) is 1 for $x \geq 0$ and 0 for $x < 0$. The DReLU function on the input of integers is defined as follows, and $\text{ReLU}(x) = \text{DReLU}(x) \cdot x$.

$$\text{DReLU}(x) = \begin{cases} 1 & ,x \geq 0 \\ 0 & ,x < 0 \end{cases}$$

As described in Section 3.1, the most significant bit indicates the sign of the underlying integers represented in the field of Mersenne prime, which means DReLU is related to extracting the most significant of its representation in the field. It is observed in [44] that $a_{\text{msb}} = (2a)_{\text{lsb}}$ if the multiplication is done over an odd ring. Hence, it holds that $\text{DReLU}(a) = 1 - (2a)_{\text{lsb}}$.

As in [44], in order to compute $[(2a)_{\text{lsb}}]_p$, we first mask $2a$ with a uniform r such that $y = 2a + r$ and then reveal y. Note that $y_{\text{lsb}} = (2a)_{\text{lsb}} \oplus r_{\text{lsb}}$ if $y \geq r$, and $y_{\text{lsb}} = (2a)_{\text{lsb}} \oplus r_{\text{lsb}} \oplus 1$ otherwise. Given the bits sharing $[r]_{\text{B}}$, we are able to decide whether $2a + r$ wraps around the field by $\Pi_{\text{Bitwise-LT}}$ described in Section 4.2. It holds that $(2a)_{\text{lsb}} = y_{\text{lsb}} \oplus r_{\text{lsb}} \oplus (y < r)$.

Protocol 5.1. Π_{DReLU}

Input: $[a]_p$ where $a \in \mathbb{F}_p$
Output: $[\text{DReLU}(a)]_p$
Common Randomness: $([r]_p, [r]_{\text{B}}) \leftarrow \mathcal{F}_{\text{SolvedBits}}$.

1. $[y]_p \leftarrow [2a + r]_p$ and reveal $y \leftarrow \Pi_{\text{Reveal}}([y]_p)$.
2. $[b]_p \leftarrow y_{\text{lsb}} \oplus [r_0]_p$.
3. Run $[c]_p \leftarrow \mathcal{F}_{\text{Bitwise-LT}}(y, [r]_{\text{B}})$
4. Output $1 - [b]_p \oplus [c]_p$

The detailed protocol is described in Protocol Π_{DReLU}. Note that Step 4 can be realized by a DN multiplication. In the online phase, the complexity is 3 rounds with $4 + 2\ell$ field elements per party (including approximately 2 for Π_{Reveal}, 2ℓ for $\Pi_{\text{Bitwise-LT}}$, and 2 for Π_{Mult}). As for the preprocessing phase, all random values can be generated in 2 rounds with $1 + 10\ell$ field elements per party (including 3ℓ for $\Pi_{\text{SolvedBits}}$, 7ℓ for $\Pi_{\text{Bitwise-LT}}$, and 1 for Π_{Mult}).

Theorem 5.1. Π_{DReLU} *securely realizes* $\mathcal{F}_{\text{DReLU}}$ *in the* $(\mathcal{F}_{\text{Bitwise-LT}}, \mathcal{F}_{\text{Mult}})$*-hybrid model with abort, in the presence of a fully semi-honest adversary controlling* t *corrupted parties.*

Proof. The correctness follows easily from $(2a)_{\text{lsb}} = y_{\text{lsb}} \oplus r_{\text{lsb}} \oplus (y < r)$. As for privacy, the revealed value $y = 2a + r$ in Step 1 leaks no information about a, as r is uniformly random. Then the invocation of the ideal functionality $\mathcal{F}_{\text{Bitwise-LT}}$ is private. □

5.2 Vectorized Two-Layer DN Multiplication

In the context of neural networks, several operators are derived from the DReLU operation. One crucial observation is that the final step of the Π_{DReLU} protocol involves a multiplication. Additionally, other operators like ReLU and Maxpool can be seen as a combination of a two-layer multiplication, along with DReLU. In this subsection, we extend and simplify the techniques introduced in [22] to efficiently compute vectorized two-layer multiplication with a single round of online complexity.

The vectorized two-layer multiplication protocol aims to produce the outputs $\{[xyz_i]_p\}_{i=1}^m$ given the inputs $[x]_p$, $[y]_p$, and $\{[z_i]_p\}_{i=1}^m$. The basic idea behind this protocol is as follows:

1. In the standard DN multiplication protocol, when computing $[xy]_p$, each party receives a value $u = xy + r$, where r is a random value.
2. We can utilize the fact that $0 = z_i + (-z_i)$, where z_i is a known input value. If we can prepare Beaver triples

Protocol 5.2. $\Pi_{\text{2L-DN}}$

Input: $[x]_p, [y]_p$ and $\{[z_i]_p\}_{i=1}^m$
Output: $\{[xyz_i]_p\}_{i=1}^m$
Common Randomness: $m+1$ pairs of double sharings $([r]_p, \langle r\rangle_p)$ and $\{([r_i]_p, \langle r_i\rangle_p)\}_{i=1}^m$.

1. Compute $\langle u\rangle_p = [x]_p \cdot [y]_p + \langle r\rangle_p$.
   Compute $\langle u_i\rangle_p = [r]_p \cdot [-z_i]_p + \langle r_i\rangle_p$.
2. Reveal $u \leftarrow \Pi_{\text{Reveal}}(\langle u\rangle_p)$ and $u_i \leftarrow \Pi_{\text{Reveal}}(\langle u_i\rangle_p)$.
3. Compute $[c_i]_p = u_i - [r_i]_p$ for $1 \le i \le m$.
4. For $i = 1, \ldots, m$, locally compute:
   $[xyz_i]_p = u \cdot [z_i]_p + [c_i]_p$

$([r]_p, [-z_i]_p, [-rz_i]_p)$ for $1 \le i \le m$, then it becomes possible to compute $[xyz_i]_p$ locally for each $1 \le i \le m$.

3. It is worth noting that computing $[rz_i]_p$ and $[xy]_p$ can be carried out in parallel, resulting in a 1-round online complexity.

By following this approach, we can effectively compute the vectorized two-layer multiplication protocol with improved efficiency, reducing the online complexity to just one round with $2(m+1)$ field elements per party. In the preprocessing phase, it generates $m+1$ pairs of double sharings with communication of $m+1$ field elements per party.

Theorem 5.2. $\Pi_{\text{2L-DN}}$ *securely realizes* $\mathcal{F}_{\text{2L-DN}}$ *in the* $\mathcal{F}_{\text{Mult}}$*-hybrid model with abort, in the presence of a fully semi-honest adversary controlling* t *corrupted parties.*

Proof. According to the protocol, we have $u = xy + r$ and $u_i = -rz_i + r_i$ for $1 \le i \le m$. Therefore $c_i = -rz_i$ for $1 \le i \le m$. Since u is public and $u \cdot z_i + c_i = (xy + r) \cdot z_i + c_i = xyz_i$, then Step 4 holds. The privacy follows from the fact that the protocol parallelly invokes the ideal functionality $\mathcal{F}_{\text{Mult}}$. □

5.3 ReLU

We now use our vectorized two-layer multiplication protocol to realize ReLU. Note that $\text{ReLU}(a) = \text{DReLU}(a) \cdot a$. The last step of $\text{DReLU}(a)$ is $1 - b \oplus c$, which can be rewritten as $1 - (b-c) \cdot (b-c)$ for $b, c \in \{0,1\}$. Therefore, $\text{ReLU}(a) = a - a(b-c)(b-c)$, which could be realized using our two-layer multiplication protocol. The online complexity of this protocol is 3 rounds with $6 + 2\ell$ field elements per party (including 2 for Π_{Reveal}, 2ℓ for $\Pi_{\text{Bitwise-LT}}$, and 4 for $\Pi_{\text{2L-DN}}$ where $m = 1$). Details are given in Protocol Π_{ReLU}.

As for the preprocessing phase, all random values can be generated in 2 rounds with $2 + 10\ell$ field elements per party (including 3ℓ for $\Pi_{\text{SolvedBits}}$, 7ℓ for $\Pi_{\text{Bitwise-LT}}$, and 2 for $\Pi_{\text{2L-DN}}$).

Protocol 5.3. Π_{ReLU}

Input: $[a]_p$ where $a \in \mathbb{F}_p$
Output: $[\text{ReLU}(a)]_p$
Common Randomness: $([r]_p, [r]_{\text{B}}) \leftarrow \mathcal{F}_{\text{SolvedBits}}$.

1. $[y]_p \leftarrow [2a + r]_p$ and reveal $y \leftarrow \Pi_{\text{Reveal}}([y]_p)$.
2. $[b]_p \leftarrow y_{\text{lsb}} \oplus [r_0]_p$.
3. Run $[c]_p \leftarrow \mathcal{F}_{\text{Bitwise-LT}}(y, [r]_{\text{B}})$
4. Run $[t]_p \leftarrow \mathcal{F}_{\text{2L-DN}}([b-c]_p, [b-c]_p, \{[a]_p\})$.
5. Output $[a]_p - [t]_p$.

Theorem 5.3. Π_{ReLU} *securely realizes* $\mathcal{F}_{\text{ReLU}}$ *in the* $(\mathcal{F}_{\text{Bitwise-LT}}, \mathcal{F}_{\text{2L-DN}})$*-hybrid model with abort, in the presence of a fully semi-honest adversary controlling* t *corrupted parties.*

Proof. As for the correctness, we have $\text{DReLU}(a) = 1 - b \oplus c = 1 - (b-c) \cdot (b-c)$ as described in Step 4 of Π_{DReLU}. Hence, it holds that $\text{ReLU}(a) = \text{DReLU}(a) \cdot a = a - (b-c) \cdot (b-c) \cdot a$. The correctness holds due to the correctness of Π_{DReLU} and $\Pi_{\text{2L-DN}}$.

As for privacy, the revealed value $y = 2a + r$ in Step 1 leaks no information about a, as r is uniformly random. Then the following invocations of the ideal functionalities $\mathcal{F}_{\text{Bitwise-LT}}$ and $\mathcal{F}_{\text{2L-DN}}$ are private. □

5.4 Maxpool

Maxpool is the key component in convolutional neural networks (CNN). When they operate on a vector of m elements, Maxpool returns the maximum element. Assume that m is the power of two for simplicity.

The crucial operation is the comparison that can be computed with DReLU. It is easily to check that $(a < b) = 1 - \text{DReLU}(a-b)$. We can represent $\text{Max}(a,b)$ as follows, that is b if $a < b$ and a otherwise.

$$\begin{aligned}\text{Max}(a,b) &= \text{DReLU}(a-b) \cdot a + [1 - \text{DReLU}(a-b)] \cdot b \\ &= \text{ReLU}(a-b) + b\end{aligned}$$

Hence, it can be realized with the same complexity as Π_{ReLU}.

To find the maximum value of m elements, we first group the values into pairs and compare each pair to obtain the maximum of two, resulting in a vector of size $m/2$. This process can be repeated for $\log m$ times. Details are given in Protocol Π_{Maxpool}.

It consists of $\log m$ rounds and $m-1$ invocations of ReLU, which results in the online complexity of $3 \log m$ rounds with $(m-1) \cdot (6 + 2\ell)$ field elements per party. As for the preprocessing phase, all random values can be generated in 2 rounds with $(m-1) \cdot (2 + 10\ell)$ field elements per party.

Protocol 5.4. Π_{Maxpool}

Input: $[a_1]_p, \ldots, [a_m]_p$ assuming m is powers of two.
Output: $[a_k]_p$ where $a_k = \text{Maxpool}(a_1, \ldots, a_m)$.

1. If $m = 1$: Output $[a_1]_p$
2. Set $\boldsymbol{a}^1 \leftarrow ([a_1]_p, \ldots, [a_m]_p)$ and $s \leftarrow m$.
3. For $i = 1, \ldots, \log m$:
   a. $s \leftarrow s/2$.
   b. Set $([b_1]_p, \ldots, [b_s]_p, [c_1]_p, \ldots, [c_s]_p) \leftarrow \boldsymbol{a}^i$.
   c. For $j = 1, \ldots, s$: $[e_j]_p \leftarrow \mathcal{F}_{\text{ReLU}}([b_j - c_j]_p) + c_j$.
   d. If $s = 1$: Output $[e_1]_p$.
      Else: Set $\boldsymbol{a}^{i+1} \leftarrow ([e_1]_p, \ldots, [e_l]_p)$

Theorem 5.4. Π_{Maxpool} *securely realizes* $\mathcal{F}_{\text{Maxpool}}$ *in the* $\mathcal{F}_{\text{ReLU}}$*-hybrid model with abort, in the presence of a fully semi-honest adversary controlling* t *corrupted parties.*

Proof. We have $\text{Max}(b_j, c_j) = \text{ReLU}(b_j - c_j) + c_j$ as computed in Step c. The process can be described in a binary tree of depth $\log m$. Each node (except the leaf nodes) performs the Max operation on two child nodes and the root node outputs the maximum value. The privacy follows from the fact that the protocol only parallelly invokes $\mathcal{F}_{\text{ReLU}}$. □

6 Evaluations

We first summarize the theoretical round and communication complexity in Table 1. The round complexity including the online and preprocessing phases is independent of ℓ. Then we evaluate the performance of oblivious inference on 3 networks using MNIST. A number of prior works [24, 31, 34, 35, 42, 44, 45] evaluate over these networks.

Protocols	Rounds		Communication	
	Online	Prep.	Online	Prep.

Π_{ReLU}	3	2	$6+2\ell$	$2+10\ell$
Π_{Maxpool}	$3\log m$	2	$(m-1)(6+2\ell)$	$(m-1)(2+10\ell)$

Table 1: Round and communication complexity of building blocks. Numbers of communication are reported in field elements per party.

6.1 Experimental Setup

We have implemented this framework using approximately 15.4k lines of code (LOC) in C++. Our implementation leverages the communication backend of MP-SPDZ [25] and the neural network frontend of Falcon [45]. We conducted performance evaluations for inference in various settings involving different numbers of parties, including 3-party computation (3PC), 7PC, 11PC, 21PC, 31PC, and 63PC. Our experiments were conducted on a total of 11 servers, each of which was equipped with an AMD EPYC 7B12 64-core processor with 512GB of RAM.

To simulate different network conditions, we utilized the Linux `tc` command. We considered two network settings: a Local Area Network (LAN) setting with a shared 15 Gbps connection and an average Round-Trip Time (RTT) latency of approximately 0.3ms, and a Wide Area Network (WAN) setting with an RTT latency of 40ms and a maximum throughput of 100Mbps. In order to ensure reliable results, we collected data from 10 independent runs for each data point in our experiments, and the reported results are presented as the average values obtained from these runs.

In our implementation, all arithmetic operations on the shares are performed modulo $p = 2^{31} - 1$, with a fixed-point precision of 12 bits. These operations are carried out on 32-bit integers. Thanks to the 1-bit gap of the truncation protocol, we can use such a small prime for the underlying protocol. This enables us to get improved communication and round complexity without losing accuracy. To accelerate matrix multiplication, we utilize the Eigen library [23], which supports faster computation on our custom field type. The computations are parallelized using 16 cores to optimize Eigen's algorithm. Additionally, the servers employ hardware-accelerated AES-NI instructions for efficient random number generation. Furthermore, we incorporate an optimization technique inspired by the implementation of Falcon [45]. Specifically, we swap the order of the ReLU layer and the subsequent Maxpool layer to enhance performance. Overall, these optimizations and hardware acceleration techniques contribute to the efficiency and speed of our implementation.

Networks and Datasets. We employ the widely used MNIST dataset [46], which consists of a collection of 28×28 pixel images depicting handwritten numbers. The objective is to accurately predict the corresponding number for each image. We select three standard neural networks from the field of privacy-preserving machine learning. Network-A is a 3-layer DNN network derived from SecureML [35]. Network-B is a 3-layer CNN network derived from Chameleon [42]. Network-C is a 4-layer CNN network derived from MiniONN [31]. For more specific information and details about these neural networks, please refer to Appendix E.

6.2 Performance of Oblivious Inference

Table 2 and Table 3 present the specific performance results for evaluating different networks in the LAN and WAN settings, respectively. Furthermore, Table 4 provides the commu-

Table 3: Online and preprocessing time for oblivious inference in the WAN setting. All numbers are reported in seconds.

nication size observed during the evaluation of these networks with varying numbers of parties. The performance evaluation focuses on a single batch inference.

For 63 parties, the online (preprocessing) running time of evaluating Network C is only $0.1(1.21)$ seconds and $4.6(10.7)$ seconds in the LAN and WAN setting, respectively. The online and preprocessing communication cost of evaluating Network C are 2.82 MB and 18.3 MB respectively. As far as we know, our protocol is the first fully implemented PPML protocol that can support up to 63 parties.

Analysis of the Online Performance. We have observed that in the LAN setting, the time required for computation is directly proportional to the number of parties involved. This is due to the fact that the party responsible for collecting shares of a degree-$2t$ (or degree-t) sharing needs to perform the reconstruction of the secret and send it back to the other parties. As the number of shares to be collected increases, the computation cost also increases, thus impacting the overall inference performance.

On the other hand, in the WAN setting, we have noticed that the online time remains relatively consistent across different numbers of parties. In this scenario, the round complexity becomes the dominant factor affecting the inference performance rather than the computation cost.

Comparison to Prior Work In the honest-majority setting, most PPML protocols primarily focus on the three-party case [8, 12, 29, 34, 39, 44, 45] and the four-party case [4, 9, 13, 28]. These protocols often face challenges when extending to a larger number of parties. While general MPC protocols like [10, 14, 16, 18, 26, 27] can be used, they are not scalable, particularly in the context of PPML with a large number of parties.

Table 5: Comparing the performance of Falcon and our protocol.

Our protocol is specifically designed to support a large number of parties in PPML. The observed performance aligns with our expectations. Additionally, we compare our protocol with the state-of-the-art three-party protocol Falcon [45], which focuses on power-of-2-rings case. It indeed performs truncation as ABY3 [34], inheriting the large gap. For comparison protocol, the main idea of comparison is to indicate the first bit (from the MSB) where two numbers differ. Falcon uses a more indirect and complicated way to determine it with logarithmic rounds while we use our improved primitive (prefix-OR) with 1 round. Roughly speaking, the underlying reason is that some primitives are much more costly in the ring setting than in the field setting, e.g. prefix-multiplication.

In Table 5, we present a performance comparison between Falcon and our protocol for different networks in semi-honest honest-majority settings. It is worth mentioning that the source codes of Falcon [45] do not contain the preprocessing. In the online phase, our protocol demonstrates a speed improvement of 1.5× to 1.9× compared to Falcon in the LAN setting and 1.4× to 1.8× in the WAN setting.

A Protocol Hierachy

An overview of the different protocols considered in this work is informally described in Figure 1.

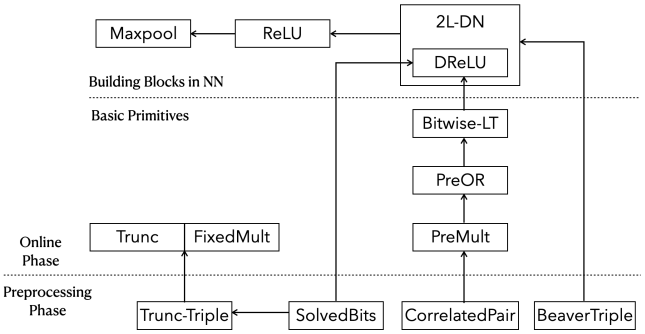

Figure 1: Hierachy among the protocols considered in this work. An arrow pointing from A to B means that protocol B requires protocol A.

Here we list the required randomness that can be generated in the preprocessing phase. These random materials are essentially derived from the basic random sharings and double random sharings in DN protocol (that are omitted here). For brevity, the notation r below denotes a uniformly random element in $\mathbb{F}_p$, so is r_i.

- Trunc-Triple: The truncation triple is in the form of $([r']_p, [r]_p, [r_{\text{msb}}]_p)$ or $([r']_p, \langle r\rangle_p, [r_{\text{msb}}]_p)$ where $r' = \text{Trunc}_d(r)$ and r_{msb} corresponds to the MSB of r.
- SolvedBits: This is a pair in the form of $([r]_p, [r]_{\text{B}})$.
- CorrelatedPair: The correlated pairs are a sequential of random sharings $\{([r_i]_p, [r'_i]_p)\}_{i=1}^{t}$ where $r'_1 = r_1^{-1}$ and $r'_i = r_{i-1} r_i^{-1}$ for $i > 1$ such that $r_i \Pi_{j=1}^{i} r'_i = 1$.
- BeaverTriple: The beaver triple is in the form of $([a]_p, [b]_p, [c]_p)$ such that $c = a \cdot b$.

B Functionality Description

Functionality B.1. $\mathcal{F}_{\text{Rand}}$

Input: The functionality receives no inputs.
Output: Compute the following

1. Randomly sample $r \in \mathbb{F}_p$.
2. Distribute shares of $[r]_p$ to the parties.

Functionality B.2. $\mathcal{F}_{\text{DoubleRand}}$

Input: The functionality receives no inputs.
Output: Compute the following

1. Randomly sample $r \in \mathbb{F}_p$.
2. Distribute shares of $[r]_p$ and $\langle r\rangle_p$ to the parties.

Functionality B.3. $\mathcal{F}_{\text{Mult}}$

Input: The functionality receives inputs $[a]_p$ and $[b]_p$.
Output: Compute the following

1. Reconstruct a and b to compute ab.
2. Distribute shares of $[ab]_p$ to the parties.

Functionality B.4. $\mathcal{F}_{\text{SolvedBits}}$

Input: The functionality receives no inputs.
Output: Compute the following

1. Randomly sample $r \in \mathbb{F}_p$.
2. Compute the decomposed bits $(r_0, r_1, \ldots, r_{\ell-1})$ such that $r = \sum_{i=0}^{\ell-1} r_i \cdot 2^i$.
3. Distribute the shares of $[r]_p$ and $[r]_{\text{B}}$ to the parties.

Functionality B.5. $\mathcal{F}_{\text{Trunc-Triple}}$

Input: The functionality receives no inputs.
Output: Compute the following

1. Sample a random element $r \in \mathbb{F}_p$ and compute $r' = \text{Trunc}_d(r)$ and r_{msb}.
2. Distribute the shares of this triple $([r']_p, [r]_p, [r_{\text{msb}}]_p)$ to the parties.

Functionality B.6. $\mathcal{F}_{\text{Trunc}}$

Input: The functionality receives inputs $[a]_p$.
Output: Compute the following

1. Reconstruct a.
2. Compute $b = \text{Trunc}_d(a)$.
3. Distribute shares of $[b]_p$ and send back to the parties.

Functionality B.7. $\mathcal{F}_{\text{Fixed-Mult}}$

Input: The functionality receives inputs $[a]_p$ and $[b]_p$.
Output: Compute the following

1. Reconstruct a and b.
2. Compute $c = ab$ and compute $d = \text{Trunc}_d(c)$.
3. Distribute shares of $[d]_p$ and send back to the parties.

Functionality B.8. $\mathcal{F}_{\text{PreMult}}$

Input: The functionality receives inputs $\{[a_i]_p\}_{i=1}^t$.
Output: Compute the following

1. Reconstruct $a_1, \ldots, a_t$.
2. Compute all prefix products $a_1, a_1 \cdot a_2, \ldots, \Pi_{i=1}^t a_i$.
3. Distribute the shares of these products to the parties.

Functionality B.9. $\mathcal{F}_{\text{MultPub}}$

Input: The functionality receives inputs $[a]_p$ and $[b]_p$.
Output: Compute the following

1. Reconstruct a and b to compute ab.
2. Send ab to the parties.

Functionality B.10. $\mathcal{F}_{\text{PreOR}}$

Input: The functionality receives inputs $[a_1]_p, \ldots [a_\ell]_p$ where $a_i \in \{0,1\}$.
Output: Compute the following

1. Reconstruct $a_1, \ldots, a_\ell$.
2. Compute all prefix-ORs $a_1, a_1 \vee a_2, \ldots, \vee_{i=1}^{\ell} a_i$.
3. Distribute the shares of these prefix-ORs to the parties.

Functionality B.11. $\mathcal{F}_{\text{Bitwise-LT}}$

Input: The functionality receives inputs a and $[b]_{\text{B}}$ where $a, b \in \mathbb{F}_p$.
Output: Compute the following

1. Reconstruct $b_0, \ldots, b_{\ell-1}$ to compute $b = \sum_{i=0}^{\ell} 2^i \cdot b_i$.
2. Compute $c = (a < b)$ where $c \in \{0,1\}$.
3. Distribute the shares of $[c]_p$ to the parties.

Functionality B.12. $\mathcal{F}_{\text{DReLU}}$

Input: The functionality receives inputs $[a]_p$.
Output: Compute the following

1. Reconstruct a to compute $b = \text{DReLU}(a)$.
2. Distribute the shares of $[b]_p$ to the parties.

C Security Proofs

We only describe the simulation for protocol $\Pi_{\text{Fixed-Mult}}$, and the simulation for protocol Π_{Trunc} is similar. The simulations for the remaining protocols are mostly simple compositions of local computations and invocations of ideal functionalities.

We will construct a simulator $\mathcal{S}$ to simulate the behaviors of honest parties. In the beginning, $\mathcal{S}$ receives the input shares of $[a]_p$ and $[b]_p$ held by corrupted parties.

When invoking $\mathcal{F}_{\text{Trunc-Triple}}$, $\mathcal{S}$ invokes the simulator of $\mathcal{F}_{\text{Trunc-Triple}}$ and receives from the adversary the shares of $([r']_p, \langle r \rangle_p, [r_{\text{msb}}]_p)$ held by corrupted parties.

Functionality B.13. $\mathcal{F}_{\text{2L-DN}}$

Input: The functionality receives inputs $[x]_p, [y]_p$ and $\{[z^{(i)}]_p\}_{i=1}^m$.
Output: Compute the following

1. Reconstruct x, y and $\{z^{(i)}\}_{i=1}^m$ to compute $\{xyz^{(i)}\}_{i=1}^m$.
2. For $i = 1, \ldots, m$: Distribute the shares of $[xyz^{(i)}]_p$ to the parties.

Functionality B.14. $\mathcal{F}_{\text{ReLU}}$

Input: The functionality receives inputs $[a]_p$.
Output: Compute the following

1. Reconstruct a to compute $b = \text{ReLU}(a)$.
2. Distribute the shares of $[b]_p$ to the parties.

Functionality B.15. $\mathcal{F}_{\text{Maxpool}}$

Input: The functionality receives inputs $[a_1]_p, \ldots, [a_m]_p$.
Output: Compute the following

1. Reconstruct $a_1, \ldots, a_m$.
2. Compute $k = \text{argmax}\{a_1, \ldots, a_m\}$.
3. Distribute the shares of $[a_k]_p$ to the parties.

In Step 1, for each honest party, $\mathcal{S}$ samples a random element as its shares of $\langle ab + r + 2^{\ell-2} \rangle_p$. For each corrupted party, $\mathcal{S}$ computes its share of $\langle ab + r + 2^{\ell-2} \rangle_p$. In Step 2, depending on whether $P_{\texttt{pking}}$ is a corrupted party, there are two cases:

- If $P_{\texttt{pking}}$ is an honest party, $\mathcal{S}$ uses these shares to reconstruct the secret $c = ab + r + 2^{\ell-2}$, and sends c back to corrupted parties.

- If $P_{\texttt{pking}}$ is a corrupted party, $\mathcal{S}$ sends the shares of $[ab + r + 2^{\ell-2}]_p$ of honest parties to $P_{\texttt{pking}}$. $P_{\texttt{pking}}$ also receives the shares from corrupted parties. Then $P_{\texttt{pking}}$ can reconstruct c and send c back to corrupted parties.

In the following steps, $\mathcal{S}$ respectively computes the shares of $[e]_p$ and $[f]_p$ held by corrupted parties. Note that $\mathcal{S}$ has computed the shares of $[r_{\text{msb}}]_p$ and $[r']_p$ held by corrupted parties when simulating $\mathcal{F}_{\text{Trunc-Triple}}$.

In the real view, c is uniformly random since r is uniformly random. Hence, the view generated by the simulator $\mathcal{S}$ is indistinguishable from the real view underlying the security of $\mathcal{F}_{\text{Trunc-Triple}}$.

D Simulate Multi-party Computation on Limited Servers

We use 11 servers to simulate a range of parties. In the setting of 3PC, 7PC, and 11PC, a single party controls a single server. In the settings of 21PC, 31PC and 63PC, we run multi-parties on a single server simultaneously with different ports where we guarantee that the number of parties on different servers differs by up to one. We use the Linux `tc` command to set the latency and the bandwidth on both the Network Interface Controller (NIC) with regard to the IP address for parties on different servers and the local loopback NIC for parties on the same server, which ensures the ping-time and the throughput in each pair of parties is almost consistent.

E Neural Networks

Network-A Network-A is a 3-layer Deep Neural Network (DNN) from SecureML [35] which consists of 2 fully connected hidden layers with ReLU activations, each having 128 nodes along with a 10 node output layer.

Network-B Network-B is a 3-layer Convolutional Neural Network (CNN) derived from Chameleon [42] where the first layer is a 2-dimensional convolutional layer with a kernel of 5×5, stride of 2 (without padding), and 5 output channels. The activation function next is ReLU. The size of the kernel is optimized to 2×2 in Falcon [45]. The second hidden layer is a fully connected layer from a vector of size 980 to a vector of size 100, followed by ReLU activations. The last layer is a 10 node output layer from a vector of size 100 to a vector of size 10.

Network-C Network-C is a 4-layer CNN selected from MiniONN [31] with 2 convolutional and 2 fully-connected layers. The first layer is a 2-dimensional convolutional layer with 1 input channel, 16 output channels and a 5×5 kernel of stride of 1 (without padding). The activation functions following is a 2×2 Maxpool of stride 2, followed by ReLU activations, where the order of these two activation functions is swapped to optimize runtimes in Falcon [45]. The second layer is a 2-dimensional convolutional layer with 16 input channels, 16 output channels and another 5×5 kernel of stride 1 (without padding), followed by a 2×2 Maxpool of stride 2 and ReLU once again as activation functions. The third layer is a fully connected layer from a vector of size 256 to a vector of size 100 with ReLU activations. The last layer is a 10 node output layer as well.

Lightweight Authentication of Web Data via Garble-Then-Prove

Xiang Xie [*] Kang Yang [†] Xiao Wang [‡] Yu Yu [§]

Abstract

Transport Layer Security (TLS) establishes an authenticated and confidential channel to deliver data for almost all Internet applications. A recent work (Zhang et al., CCS'20) proposed a protocol to prove the TLS payload to a third party, without any modification of TLS servers, while ensuring the privacy and originality of the data in the presence of malicious adversaries. However, it required maliciously secure Two-Party Computation (2PC) for generic circuits, leading to significant computational and communication overhead.

This paper proposes the garble-then-prove technique to achieve the same security requirement without using any heavy mechanism like generic malicious 2PC. Our end-to-end implementation shows 14× improvement in communication and an order of magnitude improvement in computation over the state-of-the-art protocol. We also show worldwide performance when using our protocol to authenticate payload data from Coinbase and Twitter APIs. Finally, we propose an efficient gadget to privately convert the above authenticated TLS payload to additively homomorphic commitments so that the properties of the payload can be proven efficiently using zkSNARKs.

1 Introduction

Transport Layer Security (TLS) [26, 55] is the most widely deployed cryptographic protocol for secure communication on the Internet. It provides end-to-end security against active attackers between a client, namely $\mathcal{C}$ and a TLS server, namely $\mathcal{S}$. However, if the client wants to use the TLS payload data in a different application, TLS does not guarantee the originality of the data. In particular, a malicious client could come up with a valid TLS transcript for any payload of its choice. The issue stems from the fact that the TLS protocol assumes that both client $\mathcal{C}$ and server $\mathcal{S}$ are honest, but in this new setting, the client can be malicious. For most websites, this is solved by having a user authenticate one website in connection with the other website that needs the data. Doing so under the client's authorization allows the two websites to share data directly and thus ensures no malicious client can break integrity. However, such a solution is not perfect. First, users are often forced to share more information than needed, e.g., to prove that their credit score is higher than a threshold, they need to share the score entirely. Second, this solution requires adding new web infrastructures, which could hinder the deployment, especially when connecting Web2 data to Web3 applications.

A recent work, DECO [71], proposed a solution that does not require any change on the TLS server side. From a high-level view, they ask a prover $\mathcal{P}$ (i.e., a user that intends to prove the originality of the data) and a verifier $\mathcal{V}$ (i.e., a third party) to jointly emulate the computation of the TLS client $\mathcal{C}$ who interacts with $\mathcal{S}$. Since neither $\mathcal{P}$ nor $\mathcal{V}$ ever holds TLS session keys, their capability is the same as man-in-the-middle attackers and thus cannot forge a valid TLS transcript for unauthorized data. In DECO, most of $\mathcal{C}$'s computation is emulated using a maliciously secure Two-Party Computation (2PC) protocol, which ensures that no derivation from the protocol can help the malicious party break the privacy or integrity requirement when interacting with $\mathcal{S}$. To prove statements on the TLS payload, $\mathcal{P}$ proves to $\mathcal{V}$ the correct decryption of the ciphertext (to obtain a plaintext) and desired statements on the plaintext using zkSNARKs [8, 10, 30, 33].

Generic 2PC protocols in the malicious setting have been studied extensively in the past decade (e.g., [15, 50, 51, 53, 59]). DECO used an implementation of the authenticated garbling [36, 43, 62, 67], the state-of-the-art malicious 2PC framework that significantly reduces the overhead compared to the semi-honest counterparts. However, even based on the latest advances [23, 27], the computation and communication cost of maliciously secure 2PC is still much higher than its semi-honest counterparts. Moreover, these protocols with malicious security often require storing preprocessed authen-

[§] Shanghai Jiao Tong University & Shanghai Qi Zhi Institute, yuyu@cs.sjtu.edu.cn

ticated triples, thus incurring a huge memory overhead. The complexity of the maliciously secure protocol also makes it difficult to implement and deploy such a protocol. As a result, the DECO protocol still requires 475 MB of communication to authenticate a 2KB-sized payload via TLS and more than 50 seconds to finish under a WAN network.

1.1 Our Contribution

In this paper, we design a new protocol for web-data authentication to third parties with improved efficiency. We propose the garble-then-prove technique that can realize a special class of two-party computation functionalities against malicious adversaries, with almost no overhead compared to their semi-honest counterparts. We elaborate on our key concepts and contributions below and refer to Section 3 for an overview of our core techniques.

Eliminating malicious 2PC via garble-then-prove. We avoid the use of maliciously secure 2PC, as a result of deeply understanding the features of authenticating web data in TLS. We observe that since $\mathcal{V}$ is the verifier, the security requirements for $\mathcal{V}$ and the prover $\mathcal{P}$ differ in many ways. **During** the secure TLS emulation, a corrupted $\mathcal{V}$ shall not learn the session keys as it immediately reveals $\mathcal{P}$'s private input; however, we can tolerate a corrupted $\mathcal{P}$ learning some information about the session keys: since $\mathcal{V}$ does not have long-term secrets, the damage is remediable. We only require $\mathcal{P}$'s cheating behavior to be identifiable by $\mathcal{V}$ later. **After** the completion of the joint TLS emulation, all of $\mathcal{V}$'s shares of the TLS secrets can be opened to $\mathcal{P}$ since $\mathcal{P}$ can no longer alter the TLS protocol. Simply put, our security requirement is as below: $\mathcal{P}$ and $\mathcal{V}$ start with inputs $x_{\mathcal{P}}$ and $x_{\mathcal{V}}$ respectively and shall get outputs $y_{\mathcal{P}}, y_{\mathcal{V}}$ such that $(y_{\mathcal{P}}, y_{\mathcal{V}}) = f(x_{\mathcal{P}}, x_{\mathcal{V}})$ for some two-output function f. If $\mathcal{P}$ cheats, it can replace the function to one of its own choice but $\mathcal{V}$ cannot cheat in any way. During the checking phase, $\mathcal{P}$ will be given $x_{\mathcal{V}}$ and $\mathcal{V}$ should be notified if $\mathcal{P}$ cheated during the evaluation phase.

To accomplish this task, $\mathcal{P}$ first sends $\mathcal{V}$ a garbled circuit for f; they also use an OT with malicious security to let $\mathcal{V}$ get garbled labels on its input. Two parties then can obtain their outputs but there is no way to ensure correctness. For that, we ask $\mathcal{P}$ to commit to $\mathcal{V}$ its input $x_{\mathcal{P}}$ and output $y_{\mathcal{P}}$. Now, $\mathcal{V}$ has shares $x_{\mathcal{V}}, y_{\mathcal{V}}$ and commitments of $x_{\mathcal{P}}, y_{\mathcal{P}}$. After $\mathcal{P}$ gets $x_{\mathcal{V}}$, thus also $y_{\mathcal{V}}$, $\mathcal{P}$ can use a Zero-Knowledge (ZK) protocol to prove that $(y_{\mathcal{P}}, y_{\mathcal{V}}) = f(x_{\mathcal{P}}, x_{\mathcal{V}})$ w.r.t. the committed values. $\mathcal{P}$ could launch a selective failure attack on $x_{\mathcal{V}}$ (leaking one-bit of information), but it is meaningless since $x_{\mathcal{V}}$ is always given to $\mathcal{P}$ in the proving phase. For obvious reasons, we refer to this technique as *garble-then-prove*. This technique can be also applied in, e.g., QUIC [24, 39], OAuth [35] and OpenID Connect [58], to authenticate web data.

TLS-specific protocol optimization. Building on the above idea, we further optimize other TLS building blocks in various ways. For example, we show how to carefully select values to reveal, without providing any party an extra capacity, during the derivation of TLS session keys, leading to a more than 2-fold reduction in handshake circuit size. We also pull the computation of the Galois Message Authentication Code (GMAC) tags out of circuits and instead use Oblivious Linear Evaluation with errors (OLEe) [1] to compute additive sharings of the powers of a random element needed for GMAC, reducing the cost of GMAC computation by more than two orders of magnitude. Doing so would allow the adversary to gain one bit of information of the TLS session key, but that would not reduce the overall concrete security, for a reason similar to prior works, e.g., [44, 67].

Efficient commitment conversion. To prove statements on the TLS data using zkSNARKs, DECO embeds the TLS ciphertext into the statements and then proves in ZK the correctness of decryption. For our protocol, we use the recent vector OLE (VOLE) based interactive zero-knowledge proofs [7, 28, 63, 66] during the garble-then-prove execution. This means that at the end of the protocol, two parties hold information-theoretic MACs (IT-MACs) on each bit of the query and response involved in the TLS. One could prove statements using VOLE-based ZK proofs or, alternatively, convert them to commitments friendly to zkSNARKs. First, we convert IT-MACs over $\mathbb{F}_2$ to IT-MACs over $\mathbb{F}_q$, ensuring the values are consistent. This protocol can be viewed as a special version of zero-knowledge via garbled-circuit protocol [41] over garbling of Boolean-to-arithmetic identity gates [6]. This makes the cost conversion in the malicious case almost the same as the semi-honest setting. Then we convert arithmetic IT-MACs to zkSNARK-friendly commitments, which can be achieved with high efficiency, since both representations are additive-homomorphic. In this way, without using zkSNARKs, we can convert the plaintext query and response to additively homomorphic commitments, which can then be connected to various zkSNARKs, e.g., [17, 18, 20].

Full-fledged implementation. We implemented our protocol and report detailed performance in Section 5. Our protocol outperforms DECO by more than an order of magnitude: 14× improvement in communication and 7.5× to 15× improvements in running time. We also push through the last mile to connect our implementation with real-world APIs connected via TLS. In Section 5.3, we include two examples of using our protocol to authenticate API results from Coinbase and Twitter. We report the performance when the prover is located in 18 cities worldwide with various network conditions. We also show a summary of the performance in Table 1, where we can see that the whole protocol only takes around 7 seconds (4 seconds of online time) when a user in Tokyo proving to a verifier in California about its Coinbase/Twitter API payload.

[1] OLEe provides a weaker security in which the malicious party can introduce an error into the OLE output, but it can be generated more efficiently.

Region of prover $\mathcal{P}$	Oregon	Virginia	Milan	Singapore	Tokyo
Coinbase	1.66 (2.43)	2.85 (4.98)	6.47 (11.9)	6.05 (11.7)	3.94 (7.35)
Twitter	0.94 (1.71)	2.08 (4.10)	5.21 (10.8)	5.78 (11.7)	3.56 (7.12)

Table 1: **Performance summary of our protocol.** All numbers are reported in seconds, based on the Coinbase API to query account balance (426-byte query and 5701-byte response) and the Twitter API to query the number of followers (587-byte query and 894-byte response). Both online time and total time (in parentheses) are reported. Verifier $\mathcal{V}$ is always located at California.

2 Preliminaries

We describe the TLS building blocks and model the security of authenticating web data. The cryptographic preliminaries to comprehend our protocol are described in Section A.

Notation. We use λ to denote the computational security parameter. We use $x \leftarrow S$ to denote that sampling x uniformly at random from a finite set S. For an algorithm A, we use $y \leftarrow \mathsf{A}(x)$ to denote the operation of running A on input x and setting y as the output. We will use bold lower-case letters like $\boldsymbol{x}$ for column vectors, and denote by x_i the i-th component of $\boldsymbol{x}$ with x_1 the first entry. For $a, b \in \mathbb{N}$, we write $[a,b] = \{a, \ldots, b\}$. We write $\mathbb{F}_{2^\lambda} \cong \mathbb{F}_2[X]/f(X)$ for some monic, irreducible polynomial $f(X)$ of degree λ. Depending on the context, we use $\{0,1\}^\lambda$, $(\mathbb{F}_2)^\lambda$ and $\mathbb{F}_{2^\lambda}$ interchangeably, and thus addition in $(\mathbb{F}_2)^\lambda$ and $\mathbb{F}_{2^\lambda}$ corresponds to XOR in $\{0,1\}^\lambda$ and a string $a \in \{0,1\}^\lambda$ is also a vector in $(\mathbb{F}_2)^\lambda$. For a bit-string x, we use $\mathsf{lsb}(x)$ to denote the least significant bit of x. For a prime p, we denote by $\mathbb{Z}_p$ a finite field.

We use $[x]_p = (x_\mathcal{P}, x_\mathcal{V})$ to denote an additive secret sharing of x over $\mathbb{Z}_p$ between $\mathcal{P}$ and $\mathcal{V}$ holding $x_\mathcal{P}$ and $x_\mathcal{V}$ respectively. When the field is $\mathbb{F}_{2^{128}}$, we denote by $[x]_{2^{128}}$. For details of additive secret sharings, we refer to the reader for Section A. Let $[\![x]\!] = (x, \mathsf{M}[x], \mathsf{K}[x])$ be an Information-Theoretic Message Authentication Code (IT-MAC) such that $\mathsf{M}[x] = \mathsf{K}[x] + x \cdot \Delta$, where the message x and MAC tag $\mathsf{M}[x]$ are held by a party $\mathcal{P}$, and keys $\mathsf{K}[x], \Delta$ are obtained by another party $\mathcal{V}$. We give more details of IT-MACs in the full version [65, Section A].

2.1 TLS Building Blocks

Transport Layer Security (TLS) is a family of protocols that guarantee privacy and integrity of data between a client $\mathcal{C}$ and a server $\mathcal{S}$. It consists of two protocols: (a) the handshake protocol in which handshake secrets are established and the secrets are in turn used to generate application keys; (b) the record protocol where data is transmitted with confidentiality and integrity via encrypting and authenticating the data with the application keys. Our protocol focuses on authenticating web data for TLS 1.2 [26], and is able to be extended to TLS 1.3 [55] that is shown in Section 4.3, where both of TLS 1.2 and TLS 1.3 adopt HMAC to derive secrets and keys. [2] While TLS provides different modes, we focus on the following most popular modes:

ECDHE_RSA_AES128_GCM_SHA256
ECDHE_ECDSA_AES128_GCM_SHA256,

where the hash function H is instantiated by SHA256, and a stateful Authenticated Encryption with Associated Data (AEAD) scheme is instantiated by AES128 in the GCM mode. ECDHE adopts the elliptic-curve Diffie-Hellman (DH) key exchange protocol to establish ephemeral secrets.

Our protocol is easy to be extended to support that AEAD scheme is instantiated by AES256_GCM and H is replaced with SHA384, and also allows one to use other digital signature (e.g., DSA). Besides, our protocol can be straightforwardly extended to support ECDH in which the server uses a static DH value (rather than an ephemeral DH value). We did not optimize our protocol to realize the CBC mode in TLS 1.2, since this mode has been demonstrated to be vulnerable to the timing attack against several TLS implementations [5], and the GCM mode is preferred over CBC [2]. In addition, TLS 1.3 did not support the CBC mode any more. Our garble-then-prove approach can be also generalized to other modes such as CHACHA20_POLY1305_SHA256 and AES128_CCM_SHA256. In the full version [65], we describe the TLS 1.2 protocol in detail. Below, we describe several key building blocks used in the TLS protocol.

HMAC. Given a key k and a message m as input, the well-known pseudo-random function HMAC is defined as follows:

$$\mathsf{HMAC}(k,m) = \mathsf{H}(k \oplus \mathrm{opad}, \mathsf{H}(k \oplus \mathrm{ipad}, m)),$$

where opad and ipad are two public strings with length of 512 bits (i.e., the repeated bytes of 0x36 and 0x5C respectively). Here we always assume that k has at most 512 bits, which is the case for TLS. When the bit-length of k is less than 512, it will be padded with 0 to achieve 512 bits. As described above, we focus on considering that H is instantiated by SHA256. In particular, SHA256 adopts the Merkle-Damgård structure with block size of 512 bits, and uses f_H as the one-way compression function with output length of 256 bits. For example, $\mathsf{H}(m_1, m_2)$ is computed as $f_\mathsf{H}(f_\mathsf{H}(IV_0, m_1), m_2)$ where $m_1, m_2 \in \{0,1\}^{512}$ and IV_0 is a fixed initial vector.

Key derivation. Here we focus on the Pseudo-Random Function (PRF) in TLS 1.2 [26], where the PRF is used to derive

[2] For now, about 77%∼79% websites use TLS 1.2, while about 9%∼20% websites adopt TLS 1.3 [1].

handshake secrets and application keys and adopts HMAC as its core. TLS 1.3 [55] adopts the HKDF function [46, 47] as its key derivation function, where this function is also based on HMAC. We refer the reader to Section 4.3 for the details of HKDF. Specifically, the PRF function with output length ℓ in TLS 1.2 is defined below:

$$\mathsf{PRF}_\ell(k, label, msg) = \mathsf{HMAC}(k, M_1 \| label \| msg) \| \ldots \| \mathsf{HMAC}(k, M_{n-1} \| label \| msg) \| \mathsf{Trunc}_m(\mathsf{HMAC}(k, M_n \| label \| msg)),$$

where $n = \lceil \ell/256 \rceil$, $m = \ell - 256 \cdot (n-1)$, $M_1 = \mathsf{HMAC}(k, label \| msg)$ and $M_{i+1} = \mathsf{HMAC}(k, M_i)$ for $i \in [1, n-1]$. For a bit-string x, $\mathsf{Trunc}_m(x)$ denotes truncating x to the leftest m bits.

Stateful AEAD scheme. The TLS protocol adopts a stateful AEAD scheme $(\mathsf{stE.Enc}, \mathsf{stE.Dec})$ to encrypt/decrypt messages in the handshake and record layers. The encryption algorithm $\mathsf{stE.Enc}(\mathsf{key}, \ell_C, \mathrm{H}, \mathbf{M}, \mathsf{st}_e)$ takes as input a secret key key, a target ciphertext length ℓ_C, a header H, a message $\mathbf{M}$ and a state st_e, and outputs a ciphertext CT. The decryption algorithm $\mathsf{stE.Dec}(\mathsf{key}, \mathrm{H}, \mathrm{CT}, \mathsf{st}_d)$ takes as input key, a header H, a ciphertext CT and a state st_d, and outputs a plaintext $\mathbf{M}$ or a special symbol $\perp$ indicating that the ciphertext is invalid. When the AEAD scheme is instantiated by AES128_GCM, $\mathsf{stE.Enc}(\mathsf{key}, \ell_C, \mathrm{H}, \mathbf{M}, \mathsf{st}_e)$ has the following steps:

1. Compute $\mathrm{Z}_0 := \mathsf{AES}(\mathsf{key}, \mathsf{st}_e)$ and update $\mathsf{st}_e := \mathsf{st}_e + 1$.
2. Suppose $\mathbf{M}$ is padded as $(\mathrm{M}_1, \ldots, \mathrm{M}_n)$ with $\mathrm{M}_i \in \{0,1\}^{128}$. From $i = 1$ to n, compute $\mathrm{Z}_i := \mathsf{AES}(\mathsf{key}, \mathsf{st}_e)$ and $\mathrm{C}_i := \mathrm{Z}_i \oplus \mathrm{M}_i$ and update $\mathsf{st}_e := \mathsf{st}_e + 1$. Set $\mathbf{C} := (\mathrm{C}_1, \ldots, \mathrm{C}_n)$.
3. Suppose that the header H has been padded as an element in $\mathbb{F}_{2^{128}}$. Let ℓ_H be the bit length of H. Given a vector $\mathbf{X} \in (\mathbb{F}_{2^{128}})^m$, the GHASH polynomial $\Phi_{\mathbf{X}} : \mathbb{F}_{2^{128}} \to \mathbb{F}_{2^{128}}$ is defined as $\Phi_{\mathbf{X}}(h) = \sum_{i=1}^{m} X_i \cdot h^{m-i+1} \in \mathbb{F}_{2^{128}}$. Compute $h := \mathsf{AES}(\mathsf{key}, \mathbf{0})$ and a GMAC tag $\sigma := \mathrm{Z}_0 \oplus \Phi_{(\mathrm{H}, \mathbf{C}, \ell_H, \ell_C)}(h)$.
4. Output $\mathrm{CT} = (\mathbf{C}, \sigma)$.

Algorithm $\mathsf{stE.Dec}(\mathsf{key}, \mathrm{H}, \mathrm{CT}, \mathsf{st}_d)$ has the same steps as stE.Enc, except for the following differences:

- Parse CT as $(\mathbf{C}, \sigma)$ and $\mathbf{C}$ as $(\mathrm{C}_1, \ldots, \mathrm{C}_n)$. Compute $\mathrm{M}_i := \mathrm{Z}_i \oplus \mathrm{C}_i$ for $i \in [1, n]$ and set $\mathbf{M} = (\mathrm{M}_1, \ldots, \mathrm{M}_n)$.
- Compute a tag σ' as described above and check $\sigma = \sigma'$.
- If the check passes, output $\mathbf{M}$. Otherwise, output $\perp$.

2.2 Security Model and Functionalities

We use the standard ideal/real security model (shown as below) to prove security of our protocol. We describe the definitions of ideal functionalities for Oblivious Transfer (OT) and OLEe in Section A. The functionalities for additively homomorphic commitments, standard commitments and Interactive Zero-Knowledge (IZK) proofs along with their instantiations can be found in the full version [65, Section A].

Functionality $\mathcal{F}_{\mathsf{AuthData}}$

This functionality interacts with a prover $\mathcal{P}$, a verifier $\mathcal{V}$, a server $\mathcal{S}$ and an adversary.

- Upon receiving $(\mathsf{sid}, \mathsf{Query}, \alpha, \mathcal{S})$ from $\mathcal{P}$ and $(\mathsf{sid}, \mathsf{Query})$ from $\mathcal{V}$, where sid is a session identifier, Query is a query template and α is a private input for Query,
  1. Compute a query $Q := \mathsf{Query}(\alpha)$, and then send a pair (sid, Q) to $\mathcal{S}$.
  2. Receive a response (sid, R) from $\mathcal{S}$ and then store a tuple (sid, Q, R).
  3. Send $(\mathsf{sid}, |Q|, |R|, \mathcal{S})$ to the adversary.
- Upon receiving $(\mathsf{commit}, \mathsf{sid}, \mathsf{cid})$ from $\mathcal{P}$, where cid is a fresh commitment identifier, if a tuple (sid, Q, R) was previously stored, update it as $(\mathsf{sid}, \mathsf{cid}, Q, R)$, and send $(\mathsf{committed}, \mathsf{sid}, \mathsf{cid})$ to $\mathcal{V}$ and the adversary.
- Output $(\mathsf{sid}, \mathsf{cid}, Q, R)$ to $\mathcal{P}$ and $(\mathsf{sid}, \mathsf{cid}, \mathcal{S})$ to $\mathcal{V}$.

Figure 1: **Functionality for authenticating web data.**

Ideal/real security model. We use the standard ideal/real paradigm [19, 32] to prove security of our protocol in the presence of a *malicious, static* adversary. In the *ideal-world* execution, the parties interact with a functionality $\mathcal{F}$, and some of them may be corrupted by an *ideal-world adversary* (a.k.a., *simulator*) $\mathcal{S}$. In the *real-world* execution, the parties interact with each other in an execution of protocol Π, and some of them may be corrupted by a *real-world adversary* $\mathcal{A}$ (that is often called an adversary for simplicity). We say that protocol Π securely realizes functionality $\mathcal{F}$, if the output of the honest parties and $\mathcal{A}$ in the real-world execution is computationally indistinguishable from the output of the honest parties and $\mathcal{S}$ in the ideal-world execution. We consider security with abort, and thus allow the ideal-world/real-world adversary to abort the functionality/protocol execution at some point. We prove security of our protocol in the $\mathcal{G}$-hybrid model in which the parties execute a protocol with real messages and also have access to a sub-functionality $\mathcal{G}$.

Use case. Similar to DECO [71], our protocol involves three parties: a prover $\mathcal{P}$, a verifier $\mathcal{V}$ and a TLS server $\mathcal{S}$, where $\mathcal{P}$ and $\mathcal{V}$ jointly play the role of the client to interact with the server $\mathcal{S}$. Prover $\mathcal{P}$ has data stored on $\mathcal{S}$, and intends to prove to $\mathcal{V}$ about properties of the data, without any modification to the TLS server. For example, a Coinbase user (i.e., $\mathcal{P}$) wants to prove to a loan agency (i.e., $\mathcal{V}$) that his wallet balance satisfies an agreed-upon predicate (e.g., it is greater than a threshold).

Ideally, the user wants to prove it without revealing any other information (e.g., transaction details or the exact balance). Our protocol enables this: (1) $\mathcal{P}$ interacts with $\mathcal{S}$ via TLS to get the balance; (2) $\mathcal{P}$ can prove to $\mathcal{V}$ that the balance sent over the TLS protocol satisfies the predicate. The protocol ensures that $\mathcal{V}$ learns nothing except for that the predicate is true, and that $\mathcal{P}$ cannot use an inconsistent balance. We refer the reader to [71] for more application examples.

Functionality for authenticating web data. We model the security of authenticating web data by giving an ideal functionality. At a high level, the protocols to authenticate web data will involve the following steps performed in a secure and distributed way:

1. $\mathcal{P}$ and $\mathcal{V}$ (on behalf of the client) run the TLS protocol with $\mathcal{S}$ to establish an authenticated and confidential channel.
2. Under the secure channel, $\mathcal{P}$ sends a query Q to $\mathcal{S}$ and receives a response R from $\mathcal{S}$.
3. $\mathcal{P}$ sends the commitment of (Q,R) to $\mathcal{V}$, and convinces $\mathcal{V}$ that the commitment is correct on a valid pair (Q,R).
4. Given (Q,R) and its commitment, $\mathcal{P}$ can prove in zero knowledge to $\mathcal{V}$ that (Q,R) satisfies some statement.

In this paper, we focus on constructing a secure protocol to realize the first three steps. The final step can be realized using a variety of zero-knowledge proofs such as zk-SNARKs [10, 30, 33]. In this setting, the server $\mathcal{S}$ is always honest to run the protocol, [3] and so the security only needs to be guaranteed when either $\mathcal{P}$ or $\mathcal{V}$ is corrupted. For adversarial model, we consider a static, malicious adversary $\mathcal{A}$ who can corrupt one of $\mathcal{P}$ and $\mathcal{V}$ and may deviate the protocol arbitrarily. The ideal functionality for authenticating web data is defined in Figure 1, and builds upon the definition of the oracle functionality in [71]. Following an example in [71], a query template could be $\mathsf{Query}(\alpha)$ = "stock price of GOOG on June 1st, 2023 with API key = α".

Functionality $\mathcal{F}_{\mathsf{AuthData}}$ (shown in Figure 1) implies the following security properties, where similar properties were described in DECO [71].

- *Prover-integrity* : A malicious prover $\mathcal{P}$ cannot cause the query and response, whose commitments are sent to an honest verifier $\mathcal{V}$, to be inconsistent from that received or sent by the server $\mathcal{S}$.
- *Verifier-integrity* : A malicious verifier $\mathcal{V}$ cannot cause $\mathcal{P}$ to receive an incorrect response, i.e., if $\mathcal{P}$ outputs (Q,R), R must be $\mathcal{S}$'s response to the query Q sent by $\mathcal{P}$.
- *Privacy* : A malicious verifier $\mathcal{V}$ cannot learn any information on query Q and response R, except for the public information $(|Q|,|R|,\mathsf{Query})$ and which server $\mathcal{S}$ is accessed.

[3] We do not require any server-side modification or cooperation.

In the ideal world, all channels between honest parties and functionality $\mathcal{F}_{\mathsf{AuthData}}$ are confidential and authenticated. This guarantees the privacy of secret values Q,R. As in [71], we always consider that the length of a query $|Q|$, the length of a response $|R|$ and the name of a server $\mathcal{S}$ are known by the adversary. We use an identifier cid to represent a commitment on the query Q and response R. From the definition of $\mathcal{F}_{\mathsf{AuthData}}$, we have that the query-response pair (Q,R) committed by $\mathcal{F}_{\mathsf{AuthData}}$ are always consistent. The adversary who corrupts $\mathcal{P}$ can only get an identifier cid and has no way to tamper the values committed, which guarantees the prover-integrity. The honest prover $\mathcal{P}$ will always output a response R from $\mathcal{F}_{\mathsf{AuthData}}$, which is consistent with Q. Thus, the adversary who corrupts $\mathcal{V}$ cannot make the honest prover receive an inconsistent response, which guarantees the verifier-integrity.

3 Technical Overview

Third-party authentication of TLS payload could be achieved using a malicious 2PC protocol with a high overhead [71]. Our key technique is to first garble and evaluate circuits, and then prove the correctness of the resulting outputs in zero-knowledge. This enables us to use lightweight MPC building blocks, i.e., plain Two-Party Computation protocols based on Garbled Circuits (GC-2PC) that are the same as semi-honest protocols [56, 69, 70] except for using malicious OT instead of semi-honest OT, and the recent VOLE-based interactive zero-knowledge (IZK) proofs [7, 28, 63]. Our garble-then-prove technique can be used to authenticate web data for TLS, and may also be of independent interest for other applications in which all secrets are able to be known by a prover at the end, e.g., authenticating data from protocols like QUIC [24, 39], OAuth [35] and OpenID Connect [58].

We also present a technique to convert from IT-MACs to additively homomorphic commitments that are friendly to zk-SNARKs. This technique could also be used in other applications such as zero-knowledge machine learning [64]. Through the TLS application, we give an overview of these techniques. Furthermore, we provide several tailored optimizations to further improve the efficiency, based on the details of the TLS protocol. To help better understand our protocol, we first give a detailed overview of the TLS protocol.

3.1 An Overview of the TLS Protocol

In Figure 2, we provide a pictorial overview, and show complete details in the full version [65]. The protocol is executed between a TLS client ($\mathcal{C}$) and a TLS server ($\mathcal{S}$). It can be roughly divided into 4 phases:

- **Phase 1: pre-master secret.** $\mathcal{C}$ samples a random nonce $r_C \leftarrow \{0,1\}^{256}$, and then sends $\text{REQ}_C = r_C$ to $\mathcal{S}$. Then, $\mathcal{S}$ samples a random nonce $r_S \in \{0,1\}^{256}$, a random element $t_S \in \mathbb{Z}_q$, and computes a group element $T_S := t_S \cdot G$. $\mathcal{S}$ sends

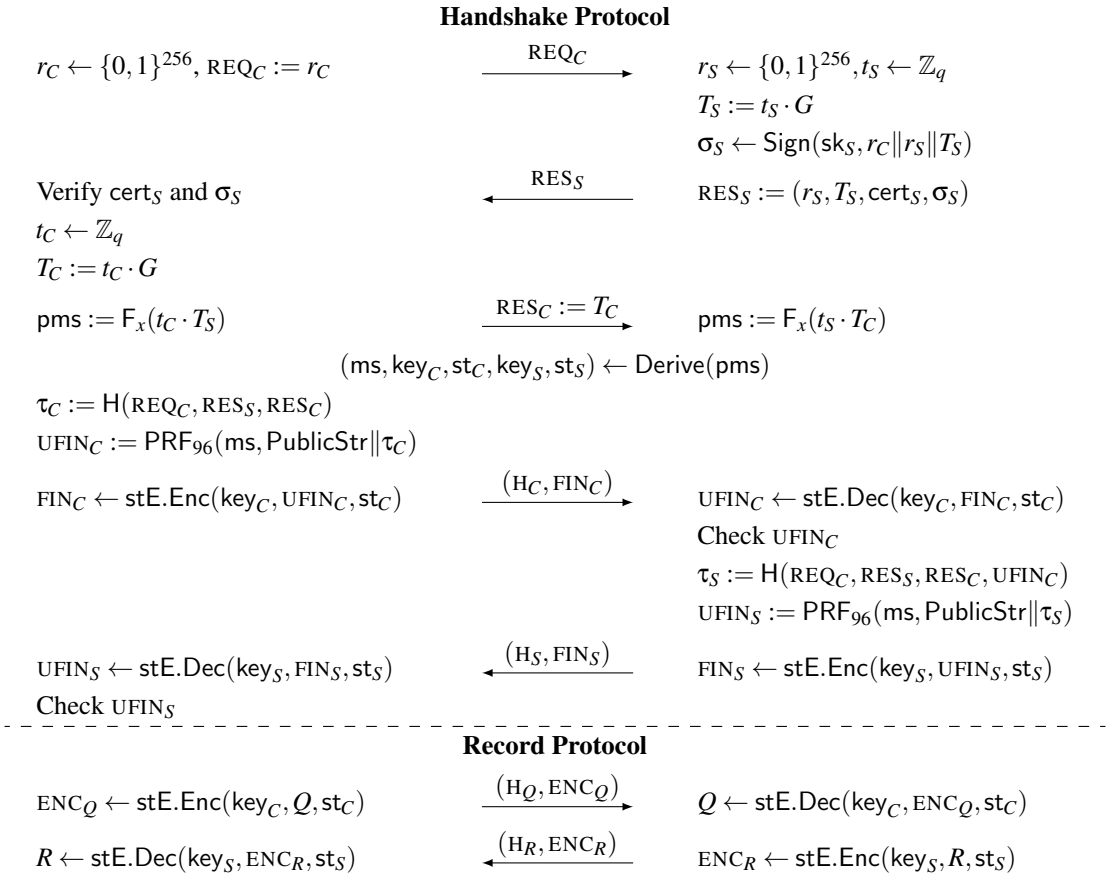

Figure 2: **Graphical depiction of TLS.** PublicStr refers to strings defined in the TLS specification. H_C, H_S, H_Q and H_R are public metadata headers defined by the TLS specification. Some details are omitted.

back $\text{RES}_S = (r_S, t_S, \text{cert}_S, \sigma_S)$, where cert_S is a certification and σ_S is a signature on (r_C, r_S, T_S). To finish the key-exchange protocol, $\mathcal{C}$ sends back a random group element $T_C := t_C \cdot G$. Now both parties agree on a pre-master secret $\text{pms} = \text{F}_x(t_C \cdot T_S) = \text{F}_x(t_S \cdot T_C)$, where F_x is a function mapping an elliptic-curve point to its x-coordinate.

- **Phase 2: TLS session keys.** With pms, $\mathcal{C}$ and $\mathcal{S}$ compute a master secret $\text{ms} := \text{PRF}_{384}(\text{pms}, \text{“master secret”}, r_C \| r_S)$. Then, both parties compute a tuple $(\text{key}_C, IV_C, \text{key}_S, IV_S) := \text{PRF}_{448}(\text{ms}, \text{“key expansion”}, r_S \| r_C)$, where $\text{key}_C, \text{key}_S \in \{0,1\}^{128}$ are two application keys and $IV_C, IV_S \in \{0,1\}^{96}$ are the initial states st_C, st_S of AEAD encryption. In Figure 2, we refer to the whole process as Derive.
- **Phase 3: Finished messages.** Two parties exchange test messages, which have already been known by them, over the established AEAD-encrypted channel. The client's message is $\text{UFIN}_C = \text{PRF}_{96}(\text{ms}, \text{“client finished”}, \tau_C)$, where τ_C is the hash of the TLS transcripts so far. $\mathcal{C}$ sends the AEAD ciphertext FIN_C of this message, which is encrypted with key_C and st_C, to $\mathcal{S}$. The server decrypts FIN_C and checks if UFIN_C is correct based on the same session key and values. Then $\mathcal{S}$ sends back a similarly encrypted message, and $\mathcal{C}$ checks its correctness.
- **Phase 4: Exchange payload.** Finally, two parties exchange their application payload. The exact process is essentially the same as Phase 3, with updated states for AEAD (based on AES-GCM), except that now the underlying payload is provided by the client and server based on the application. This phase could exchange several rounds of payload, depending on the application. In Figure 2, we only show one round of payload for simplicity. The following technical overview focuses on the one-round case, and our protocol can be extended to support multiple rounds of payload (see Section 4.2 for details).

3.2 Our Protocol Design

Now we introduce high-level ideas of our protocol based on the key observations described in Section 1.1. When describing our protocol, we use a prover $\mathcal{P}$ and a verifier $\mathcal{V}$, who jointly emulate $\mathcal{C}$, the TLS client.

3.2.1 Phase 1: Generating pre-master secret

The process of generating pre-master secret pms in TLS is essentially a Diffie-Hellman (DH) key exchange. Since neither $\mathcal{P}$ nor $\mathcal{V}$ can know the outcome, they need to jointly emulate the TLS client. The first round of interaction of messages $(\text{REQ}_C, \text{RES}_S)$ can be done by $\mathcal{P}$ alone without $\mathcal{V}$. The message RES_C and DH secret needs to be distributively computed by $\mathcal{P}$ and $\mathcal{V}$. In more detail, $\mathcal{P}$ and $\mathcal{V}$ pick $t_\mathcal{P} \leftarrow \mathbb{Z}_q$, and $t_\mathcal{V} \leftarrow \mathbb{Z}_q$ respectively; $\mathcal{V}$ sends $t_\mathcal{V} \cdot G$ to $\mathcal{P}$, who defines $\text{RES}_C := (t_\mathcal{P} + t_\mathcal{V}) \cdot G$ and sends it to the server. In particular, $\mathcal{P}$ and $\mathcal{V}$ have an additive secret sharing (i.e., $t_\mathcal{P} \cdot T_S$ and $t_\mathcal{V} \cdot T_S$) of the DH secret $(t_\mathcal{P} + t_\mathcal{V}) \cdot T_S$. The above step is similar to the previous protocols [60, 71], who then use a fully secure multiplicative-to-additive conversion protocol, a.k.a, Oblivious Linear Evaluation (OLE), to convert an additive sharing of the EC point $(t_\mathcal{P} + t_\mathcal{V}) \cdot T_S$ to an additive sharing of its x-coordinate (i.e., pms).

Obtaining fully secure OLE is often expensive and requires tailored zero-knowledge proofs or excessive communication. However, in this particular setting, we show that an OLE with error (OLEe), where the error could even depend on parties' inputs, is already sufficient. Such an OLEe can be efficiently computed using $\log q$ correlated OTs without the need of any extra checks. This would lead to one-bit information leakage about pms to the adversary who corrupts the prover $\mathcal{P}$. However, due to the TLS protocol, pms is of high entropy and we can show that such leakage does not help the adversary in guessing the whole secret pms. Intuitively, such an error could only lead to the selective-failure attack, which allows the adversary to guess c bits of the secret with probability 2^{-c}, but if the guess is incorrect the protocol execution aborts. Such an attack does not reduce concrete security since the adversary could bet on c bits of the secret too. A similar analysis has already been used in designing maliciously secure protocols (e.g., [22, 44, 67]).

3.2.2 Phase 2: Deriving TLS session keys

Now $\mathcal{P}$ and $\mathcal{V}$ hold an additive secret sharing of pms and need to derive additive sharings of TLS session keys using PRF based on HMAC-SHA256. This is the most expensive part for TLS handshake in DECO, who implemented this step using a fully malicious 2PC protocol to compute a circuit containing 779,213 AND gates. We show how to achieve a 16× improvement in communication.

Eliminating malicious 2PC via garble-then-prove. We observe that using a fully malicious 2PC is a complete overkill for applications that allow a verifier to reveal all its secrets to a prover later (e.g., authenticating web data for TLS). In our protocol, we use a plain GC-2PC protocol with malicious OT between $\mathcal{P}$ and $\mathcal{V}$ to jointly derive session keys. In more detail, $\mathcal{P}$ is the circuit garbler and $\mathcal{V}$ is the circuit evaluator. Any value that needs to be revealed to both parties is revealed to $\mathcal{V}$ first (by letting $\mathcal{P}$ send the decoding information to $\mathcal{V}$), who sends back the value to $\mathcal{P}$. In this way, $\mathcal{V}$ cannot break the privacy requirement of the function being computed (but can still change the output, which can be detected later). However, a malicious $\mathcal{P}$ can cheat in a seemingly catastrophic way: a malicious $\mathcal{P}$ could change a Garbled Circuit (GC) to control the output to be anything (could even be pms or something that can help $\mathcal{P}$ recover pms).

As we discussed in the main philosophy, instead of preventing $\mathcal{P}$ from cheating, we ensure that $\mathcal{P}$'s cheating behavior can be caught by $\mathcal{V}$ in hindsight. In more detail, we ask $\mathcal{P}$ to also commit to $\mathcal{V}$ its input, i.e., $\mathcal{P}$'s share of pms. Since we reveal the value to two parties by $\mathcal{V}$ getting it first, $\mathcal{P}$'s cheating behavior is "well-defined": $\mathcal{V}$ has its own share of pms, the commitment of the other share of pms, and the output of the GC that $\mathcal{P}$ garbled. If we later reveal $\mathcal{V}$'s secret to $\mathcal{P}$ after the TLS protocol terminates, $\mathcal{P}$ has all secrets (in particular, $\mathcal{P}$ knows $\mathcal{V}$'s share of pms) and can use a ZK protocol to prove that all outputs obtained by $\mathcal{V}$ are correct. We emphasize that $\mathcal{P}$ does not prove the correctness of the GC, and thus we are using GC in a black-box way. In conclusion, although $\mathcal{V}$ does not have a guarantee on $\mathcal{P}$'s honesty during the protocol execution, $\mathcal{V}$ can detect any cheating in hindsight as long as the GC output is first revealed to $\mathcal{V}$.

This optimization alone significantly reduces the overhead of the protocol as it eliminates the need of a malicious 2PC protocol, which is expensive in computation/communication but also requires memory linear to the circuit size to store the preprocessing triples. We formally model the 2PC with garble-then-prove approach as an ideal functionality $\mathcal{F}_{\mathsf{GP2PC}}$ shown in the full version [65, Section 4.1], and show how to instantiate $\mathcal{F}_{\mathsf{GP2PC}}$ using plain GC-2PC with malicious OT and interactive ZK, which is described in the full version [65, Section 4.2]. The 2PC protocol with garble-then-prove approach may be of independent interest, and may be applied in other scenarios such that all $\mathcal{V}$'s secrets are allowed to be revealed to $\mathcal{P}$ at the end.

TLS-specific circuit optimization. Our second optimization is to minimize the circuit to be computed in the protocol above. By using unique features of how session keys are derived in TLS, we are able to reduce the circuit size from 779,213 to 289,827 AND gates, a 2.7× improvement. Let's look at master secret ms as an example, which has a 384-bit output. The exact derivation formula is as follows:

$$
\begin{aligned}
&V = \text{"master secret"} \| r_C \| r_S \in \{0,1\}^{592},\\
&M_1 = \mathsf{HMAC}(\mathsf{pms}, V) \in \{0,1\}^{256},\\
&M_2 = \mathsf{HMAC}(\mathsf{pms}, M_1) \in \{0,1\}^{256},\\
&\mathsf{ms} = \mathsf{HMAC}(\mathsf{pms}, M_1 \| V) \| \mathsf{Trunc}_{128}\big(\mathsf{HMAC}(\mathsf{pms}, M_2 \| V)\big).
\end{aligned}
$$

In the above equation, $\mathsf{HMAC}(k,m) = \mathsf{SHA256}(k \oplus \text{opad}, \mathsf{SHA256}(k \oplus \text{ipad}, m))$, and that $\mathsf{SHA256}(m_1, m_2, m_3) = f_\mathsf{H}(f_\mathsf{H}(f_\mathsf{H}(IV_0, m_1), m_2), m_3)$ where m_i's are 512-bit strings.

To compute an HMAC-SHA256, we need at least 4 SHA256 compress calls: 2 calls to compute the outer hash and at least 2 calls to compute the inner hash; if m is longer than 447 bits, the inner hash requires even more calls.

Although there are totally 19 SHA256 compression calls to derive ms, we found that only 6 of them need to be computed in GC-2PC. First, $IV_1 = f_{\mathsf{H}}(IV_0, \mathsf{pms} \oplus \mathrm{ipad})$ and $IV_2 = f_{\mathsf{H}}(IV_0, \mathsf{pms} \oplus \mathrm{opad})$ only need to be computed once in GC-2PC and they can be kept as garbled labels to be reused in all HMAC computation. Second, the messages to all HMAC are public, which can be used for optimization: we reveal the value IV_1 while keeping IV_2 secret, so that subsequent computation taking IV_1 and the message can be done locally. We show the exact computation as follows:

$$
\begin{aligned}
M_1 &= f_{\mathsf{H}}\big(f_{\mathsf{H}}(IV_0, \mathsf{pms} \oplus \mathrm{opad}), f_{\mathsf{H}}(f_{\mathsf{H}}(IV_0, \mathsf{pms} \oplus \mathrm{ipad}), \\
&\qquad m_1), m_2)\big) \\
M_2 &= f_{\mathsf{H}}\big(f_{\mathsf{H}}(IV_0, \mathsf{pms} \oplus \mathrm{opad}), f_{\mathsf{H}}(f_{\mathsf{H}}(IV_0, \mathsf{pms} \oplus \mathrm{ipad}), M_1)\big) \\
\mathsf{ms} &= f_{\mathsf{H}}\big(f_{\mathsf{H}}(IV_0, \mathsf{pms} \oplus \mathrm{opad}), f_{\mathsf{H}}(f_{\mathsf{H}}(f_{\mathsf{H}}(IV_0, \mathsf{pms} \oplus \mathrm{ipad}), \\
&\qquad M_1 \| V_1), V_2)\big) \| \mathsf{Trunc}_{128}\big(f_{\mathsf{H}}\big(f_{\mathsf{H}}(IV_0, \mathsf{pms} \oplus \mathrm{opad}), \\
&\qquad f_{\mathsf{H}}(f_{\mathsf{H}}(f_{\mathsf{H}}(IV_0, \mathsf{pms} \oplus \mathrm{ipad}), M_2 \| V_1), V_2)\big)\big),
\end{aligned}
$$

where red refers to computation in GC-2PC, green refers to local computation, and blue refers to reused values. In the above equations, (m_1, m_2) and (V_1, V_2) are the bit-strings about V when suitably padding V to specific bits. The process of deriving $(\mathsf{key}_C, IV_C, \mathsf{key}_S, IV_S)$ is very similar to the above and also takes 6 SHA256 compression calls. Later, computing UFIN_C takes another 2 compression calls in GC-2PC. As a result, the whole circuit computing all needed HMAC takes 289,827 AND gates. This optimization is secure in the random oracle model (see the full version [65, Section E] for details).

3.2.3 Phase 3: Finished messages

Using a similar protocol, we compute (UFIN_C, UFIN_S) and reveal them to both parties. [4] Now the main task is to perform AEAD encryption/decryption on public plaintext/ciphertext and secretly shared AEAD keys. Our focus in this paper is AES-GCM (see Section 2.1 for a quick recall of the scheme), which is the main scheme used over the Internet right now. We take distributedly performing AEAD encryption as an example, and performing AEAD decryption is totally similar. Note that DECO mainly supports CBC-HMAC and could support AES-GCM by computing in a Boolean circuit all ciphertext blocks C_i's and powers h^i's using a fully malicious 2PC, where $\mathrm{C}_i = \mathsf{AES}(\mathsf{key}, \mathsf{st} + i) \oplus \mathrm{M}_i$ for a state st and a plaintext M_i, $h = \mathsf{AES}(\mathsf{key}, \mathbf{0})$ and $\mathsf{key} \in \{\mathsf{key}_C, \mathsf{key}_S\}$ is an application key. By revealing C_i to both parties while only revealing an additive sharing of h^i, $\mathcal{P}$ and $\mathcal{V}$ can compute an additive sharing of the GMAC tag locally. This method can be very costly since it requires securely computing a number of finite field multiplications equal to the number of AES calls. What's more, the circuit to compute a multiplication over $\mathbb{F}_{2^{128}}$ has at least 8,765 AND gates, even larger than the AES circuit itself!

AES-GCM computation consists of two tasks: computing the ciphertext and computing the GMAC tag. The first task is relatively easy as we can use the garble-then-prove approach again to avoid malicious 2PC, where the plaintext is known by both parties in this phase. However, computing the GMAC tag is more complicated. Roughly speaking, the GMAC tag is an inner product between a public vector over $\mathbb{F}_{2^{128}}$ and a private vector $(\mathrm{Z}_0, h^1, \ldots, h^n)$ where $\mathrm{Z}_0 = \mathsf{AES}(\mathsf{key}, \mathsf{st})$ is shared by both parties. Revealing any term in the second vector would allow the adversary to forge a GMAC tag on any message of its choice. Computing Z_0 can be done in GC-2PC; however, since we reveal the additive shares of Z_0, meaning that the output is not well defined from $\mathcal{V}$'s perspective, the garble-then-prove approach does not immediately work. To solve this issue, we ask $\mathcal{P}$ to commit to its share of Z_0. After the completion of the TLS protocol, when $\mathcal{P}$ knows all secrets, $\mathcal{P}$ will prove the computation with respect to the above commitment. To avoid computing h^i in circuits, we also reveal the additive shares of h together with Z_0. Then two parties use an OLEe over $\mathbb{F}_{2^{128}}$ to compute additive sharings on all powers of h. This way, each term only needs *2KB* communication, 100× smaller than computing in GC-2PC! Similar to the use of OLEe in phase 1, this also introduces a chance of a selective failure attack; however, it can be easily shown that providing multiple chances of selective failure attacks does not provide any more power to the adversary.

3.2.4 Phase 4: Payload

This phase is the first time $\mathcal{P}$ provides a private input (namely the query string) that is not part of the TLS execution. The overall protocol is similar to phase 3 how we compute the finished messages, except that the plaintext to AES-GCM-based AEAD is not public anymore. Therefore, we can mostly follow the phase-3 protocol except that $\mathcal{P}$ XOR its query to the additive share of AES output, and then sends the resulting value to $\mathcal{V}$. In this way, $\mathcal{V}$ can obtain the ciphertext directly by XORing the resulting value with its additive share.

After obtaining the AEAD cihertexts ENC_Q and ENC_R on the query Q and response R from $\mathcal{P}$, $\mathcal{V}$ opens $t_{\mathcal{V}} \in \mathbb{Z}_q$ to $\mathcal{P}$, who can replay the whole TLS protocol to obtain all values computed in GC-2PC. At this point, $\mathcal{V}$ holds 1) the commitment to $\mathcal{P}$'s share of pms; 2) the commitments to all values revealed from GC-2PC as XOR shares of AES outputs; 3) the values revealed from GC-2PC to both parties. Now $\mathcal{P}$ can prove to $\mathcal{V}$ in zero-knowledge that the whole computation is correct with respect to the commitments and values that $\mathcal{V}$ has. The circuit proven in ZK includes 1) the circuit computed

[4] We could postpone the verification of UFIN_S to the phase in which $\mathcal{P}$ obtains all secrets and then can *locally* check UFIN_S. This optimization removes the GC-2PC to compute UFIN_S (see Section 4.2 for more details).

in GC-2PC and 2) the decryption of the ciphertext to the response. However, the cost of ZK is significantly smaller than GC-2PC: when using the latest VOLE-based ZK [66], the communication of ZK is only 1 bit per AND gate, compared to 256 bits per AND gate required by the GC-2PC protocol [70]. During the process of ZK, $\mathcal{P}$ also needs to commit to the plaintext of the query and response to prove AEAD computation. They will be converted to a ZK-friendly format in the next phase.

3.2.5 Converting to ZK-Friendly Commitments

Now $\mathcal{V}$ has commitments of the query Q and response R that $\mathcal{P}$ knows. Their correctness has been verified by $\mathcal{V}$ through VOLE-based ZK. Such commitments are instantiated by IT-MACs and denoted by $[\![\boldsymbol{u}]\!] = ([\![u_1]\!], \ldots, [\![u_\ell]\!])$, where for each $i \in [1,\ell]$, $u_i \in \{0,1\}$, $(u_i, \mathsf{M}[u_i])$ is obtained by $\mathcal{P}$, $(\mathsf{K}[u_i], \Delta)$ is held by $\mathcal{V}$, and $\mathsf{M}[u_i] = \mathsf{K}[u_i] \oplus u_i\Delta$.

We first convert the IT-MACs from binary field $\mathbb{F}_{2^\lambda}$ to a large field $\mathbb{Z}_q$ for a prime q. Let $\mathsf{H} : \{0,1\}^\lambda \to \mathbb{Z}_q$ be a random oracle. For each component u_i, $\mathcal{V}$ computes $\widetilde{\mathsf{K}}[u_i] := \mathsf{H}(\mathsf{K}[u_i])$ and sends $W_i := \mathsf{H}(\mathsf{K}[u_i]) - \mathsf{H}(\mathsf{K}[u_i] \oplus \Delta) + \Gamma \in \mathbb{Z}_q$ to $\mathcal{P}$, who computes $\widetilde{\mathsf{M}}[u_i] := \mathsf{H}(\mathsf{M}[u_i]) + u_i \cdot W_i = \widetilde{\mathsf{K}}[u_i] + u_i \cdot \Gamma$, where $\Gamma \in \mathbb{Z}_q$ is a uniform global key known to $\mathcal{V}$. We also ask $\mathcal{P}$ to commit to (Q,R) using an additively homomorphic commitment (e.g., Pedersen [54] and KZG [42]) that is friendly to zkSNARKs. To check consistency between IT-MACs over $\mathbb{Z}_q$ and additively homomorphic commitments, we reveal a random linear combination of the values committed in two formats, where the random challenges are chosen by $\mathcal{V}$.

There are several extra considerations. First, the random linear combination would lead to some leakage, so both parties need to generate one more random value committed in both formats to mask the linear combination before it is revealed. Two commitments of the random value only need to be consistent in the honest case. Second, the values $\{W_i\}$ may *not* be computed correctly and thus after $\mathcal{P}$ opens the linear combination, $\mathcal{V}$ needs to open the values $\{W_i\}$ by revealing Δ and Γ, so that $\mathcal{P}$ can check that all values are computed correctly. Finally, the final check does not need to be done over bits but any packing of the values. This could significantly reduce the number of additively homomorphic commitments. In addition, two additional checks need to be performed to prevent the possible privacy leakage on $\boldsymbol{u}$ by using inconsistent Δ and Γ. See the full version [65, Section C] for details.

3.3 Protocol Summary

Previous discussions provide a high-level intuition on how we design the protocol. However, partially due to the complexity of TLS, the whole protocol is very complicated. Below, we provide a summary of the whole protocol omitting the details when considering the optimization shown in Footnote 4. The exact details of our protocol, along with the proof of security, can be found in Section 4 and related appendices.

1. $\mathcal{P}$ samples and sends REQ_C to $\mathcal{S}$ and gets back RES_S.
2. $\mathcal{P}$ forwards (REQ_C,RES_S) to $\mathcal{V}$, who sends $t_\mathcal{V} \cdot G$ to $\mathcal{P}$. Then $\mathcal{P}$ picks $t_\mathcal{P}$ and sends $(t_\mathcal{P} + t_\mathcal{V}) \cdot G$ to $\mathcal{S}$. Then $\mathcal{P}$ and $\mathcal{V}$ run the conversion from an elliptic-curve point to its x-coordinate, based on OLE with errors, so that two parties obtain an additive sharing of pms.
3. Two parties run the GC-2PC protocol with the garble-then-prove technique to derive the key material and client finished message. In particular, they obtain: 1) XOR shares of $h_C = \mathsf{AES}(\mathsf{key}_C, \mathbf{0})$ and $\mathrm{z}_C = \mathsf{AES}(\mathsf{key}_C, \mathsf{st}_C)$; 2) initial vectors IV_C, IV_S, intermediate public values revealed in HMAC-based PRF, UFIN_C and its AES encryption; 3) $\mathsf{pms}, \mathsf{ms}, \mathsf{key}_S, \mathsf{key}_C$ in the form of garbled labels.
4. Based on OLEe over $\mathbb{F}_{2^{128}}$, $\mathcal{P}$ and $\mathcal{V}$ compute the GMAC tag with these XOR shares on (h_C, z_C) in the offline-online mode. Then $\mathcal{P}$ assembles FIN_C and sends it to the server $\mathcal{S}$. After receiving FIN_S from $\mathcal{S}$, $\mathcal{P}$ forwards it to $\mathcal{V}$.
5. $\mathcal{P}$ and $\mathcal{V}$ execute the GC-2PC protocol with the garble-then-prove approach to generate the AES ciphertext that encrypts $\mathcal{P}$'s query and XOR shares of an AES output $\mathrm{z}_Q = \mathsf{AES}(\mathsf{key}_C, \mathsf{st}_C + 2)$. Both parties use OLEe and the XOR shares on (h_C, z_Q) to compute the GMAC tag, and then $\mathcal{P}$ sends the AEAD ciphertext ENC_Q on the query Q to $\mathcal{S}$. Then, $\mathcal{S}$ returns the AEAD ciphertext ENC_R on the response R to $\mathcal{P}$, who forwards it to $\mathcal{V}$.
6. $\mathcal{P}$ reveals its XOR shares of $h_C, \mathrm{z}_C, \mathrm{z}_Q$ to $\mathcal{V}$, who can recover $h_C, \mathrm{z}_C, \mathrm{z}_Q$ and then use them to *locally* verify the correctness of AEAD ciphertexts FIN_C and ENC_Q. Besides, ENC_R can also be locally verified by revealing the corresponding AES outputs to $\mathcal{V}$.
7. $\mathcal{V}$ sends $t_\mathcal{V}$ to $\mathcal{P}$ who checks that it is consistent with $t_\mathcal{V} \cdot G$ received earlier. $\mathcal{P}$ then computes $t_\mathcal{P} + t_\mathcal{V}$, and recovers all values in the execution of TLS, including all values revealed previously. If any value is incorrect, $\mathcal{P}$ aborts.
8. $\mathcal{V}$ now holds commitments to $\mathcal{P}$'s share of pms and values revealed as XOR shares earlier. $\mathcal{P}$ proves to $\mathcal{V}$ in zero-knowledge that these commitments are consistent with the values revealed to $\mathcal{V}$ based on the TLS specification.
9. Two parties run a protocol to convert the commitments on Q and R based on IT-MACs to additively homomorphic commitments like Pedersen on the same values.

4 Authenticating Web Data for TLS

In the full version [65, Section 4], we define an ideal functionality $\mathcal{F}_{\mathsf{GP2PC}}$ for 2PC in the garble-then-prove framework,

and then show an efficient protocol securely realizing $\mathcal{F}_{\mathsf{GP2PC}}$ by using a plain GC-2PC protocol with malicious OT and the recent interactive ZK proof based on IT-MACs. Based on $\mathcal{F}_{\mathsf{GP2PC}}$ we provide a complete description of our protocol (denoted by Π_{AuthData}) that authenticates web data for TLS 1.2 in Section 4.1. Then, we show how to extend protocol Π_{AuthData} to support multi-round query-response sessions and describe further optimizations in Section 4.2. While Π_{AuthData} focuses on the case of reading user data, we also extend it to support for writing user data in Section 4.2. In Section 4.3, we also show how to extend our protocol to support TLS 1.3.

4.1 Detailed Protocol for Authenticating Data

Our protocol Π_{AuthData} is divided into four phases, where the last three phases are jointly called online phase.

- **Preprocessing:** A prover $\mathcal{P}$ and a verifier $\mathcal{V}$ generate correlated randomness before the TLS connection.
- **Handshake:** $\mathcal{P}$ and $\mathcal{V}$ call $\mathcal{F}_{\mathsf{GP2PC}}$ to perform client operations. This phase establishes the connection with $\mathcal{S}$ while neither of $\mathcal{P}$ and $\mathcal{V}$ know any secrets or application keys.
- **Record:** $\mathcal{P}$ and $\mathcal{V}$ call $\mathcal{F}_{\mathsf{GP2PC}}$ to encrypt a query Q, and then $\mathcal{P}$ locally decrypts the ciphertext on a response R.
- **Post-record:** In this phase, the TLS protocol has terminated. Now, $\mathcal{P}$ is allowed to know all secret values in the TLS session. Then $\mathcal{P}$ and $\mathcal{V}$ call $\mathcal{F}_{\mathsf{GP2PC}}$ to prove the correctness of all values revealed to $\mathcal{V}$. Finally, both parties transform IT-MACs of Q and R into their additive-homomorphic commitments, which are connected to a variety of zk-SNARKs.

Π_{AuthData} invokes the following three sub-protocols, whose details are described in the full version [65, Section B.4].

- Sub-protocol Π_{E2F} (shown in the full version [65, Section B.1]) converts additive sharings of elliptic-curve points into that of x-coordinates, and will be used to generate an additive sharing $[\mathsf{pms}]_p$ of pre-master secret.
- Sub-protocol Π_{PRF} (shown in the full version [65, Section B.2]) calls $\mathcal{F}_{\mathsf{GP2PC}}$ to compute HMAC-based PRF in the handshake phase. Then, it proves correctness of all opened values by calling $\mathcal{F}_{\mathsf{GP2PC}}$ in the post-record phase. Protocol Π_{PRF} will be used to generate the master secret ms, application keys $\mathsf{key}_C, \mathsf{key}_S$, initial vectors IV_C, IV_S and $\mathrm{UFIN}_C, \mathrm{UFIN}_S$.
- Sub-protocol Π_{AEAD} (shown in the full version [65, Section B.3]) calls $\mathcal{F}_{\mathsf{GP2PC}}$ to compute AES blocks used for encryption/decryption of AEAD, and uses OLEe to compute GMAC tags, in the handshake and record phases. In the post-record phase, Π_{AEAD} calls $\mathcal{F}_{\mathsf{GP2PC}}$ to prove correctness of all AES blocks, and invokes $\mathcal{F}_{\mathsf{IZK}}$ to generate IT-MACs $[\![Q]\!]$ on a query Q. Sub-protocol Π_{AEAD} is used to encrypt UFIN_C, Q to obtain the ciphertexts $\mathrm{FIN}_C, \mathrm{ENC}_Q$ and decrypt FIN_S to get UFIN_S.

$\mathcal{P}$ and $\mathcal{V}$ generate authenticated bits $[\![Q]\!]$ and $[\![R]\!]$ in the post-record phase by calling an ideal functionality $\mathcal{F}_{\mathsf{IZK}}$ for ZK proofs based on IT-MACs. Functionality $\mathcal{F}_{\mathsf{IZK}}$ (shown in the full version [65, Section A.4]) is a simple extension of the ideal functionality defined in [64], and can be securely realized using the recent VOLE-based ZK protocols [7,28,63,66]. Besides, $\mathcal{P}$ and $\mathcal{V}$ call an ideal functionality $\mathcal{F}_{\mathsf{Conv}}$ (shown in the full version [65, Section C]) to convert $[\![Q]\!]$ and $[\![R]\!]$ into their additively homomorphic commitments in the post-record phase. In the full version [65, Section C], we present an efficient protocol to securely realize $\mathcal{F}_{\mathsf{Conv}}$.

We postpone the details of protocol Π_{AuthData} to the full version [65, Section B.4]. As in DECO [71], protocol Π_{AuthData} focuses on the case of one-round query-response session, i.e., a prover $\mathcal{P}$ and a verifier $\mathcal{V}$ jointly generate and send the AEAD ciphertext of *a single* query Q to a server $\mathcal{S}$ who returns the AEAD ciphertext of *a single* response R to $\mathcal{P}$. Note that one-round session is enough for a lot of applications [71]. For one-round session, $\mathcal{P}$ is *unnecessary* to decrypt the AEAD ciphertext ENC_R on the response R and verify its GMAC tag by running sub-protocol Π_{AEAD} with $\mathcal{V}$. These operations can be performed *locally* by $\mathcal{P}$ after it knows the server-to-client key key_S, where the TLS session terminates after ENC_R was received by $\mathcal{P}$ and forwarded to $\mathcal{V}$. Nevertheless, $\mathcal{P}$ and $\mathcal{V}$ still need to generate $[\![\mathsf{z}_R]\!]$ and $[\![R]\!]$ by calling functionality $\mathcal{F}_{\mathsf{IZK}}$. $\mathcal{V}$ also needs to check the correctness of the GMAC tag in ciphertext ENC_R via getting $h_S = \mathsf{AES}(\mathsf{key}_S, \mathbf{0})$ and $\mathsf{z}_R = \mathsf{AES}(\mathsf{key}_S, \mathsf{st}_d^C)$.

The security of protocol Π_{AuthData} depends on the PRF-Oracle-Diffie-Hellman (PRF-ODH) assumption, which has been used for proving the security of TLS 1.2 [40,48] and is recalled in the full version [65, Section E]. Besides, we assume that the underlying signature scheme satisfies Existential Un-Forgeability under Chosen-Message Attack (EUF-CMA).

Theorem 1. *If the PRF-ODH assumption holds and the underlying signature scheme is EUF-CMA secure, then protocol* Π_{AuthData} *securely realizes functionality* $\mathcal{F}_{\mathsf{AuthData}}$ *in the* $(\mathcal{F}_{\mathsf{OLEe}}, \mathcal{F}_{\mathsf{GP2PC}}, \mathcal{F}_{\mathsf{Com}}, \mathcal{F}_{\mathsf{IZK}}, \mathcal{F}_{\mathsf{Conv}})$*-hybrid model, assuming that the compression function* f_{H} *underlying* PRF *is a random oracle and* AES *is an ideal cipher.*

We provide a formal proof of Theorem 1 in the full version [65, Section E].

4.2 Extensions and Optimizations

Extend to multi-round query-response sessions. We are able to extend the protocol Π_{AuthData} to support multiple rounds of payload. Specifically, $\mathcal{P}$ and $\mathcal{V}$ can execute sub-protocol Π_{AEAD} (shown in the full version [65, Section B.3]) multiple times to encrypt multiple queries, where the additive

sharings of powers of $h_C = \mathsf{AES}(\mathsf{key}_C, \mathbf{0})$ need to be computed only once and are reused among these sub-protocol executions. Note that the state st_C is always increased for computing multiple AEAD ciphertexts following the TLS specification. This prevents $\mathcal{P}$ or $\mathcal{V}$ to forge GMAC tags by using the same state for different ciphertexts.

If every query is independent of previous responses (Case 1), $\mathcal{P}$ can *locally* decrypt the AEAD ciphertexts of all responses, after the TLS session terminates and it obtains the server-to-client application key key_S. If every query relies on previous responses (Case 2), $\mathcal{P}$ has to decrypt the ciphertexts of all responses via interacting with $\mathcal{V}$. This can be done by running sub-protocol Π_{AEAD} with $\mathsf{type}_1 =$ "decryption" and $\mathsf{type}_2 =$ "secret", where Π_{AEAD} was designed for supporting decryption of AEAD ciphertexts in the record phase. During the protocol execution, Π_{AEAD} also allows $\mathcal{P}$ and $\mathcal{V}$ to verify the correctness of GMAC tags in AEAD ciphertexts of responses. Therefore, in both cases, $\mathcal{P}$ can check the correctness of AEAD ciphertext on every response via sending the ciphertext to $\mathcal{V}$ and then running sub-protocol Π_{AEAD} with $\mathcal{V}$, before generating the ciphertext on the next query. In fact, this is unnecessary and the GMAC tags of AEAD ciphertexts on all responses can be verified *locally* by $\mathcal{P}$ after it knows key_S (see below for discussion of this optimization). In Case 2, the decryption of the response's ciphertext sent in the final-round session can still be performed *locally* with key_S.

In the case of multi-round sessions, both $\mathcal{P}$ and $\mathcal{V}$ can use the same approach implied in the post-record phase of main protocol Π_{AuthData} (shown in the full version [65, Section B.4]) to check the correctness of all AEAD ciphertexts on multiple queries and responses. In Case 2, we note that $\mathcal{P}$ needs to decrypt the AEAD ciphertexts on responses using key_S, and then compares the resulting plaintexts with that obtained during the execution of sub-protocol Π_{AEAD}, when it performs the local verification with key_S in the post-record phase. This verification aims to check that no error is introduced to the responses computed via the distributed decryption in sub-protocol Π_{AEAD}. Both parties are also able to obtain the IT-MACs on all responses in a way totally similar to main protocol Π_{AuthData}. Note that the IT-MACs on all queries have already been obtained during multiple executions of sub-protocol Π_{AEAD}.

Optimization. We can further optimize the efficiency of protocol Π_{AuthData} by delaying the check of UFIN_S and AEAD ciphertext FIN_S from the handshake phase to the post-record phase. That is, $\mathcal{P}$ and $\mathcal{V}$ do *not* execute sub-protocol Π_{AEAD} to generate UFIN_S and the GMAC tag used to check FIN_S. Instead, $\mathcal{P}$ can *locally* check their correctness after it obtains master secret ms. Verifier $\mathcal{V}$ checks the correctness of UFIN_S by calling the (prove) command of functionality $\mathcal{F}_{\mathsf{GP2PC}}$ with $\mathcal{P}$, and then checks the correctness of $\mathrm{FIN}_S = (\mathrm{C}, \sigma)$ in the following two steps:

1. $\mathcal{P}$ sends Z_1 to $\mathcal{V}$, and then proves $\mathrm{Z}_1 = \mathsf{AES}(\mathsf{key}_S^*, IV_S + 1)$ by calling the (prove) command of $\mathcal{F}_{\mathsf{GP2PC}}$, where key_S^* and IV_S are the server-to-client application key and initial vector whose correctness has been proved in the post-record phase. Then, $\mathcal{V}$ checks that $\mathrm{UFIN}_S \oplus \mathrm{Z}_1 = \mathrm{C}$.
2. $\mathcal{V}$ checks the correctness of GMAC tag σ in the way shown in the post-record phase of protocol Π_{AuthData}.

This has *no* impact on privacy and integrity, as this optimization only delays the check. If one of these values is incorrect, $\mathcal{P}$ or $\mathcal{V}$ aborts. Note that this optimization is supported by the TLS implementation. Furthermore, this optimization can be applied in the case of multi-round sessions. That is, $\mathcal{P}$ and $\mathcal{V}$ can delay the correctness check of all AEAD ciphertexts on responses from the record phase into the post-record phase by checking the correctness of GMAC tags via the approach shown in main protocol Π_{AuthData}. Recall that $\mathcal{P}$ also checks that the responses output by sub-protocol Π_{AEAD} are identical to that via the local decryption with key_S, when it performs the local verification in the post-record phase. This optimization allows us to reduce communication rounds and improve the whole performance.

Extend to support for writing user data. Our protocol Π_{AuthData} focuses on reading user data from a website acting as the TLS server. For most of Web2 and Web3 applications, it is sufficient. Nevertheless, for a few applications, a user (i.e., prover) may be desirable to write its data on the website (e.g., updating personal information) during the protocol execution of Π_{AuthData}. In this case, a malicious verifier $\mathcal{V}$ may tamper the queries sent from a prover $\mathcal{P}$ to the TLS server by adding some errors into the AES ciphertexts on queries. The attack would be detected by $\mathcal{P}$ after it obtains all secrets. However, the user data on the website has already been tampered. To prevent such attacks, we need to extend functionality $\mathcal{F}_{\mathsf{GP2PC}}$ to an ideal functionality $\mathcal{F}_{\mathsf{GP2PC}}^{\mathsf{noerr}}$ (defined in the full version [65, Section 4.1]) that does not allow $\mathcal{V}$ to introduce any errors. In the full version [65, Section 4.2], we show how to extend the protocol instantiating $\mathcal{F}_{\mathsf{GP2PC}}$ to securely realize $\mathcal{F}_{\mathsf{GP2PC}}^{\mathsf{noerr}}$ with no extra communication. When replacing $\mathcal{F}_{\mathsf{GP2PC}}$ with $\mathcal{F}_{\mathsf{GP2PC}}^{\mathsf{noerr}}$, protocol Π_{AuthData} would allow $\mathcal{P}$ to securely write user data.

This holds for multi-round sessions. For the multi-round session extension as described above, we point out a caveat. If the writing queries relying on previous responses, then $\mathcal{P}$ and $\mathcal{V}$ need to execute sub-protocol Π_{AEAD} to check the correctness of the AEAD ciphertext on each response except for the final response, before sending the AEAD ciphertext on the next query to the server. Otherwise, the above optimization, which locally checks the AEAD ciphertexts on all responses after obtaining key_S, can still be used.

4.3 Extending Our Protocol for TLS 1.3

While the protocol Π_{AuthData} (shown in the full version [65, Section B.4]) focuses on the case of TLS 1.2, we are also able

to extend it for TLS 1.3, and will implement the protocol to authenticate web data for TLS 1.3 in the future work. The main differences between TLS 1.2 and TLS 1.3 are the key derivation function (KDF) and the handshake phase. In this section, we focus on the handshake mode of full 1-RTT, where the optional mode of 0-RTT based on a pre-shared key can be securely computed in a similar way.

The key derivation in TLS 1.3 adopts the HMAC-based key derivation function (HKDF) [46, 47], which consists of two sub-functions: HKDF.Extract and HKDF.Expand. Specifically, $\mathsf{prk} \leftarrow \mathsf{HKDF.Extract}(salt, \mathsf{ikm})$ takes as input a non-secret random *salt* and a secret input key material ikm, and then extracts a pseudorandom key prk, i.e., $\mathsf{prk} = \mathsf{HMAC}(salt, \mathsf{ikm})$. Note that *salt* is the HMAC key, and ikm is the HMAC input. In this case, we can securely compute HKDF.Extract in the following manner:

$$\mathsf{prk} = f_{\mathsf{H}}\big(f_{\mathsf{H}}(IV_0, salt \oplus \mathrm{opad}), f_{\mathsf{H}}(f_{\mathsf{H}}(IV_0, salt \oplus \mathrm{ipad}), \mathsf{ikm})\big),$$

where red refers to computation in GC, and green refers to local computation. Then prk is expanded to an output keying material okm with a specified length. Specifically, $\mathsf{okm} \leftarrow \mathsf{HKDF.Expand}_\ell(\mathsf{prk}, info)$ takes as input prk, a public context-specific information *info* and an output length ℓ, and outputs

$$\mathsf{okm} = T_1 \,\|\, \ldots \,\|\, T_{n-1} \,\|\, \mathsf{Trunc}_m(T_n),$$

where $T_i = \mathsf{HMAC}(\mathsf{prk}, T_{i-1} \| info \| i)$ for each $i \in [1, n]$, T_0 is an empty string, $n = \lceil \ell / 256 \rceil$ and $m = \ell - 256 \cdot (n-1)$. It is easy to see that the sub-protocol Π_{PRF} (shown in the full version [65, Section B.2]) for TLS 1.2 can be directly extended to securely compute $\mathsf{HKDF.Expand}_\ell(\mathsf{prk}, info)$ for TLS 1.3. In particular, the circuit optimization for PRF in TLS 1.2 is able to be applied for HKDF.Expand in TLS 1.3.

In the handshake phase of TLS 1.3, the client and server run the Diffie-Hellman key exchange protocol without authentication to establish a pre-master secret pms, which can be executed similar to protocol Π_{AuthData}. Then pms is derived to a handshake secret hs via HKDF.Extract, and then hs is derived to the client handshake traffic secret chts and server handshake traffic secret shts via HKDF.Expand. The secrets chts, shts are used to generate the client handshake key chk and server handshake key shk via HKDF.Expand. Then, hs is also used to derive a mater secret ms via invoking HKDF.Extract and HKDF.Expand respective once. Next, ms is used to drive four secrets with HKDF.Expand: the client application traffic secret cats, server application traffic secret sats, exporter master secret ems and resumption master secret rms. Using HKDF.Expand, the secrets cats, sats are derived to the client application key cak and server application key sak. The derivation of all secrets and keys can be securely computed by $\mathcal{P}$ and $\mathcal{V}$ by executing a protocol similar to sub-protocol Π_{PRF}.

While chk and shk are used to encrypt/decrypt the subsequent messages (e.g., client/server finished messages, signatures and certifications) in the handshake phase, cak and sak are independent and used to encrypt/decrypt application data in the record phase. Therefore, we can open chk and shk to the prover $\mathcal{P}$, and then $\mathcal{P}$ is able to *locally* perform the encryption/decryption in the handshake phase. [5] That is, it is unnecessary to run sub-protocol Π_{AEAD} (shown in the full version [65, Section B.3]) to compute stateful AEAD in the handshake phase. Besides, handshake traffic secrets chts and shts are used to produce client and server finished messages, and are independent from application traffic secrets cats and sats. In this case, we can open chts and shts to $\mathcal{P}$, and then $\mathcal{P}$ can *locally* generate the finished messages. Furthermore, ems can be computed *locally* by $\mathcal{P}$ after it knows all secrets in the post-record phase, as ems is an exporter master secret and *not* used in the record phase. The secret rms is also able to be computed *locally* by $\mathcal{P}$ after it knows all secrets in the post-record phase, if $\mathcal{P}$ and $\mathcal{V}$ will not jointly execute a session resumption with rms. The optimizations would significantly reduce the cost in the handshake phase. Overall, 21 invocations of SHA256 compression functions need to be executed in GC-2PC, compared to that 14 invocations in TLS 1.2 for our protocol and 30 invocations in TLS 1.3 for DECO [71]. As for our protocols, the communication in the handshake phase of TLS 1.3 is about 1.5× larger than that in TLS 1.2.

5 Performance Evaluation

5.1 Implementation and Experimental Setup

We implemented our protocol in C++, including 4000 lines of code of protocol development and 3000 lines of testing code. Our implementation is complete and can interact with real-world APIs. We use the EMP toolkit [61] for the implementation of the following building blocks: KOS OT [44], Ferret OT [68], half-gates-based GC with optimization of concrete security [34, 70] and interactive ZK (called QuickSilver) [66]. We leave it as the future work to incorporate the recent three-halves GC construction [56] to further reduce the communication cost of our protocol.

All benchmarks are performed over AWS m5.large instances, with 2 vCPUs and 8 GB of memory. Note that our protocol only needs about 150 MB of memory for 2KB query and response. Every experiment involves three parties: the TLS server $\mathcal{S}$, the prover $\mathcal{P}$ and the verifier $\mathcal{V}$. Except for the global-scale experiment based on real-world APIs in Section 5.3, we place $\mathcal{S}$ and $\mathcal{P}$ on the same machine and $\mathcal{V}$ on a different machine with changing network condition, where the communication between $\mathcal{S}$ and $\mathcal{P}$ is negligible compared to that between $\mathcal{P}$ and $\mathcal{V}$. We use one thread for all running time, and adopt tc to manually control the network bandwidth and roundtrip latency to desired levels. The running time and communication reported in this section are the end-to-end performance, including the preprocessing and setup costs.

[5] This observation has been found in DECO [71].

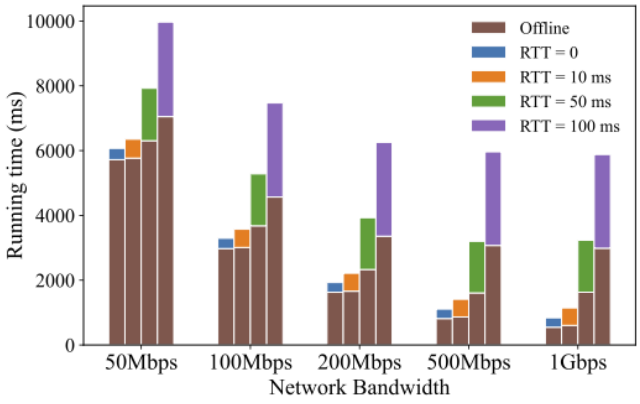

Figure 3: **Performance of our protocol under different network bandwidths and latency.** The length of query and response is 2 KB.

5.2 Scalability of Our Protocol

Performance of protocol Π_{AuthData}. In Figure 3, we show the performance of our protocol Π_{AuthData} (shown in the full version [65, Section B.4]) under different bandwidths and latency, while fixing the query and response to 2KB. We show both the offline cost (which can be done before the TLS connection) and the online cost (which can only be done during the TLS connection). Overall, our protocol is highly efficient. For example, under a realistic network with 200 Mbps bandwidth and 50 ms latency, the end-to-end running time is under four seconds while the runtime in the online phase is less than two seconds.

We can also see that the online performance is highly dependent on the latency: it is less than 50 ms when the latency is low, but could be up to 3 seconds when the latency is as high as 100 ms. This matches the roundtrip complexity that we measured from our implementation, which needs 31 roundtrips of communication. The offline cost is less affected by the latency but more on the network bandwidth; this is because the transmission of garbled circuits, which is majority of the communication of our protocol, is in the offline phase.

Comparison with prior work. We compare the performance of our protocol with DECO [71]. Since the code of DECO is not open sourced and that the performance of malicious 2PC has been constantly improving, we benchmark the performance based on the latest implementation of authenticated garbling. We also incorporate the Ferret OT [68] to the implementation to further reduce the communication cost. This is the most practically efficient malicious 2PC implementation so far. We only included the time needed in malicious 2PC, which includes computing the TLS session keys and 4 AES-GCM ciphertexts. When computing the GMAC tag, we assume that one field multiplication over $\mathbb{F}_{2^{128}}$ takes 8,765 AND gates, including 8,192 ANDs to compute the multiplication and 573 ANDs to compute the reduction. Note that there exists more efficient garbling for binary extension field multiplication [38] but only in the semi-honest setting. This is a lower bound as the DECO protocol also includes other components. All performance numbers are measured using the same type of AWS instances. The result of the comparison is shown in Table 2, where we can observe roughly 14× improvement in communication and 7.5× to 15× improvement in running time over LAN and WAN.

We record the peak memory usage of both protocols. Under 2KB query and response, the malicious 2PC needed in DECO requires a peak memory of 3 GB while our protocol only needs about 150 MB of memory. The huge difference is mainly due to the fact that authenticated garbling requires storing preprocessed triples for all AND gates in the circuit before the execution (to achieve constant roundtrips), while all building blocks that we use can be streamed without the need to store them all at once.

Performance of conversion. We also benchmarked the performance of commitment conversion of our protocol in different network settings, which is shown in Table 3. The IT-MAC-based commitments on payload is converted to Pedersen commitments [54]. We observe that in both WAN and LAN settings, the conversion protocol is very cheap compared to the overall web authentication protocol, and the cost of conversion is linear to the payload size. It takes roughly 37 ms to convert an additional kilobyte of payload to Pedersen commitments under LAN and roughly 67 ms per KB under WAN. The basetime in WAN is higher due to the higher latency.

5.3 Global-Scale Benchmarks

We integrate our protocol to access real-world web servers and test the performance, as shown in Figure 4. Specifically, we utilize provided APIs to query Coinbase and Twitter servers.

- **Coinbase API:** We benchmark fetching the balance of BTC using the prover's API secret [3]. It has a query of size 426 bytes and response of size 5701 bytes. Our protocol communicates 17.6 MB in the offline phase and 0.9 MB in the online phase.
- **Twitter API:** We benchmark using the prover's credential token to retrieve the number of followers [4]. This API has a query size of 587 bytes and response size of 894 bytes. Our protocol communicates 18.9 MB in the offline phase and 0.4 MB in the online phase.

In all experiments, the verifier $\mathcal{V}$ is deployed in the US West (represented by the purple circle), while the provers (represented by the blue circles) are distributed across 18 cities worldwide. All prover and verifier machines are hosted in AWS while the TLS server is hosted by Coinbase/Twitter, which may have nodes close to the prover. The online time required for the process ranges from 0.3 seconds to 10 seconds, depending on the round-trip time between the prover

	Communication cost				WAN (100 Mbps, RTT = 50 ms)				LAN (1 Gbps, RTT = 0 ms)			
Payload	256 B	512 B	1 KB	2 KB	256 B	512 B	1 KB	2 KB	256 B	512 B	1 KB	2 KB
DECO [71]	206 MB	255 MB	345 MB	475.7 MB	24 s	27.2 s	36.3 s	51.6 s	5.91 s	6.46 s	8.9 s	11.21 s
This work	15.2 MB	17.8 MB	22.9 MB	33.3 MB	3.19 s	3.43 s	3.96 s	4.9 s	0.46 s	0.51 s	0.61 s	0.72 s

Table 2: **Comparing the performance of DECO [71] and our protocol under LAN and WAN.**

	WAN (100 Mbps, RTT = 50 ms)				LAN (1 Gbps, RTT = 0 ms)			
Payload	256 B	512 B	1 KB	2 KB	256 B	512 B	1 KB	2 KB
Conversion	161 ms	173 ms	202 ms	278 ms	11 ms	20 ms	38 ms	76 ms

Table 3: **Performance of commitment conversion with different payload length under LAN and WAN.**

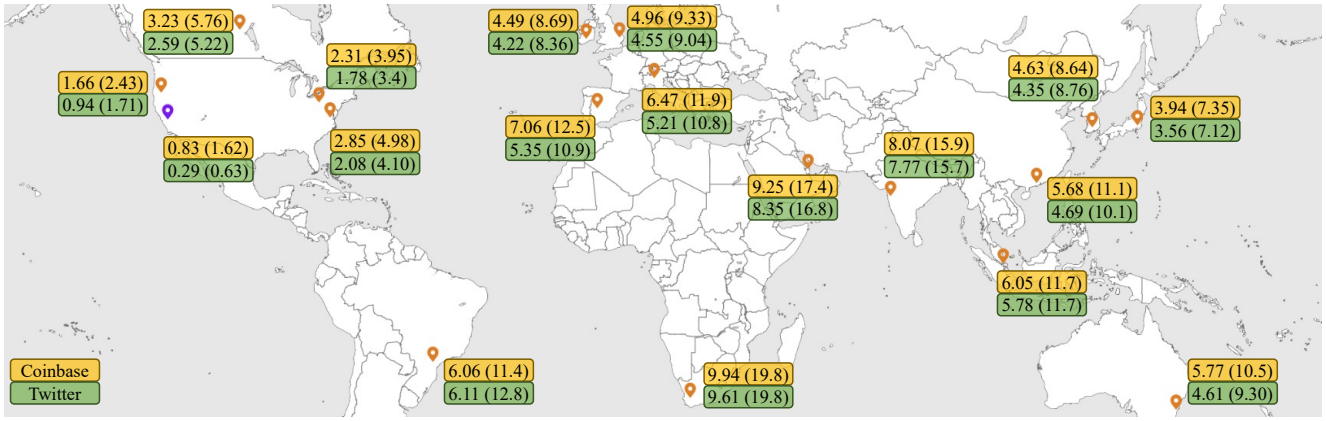

Figure 4: **Online and total performance of accessing Coinbase and Twitter servers with globally distributed provers.** All numbers are reported in seconds in the form of "online time (total time)". The verifier is fixed at California. The server is hosted by Coinbase/Twitter, which may have mirrors in various locations.

and verifier, which aligns with our expectation. From the experimental results shown in Figure 4, we conclude that our protocol is concretely efficient for real-world applications.

The performance of our protocol only depends on the bandwidth and latency in different network settings, and is independent of the concrete city in which the verifier locates. In practical scenarios, one could deploy multiple verifiers in proximity to the provers. This deployment strategy serves to minimize the round-trip time and significantly boost the overall performance of the system.

Functionality $\mathcal{F}_{\mathsf{OT}}$

Upon receiving $(\mathsf{ot},(m_0,m_1))$ from a sender $\mathcal{P}$ and (ot,b) from a receiver $\mathcal{V}$, where $m_0,m_1 \in \{0,1\}^\ell$ and $b \in \{0,1\}$, this functionality outputs m_b to $\mathcal{V}$.

A More Preliminaries

OT. Oblivious Transfer (OT) allows a sender to transmit one of two messages (m_0,m_1) to a receiver, who inputs a choice bit b and obtains m_b. For security, b is kept secret against the malicious sender, and m_{1-b} is unknown for the malicious receiver. The standard OT functionality is recalled in Figure 5. Correlated OT (COT) is an important variant of OT where two messages m_0 and m_1 satisfy a fixed correlation, i.e., $m_0 \oplus m_1 = \Delta$. Both OT and COT correlations can be generated in the malicious setting using either the IKNP-like protocols [44,57] or the PCG-like protocols [12,13,68].

OLE with errors. Oblivious Linear Evaluation (OLE) can be viewed as an arithmetic generalization of OT, and allows two parties to obtain an additive sharing of multiplication of two field elements. When applying OLE into our protocol, we show that OLE with errors (OLEe) is sufficient, where the privacy is guaranteed against malicious adversaries but a malicious sender can introduce an error into the resulting OLE correlation.

Functionality for OLE with errors is shown in Figure 6. Without loss of generality, we focus on a finite field either $\mathbb{F} = \mathbb{Z}_p$ for a prime p or $\mathbb{F} = \mathbb{F}_{2^\lambda}$. We define a "gadget" vector $\boldsymbol{g} = (1,g,\ldots,g^{m-1})$ for $m = \lceil \log |\mathbb{F}| \rceil$, where $g = 2$ if $\mathbb{F} = \mathbb{Z}_p$ for a prime p and $g = X$ if $\mathbb{F} = \mathbb{F}_{2^\lambda}$. For a vector $\boldsymbol{x} \in \{0,1\}^m$, we have $\langle \boldsymbol{g},\boldsymbol{x} \rangle = \sum_{i=1}^m x_i \cdot g^{i-1} \in \mathbb{F}$. We also denote by $\boldsymbol{g}^{-1} : \mathbb{F} \to \{0,1\}^m$ the bit-decomposition function that maps a field element $x \in \mathbb{F}$ to a bit vector $\boldsymbol{x} \in \{0,1\}^m$, such that $\langle \boldsymbol{g}, \boldsymbol{g}^{-1}(x) \rangle = x$. Following previous work (e.g., [14]), we allow a corrupted party to choose its output. If a sender $\mathcal{P}$ is corrupted, then it can introduce an error vector $\boldsymbol{e}$ into functionality $\mathcal{F}_{\mathsf{OLEe}}$. Then, $\mathcal{F}_{\mathsf{OLEe}}$ computes an error e' relying on the input y of a receiver $\mathcal{V}$. Finally, the error e' is added into the output z_2 of $\mathcal{V}$. The introduction of errors is asymmetric, i.e., $\mathcal{V}$ is *not* allowed to add an error into the output of $\mathcal{P}$. This model the asymmetric security of the COT-based protocol [31, 45] that securely realizes functionality $\mathcal{F}_{\mathsf{OLEe}}$.

Functionality $\mathcal{F}_{\mathsf{OLEe}}$

This functionality operates over a finite field $\mathbb{F}$. Let $m = \lceil \log |\mathbb{F}| \rceil$. This functionality interacts with a sender $\mathcal{P}$, a receiver $\mathcal{V}$ and an adversary.

- Upon receiving (ole,x) from a sender $\mathcal{P}$ and (ole,y) from a receiver $\mathcal{V}$ where $x,y \in \mathbb{F}$, execute as follows:
  1. If $\mathcal{P}$ is honest, sample $z_1 \leftarrow \mathbb{F}$. Otherwise, receive $z_1 \in \mathbb{F}$ from the adversary.
  2. If $\mathcal{P}$ is malicious, receive a vector $\boldsymbol{e} \in (\mathbb{F})^m$ from the adversary, and compute an error $e' := \langle \boldsymbol{g} * \boldsymbol{e}, \boldsymbol{y} \rangle \in \mathbb{F}$ where $\boldsymbol{y} = \boldsymbol{g}^{-1}(y)$ is the bit-decomposition of $y \in \mathbb{F}$, $*$ is a component-wise product and $\langle \boldsymbol{a},\boldsymbol{b} \rangle$ denotes the inner product of two vectors $\boldsymbol{a},\boldsymbol{b}$.
  3. If $\mathcal{V}$ is honest, compute $z_2 := x \cdot y - z_1 + e' \in \mathbb{F}$ (where e' is set as 0 if $\mathcal{P}$ is also honest). Otherwise, receive $z_2 \in \mathbb{F}$ from the adversary, and recompute $z_1 := x \cdot y - z_2 \in \mathbb{F}$.
- Output z_1 to $\mathcal{P}$ and z_2 to $\mathcal{V}$.

Figure 6: **Functionality for OLE with errors.**

Additive secret sharings over fields. Our protocol will adopt additive secret sharings between $\mathcal{P}$ and $\mathcal{V}$ over a finite field $\mathbb{F}$. For a field element $x \in \mathbb{F}$, we write $[x] = (x_\mathcal{P}, x_\mathcal{V})$ such that $x_\mathcal{P} + x_\mathcal{V} = x \in \mathbb{F}$, where one of $x_\mathcal{P}, x_\mathcal{V}$ is random in $\mathbb{F}$. For an element $a \in \mathbb{F}$ only known by a party $\mathcal{V}$, two parties $\mathcal{V}$ and $\mathcal{P}$ can *locally* define an additive sharing $[a]_p = (a,0)$. It is well-known that additive secret sharings are *additively homomorphic*. In particular, give public constants $c_0,c_1,\ldots,c_\ell$ and additive sharings $[x_1],\ldots,[x_\ell]$, $\mathcal{P}$ and $\mathcal{V}$ can *locally* compute $[y] := c_0 + \sum_{i=1}^\ell c_i \cdot [x_i]$. For an additive sharing $[x]$, we define its opening procedure:

- $x \leftarrow \mathsf{Open}([x])$: $\mathcal{P}$ sends $x_\mathcal{P}$ to $\mathcal{V}$, and $\mathcal{V}$ sends $x_\mathcal{V}$ to $\mathcal{P}$ in parallel. Then, both parties compute $x := x_\mathcal{P} + x_\mathcal{V} \in \mathbb{F}$.

For a field element x only known by $\mathcal{P}$ (resp., $\mathcal{V}$), both parties can *locally* define its additive sharing $[x] = (x,0)$ (resp., $[x] = (0,x)$). When applying additive secret sharings into our protocol, we only need two types of finite fields: one is $\mathbb{Z}_p$ for a large prime p and the other is $\mathbb{F}_{2^{128}}$. The additive sharing of x is denoted by $[x]_p$ for former and $[x]_{2^{128}}$ for latter.

Holding Secrets Accountable: Auditing Privacy-Preserving Machine Learning

Abstract

Recent advancements in privacy-preserving machine learning are paving the way to extend the benefits of ML to highly sensitive data that, until now, has been hard to utilize due to privacy concerns and regulatory constraints. Simultaneously, there is a growing emphasis on enhancing the transparency and accountability of ML, including the ability to audit deployments for aspects such as fairness, accuracy and compliance. Although ML auditing and privacy-preserving machine learning have been extensively researched, they have largely been studied in isolation. However, the integration of these two areas is becoming increasingly important. In this work, we introduce Arc, an MPC framework designed for auditing privacy-preserving machine learning. Arc cryptographically ties together the training, inference, and auditing phases to allow robust and private auditing. At the core of our framework is a new protocol for efficiently verifying inputs against succinct commitments. We evaluate the performance of our framework when instantiated with our consistency protocol and compare it to hashing-based and homomorphic-commitment-based approaches, demonstrating that it is up to $10^4\times$ faster and up to $10^6\times$ more concise.

1 Introduction

Mounting concerns regarding security and privacy in Machine Learning (ML) have spurred interest in Privacy-Preserving Machine Learning (PPML) [42, 68]. These developments aim to address concerns related to user data, whether during inference or training, as well as securing ML models, as organizations seek to maintain a competitive advantage by keeping them confidential. Consequently, secure inference and secure training frameworks have emerged to address various security and privacy concerns inherent in using and training machine learning models [27, 47, 54, 56, 66, 88]. The majority of these frameworks rely on secure computation techniques [6, 50, 51], which offer security guarantees by hiding the data and/or the model during computation. While these techniques are effective in achieving the intended security goals, they also introduce new challenges due to their inherent opacity. To achieve secrecy, these technologies conceal the processes of training and inference, making it difficult to audit PPML pipelines for fairness, transparency, accountability, and other (often legally mandated) objectives. However, a variety of scenarios require both the privacy guarantees of PPML and the ability to audit the ML pipeline. For example, banks interested in collaborating on training better risk assessment algorithms (e.g., for creditworthiness) will need to rely on PPML techniques to protect both customer privacy and commercial information. At the same time, they must also fulfill legal requirements for auditability such as those of the recently enacted EU AI Act [25], which specifically calls out creditworthiness evaluation [79]. While auditability may seem to be in direct conflict with the privacy requirements of PPML, secure computation can, in principle, offer a way forward for verifying these properties while preserving privacy. However, realizing this in an efficient and robust manner is challenging.

Private ML Auditing. ML auditing involves the examination and verification of machine learning models, algorithms, and data to ensure accountability and desired properties such as fairness, transparency, and accuracy during deployment. Approaches to ML auditing can be divided into a priori and post-hoc auditing mechanisms [9]. The former focus on pre-deployment verification techniques that act as predefined sets of verifications on the model, data, or training process [22, 44], such as model and data validation tests [19, 63] or robustness [31] and fairness [7] verification. While covering important use cases of auditing, these remain limited to known prior issues, which, in the case of ML, are hard to exhaustively address given the black box nature of ML. Post-hoc audits, which are triggered in response to detecting undesirable behavior or other triggers, are therefore essential to ensure accountability in real-world deployments of ML [40, 80, 81]. For example, individuals may seek an explanation of a decision to mitigate potential harm or to investigate its fairness [62, 74]. Recent efforts have examined the realization

of a priori-auditing techniques in secure settings using a variety of ad-hoc techniques. This includes work for verifying robustness, verifiable fairness, and model and data validation techniques [19, 46, 53, 78]. Post-hoc audits, however, have received scant attention in the secure setting. Due to their on-demand nature, they present a unique set of challenges that a priori audits do not face. In this paper, we, therefore, focus primarily on achieving secure post-hoc audits for PPML.

Secure Post-Hoc Audits. In current practice, auditing of PPML systems generally requires assuming a trusted third party (which can be granted access to training data, models, and predictions) that applies traditional auditing solutions. However, in addition to undermining the privacy-preserving nature of PPML, even a trusted auditor is not sufficient to achieve robust audits. Specifically, parties might inadvertently or maliciously alter their inputs to the auditing phase so that they no longer match their original inputs to the PPML system, distorting the results of the auditing phase. Instead, the auditor would need visibility into the entire training and inference process to ensure the consistency of the audit. One might consider realizing such a trusted auditor cryptographically, by relying on (maliciously secure) Multi-Party Computation (MPC) for the entire pipeline. In practice, however, it is generally not feasible to continuously run large MPC deployments with many parties (e.g., different clients receiving inferences and/or different auditing parties). This is because MPC, in general, scales extremely poorly in the number of involved parties, and due to the complexities of maintaining (and periodically refreshing) a large amount of secret state over extended periods [41, 65, 77]. Note that PPML systems usually sidestep these issues, as training and inference can be realized as distinct phases. As a result, the (usually significant) resources utilized for training do not need to be maintained in order to perform inferences. A practical approach to cryptographic auditing for PPML, therefore, needs to maintain this decoupling while nevertheless ensuring consistent audits.

Contribution. This paper presents Arc, a new framework for privacy-preserving auditing of PPML systems. Arc is highly modular and supports a wide range of efficient PPML approaches and auditing functions, and is the first framework to efficiently implement post-hoc auditing for PPML. Our framework ties together training, inference, and auditing while maintaining consistency via the use of concise cryptographic *receipts*. Arc supports a wide range of PPML approaches, including mixed secure/plaintext settings which are common in practical deployments but pose significant challenges for auditing. The overhead of our framework is primarily determined by the efficiency of the underlying consistency mechanism. We first describe (and prove secure) our auditing protocol using a black-box definition of the consistency layer. We then present a highly efficient instantiation that makes Arc practical for a wide range of PPML deployment scenarios. Finally, we evaluate the performance of our framework when instantiated with our consistency protocol and compare it to hashing-based and homomorphic-commitment-based approaches, demonstrating that it is up to $10^4\times$ faster and up to $10^6\times$ more concise.

In the following, we discuss background and related work in §2. We present the requirements of PPML auditing systems and the design of our PPML auditing framework in §3. In §4, we formalize the Proof-of-Consistency (PoC) and present our consistency check protocol. In §5, we discuss how to realize common auditing functions under MPC. Finally, in §6, we evaluate our framework and compare against related work.

2 Background & Related Work

We briefly introduce relevant background for PPML and ML auditing, and then discuss related work.

Privacy-Preserving Machine Learning. PPML enables parties to securely train and deploy sensitive ML models in environments that involve untrusted or potentially compromised entities. There has been significant progress in PPML in recent years, leveraging advanced cryptographic techniques to ensure data privacy and model integrity [6, 14, 27, 47, 54, 56, 57, 66, 88]. Approaches that rely on MPC typically offer the best performance by distributing trust among n parties. These parties collaboratively execute training or inference computations, all while preserving the privacy of each party's inputs. Protocols are categorized based on the number of parties (t) an adversary can corrupt without breaching security, with distinctions made between a majority of honest parties ($t < \frac{n}{2}$) and a dishonest majority ($t < n$). Moreover, protocols are designed to withstand different adversarial behaviors, ranging from passive corruption, where compromised parties may collude to learn information while following the protocol honestly, to active corruption, allowing adversaries to deviate from the protocol arbitrarily. As of today, the most efficient MPC protocols for PPML rely on homomorphic secret sharing over a field $\mathbb{F}_p$ or ring $\mathbb{Z}_{2^k}$ [6]. This allows them to perform integer arithmetic by adding and scaling shares using the homomorphism of the scheme. Communication among parties is only required during the multiplication of shares. PPML frameworks frequently also offer higher-order primitives essential for machine learning, such as dot products, comparisons, bit extraction, exponentiation, and truncation [6, 27, 51, 56, 66, 88]. Different functionalities might be implemented most efficiently in different fields or rings, in which case we can use share conversion to switch between them, e.g., ring and field-based MPC. In Appendix E in the extended version of the paper [1], we discuss this technique in more detail.

ML Auditing. Auditing of ML systems is an emerging field focused on enhancing the accountability of ML algorithms.

Auditing involves verifying the compliance of organizations' ML models with safety and legal standards, e.g., ensuring they do not infringe on copyright laws. Here, we refer to auditing techniques that analyze an algorithm to offer further insights or assurances regarding the model and its predictions. This includes efforts to enhance transparency by explaining predictions, ensuring fairness, or providing accountability for the contributions of different parties. Depending on the technique, these algorithms may require access to the training data, the model, the prediction, or a combination thereof. Techniques that involve only the training data and the model can often be conducted a priori as part of an internal quality assurance process. However, such a priori techniques are inherently limited: important classes of auditing techniques fundamentally require, or only become practical with, access to the prediction sample. For example, audits for explainability/accountability or fairness, respectively. In addition, due to the nature of ML, we can frequently only identify a prediction as unwanted after the fact, potentially even only after significant time has passed. As a result, we require the ability to perform *post-hoc* auditing in real-world ML deployments.

A wide range of approaches for post-hoc auditing have been proposed in the literature, many of which build upon similar techniques. For example, many algorithms in this space rely on perturbing input data or prediction features to assess the impact of such changes on the model's behavior, effectively treating the model as a black box. These methods find application in a variety of contexts, such as providing explanations for predictions [62, 74], investigating the model's training data for biased or poisoned samples [64, 81, 90], or ensuring fairness by analyzing model predictions under hypothetical scenarios where specific input features are altered [67]. As evaluating these methods can be resource-intensive, alternative techniques employ propagation-based methods, which are more computationally efficient by assuming knowledge of the model's internal structure. These methods attribute importance to model neurons, input features, or training samples based on gradients or activations [5, 86]. These techniques share foundational computational operations with training and inference processes, such as forward passes through the neural network and backpropagation. This similarity in computational models implies that the protocols developed for training and inference can be repurposed, to some extent, for auditing purposes. In §5, we provide a detailed description of the algorithmic aspects of the auditing functions supported in our framework.

Related Work. While this is, to the best of our knowledge, the first framework for (post-hoc) PPML auditing, our work is closely related to efforts aimed at enhancing the reliability of PPML systems. Thus, we briefly discuss the most relevant related work here. Prior research primarily focuses on narrow aspects, enhancing isolated components and instantiations of the PPML pipeline as shown in Table 1. Phoenix integrates randomized smoothing techniques into Fully Homomorphic Encryption (FHE)-based ML inference to guarantee robust and fair model predictions [46]. Holmes improves the quality of MPC training to conduct distribution tests on training data via efficient interactive zero-knowledge proofs before training starts [19]. These works apply and optimize reliability techniques to PPML inference and training but do not allow for retroactive auditing of predictions or training data.

Table 1: Related work covers different subsets of the PPML pipeline by allowing to audit combinations of the training data (T), the model (M) and the inference (I), and have different overheads for compute (Co), bandwidth (Ba) and storage (St).

Another line of work enables retroactive verification of certain properties, but only for specific components of the PPML pipeline in isolation. Fairness certification allows clients to verify that their private predictions were generated by a certified model [3, 53, 78]. This is usually achieved by having a regulator sign a hash-based commitment of the model. Cerebro [93] extends MPC training by enabling an auditor to conduct post-hoc computation on parties' inputs through a consistency check involving cryptographic commitments. However, their system only allows auditing of parties' datasets individually, which significantly limits the scope of auditing. Additionally, the commitment techniques they employ to ensure the integrity of the training data do not scale to a complete PPML system handling large amounts of training data and potentially many clients.

3 Arc Design

Arc enables private and secure auditing for existing PPML systems by providing end-to-end consistency of data, model, and predictions while preserving the benefits of distinct training, inference, and auditing phases. Our framework is highly modular and supports a wide range of inference and training approaches, including deployments that mix secure computation and plaintext computation. For example, many scenarios permit the release of a differentially private model after a secure training phase, or consider secure inference for a centrally trained model. Our framework allows the execution of arbitrary auditing functions over the original training data, model, and predictions using secure multi-party computation.

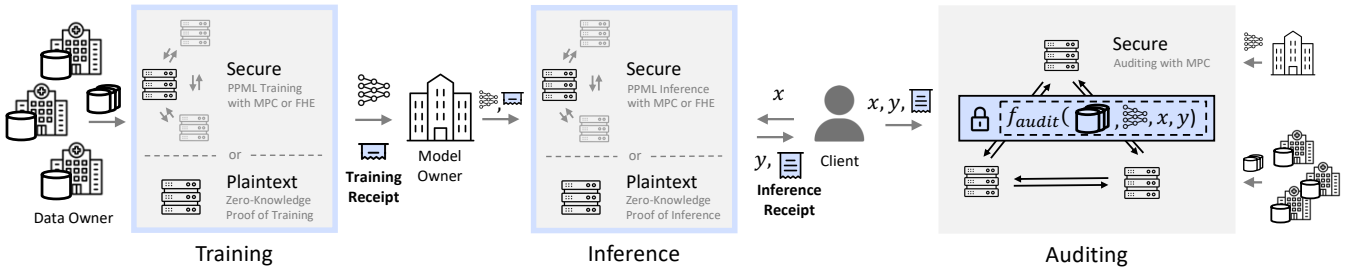

Figure 1: Overview of Arc, which augments existing PPML pipelines with an MPC auditing phase to execute auditing functions. Clients receive a receipt that can later be used to verify the consistency of the training data, model and prediction under audit.

Notably, these audits can be conducted post-hoc, i.e., long after the training or inference phases. In Fig. 1, we illustrate how Arc extends a typical PPML pipeline. Specifically, Arc augments the training phase with a consistency layer that generates a concise cryptographic receipt linking the model received by the model owners and the training data provided by the data owners. During inference, Arc's consistency layer extends this receipt to include the client's prediction sample and result. Using this receipt, the client can later request audit functions to be executed and verify that the data owners and model owners provided their original inputs. This design allows our framework to scale independently of the number of clients and predictions, as the only additional state necessary is the (concise) prediction held by the client.

Threat Model. We consider an actively malicious adversary that can (statically) compromise parties across the training, inference, and auditing phases. The adversary can observe and modify all inputs, states and network traffic of the parties it controls. We assume that at least one party that provides inputs (i.e., training data, model, or prediction sample) or receives outputs is honest. Note that because not all parties are involved in each phase, it is possible that all parties interacting in a phase are malicious. If a phase involves secure computation, we assume at least one of the computational parties is honest. Note that, certain instantiations of secure computation might impose additional constraints on the adversary. For example, Arc can be used with MPC protocols that assume an honest majority of computing parties, which are frequently significantly more efficient than their dishonest majority counterparts.

3.1 Modeling Cryptographic Auditing

A privacy-preserving auditing system must achieve secrecy, correctness, and soundness. For *secrecy*, the system must preserve the privacy guarantees of the underlying PPML systems, except for what can be inferred from the output of auditing[1]. However, to prevent unexpected leakage from malicious audit requests, the system must also be restricted to serving only valid auditing requests, i.e., those corresponding to actual predictions made by the system. Moreover, in order to allow us to rely on the results of auditing, the system must be *correct & sound*, i.e., the audit must be correctly computed even in the presence of malicious parties. In particular, the system must ensure the audit is performed on the original training data and model corresponding to the prediction that is being audited. The system must also have the ability to detect malicious disruptions of the audit process. Specifically, we want to prevent malicious parties from surreptitiously aborting the audit computation and therefore require Identifiable Abort (ID-Abort) security for the auditing phase. Otherwise, malicious actors could prevent auditing without fear of repercussion, fundamentally undermining the concept of auditability. While *publicly identifiable* abort (i.e., everyone, including input parties, learns the identity) would potentially be desirable in the secure outsourced computation (SOC) setting, protocols to achieve this introduce prohibitive overhead [26, 70] and we therefore only require traditional ID-Abort. For training and inference, in comparison, we require only security with abort, as is common in practical protocols for PPML training and inference [18, 21, 38, 66, 71, 88, 94].

As we prove our protocol secure in the real-ideal paradigm [15], we begin by modeling the ideal functionality that a privacy-preserving auditing protocol for PPML should achieve based on the requirements set out above. Despite the separation of the training, inference and auditing phases, we model the intended behavior as a single reactive ideal functionality $\mathcal{F}_{\text{Arc}}$ (cf. Fig. 2) as this directly implies input consistency. We annotate parts only relevant in the plaintext training and/or inference settings in which the adversary can generate local models and predictions (in olive and blue, respectively).

Training & Inference. The functionality allows training models on the input data (assuming the adversary does not choose to abort the computation), adding the resulting model to a list L_{M}. We assume that there is an out-of-band communication channel for learning which models exist and assume the adversary learns about any models that have been trained, even if all parties involved in the training were honest. In the functionality, we model this by leaking the model identifier to

[1] Special care should be taken when choosing auditing functions to ensure their output presents an acceptable privacy-utility trade-off.

Functionality $\mathcal{F}_{\text{Arc}}$

The functionality is parameterized by a learning algorithm $\mathcal{T}$, a set of allowed auditing functions $F_{\texttt{audit}}$, $N_{\texttt{DH}}$ data owners $\texttt{DH} = \{\texttt{DH}_1, \ldots, \texttt{DH}_{N_{\texttt{DH}}}\}$, $N_{\texttt{M}}$ model owners $\texttt{M} = \{\texttt{M}_1, \ldots, \texttt{M}_{N_{\texttt{M}}}\}$, $N_{\texttt{C}}$ clients $\texttt{C} = \{\texttt{C}_1, \ldots, \texttt{C}_{N_{\texttt{C}}}\}$, $N_{\texttt{TC}}$ training computers $\texttt{TC} = \{\texttt{TC}_1, \ldots, \texttt{TC}_{N_{\texttt{TC}}}\}$, $N_{\texttt{IC}}$ inference computers $\texttt{IC} = \{\texttt{IC}_1, \ldots, \texttt{IC}_{N_{\texttt{IC}}}\}$, $N_{\texttt{AC}}$ audit computers $\texttt{AC} = \{\texttt{AC}_1, \ldots, \texttt{AC}_{N_{\texttt{AC}}}\}$. We denote the set of all parties as $\mathcal{P} = \texttt{DH} \cup \texttt{M} \cup \texttt{C} \cup \texttt{TC} \cup \texttt{IC} \cup \texttt{AC}$, The functionality is reactive and its state consists of a set L_{M} of models and corresponding datasets, and a set L_{P} of inference samples and corresponding predictions, Operations only relevant to plaintext training are marked in olive and those only relevant to plaintext inference are marked in blue.

Training: On input $(\texttt{InputData}, D_i)$, store $(\texttt{DH}_i, D_i)$, in the plaintext setting: if $\mathcal{A}$ controls any $\texttt{TC}$, send D_i to $\mathcal{A}$. When the functionality has input D_i from all $\texttt{DH}_i$, clear all $(\texttt{DH}_i, D_i)$ and proceed with:

1. Set $J \xleftarrow{\$} \mathcal{J}$ and compute $M \leftarrow \mathcal{T}(D_1, \ldots, D_{N_{\texttt{DH}}}, J)$. In the plaintext setting: if $\mathcal{A}$ controls any $\texttt{TC}$, send (J, M) to $\mathcal{A}$
2. If $\mathcal{A}$ controls any model owners, send M to $\mathcal{A}$. Otherwise, send $\perp$ to $\mathcal{A}$. Wait for a response $a \in \{\texttt{Abort}, \texttt{Deliver}\}$.
3. If a is $\texttt{Deliver}$, choose a random identifier id_M, and append $((D_1, \ldots, D_{N_{\texttt{DH}}}), M, \mathsf{id}_M)$ to L_{M}, and send the model $(\texttt{Output}, \mathsf{id}_M, M)$ to each model owner $\texttt{M}_j$, and send (id_M) to $\mathcal{A}$. Otherwise, send $(\texttt{Output}, \perp)$ to all parties in $\mathcal{P}$.

Inference: On input $(\texttt{Predict}, \texttt{M}_j, \mathsf{id}_M, x)$ from $\texttt{C}_i$, the functionality does the following:

1. In the plaintext setting: if $\mathcal{A}$ controls $\texttt{IC}_i$, find M in L_{M} using id_M and send x, M to $\mathcal{A}$.
2. If $\mathcal{A}$ controls $\texttt{M}_j$, all $\texttt{DH}_i$, and all $\texttt{TC}_i$:
   - ask $\mathcal{A}$ for an alternative model M' and $N_{\texttt{DH}}$ datasets D'_k and training randomness J'.
   - If $\mathcal{A}$ returns $\perp$, continue with Step 3.
   - Else, if $M' = \mathcal{T}(D'_1, \ldots, D'_{N_{\texttt{DH}}}, J')$, choose a random id'_M, add $((D'_1, \ldots, D'_{N_{\texttt{DH}}}), M', \mathsf{id}'_M)$ to L_{M}, set $\mathsf{id}_M = \mathsf{id}'_M$ and send (id_M) to $\mathcal{A}$.
   - Otherwise, send $\texttt{Abort}$ to all parties.
3. Find M in L_{M} using id_M and compute $y \leftarrow M(x)$.
4. If $\mathcal{A}$ controls $\texttt{C}_i$, send (id_M, y) to $\mathcal{A}$.
5. If $\mathcal{A}$ controls $\texttt{M}_j$ or any $\texttt{IC}$, send (id_M) and (y) to $\mathcal{A}$.
6. Wait for a response $a \in \{\texttt{Abort}, \texttt{Deliver}\}$. If a is $\texttt{Abort}$, send $(\texttt{Output}, \perp)$ to all parties in $\mathcal{P}$.
   Else, if a is $\texttt{Deliver}$, send $(\texttt{Output}, \mathsf{id}_M, y)$ to $\texttt{C}_i$ and add $(\texttt{M}_j, \mathsf{id}_M, x, y)$ to L_{P}.

Auditing: On input $(\texttt{Audit}, \texttt{M}_j, \tilde{\mathsf{id}}_M, f_{\texttt{audit}}, \tilde{x}, \tilde{y}, \mathsf{aux})$ from $\texttt{C}_i$, the functionality does the following

1. If $f_{\texttt{audit}} \notin F_{\texttt{audit}}$, send $(\texttt{Malicious}, \texttt{C}_i)$ to all parties in $\texttt{AC}$ and halt.
2. If $(\cdot, \cdot, \mathsf{id}_M) \in L_{\text{M}}$, get $((D_1, \cdots, D_N), M, \mathsf{id}_M)$ from L_{M}. Else, send $(\texttt{Malicious}, \texttt{C}_i)$ to all parties in $\texttt{AC}$ and halt.
3. If $\mathcal{A}$ controls $\texttt{M}_j$ and all $\texttt{IC}_i$: append $(\texttt{M}_j, \mathsf{id}_M, \tilde{x}, \tilde{y})$ to L_{P} if $M(\tilde{x}) = \tilde{y}$, else, send $(\texttt{Malicious}, \texttt{C}_i)$ to all $\texttt{AC}$ and halt.
4. If $(\texttt{M}_j, \mathsf{id}_M, \tilde{x}, \tilde{y}) \notin L_{\text{P}}$ send $(\texttt{Malicious}, \texttt{C}_i)$ to all parties in $\texttt{AC}$ and halt.
5. Evaluate $o \leftarrow f_{\texttt{audit}}(\tilde{x}, \tilde{y}, M, D_1, \cdots, D_N, \mathsf{aux})$.
6. Send (o) to $\mathcal{A}$ if $\mathcal{A}$ controls $\texttt{C}_i$ and send $(\texttt{M}_j, \mathsf{id}_M, f_{\texttt{audit}}, \mathsf{aux})$ to $\mathcal{A}$ otherwise.
   Wait for a response $a \in \{(\texttt{Abort}, \texttt{P}), \texttt{Deliver}\}$, where $\texttt{P} \in \mathcal{P}$.
7. If a is $\texttt{Deliver}$, send $(\texttt{Output}, o)$ to $\texttt{C}$. If a is $(\texttt{Abort}, \texttt{P})$, send $(\texttt{Malicious}, \texttt{P})$ to all parties in $\texttt{AC}$.

Figure 2: Arc's Ideal Functionality.

the adversary after training. In the case of plaintext training, the functionality additionally leaks the input data and model to the adversary if it controls any training computer. Inference proceeds similarly, storing the inference result in the list L_{P}. However, we must take care to also model the special case that occurs if an adversary has control over all data owners, all training computers and at least one model owner. In this case, the adversary could locally generate a valid combination of data and model $((D_1, \cdots, D_N), M)$. In the ideal world, we model this by extending the functionality to accept such locally trained models and, if consistent with the training data, append them to L_{M} before proceeding with the inference.

Auditing. Any client that has received a prediction, can request audits of that prediction using any auditing function from a set of allowed auditing functions. During auditing, the lists L_{M} and L_{P} are used to verify that an auditing request is consistent. Similarly to the special case we had to consider during inference, we must model the ability to locally generate valid inferences if the adversary controls all inference computers and a model owner. In this case, the functionality appends such locally generated predictions to L_{P} (if internally consistent) before verifying the auditing request. During au-

diting, the adversary can still choose to abort the computation, but as we require auditing to achieve identifiable abort, the adversary must reveal the identity of at least one malicious party to the functionality. In the case of inconsistencies in the audit inputs, the functionality also aborts and identifies the (uniquely determined) party at fault to the audit computers.

3.2 Arc Protocol

Our protocol lifts existing PPML systems to the cryptographic auditing setting by augmenting training and inference to produce receipts that can later be used to verify the consistency of the training data, model, and prediction under audit. Supporting real-world deployments with many potential inference clients requires scaling independently of the number of inferences and clients in the system. At the same time, we want to minimize the state that clients need to store beyond the received predictions. In Arc, we achieve this through concise cryptographic receipts for training and inference, which allows clients to efficiently store all material necessary to later verify the consistency of training data, model, inference sample, and prediction during auditing. At the same time, receipts are cryptographically bound to specific inferences, i.e., clients cannot generate audit requests for predictions they did not receive. In the following, we give an overview of our protocol, Π_{Arc} (c.f. Fig. 3) and its building blocks. We prove the security of our protocol in the real/ideal world paradigm [15] in Appendix B in the extended version of the paper [1].

Building Blocks. We construct our protocol from several cryptographic primitives, including a reactive arithmetic black-box (ABB) interface to abstract PPML protocols. In addition, we require secure point-to-point channels between parties that participate in the same phase and, in the auditing phase, a secure broadcast channel in order to achieve identifiable abort. We assume that all parties (except for clients) have a cryptographic identity which is set up through a public-key infrastructure (PKI), and that clients can access the (public) identities of the other parties through the PKI. Our protocol makes use of standard signatures (cf. Definition A.5 in Appendix A [1]) and a Proof-of-Consistency (PoC) (cf. Definition 4.1) which acts like a commitment, but admits significantly more efficient instantiations in the secure computation setting, as we discuss in the next section. In the following, we will use commitment and PoC interchangeably.

Proof of Training/Inference. When training and inference are realized via secure computation, computational integrity follows directly from the guarantees of the underlying MPC protocol. However, supporting real-world deployment scenarios where either training or inference are computed centrally on plaintexts, requires explicit proofs of computational integrity. There has been significant work on increasingly efficient proofs for both training [36, 85] and inference [20, 48], making use of advances in SNARKs and related proof techniques. We model these as proof-of-training (PoT) or proof-of-inference (PoI) (cf. Definitions A.6 and A.7 in Appendix A [1]). Recently, Proof-of-Learning (PoL) [44] has emerged, aiming to provide an easier-to-generate alternative to PoT by relying only on heuristic assumptions rather than strong cryptographic assumptions [34]. However, PoL *verification* requires access to the original training data and is computationally expensive, requiring many epochs of (re-)training. Therefore, PoL is less attractive for our setting, where verification must be computed under MPC.

Training & Inference. The training and inference phase of Π_{Arc} both provide a layer of consistency around calls to the underlying PPML implementation (i.e., $\mathcal{F}_{\text{ABB}}.\mathsf{Train}_{\mathcal{T}}$ or $\mathcal{F}_{\text{ABB}}.\mathsf{Predict}$). While the inference computation is fully deterministic, training also requires randomness which we securely sample (i.e., $\mathcal{F}_{\text{RAND}}$ [10]) and commit to in order to prevent reordering attacks [83]. Otherwise, the two phases proceed nearly identically:

- *Input Commitments* (T.1/I.1). In addition to their inputs, parties must provide a commitment to their inputs and the protocol verifies the consistency of these commitments before proceeding. In the secure computation setting, this uses $\mathsf{PoC.Check}$ which involves an (efficient) multi-party computation. In the plaintext setting, the computing parties can simply locally recompute the commitments.
- *Computation Integrity* (T.2/I.2). After computing the underlying ML training or inference, the computing parties commit (in the secure setting, collaboratively under MPC) to the result and provide the result, commitment, and associated decommitment randomness to the output-receiving parties. As we later need to show that these outputs were the result of a valid computation, the computing parties attest to the integrity of the computation. In the secure setting, this can be achieved via a distributed signature, as at least one of the computing parties must be honest. In the plaintext setting, this requires a PoT or PoI, as we cannot rely on a split-trust assumption for integrity.
- *Input Integrity* (T.3/I.3). While the signature or proof tie the result to a valid computation, they do not provide sufficient guarantees about the inputs. Therefore, the input parties verify their inputs were used and provide signatures to attest to this.
- *Output Consistency* (T.4/I.4). The output from the computation is provided to the output-receiving parties (in the plain) along with the associated receipt data. These parties then verify that the signatures and proofs are valid, and that the outputs (and decommitment randomness) they received matches the commitments in the receipt.

Note that providing a plaintext inference result to the client is essential for a useful inference service. However, one could consider a variant of the protocol in which the model owners only receive shares of the model, rather than the plaintext model. While our protocol could be trivially extended to support this, this would both unnecessarily complicate the notation and would require the long-term storage of secret shares and potentially complicated operations such as secret-share

Figure 3: Protocol Π_{Arc}

Π_{Arc} is a protocol between N_{DH} data owners $\text{DH} = \{\text{DH}_1, \ldots, \text{DH}_{N_{\text{DH}}}\}$, N_{M} model owners $\text{M} = \{\text{M}_1, \ldots, \text{M}_{N_{\text{M}}}\}$, N_{C} clients $\text{C} = \{\text{C}_1, \ldots, \text{C}_{N_{\text{C}}}\}$, N_{TC} training computers $\text{TC} = \{\text{TC}_1, \ldots, \text{TC}_{N_{\text{TC}}}\}$, N_{IC} inference computers $\text{IC} = \{\text{IC}_1, \ldots, \text{IC}_{N_{\text{IC}}}\}$, and N_{AC} audit computers $\text{AC} = \{\text{AC}_1, \ldots, \text{AC}_{N_{\text{AC}}}\}$. Π_{Arc} is parameterized by a learning algorithm $\mathcal{T}$, a set of allowed auditing functions F_{audit}, a proof-of-consistency PoC as in Definition 4.1 [1], a signature scheme SIG as in Definition A.5 [1]. Protocol parts only relevant to plaintext training are marked in olive, and those only relevant to plaintext inference are marked in blue. In the case of plaintext training, Arc is also parameterized by a proof of training POT as in Definition A.6 [1] and, in the case of plaintext inference, a proof of inference POI as in Definition A.7 [1]. Π_{Arc} assumes access to an MPC protocol represented by instances of $\mathcal{F}_{\text{ABB}}$ and, in the case of plaintext training or plaintext inference, a distributed randomness source $\mathcal{F}_{\text{RAND}}$. Π_{Arc} also assumes access to a broadcast channel $\mathcal{F}_{\text{BC}}$ and an MPC protocol $\mathcal{F}_{\text{ABB [ID]}}$ with ID-Abort, also used by PoC internally.

Input: Each DH_i holds their training dataset $D_i \in \mathbb{F}^{l \times d_i}$ consisting of a vector of d_i input feature vectors of size l. Each client C_j holds a list of prediction samples $[x]$ where $x \in \mathbb{F}_p^l$ and a set of audit inputs which is a subset of $[x]$.

Initialize: All parties except the clients receive signing keys from $\mathcal{F}_{\text{PKI}}$. All parties receive all corresponding verification keys from $\mathcal{F}_{\text{PKI}}$. The parties also receive public setup parameters for PoC $\text{pp}_{\text{poc}} \leftarrow \text{PoC.Setup}(1^\lambda, d)$ where d is the maximum of all d_i and m, and (in the case of plaintext training) $\text{pp}_{\text{pot}} \leftarrow \text{POT.Setup}(1^\lambda)$ and (in the case of plaintext inference) $\text{pp}_{\text{poi}} \leftarrow \text{POI.Setup}(1^\lambda)$.

Training: The protocol proceeds as follows with training computers TC, data owners DH and model owners M, using a new instance of $\mathcal{F}_{\text{ABB}}$:

T.1 Each data owner DH_i samples a random decommitment value $r_{D_i} \xleftarrow{\$} \mathcal{R}$ and:

- Inputs D_i to $\mathcal{F}_{\text{ABB}}$ or sends (D_i, r_{D_i}) to all TC.
- Computes a commitment to the training dataset $c_{D_i} = \text{PoC.Commit}(\text{pp}_{\text{poc}}, D_i, r_{D_i})$ and sends (c_{D_i}) to all TC.
- Executes PoC $\text{PoC.Check}(\text{pp}_{\text{poc}}, c_{D_i}, [\![D_i]\!]; D_i, r_{D_i})$ with all TC or each TC verifies that $c_{D_i} = \text{PoC.Commit}(\text{pp}_{\text{poc}}, D_i, r_{D_i})$ for all DH_i.

T.2 Each training computer TC_j:

- Samples $[\![r_M]\!], [\![r_J]\!], [\![J]\!]$ using $\mathcal{F}_{\text{ABB}}.\text{RAND}$ or all TC and M receive r_M, r_J, J from $\mathcal{F}_{\text{RAND}}$.
- Invoke $\mathcal{F}_{\text{ABB}}.\text{Train}_{\mathcal{T}}([\![D_1]\!], \ldots, [\![D_{N_{\text{DH}}}]\!], [\![J]\!])$ to compute the model $[\![M]\!]$ or compute $M \leftarrow \mathcal{T}(D_1, \ldots, D_{N_{\text{DH}}}, J)$.
- Using $\mathcal{F}_{\text{ABB}}$, commit to the model $[\![c_M]\!] = \text{PoC.Commit}(\text{pp}_{\text{poc}}, [\![M]\!], [\![r_M]\!])$, randomness $[\![c_J]\!] = \text{PoC.Commit}(\text{pp}_{\text{poc}}, [\![J]\!], [\![r_J]\!])$ and open c_M, c_J to all TC, DH and M or compute $c_M \leftarrow \text{PoC.Commit}(\text{pp}_{\text{poc}}, M, r_M)$ and $c_J \leftarrow \text{PoC.Commit}(\text{pp}_{\text{poc}}, J, r_J)$.
- Compute $[\![\sigma_{\text{TC}}]\!] \leftarrow \text{SIG.DistSign}(\text{sk}_{\text{TC}_j}, c_{D_1} \| \ldots \| c_{D_{N_{\text{DH}}}} \| c_M \| c_J)$ and open σ_{TC} to M, DH using $\mathcal{F}_{\text{ABB}}$ or $\pi_{\text{T}} \leftarrow \text{POT.Prove}(\text{pp}_{\text{pot}}, (c_{D_1}, \ldots, c_{D_{N_{\text{DH}}}}, c_M, c_J); D_1, \ldots, D_{N_{\text{DH}}}, M, J, r_{D_1}, \ldots, r_{D_{N_{\text{DH}}}}, r_M, r_J)$.
- Send $(c_{D_1}, \ldots, c_{D_{N_{\text{DH}}}})$ and open $[\![M]\!], [\![r_M]\!]$ to M using $\mathcal{F}_{\text{ABB}}$ or send $(c_{D_1}, \ldots, c_{D_{N_{\text{DH}}}}, c_M, c_J, \pi_{\text{T}}, M, r_M, r_J, J)$ to all M.
- Send $(c_{D_1}, \ldots, c_{D_{N_{\text{DH}}}}, c_M, c_J, \pi_{\text{T}})$ to all data owners DH.

T.3 Each DH_i checks that it received the same $(c_{D_1}, \ldots, c_{D_{N_{\text{DH}}}}, c_M, c_J, \pi_{\text{T}})$ from all TC, $\text{SIG.Verify}(\text{pk}_{\text{TC}}, c_{D_1} \| \ldots \| c_{D_{N_{\text{DH}}}} \| c_M \| c_J, \sigma_{\text{TC}})$ or $\text{POT.Verify}(\text{pp}_{\text{pot}}, c_{D_1}, \ldots, c_{D_{N_{\text{DH}}}}, c_M, c_J, \pi_{\text{T}})$, and its c_{D_i} is contained in $c_{D_1}, \ldots, c_{D_{N_{\text{DH}}}}$ and aborts otherwise. Then, each computes $\sigma_{\text{T}}^i \leftarrow \text{SIG.Sign}(\text{sk}_{\text{DH}_i}, c_{D_1} \| \ldots \| c_{D_{N_{\text{DH}}}} \| c_M \| c_J)$ and sends σ_{T}^i to all M.

T.4 Each model owner M_k checks each of the following and aborts if any fail:

- Verify that the $(c_{D_1}, \ldots, c_{D_{N_{\text{DH}}}}, \sigma_{\text{TC}})$ (and $c_M, c_J, M, r_M, r_J, J, \pi_{\text{T}}$) received from each TC are consistent with each other.
- $c_M = \text{PoC.Commit}(\text{pp}_{\text{poc}}, M, r_M)$ and $c_J = \text{PoC.Commit}(\text{pp}_{\text{poc}}, J, r_J)$.
- The list of signatures $\text{SIG.Verify}(\text{pk}_{\text{DH}_i}, c_{D_1} \| \ldots \| c_{D_{N_{\text{DH}}}} \| c_M \| c_J, \sigma_{\text{T}}^i)$ for each DH_i.
- $\text{SIG.Verify}(\text{pk}_{\text{TC}}, c_{D_1} \| \ldots \| c_{D_{N_{\text{DH}}}} \| c_M \| c_J, \sigma_{\text{TC}})$ or $\text{POT.Verify}(\text{pp}_{\text{pot}}, c_{D_1}, \ldots, c_{D_{N_{\text{DH}}}}, c_M, c_J, \pi_{\text{T}})$.

Inference: The protocol proceeds as follows between inference computers IC, client C_i and model owner M_k, using a new instance of $\mathcal{F}_{\text{ABB}}$:

I.1 C_i sends c'_M (identifying the requested model) to all IC, and inputs a prediction sample x to $\mathcal{F}_{\text{ABB}}$ or sends x to all IC, then:

- All IC ask M_k to send $(c, \sigma_{\text{T}}, \sigma_{\text{TC}}$ or $\pi_{\text{T}})$ where $c = (c_{D_1}, \ldots, c_{D_{N_{\text{DH}}}}, c_M, c_J)$ to IC, and input the model M to $\mathcal{F}_{\text{ABB}}$ or send M, r_M to IC.
- The inference computers abort if $c_M \neq c'_M$.
- M_k executes $\text{PoC.Check}(\text{pp}_{\text{poc}}, c_M, [\![M]\!]; M, r_M)$ with all IC or each IC checks $c_M = \text{PoC.Commit}(\text{pp}_{\text{poc}}, M, r_M)$ and aborts if it fails.

I.2 Each inference computer IC_j:

- Computes $[\![y]\!]$ by invoking $\mathcal{F}_{\text{ABB}}.\text{Predict}([\![M]\!], [\![x]\!])$ or computes $y \leftarrow M(x)$.
- Samples $[\![r_x]\!], [\![r_y]\!]$ using $\mathcal{F}_{\text{ABB}}.\text{RAND}$ or all IC and DH_i receive r_x, r_y $\mathcal{F}_{\text{RAND}}$.
- Computes $[\![c_x]\!] = \text{PoC.Commit}(\text{pp}_{\text{poc}}, [\![x]\!], [\![r_x]\!])$ and $[\![c_y]\!] = \text{PoC.Commit}(\text{pp}_{\text{poc}}, [\![y]\!], [\![r_y]\!])$ and opens c_x and c_y to IC, C_i and M_k using $\mathcal{F}_{\text{ABB}}$ or computes $c_x = \text{PoC.Commit}(\text{pp}_{\text{poc}}, x, r_x)$ and $c_y = \text{PoC.Commit}(\text{pp}_{\text{poc}}, y, r_y)$ and send (c_x, c_y) to C_i and M_k .
- Computes $[\![\sigma_{\text{IC}}]\!] \leftarrow \text{SIG.DistSign}(\text{sk}_{\text{IC}_j}, c \| c_x \| c_y)$ & opens σ_{IC} to C_i, M_k using $\mathcal{F}_{\text{ABB}}$ or $\pi_{\text{I}} \leftarrow \text{POI.Prove}(\text{pp}_{\text{poi}}, c_M, c_x, c_y; M, x, y, r_M, r_x, r_y)$.
- Sends $(c, \sigma_{\text{T}}, \sigma_{\text{TC}}$ or $\pi_{\text{T}})$ to C_i and open $([\![y]\!], [\![r_x]\!], [\![r_y]\!])$ with $\mathcal{F}_{\text{ABB}}$ to C_i, or send $(c, \sigma_{\text{T}}, \sigma_{\text{TC}}$ or $\pi_{\text{T}}, \pi_{\text{I}}, y, r_x, r_y)$ to C_i. Sends (c, π_{I}) to M_k.

I.3 The model owner checks that it receives the same (c, c_x, c_y), that $\text{SIG.Verify}(\text{pk}_{\text{IC}}, c \| c_x \| c_y, \sigma_{\text{IC}})$ or $\text{POI.Verify}(\text{pp}_{\text{poi}}, c_M, c_x, c_y, \pi_{\text{I}})$, aborting otherwise, and computes $\sigma_{\text{I}} \leftarrow \text{SIG.Sign}(\text{sk}_{\text{M}_k}, c \| c_x \| c_y \| \sigma_{\text{T}} \| \sigma_{\text{TC}}$ or $\pi_{\text{T}} \| \sigma_{\text{IC}}$ or $\pi_{\text{I}})$ and sends σ_{I} to C_i.

I.4 The client C checks each of the following and aborts if any fails:

- Verify that the $(c, c_x, c_y, \sigma_{\text{T}}, \sigma_{\text{TC}}$ or $\pi_{\text{T}}, \sigma_{\text{IC}}$ or $\pi_{\text{I}}, y, r_y, r_x)$ received from each TC are consistent with each other.
- $\text{SIG.Verify}(\text{pk}_{\text{M}_k}, c \| c_x \| c_y \| \sigma_{\text{T}} \| \sigma_{\text{TC}}$ or $\pi_{\text{T}} \| \sigma_{\text{IC}}$ or $\pi_{\text{I}}, \sigma_{\text{I}})$ is a valid signature by pk_{M}.
- Verify that $c_x = \text{PoC.Commit}(\text{pp}_{\text{poc}}, x, r_x)$ and $c_y = \text{PoC.Commit}(\text{pp}_{\text{poc}}, y, r_y)$.
- The list of signatures $\text{SIG.Verify}(\text{pk}_{\text{DH}_i}, c, \sigma_{\text{T}}^i)$ for each DH_i, and $\text{SIG.Verify}(\text{pk}_{\text{IC}}, c \| c_x \| c_y, \sigma_{\text{IC}})$ or $\text{POI.Verify}(\text{pp}_{\text{poi}}, c_M, c_x, c_y, \pi_{\text{I}})$.

Figure 3: Protocol Π_{Arc} (cont.)

Auditing: The protocol proceeds as follows on a new instance of $\mathcal{F}_{\text{ABB [ID]}}$ between computing parties $\texttt{AC}$, a client $\texttt{C}_j$ and the model owner $\texttt{M}_k$:

A.1 The client $\texttt{C}_j$ inputs (x, y) to $\mathcal{F}_{\text{ABB [ID]}}$ and broadcasts $(c, c_x, c_y, \sigma_{\text{I}}, \sigma_{\text{T}}, \sigma_{\texttt{TC}}$ or $\pi_{\text{T}}, \sigma_{\texttt{IC}}$ or $\pi_{\text{I}}, \mathsf{pk}_{\texttt{M}_k}, f_{\texttt{audit}}, \mathsf{aux})$ to all parties using $\mathcal{F}_{\text{BC}}$.

A.2 All parties check that $\mathsf{pk}_{\texttt{M}_k}$ is a valid identity from $\mathcal{F}_{\text{PKI}}$, verify the model owner signature with $\mathsf{SIG.Verify}(\mathsf{pk}_{\texttt{M}_k}, c \,\|\, c_x \,\|\, c_y \,\|\, \sigma_{\text{T}} \,\|\, \sigma_{\texttt{TC}}$ or $\pi_{\text{T}} \,\|\, \sigma_{\texttt{IC}}$ or $\pi_{\text{I}}, \sigma_{\text{I}})$ and check that $f_{\texttt{audit}} \in F_{\texttt{audit}}$. Otherwise, each party aborts marking $\texttt{C}_j$ as malicious.

A.3 **Verify Audit Requester:** The client $\texttt{C}_j$ runs $\mathsf{PoC.Check}_{\text{[ID]}}(\mathsf{pp}_{\mathsf{poc}}, c_x, [\![x]\!]; x, r_x), \mathsf{PoC.Check}_{\text{[ID]}}(\mathsf{pp}_{\mathsf{poc}}, c_y, [\![y]\!]; y, r_y)$ with the audit computers to prove to the $\texttt{AC}$ that its inputs x and y are consistent with c_x and c_y. If any of the checks fail, $\texttt{AC}_i$ aborts marking $\texttt{C}_j$ as malicious.

A.4 **Verify Inference:** The model owner inputs the model M to $\mathcal{F}_{\text{ABB [ID]}}$:

- The model owner $\texttt{M}_k$ runs $\mathsf{PoC.Check}_{\text{[ID]}}(\mathsf{pp}_{\mathsf{poc}}, c_M, [\![M]\!]; M, r_M)$ with the audit computers acting as the verifiers to proof that its model input is consistent with c_M from $\texttt{C}_j$. Each $\texttt{AC}_i$ aborts marking $\texttt{M}_k$ as malicious if verification fails.
- Each audit computer computes $\mathsf{SIG.Verify}(\mathsf{pk}_{\texttt{IC}}, c \,\|\, c_x \,\|\, c_y, \sigma_{\texttt{IC}})$ or $\mathsf{POI.Verify}\ (\mathsf{pp}_{\mathsf{poi}}, c_M, c_x, c_y, \pi_{\text{I}})$.

A.5 **Verify Training:** Each data owner $\texttt{DH}_i$ inputs their dataset D_i to $\mathcal{F}_{\text{ABB [ID]}}$.

- Each data owner $\texttt{DH}_i$ performs $\mathsf{PoC.Check}_{\text{[ID]}}(\mathsf{pp}_{\mathsf{poc}}, c_{D_i}, [\![D_i]\!]; D_i, r_{D_i})$ with the audit computers acting as verifiers to proof that its input $[\![D_i]\!]$ is consistent with c_{D_i}. $\texttt{AC}_j$ also checks $\mathsf{SIG.Verify}(\mathsf{pk}_{\texttt{DH}_i}, c, \sigma_{\text{T}})$ for each $\texttt{DH}_i$. If verification fails, $\texttt{AC}_j$ aborts marking $\texttt{M}_k$ as malicious.
- Each audit computer computes $\mathsf{SIG.Verify}(\mathsf{pk}_{\texttt{TC}}, c, \sigma_{\texttt{TC}})$ or $\mathsf{POT.Verify}\ (\mathsf{pp}_{\mathsf{pot}}, c, \pi_{\text{T}})$.

A.6 The audit computers compute $[\![o]\!] \leftarrow \mathcal{F}_{\text{ABB [ID]}}.\mathsf{Audit}(f_{\texttt{audit}}, [\![D_1]\!], \ldots, [\![D_{N_{\texttt{DH}}}]\!], [\![M]\!], [\![x]\!], [\![y]\!], \mathsf{aux})$ and use $\mathcal{F}_{\text{ABB [ID]}}$ to open o at $\texttt{C}_j$.

maintenance and re-sharing to new sets of entities [41, 65, 77], a complexity which we aim to avoid in our design.

The receipt received by the model owners after training comprises commitments to the training data, the training randomness and the resulting model; the data owners's signatures; and either the signature from the computing parties or a proof of training. During inference, the model owners provide this training receipt instead of merely the model commitment. As a result, the inference receipt is essentially an extension of the training receipt and includes the equivalent commitments and signatures (or proofs, where applicable) for both training and inference. Therefore, the conciseness of the underlying commitments (i.e., PoC) is crucial to ensuring that the overhead imposed upon the client due to the need to store this receipt is minimized.

Auditing During auditing, the client provides the receipt and inputs the prediction sample and result into the MPC computation. Meanwhile, the model owners and data owners need to provide their respective inputs. The protocol first confirms that the signatures (or proofs, where applicable) in the receipt are valid, in reverse order, i.e., beginning with the last signature generated at the end of inference. Then, it uses PoC.Check to verify the consistency of the provided inputs with the commitments in the receipt. Finally, after all checks have passed, the protocol computes the audit function (i.e., $\mathcal{F}_{\text{ABB}}.\mathsf{Audit}$). Should any of the checks fail, the protocol aborts and identifies the party at fault. During the auditing phase, we can rely on the fact that an honest client will only ever accept valid receipts, as the proof of computational integrity (or, in the secure computation setting, signatures) allow them to verify that the receipt was generated correctly. At the same time, these checks prevent the adversary from constructing a valid malicious receipt that would incriminate an honest party. As a result, any inconsistency between the receipt and the input data provided to the audit phase can be uniquely attributed to the party providing the corresponding auditing input. For more details, we refer to the proof in Appendix B [1].

4 Proof of Consistency

In our auditing protocol Π_{Arc}, we assume access to a Proof-of-Consistency protocol PoC that allows a party to commit to their (secret) inputs and later allows the parties to collaboratively check that a given (set of) secret shared[2] values is consistent with the provided commitment. Note that PoC might seem related to Verifiable Secret Sharing (VSS), which guarantees that parties receive a valid sharing of a given value. However, this is orthogonal to our requirement of ensuring consistency of *inputs* across different phases and, therefore, different sharings of that value. In theory, the consistency guarantees required for Arc could also be achieved straightforwardly by using standard commitments. However, as we show in our evaluation, such approaches incur significant performance overheads, especially during verification, making practical deployment infeasible.

4.1 Defining Proof-of-Consistency

In the following, we provide the formal definition of PoC and the properties it needs to achieve before discussing several approaches based on existing literature and highlighting their inherent limitations with regard to efficiency and succinctness.

Definition 4.1 (Proof-of-Consistency Protocol)**.** A valid Proof-of-Consistency is an interaction between a Prover $\mathbb{P}$ and a set of $N-1$ Verifiers $\mathbb{V}$. This protocol allows the verifiers to check that a vector $[\![\mathbf{x}]\!] = ([\![\mathbf{x}_1]\!], \ldots, [\![\mathbf{x}_d]\!])$ stored in an ideal functionality $\mathcal{F}_{\text{ABB}}$ is consistent with a commitment c to $\mathbf{x} = (\mathbf{x}_1, \ldots, \mathbf{x}_d) \in \mathbb{F}_p^d$. A Proof-of-Consistency is defined

[2] More precisely, in the representation used by $\mathcal{F}_{\text{ABB}}$.

as a set of protocols (PoC.Setup, PoC.Commit, PoC.Check) where:

- $\mathsf{PoC.Setup}(1^\lambda, d) \to \mathsf{pp}_{\mathsf{poc}}$: prepares public parameters pp supporting inputs of size d.
- $\mathsf{PoC.Commit}(\mathsf{pp}_{\mathsf{poc}}, \mathbf{x}, r) \to c$: An algorithm in which the prover generates a commitment to (a vector of) inputs $\mathbf{x}$ with randomness r.
- $\mathsf{PoC.Check}(\mathsf{pp}_{\mathsf{poc}}, c, [\![\mathbf{x}]\!]; \mathbf{x}, r) \to \{0,1\}$: A protocol where the prover convinces the verifiers that the commitment c is consistent with $[\![\mathbf{x}]\!]$. Only the prover knows $\mathbf{x}$ and r.

A valid Proof-of-Consistency should satisfy correctness, soundness and zero-knowledge, which we formally define in Appendix C. In addition to the formal requirements, a PoC instantiation should yield succinct commitments and its protocols should be efficiently computable (specifically, require minimal MPC operations in PoC.Check) in order to be practical for ML. Succinctness is crucial for ensuring efficient communication and storage, especially when dealing with large input sizes and resource-constrained clients. In the following, we discuss existing approaches and how they fall short in our setting. We refer to Appendix D in the extended version of the paper [1] for formal definitions of the corresponding protocols.

Direct Commitments [2, 53, 78]. A straightforward approach to PoC is to use a cryptographic commitment scheme to instantiate PoC.Setup and PoC.Commit with COM.Setup and COM.Commit, respectively. In PoC.Check, the commitment is verified with respect to the secret shared inputs $[\![\mathbf{x}]\!]$ and decommitment $[\![r]\!]$ by computing COM.Verify using $\mathcal{F}_{\text{ABB}}$. This typically requires recomputing the commitment under MPC, because the usual implementation of COM.Verify is to re-compute the commitment $c' \leftarrow \mathsf{COM.Commit}([\![\mathbf{x}]\!], [\![r]\!])$ and checking that $c' = c$. Related work has suggested to use this protocol with commitments based on a collision-resistant hash function, such as SHA-2 [53], SHA-3 [78] and MPC-friendly constructions such as LowMCHash-256 [2]. The advantage of this approach lies in its succinct commitment size which is typically constant. However, despite its efficient storage needs, the hash-based approach incurs significant computational costs during verification. This is primarily due to hashes relying on non-linear operations, which are expensive to compute in MPC.

Homomorphic Commitments [93]. To mitigate the MPC cost of PoC.Check, one can rely on homomorphic commitments such as Pedersen commitments instantiated using an elliptic curve group [72, 93]. Instead of calling COM.Verify for the full input vector $[\![\mathbf{x}]\!]$, parties use the homomorphism to compute a linear combination of commitments to individual elements x_i, trading off MPC overhead with local computation. As a result, parties only compute a single commitment $\tilde{c}' = \mathsf{COM.Commit}(\sum_i \gamma^i \cdot [\![x_i]\!])$ with $\mathcal{F}_{\text{ABB}}$ in PoC.Check and compare the result with $\tilde{c}' = \sum_i \gamma^i \cdot c_i$. Unfortunately, a downside of this approach is that commitments to individual elements must be stored, resulting in a size that is linear in $|\mathbf{x}|$. This approach results in a PoC.Check that is asymptotically more efficient than the hash-based approach. In practice, hash-based approaches remain more concretely efficient for very small inputs. However, the Pedersen commitment approach becomes more efficient already for moderate input sizes.

4.2 Arc PoC Protocol

The key insight of our efficient PoC protocol is that we do not actually need to compute COM.Commit in order to verify that the $[\![\mathbf{x}]\!]$ in $\mathcal{F}_{\text{ABB}}$ matches the input $\mathbf{x}$ of COM.Commit. Instead, we propose a protocol that allows the prover $\mathbb{P}$ to convince the verifiers of this fact with a polynomial identity test. Towards this, we first define a polynomial $g(B) := \sum_{i=1}^{d} x_i \cdot B^i$, i.e., interpreting the elements of $\mathbf{x} \in \mathbb{F}_p^d$ as the coefficients of the polynomial. The prover commits to g using a (homomorphic) polynomial commitment scheme [49] to obtain a constant-size commitment c. In PoC.Check, the parties then first collaboratively sample a point $\beta \xleftarrow{\$} \mathbb{F}_p$ and then evaluate the polynomial at β (using $\mathcal{F}_{\text{ABB}}$) by computing $\rho := \sum_{i=1}^{d} [\![x_i]\!] \cdot \beta^i$ and opening ρ. This is cheap in MPC because it only involves addition and scaling operations on the secret shares $[\![\mathbf{x}]\!]$ which can be executed locally. The prover, who originally committed to $\mathbf{x}$ with c, can now do a polynomial commitment opening proof to show that $g(\beta)$ equals ρ. The other parties verify this evaluation proof, which, if valid, implies that the polynomial in $\mathcal{F}_{\text{ABB}}$ is (with high probability) equal to the one committed to with c. One caveat with this approach is that ρ reveals information about $\mathbf{x}$. We can overcome this by generating and committing to a random polynomial g_ω at the beginning of PoC.Check and use it to (additively) mask g. We can then evaluate and open $g(\beta) + g_\omega(\beta)$ which is now indistinguishable from random. The prover and verifiers proceed with the evaluation proof as before, but on the combined commitment of g and g_ω, using the homomorphic property of the polynomial commitment scheme. In the following, we provide a formal definition:

Protocol 4.2 (Consistency Check)**.** Let $\mathcal{F}_{\text{ABB}}$ be an instance of an ideal MPC functionality over a field $\mathbb{F}_p$, let $\mathcal{F}_{\text{RAND}}$ be an ideal functionality that returns a random element from $\mathbb{F}_p$ and let $\mathbf{x} = (x_1, \ldots, x_d) \in \mathbb{F}_p^d$ by the input of prover $\mathbb{P}$. Let $[\![\mathbf{x}]\!] = ([\![x_1]\!], \ldots, [\![x_d]\!])$ be the input of the prover $\mathbb{P}$ to $\mathcal{F}_{\text{ABB}}$. Let PC be a polynomial commitment scheme as in Definition A.2 [1] that is also homomorphic as in Definition A.4 [1]. The protocol Π_{cc} works as follows:

- $\mathsf{CC.Setup}(1^\lambda, d) \to \mathsf{pp}$: Run $\mathsf{pp} \leftarrow \mathsf{PC.Setup}(d)$, where d is the number of elements in the input.
- $\mathsf{CC.Commit}(\mathsf{pp}, \mathbf{x}, r) \to c$: The prover computes a polynomial commitment $c \leftarrow \mathsf{PC.Commit}(\mathtt{pp}, g, r)$ where g is defined as $g(z) = \sum_{i=1}^{d} x_i \cdot z^i$. The prover outputs c.

- $\mathsf{CC.Check}(\mathsf{pp}, c, [\![\mathbf{x}]\!]; \mathbf{x}, r) \to \{0,1\}$: The protocol proceeds as follows:
  1. The prover samples a masking value $\omega \xleftarrow{\$} \mathbb{F}_p$ and commitment randomness $r_\omega \xleftarrow{\$} \mathbb{F}_p$ and computes a polynomial commitment $c_\omega \leftarrow \mathsf{PC.Commit}(\mathsf{pp}, g_\omega, r_\omega)$ to a degree-0 polynomial $g_\omega(z) = \omega$. The prover sends c_ω to all parties and inputs ω to $\mathcal{F}_{\text{ABB}}$.
  2. The parties invoke $\mathcal{F}_{\text{RAND}}$ to obtain a random challenge $\beta \xleftarrow{\$} \mathbb{F}_p$.
  3. The parties invoke $\mathcal{F}_{\text{ABB}}$ to compute $[\![\rho]\!] := [\![\omega]\!] + \sum_{i=1}^{d} [\![x_i]\!] \cdot \beta^i$ and subsequently open ρ.
  4. The prover $\mathbb{P}$ generates a proof $\pi \leftarrow \mathsf{PC.Prove}(\mathsf{pp}, c + c_\omega, g + g_\omega, r + r_\omega, \beta, \rho)$ and sends π to each verifier $\mathbb{V}$.
  5. Each verifier runs $\mathsf{PC.Check}(\mathsf{pp}, c \cdot c_\omega, \beta, \rho, \pi)$. If verification passes, they output 1, otherwise 0.

Intuitively, security follows from the fact that if the committed polynomial is not equal to the polynomial evaluated on the secret shares, then the prover can only open the commitment to ρ with negligible probability. We provide a formal security proof in Appendix C (Lemma C.1). The protocol Π_{cc} can be extended to provide ID-Abort, denoted as $\Pi_{\text{cc [ID]}}$, by using a broadcast channel for the prover in Step 4 and using an MPC protocol that provides identifiable abort ($\mathcal{F}_{\text{ABB [ID]}}$).

Cost Analysis. Many polynomial commitment schemes have a constant storage overhead independent in the input size, resulting in each party having to store only a single, constant-sized commitment for each input vector. Our protocol can be instantiated with any homomorphic polynomial commitment scheme and inherits the efficiency profile of the underlying scheme. If instantiated with KZG polynomial commitments [49], we achieve a constant storage overhead independent of the input size and a constant verification time. Although the public setup parameters of KZG are of size $O(d)$, we can consider them as system parameters and reuse them for the input of each party [49]. Hence, our protocol only requires a storage overhead linear in the size of the input and the number of parties, i.e., $O(N+d)$. If used with an inner-product argument-based polynomial commitment, the commitment size could also be made constant (e.g., a single Pedersen Vector Commitment (PVC)). However, the verification time would be linear in the input size [11].

EC-MPC. Prior work has observed that most secret-sharing-based MPC protocols for finite field arithmetic generalize to arithmetic circuits involving elliptic curve points [70, 84]. Using such protocols with additional support for computations over an elliptic curve group $\mathbb{G}$ of order p (which we denote as $\mathcal{F}_{\text{ABB}}^{[\text{EC}]}$) when instantiating PoC offers a significant improvement to performance. Specifically, we can accelerate the execution of our PoC.Commit algorithm under secure computation (i.e., the creation of output commitments).

Batch verification Our protocol Π_{cc} allows the verifier to check the integrity of the prover's input by verifying one pairing equation. However, the verifier still needs to perform this check for each input party. We can optimize this further for KZG commitments by leveraging their homomorphic property [35, 49] (Definition A.4 [1]). Let $c_1, \ldots, c_N$ be the set of commitments and $\rho_1, \ldots, \rho_N$ the set of target evaluations for each prover $\mathbb{P}_1, \ldots, \mathbb{P}_N$ at a common random point $\beta \in \mathbb{F}_p$ from Step 3 of the consistency check. The verifier first computes a random linear combination of the commitments as $\tilde{c} := \sum_i^N \gamma^i c_i$ for a randomly sampled $\gamma \in \mathbb{F}_p$, as well as the corresponding evaluation $\tilde{\rho} =: \sum_i^N \gamma^i \rho_i$ and aggregate proof $\tilde{\pi} =: \sum_i^N \gamma^i \pi_i$. The verifier can then check this aggregated commitment using $\mathsf{PC.Check}(\mathsf{pp}, \tilde{c}, \beta, \tilde{\rho}, \tilde{\pi})$. This allows the verifier to check, in the optimistic case, only one pairing equation instead of N at the cost of a negligible statistical error. Security follows from the fact that the aggregated polynomial commitment $\tilde{c}$ will only agree with the aggregated evaluation point $\tilde{\rho}$ at a random point β with negligible probability due to the Demillo-Lipton-Schwartz-Zippel Lemma ([29]). If verification passes, this implies that all commitments open to the correct evaluation point with overwhelming probability. If verification fails, this must mean that at least one of the commitments is inconsistent with high probability. In this case, the verifier can proceed to check the commitments and proofs individually.

5 Auditing Functions

Until now, our discussion has centered around the cryptographic protocol that enables robust and secure audits of private models. We now focus on how we realize the audit functionality enabled by our framework. The algorithmic side of auditing for ML is an active area, and alternative instantiations that enable different properties exist or are actively being developed (see Table 2 for an overview). In our work, we focus

on post-hoc audits, specifically accountability (sample/party attribution), explainability (feature attribution), and robustness & fairness (certification). While Arc's design is highly extensible with additional auditing functionalities (similar to how we support a wide range of PPML systems), here we focus our discussion on auditing functions currently implemented in our framework. In Appendix G in the extended version of the paper [1], we provide a more detailed description of each function.

5.1 Robustness & Fairness

The community has devised a range of techniques to show that a model is robust against adversarial examples [37, 91], i.e., that the model is stable to small variations in the input. While *global* robustness guarantees are more naturally realized as a-priori checks, *local robustness* [24], which certifies that a model consistently produces the same prediction y for all inputs within a radius R around the original input x, naturally suits the post-hoc auditing setting we consider. In Arc, we adapt the algorithm proposed by Jovanovic et al. [46] for FHE to the MPC setting. The algorithm samples n perturbed inputs around the input x by adding Gaussian noise and obtaining predictions for these samples. Finally, a statistical check is conducted to assess whether the obtained prediction y remains invariant to these perturbations with high probability. The output of the auditing function is a boolean indicating whether the model is locally robust with confidence $1-\alpha$. We can extend the same technique to achieve fairness guarantees, as there is a well-established connection between robustness and individual fairness [32, 46, 76, 92]. It is sufficient to change the closeness metric of the sampling procedure to generate perturbed inputs that are close to x in terms of fairness (i.e., inputs that should be treated similarly have a small distance).

5.2 Accountability

We consider two flavors of accountability mechanisms that attribute responsibility for decision made by a model: *sample* attribution identifies the influence of individual data samples on a prediction, while *party* attribution merely provides the relative influence of each data owner's dataset, providing auditability while revealing less information. A variety of methods to identify the impact of individual data samples exist [39, 45, 52, 55, 81], however, some (e.g., influence functions [55]) require substantial computational resources (e.g., inverting the Hessian matrix of the loss function) which makes them prohibitively expensive under secure computation. In Arc, we leverage an approach using KNN-Shapley values [45], i.e., Shapely values of a KNN classifier on the training data's latent space representation. As there exists a closed-form formulation of the Shapley values for KNN [45], this allows an efficient MPC realization. For party attribution, Arc uses an efficient unlearning approach [64]. The key idea here is that if a suspicious prediction (x,y) was (at least partially) the result of data provided by a data owner, then excluding that party's data will lead to the absence (or weakening) of the suspicious prediction. Rather than recomputing leave-out models from scratch, we use an algorithm [64] that uses unlearning of the data of a party from the original model [81], which requires only a small number of training epochs until sufficient differences are detectable.

5.3 Explainability

A wide range of methods has been proposed to explain the predictions of complex models [62, 74, 82]. Of these, we consider additive feature attribution methods [62] as particularly suitable for privacy-preserving auditing as they provide an attractive trade-off between leakage and utility. These methods highlight which features of a prediction sample are most influential for the prediction, even for complex ML models. They achieve this by approximating the target model's behavior locally (around the given prediction) with a simple and explainable (e.g., linear) model. In Arc, we leverage KernelSHAP [62] to approximate the local decision boundary of the classifier, through a linear regression on the features. We sample points around the prediction sample and weigh them based on their distance to the sample as measured by the Shapely kernel. As a result, the regression coefficients directly correspond to the Shapley values of the features.

6 Evaluation

In this section, we evaluate the performance of Arc in the training, inference and auditing phases for different workloads and auditing functions. We evaluate the overhead of our protocol when instantiated with different approaches to the consistency layer PoC. For training and auditing, we focus on the MPC versions of our protocol, as these are the most established forms of verifiable ML computation.

Implementation. Our implementation is based on MP-SPDZ [50], a popular framework for MPC computation that supports a variety of protocols. We extend MP-SPDZ with protocols for share conversion and elliptic curve operations on the pairing-friendly BLS12-377 curve [12] provided by the `libff` library [23]. We use ECDSA signatures on the secp256k1 curve [17] for which a distributed signing protocol was previously implemented in MP-SPDZ [28]. For the evaluation proofs of the polynomial commitments, we use the implementation of the KZG polynomial commitment scheme [49] provided by Arkworks' `poly-commit` library [4]. We perform share conversion (cf. Appendix E [1]) to convert between $\mathbb{Z}_{2^{64}}$ and the scalar field $\mathbb{F}_{\text{BLS12-377}}$. The MPC computations for ML training, inference, and auditing functions are expressed in MP-SPDZ's domain-specific language. We rely on the higher-level ML primitives that MP-SPDZ provides that use mixed-circuit computation. Note that we perform exact truncation instead of probabilistic truncation

for fixed-point multiplication because the latter has recently been shown to be insecure [61].

To compare the performance of our consistency layer to other approaches (cf. 4.1), we additionally implement a version of PoC based on the SHA3-256 cryptographic hash function denoted by $\mathsf{PoC}_{\mathsf{SHA3}}$ that internally uses the Bristol-fashion circuit implementation of the Keccak-f sponge function [69]. We also implement a version $\mathsf{PoC}_{\mathsf{PED}}$ based on Cerebro [93] that uses Pedersen commitments by adapting the open-source implementation provided by the authors. We make the implementation of our protocol and the various consistency layers that we evaluate available as open-source[3].

Experimental Setup. We run Arc on a set of AWS `c5.9xlarge` machines running Ubuntu 20.04, each equipped with 36 vCPUs of an Intel Xeon 3.6 Ghz processor and 72 GB of RAM. For the BERT transformer model, we use `c5.24xlarge`, featuring 96 vCPUs of an Intel Xeon 3.6 Ghz processor and 192 GB of RAM, as it provides sufficient memory to fit the significantly larger model. The machines are connected over a local area network (LAN) through a 12 Gbps network interface with an average round-trip time (RTT) of 0.5 ms. We additionally perform our experiments in a simulated wide area network (WAN) setting using the `tc` utility to introduce an RTT of 80 ms and limit the bandwidth the 2 Gbps. We report the total wall clock time and the total communication cost in terms of the data sent by each party. This includes the time and bandwidth required for the online phase and the preprocessing phase that sets up the correlated randomness necessary for the MPC protocol. We also report the storage overhead for which we apply log scaling as the overhead varies significantly between different PoC approaches and settings. In experiments in the WAN setting and those involving maliciously secure protocols, we estimate the ML training operations based on 5 and 50 batches of gradient descent, respectively. For the BERT transformer model, we extrapolate further due to the significant size of the model and training data. For the related work, which has overhead linear in the size of the input, we also extrapolate results for some of the larger instances.

We evaluate the computational phases in the 3-party computation (3PC) setting with a maliciously secure-with-abort protocol that combines SPDZ-wise redundancy with replicated secret sharing over a 64-bit ring [27]. We also evaluate the performance of a semi-honest protocol based on replicated secret sharing. These protocols are representative of the most efficient MPC protocols in the malicious and semi-honest settings for ML workloads. We apply an optimization for the auditing phase that uses the fact that all inputs in this phase are authenticated using commitments. This allows us to optimistically use a security-with-abort protocol and, only, if the protocol aborts, restart the computation with a less efficient identifiable-abort protocol with the guarantee that this execution uses the same inputs. We choose the 3PC setting because it allows for the most efficient MPC protocols, favoring $\mathsf{PoC}_{\mathsf{PED}}$ and $\mathsf{PoC}_{\mathsf{SHA3}}$ whose Check relies more heavily on MPC computation. Other settings such as 2-party computation (2PC) or non-optimistically executing the auditing would require more expensive MPC protocols, resulting in a higher overhead for the computation. This would increase the relative overhead of the related approaches compared to ours.

	Storage	Prover Comp.	Verifier Comp.
$\mathsf{PoC}_{\mathsf{SHA3}}$	N	-	$d \cdot N$ (mpc)
$\mathsf{PoC}_{\mathsf{PED}}$	$d \cdot N$	-	$d \cdot N$ (local) $+ N$ (mpc)
Ours	N	d (local)	N (mpc)

Table 3: Asymptotic computational complexity (in big-O notation) and storage requirements of the consistency approaches we evaluate for a computation with N input parties each with d input elements. We differentiate between local and MPC computation. For $\mathsf{PoC}_{\mathsf{SHA3}}$, we consider Keccak-f operations. For $\mathsf{PoC}_{\mathsf{PED}}$ and ours, we consider group operations.

Scenarios. We evaluate four auditing functions from the previous section, (i) Robustness, (ii) Fairness (cf. §5.1), (iii) KNN-Shapley (cf. §5.2) and (iv) Kernel-SHAP (cf. §5.3), on the following models and datasets.

(W1:Adult): A logistic regression model with 3k parameters trained on the Adult [8] binary classification task for 10 epochs to predict whether a person's income exceeds $50k per year.

(W2:MNIST): A LeNet model consisting of 431K parameters, referred to as 'model C' in prior work [51, 87] trained on the MNIST image classification task [60] for 20 epochs.

(W3:CIFAR-10): A variant of AlexNet [59] as used in Falcon [88], comprising 3.9 million parameters trained on the CIFAR-10 image classification task [58] for 40 epochs.

(W4:QNLI): A BERT transformer model [30] with sequence length 128, comprising 85 million parameters, finetuned for one epoch on 2500 samples of the Stanford Question Answering reading comprehension dataset [73, 89].

6.1 Evaluation Results

We evaluate the overhead that Arc imposes on the training, inference and auditing phases. The main overhead of the consistency layer in training and inference consists of two parts: Verifying the inputs of the computation using PoC.Check and, afterwards, computing the output commitments using PoC.Commit. Other components, such as those related to the signatures are negligible in comparison: distributed signing takes at most 300ms for the WAN and verifying a signature is a local operation taking 1ms. Clients only have to store a single ECDSA signature of 64 bytes for the model owner and each data owner, and a joint signature of 64 bytes for the

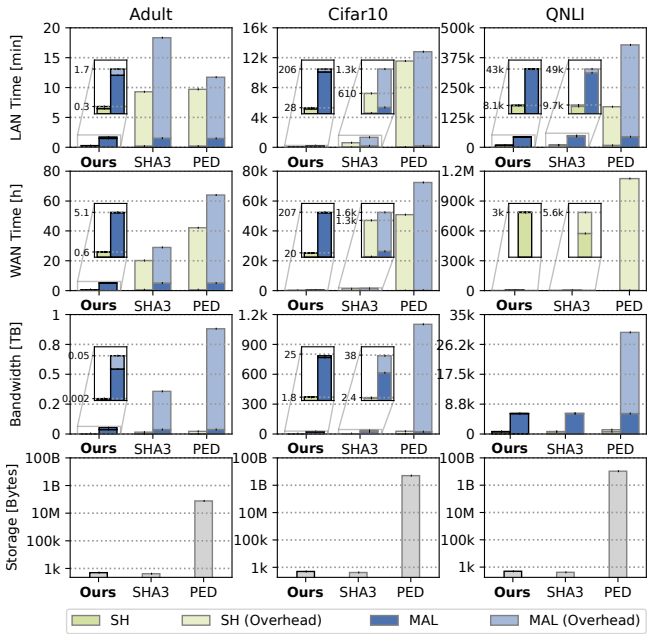

Figure 4: Evaluation of Arc comparing the approaches relative to a single epoch of PPML training.

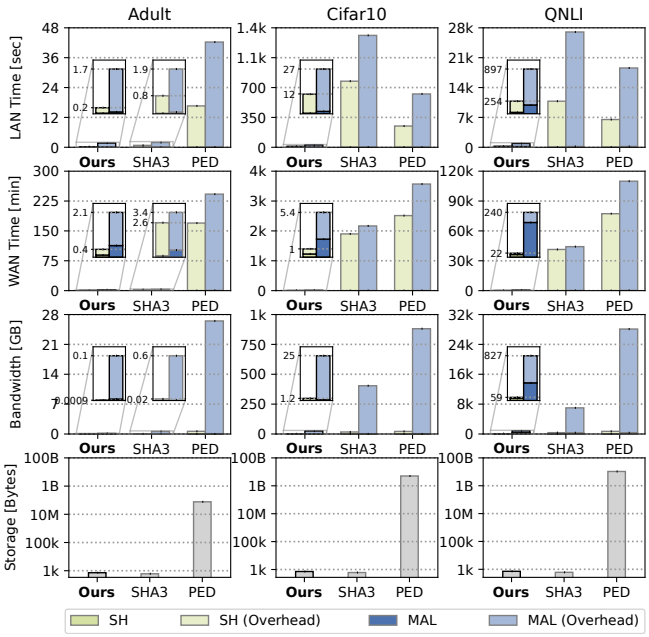

Figure 5: The overhead of our system's consistency protocol relative to a single PPML inference for our three scenarios.

inference computers and the training computers. We provide an analysis of the asymptotic complexity of the different approaches in Table 3 and focus on the concrete performance numbers for the rest of this section.

Training. We show the wall-clock time and bandwidth of a single training epoch in Fig. 4, differentiating between the overhead induced by our framework and the cost of the underlying PPML training. In total, PPML training (W1:Adult) takes 119 seconds, with consistency adding 5 seconds for ours, 545 seconds for $\mathsf{PoC}_{\mathsf{SHA3}}$, and 570 seconds for $\mathsf{PoC}_{\mathsf{PED}}$. For (W2:MNIST), this is 123 minutes (+ 1.3 minutes, 2.9 hours, or 22 hours), for (W3:CIFAR-10), 15 hours (+ 4.1 minutes, 9.8 hours, or 8 days), and for (W4:QNLI), this is 5.4 days (+ 11 minutes, 1.1 days, or 16 weeks), in the semi-honest LAN setting. We refer to Appendix F [1] for a full report of end-to-end training results and further results for (W2:MNIST) which have been omitted here due to space constraints. Note that we do not evaluate (W4:QNLI) training in the malicious WAN setting, as this is beyond the current state of the art for PPML. Since the bandwidth overhead is not significantly affected by network delays, we only present the bandwidth results once. As storage is, additionally, also independent of the chosen MPC protocol, we do not differentiate between semi-honest and malicious settings for storage.

We observe that the overhead of the baseline approaches varies significantly for training. The timing overhead induced by $\mathsf{PoC}_{\mathsf{PED}}$ is 66-500x compared to training but only 0.1-26x with $\mathsf{PoC}_{\mathsf{SHA3}}$ in the LAN setting. In the WAN setting the relative overhead further increases to at most three orders of magnitude because of the large number of MPC round-trips required to compute the operations related to hash functions and elliptic curve operations. In comparison, our consistency check protocol, which outperforms the related approaches across all configurations, introduces only 0.001-1.35x overhead in the LAN and less than 1.02x in the WAN setting. This is because our protocol features more local computation than MPC computation and is therefore less impacted by the slowdown induced by network delays. Overall, we conclude that the overhead of our approach, and also of $\mathsf{PoC}_{\mathsf{SHA3}}$, is effectively negligible in the context of PPML training. In contrast, we observe that the $\mathsf{PoC}_{\mathsf{PED}}$ approach is infeasible for all but the simplest models. The primary cost of $\mathsf{PoC}_{\mathsf{PED}}$ is the time required to compute the individual Pedersen commitments to the model parameters; the overhead during verification is much smaller as this only involves computing a commitment for each of the three input parties. Finally, the bandwidth and storage required for $\mathsf{PoC}_{\mathsf{PED}}$ are significant as it needs to commit to each input element individually. Meanwhile, the storage overhead of our approach is independent of the dataset and model sizes and similar to that of the hash-based approach with 496 bytes compared to 416 bytes for $\mathsf{PoC}_{\mathsf{SHA3}}$.

Inference. Model inference is a significantly smaller operation than training, resulting in a larger relative consistency overhead As shown in Fig. 5, the consistency operations are at least an order of magnitude slower than the inference itself, even for our approach. However, in absolute numbers, the overhead introduced by our approach is very small across all configurations, ranging from a few seconds to a few minutes for the large transformer model. In contrast, the overhead for $\mathsf{PoC}_{\mathsf{SHA3}}$ quickly becomes prohibitive for all but the smallest

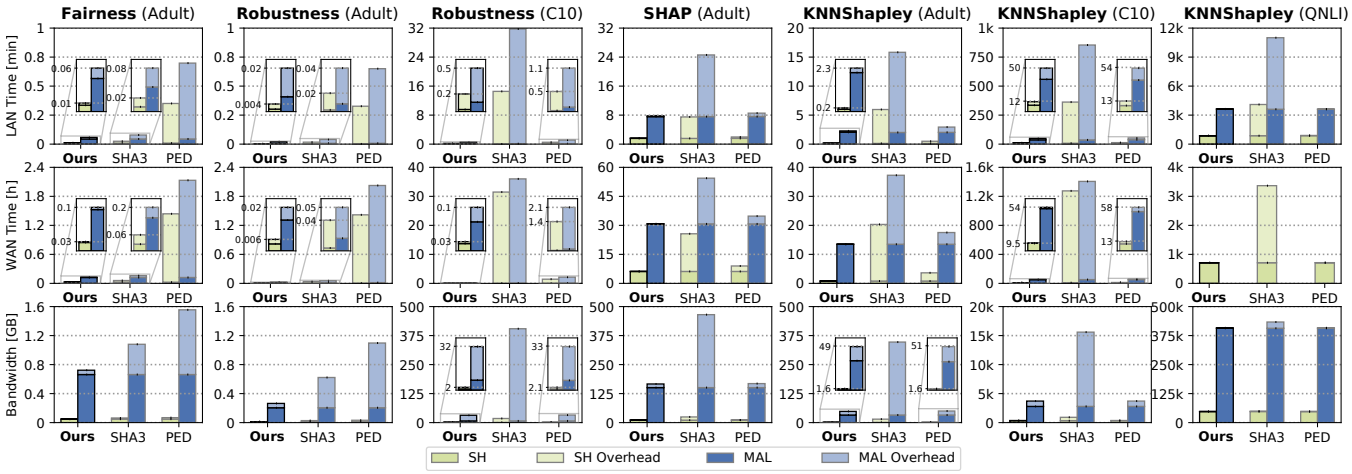

Figure 6: The overhead of Arc's consistency layer relative to the cost of the auditing function computation in MPC for four different auditing functions across our three scenarios.

models, already requiring over thirty hours in the WAN setting for a single (W3:CIFAR-10) inference. $\mathsf{PoC}_{\mathsf{PED}}$ outperforms $\mathsf{PoC}_{\mathsf{SHA3}}$ in some cases, it induces similarly prohibitive overheads across all configurations.

A significant fraction, 35-66%, of the overhead in our approach is the result of the share conversion from the PPML protocol's computation domain $\mathbb{Z}_{2^{64}}$ to the scalar field domain $\mathbb{F}_{\text{BLS12-377}}$. The conversion requires a bit decomposition and re-composition for each input parameter which is expensive and scales linearly in the input size. Although this overhead is significant, it is small concretely, with 25 seconds in the active security setting for (W3:CIFAR-10). In the case that lower latency is required, the $\mathbb{Z}_{2^{64}}$ secret shares of the model can be cached on the inference servers after a single conversion to $\mathbb{F}_{\text{BLS12-377}}$ and verification with PoC.Check. When scaling to larger models, $\mathsf{PoC}_{\mathsf{PED}}$ and $\mathsf{PoC}_{\mathsf{SHA3}}$ become prohibitively expensive concretely with a 250-6000x slowdown compared to a single inference. As in training, we observe that the storage required for the client receipts is comparable for our approach and $\mathsf{PoC}_{\mathsf{SHA3}}$, resulting in only 720 bytes and 608 bytes, respectively, per prediction. Most importantly, these are independent of the model and training data size. Meanwhile, $\mathsf{PoC}_{\mathsf{PED}}$ requires storage that is linear in the number of input elements, e.g., requiring 5GB for (W3:CIFAR-10) and 11GB for (W4:QNLI). This results in $\mathsf{PoC}_{\mathsf{PED}}$ inducing prohibitive storage requirements for all but the simplest models.

Auditing. We present the wall-clock time and bandwidth overhead for different auditing functions in Fig. 6. Note that we do not evaluate auditing on (W4:QNLI) for the malicious WAN setting, as the complexity of evaluating auditing functions on such a complex model in this setting is pushing the boundaries of what is possible with current PPML techniques. Across all settings, Arc significantly outperforms related approaches in terms of runtime, with a storage overhead comparable to the hash-based approach. As we move to larger input sizes, for instance in the case of KNN-Shapley that considers the full training dataset, the main cost of our approach after share conversion is the multi-scalar multiplication (MSM) required to compute the opening proof of the polynomial commitment. Each prover party must compute an MSM that is linear in the size of its input. Due to the properties of KZG, the other parties only have to check one pairing equation per prover, which we can further reduce to a single pairing equation due to the batch verification (c.f. §4.2). We also observe that, for larger models, $\mathsf{PoC}_{\mathsf{PED}}$ outperforms $\mathsf{PoC}_{\mathsf{SHA3}}$ and approaches the performance of our approach. This is primarily because there is no need for computing and storing commitments to the output during the auditing phase, sidestepping the major weaknesses of the $\mathsf{PoC}_{\mathsf{PED}}$ approach. In fact, as model sizes increase, the high constant overhead of the Pedersen commitments becomes less noticeable. However, our approach continues to outperform $\mathsf{PoC}_{\mathsf{PED}}$ both asymptotically (cf. Table 3) and also concretely across all configurations.

In conclusion, we observe that our approach outperforms the related work both asymptotically and concretely across all configurations. While $\mathsf{PoC}_{\mathsf{PED}}$ and $\mathsf{PoC}_{\mathsf{SHA3}}$ approach the performance of our solution in some phases (for certain configurations), they remain prohibitively expensive from an end-to-end perspective. Meanwhile, we demonstrate that Arc instantiated with our efficient PoC protocol is highly practical across a wide range of settings, including scaling up to large and complex models that push the boundary of the current state of the art in privacy preserving machine learning.

C Consistency Check

In the following, we proof that our approach (Π_{cc}) fulfills the properties for a Proof-of-Consistency (Definition 4.1), which are defined below. We then provide formal definitions for the strawman constructions discussed in §4.1. In addition, we briefly discuss how to efficiently realize $\mathcal{F}_{\text{ABB}}^{[\text{EC}]}$ for Pedersen Vector Commitments.

A valid Proof-of-Consistency as in Definition 4.1 satisfies the following properties:

- **Correctness:** If $[\![\mathbf{x}]\!]$ is a valid input of $\mathbf{x}$ to $\mathcal{F}_{\text{ABB}}$ and c is a valid commitment to $\mathbf{x}$ computed as $\mathsf{PoC.Commit}(\mathsf{pp}_{\mathsf{poc}}, \mathbf{x}, r)$ for all public parameters $\mathsf{pp}_{\mathsf{poc}} \leftarrow \mathsf{PoC.Setup}(1^{\lambda}, d)$ and randomness $r \xleftarrow{\$} \mathcal{R}$, then $\mathsf{PoC.Check}(\mathsf{pp}_{\mathsf{poc}}, c, [\![\mathbf{x}]\!]; \mathbf{x}, r) = 1$ with overwhelming probability.
- **Soundness:** If there exists no $\mathbf{x}$ such that $\mathcal{F}_{\text{ABB}}$ holds $[\![\mathbf{x}]\!]$ and $c = \mathsf{PoC.Commit}(\mathsf{pp}_{\mathsf{poc}}, \mathbf{x}, r)$ for all public parameters $\mathsf{pp}_{\mathsf{poc}}$ and for randomness $r \xleftarrow{\$} \mathcal{R}$, then for all $\lambda \in \mathbb{N}$, and for all polynomial-time adversaries $\mathcal{A}$ on input $(\mathsf{aux}_{\mathcal{A}}, [\![\mathbf{x}]\!], r, c))$, the probability that $\mathsf{PoC.Check}(\mathsf{pp}_{\mathsf{poc}}, c, [\![\mathbf{x}]\!]; \mathbf{x}, r) = 1$ is negligible in λ.
- **Zero-knowledge:** For every probabilistic polynomial-time interactive machine $\mathbb{V}'$ that plays the role of the verifiers, there exists a probabilistic polynomial-time algorithm $\mathcal{S}$ such that for any $[\![\mathbf{x}]\!]$, randomness r and $c = \mathsf{PoC.Commit}(\mathsf{pp}_{\mathsf{poc}}, \mathbf{x}, r)$ the transcript of the protocol between $\mathbb{V}'$ and $\mathbb{P}$ and the output of $\mathcal{S}$ on input ($[\![\mathbf{x}]\!]$, r, c) are computationally indistinguishable.

We now prove that our protocol for input consistency satisfies these properties.

Lemma C.1. Π_{cc} is a Proof-of-Consistency (Definition 4.1).

Proof. The protocol Π_{cc} in Protocol 4.2 satisfies the properties of a PoC:

- **Completeness:** From the correctness of the MPC protocol, it holds that $\rho = \omega + \sum_{i=1}^{d} x_i \cdot \beta^i$. Further, the opening proof of the polynomial commitment $(c \cdot c_\omega)$ also evaluates to ρ at β due to the homomorphic property of the scheme. The verifiers accept because of the completeness of the polynomial commitment scheme.
- **Soundness:** Let ω be a random value, $\hat{f} = f + f_\omega$ be the polynomial defined as in the protocol as $\hat{f}(z) = \omega + \sum_{i=1}^{d} x_i \cdot z^i$, let $[\omega]$ be a secret-sharing of ω and let $[\mathbf{x}]$ be a secret-sharing of $\mathbf{x}$. If the verifiers do not hold a valid secret-sharing $[\omega]$ or $[\mathbf{x}]$, then the MPC protocol in Step 3 aborts. Otherwise, the correctness of the MPC protocol guarantees that a valid secret-sharing of $[\omega]$ and $[\mathbf{x}]$ implies that ρ equals $\omega + \sum_{i=1}^{d} x_i \cdot \beta^i$ and that $\hat{f}(\beta) = \rho$ or the protocol aborts. Let c' be a polynomial commitment such that $c' \neq \mathsf{PC.Commit}(\mathtt{pp}, \hat{f}, r + r_\omega)$. Then, from the polynomial binding property of the polynomial commitment scheme, either c' is a commitment to a different polynomial f' or the verifiers reject the proof in Step 5 with overwhelming probability. In the case that c' is a commitment to a different polynomial f', the verifiers only accept $\mathsf{PC.Check}(\mathsf{pp}, c', \beta, \rho, \pi)$ if f' agrees with $\hat{f}$ at point β because of the evaluation binding property of the polynomial commitment. Because β was sampled uniformly at random, from the Demillo-Lipton-Schwartz-Zippel Lemma [29], it holds that:

$$\Pr\left[\mathsf{PC.Check}(\mathsf{pp}, c', \beta, \rho, \pi) = 1\right] \leq \frac{d}{p} \ ,$$

  which can be made negligible by choosing a suitably large p. Thus, the verifiers reject with overwhelming probability.
- **Zero-knowledge:** The simulator $\mathcal{S}$ works as follows: It samples d random coefficients that define the polynomial f and one random coefficient to define the polynomial f_ω. Then, it samples a random point $\beta \xleftarrow{\$} \mathbb{F}_p$ and runs the MPC simulator to produce the transcript for the computation of ρ. Finally, it samples $r, r_\omega \xleftarrow{\$} \mathbb{F}_p$ and computes $c = \mathsf{PC.Commit}(\mathsf{pp}, f, r)$, $c_\omega = \mathsf{PC.Commit}(\mathsf{pp}, f_\omega, r_\omega)$ and $\pi = \mathsf{PC.Prove}(\mathsf{pp}, c \cdot c_\omega, f + f_\omega, r + r_\omega, \beta, \rho)$ and outputs $(c, c_\omega, \pi, \rho, \beta)$. The indistinguishability with the real execution follows from the fact that ρ is uniformly distributed in $\mathbb{F}_p$ because of ω, the properties of the MPC protocol and the hiding property of the polynomial commitment scheme.

Secure Account Recovery for a Privacy-Preserving Web Service

Ryan Little
Boston University

Georgetown University

Mayank Varia
Boston University

Abstract

If a web service is so secure that it does not even know—and does not want to know—the identity and contact info of its users, can it still offer account recovery if a user forgets their password? This paper is the culmination of the authors' work to design a cryptographic protocol for account recovery for use by a prominent secure matching system: a web-based service that allows survivors of sexual misconduct to become aware of other survivors harmed by the same perpetrator. In such a system, the list of account-holders must be safeguarded, even against the service provider itself.

In this work, we design an account recovery system that, on the surface, appears to follow the typical workflow: the user types in their email address, receives an email containing a one-time link, and answers some security questions. Behind the scenes, the defining feature of our recovery system is that the service provider can perform email-based account validation without knowing, or being able to learn, a list of users' email addresses. Our construction uses standardized cryptography for most components, and it has been deployed in production at the secure matching system.

As a building block toward our main construction, we design a new cryptographic primitive that may be of independent interest: an oblivious pseudorandom function that can either have a fully-private input or a partially-public input, and that reaches the same output either way. This primitive allows us to perform online rate limiting for account recovery attempts, without imposing a bound on the creation of new accounts. We provide an open-source implementation of this primitive and provide evaluation results showing that the end-to-end interaction time takes 8.4-60.4 ms in fully-private input mode and 3.1-41.2 ms in partially-public input mode.

Content Warning: *This paper discusses, at a high level, the issue of sexual assault on college campuses, particularly in Section 1. From Section 3 onward, the paper is more focused on the technical design of the account recovery protocol.*

1 Introduction

Account recovery—the ability for users to regain access to their accounts after losing their password—is a near-ubiquitous feature of account-based web services. However, the typical account recovery system is not private, and relies on the web service to retain some information about the existence of an account under some identity (e.g., a username or email address). In this work, we designed an account recovery process to be compatible with a secure matching system operated by a nonprofit organization, Callisto, that uses conventional account recovery workflows but does not retain any plaintext information about a user's email address, username, security questions, or security answers. As of October 2023, this protocol has been deployed by Callisto for their matching system, which is currently available on college campuses across the United States.

We discuss the application space of secure matching systems to provide context for this work, and then elaborate on the challenge of account recovery in this setting and provide details about our protocol. While this protocol was designed to support Callisto's secure matching system, our cryptographic techniques are generic and may also be used independently by other web services that want to enable account recovery without collecting personal information about users.

Overview of secure matching systems. Secure matching systems are cryptographic tools that intend to support survivors of sexual assault by connecting them with one another. Although statistics may be difficult to capture, there is evidence that sexual assault is highly prevalent on college campuses, in particular. A 2019 study across 33 universities found that 13% of students experienced sexual assault while enrolled [21]. Due to mandatory reporting policies that limit survivors' control over their own narratives, victim-blaming, fear of retaliation, and other barriers, survivors rarely formally report incidents of sexual assault [32, 37, 55]. For those who do, survivors may experience retraumatization through interactions with the police and/or the legal system and may ulti-

mately feel failed by formal avenues of pursuing justice [54]. Inspired by the #MeToo movement, secure matching systems [6, 39, 48, 49, 61] allow survivors of sexual assault to document their experiences and securely connect with other survivors who have been harmed by the same perpetrator to seek mutual support and explore different pathways either collectively or individually, since healing and seeking justice may look different for each survivor.

Callisto is a nonprofit organization that currently deploys a free secure matching system across college campuses in the United States [14]. Callisto allows survivors of sexual assault to document details of their assault in an encrypted record (for potential future use) and participate in matching with other survivors. If two or more survivors match by providing identifying information about the same perpetrator, contact information for each survivor is revealed to a legal options counselor (a lawyer) so that rather than being cryptographically protected, the same information is then protected by attorney-client privilege [15]. Prior to a match, information about both a survivor and perpetrator is not accessible to Callisto. Once connected to a legal options counselor, survivors are then offered the opportunity to connect with one another. Upon connecting, they may choose to collectively pursue legal justice, restorative justice, or nothing at all. Matching enables survivors to seek support from a legal options counselor and one another to explore options (individually or collectively) for action, ideally providing each survivor more support when decision-making about their options for pursuing further action, should they want to.

The challenge of account recovery. In standard account recovery processes, the service provider typically stores an email address that it uses for validation and to share a link that allows a user to regain access to their account. Since contact information about a survivor may reveal sensitive information (in our setting, whether an individual is a survivor of sexual assault), privacy-respecting service providers like Callisto cannot store any contact information about its users. Maintaining a list of account-holders creates a sensitive and valuable asset that may be targeted by bad actors. It may also create vulnerability toward legal threats, through subpoenas for information about account holders. Hence, a secure matching system must protect both *data* and *metadata*—even against the service provider itself, or anyone who might attempt to compromise it. In more detail:

1. All data submitted by survivors must be encrypted with a key derived from the user's password, so that the service cannot access user-submitted information (e.g. identifying information about a user, details of their assault) until they have reached the matching threshold. This cryptographic problem has been addressed in prior works [6, 39, 48, 49, 61] with general-purpose secure multi-party computation (MPC) and specific primitives like oblivious pseudorandom functions, group signatures, and verifiable secret sharing.
2. Additionally, the service provider must not have (or even have a simple way to recover) a list of all account-holders, since even the fact of a survivor using the system is extremely sensitive. On its own, this problem can be addressed using cryptographically oblivious login mechanisms (e.g., [45]), along with network and systems security precautions supporting anonymous communications and not keeping long-term logs that could later be exfiltrated by a hacker or compelled by an authority.

When addressing these two requirements together, one runs into a practical challenge: *what happens if an account-holder forgets their password*? This issue is inevitable in a system where strong, unique passwords are encouraged but logins are infrequent, and by default it would make all of the user's encrypted data irrecoverable.

In a typical website, account recovery involves the service provider sending an email to the email address on file; however, this is incompatible with our no-metadata requirement. Even federating the email address list and the delivery of emails among multiple servers using secure multi-party computation [1, 38, 64] is insufficient for our needs because it is slow, difficult to implement, and (most importantly) is still vulnerable to the risk of all servers being compelled to disclose their secret shares of the email list.

1.1 This work

In this work, we describe the design of an account recovery system such that a web service provider (like Callisto) *does not store email addresses, and cannot easily provide a list of all email addresses even if compelled to do so (e.g., through a subpoena).*

Protocol design. At a high level, our cryptographic protocol involves a client who (if honest) wishes to regain access to their account, along with a collection of recovery servers. The protocol uses email validation and a set of security questions/answers to determine whether the client should be given access to the account. Only the client recovers the cryptographic key that protects their account data; the recovery servers never see the security answers or key material.

In more detail, our protocol has two phases: some work is performed during *account creation* when the client knows their password and cryptographic key material, and subsequently the client can run an *account recovery* procedure if they forget the password and associated key. The recovery procedure itself contains three parts: request, verification, and restoration. First, the client requests recovery by (obliviously) providing their email address and responses to any generic questions (e.g., a phone number). Second, the servers verify that the client has control of this email address. Third, the servers fetch the client-specific security questions; the client's

answers to these questions can be used to restore access to their account.

Design requirements. Our protocol is grounded in the framework of trauma-informed design that acknowledges the impact trauma may have on the user experience and seeks to avoid retraumatization [15, 25, 63]. When designing an account recovery process that is trauma-informed in this setting, the user's interactions with the process must be familiar and easy to use: in particular, it must adhere to an expected account recovery workflow (e.g., "click on a link"), run seamlessly in a web browser, and not impose any restrictions or rate-limiting of legitimate uses.

On the back-end, our protocol had to accommodate the resource constraints of Callisto. For ease of deployment and maintenance on the web, the recovery servers must run on commodity hardware and the protocol must only use standard public and symmetric key cryptography in widely used and available software libraries.

Our protocol has been implemented and tested, and as of October 2023 is running live in production within Callisto's secure matching system. It uses only the cryptographic primitives that were already in place for Callisto's existing matching process, for ease of development and maintenance. However, we emphasize that our account recovery protocol is independent of Callisto's services; it is generic and can be used by any privacy-respecting website that desires not to keep personally-identifiable logs about their users.

Security guarantees. Our protocol provides security against three types of attackers. As with account recovery in other web services, email validation is our main security protection against external attackers. If an attacker has additionally compromised some of our recovery servers, they must still perform an online dictionary attack to obtain any email address, which we rate-limit through honest recovery servers. Finally, even if all of the recovery servers are compromised then an offline dictionary attack is still needed—which is not impossible, but onerous enough to allow Callisto to defend itself against legal compulsion of the email list.

The challenge of rate-limiting. Beyond standard symmetric key crypto primitives and a slow hash function, the only crypto primitive that we require is an *oblivious pseudorandom function* (OPRF). The client independently interacts with each server to compute an OPRF for two distinct reasons: (a) to hide the client's email address, contact information, and security answers from the recovery servers, and (b) as part of our rate-limiting mechanism, whereby an honest recovery server can detect and stop a brute-force dictionary attack of contact information or security answers.

The idea of using an OPRF for rate-limiting is not new. Several prior works have designed *partially* oblivious pseudorandom functions (pOPRFs) where the server publicly sees some information about which account is being accessed. This approach can aid in rate-limiting (e.g., [33, 67]).

However, rate-limiting in our context is challenging. This is because we need to hide the contact info and security answers during *both* account creation and recovery, but we want rate-limiting *only* in account recovery. Account creation is a delicate moment for a survivor, and we do not want to risk re-traumatizing them by denying signups due to rate-limiting.

K-pop: a new type of OPRF. As a result, in this work we design a new kind of primitive that can operate either as a pOPRF or as an OPRF. Identical outputs are produced in either mode. During account creation, we desire a pOPRF that uses a fresh public nonce as input, so that the servers are assured that this PRF query is for a new account and therefore do not need to impose rate-limiting. During account recovery, we desire a standard OPRF to hide which account is being accessed; hence, only here is rate-limiting needed.

We call this new primitive a *kaleidoscopic partially oblivious PRF*, or K-pop. In this work, we provide a formal definition of a K-pop along with a construction from any group where the Discrete Diffie-Hellman assumption is hard (e.g., elliptic curve groups), in the random oracle model.

1.2 Our contributions

In summary, this work provides three contributions.

First, we contribute a new primitive called a *kaleidoscoping partially oblivious PRF*, or K-pop. This function can be calculated either as an OPRF or pOPRF, and reaches the same result either way. We construct a K-pop without bilinear maps and provide an open-source implementation of this construction.

Second, we use the K-pop in order to construct an interactive protocol for account recovery where even the service provider does not require, and does not learn, the email addresses of its account-holders. This construction uses only standard public and symmetric key primitives that are available in many crypto libraries. This construction has been developed, tested, integrated, and deployed within Callisto's matching system.

Third, we provide two proofs of security of our account recovery protocol: a game-based security analysis against static adversaries, and a universally composable (UC) security [18] analysis against adaptive adversaries. In both analyses, a key challenge is to ensure security up to abort against malicious adversaries, but while avoiding the use of zero knowledge proofs (and therefore, also avoiding verifiable OPRFs).

1.3 Ethics and limitations

The question of whether a new technology is even needed and appropriate must be determined in consultation with subject-matter experts and in partnership with relevant communities.

Since these systems are intended to support survivors of sexual assault, designing any cryptosystem (new or otherwise) should only be done if deemed necessary and useful to survivors. *Development of this account recovery protocol was specifically requested by Callisto*, based on their users' needs.

We wish to stress the importance of developing technology through a trauma-informed lens that minimizes the risk of retraumatization. Lack of account recovery may exacerbate existing trauma as it prevents survivors from accessing prior information they had submitted. This may produce feelings of loss of control as personal details about sexual violence they had experienced are rendered inaccessible. Reactions to trauma, such as heightened anxiety and hypervigilance, can also impact survivors' interactions with technology [25]. It is therefore critical that an account recovery process is familiar and easy to use so as to not increase survivors' cognitive burden. When creating this account recovery process, we worked extensively with Callisto to make sure that the design would meet their technical constraints and also enable them to use a common and familiar user interface on the front end. As part of our ongoing work together, we have been in regular communication with Callisto about the publication of this work, which they are supportive of.

Both our problem formulation and our proposed solution have important limitations. First, our threat models are tailored to the specific needs of Callisto. Assumptions made in some of our threat models, such as honest server behavior during account creation and a non-colluding set of servers, may not be reasonable for other web services. Second, implementing our protocol necessarily increases the attack surface of the web service. A security bug in implementation could expose user information and put vulnerable users at risk. Third, providing stronger anonymity on the Internet may not always be a desirable goal, and we stress the importance of working with domain experts to determine the appropriate balance between any privacy technology and other social principles, policy objectives, or legal requirements in the context of a particular web service.

Lastly, our work does not address the structural barriers that make it difficult for survivors of sexual assault to find support and seek their own pathways toward accountability and healing. We note the significant barriers survivors face in addressing harms due to victim-blaming and institutional failures. Our protocol, and secure matching systems in general, are not solutions to this root problem, but nevertheless may be helpful to some survivors when navigating their options.

2 Technical Overview

In this section, we provide an informal summary of the technical contributions in this work. We begin by detailing the system setup, threats considered, and rationale for our design choices. Then, we describe our K-pop and account recovery constructions and explain how they build upon prior work.

2.1 Design principles and threat model

In this section, we take a deeper dive into the security threats and design considerations that influence our protocol design.

System setup. The account recovery system contains two types of actors: one or more clients who possess user accounts in the system, and a collection of N servers who participate in account recovery. The design follows the 'anytrust' paradigm in which only one server needs to be honest to provide the strongest security, and it also provides some meaningful security guarantees even if all N servers are compromised. Here, an honest server has two responsibilities: not sharing its OPRF secret key with the other servers, and properly enforcing rate limits on requests from clients and the other servers. All network communications are protected using TLS, and the adversary is presumed to have some amount of network control but not a fully global view—for instance, we presume that the adversary does not have full visibility or control of the client's email service provider.

Design principles. In this section, we expand upon the design requirements discussed in §1.1. Then, we describe some design accommodations that were deemed acceptable in our setting by our team and Callisto. While admittedly some of these principles are specific to our specific tech transition, nevertheless we believe that many of our design principles—and the motivations behind them—may generalize to other web services that want private account recovery.

As discussed in §1.3, our account recovery system is designed for survivors of sexual assault who may be using the system while having just experienced trauma. It is essential that any technology that is built is trauma-informed and is designed to account for these experiences to avoid retraumatization. Since user accounts for Callisto's matching system contain personal information that may include details about sexual assault, it is imperative that survivors are able to access their accounts quickly and seamlessly. Therefore, an account recovery process must be easy and familiar for survivors to use. As such, we designed a protocol to be compatible with a front-end user experience that is common to account recovery: a user enters their email along with additional contact information and receives security answers they must respond to. Survivors should not be burdened with learning new mechanisms that are complicated or unfamiliar. Trauma-informed design principles such as *safety* and *trust* [63] are pursued by creating an account recovery process that operates in a predictable manner while respecting the privacy of the user's personal information.

We impose three server-side requirements. First, the recovery servers must run on commodity machines without making any specific assumptions about the hardware. These constraints are common in many web applications on the cloud, and in particular we rejected the use of trusted hardware due

to concerns about cost, challenges with upgrades and maintenance, and security vulnerabilities (e.g., [13,23,34,51,52,68]). Second, to simplify software development and maintenance, the recovery servers must only use common crypto primitives with widely-used software libraries. In particular, we avoided the use of pairing-based cryptography since these libraries are less widely available in deployment settings and less understood by the general software engineering community. Third, for ease of deployment, the recovery servers must be able to communicate independently with the client (e.g., to execute separate instances of the OPRF protocol) rather than with each other; that said, they can maintain joint state like a counter acting as a nonce.

On the flip side, a non-collusion assumption in the anytrust setting was deemed acceptable if it provides defense-in-depth such that no collection of all-but-one recovery servers (or the engineers who administer them) can recover email addresses. Moreover, we deemed it to be acceptable if the recovery servers learn the client's email address at the moment of account creation for two reasons: (a) the website's onboarding process already involves sending an email at the moment of account creation, and (b) the main threat was deemed to be bulk, retrospective extraction of already-registered accounts rather than the smaller set of accounts created or recovered during the interval of server compromise.

We remark that it is possible to protect addresses even during the act of email delivery by using MPC for TLS [1,64], but even that would not prevent against a different threat: one of compulsion. Due to our focus on trauma-centered design and ensuring that the secure matching system itself could not be used to harm survivors, it was important to consider the possibility that all servers become under control of a single adversary through technical or legal means, and even then to avoid a large-scale breach of users' identity and data.

Threats and security guarantees. We require that the account recovery system provide correctness (up to abort) and privacy against three types of malicious adversaries. We emphasize upfront that this work focuses on threats and mitigations at the cryptographic level. As stated in §1.3, this work does not impose any new barriers to an adversary's ability to exploit a web service; instead, we seek to mitigate the damage of an adversary who controls some or all recovery servers.

1. An *external adversary* who interacts with the recovery system protocols (but lacks control of any recovery server) should be unable even to determine whether any email address they do not control corresponds to an account in the system. Looking ahead, our account recovery protocol achieves this goal by not providing any information to the client to determine whether an email address matches an account in the system—at least, not until the moment that an honest client receives an email in her inbox.
2. An *internal adversary* who has compromised some of the recovery servers must be restricted from performing a brute-force attack of email addresses. The threat here is that an internal adversary might conduct a probing attack in which it pretends to be a client, submits a variety of different email addresses, and uses its insider access to determine whether an account exists by observing whether an email is sent out to the victim. We address this threat in two ways: first to require some additional information beyond the email address even at the first step of recovery request, and second to have the honest server(s) perform online rate limiting of the attacker. In particular, we intentionally avoid providing any deterministic function of the client's data to an individual server, because that could be used to perform an offline dictionary attack.
3. A *legal adversary* that subpoenas all recovery servers must still need to execute a (now inevitable) offline brute-force attack to learn any account information, and furthermore they must be required to perform a brute-force attack after the last server has been compromised. Looking ahead, our recovery request and account restoration protocols provide this guarantee through their use of a slow, password-based hash function to make offline dictionary attacks slower and more costly. Moreover, the slow hash function requires the outputs of the K-pop, which prevents so-called "pre-computation attacks" [45] and ensures that the expensive offline attack must occur after the servers are corrupted.

Finally, all of these security properties must hold even against honest clients who have performed account recovery or changed their security questions, potentially several times. Looking ahead, our account recovery protocol uses client and server nonces to ensure domain separation of the space that must be brute-forced before vs. after an account reset.

2.2 Our model of account recovery

Our account recovery protocol has 4 procedures: account creation and the 3 parts of account recovery (plus a simple initialization step for the servers to generate their cryptographic keys). We presume the client (who we call Alice) already has a web account with a key k_u (e.g., derived from her password) that is used for encryption of her account data at rest.

Account creation. The client Alice begins this procedure with her user account key k_u, and the goal is for her to prepare and upload some cryptographic material that facilitates later recovery of k_u. Specifically, she (obliviously) provides her account's email address E, responses to additional generic questions like her phone number x, a set of personalized security questions Q together with their corresponding answers A and a recovery email address e where she would like to be

contacted if recovery is needed (this can, but does not have to, be the same as the account email address E). Anyone who later proves ownership of the recovery email account e and knows the answers x and A to the generic and personalized security questions will be able to recover the account key k_u.

Recovery request. After Alice forgets her password, she (obliviously) submits her email address E and her responses x to any additional questions asked of everyone. Importantly, Alice herself receives no output from this protocol; she does not yet know whether E and x matched any previously-created accounts. If a match exists, then the servers receive (secret shares of) Alice's recovery email address e and security questions Q. This stage has two purposes: involving the servers for online rate-limiting of any dictionary attack, and providing the servers with the information they need to perform verification and ask personalized security questions to the client.

Account verification. The servers send an email to Alice's recovery address e containing a one-time link. In this work, we model the email delivery as an instance of secure message transmission $\mathcal{F}_{\mathsf{SMT}}$. This functionality can be instantiated by the servers in the clear (in which case they temporarily learn Alice's email address and must then delete it afterward) or using secure multi-party computation (so that they can jointly send the email while individually not learning e) [1, 38, 64].

Account restoration. This stage begins when the client clicks on the link from the email, which (among other things) contains her security questions Q. The client obliviously provides her corresponding security answers A, which—if correct—can be used to recover her key k_u. The servers receive no output from restoration. Upon restoration, Alice should immediately re-run account creation to choose a new password for her account and select (possibly new, or possibly the same) security questions and answers to protect her keys.

2.3 Related work

In this section, we describe some prior work that informs our choice of a protocol design.

Secure matching systems. Secure matching systems[1] are cryptographic protocols that aim to augment informal "whisper networks" that exist in many communities such as college campuses. They permit a collection of survivors of sexual assault to determine whether they have been harmed by the same individual—even though the survivors have never met each other, never communicate directly with each other, and may never be online at the same time as each other. To accomplish this goal, secure matching systems use special-purpose secure computation among a non-colluding set of servers.

The work of Rajan et al. [61] was the first to construct a cryptographically secure matching system; their work relies on non-collusion of two servers, and it provides confidential matching when two survivors provide identifying information about the same individual. Subsequent works achieved stronger functionality and integrity guarantees, at the expense of requiring a public key infrastructure and an honest majority among 3 or more servers. WhoToo [49] allows for each survivor to choose their own matching threshold (potentially greater than two), and adds traceability for false accusations. Arun et al. [6] contribute a constant-time matching protocol to determine, after each submission, whether any collection of reports has exceeded the threshold. WhoToo+ [39] fixes some ambiguities in WhoToo and extends it also to support matching with a constant number of online operations. Finally, Shield [48] improves upon the work of Arun et al. in two ways: hiding the threshold chosen by each survivor, adding integrity checks against fake and duplicative submissions.

MPC and TEEs. Secure multi-party computation (MPC) is a cryptographic technique for a collection of servers to perform a joint computation while not learning any of the underlying data. While the fundamental concepts of MPC have been known for four decades [10, 11, 24, 35, 70], MPC on its own is typically incapable of withstanding the threat of legal adversaries, as we describe in more detail in §2.5.

Trusted execution environments (TEEs) offer an alternative method to protect sensitive data using hardware isolation (rather than cryptography). They have been proposed in commercial processors (e.g., [4,5,26,46,66]), academic prototypes (e.g., [27, 40, 62, 69]), and cloud-based services [3, 36, 57]. However, nearly all of these systems are subject to both physical and remote attacks (e.g., [13, 23, 34, 51, 52, 68]), and it remains an open question as to what extent the vision of trusted hardware can be realized. For these reasons and due to our design requirement to operate on general-purpose hardware, we avoid use of TEEs in this work.

Oblivious PRFs. A pseudorandom function (PRF) is a deterministic but "random-looking" function $y = f_k(x)$ in which the mapping between the input x and output y is unpredictable without knowledge of the secret key k. An oblivious PRF is an interactive protocol to evaluate $f_k(x)$ that hides the server

[1] While some other works in this area refer to these systems as "secure allegation escrows," we have selected an alternative name based on Callisto's terminology for their service [16], which they describe as a "matching system." The use of the term "allegation" may *unintentionally* imply a lack of belief in survivors' experiences. As advocates have noted in a guide on language use for sexual assault [47], "Many people say they use the word 'alleged' to refer to sexual assault cases, because they have not reached a final resolution within the criminal justice system ... However, it is important to keep in mind that only a miniscule percentage of sexual assaults ever make their way through the entire criminal justice process. ... [A]lmost all sexual assaults remain "unresolved" by the legal system, and it would be inappropriate to refer to all such reports (or even disclosures) of sexual assault as 'alleged.'"

key k and the client input x from each other; it also allows the server to perform service-wide rate-limiting by refusing to participate after some number of queries within a time period. A *partially* oblivious pseudorandom function (pOPRF) has two inputs $f_k(x_{\mathsf{kal}}, x_{\mathsf{priv}})$, where the server provides k and x_{kal}, and the client provides x_{priv}. This additional 'nonce' or 'salt' input x_{kal} can be used to perform per-account rate-limiting while still hiding the client's input x_{priv}.

There are a wide variety of OPRF works in the literature, starting with the work of Naor and Reingold [58]. Modern constructions tend to be based on a Hashed-Diffie-Hellman PRF $f_k(x) = H(x)^k$ that is secure in the random oracle model, or the Dodis-Yampolskiy PRF $f_k(x) = g^{1/(k+x)}$ [31]; we will use some ideas from both of these constructions in this work. Both styles of OPRFs also have verifiable counterparts that add integrity checks [33,42], often via zero-knowledge proofs (which we purposely avoid in this work as discussed in §2.1). We refer readers to the SoK by Casacuberta et al. [22] for additional OPRF and pOPRF constructions.

Among their many uses, OPRFs and pOPRFs have found value in several applications involving oblivious interactions on the web with passwords or other low-entropy secrets, such as (threshold) password-protected secret sharing [8, 42, 44], password hardening services [33, 50], compromised password checkers [60, 65], password-authenticated key exchange [42, 45, 67], and single sign-on [9]. Many of these works also provide universally composable (UC) security models of OPRFs, optionally with a threshold or verifiability requirement. Looking ahead, we use the UC modeling of Jarecki et al. [44] in this work, which is intentionally designed to avoid the verifiability requirement. We also desire security against pre-computation attacks, as defined within OPAQUE [45].

2.4 Overview of our K-pop protocol

In this section, we provide an informal overview of our construction of a *kaleidoscoping partially oblivious PRF*, or K-pop. As a reminder, this is a function that can be calculated as an OPRF or pOPRF, and reaches the same result either way. In other words, the input x_{kal} is *kaleidoscopic* in that it can be rapidly changed between being client- or server-provided.

We observe that if bilinear maps are permissible, then it is straightforward to build a K-pop. Concretely, the Pythia pOPRF of Everspaugh et al. [33] is computed as $f_k(x_{\mathsf{kal}}, x_{\mathsf{priv}}) = e(H_1(x_{\mathsf{kal}}), H_2(x_{\mathsf{priv}}))^k$, where H_1 and H_2 are random oracles. Using standard techniques for oblivious exponentiation (shown in §3), this function f can be easily computed either as an ordinary OPRF (where the client computes the bilinear map and the server obliviously exponentiates by k) or as a pOPRF (where the client blinds the left input before the server computes the bilinear map).

However, introducing a bilinear map violates our design principle only to use widely available crypto libraries. As a result, we have designed a K-pop that can be built purely from group and finite field operations, in the random oracle model. Constructing this is non-trivial, as there are no OPRFs and pOPRFs in the literature [22] that already compute the same outputs as each other.

Our starting point for this work is the recent pOPRF of Tyagi et al. [67]. It uses the pseudorandom function family $f_k(x_{\mathsf{priv}}, x_{\mathsf{kal}}) = H_2(x_{\mathsf{kal}}, x_{\mathsf{priv}}, H_1(x_{\mathsf{priv}})^{1/(k+H_3(x_{\mathsf{kal}}))})$, which combines characteristics of the Hashed-DH and Dodis-Yampolskiy OPRFs described in §2.3. We extend this construction to a K-pop by providing an OPRF protocol as well, which uses additively homomorphic encryption between the server (who holds k) and the client (who holds x_{kal}) to compute the exponent $\frac{1}{k+H_3(x_{\mathsf{kal}})}$ that is used in oblivious exponentiation. While the OPRF mode requires a larger number of public-key operations, this mode of our K-pop only needs to be executed in the (less frequent) account recovery phase.

2.5 Overview of our account recovery protocol

This section provides a high-level description of our account recovery protocol. To provide some intuition about the challenges involved in this construction, we iteratively build it up by describing several ideas that look promising but ultimately fall short of meeting our objectives. We then propose changes until arriving at our final construction.

MPC-based approaches. A natural approach here is to use MPC, either generally (e.g., run account recovery as a large circuit) or using private information retrieval, encrypted database search, or other special-purpose primitives. Within our 3-step recovery request, verification, and restoration procedure, it might seem at first glance that the hardest approach to satisfy with MPC is the email verification step. But actually this part is mostly a solved problem: Abram et al. [1] showed how a coalition of MPC servers can collectively emulate TLS 1.3 communications, and MPCAuth [64] applied this technique to email delivery in such a way that the servers never learn the client's email address or contents of the email.

Instead, the primary challenge is to withstand the threats of an internal and legal adversary during the recovery request and restoration steps, since MPC-based approaches typically do not (a) provide any form of rate-limiting of queries or (b) stop a colluding coalition of all servers from instantly reconstructing all data. Here the recent TLS-OPAQUE construction of Hesse et al. [38] is more promising: it uses secure computation of TLS for email delivery along with an OPRF that could be adapted to ensure that the client's data (e.g., email address and security questions/answers) is protected by online rate limiting if even a single server is honest and requires an offline dictionary attack even after all servers are corrupted. In this work, we purposely choose not to use any form of MPC-for-TLS since (a) it is slow and non-standard to implement, (b) it is not necessary to satisfy our design principles (§2.1), and (c) even with MPC-for-TLS, it remains unclear

how to protect the client's data using an OPRF. We focus on this latter question next.

OPRF-based approaches. When using an OPRF in account recovery, an initial thought might be for recovery request to involve a standard OPRF on the email address E: that is, to have the client and servers calculate $y = f_k(E)$ and to protect the client's user account key using y. However, this approach would allow an external adversary to conduct a brute-force search of others' email addresses. A better approach is to reveal y only after verifying that the client controls the email address. Even so, an internal adversary (who maliciously also acts as a client) could perform a brute-force search of email addresses and recover user data; ultimately, email addresses do not have enough entropy on their own.

Hence, we wish to add additional questions, but here we face a chicken-and-egg issue. Ideally, we want each client to be able to choose their own custom security questions, and then construct some method where the OPRF output y is used by the servers to retrieve each client's custom questions. But since a retrieving client has forgotten all passwords and crypto keys, any brute-force attacker would also be able to read the same security questions. Hence, an internal adversary could use the mere fact that security questions have been successfully retrieved to conclude that an email address E must be registered in the system.[2] We resolve this issue by allowing for generic questions for additional information x (e.g., a phone number) and computing the OPRF as $y = f_k(E,x)$ where y is used as a key to unlock a second layer of custom security questions. In this way: the generic questions provide increased resistance against brute-force attack by an internal adversary, and the custom questions provide stronger (and industry standard) protection against external adversaries.

The next challenge is that if the same OPRF $y = f_k(E,x)$ is used during account creation and recovery, then both need to be rate-limited or else an internal adversary could use account creation requests to brute-force y. We resolve this issue by using a K-pop togther with a server-chosen nonce n that is guaranteed to be unique for all account creation requests. Then, we can run a pOPRF $y = f_k(n,(E,x))$ during account creation and the corresponding OPRF during recovery. With a K-pop, we can enforce rate-limiting of account recovery requests in such a way that we do not know which account is being recovered and need not rate-limit account creation.

Finally, any OPRF-based approach (on its own) does nothing against a legal adversary in control of all servers, since a PRF provides no security against the key-holder. We resolve this issue by feeding y into a slow cryptographic hash function H that can slow down the rate of offline brute-force attempts. Importantly, the OPRFs of all servers are performed first and only the results are fed into H, so that this offline brute-force attack must occur *after* the moment that all server keys are compromised. In this way, our construction is secure against pre-computation attacks [45]. This finally yields a secure construction, which we describe in detail in §4.

[2] We remark that this leakage is not inherent from a cryptographic perspective; indeed, it is possible to calculate the security questions pseudorandomly from the email address E so that it can be retrieved whether or not E was ever registered in the system. But we rejected this approach because it went against our goal of trauma-informed care: if a survivor accidentally mistyped their email address, we did not want to subject them to try in vain to respond to an incorrect set of security questions.

Symbol	Description
$\mathbf{C}$	Client
$\mathbf{S}_i$	Recovery server i
N	Number of recovery servers (default is $N = 2$)
λ	Cryptographic security parameter, e.g., 256 bits
k_u	Client's user account key (which decrypts account data)
H	Cryptographic hash function, modeled as a random oracle
E	Client's email address associated with the account
x	Client's answers to any generic questions (e.g., contact info)
e	Client's recovery email address (can be the same as E)
Q	Security questions chosen by the client
A	Answers to the client-chosen security questions
n	Nonce chosen publicly by the recovery servers
m	Nonce chosen privately by the client
r	Recovery string, set as $r = e \Vert Q \Vert m \Vert padding$
ℓ	fixed length of the recovery string after padding is applied
D	Database held by both recovery servers (this stores all data provided by all clients during account creation)
$\hat{E}_i$	Result of the K-pop run in recovery request with server i
$\hat{A}_i$	Result of the K-pop run in recovery restoration with server i
id	Client's identifier for her record in the database D
$\mathsf{ct}_r, \mathsf{ct}_u$	Ciphertexts produced by the client to store in the server database; they are a one-time pad of r and k_u, respectively
k_E, k_A	One-time pad keys for the ciphertexts above
k	Server's secret key for an OPRF
x_{priv}	Client's private input to an OPRF or pOPRF
x_{kal}	Input provided by the server in a pOPRF, or by the client in an OPRF

Table 1: Notation used in this paper.

3 Kaleidoscopic Partially Oblivious PRF

In this section, we define and construct a new primitive that we call a *kaleidoscopic partially oblivious PRF*, or K-pop for short. This primitive is named for the fact that it can be quickly changed between an OPRF and a pOPRF at will.

3.1 Preliminaries

In this section, we briefly introduce the notation and OPRFs that we use in this work. We describe other cryptographic primitives (hash functions, Diffie-Hellman groups, and additively homomorphic encryption) in the full version of this work [53].

Notation. In this work, we often use upper-case letters like S to denote finite sets, and calligraphic letters $\mathcal{D}$ to denote distributions. The notation $x \leftarrow \mathcal{D}$ means to sample x from the distribution $\mathcal{D}$, and the notation $x \leftarrow S$ means to select

Functionality $\mathcal{F}_{\mathsf{SMT}}$

- Upon invocation, with input $(\mathsf{send}, \mathsf{sessionid}, R, m)$ from a sender party S that is intended for a receiver party R, send a message $(\mathsf{sent}, \mathsf{sessionid}, S, R, |m|)$ to the adversary $\mathcal{A}^*$.
- Upon receiving message $(\mathsf{delivered}, \mathsf{sessionid})$ from $\mathcal{A}^*$: If not yet generated output, then output $(\mathsf{sent}, \mathsf{sessionid}, S, R, m)$ to R.
- Upon receiving message $(\mathsf{corrupt}, \mathsf{sessionid}, m', R')$ from the environment **Env**: record being corrupted. Additionally, if no output has been generated yet, then output $(\mathsf{sent}, \mathsf{sessionid}, S, R', m')$ to R'.

Figure 1: Secure message transmission functionality $\mathcal{F}_{\mathsf{SMT}}$, adapted from [18]. In this work, we model both network communication via TLS and the act of sending an email from the servers to the client's email provider as instantiations of $\mathcal{F}_{\mathsf{SMT}}$.

Functionality $\mathcal{F}_{\mathsf{OPRF}}$

An instance of this functionality is uniquely defined by a session id $\mathsf{sessionid} = (\mathsf{OPRF}, \mathsf{sid})$ containing the party ID of the server (sid). The functionality interacts with both the server $\mathbf{S}_{\mathsf{sid}}$ and anyone who acts in the role of a client $\mathbf{C}$, including possibly the adversary $\mathcal{A}^*$.

- Upon receiving $(\mathsf{Init}, \mathsf{sessionid})$ from the server $\mathbf{S}_{\mathsf{sid}}$, uniformly sample $\mathsf{kid} \leftarrow\$ \{0,1\}^\lambda$, and initialize an empty table $T(\mathsf{kid}, x)$.
- Upon receiving $(\mathsf{Eval}, \mathsf{sessionid}, \mathsf{qid}, x)$ from a client $\mathbf{C}$ (which can be adversary $\mathcal{A}^*$) where qid is a unique identifier for this Eval query: end this invocation if called before Init. Otherwise, record $\langle \mathsf{qid}, \mathbf{C}, x \rangle$ and send $(\mathsf{EvalContinue}, \mathsf{sessionid}, \mathsf{qid})$ to $\mathcal{A}^*$.
- Upon receiving $(\mathsf{EvalContinue}, \mathsf{sessionid}, \mathsf{qid}, \mathsf{kid}^*)$ from $\mathcal{A}^*$: end this invocation if there is no record with qid. Otherwise, find and delete record $\langle \mathsf{qid}, \mathbf{C}, x \rangle$. If $\mathbf{S}_{\mathsf{sid}}$ is honest, set $\mathsf{kid}^* \leftarrow \mathsf{kid}$ (i.e., use the correct key). Next, fetch $\rho \leftarrow T(\mathsf{kid}^*, x)$ as follows:
  - If $T(\mathsf{kid}^*, x)$ is defined, then look up $\rho \leftarrow T(\mathsf{kid}^*, x)$ and send $(\mathsf{EvalComplete}, \mathsf{sessionid}, \mathsf{qid}, \rho)$ to $\mathbf{C}$.
  - Otherwise pick ρ at random from $\{0,1\}^\ell$, assign $T(\mathsf{kid}^*, x) := \rho$, and send $(\mathsf{EvalComplete}, \mathsf{sessionid}, \mathsf{qid}, \rho)$ to $\mathbf{C}$.
- Upon receiving $(\mathsf{OfflineQuery}, \mathsf{sessionid}, x, \mathsf{kid}^*)$ from $\mathbf{C}$: fetch $\rho \leftarrow T(\mathsf{kid}^*, x)$ as above. Send $(\mathsf{OfflineQuery}, \mathsf{sessionid}, \rho)$ to $\mathbf{C}$.
- Upon receiving $(\mathsf{corrupt}, \mathsf{pid})$ from the environment **Env**: mark the party corresponding to pid as corrupted. Additionally:
  - For corruption of the server, send kid to the adversary.
  - For corruption of a client $\mathbf{C}$, send all corresponding records $\langle \mathsf{qid}, \mathbf{C}, x \rangle$ to the adversary.

Figure 2: Functionality $\mathcal{F}_{\mathsf{OPRF}}$, based on Jarecki et al. [43] modified to use a unique query identifier qid like Das et al. [28] to track commands sent to $\mathcal{F}_{\mathsf{OPRF}}$ about the same evaluation query. $\mathcal{F}_{\mathsf{OPRF}}$ does not guarantee honest behavior by the server; the key identifier kid corresponds to the server's choice of key to use when responding to each query. OfflineQuery allows anyone to evaluate the OPRF on input x and key id kid^* of their choice—which is unlikely to match the honest kid unless $\mathbf{S}$ is corrupted.

x uniformly at random from the set S. We also use $[n] = \{1, \ldots, n\}$ to denote the set of integers from 1 to n, inclusive.

We denote the protocol participants using bold letters. A client is denoted as $\mathbf{C}$, and a server is denoted as $\mathbf{S}$. For protocols that contain multiple servers, we use subscripts to distinguish them: server 1 is denoted as $\mathbf{S}_1$, server 2 is $\mathbf{S}_2$, and so on. We also use **Adv** to denote a real-world adversary who attempts to attack our protocol—either maliciously or semi-honestly, as stated in the respective theorem statements—and **Sim** to denote the corresponding ideal-world simulator. See Table 1 for a detailed list of all variables used in this work.

Oblivious pseudorandom function. As described in §2.3, an OPRF is an interactive two-party protocol in which a client $\mathbf{C}$ has input x, a server $\mathbf{S}$ has input k, and they jointly compute $y = f_k(x)$ in such a way that neither party learns anything about the other input. However, the server can deviate from the protocol, and correctness is not guaranteed in this case. Formally, we model an OPRF as an instantiation of the UC functionality $\mathcal{F}_{\mathsf{OPRF}}$ shown in Figure 2, which we adapt from Jarecki et al. [43] with a small tweak to add support for server-side rate-limiting. If a client submits an input x and the server is honest, then the client receives the correct output—potentially after some adversarially-chosen delay since this is an interactive protocol. If the server is malicious, then it could act as though it used a different key or produce a random output, which the functionality also accounts for.

3.2 Defining K-pop

Like an OPRF or pOPRF, a K-pop is an interactive protocol between two participants who we call the *client* $\mathbf{C}$ and the *server* $\mathbf{S}$. Concretely, a K-pop is a keyed family of pseudorandom functions with two inputs $f_k^{\mathsf{K\text{-}pop}}(x_{\mathsf{kal}}, x_{\mathsf{priv}})$. Looking ahead to our account recovery protocol: the client will execute independent instances of K-pop with each recovery server.

The K-pop can be computed either as a pOPRF or OPRF. Concretely, the input x_{kal} is *kaleidoscopic* in that it can be rapidly changed between being public to the server (in pOPRF mode) or private to the client (in OPRF mode). Importantly, the K-pop returns the same answer in either mode.

We formalize these requirements through the UC functionality $\mathcal{F}_{\mathsf{K\text{-}pop}}$ provided in Figure 3, which codifies both the functionality and security requirements of K-pop. It calls the OPRF functionality $\mathcal{F}_{\mathsf{OPRF}}$ (Fig. 2) as a subroutine. We stress that $\mathcal{F}_{\mathsf{K\text{-}pop}}$ makes the *same* call to $\mathcal{F}_{\mathsf{OPRF}}$ whether the input

Functionality $\mathcal{F}_{\text{K-pop}}$

An instance of this functionality is identified by a session id $\mathsf{sessionid} = (\mathsf{K\text{-}pop}, \mathsf{sid})$ containing the party ID sid of its server. It interacts with the server $\mathbf{S}$ and any client $\mathbf{C}$ (possibly the adversary $\mathcal{A}^*$), it has a subroutine $\mathcal{F}_{\mathsf{OPRF}}$ and a query limit L, and it operates as follows.

- Upon receiving $(\mathsf{Init}, \mathsf{kid})$ from server $\mathbf{S}_{\mathsf{sid}}$: set $\mathsf{ctr} \leftarrow 0$ and send $(\mathsf{Init}, \mathsf{kid})$ to $\mathcal{F}_{\mathsf{OPRF}}$. (Other methods abort if called before Init.)
- Upon receiving (Reset) from the server $\mathbf{S}_{\mathsf{sid}}$: set $\mathsf{ctr} \leftarrow 0$ and send the message $(\mathsf{ResetComplete})$ to $\mathcal{A}^*$.
- Upon receiving $(\mathsf{Eval}, \mathsf{sessionid}, \texttt{OPRF-mode}, \mathsf{qid}, x_{\mathsf{kal}}, x_{\mathsf{priv}})$ or $\boxed{(\mathsf{Eval}, \mathsf{sessionid}, \texttt{pOPRF-mode}, \mathsf{qid}, x_{\mathsf{kal}}, x_{\mathsf{priv}})}$ from a client $\mathbf{C}$:
  - Send an error $(\mathsf{Eval}, \mathsf{sessionid}, \mathsf{qid}, \perp)$ to $\mathcal{A}^*$ if there was a prior message with qid, or if $\mathbf{S}$ is honest and $\mathsf{ctr} > L$.
  - $\boxed{\text{If in pOPRF mode: send } (\mathsf{Eval}, \mathsf{sessionid}, \mathsf{qid}, x_{\mathsf{kal}}) \text{ to } \mathcal{A}^*, \text{ and wait for a response } (\mathsf{EvalContinue}, \mathsf{sessionid}, \mathsf{qid}).}$
  - Increment query counter $\mathsf{ctr} \leftarrow \mathsf{ctr} + 1$, and send $(\mathsf{Eval}, \mathsf{sessionid}, \mathsf{qid}, (x_{\mathsf{kal}}, x_{\mathsf{priv}}))$ to $\mathcal{F}_{\mathsf{OPRF}}$ on behalf of $\mathbf{C}$.
- Upon receiving $(\mathsf{EvalComplete}, \mathsf{sessionid}, \mathsf{qid}, \rho)$ from $\mathcal{F}_{\mathsf{OPRF}}$: output $(\mathsf{EvalComplete}, \mathsf{sessionid}, \mathsf{qid}, (x_{\mathsf{kal}}, x_{\mathsf{priv}}), \rho)$ to client $\mathbf{C}$.
- Upon receiving $(\mathsf{OfflineQuery}, \mathsf{sessionid}, x_{\mathsf{kal}}, x_{\mathsf{priv}}, \mathsf{kid}^*)$ from $\mathbf{C}$: send this message to $\mathcal{F}_{\mathsf{OPRF}}$, and send its response to client $\mathbf{C}$.
- Upon receiving $(\mathsf{corrupt}, \mathsf{pid})$ from the environment $\mathbf{Env}$: mark the party with pid as corrupted, and send $(\mathsf{corrupt}, \mathsf{pid})$ to $\mathcal{F}_{\mathsf{OPRF}}$.

Figure 3: Functionality $\mathcal{F}_{\text{K-pop}}$ with subroutine $\mathcal{F}_{\mathsf{OPRF}}$. Differences between OPRF and pOPRF modes are shown in a box. $\mathcal{F}_{\text{K-pop}}$ maintains a counter ctr of the number of Eval queries, and it enforces a limit of L evaluations between Reset commands.

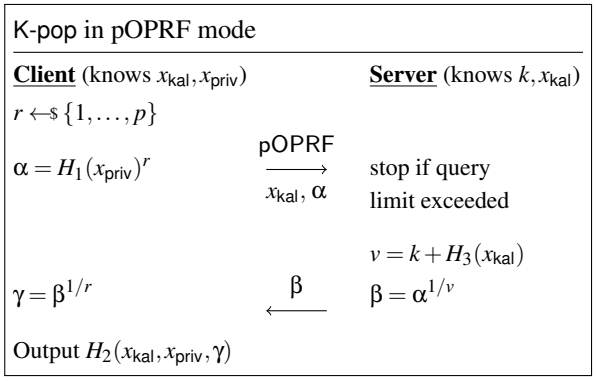

Figure 4: K-pop in pOPRF mode, where both the client and server know x_{kal}. The server need not be honest; it can use incorrect k^* or x^*_{kal} in its oblivious exponentiation. All communications use secure message transmission $\mathcal{F}_{\mathsf{SMT}}$ (Fig. 1).

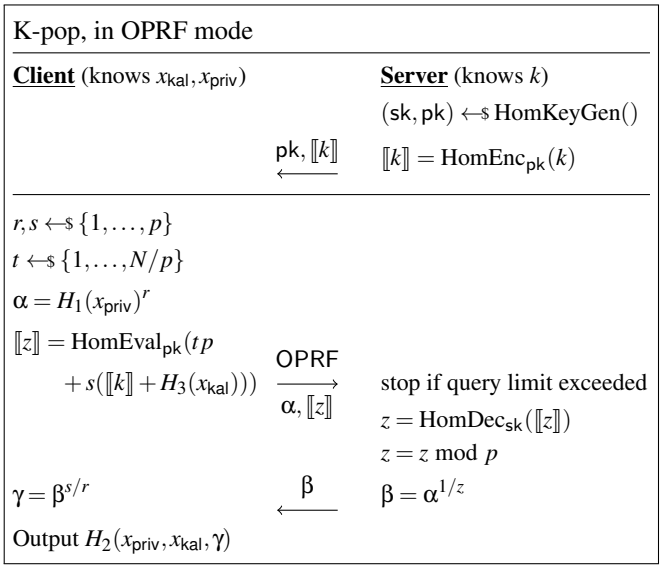

Figure 5: K-pop in OPRF mode, where x_{kal} and x_{priv} are both private inputs supplied by the client. All communications use secure message transmission $\mathcal{F}_{\mathsf{SMT}}$ (Fig. 1). The first message can be sent in a preprocessing step or using a PKI.

x_{kal} is provided by the server (in pOPRF mode) or by the client (in OPRF mode). Since $\mathcal{F}_{\mathsf{OPRF}}$ does not know whether it was called in OPRF or pOPRF mode, its response must be the same in both cases; in other words, $\mathcal{F}_{\text{K-pop}}$ ensures identical outputs in the OPRF and pOPRF modes by design. Also, note that if the parties are honest, then $\mathcal{F}_{\text{K-pop}}$ is guaranteed to be deterministic and repeatable because $\mathcal{F}_{\mathsf{OPRF}}$ is.

However, if the server $\mathbf{S}$ is malicious, then in pOPRF mode it *can* ignore the agreed-upon x_{kal} and choose a different x^*_{kal}. While one could incorporate a verifiability guarantee into a K-pop, we choose not to do so because it is not needed in our account recovery protocol in §4 and this way we do not need to use zero knowledge proofs. Instead, we leave it up to any protocol that uses K-pop to detect and abort in case of malicious server behavior.

3.3 Constructing K-pop

In this section, we construct a K-pop by combining and extending techniques from Tyagi et al. [67] and Miao et al. [56]. Specifically, our K-pop construction computes the same function as the pOPRF of Tyagi et al. [67]:

$$f_k^{\text{K-pop}}(x_{\mathsf{kal}}, x_{\mathsf{priv}}) = H_2\left(x_{\mathsf{kal}}, x_{\mathsf{priv}}, H_1(x_{\mathsf{priv}})^{1/(k+H_3(x_{\mathsf{kal}}))}\right).$$

Here, H_1 is a cryptographic hash function whose output is a point on an elliptic curve group, and H_2 and H_3 are random oracles that return finite field elements. We use x_{priv} and x_{kal} to

denote the inputs, where x_{priv} is always a secret input supplied by the client, and x_{kal} is the kaleidoscopic input. In the OPRF mode, x_{kal} is chosen by the client and kept secret from the server; by contrast, in the pOPRF mode, x_{kal} is known and agreed upon by the client and server.

This construction by Tyagi et al. [67] combines ideas from two prior PRF families: the Dodis-Yampolskiy [31] PRF $f_k(x) = g^{1/(k+x)}$ and the Hashed-DH PRF $f_k(x) = H(x)^k$. The outer-most hash function H_2 is useful to provide extraction for UC security, in the random oracle model [42]. Below, we reproduce the pOPRF design of Tyagi et al. [67], and then we construct an OPRF that computes the same result. In both cases, we model all network communications with a secure message transmission functionality $\mathcal{F}_{\mathsf{SMT}}$ in Fig. 1; that said, it is sufficient to use an authenticated communication channel as defined in several prior works (e.g., [7, 18–20]).

pOPRF Mode. We begin by describing the K-pop in pOPRF mode. Because the server knows x_{kal}, it can compute $(k+H_3(x_{\mathsf{kal}}))^{-1}$ and use this as the exponent in a two-message oblivious exponentiation protocol with the client, as illustrated in Figure 4. Finally, the client computes the outer hash function H_2. This mode exactly follows the work of Tyagi et al. [67] (but without a zero knowledge proof), and it is the more efficient of the two modes: it requires 3 group exponentiations along with some hash function evaluations.

OPRF Mode. It remains to compute the same function in OPRF mode, in which x_{kal} (like x_{priv}) is a secret known only to the client that the server is not supposed to learn. Rather than having the server compute $v = k + H_3(x_{\mathsf{kal}})$ directly, in this mode we have the client and server compute v together, using additively homomorphic encryption so that neither party learns any intermediate state along the way. Let p denote the order of the elliptic curve group, and let the notation $[\![x]\!]$ denote a homomorphic encryption of the plaintext value x.

First, we describe the main technique under the simplifying assumption that the plaintext space of the homomorphic encryption algorithm is also a group of order p. With this simplifying assumption, we can perform a secure computation of the required addition and multiplicative inversion as follows.

1. The server chooses an ephemeral key pair for homomorphic encryption, computes $[\![k]\!] = \mathrm{HomEnc}(k)$, and sends this ciphertext to the client.
2. The client chooses two blinding factors $r, s \leftarrow \{1, \ldots, p\}$. The client computes the group element $\alpha = H_1(x_{\mathsf{priv}})^r$ in the same way as in the pOPRF mode, and also uses homomorphic addition and scalar multiplication to compute the ciphertext $[\![z]\!]$ corresponding to the plaintext $z = s(k + H_3(x_{\mathsf{kal}}))$. The client sends α and $[\![z]\!]$ to the server.
3. The server decrypts z, inverts it, and sends $\beta = \alpha^{1/z} = H_1(x_{\mathsf{priv}})^{\frac{r}{s(k+H_3(x_{\mathsf{kal}}))}}$ to the client.
4. The client computes $\gamma = \beta^{s/r} = H_1(x_{\mathsf{priv}})^{1/(k+H_3(x_{\mathsf{kal}}))}$.

Correctness is clear by inspection, and privacy against the server follows from the fact that z is blinded using s so that the server cannot learn the client's x_{kal}.

The remaining challenge is to address the fact that the exponents and HomEnc plaintexts are *not* from the same group, which we handle using a technique from Miao et al. [56]. Concretely, let $N \gg p$ denote the order of the plaintext space within an additively homomorphic encryption scheme, like Paillier [59] or Camenisch-Shoup [17] encryption (for the latter, we omit the integrity check). The issue here is that we wanted the homomorphic evaluation to produce $z = s(k + H_3(x_{\mathsf{kal}})) \bmod p$ because the server plans to use z as an exponent, but the homomorphic evaluation performs the calculation mod N instead. If $N \gg p^2$ then the calculation $z = s(k + H_3(x_{\mathsf{kal}})) \bmod N$ does not perform any modular wrapping at all, so the blinding is ineffective and revealing z to the server would allow it to learn information about the size of the client's secrets s and $H_3(x_{\mathsf{kal}})$. Fortunately, there is a simple solution to this problem shown by Miao et al. [56]: add a random multiple of p, so that the resulting plaintext is $z = s(k + H_3(x_{\mathsf{kal}})) + tp \bmod N$, where $t \leftarrow \{1, \ldots, N/p\}$ is another blinding factor chosen by the client. In this way, z still reduces to the correct exponent mod p with overwhelming probability, and its size does not reveal information about the client's secret inputs.

This protocol requires 3 group exponentiations (just like pOPRF mode) along with one homomorphic encryption, evaluation, and decryption. We illustrate the protocol in Figure 5 and prove the following theorem in the full version [53].

Theorem 1. *Assume that group G satisfies the one-more gap strong Diffie-Hellman inversion assumption and that* HomEnc *satisfies indistinguishability under a chosen plaintext attack (IND-CPA). Then, the* K-pop *protocol $\Pi_{\mathsf{K\text{-}pop}}$ (in Figures 4-5) UC-realizes the ideal functionality $\mathcal{F}_{\mathsf{K\text{-}pop}}$ in the presence of a programmable random oracle $\mathcal{F}_{\mathsf{pro}}$.*

4 Account Recovery

In this section, we describe our cryptographic protocol for private account recovery. Our protocol consists of the four stages described in §2.2: *account creation*, *recovery request*, *account verification*, and *account restoration*. Below we describe constructions for each protocol, with full details provided in Figures 6-8. For simplicity, our constructions are written here for the setting of $N = 2$ servers, but the protocols immediately generalize to allow for more servers. We provide a security analysis of this protocol in §4.6 and the the full version of this work [53].

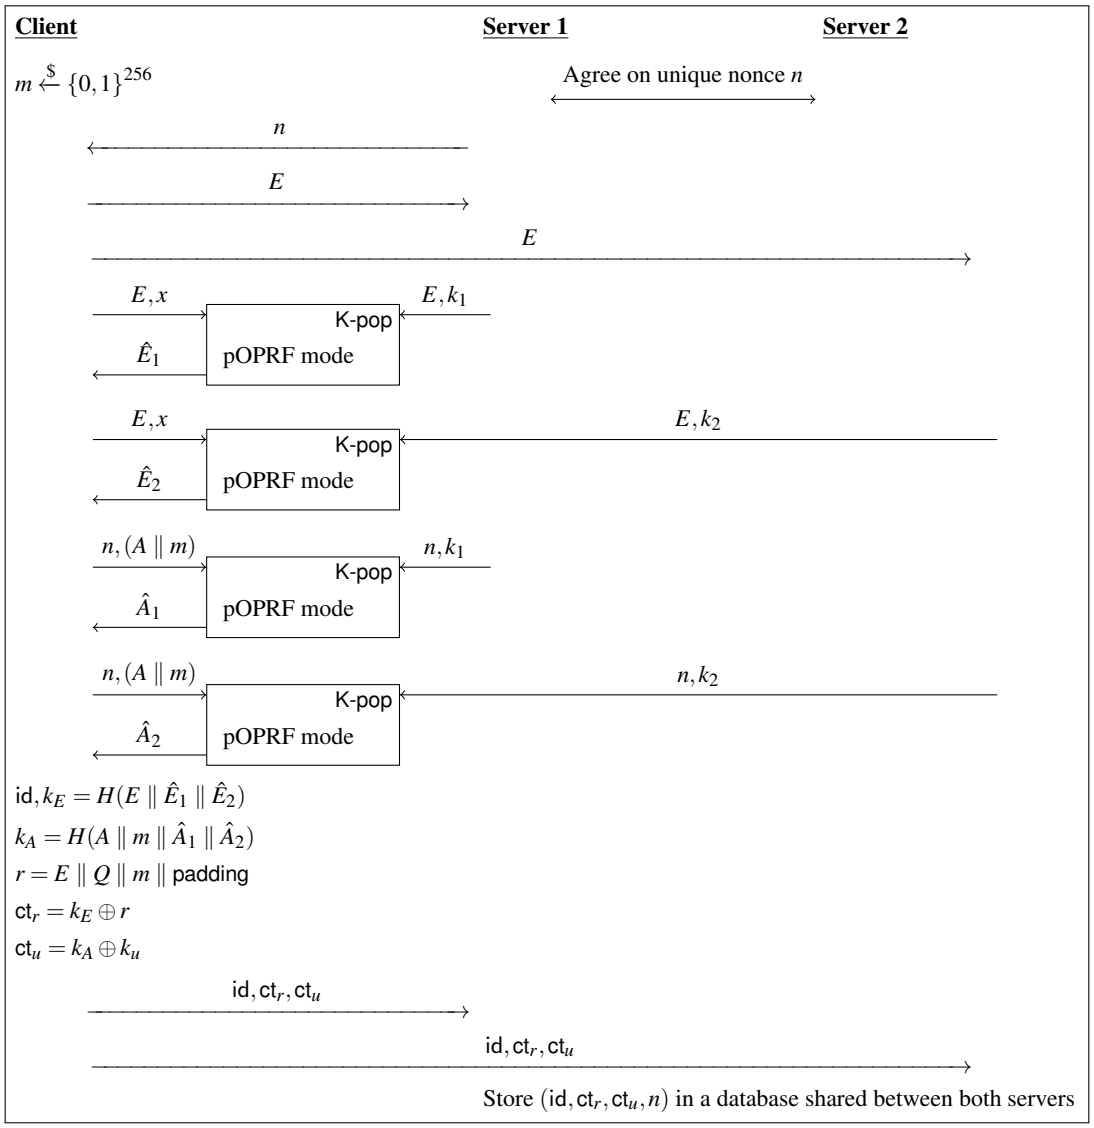

Figure 6: Account Creation

4.1 Initialization

Each server independently and secretly chooses a K-pop key. We denote server i's K-pop key as k_i. Additionally, a common database DB is initialized, and each server is granted read/write access.

4.2 Account creation

Account creation allows a client to register a new account in the system. We depict the complete procedure in Figure 6. The client begins by choosing the following information:

- E, the client's official email address for this account,
- e, a personal email address to use in account recovery,
- x, additional personal information provided in response to any generic questions, such as a telephone number,
- k_u, a cryptographic key used to encrypt all account data,
- Q, a set of client-chosen security questions,
- A, the client's answers to the security questions Q,
- m, a randomly generated nonce of length λ, where λ denotes the security parameter (e.g., 256 bits), and
- $r = e \parallel Q \parallel m$, a recovery string padded to fixed length ℓ.

First, the servers jointly agree on a unique nonce n for the client. This nonce is immediately sent to the client, who sends back their email string E to both servers. The servers should verify the client's email at this point by emailing them a link. Also, providing E to the servers serves a cryptographic purpose in our protocol: the client makes a K-pop query to

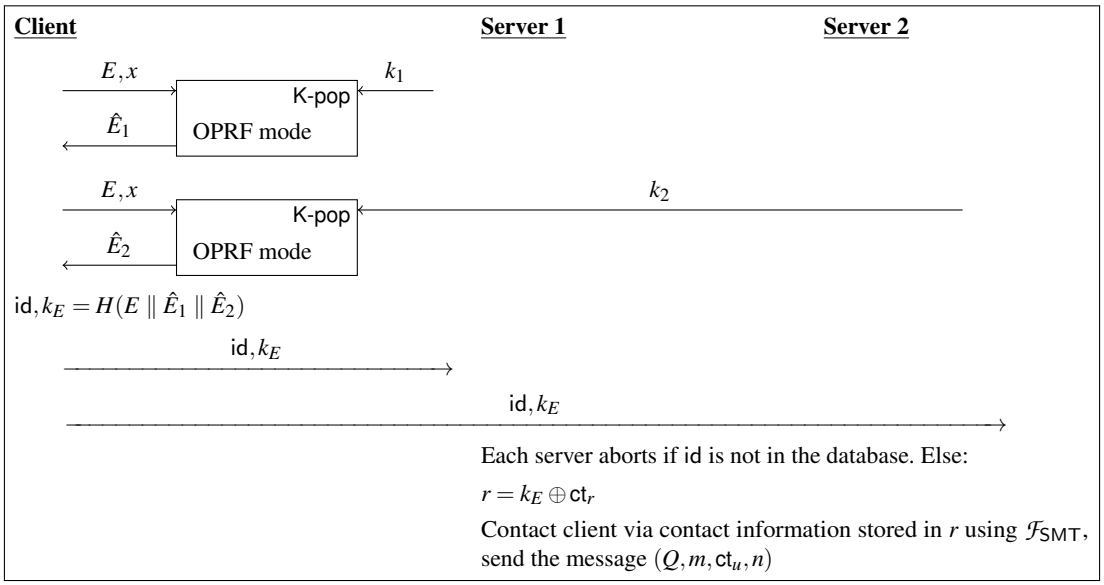

Figure 7: Recovery Request

each server in pOPRF mode, using email E as the public input and personal info x as the private input. Let $\hat{E}_1$ and $\hat{E}_2$ denote the respective K-pop outputs to the client.

Next, the client computes $H(E \parallel \hat{E}_1 \parallel \hat{E}_2)$, where H is a slow password-based key derivation function of variable output length (modeled as a random oracle). The slowness of this function is the reason why our construction provides offline rate limiting against a legal adversary, and the fact that it uses the outputs of the K-pop means that an offline attack can only be performed *after* the adversary compromises all servers. We parse the output of H into two strings: id is the first λ bits of this output, and k_E is the next ℓ bits. This ensures that k_E is the same length as r. The client then computes a one-time-pad ciphertext ct_r of r encrypted under key k_E.

Then, the client makes another K-pop query to each server in pOPRF mode, this time using n as the public input and $A \parallel m$ as the private input, receiving back the respective outputs $\hat{A}_1$ and $\hat{A}_2$. Using the same password-based key derivation function H, they compute $k_A = H(A \parallel \hat{A}_1 \parallel \hat{A}_2)$, where k_A is of length λ. The client then XOR-s k_A with their user key to produce a one-time-pad ciphertext ct_u. Finally, the client sends $\mathsf{id}, \mathsf{ct}_r$, and ct_u to each server. The servers store these values together with the nonce n in a single row of the shared database DB.

4.3 Recovery request

In this stage, the client initiates a request to recover their account after losing their user key. We assume that the client still remembers the same email string E and personal information string x used during account creation. We depict the full protocol in Figure 7.

Recovery requests begin with the client making a K-pop query to each server in OPRF mode, using inputs E and x, and receiving back outputs $\hat{E}_1, \hat{E}_2$. Note that the inputs are the same ones the client provided to the K-pop during account creation, but this time E is a private input instead of a public input. Since both K-pop modes of operation compute the same function, the outputs are the same as in account creation.

The client computes $\mathsf{id}, k_E = H(E \parallel \hat{E}_1 \parallel \hat{E}_2)$, and sends id and k_E to each server. The servers can then look up id in their shared database and retrieve the corresponding ct_r ciphertext. Both servers can decrypt this with k_E to reveal the client's r string, which consists of their recovery email address e, security questions Q, and nonce m.

To impose rate limiting on recovery requests, each server can restrict the number of K-pop queries they respond to in OPRF mode. This limit will not restrict the server's ability to process account creations, since all K-pop operations in account creation are run in pOPRF mode.

4.4 Account verification

In this stage, the recovery servers send an email to the recovery address e. This email contains a customized link that encodes the message (Q, m, ct_u, n). The servers only agree to participate in account restoration if the client clicks on this link within a short time interval.

Our protocol supports two options for account verification. First, the verification step can be done non-cryptographically by having the recovery data r revealed to the servers at the end of the recovery phase, in which case they can send an email in the clear to the recovery address e. This approach has the advantage of being easier to implement, since all other

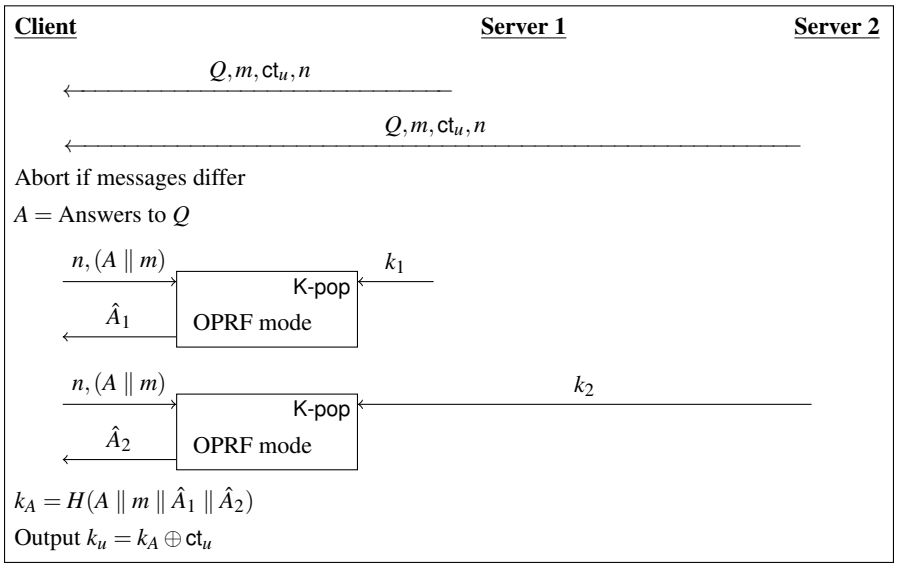

Figure 8: Account Restoration

aspects of our account recovery protocol use standard public and symmetric key primitives, but it has the disadvantage that the servers temporarily learn the contact info of clients during account recovery and must be trusted to delete this information promptly. (Still, we stress the importance here of learning at most the email addresses of clients who perform account recovery, rather than a full list of account-holders.) Second, the servers can jointly perform account verification under secure multi-party computation, in order to prevent any server from learning the client's email address. In this case, either the Oblivious TLS protocol of Abram et al. [1] or the MPCAuth protocol [64] would suffice.

In our modeling, we consider both of these options as instantiations of the UC functionality for secure message transmission $\mathcal{F}_{\mathsf{SMT}}$, as shown in Figure 1.

4.5 Account restoration

This final stage of the protocol is shown in Figure 8. Conceptually, this stage is most similar to recovery request, in that it starts with the client submitting K-pop queries to each of the servers in OPRF mode, this time with inputs $x_{\mathsf{priv}} = (A \parallel m)$ and $x_{\mathsf{kal}} = n$. Additionally, the client computes a slow hash function on the OPRF inputs and outputs. One difference between the stages is that account restoration is intended to provide an output to the client, not the servers. Ergo, recovering the one-time pad key k_A from the OPRF outputs is nearly the end of the protocol; all that remains is to use this ephemeral key to recover the user account key k_u.

After the client's account has been restored, it is crucial that they immediately reset their account information (e.g., the password that they have forgotten) so they maintain access in the future. While most of the reset process involves properties of the service outside of our modeling, one step that is crucial is to perform another instance of account creation in order to choose a new nonce to protect the account going forward (and optionally new security questions and answers, if desired).

4.6 Security analysis

In this work, we provide game-based and simulation-secure security analyses of our account recovery construction.

First, we provide an indistinguishability game-based security analysis in the full version of this work [53] Our game defines an adversarial model in which the attacker can statically corrupt one of two recovery servers, and adaptively corrupt any number of clients. The adversary can additionally control when honest clients create accounts and run account recovery. The adversary wins if they are able to distinguish between an uncorrupted client's real user key and a randomly sampled key. We prove that our account recovery scheme has the following security.

Theorem 2. *An adversary that sends at most q messages to honest parties has advantage at most $\frac{q}{|A|} + \varepsilon$ in the random oracle model, where ε is negligible in the security parameter, and A is a set of possible security question answers from which real clients' answers are uniformly sampled.*

This result demonstrates the effectiveness of rate-limiting against internal adversaries. Rate-limiting allows honest recovery servers to effectively impose a q value limiting the number of queries that other servers can make. The honest parties can therefore restrict the advantage of internal adversaries via the choice of q.

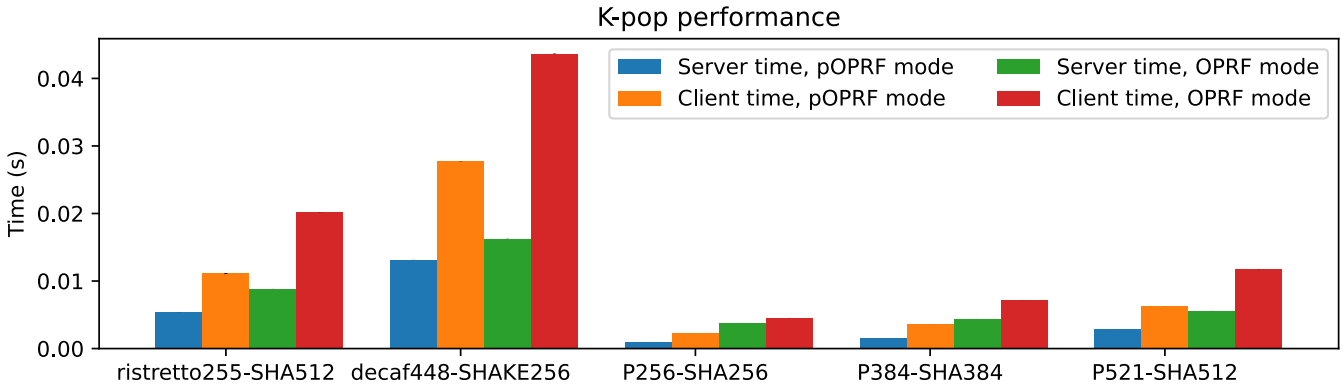

Figure 9: Performance of K-pop implementation over different choices of elliptic curve group and cryptographic hash function. Each bar represents the average of 1000 measurements.

Our game-based analysis additionally shows that our account recovery construction detects adversarial deviations from the protocol during account recovery and restoration and therefore provides security up to abort, even though our K-pop on its own does not provide verifiability. This proof is conceptually the simpler one to understand, but it restricts the adversary to a single server corruption and only protects accounts created prior to the corruption.

Second, in the full version [53], we provide a simulation-based analysis with universally composable (UC) security in the model of Canetti [18]. We write a protocol description Π_{acc} in the UC style, contribute an idealized version of our protocol as the functionality $\mathcal{F}_{\mathsf{acc}}$, and prove the following.

Theorem 3. *Protocol* Π_{acc} *UC-realizes functionality* $\mathcal{F}_{\mathsf{acc}}$ *in the random oracle model.*

This analysis provides a stronger guarantee because it does not restrict the power of the adversary: it can act maliciously from the beginning and in all phases of account creation, recovery, verification, and restoration. To prove Theorem 2, we construct a simulator **Sim** and argue the environment **Env**'s view is identically distributed whether it interacts with (a) Π_{acc} and real-world adversary **Adv** in the $\mathcal{F}_{\mathsf{K\text{-}pop}}$-hybrid world or (b) $\mathcal{F}_{\mathsf{acc}}$ and **Sim** in the ideal world. Our formal theorem statements and proofs are provided in the full version [53].

5 Implementation

We provide an open-source implementation of the K-pop construction (from §3.3) in Sage.[3] We emphasize that this codebase is distinct from Callisto's own implementation in TypeScript for use on the web.

Our code is based on an implementation [41] of RFC 9497 [30], which standardizes the pOPRF construction of Tyagi et al. [67]. Our implementation of the K-pop in pOPRF mode uses their code directly, with the only modification being the removal of zero-knowledge proofs (since our construction does not require verifiability). For the OPRF mode, we instantiate the additively homomorphic encryption scheme using an open-source implementation [29] of Paillier encryption with a key length of 2048 bits.

5.1 Single-threaded experimental results

We evaluated our implementation on a 1.6GHz Intel Core i5-10210U CPU with 16GB RAM. Figure 9 shows the client-side and server-side performance of the K-pop in both modes of operation for five different choices of Diffie-Hellman group and hash function. Excluding network time, the end-to-end time of a K-pop interaction takes 3.1-41.2 ms in pOPRF mode and 8.4-60.3 ms in OPRF mode, depending on the choice of group and hash function.

Our proof-of-concept implementation is not optimized for speed, and we expect that the computation time can be reduced further. Even so, already these benchmarks lend credence to the efficiency of the account recovery protocol, which requires two separate instances of the K-pop together with a small number of hash function operations, XORs, and database operations. Since all of these server-side costs are negligible compared to the K-pop, our benchmarks show that in a 2-server account recovery system, account creation and the entire recovery procedure each run in 12.4-164.8 ms, ignoring network latency. The client-side runtime would be dominated by the (tunable) cost of the slow, memory-hard hash function like argon2 [12] or scrypt [2].

5.2 Multiprocessing experimental results

In a real-world deployment of our account recovery system, the server side work can scale to a larger number of clients

[3] Our K-pop implementation code is available at https://github.com/ryanjlittle/kpop-oprf.

Figure 10: Amortized evaluation time in milliseconds of K-pop server running on $P \in \{1,2,4\}$ parallel cores. Each data point is the average of 512 measurements.

by running many K-pop instances in parallel. We attempted to measure the performance in this setting by evaluating our K-pop implementation locally running on multiple cores. We simulated 512 (single-process) clients simultaneously interacting with one server that delegates the server response for each client to one of P processes run on separate parallel cores, for $P \in \{1,2,4\}$. The work is evenly split such that each core handles $512/P$ clients.

The performance results for this experiment are given in Figure 10. Experiments were run on an 4-core 1.6 GHz Intel Core i5-10210U CPU with 16GB RAM. On $P = 4$ cores, the server performance is 2-3 times faster than a single-core implementation, depending on the mode of operation and ciphersuite. The run times for $P = 1$ core are slightly higher than the results of the experiment of §5.1 due to overhead from multiprocessing.

6 Conclusion

In summary, this work designs an account recovery protocol that works under stringent functionality and privacy requirements. First, the service provider cannot know or learn the email addresses of all clients. Second, the clients must be able to follow a 'normal' account recovery workflow and have the ability to choose their own security questions—but again, without creating a visible mapping between identities and their choice of security questions. Third, a non-collusion assumption might be broken, and even in this setting the protocol must resist the adversary's ability to recover client data. Finally, our design uses the cryptographic building blocks that our partner organization, Callisto, already understood and knew how to implement and maintain, such as an oblivious pseudorandom function.

Our design is inspired by the application to a secure matching system, and it has been deployed for use in this setting. That said, at least the first three requirements from above are generic and can apply to other account-based privacy-preserving services as well. This work shows that strong security and privacy can be compatible with usability and quality-of-life features like account recovery.

Abstract

At-risk populations need direct support from computer security and privacy consultants, what we refer to as a security intervention. However, at-risk populations often face security threats while experiencing traumatic events and ensuing traumatic stress reactions. While existing security interventions follow broad principles for trauma-informed care, no prior work has studied the domain-specific effects of trauma on intervention efficacy, nor how to improve the ability of tech abuse specialists to navigate them.

We perform a multi-part study into traumatic stress in the context of digital security interventions. We first interview technology consultants from three computer security clinics that help intimate partner violence survivors with technology abuse. We identify four challenges reported by consultants emanating out of traumatic stress, some of which appear to be unique to the digital security context. To better understand these challenges, we analyze transcripts of sessions at one of the clinics, extracting five patterns of how stress reactions affect consultations. We use our findings to develop new recommended best practices, including a new intervention protocol design to help guide security interventions.

1 Introduction

A growing body of research has highlighted the computer security and privacy needs of at-risk populations who face either increased likelihood of technology abuse or outsized harms should abuse occur [50]. Examples include survivors of intimate-partner violence (IPV) [15, 30, 48, 49], the LGBTQ+ community [29], the elderly [37], refugees [44], and human trafficking victims [11]. Each of these populations navigate unique security and privacy threats, and may disproportionately benefit from personalized expert guidance from e.g. company customer service [42, 53], technology abuse clinics [15, 30, 48], or NGOs [44]. Throughout this paper, we refer to such tailored guidance as *security interventions*, in which an expert *consultant* provides support to a *client*.

At-risk populations often seek security interventions while coping with traumatic events, such as abuse or political violence. Trauma can cause stress reactions that may have profound impact, such as fatigue, anxiety, or even hallucinations [25]. Thus, experts in security and privacy for at-risk users suggest that accessible and effective security interventions be *trauma-informed* [4, 5]. As in other service provision contexts, like trauma-informed lawyering [31] or investigation [8], this requires a domain-specific understanding of how traumatic stress affects services.

Yet, no prior work has investigated how traumatic stress impacts computer security interventions. Charting this gap is critical. Failing to account for distinct patterns of traumatic stress within security interventions risks not just inefficient service, but potential harm to client well-being. For example, a well-meaning and compassionate technology consultant might unwittingly encourage conversation that triggers anxiety attacks—or even inadvertently validate stress-induced hallucinations of technology abuse.

In this paper, we examine how traumatic stress impacts computer security interventions. We do so through a two-part study centered on three technology abuse clinics for IPV survivors. At these clinics, designed with the best trauma-informed practices available at the time, consultants work with IPV survivors experiencing technology abuse, such as account compromise by an abusive partner, potential spyware, and harassment on social media [15, 30].

The first study consisted of semi-structured interviews with 11 technology consultants across the three technology abuse clinics. Interviews sought to understand the traumatic stress reactions that manifest during client sessions, the challenges those responses present, and consultants' preparedness to navigate those challenges. The second study was conducted in collaboration with subject matter experts in mental health (hereafter, SMEs) and included qualitative analysis of 18 transcripts from sessions conducted at a technology abuse clinic. Analysis focused on patterns of traumatic stress reactions that presented during client-consultant interactions, with the SMEs providing clinically-informed explanations

for these patterns. Drawing on the findings from both studies and the clinical expertise of the SMEs, we introduce six *care practices* for consultants to use during sessions and design a security intervention protocol that refines the Havron et al. [30] understand-investigate-advise protocol to concretize how these care practices can be deployed.

In doing so, we offer the following contributions:

- a cross-site examination of how technologists currently experience and respond to traumatic stress reactions,
- a model, based on primary sources, of how traumatic stress manifests during delivery of security interventions,
- a set of guidelines for trauma-informed care uniquely tailored to computer security clinics serving IPV survivors,
- and a suggested revision to existing intervention protocol, that better operationalizes trauma-informed care.

Our findings are already being incorporated into new training materials and new organizational practices at one of the three clinics. These will be disseminated to other clinics, helping improve intervention delivery.

More broadly, our findings suggest that security intervention delivery benefits from a bespoke understanding of traumatic stress reactions. Future work could explore the generalizability of our results in additional contexts including other at-risk populations or intervention sites (e.g., computer security customer support systems). Our methodological approach should be useful to guide such future work.

2 Related Work

Technology abuse in IPV. Intimate partner violence (IPV) is a widespread social ill affecting one out of three women and one out of six men at some point in their lives [46]. While perhaps most often associated with physical, sexual, or emotional violence, the majority [39] of IPV situations include some form of technology abuse: the abuser uses technology as a means to harass, surveil, control, or otherwise harm their target. While scholars refer to this phenomenon using a variety of names, in this paper we use tech(nology) abuse. [14, 36].

A now large body of literature has documented the wide range of ways in IPV abusers weaponize technology, via reports from survivors or professionals working with them [18, 27, 28, 35], as well as from online forums where abusers discuss abuse tactics [3, 47]. Examples include installing spyware onto a partner's device, using Bluetooth or GPS tracking devices, compromising email accounts, harassment via social media or text messaging, and distributing non-consensual intimate imagery (NCII). Not only is tech abuse complex aggregated across survivor experiences, but one individual may suffer from multiple forms of tech abuse [27]. At the same time, as Chen et al. [12] explore, technology abuse may be a source of trauma or re-traumatization, and traumatic stress reactions may impact peoples' technology experience.

Traditional computer security approaches, such as usability audits of account security interfaces or "smart labels" warning consumers of privacy issues for household devices, can help mitigate tech abuse [16, 20]. However, navigating the technical and emotional complexity of tech abuse remains non-trivial, and researchers and practitioners have therefore argued that we must complement those approaches with direct, personalized support for survivors experiencing technology abuse [14, 26, 30].

Human-based security interventions. Digital security mechanisms and policies are frequently complemented with what we will refer to as human-based interventions for targets of digital attacks. Here, we discuss examples of such human-based interventions, focusing on interventions provided to individuals, rather than interventions directed at organizations such as companies or non-profits.

For our purposes, a security intervention arises when a (potential) target of a digital attack enlists the assistance of a trained professional, who has both the technical expertise and access to tools that may help the victim discover and remediate the attack. Examples that can fall into this class include customer support for a product, consumer help desks like Apple's Genius bar, consumer IT tech support companies offering security services, and private forensics services.

A small amount of academic work has started investigating these kinds of commercial interventions. Sharif et al. [42] studied the types of security issues reported by individuals to a security company's customer service system, and how well those aligned with expert's perspectives on security. The study used customer service logs from NortonLifelock, a large consumer antivirus and fraud protection company. Roundy et al. [53] used the same dataset to investigate how IPV presents to customer service agents, and used semi-structured interviews to gather suggestions from IPV survivor support professionals about how to improve customer service delivery.

This paper focuses on technology abuse clinics, a newer form of security intervention that is qualitatively different from the commercial interventions described above. These clinics aim to assist specific at-risk populations with addressing technology-enabled abuse, using volunteers trained in both population-specific issues and as well as computer security best practices. The approach also goes by the moniker clinical computer security (c.f., [30]). The most mature examples of such clinics have arisen in the context of IPV [15, 30]. These clinics emanated out of academic environments, with initial evaluation of their success primarily via qualitative methods [26] and surveys [15].

Subsequently, a line of work has investigated clinic service delivery. Tseng et al. [48] analyzed a COVID19-inspired rapid shift of a clinic to operate remotely, highlighting among other findings the emotional and time management burdens, as well as the difficulty of conclusively determining explanations of client experiences, particularly as those challenges

intersect with remote service delivery. Tseng et al. [49] later explored how to adopt a feminist ethic of care to enable better customizing interventions to individual IPV survivors. Their work highlights the challenges around establishing service scope boundaries, the difficulty of finding service endpoints, and the difficulty of navigating client hypervigilance in light of the typical inability to find conclusive "ground truth" that explain tech abuse experiences. Some of our findings reinforce those in [48, 49], as we will discuss in later sections. Finally, Slupska and Strohmayer [45] interview tech-abuse advocates, highlighting in particular the importance of networks of other practitioners that advocates can employ to help support survivors with specific issues.

Prior work has therefore acknowledged the complex emotional landscape of interventions, the possibility of some traumatic stress reactions, and the need to be trauma-informed. But prior work has not studied the role of traumatic stress reactions in computer security interventions.

3 Trauma and Intervention Design

In this section, we provide background on trauma and traumatic stress reactions, with a specific focus on how direct service providers incorporate trauma-informed care into their practices. We also include a composite vignette illustrating how traumatic stress reactions typically manifest in computer security clinics, then conclude by detailing how these implications influenced our study design.

Trauma and trauma-informed care. According to the United States' Substance Abuse and Mental Health Administration (SAMHSA), trauma "results from an event, series of events, or set of circumstances experienced by an individual as physically or emotionally harmful or life threatening and that has lasting adverse effects on the individual's functioning and mental, physical, social, or spiritual well-being" [25].

Exposure to IPV is associated with an increased likelihood of long-term traumatic stress reactions, with rates of post-traumatic stress disorder (PTSD) among IPV survivors estimated at 2-3 times that of the general population [17]. Even when exposure to trauma does not result in long-term effects, trauma can cause short-term *stress reactions* [25]. Some non-comprehensive examples include physical (e.g., extreme fatigue, hyper-arousal), emotional (anxiety, grief, shame, hopelessness), behavioral (avoidance of triggering situations), and cognitive (hyper-vigilance to threats, flashbacks).

Mental health clinicians have robust evidence-based approaches for supporting people experiencing stress reactions [43, 51]. This includes a range of treatments provided by licensed psychiatrists, psychologists, and social workers [21]. Yet, people experiencing traumatic stress regularly seek support from direct service providers outside of the mental health community. Mental health clinicians have played a key role in advancing trauma-informed practices for direct service providers — who are not mental health clinicians — to use in supporting people experiencing traumatic stress reactions, including survivors of IPV. This includes trauma-informed interviewing practices for law enforcement [8], trauma-informed legal advocacy in family law settings [1], and trauma-informed patient care in medical settings [40].

Regardless of the setting, a central principle guides trauma-informed IPV care: all elements of service delivery should be shaped by an understanding of how abuse impacts the lives of clients [19]. While specific approaches may vary, empathy and validation are central to the provision of trauma-informed care [33], both of which help to convey to an individual that they are heard and believed, that their emotions are rational, and that they are not being judged. Empathy and validation are also important tools for developing rapport and trust with individuals experiencing stress reactions, a crucial element for providing effective direct service support.

IPV security clinics were consciously designed to incorporate trauma-informed care practices into their service models. The technologists (referred to as consultants) receive specialized trauma-informed care training before beginning direct service work with survivors (referred to as clients) [13, 15]. These practices are further embedded within the structure of clinic sessions, beginning with the understand-investigate-advise framework developed by Havron et al. [30]. This protocol provides guidance to consultants when working with clients, suggesting that consultants "*understand* the client's technology issues, *investigate* their devices and accounts, and *advise* the client on next steps" [30]. While the entirety of the protocol is client-centered and trauma-informed, the 'understand' phase of the protocol in particular emphasizes active listening, a practice of attuning to the speaker's emotional and explicit delivery, and verbally reflecting that back to the speaker in order to both empathize with and validate the client's experiences and chief concerns.

Technology abuse clinics and stress reactions. To concretize the subtleties of navigating stress reactions when working with clients, we include below a composite example that is reflective of the authors' experiences working with hundreds of survivors of tech abuse at computer security clinics. This composite focuses on challenges associated with traumatic stress reactions that commonly emerge in a clinic session.

A client Casey is referred to a technology abuse clinic by their social worker: Casey mentioned being afraid to use their email for fear of it being monitored by their ex-partner. The clinic uses the *understand, investigate, advise* method discussed above via a remote consultation over the phone, similar to the procedures described in Tseng et al. [48]. In the course of the session, a number of challenges unfold for the technology consultant Taylor who volunteered to help Casey:

- Taylor asks Casey why they sought tech support. Casey

provides a long history of their emotional and physical abuse, which takes time. While sharing this history, Casey becomes emotionally distraught, stating that they "feel hopeless" about escaping the abuser's reach.

- Casey describes problems that are technologically implausible, such as "every time I buy a new phone, he immediately hacks it". Casey describes how every phone exhibits behaviors that indicate it is "hacked", and that they've been avoiding use of their phones as a result. Casey's fear and frustration is palpable.
- Casey is unsatisfied with the account security checks that Taylor suggests. Casey insists that these are insufficient to catch their ex-partners' "hacking". Taylor tries to explain why it is useful to inspect account security, but Casey is frustrated, pointing out that they read many articles online about powerful hacking tools.
- The consultation goes past its scheduled end time. Taylor is disappointed and demoralized that they were unable to make meaningful progress in the session.

This vignette illustrates how traumatic stress reactions can color delivery of computer security interventions. Casey displays hopelessness, hypervigilance and avoidance towards technology, along with fear and frustration. Taylor must navigate this emotional landscape while interpreting Casey's descriptions of the technology abuse, unpicking where they align with the attack vectors that Taylor's expertise suggest are most plausible. Taylor is committed to trauma-informed service delivery, offering validation to Casey throughout the appointment. Nonetheless, Taylor worries that this validation is contributing to Casey's fears, and believes that Casey would benefit from professional counseling to cope with the emotional toll of the abuse.

Open questions. Our experience working with IPV survivors, as captured by the example above, suggests that we have more to learn about how traumatic stress reactions impact security interventions. Yet as discussed in the last section, beyond experience-informed anecdotes, no structured investigation has been conducted into whether current intervention designs and consultant training practices are sufficiently addressing the needs of clients experiencing traumatic stress reactions during sessions. In response, three key research questions guide the studies we introduce below:

(1) What challenges related to traumatic stress reactions do consultants encounter during sessions with clients?

(2) Are there patterns that capture how traumatic stress reactions interact with technology-enabled abuse that may inform best practice for security interventions?

(3) Are existing trauma-informed care practices used by, e.g., mental health professionals applicable to computer security interventions? If so, which ones, and how should they be integrated?

To answer these questions, we use a multi-part study design that builds from existing literature on trauma-informed practices in computing [12] and interdisciplinary work on traumatic stress reactions [25, 33]. The first phase of the study entailed semi-structured interviews with technology consultants volunteering or working at computer security clinics in a direct service role. The second phase engaged subject matter experts in analysis of transcripts from a computer-security clinic documenting consultant-client interactions. Subsequent sections of this paper detail the specific methodology for each phase of the study.

Ethics. Drawing on best practices for conducting research with at-risk populations [4], we did not directly recruit survivors into this study as we had access to pre-existing data sources that produced a rich dataset pertaining to survivors' experiences accessing computer security clinic services. The data was collected under an IRB-approved study — survivors (clinic clients) opted into participation and received service regardless of research participation.

Additionally, this study does not include clinical diagnoses of clients. Despite involving subject matter experts in mental health in the study design and analysis, a diagnosis requires direct interaction between a client and a mental health professional, which this study does not entail. The SMEs identify patterns of traumatic stress reactions, but do not provide specific clinical diagnoses.

Lastly, we recognize the sensitivity of studying client-consultant interactions for both parties involved. Though such studies are necessary for advancing best practices, we view consultants as contributing emotionally-taxing labor under the best guidance available at the time, and take care to avoid reproducing their interactions in a disparaging light.

Positionality. Collectively, the authorship team has over 50 years of experience providing direct services to thousands of IPV survivors. The second, third, and fourth authors are SMEs in mental health, each being Master's level licensed clinicians with social work degrees who specialize in working with clients experiencing tech abuse. The remaining authors all have extensive experience providing direct services to survivors, operating technology abuse clinics, and conducting research on IPV and digital safety.

Our analytical lenses draw on anti-oppression frameworks that recognize how survivors are impacted by intersectional social and political identities [32]. These frameworks prioritize survivors' agency in navigating trauma. Our experiences and analytical lenses informed all aspects of this study, including our methodological choices to rely on pre-existing data and to mitigate unnecessary exposure of the research team to traumatic content. Throughout all phases of the study, we engaged in a reflexive practice, regularly discussing questions of ethics and bias, including our professional interest in the study recommendations.

Clinic	Locale	# Consultants		Host Site	Modality
		Study	Total		
MTC	Madison	2	4	UW-Madison	in-person
CETA	NYC	7	25	Cornell Tech	audio call
TECCC	Seattle	2	4	DV Service	video call

Figure 1: Breakdown of consultant participation by clinic.

4 Mapping Consultant Experiences

We start with an exploratory study with tech consultants at tech abuse clinics. We chose to begin by interviewing consultants to identify gaps in current trauma-informed training that have deleterious effects on computer security interventions, and to develop an initial mapping of how traumatic stress manifests during client-consultant interactions.

4.1 Methodology

Recruitment. We recruited 11 technology consultants for semi-structured interviews from three computer security clinics: the Madison Tech Clinic (MTC), the Clinic to End Tech Abuse (CETA) in New York City (NYC), and the Technology Enabled Coercive Control Clinic (TECCC) in Seattle. Figure 1 summarizes the number of participants from each clinic and the total number of consultants affiliated with each clinic at the time of the study in Spring of 2023.

Consultants from MTC and TECCC live and work in the same geographic area as the clinic, while consultants from CETA engage in remote consultations from their home locations across the US, Canada, and Europe. Consultants were eligible to participate in the study if they had participated in at least two or more client sessions in the six months prior to the interview. Because of the smaller sizes of MTC and TECCC, all eligible and willing participants were interviewed. At CETA, solicitation ceased at saturation, when interviews became repetitive.

Supervisors at each clinic helped determine eligibility, and eligible consultants were contacted by either the first or last author with an invitation to participate in a Zoom-conducted interview. Potential participants were informed that declining would not impact their relationship with either the host clinic or its affiliate partners. No compensation was offered for participation. We received IRB approval for this study.

Analysis. Interview questions focused on the challenges that arose during consultant-client interactions (e.g.: *How well did trauma-informed care training align with your in-session experiences? Are there situations that you feel training did not prepare you for?*). All participants consented to audio recording, and recordings were transcribed and anonymized by the interviewer before analysis.

The first and last authors used reflexive thematic analysis to identify common themes across the interview data, following the six-phase process outlined by Braun and Clarke [7]. Consistent with our study design that incorporates existing work in trauma-informed care, we used a hybrid approach of deductive and inductive analysis [24], beginning with codes that represented anticipated themes, and then modifying the codebook (available in Appendix B) as new codes emerged. This resulted in 5 parent codes and 24 additional subcodes. For example, the parent code *consultant strategies* included subcodes such as *validate client* or *try to set expectations*.

Four themes were identified that described challenges related to mental health and a need for additional support. These four themes, which we call challenges, were consistent across participants from all three clinic sites. To help preserve consultant anonymity, we label consultant quotes as C1–C11, rather than identifying the clinic with which a consultant is associated. Below, we italicize direct quotes, which may be lightly edited to avoid identifiability without changing meaning.

In what follows, we detail four challenges (labeled CH1–CH4 in the summary table in Figure 2) regarding client-consultant interactions and how established trauma-informed care practices fall short in supporting technology consultants' direct-service work with IPV survivors.

4.2 Findings

Challenge 1: Managing time for security inventions. Many clients do not delineate between tech abuse and other forms of abuse, in part because tech abuse can affect many different areas of a client's life. Thus, when clients are asked to describe their technology concerns, they often share it in the context of longer narratives. During interviews, consultants explained that they struggle to maintain a balance between making space for clients to process their experiences, while also adequately delivering security interventions in the constrained amount of time available for a session.

Consultants described a pattern in which they ask clients general questions about their technology concerns at the beginning of the session, and clients *"start expressing everything they've been through. Sometimes it's overwhelming"* (C1).

Drawing on their training, tech consultants recognized that clients often have few spaces to disclose their experiences of tech abuse, and many clients understandably do not delineate tech abuse from other forms of abuse. Consultants also pointed out that the non-technical information and abuse history may offer valuable insight to decipher technology abuse, making this overlap diagnostically relevant. For example, a client might recall an opportunity the abuser had to access their device during a memorable incident of physical abuse, or share who owned certain accounts in the context of detailing a pattern of financial abuse.

Yet, offering unbounded time for therapeutic processing at the possible cost of service delivery was a frequent point of tension for consultants. While validation was an important part of the service, consultants worried that an overempha-

Label	Finding
	Challenges Identified in Consultant Interviews (§4)
CH1	Consultants struggle to understand tech abuse without enabling potentially harmful or time-consuming abuse narratives.
CH2	Clients may have unrealistic expectations for technical solutions, leading to frustration or desperation.
CH3	Fears about technology are often misplaced, but countering such fears seems anti-thetical to trauma-informed training.
CH4	Consultants are unsure if or how to ethically end services, especially when tech abuse is indistinguishable from paranoia.
	Patterns Identified in Transcript Analysis (§5)
TP1	Clients describe tech abuse with uninterrupted narratives, potentially retraumatizing clients.
TP2	Security and privacy diagnostic processes may be seen as threatening to clients due to historical systems trauma.
TP3	Pre-conceived theories about tech abuse may be protective, and clients may not be ready to accept new information.
TP4	Difficulty managing disparate tech concerns contributes to distress near end of session–the “doorknob" problem.
TP5	Consultants struggle to deflect non-technical concerns or articulate technical limitations, tending to overavailability.
	Subject Matter Expert-Advised Care Practices (§6)
CP1	Refocus clients to tech concerns by compassionately interrupting or using validation as a pivot point.
CP2	Be transparent about security and privacy diagnostic procedures to ease fears and build trust.
CP3	Counter existing beliefs by validating experiences (not explanation), then helping re-interpret tech phenomena.
CP4	Scope technical concerns explicitly early on, including prioritizing highest-risk concerns.
CP5	Have and enforce boundaries on the service, couched in organizational limits, including an exit strategy.

Figure 2: A summary of our findings. Challenges (CH) were identified in tech consultant interviews (Section 4). Patterns (TP) of traumatic stress reactions were extracted from session transcripts (Section 5). Care practices (CP) (Section 6) were offered by subject matter experts (SMEs) in mental health who also helped identify transcript patterns.

sis on validation could mean *“sometimes we’re not actually carrying out any security checks”* (C5).

Consultants also explained that clients may become increasingly distressed while sharing their abuse history, and consultants were unsure *“whether to let them continue talking and get more emotional or whether to stop them”* (C8). As one consultant neatly captured, unchecked story-telling could hinder delivery of security interventions:

> *Some of this is helpful. Some of this is not. All of it is taking up some time. How much is appropriate? Am I doing [clients] a disservice by just letting [them] continue talking?* (C10)

While several consultants found *“interrupting clients in the kindest way possible”* (C6) to be useful, consultants generally expressed reluctance to interrupt clients. Reasons cited for their hesitancy to interrupt included not knowing how to effectively interrupt, concern that interrupting would harm their rapport with the client, or that interrupting seemed incompatible with empathetic service delivery.

Challenge 2: Communicating technical limits. several reasons why they find it difficult to manage client expectations about their ability to address tech concerns. First, tech abuse in particular can extend abusers’ ability to cause harm over long distances and/or time, increasing the sense of hopelessness and inescapability associated with technology abuse in particular. As one consultant noted, *“Sometimes the crisis scenario has been going on for I don’t know how long. [A session] could go on for hours”* (C11).

Second, tech clinics are not equipped to help with every facet of tech abuse, some of which may require advanced diagnostic tools (e.g., suspected use of sophisticated spyware) and some of which may be better handled by other systems (e.g., legal injunctions against harassment). As a consequence of these two factors, clients may arrive at the session with unrealistic hopes for what the consultant may be able to do in a time and resource-constrained setting.

Clients may respond to these service limitations with a variety of traumatic stress reactions, often near the end of the session. One common reaction reported by consultants was frustration or even anger upon realizing that the security interventions at the clinic’s disposal were insufficient for the client’s needs. This ranged from clients expressing that the security interventions were too elementary for what they believed they needed, to the less common extreme of clients making (unfulfilled) threats to take legal action against the clinic.

Another common reaction that consultants cited was desperation for additional service. Clients were sometimes convinced that additional sessions might yield new information, even when consultants explain that they have no additional help to offer. As one consultant described,

> *After we say we haven’t really found anything...they’ll come back two or three months later and it’s the same exact concerns. But then it’s like, how do you set those boundaries? And when?* (C9)

Tseng et al similarly surfaced the difficulty in finding natural endpoints for service [48, 49]. Our study finds that this is not limited only to longer-term care models, and this challenge manifests across clinics with different service models.

Consultants in short-term service models also experience difficulty with time boundaries during a single session and pressure to continuously extend the depth and complexity of security interventions that they offer. One consultant summed up the predicament, stating: *"It's really hard to say no, because this is someone who's asking for your help and you do have the expertise to help them"* (C8).

Challenge 3: Unhealthy validation of technical fears. Clients often enter sessions with misunderstandings regarding the ease with which technology can be "hacked". This includes *"clients believing that normally functioning technology is being maliciously used against them"* (C6), such as unsubstantiated fears that phone calls are being monitored.

As one consultant noted, these misunderstandings are exacerbated by social attitudes towards cybersecurity, saying, *"Hollywood and tech companies keep people wondering about what is and isn't possible. For survivors, that leads to confusion"* (C4). Multiple consultants acknowledged that some client's fears might sound outlandish on face, but saw those fears as reasonable given the abuse, disinformation, and the abstruseness of many technology interfaces.

Tech consultant are therefore often required to counter such (mis)beliefs. However, this creates tension with a core tenet of trauma-informed care: *validation*, or the practice of explicitly affirming the worthiness of a survivor-client's feelings and experiences. Validation is heavily emphasized in consultant IPV training, in part because research confirms that survivors' valid technology concerns are particularly likely to be dismissed or minimized by people in positions of power (e.g., law enforcement, judicial officers) [52].

Consultants considered validation a crucial part of their practice. Sensitive to the fact that many clients *"might not have folks that believe them"* (C7) outside of the consultation, consultants observed that from their position as tech experts *"validating their concern and just listening to them...relieves their anxiety"* (C9). Aiming to counteract the minimization and dismissal that clients may have encountered elsewhere, consultants explain that they *"prioritize making [clients] feel heard and that they are not crazy because it's something people hear so often"* (C8).

Yet, consultants also express worry that for some clients, blanket validation could be unhealthy. When tech fears are not based in technical realities, validating that fear *"could be dangerous because if nothing is happening, it might make them more paranoid"* (C8). Though sympathetic to the client's confusion, consultants explained that they *"struggle to navigate validating feelings, but not necessarily technical concerns when there's no technical evidence"* (C5).

This was particularly thorny in the less common scenario that the client held more extreme beliefs. While quick to note this was not the dominant scenario they encountered, one consultant nevertheless explained that when working with clients whose beliefs included conspiratorial elements, *"you almost feel like you're validating someone's experience in ways that are unhelpful in the long run"* (C6).

In summary, the trauma-informed practice of validation becomes non-trivially complicated when navigating the ambiguity resulting from attempts to diagnose security and privacy risks with the limited set of tools available to tech clinics. As one consultant asked: *"What is healthy validation and what is not? It's not like there is a right answer, is there?"* (C11).

Challenge 4: Consultants lack an exit strategy. Across the interviews, consultants were reluctant to discuss encountering serious mental health issues. Participants repeatedly emphasized that serious mental health issues were not representative of the clients they typically work with and feared contributing to the systematic dismissal, stigmatization, and invalidation that many survivors already face.

Complicating this, consultants pointed out that they lacked a full set of diagnostic tools and computer security training to distinguish between a mental health crisis or high-risk, edge-cases of sophisticated technology abuse. One consultant described the precarity of working with clients whose concerns fell in this gray area:

> *I'm not about to diagnose anyone with anything, but some clients go very deep down the rabbit hole with their technology. And something like a configuration file on their Android phone, they might think that's spyware. Or they might think that there's something going on that, from a technologist's standpoint, isn't—I don't want to say it's not possible, because I don't know if it's possible.* (C7)

Though the use of sophisticated nation-state level spyware (e.g., NSO Pegasus [34]) against civilian targets is a well-documented occurrence, the current consensus among experts is that such sophisticated attacks would be rarely encountered in IPV, with less sophisticated abuse tools the empirically more relevant threat [2, 10, 38]. Consultants at IPV clinics are therefore mostly not equipped with training or tools that might help rule out use of more sophisticated attack tools, which, in turn, would aid in differentiating such threats from a client's conspiratorial or delusional beliefs.

Consultants question whether they should end service all together when they recognize that the client's beliefs or emotional state are beyond what the clinic is equipped to disambiguate or otherwise safely handle. And, if they ultimately believe this the best course of action, consultants were unsure how to do so:

> *The client was, you know crying, running from one room to another...just a very chaotic scene. [I had] to cut off the conversation, because it was not good for me and I doubt it was good for them. When someone is in more of a crisis state, there's a shared*

intensity to it. So I feel that stress, because I want to do things ethically and responsibly. (C11)

Other consultants, often those who self-identified as being highly-experienced, shared similar anecdotes. In some cases, clients had technical issues the consultant was capable of addressing, but the client struggled with emotional regulation enough that the consultant could not identify or deliver a security intervention. In others, the client had severe issues with reality testing, such as a high degree of paranoia or conspiratorial thinking, that either lacked technical plausibility or that the consultant lacked the tools to disambiguate.

In these situations, consultants reported doubt that the services offered by the clinic were beneficial for the client or indeed whether they were appropriately equipped to safely provide service without direct oversight from professionally-trained mental health experts.

While none of the clinics operate with the resources or training to provide this form of support, the inherent nature of the service means that consultants must navigate the possibility of encountering such clients. Organizational level practices, such as robust screening processes at intake, can mitigate the likelihood of these situations occurring, but consultants still need ethical exit strategies to facilitate hand-off from certain consultations to more appropriately equipped services.

5 Analyzing Transcripts of Clinic Sessions

Our study with consultants surfaced common challenges related to traumatic stress reactions across all three clinics. These challenges indicate that delivery of security interventions is meaningfully affected by the impacts of traumatic stress, and that current trauma-informed care training is insufficient to fully address these complexities. Seeking a deeper understanding of the role of traumatic stress in security interventions, we turn to a more granular investigation by analyzing session transcripts to identify patterns in how stress reactions arise.

5.1 Methodology

CETA has an ongoing IRB-approved research study on technology abuse. At the start of a client session, the client is consented into research participation and, if so, for permission to audio record sessions. Clients are informed that they will receive the same service from the clinic whether or not they consent, and client support proceeds the same regardless of research participation. Session transcripts offer unique insight into the dynamics of client-consultant sessions, while also obviating the need to conduct a separate research study directly with survivors which could, itself, be a source of burden or even trauma for them (see [4]).

At the time of the study, the CETA transcript database contained 218 anonymized transcripts from phone-based appointments with 161 different clients. All 18 transcripts considered below involved distinct clients. CETA does not collect or retain demographic information about individual clients represented in the data, and the nature of our study does not support demographic-level analyses. However, CETA serves a diverse, minority-majority population: 78% of clients seeking IPV services in New York City are female, with 59% being foreign born, 66% being non-white, and 5–8% identifying as LGBTQ+.

To provide clinical insight to our analysis, the subject matter experts (SMEs) among our authorship team (see Section 3) participated in coding the transcripts and in augmenting the transcripts with annotations.

Coding. Lacking prior validated techniques for prescreening transcripts for inclusion through, e.g., keyword search, we randomly sampled transcripts. SMEs drew on their professional expertise to designate an initial set of codes for analyzing the transcripts that were indicative of traumatic stress reactions. The first author and an SME then refined the codebook over an initial sample of six transcripts, meeting regularly to confer and discuss newly emerging codes [24]. This resulted in a codebook with a total of 23 codes, available in the Appendix B: 13 codes representing traumatic stress reactions and 10 codes describing consultant demeanor.

Examples of codes representing traumatic stress reactions include: *information dumping*, *physical symptoms*, and *anger, frustration, and resentment*. The authorship team then used this codebook to analyze an additional 12 randomly selected transcripts, working in pairs that included an SME. We identified saturation as the point when no new codes were being generated and all identified codes had been applied with expected frequency, and ended sampling. By expected frequency, we mean that traumatic stress reactions appeared in the data at what SMEs found consistent with professional experience, with codes indicating common reactions like *hypervigilance* appearing over 80 times but rarer, more serious reactions like *hallucinations, delusions, and psychosis* appeared fewer than 25 times. Ultimately, 18 transcripts were analyzed for the study. Below, references to transcripts are labeled T1–T18.

Annotations. During the coding process, SMEs noted that traumatic stress reactions are often not explicit in the text of an interaction. For example, an interaction in which a client repeatedly avoided a question from a consultant was coded as a potential marker for anxiety, even though the client did not explicitly state "I feel anxious".

To capture these nuances, we introduced a protocol for annotating transcripts after coding them. In keeping with our ethical commitment to reduce the emotional burdens and time commitments placed on the SMEs (who work as full-time practitioners with survivors), our annotation protocol incorporated a collaborative focus group approach in which

the SMEs provided clinical analysis of the transcripts during structured sessions.

We held eight focus groups over Zoom attended by one or more SMEs, in addition to a non-SME facilitator. Each focus group analyzed 1–2 transcripts. The facilitator started each session by providing a brief overview of the interactions in the transcript. The facilitator then instructed the SMEs to read segments that had been previously coded, after which the SMEs were prompted with questions such as: *Why did this interaction suggest hypervigilance? What might have caused this reaction?* This analysis was captured by the facilitator via annotations of the transcript segment.

As part of our ethical strategy to reduce vicarious trauma, we were reflective about identifying saturation points as soon as possible: focus groups were ended when all codes had been encountered and SMEs explicitly noted that their annotations and analysis were repetitive. This process resulted in annotations of nine transcripts across eight sessions.

Analysis. The coded and annotated transcripts formed the basis for our analysis. When reflecting on potential themes, the first and last authors considered the transcript segment, the code, and the annotations provided by the SMEs together. Other than the inclusion of annotations, the first and last authors used a similar analysis process in developing themes as in Section 4.1. We identified five patterns and mitigation strategies, which we outline below.

To provide additional context, we note whether these patterns tend to occur during a specific stage in the *understand-investigate-advise* protocol. An overview of how these patterns relate to each stage in the consultation protocol as well as their relationship with challenges identified by consultants is presented in Figure 3.

5.2 Findings

We start by discussing five patterns identified during our transcript review, including the SME-informed explanations of why those patterns might occur. We summarize these patterns, labeled as TP1–TP5, in Table 2. We discuss practical tools to help consultants navigate these patterns in Section 6.

In what follows, we ground our findings with examples from session transcripts of client-consultant interactions. In order to protect the privacy of clients and consultants, we primarily use composite examples that represent common interactions across multiple sessions. We include direct quotes only when the speaker would not be recognizable by quote.

Pattern 1: Uninterrupted narratives. Consistent with consultant experiences in CH1, SMEs identified a pattern in which open-ended questions about the client's technology concerns were answered by detailed, non-linear narratives of their abuse history. This was especially common during the early, exploratory phase of the session, where a session transcript might entail upwards of ten minutes of clients continuously speaking about both technical and non-technical concerns. During these long narratives, consultants typically listened without speaking or occasionally offered a validating response of "I see" or "I'm sorry that happened."

Sharing these stories without interruption and receiving validation can help establish needed rapport, especially early on. However, SMEs raised several potential pitfalls. While an obvious drawback concerns time management, others were specific to traumatic stress reactions. Namely, revisiting potentially traumatic experiences at length and in depth can be *retraumatizing*, engendering reactive states for survivors that can hinder their ability to effectively and productively engage with technology support services [19].

Shorter but emotionally charged client narratives also occurred during walkthroughs of security interventions, especially when clients found something confusing or unfamiliar. If clients had already shared longer narratives early on (such as a story about how the abuse had affected their children), they would often reference those narratives again later: *"It just sucks for my kids, you know?"* (T4). Indeed, one client alluded to this process of retraumatization directly, saying: *"It's all triggering. It reminds me of how chaotic these moments were when I was receiving this stuff"* (T16).

This apparent switching between the concrete task at hand and recounting experiential anecdotes might also have long-term impacts. As tech consultants are unable to provide long-term therapeutic support, negative or unsatisfying experiences with sharing sensitive stories during the clinic session might even discourage the client from sharing those experiences in more appropriate professional settings. Similarly, SMEs pointed out that if clients did not understand that they were not obligated to disclose weighty, sensitive information in order to receive help, this might discourage clients who were not ready to make such disclosures from seeking support for technology or security intervention services in the future [23].

Pattern 2: Identifying security concerns. Another pattern of traumatic-stress reactions surfaced during the diagnostic, investigative portions of sessions. As previously noted, clients often arrive with vague or technically imprecise descriptions of their experiences, stating that their phone or device was 'hacked', 'cloned', or being 'constantly monitored'. To help pinpoint explanations, consultants embark on a series of questions intended to differentiate possible security risks, a process which could quickly become tense.

This most often manifested as evasiveness or frustration when asked diagnostic questions without context. For example, one client avoided answering whether the abusive party had been able to physically handle the device (T2), possibly wary that her concerns might be dismissed should she answer no. In another, a client repeatedly dodged a direct question about whether unusual behavior had persisted after switching devices by repeating what they had heard from a friend (T13).

Protocol Stage	Goals	Identified Challenges (CH)		Identified Patterns (TP)	
Understand	active listening to understand client issues, open-ended exploratory questions, mapping of potential threats	time management information dumping	CH1	retraumatization information dumping	TP1
Investigate	manually check security and privacy configurations, identify potential safety risks, document suspicious settings	unrealistic expectations ambiguous outcomes	CH2 CH3	systems trauma protective beliefs	TP2 TP3
Advise	devise likely explanations, provide safety information and education, suggest tools or strategies for improving safety	service overusage exiting unsafe situations	CH2 CH4	"doorknob" phenomenon overavailability	TP4 TP5

Figure 3: A description of the understand-investigate-advise protocol, annotated with where consultant-identified *challenges* (CH) and transcript-identified *patterns* (TP) most commonly surface, using the labels from Figure 2.

Consultants, sensing the fragility of the moment, would often pause diagnostic process to try and re-establish rapport.

SMEs explained that diagnostic questions can be particularly loaded for clients whose past experiences with "the system" have taught them that failing to fit neatly into apparently arbitrary criteria might result in their concerns being wholesale dismissed. This is possible for all survivors, but especially likely for marginalized populations such as LGBTQ+ and/or immigrant survivors. Such experiences are known as *systems trauma* [9]. As consultants noted and as prior research supports, survivors are especially likely to have invalidating experiences when seeking help for technology abuse [52].

Second, clients might not be familiar with the diagnostic protocols that consultants use to help tease out and organize tech abuse concerns. Consequently, when asked diagnostic questions without an explanation of why that question is necessary, clients may be skeptical of how their answers will affect the service they receive or whether the question itself is a sign of doubt.

Pattern 3: Countering existing beliefs. The delicacy of navigating exchanges in which clients disclosed fears which were not technically plausible was frequently observed. As consultants interviews also suggested in CH3, clients often arrive at the clinic with an explanation or theory in mind as to how the tech abuse is being conducted. Notably, prior research has confirmed that abusers tend to overstate their technical abilities as a control tactic, causing survivors to believe that the technical explanation for their experiences is highly sophisticated [14]. Thus, when consultants attempted to push back on this belief, subsequent interaction between clients and consultants were fraught.

This tension was observed in several transcripts (T2, T5, T15, T16). While individual circumstances are too identifying for detailed description, they all centered around a belief that the abuser had abilities allowing them to totally and immediately monitor or manipulate the client's electronic devices. The SMEs recognized the predicament in steering the session: if consultants pushed too hard, they risked the client shutting down or becoming unreceptive to new information. However, blanket validation could be interpreted as endorsing misconceptions about the technical capabilities of abusers.

In such scenarios, SMEs explained that clients often hold these beliefs as a form of protection against danger or difficult emotions, thus it may feel threatening for clients to release those protective beliefs, especially in the moment. Nonetheless, they pointed out that the safety information provided by consultants could be valuable for managing traumatic stress reactions in the long-term.

For example, *hypervigilance* is a common traumatic stress reaction in which survivors are highly sensitive to warning signs of danger or abuse. This adaptation, while protective during on-going abuse, can become problematic when benign events are misidentified as threats [41]. Thus, technologists are positioned to supply clients with accurate information about security and privacy risks that, accompanied by therapeutic treatments, could potentially aid in managing anxiety, hypervigilance, and other traumatic-stress reactions related to the technology abuse.

Pattern 4: The "doorknob" phenomenon. The well-documented tendency of tech abuse being deployed in complex, disparate methods for even a single client was evident in the transcripts. Clients often arrived wanting to understand the security and privacy risks of each of many devices. In part owing to the cognitive impact of traumatic stress and the obfuscated nature of tech abuse, clients may struggle to organize those concerns into manageable task. Thus, tech consultants faced difficulty in scoping sessions for what could reasonably be accomplished in the allotted time.

SMEs noted that sessions lacked clear boundaries around length, ranging from 60–90 minutes. Additionally, consultants sometimes struggled to manage the pace of the appointment when clients shared many disparate concerns. This contributed to a familiar pattern of distress known as the "doorknob" phenomenon [22] near the end of sessions: when clients ask a rapid series of questions or raise new, seemingly urgent issues at the end of an appointment, just as the provider reaches for the door to exit the office.

In one sampled transcript, a consultant began summarizing completed and outstanding tasks, at which point the client began a block of questions related to hardware security, an upcoming court date, utility plans, and online blocking mechanisms (T4). In other end-of-session examples, clients apolo-

gized for wasting the consultant's time (T9), and in a more extreme example, explicitly alluded to panic when the consultant alluded to wrapping up (T5).

Pattern 5: Out-of-scope concerns The overwhelming majority of transcripts depicted momentary traumatic stress reactions occurring in the context of a session that otherwise consisted of security interventions and rather dry discussion of technical details. However, as consultants described in CH5, in two transcripts (T5, T15) in which the each client showed severe signs of difficulty distinguishing reality from conspiracy or paranoia, and a third (T9) demonstrated a fundamental mismatch vis-a-vis the client's needs and the clinic's scope.

More commonly, clients sometimes disclose urgent needs that were beyond the scope of the clinic. This included tech-based concerns, like home visits to search for tracking devices or collecting evidence for a court case. It also included non-technical concerns such as difficulty affording food or basic utilities or needing medical care. In all cases, consultants offered compassionate and empathetic responses, but frequently struggled to articulate limits on what the service was capable of providing.

In general, we noted a tendency towards *overavailability*, observing that consultants rarely explicitly set boundaries around ending service with a client. Consultants almost always closed sessions by asking clients if they would like another appointment, even if they had done a thorough job addressing all concerns during the session.

This is consistent with the difficulty in drawing boundaries reported by consultants in interviews and in Tseng et al [49]. SMEs were able to provide additional context on why ending service with intentionality was consistent with compassionate care. If the client was navigating a fundamental mistrust of technology, the client could likely find fodder to discuss with the consultant indefinitely, setting them up for infinite appointments and increasing the likelihood of an abrupt cutoff.

Tech abuse, in particular, can manifest in a manner that lacks the natural endpoint found in, e.g. housing or job placement. Organizational processes (screening, appointment caps) can provide structure that encourages or builds in service limits. However, even with organizational support, our findings here reinforce a need to equip tech consultants with the ability to articulate and enforce service limitations.

6 Care Practices for Security Interventions

Towards identifying opportunities for practical improvements concurrently with problems, we also asked our SMEs to share strategies for the challenges and patterns uncovered in consultant interviews and transcript analysis. During focus groups, SMEs recommended five targeted strategies for consultants to use during client sessions. Following the work of Tseng et al. [49], we term these strategies *care practices*.

Practice #1: Refocus the conversation. Consultants were understandably reluctant to interrupt clients, and viewed active listening as foundational to trauma-informed care. While SMEs saw this benefit, they explained that compassionate, trauma-informed care included helping survivors be intentional in when and whom they shared emotionally-charged and potentially re-traumatizing stories. While avoiding re-traumatization entirely is unrealistic, SMEs suggested two methods for gently refocusing clients when experiential sharing began to dominate the session.

First, SMEs encouraged consultants to interrupt or "pause" clients when they were speaking at length about tangentially related subjects. SMEs pointed to a consultant who positively modeled this with a client. Having already discussed multiple devices, the consultant stopped the client from revisiting concerns about yet another, since-abandoned device by saying: *"Taking it one step at a time, right? Let's focus on securing the phone that you have with you."* (T13) Similarly, another consultant diverted a client mid-narrative by saying: *"I'm just going to focus us on the task at hand, the Internet connection."* (T9). As SMEs noted, a gentle interruption *was* compassionate when it helped clients meet their goals for the session or de-escalated trauma stress reactions.

Second, SMEs noted that validating a client's experiences can serve as a method for redirecting the conversation toward a relevant security intervention. By acknowledging the worry that the client is expressing about a security concern or the abuse more broadly, the consultant can refocus the client by explaining how the clinic session may address that worry. A consultant modeled this strategy when a client became distressed while discussing circumstances around interactions with law enforcement. The consultant replied:

> *I'm so sorry to hear that. That sounds really scary but I'm glad you shared that so we know to document any potential evidence we see today.* (T8)

Validating statements such as this tactfully acknowledges the client's distress, but simultaneously refocus the session back to the security intervention. Such redirection tactics are particularly useful for tech consultants, who are navigating concrete and technical solutions that require attention and focus against an emotionally charged backdrop.

Practice #2: Demystify tech through transparency. To minimize the likelihood of recalling past traumatic or invalidating experiences with "the system", SMEs suggested demystifying the tech diagnostic process by being transparent about what the consultant is doing and why, at each step. For example, consultants can be upfront about having a list of diagnostic questions, and reassure clients that their answers to those questions should help narrow down possible explanations. One consultant modeled this, saying *"I want to understand what's going on a little better and just like going to the doctor, I'm going to have questions"* (T13).

As another example, consultants can acknowledge that they will be moving through a series of security interventions, some or all of which might not yield any new information. One consultant demonstrated this when a client became frustrated with a suggested security intervention, saying

> *Sorry if anything we do is repetitive. We take your safety really seriously, so we're not going to skip anything unless you tell us to.* (T4)

Slupska et al [45] identify *demystification* of technology as an "interwined emotional and technical support practice" and our findings are consistent with this description; however, we find that when clients are receiving dedicated tech services, the entire session or service itself may be viewed as an opaque tech phenomenon. Here, demystification is a necessary component of building trust and rapport for the service as a whole.

Practice #3: Validate experiences, not tech explanations. As SMEs warned, a client who enters with a preconceived explanation about the nature of their tech abuse may not be able to accept information that threatens the validity of that explanation. The SMEs recommended that consultants be aware of this, and offered a two-part strategy in which consultants first validate the client and then offer alternative explanations.

Crucially, practitioners recommended avoiding validation that engages directly with the misbelief itself. Instead, they provided several components of the client's experience to safely validate. This avoids seeming contradictions later on, while still signaling that the consultant is actually hearing the client, not reacting with a knee-jerk dismissal.

These components included the *disruptiveness of the distress*. For example, rather than affirming that the client's phone is "hacked", the consultant can instead affirm the logistical difficulty of *avoiding using your phone*. Additionally, consultants can use their credibility as technologist to *validate the complexity* of understanding how to secure a piece of technology, especially in the face of misinformation, and the client's labor in navigating that confusion.

When offering alternate explanations, SMEs again offered several tools. Some examples include transparency around the logical process that lead to that explanation, tools for testing theories in the future, and how to disengage if the client rejects the offered explanation.

Similarly, consultants can provide limited *psychoeducation* [6] for clients, explaining to clients the manipulation tactics that perpetrators often deploy in the context of tech abuse. Examples include the research-supported pattern of perpetrators overstating their technical abilities as a tool to instill fear in victims, exploiting, e.g., attempted log-in notifications as a communication mechanism, or the tendency of abusers to use one or two pieces of information to gain credibility when they falsely claim that they "see everything".

Practice #4: Set expectations for the session. Best practice encourages having firm boundaries around the length of an appointment. This is especially important given the far-ranging nature of tech abuse which lends itself to an overwhelming amount of ground to cover. Perhaps unintituively, how a session ends is largely influenced by how it begins. Thus, SMEs recommended engaging the client in explicitly establishing a timeline and agenda together early on, a practice which helps build rapport and manage expectations.

This includes beginning an appointment by noting the length of the appointment, and periodically incorporate time cues throughout the session. For example, half way through an appointment a consultant might state: *I think that within the 30 minutes we have, we would be able to walk-through the security of your email account.* As the SMEs explained, time cues can serve as an important grounding tactic for clients who may be experiencing traumatic stress reactions.

Similarly, the SMEs highlighted the importance of working with clients to identify their most pressing concerns (referred to as chief concerns by Havron et al. [30]) at the start of the appointment, in order to ensure their most urgent concerns aren't overlooked. Good prioritization, according to the SMEs, should recap a client's concerns, and encourage feedback on a plan for how and when they will be addressed. Within the context of tech abuse, this includes accounting for which technical concerns are having the deepest impact on the client's ability to function. For example, a consultant might say: *Of all your concerns, it sounds like the phone and email are your priority. We can focus on that today and discuss other concerns in a follow-up. Is that okay?*

This pacing approach removes responsibility from the client for maintaining the cognitive load of both task organization and time management, while still making sure the client's priorities are acknowledged and reflected by the session.

Practice #5: Set (and embrace) limits for the service. A single service provider is incapable of attending to all of a client's multi-faceted needs, and SMEs were cognizant of the pressure technology consultants might feel when clients brought up issues beyond the clinic's purview. Unfortunately, in the ever-shifting landscape of tech abuse, clients will inevitably have concerns both technical and non-technical that the service is not equipped to address.

Along with an agenda for the session itself, expectations for the limits of the service should also be set at the start of service. An initial session should frame the conversation as a means to understand *if* the clinic may help, not *how*. This framing builds an exit hatch into the session—if initial exploration reveals that the clinic cannot address the client's needs, they can refer back to the expectation set at the beginning.

In cases where clients explicitly raised non-technical issues or needs that would be best met by other services, such as the mental health impact of the tech abuse or financial difficulties, consultants can offer to echo those concerns back to the social

worker who referred the client to the service. However, SMEs agreed that caution was needed in directly recommending therapy services. If unsolicited, such recommendations could be inappropriate or offensive.

Crucially, SMEs offered useful criteria for reframing the decision to end service, especially when encountering clients who raised technical concerns that could not be disambiguated from signs of paranoia by the clinic. Instead of focusing on plausibility of concerns, SMEs suggested that continued service instead be contingent on whether the consultant finds that they are able to gain *traction* in diagnosing tech issues and/or identifying a set of finite, actionable tasks within the clinic's purview. If the consultant finds that they are unable to understand the client's concerns or that the client's concerns shift too rapidly, as observed in a couple transcripts, this signified a lack of traction. This framing offered reasonable criteria to end service.

More broadly, this practice can also be viewed as asking consultants to set expectations for themselves and the service as a whole. Without internalizing these inherent limits, consultants may face overly high expectations concerning what they are able to accomplish in their role, increasing the risk of burnout or dissatisfaction. Conversely, understanding the organization's remit and staying firmly within that lane can be empowering for consultants. This is especially important for tech consultants, as our findings suggests that security and privacy services are particularly likely to encounter situations in which it is difficult to disambiguate serious mental health issues from low-probability but feasible security risks.

7 Embedding Care Practices into a Protocol

In this section, we demonstrate how the care practices described above could be embedded into the structure of security intervention delivery. We are inspired by the understand-investigate-advise (UIA) protocol which was introduced by Havron et al. [30] (discussed in Section 2). It embedded trauma-informed practices into its design: for example, it encouraged active listening as an initial stage, framed the consultant role as advisory rather than instructive, and incorporated hand-offs for professional safety planning.

However, as Figure 3 shows, certain traumatic stress reactions tend to occur during particular stages of the protocol, suggesting it would benefit from refinement. Thus, we propose an alternate protocol in Figure 4. New stages are highlighted in yellow. All stages incorporate one or more suggested care practices intended to alleviate the recurrent patterns of traumatic stress reactions documented in our study. We discuss each stage in order below, connecting it back to our example of Casey and Tyler from Section 3.

- **Orient.** Given the tendency for clients to arrive at tech clinics with outsized hopes, SMEs viewed setting expectations early as a crucial practice for tech consultants. Thus, we devote an initial stage to this practice. In the example of Casey and Tyler, Tyler could begin the session by acknowledging that the clinic has a limited set of tools that might not meet all or any of Casey's needs.
- **Understand.** In this stage, we find it most useful to utilize strategies that can pause the client or gently steer them away from sharing re-traumatizing information, as in CP1. Going back to our example, Tyler could stop Casey when Tyler notices Casey's emotional state escalating, by saying, for example, *"Casey, can I stop you for a moment? I'm happy to listen, but I have some questions that might be important to clarify first."*
- **Plan.** We insert a planning stage as a bridge between the more open-ended exploration of *understand* and the concrete tasks in *investigate*. This is a moment to acknowledge that the tools available to the clinic might have limited use, and to check whether the client would like to proceed. For example, Tyler can use this moment to tell Casey, *"We can start by ruling out some common causes, and talk about next steps based on what we find. How does that sound?"*
- **Investigate.** The investigation stage benefits greatly from transparency throughout the process (CP2). Having set expectations in prior stages means that although Casey might not feel the interventions are powerful enough for their situation, they are entering with an understanding of what to expect and why it might be beneficial. Continuing to explain the logic behind each check and its necessity maintains this rapport.
- **Advise.** Consultants demonstrated a strong capacity for compassionately dispensing safety information about technology. This practice can be strengthened with a specific understanding of how to validate experiences without validating explanations. For example, Tyler, having practiced this skill, might say *"I know how important securing this account is; based on the steps we took, we can rule out account compromise here."*
- **Wrap up.** We encourage firm endings via a "wrap up" stage. At this point, if Tyler has exhausted the available security interventions and Casey is still not satisfied with the lack of explanations, Tyler can fall back on the initial expectations set at the beginning, saying, *"I'm sorry that we didn't find an explanation, but I don't think more sessions would be fruitful."*

8 Discussion

This is an initial study examining how traumatic stress reactions affect computer security interventions. We recognize that in studying traumatic stress, we have highlighted significant negative impacts on both consultants and survivors during computer security interventions. Despite the neces-

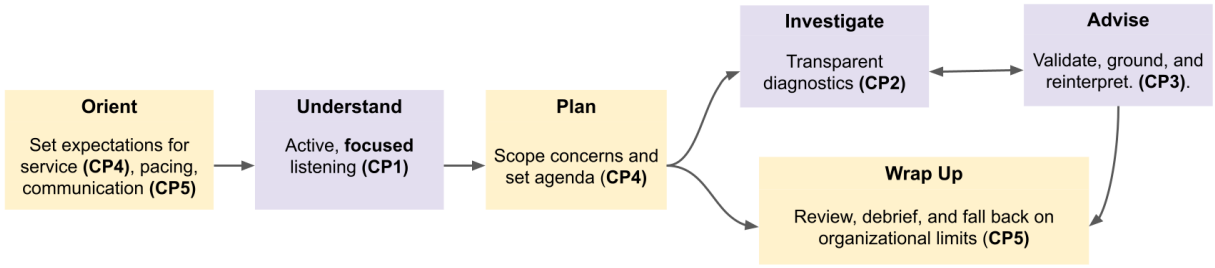

Figure 4: Diagrammatic summary of a new tech consultation protocol, based off UIA [30], labeled with practices from Figure 2.

sity of surfacing these pitfalls towards improving services, it is important to recognize the many positive effects of these services for both clients and consultants; we highlight these throughout below.

Returning to the questions that guided these studies (see Section 3), we began by asking what challenges related to traumatic stress reactions do technology consultants encounter during sessions with clients. We were especially interested in consultants' perspectives on why certain types of interactions were challenging, and their answers pinpointed specific, actionable gaps in trauma-informed training.

We also note that both studies demonstrate that consultants are engaging in emotionally intensive labor during sessions that may expose them to vicarious trauma. Elsewhere in interviews, consultants often described their work as rewarding and meaningful, and analysis of session transcripts overwhelmingly reinforced that consultants compassionately deliver useful safety information.

We anticipate that the findings of this study will validate consultant experiences by highlighting areas for necessary improvements to training. We hope future studies seeking to further understand how traumatic stress reactions affect computer security interventions will include specific focus on mitigation strategies for vicarious trauma.

In our second research question, we were interested in identifying patterns regarding how and when traumatic stress reactions occur during sessions. Resulting analysis allowed us to identify how traumatic stress reactions map on to the flow of a session. While our transcript study only drew from a single clinic, the interview component showed that consultants have difficulty navigating similar types of interactions across all sites, suggesting that these challenges follow patterns that are agnostic to location or modality (e.g., video call, phone call, or in-person). Thus, in addition to enhanced trauma-informed training, the results from this study also suggest that training focused on how traumatic-stress reactions present across the structure of a session may benefit consultants.

The challenges identified by consultants in Section 4 were supported by analyzing the transcripts in Section 5. Indeed, the additional analysis provided by the SMEs showed that subject matter expertise can identify new issues, such as the tensions during diagnostic questions in TP2. They can also provide useful context for reframing challenges, such as the potential for long narratives to not only create time pressure (CH1) but also to potentially retraumatize clients (TP1).

Our third research question aimed to identify potential strategies for mitigating traumatic stress reactions during clinic sessions. While SMEs suggested specific mitigation strategies, the consistent patterns that emerged from both studies suggest that re-structuring sessions at key moments where traumatic stress reactions tended to occur might be beneficial for both the clients and the consultants managing the sessions. Our proposed protocol builds on prior work [30] by identifying these critical moments and explicitly including steps to preemptively incorporate mitigation strategies.

Beyond advancing clinical computer security protocols, this work builds on literature spanning multiple disciplines. Most crucially, our findings position digital security and privacy workers as front-line service providers. Prior work has demonstrated intersections between at-risk populations and digital safety advocates, including journalists, activists, and refugees of war or natural disasters. While we focus on survivors of IPV, we view these studies as affirming the need for trauma-informed protocols similar to other roles such as public defenders, prosecutors, social workers, and health care providers when working with vulnerable populations writ large. We believe our study design, especially our approach to including mental health clinicians as subject matter experts, can inspire similar future work.

Future Work. As stated, we are interested in developing trauma-informed protocols for other at-risk populations besides IPV survivors such as those outlined above. We also see potential for additional studies using ethnography-inspired approaches that include mental health professionals observing sessions or examining other IPV contexts, such as temporality (e.g., during separation versus years after), or exposure to different types of abuse (e.g., image-based abuse, trafficking, identity theft).

Solutions offered here center on consultants, but we note a need for organizational-level practices, such as robust screening and intake processes and incorporating oversight from mental health professionals into high-risk sessions, and embedding these practices into training. More broadly, this work

raises questions regarding the unique characteristics of traumatic stress reactions in relation to technology abuse. Our findings indicate that therapeutic treatments for stress reactions like hypervigilance may require input from security and privacy professionals, and future work may explore collaborative tool development for such treatments.

Limitations. This study focused on computer security interventions for survivors of IPV, and our results may not extend to security interventions in other contexts (e.g., other populations, general security customer support, etc.). However, our paper's methodological approach—combining semi-structured interviews of tech consultants, along with SME-assisted analysis of client-consultant interactions to develop new best practices—should be useful in future studies investigating other contexts such as those outlined above.

Related to the scoping limitations, while consultants identified common challenges consistent across all three sites, the transcripts used in this study were from a single clinic. Though this clinic serves a large, diverse population, minor differences in clinic protocol such as training or modality (e.g., remote, in-person) may not be accounted for. Similarly, our random sample of transcripts may have failed to capture nuances that depend on specific demographics or intersectionality, such as survivors marginalized by race or sexuality.

Finally, the sampled database only includes textual transcripts from sessions in which clients consented to research. Thus, nuances that might be available in audio recording, video recording, or in person observation can be lost. Likewise, trauma may play a role in motivating or deterring a client from consenting to participate in research, resulting in potential bias within our sample. Though our incremental sampling approach was designed to account for this, it is possible that clients experiencing certain types of traumatic stress reactions (e.g., hopelessness, hypervigilance) may be more or less likely to consent to research.

A Consultant Interview Guide

1. **Warm Up:** How long have you been a consultant? How does the volunteer role relate to your professional experience?
2. **Behavioral Responses**
    - Without identifying any clients, can you think of some instances where a client hass behaviors, communication styles, or emotional reactions that make it challenging to deliver technology services?
    - Are there times where you felt like attending to the client's emotional state or behaviors took precedence over providing technology services?
    - Are there times when you felt like this wasn't the appropriate service for what the client needed?
    - How do you navigate situations where there is a gap between what they believe is happening and what you see as a technologist?
    - How do you gauge clients' moods in sessions? What has clued you in to a change in mood of the appointment?
    - Are there certain indicators that you are attuned that you associate with these types of sensitivities? This can be in the referral form or during the appointment.

3. **Probing for preparation:** Consultants receive 5 hours of training on trauma interventions, as well as taking time shadowing.
    - How well did that training align with what you experienced as a consultant?
    - Are there any situations during a client session that you felt very prepared to handle?
    - Are there any situations or incidents during a client session that you felt unsure of what to do or unprepared, or like you might have not handled as well as you wanted? E.g. a client discloses ideation of self-harm (or if this has happened, what did you do?)
4. **Probing for resources:**
    - What resources do you turn to help manage these situations, either with processing what happened or seeking concrete advice?
    - Are there resources (additional training) you wish you had, but don't currently? What do you need to support your role in sessions/appointments?
    - What are some things you would like to do or say with clients but find difficult in the moment? Ex: interrupting
    - What are your go-to approaches or phrases? Were there times where they didn't work or where you felt were insufficient?
5. **Closing Questions**
    - What do you think contributes to a holistically beneficial clinic experience?
    - What would you want in an ideal world?
    - Is there anything else you'd like to tell us on this topic?

B Codebooks

The codebook for the consultant interviews appears in Figure 5. The codebook for the transcript analysis appears in Figure 6.

Theme/Code
Common client behavioral responses
Common keywords and cues
Distinguishing hypervigilance from paranoia
Anger, frustration, resentment
Intense distress or overwhelm
Anxiety, panic, or fear
Unspecified, extreme emotional dysregulation
Consultant strategies
Felt prepared and/or effective
Set boundaries with client
Try to set expectations with client
Reframe, refocus, or clarify
Provide safety information/tools
Validate client/empathy
Training and Resources
Lecture/DV 101
Field training/shadowing
Taking cases
Professional background (external)
Clinic-specific documents/resources
Clinic Structure and Ongoing Support
Buddy system
Advocate/support worker
Post appointment debrief
Clinic management
Desirables/Outcomes/Needs
Additional training
Consultant felt overwhelmed
Felt unprepared and/or ineffective

Figure 5: Codes used to analyze consultant experiences. Bolded items are high-level themes.

Theme/Code
Traumatic Stress Reaction
Hypervigilance
Exhaustion, fatigue, and resignation
Anxiety, panic, or fear
Impaired functioning/interference with daily life
Delusions, hallucinations, or psychosis
Institutional or social betrayal
Physical Symptoms
Cognitive processing issues (focus, memory)
Anger, frustration, resentment
Intense distress or overwhelm
Information dump
Self-editing
Shame, guilt, self-blame
Consultant behaviors or strategies
Consultant trying to set pace
Consultant seems overwhelmed
Consultant attempts to reframe, refocus, and/or clarify
Consultant offers validation
Consultant provides safety education, information, or tools
Consultant offering hope
Consultant setting expectations
Consultant building trust, rapport, consent culture

Abstract

When developing security and privacy policy, technical solutions, and research for end users, assumptions about end users' financial means and technology use situations often fail to take users' income status into account. This means that the status quo may marginalize those affected by poverty in security and privacy, and exacerbate inequalities. To enable more equitable security and privacy for all, it is crucial to understand the overall situation of low income users, their security and privacy concerns, perceptions, behaviors, and challenges. In this paper, we report on a semi-structured, in-depth interview study with low income users living in Germany ($n = 28$) which we understand as a case study for the growing number of low income users in global north countries. We find that low income end users may be literate regarding technology use and possess solid basic knowledge about security and privacy, and generally show awareness of security and privacy threats and risks. Despite these resources, we also find that low income users are driven to poor security and privacy practices like using an untrusted cloud due to little storage space, and relying on old, broken, or used hardware. Additionally we find the mindset of a—potentially false—sense of security and privacy because through attacking them, there is "not much to get". Based on our findings, we discuss how the security and privacy community can expand comprehension about diverse end users, increase awareness and design for the specific situation of low income users, and should take more vulnerable groups into account.

1 Introduction

Poverty has been increasing wordwide during the past decades and is divided in two categories: *Extreme poverty* defines an income so low that it is impossible for the person or family to meet basic needs of life including food, shelter, safe drinking water, education, and healthcare. *Relative poverty* defines a household income that is below 60% of the median household income of a state or country, leading relatively poor people to struggle with all sorts of social marginalization [1], where technology use and security and privacy issues are not exempt.

Extremely valuable work by Redmiles et al. has shown that, statistically, low-income populations in the US do not experience *more* theft of personal information, account compromise, non-consensual posting of information, and scamming [2]. However, other aspects of security and privacy—which may be more difficult to study in a census-representative survey such as [2]—may affect low-income users differently, and inequitably. For example, consider the pay-for-privacy business model [3]. While many popular technologies have free versions, some offer better privacy to those who pay (e.g., offering an ad-free version), and others are entirely unavailable without payment (e.g., a paid VPN service). Paying for privacy presents a barrier to security and privacy to those in relative and extreme poverty.

The pay-for-privacy model [3] is not the only reason to consider the effect of poverty on users' security and privacy needs and experiences: prior work has shown that those accessing technology through intermediaries, or using shared technologies—factors which can coexist with poverty—directly face barriers to security and privacy specifically because of their technical practices, which are, in some cases, enforced by their economic situations [4]. This body of literature examines the security and privacy experiences, needs, and barriers of vulnerable or marginalized populations—many (but not all) of whom can experience poverty, e.g., refugees, sex workers [5, 6].

While the lack of resources is a theme in prior work about vulnerable populations, and appears as a factor (direct or indirect) that contributes to vulnerability, there is little work in our field with poverty itself as a primary focus [2], though some have found that certain demographic factors that tend to *correlate* with poverty (such as education) affect security and privacy needs, experiences, and mental models [7, 8].

We observe, thus, that there are many valuable studies that study security and privacy for people who experience poverty, but do not engage *directly* with the idea of poverty as a potential factor in vulnerability. In this paper, we begin to fill

this gap, by directly examining the effects of poverty on one's security and privacy technology use and threat model. In contrast to the valuable body of work about users in *extreme* poverty in the global south (e.g., [4, 9]), we focus on users in *relative* poverty in Germany in order to form a basis for understanding how income and security and privacy relate to each other in a rich country in the global north. We explore threat models and technology use in order to understand how those in poverty define security and privacy, and then to elicit technical and societal barriers to security and privacy. By focusing directly on poverty, we shed light on security and privacy related challenges of the growing number of people living in relative poverty in global north countries where more and more public and private services have moved online [10, 11], especially since during the pandemic internet use has become increasingly important to the population [12, 13], which reinforces income related divides that represent an important realm of social inequality [14, 15, 16].

We address the following research questions:

- **RQ1:** What security and privacy actions and practices do people living in relative poverty in Germany employ in their everyday lives?
- **RQ2:** What is important to them in the context of digital security and privacy?
- **RQ3:** What technology and assets do they use and/or seek to protect?

Through 28 in-depth interviews with relatively poor users in Germany, we find that they generally have a high level of security and privacy awareness—in line with Redmiles et al [2]—but they lack suitable instruments to protect themselves better, especially when it comes to resources like time, money to purchase state of the art hardware, and protective software, as well as resources to gain more specific knowledge about security and privacy. We find, for example, that users in relative poverty use technologies that cost less (e.g. second-hand phones, free cloud storage services) despite either having security and privacy concerns (e.g., about data privacy properties of free storage) or despite the practices putting them, objectively, at risk (e.g., use of second-hand devices that have not been sanitized properly [17, 18]).

We also emphasize that *poverty cannot be solved with technology:* there are underlying power and social structures that enforce generational or situational poverty; technology, even perfectly secure and usable technology, cannot solve these issues. However, we, as computer security researchers, have the obligation to ensure that our community produces technology that equitably distributes security and privacy, and we know, from our work and from prior work, that misalignments in technical design are inequitably distributed, often in ways that align with other forms of societal oppression. We have positioned this paper for the technical computer security community in order to show how many current technical designs and paradigms present systematic barriers to security and privacy for people experiencing poverty, and to encourage this community to adapt to equitably serve people experiencing poverty. We do *not* mean to presuppose that people in poverty *should* be using technology, nor that technology will solve a sociological issue, and we emphasize that in *addition* to ensuring that technical designs align with poor people's needs, we must also advocate for other, non technical changes (e.g., policy changes) in order to address poverty itself.

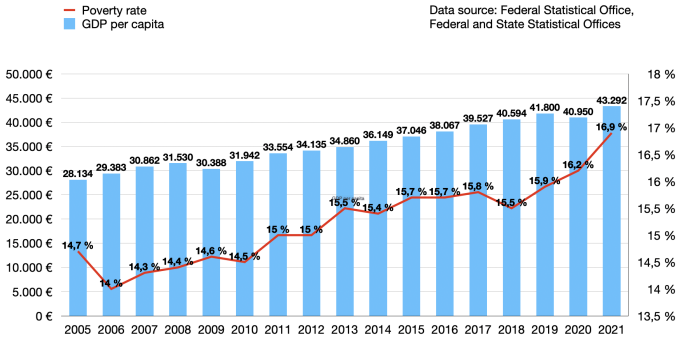

Figure 1: Poverty Rate - GDP per capita.[1]

2 Background

With its important low-wage-industry,[1] Germany is a prime example for the economies of western countries [21], characterized by labor market stratification [22], and increasingly deregulated welfare state policies and institutions [23]. Like other countries in the global north, Germany has a constant gain in poverty although economic performance and the GDP are continuously growing [24], as the latest poverty report indicates (see Fig. 1). The poverty report is published annually by an association of social movements (Paritätischer Gesamtverband) and is based on data from the micro census, which is collected annually by the Federal Statistical Office (Destatis) [26]. According to the poverty report, people are considered "poor" if their income is less than 60 percent of the median income of the country. For a single person living in Germany, this means a yearly income of about 15,000€; for a family composed of two adults and two children, the poverty rate limit is set at 31,500€ [1]. Of the approximately 84,3 million people living in Germany, 14,1 million are considered "poor"; they make up 16,9% of the whole population [27].

[1]More than one in five employees in Germany has a gross hourly wage of less than 11.40 Euros. No other European country with a comparable level of economic development has a low-wage sector that large and persistent: Between 1995 and 2020, the ten percent of the lowest incomes only increased by four percent, while the top ten percent achieved an increase of 50 percent [19, 20].

With some differences regarding the specifics in socioeconomic structure, we argue that overall Germany can be seen as an illustrative case for other countries in the global north, characterized by a strong economy combined with an increasing poverty rate where the population overall has access to technology and the internet, but a growing number of technology users face challenges associated with low income. People affected by poverty generally face barriers and challenges regarding technology and internet access [28]. They also benefit much less from internet use than affluent people [29].

3 Related Work

In this section, we discuss related work in three areas: income status and technology in general, low income in relation to digital security and privacy, and security and privacy behavior, attitudes, and threat models associated with low income.

As early as 2001, Pippa Norris described the entanglement of social, political, and digital inequalities between affluent technology users and users affected by poverty, both within distinct state populations as well as on a global scale [30]. Due to an overall increase in technological penetration and availability across the world [31], questions of technology and internet access are still important but the divide between the rich and poor now takes up plural dimensions that also fuel the interdependence between digital security and inequality [32].

A lot of insightful and valuable research focuses on technology related inequalities in the global south, describing how global digital disparities and access inequalities play out in Bangladesh [33], Georgia [34], the Arab world [35], Mexico [36, 37], Brazil [38], and many other countries. But in countries of the global north like the USA, South Korea [39], UK [40], Italy [41], Canada [42], Japan [43], and Germany [44], income related inequalities are also found to be constantly increasing [45]. These also affect and enforce already present inequalities between genders, age groups, and people living in different geographic locations [46].

Users of low income not only possess less powerful devices but also employ technology and use the internet in ways that give them significantly less financial and social advantages than users of higher income. For example, lower income individuals were shown to be more dependent on their smartphones, to have limited internet access, and to perform less news and information activity than higher income users [47].

Low Income, Security and Privacy: The security and privacy community has increasingly focused on understanding how marginalized and vulnerable populations experience security and privacy, deemed *inclusive security and privacy* [48, 49]. Prior work has focused on the technical use, non-use, needs, mental models, and issues faced by refugees in the US [6], undocumented migrants [50], survivor-victims of trafficking [51], and sex workers [5]—with nuanced findings specific to each group studied, as well as an overall sense that technology and security and privacy in particular do not often fit the needs of marginalized groups [52]. Others have explored the relationships of caretaking and assistance (or lack thereof) with security and privacy and technology, e.g., in libraries [53], during Covid-19 [13, 11], and for the elderly [54]. While many of the groups studied in our field experience poverty, and the lack of financial resources appears for some as connected to security and privacy behaviors, mental models, and experiences, our research community has yet to engage directly, holistically, and qualitatively with the idea of poverty and computer security.

People experiencing poverty are described to be part of "at risk populations" for disproportionate harms and a broad set of attacks like online hate and harassment [52], appear to be forced using less secure software like food sharing apps due to lack of money [55], or face surveillance issues, for instance, related to smart home technologies in public housing facilities [56]. Contrary to the assumption that security and privacy issues lie within the responsibility of low income users who show harmful usage patterns, attitudes, and little literacy, this work shows that security and privacy, moreover, are themselves subject to barriers that need further scrutiny [57].

As people of low income make up an increasingly vulnerable user group that is subject to intensive data gathering, predictive analysis and policing, comprehensive surveillance, and other frequent security and privacy violations [14, 58]—often lacking legal protection [59]—more research is needed to better understand their situation. Currently, the status quo in security and privacy research and design may marginalize users of a low income, both in their everyday lives and during many types of low wage work like gig work. It is shown that security and privacy issues are amplified by work related and private technology available to low income users as well as their specific usage patterns like a higher reliance on mobile connectivity and a greater social media use [59, 60, 61].

Low Income, Behavior, Attitudes, and Threat Models: Low income related challenges in security and privacy among other things are tied to specific threat models, beliefs, advice sources, and behaviors that depend on one another [7, 62]. Prior work has shown that low income users are very well aware of many security and privacy risks and exhibit at least some protective strategies, but are found to lack fitting instruments and suitable resources to better protect themselves [59]. It was highlighted for example, that security and privacy incidents are not causally tied to a low income but are equally distributed through users with differing socioeconomic status [62]. However, it was shown that people of lower income were more vigilant online than people of higher income [52], which surprisingly increased and amplified their already disadvantageous access and usage patterns, as they declined to use online services [63], thus it is important not to understand low income users as a homogeneous group, but to recognize

the characteristics and features of different members as well as their specific connections to other at-risk factors.

We decided on in-depth interviews for our research approach to gain detailed insights into participants' everyday security and privacy actions an practices, as well as their perceptions, behaviors, and reasoning related to security and privacy. We leveraged 28 in-depth interviews with German low income end users to investigate the broader picture of how security and privacy interacts with poverty in countries of the global north, specifically focusing on what is important to them in the context of digital security and privacy and what technology and assets they use and/or seek to protect.

Security, privacy, and sanitization of second-hand devices: For decades, through changing hardware, software, and UI standards, prior work has shown that when users get rid of computers (phones, computers, harddrives, etc), they do not fully sanitize them [64]. Garfinkel et al. showed, through forensic analysis of 158 harddrives in the early 2000s, that used harddrives are difficult to sanitize properly, citing inherent limitations of physical hardware on spinning disks [18]. A decade later, Glisson et al. analyzed 49 cellphones purchased from auctions and pawn shops, finding personal information on all "despite in some cases deliberate attempts by previous users to delete data" [65]. Recent work has also shown significant personal information left on Internet of Things devices [66], SD cards [67], and phones and tablets [68], with some evidence by the prior user to remove their information [67, 69]. Ceci et al. sampled users and found that users do indeed have security and privacy concerns when choosing whether to getting rid of old devices, and that they sometimes *try* to sanitize the devices, but are unable to do so fully because the tools they used were not sufficient [70]. Participants in our work focus on *acquiring* second hand devices—rather than selling or donating them, as in prior work—due to their significantly lower cost than new devices. Our work builds on this body of prior work, then, by understanding the mental model of those in the market for second-hand devices.

4 Interview Study

In this section, we outline the interview approach including the interview procedure. We will elaborate on the recruitment, the structure of our interview guide, the subsequent coding and analysis steps, as well as on ethical considerations, and potential limitations.

4.1 Study Setup

To investigate different employments, experiences, and concerns with security and privacy of low income technology users, we conducted semi-structured interviews ($n = 28$) with people from various backgrounds, education levels, and employment statuses that had 60% or less of Germany's median income at their disposal between May and September 2022. Because of the exploratory nature of the study, and because we focused our investigation on user trade-offs and behavior when using technology on an everyday basis, we opted for interviews as a qualitative approach. The interview as an instrument allows us to explore participants' experiences and concerns in-depth by asking follow-up questions.

Interview Guide: The interviews were conducted with an established interview guide based on our research questions that were tied back to an examination of previous and ongoing related work. First, participants consented to partake in the study before starting the interview, then we asked what devices, apps and other connected technology they are using on an everyday basis. We then asked the participants to describe important and private data, to talk about account sharing, and to report on possible security and privacy incidents in the past. If not mentioned, the remaining questions focused on perceived challenges with, worries about, and experiences with security and privacy.

The initial interview guide was tested with voluntary contacts from our professional network. After their feedback during the pilot phase, we performed minor changes regarding the question order for a better interview flow, and to improve question clarity. We also added follow-up questions to cover relevant areas in-depth until saturation was reached after the fifth interview.[2]

Recruitment and Inclusion Criteria: We based our recruitment approach around covering a diverse set of participants utilizing Open Source Components (OSCs), and employed multiple recruitment channels to better reach a diverse set of low income technology users from different age, educational, work-related, and national contexts. We recruited 28 participants, slightly over-sampling female participants (60% to 40%), from three different age groups (18-25: 18%; 26-34: 54%; 35-67: 28%), different education levels (no degree 4%; high school 46%; BA 22%; MA 28%), and varied employment statuses (no employment 25%; student 39%; self-employed 8%; employed 28%) offline via our professional network, local NGOs consulting unemployed people in Germany, as well as online through second hand goods advertising mailing lists, poverty related twitter hashtags, and Facebook groups:

1. Offline. For recruiting low income users that may not have high internet and technology literacy, we distributed recruitment posters throughout our professional network, and displayed recruitment material at relevant places like NGO offices.

2. Online. In addition to participants recruited offline, we recruited through a varied set of online spaces like second hand goods mailing lists, Facebook groups, and twitter

[2]The full interview guide can be found at https://osf.io/TJA6H/.

hashtags related to low income, poverty activism, and the experience of poverty.

For an overview of the interviewed participants' demographics see also Table 3 in the appendix. Through an invitation link or by scanning a QR code put on recruitment posters, participants were led to a short demographic Qualtrics survey determining whether they could be included in the study.[3]

Participants qualified if they were older than 18 and their household had at most 60% of Germany's net median income (the definition of relative poverty). Participants who were detected to have more than 60% of the median income were not included in the interview sample. As compensation for their valuable time as interviewees, we offered all participants an allowance of 40 €.

Interview Procedure: We conducted the *28* interviews virtually, mostly via our self-hosted instance, or any other tool of the participant's choice (e. g., *Zoom*), or through a phone call, which we recorded after the participant's consent. On the recruiting material, we advertised the interviews with a duration between 60 and 90 minutes depending on answer duration and scheduled all interviews with Calendly or through messaging via email, Facebook or twitter. All interviews were conducted in German and lasted between 40 and 90 minutes.

Overall, the interviews were based around non-leading, open questions, allowing the participants to develop their thoughts and answers. Each interview section started with general questions, allowing participants to freely state what they had on their mind. We asked follow-up questions to elaborate on specific topics if necessary. To avoid priming, we did not use technical or security and privacy specific vocabulary or suggestive argument patterns, and did not judge the answers regarding specific security and privacy practices.

4.2 Interview Structure

The interviews were structured in five main sections consisting of a set of one or two opening questions as well as follow-up questions. Before starting the interview, we provided participants with a general introduction of ourselves, our research project, and an explanation of our goals and the interview process, as well as the interview's role in that process. We emphasized that participation in the interview is voluntary, and that participants could skip any question for any reason without any negative impact on the interview procedure. We made clear that we were not judging their thoughts and knowledge about, behaviors with, and any reported incidents regarding security or privacy. We pointed out that their personal thoughts and opinions were of interest to us and that there was no right or wrong answer. Moreover, we guaranteed full de-identification of any quotes we might use.

[3] Survey questions can be found at https://osf.io/TJA6H/.

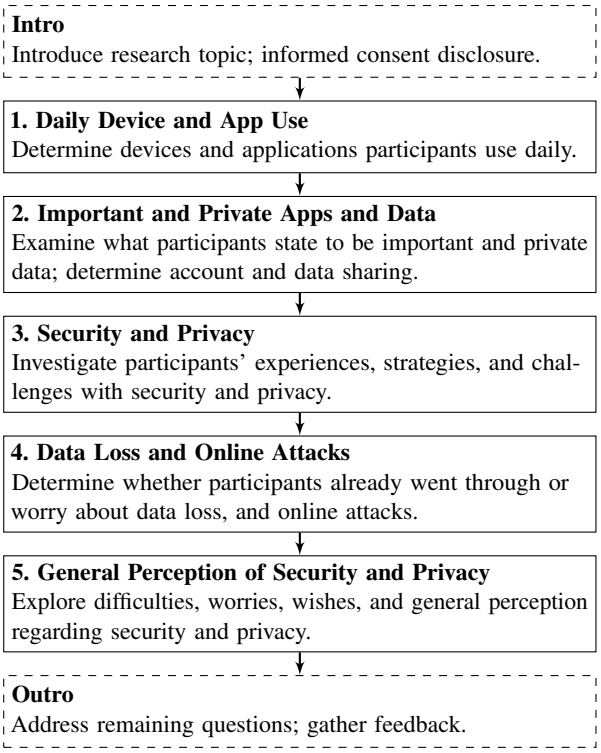

Figure 2: Overview of the interview sequences and procedure. Due to our semi-structured interview approach, participants were allowed to diverge from this interview flow at any time and elaborate on related topics.

After answering and clarifying any remaining questions and obtaining consent for the interview procedure, recording, and data handling, we started recording and began the actual interview with the following structure:

1. Apps and Devices: In the first interview section we asked participants to talk about the devices and apps they use on an everyday basis. This section intends to first gather information on the specificities of low income users' devices and usage patterns. If addressed by the participants, we also discussed old, broken, or already used devices. We report these results in Section 5.1.

2. Important and Private Apps and Data: This section investigates what participants classify as important and private apps and data. It serves to determine which data and apps low income participants describe as important and private, whether they share those data with anyone, and whom they would not want these data and apps being shared with. It also determines participants' experiences and practices of account sharing. We report these results in Section 5.3.

3. Security and Privacy: The third block of questions covers the experiences, behaviors, and challenges with security and privacy participants report about. We asked our interviewees whether they have tried to make themselves more secure

and private in the past, and what makes them sure whether they are secure and private or not. This section serves to determine the security and privacy literacy of low income users as well as their everyday security and privacy strategies. We report these results in Section 5.2.

4. Data Loss and Online Attacks: The fourth section focuses on whether the participants were subject to data loss or online attacks in the past or are worried about online attacks or losing data in the future. Our questions covered aspects such as whether participants worry someone might have access to their important and private data, and if participants think that their person would play a special role regarding online attacks. We also asked how safe and private our participants feel overall and why. We report these results in Section 5.4.

5. General Perception of Security and Privacy: In our final interview section, we investigate our participants' general views on the importance, impacts, and significance of security and privacy in their everyday lives. We were interested in whether our participants would like to change anything regarding their overall security and privacy and how they would make these changes possible. We report these results in Section 5.4.

Following the interview sections, we asked our participants if there was any topic we did not address so far as well as for any additional insights and aspects that we might have missed or they wanted to talk about. We also offered them the opportunity for questions and comments, and after completing the interview, we thanked them for their valuable time and the effort they took while participating in the study.

4.3 Coding and Analysis

Before evaluating, we recorded the interviews digitally, and transcribed them via a GDPR-compliant service, and manually reviewed all transcripts for potential mistakes. We analyzed all interview answers in an iterative open-coding approach [71, 72, 73]. One researcher coded the interview recordings and developed an initial codebook based on the interview guide as well as impressions gained during the interview procedure. The codebook was progressively discussed with other team members, and the feedback was implemented in the codebook, resolving conflicts by consensus or by introducing new (sub)codes after each iteration. The interviews were coded according to the codebook in multiple rounds until saturation was reached and no new codes or themes emerged [74, 75]. Although saturation can be problematic when not well defined [76], we felt it fit our data and it was clear to us when no new codes or themes emerged [74, 75]. The presentation of the paper and the research questions evolved together, explaining the similarities in structure. We did inductive coding [77], iteratively defining research questions, codes, and themes during our analysis: We conducted the interviews with open questions, and generated analysis from data. We took memos during the interviews to find themes and discussed them within the research team. We developed analysis from individual codes to interpretation and theorizing through thematic analysis [78]: Once a topic repeatedly appeared in the interviews, it became a theme. For example, participants repetitively report using old, broken and/or already used hardware, as shown in Table 1, which became the theme *old, broken, and already used devices*. Multiple themes contribute to answering research questions. For example, the theme *old, broken, and already used devices* contributes to RQ3, which is aiming to shed light on the technology and assets participants use and/or seek to protect. As surfaced in the interviews, the use of old, broken and/or already used hardware leads participants to mix private and work related device use (Section 5.1), and to opt into distrusted cloud services (Section 5.2), or into Google services although they mostly do not feel good about it (Section 5.4), because old hardware does not have enough storage space. Also, broken hardware influenced participants' evaluation of assets they seek to protect: As their data is either stored by untrusted cloud services or on hardware tending to break easily, as it is old or already broken, participants show resignation towards protecting their data.

Themes correspond with our results section: use of second hand devices out of necessity; ubiquitous use of broken or/and old devices; mix of private and work devices; Google as a quandary (e.g. little storage space forces into cloud computing); insufficient security and privacy resources other than money related to poverty; a strong feeling of being tracked; false feeling of safety a) because of living in Germany and b) until a security or privacy issue happens; high impact of data loss despite of low risk. Our approach does not necessitate the reporting of intercoder agreement, as each conflict was resolved in situ when it emerged, which resulted in a hypothetical final agreement of 100% [79]. The final codebook of 81 items is included at `https://osf.io/TJA6H/`.

4.4 Ethical Considerations & Data Protection

Our study was realized following the ethical principles for computer security and privacy research involving information and communication technologies outlined in the Menlo report [80], and was positively reviewed by our institution's ethics board and data protection office. The research plan, study procedure, and all involved research parties adhered to the strict German data and privacy protection laws, as well as the General Data Protection Regulation (GDPR). All data was collected, handled, and stored in compliance with the EU GDPR; personally identifiable data was stored using a secure cloud collaboration software. To transcribe the interviews, we commissioned an EU-based, fully GDPR-compliant transcription service.

We provided the participants thorough information about our study procedure and data handling, and offered to answer

any questions they might have before signing up for interviews. We stressed that participants could skip any question for any reason such as not knowing an answer, not wanting to answer, not being allowed to answer, or not feeling comfortable with the question, and told them that they could drop out of the interview process at any time.

To protect participants' identities, we did not ask for granular demographic data: in our pre-survey, we only asked for age groups, and income brackets (monthly, related to the German median income). However, many participants mentioned more granular income data unprompted during the interviews. We asked participants their gender, and did not systematically ask for race or migration history; again, many participants shared this information unprompted during the interview. We similarly did not ask for but often received information on chronic diseases, disabilities, as well as other circumstances and life events relevant to participants' socioeconomic status.

4.5 Limitations

Our study has several limitations that are typical for this kind of interview study, including potential over- and under-reporting, self-report, recall, and social-desirability biases, as well as sampling bias. Our sample is a convenience sample which may not be representative of the larger population of low income technology users. As many participants were recruited online, we may not have studied low income users that do not use the internet on an everyday basis or do not possess technological devices.

The household sizes ranged from one person households, families with up to 1 child to two or multiple adults living without children. Following the qualitative and explorative nature of the study, the demographics are not representative of people living in poverty in Germany. We sampled relatively highly educated people, and we were unable to reach people that do not use technology.

Interviewees who agreed to participate in our study might be more or less aware of the overall problematic revolving around living with a low SES, as some were members of Facebook groups or twitter hashtags tackling poverty as a social problem to be solved.

We conducted our interviews in German, so we have no insight into non-German-speaking low income technology users. As German is the de-facto "common language" in Germany, we consider this to be a negligible drawback still allowing us to reach a meaningful set of low income technology users. We attempted to mitigate social desirability bias by emphasizing that there are no right or wrong answers to our question about security and privacy, and that what matters is the everyday practice and experience of the respective user. We made clear that we were not going to judge the participants or their answers in any way but were genuinely interested in their experiences and thoughts. At any suitable moment, we also reminded our participants that they could skip questions without giving a reason.

5 Results

Our data focuses on how relative poverty affects (or does not affect) one's threat model and technology usage. As discussed, prior work finds that certain sub-populations experiencing poverty encounter certain barriers to security and privacy that are anecdotally related to poverty; our work engages, deeply and qualitatively, with specific reasons that poverty can present a barrier to security and privacy: old and second-hand hardware may have insufficient storage space (Section 5.1) or may be technically unsupported or improperly sanitized (Section 5.1), the use of untrusted software because it is free (e.g., free cloud backups of personal data, Section 5.2), and the feeling that poverty lowers the value of their data to a potential attacker (reflecting a misunderstanding of how and why many identity theft and cyber attacks occur, Section 5.3). We also explore how participants conceptualize *adversaries* (Section 5.4), amplifying their concerns about ad tracking and being unable to pay for privacy by using products for which they do not feel they trade privacy for access/cost (Section 5.4). Finally, also lacking financial, time and emotional resources related to poverty may impede security and privacy (e.g. participants don't want to deal with something they cannot afford anyway (Section 5.4)).

5.1 Hardware: Mixed Use, Typically Older, Secondhand, or Cheap Hardware

Although new smartphones, tablets, and laptops cost hundreds or thousands of euros (a significant fraction of the annual 15000€ income of someone in relative poverty in Germany), they are effectively required for modern day life in a rich industrialized country like Germany. Employers may require workers to be available via telephone and computer without providing either device. Additionally, social technology use is a critical part of our personal lives and exclusion from technology use (e.g., exclusion from social media, connections with far-away loved ones) can be painful [81]. We thus begin by exploring the *hardware* ownership and usage of people in relative poverty, for whom the cost of hardware may be a burden. We observe that both *mixed use* and *second hand* devices can present security and privacy risks to users and prior owners, since they are often improperly sanitized.

We observe that the hardware they use is influenced by poverty as most interviewees rely on old, used, and broken hardware because they cannot afford new devices. The hardware influences what is important to them and what they seek to protect: Although they find pictures, work and health related documents, and private communication data important, interviewees report that they cannot afford to protect them properly. They try their best to protect data that is important to them but always choose the cheapest options. One participant

explicitly and unprompted stated to use a hard drive regularly (P4). Finally, they simply accept the idea and the occurrence of losing data. Additionally, their devices must be affordable and thus do not have much storage space, which forces them to opt into cloud solutions they do not really trust.

Old, Broken, and Already Used Devices: Few participants report using new devices. Most participants report to take over old, broken or already used devices (Table 1) from friends and family members or to buy second hand hardware online, as they prioritize buying food, clothing, and saving for unexpected expenses (P9; P12; P18; P20), like a broken fridge or washing machine (P26). Participants also report often replacing their acquired devices as they break easily, which influences them not to trust the hardware they use:

> "*You must know that I have a very stupid history if you look at the last four or five years. My biography with smartphones is not particularly good, because I never get a new one, but always used ones. And then they usually don't last.*" — *P19*

We find that relying on broken, used, or old devices fills an important connectivity gap for low income users, giving them an opportunity to stay connected professionally and privately (P2; P26). However, these previously used devices can present a security and privacy risk. Prior work has shown that phones and other devices are often improperly sanitized before being passed to a second owner, presenting risks of malware and unwanted programs from the prior owner, and putting the onus on the new owner to ensure that all settings, accounts, data are *their* own in order to avoid tracking between owners. Additionally, Roberts et al. showed that pre-owned devices can contain illegal data or evidence of crimes, which could implicate second owners [17]. Older devices also can present security and privacy concerns, as there is a point at which developers stop issuing security updates, or the old hardware cannot run the newest versions of software.

Mixing Private and Work Related Smartphone Use: Most participants report to use their smartphones for almost everything, including online banking (P10), or even to rely on smartphone use exclusively (P18). Some participants distinguish hardware use between professional and private (P19), but almost every participant mixed private and professional device use (P24). A reason for mixed use is the technical insufficiency of participants' old devices, as P2 reports:

> "*I do have a work laptop, so to speak, but connecting to the office server doesn't work so well and that's why I actually use my own laptop for everything. But that's also why I'm using my cell phone right now, because I don't have a webcam on my old laptop and that's why I've always used the work laptop for Zoom.*" — *P2*

While the mix of work and personal use is not uncommon, as a number of employers expect employees to use their own phones and computers for work—particularly during the pandemic—it can be dangerous for both employee and employer. Employees may be required to sign invasive contracts that give employers control over *all* the data on their device (subjecting them to loss of personal data if the employer exercises the option to wipe the device), while employers' company data may become compromised from something the employee does on their personal time, on their own device.

5.2 Software: Shared Paid Streaming Accounts, Coerced Free Cloud Storage, Online Second Hand Platforms

Not all software and services are free and so those that are not can create a financial burden for relatively poor people. We find that participants' use of *free* communication apps and social media is not remarkably different: all participants report to mostly use communication apps like mailing, WhatsApp, Signal, Telegram, as well as social media apps like Instagram and Facebook. However, we find that in response to the need to back up and store their personal data, participants may turn to free cloud storage services because they are unable to buy hardware with an appropriate amount of storage space. Significantly, they *may not trust these free cloud services to not violate their privacy* but use them because they are free. Additionally, we find that participants frequently use online second hand platforms that require sharing private information with strangers. This may adversely impact their privacy, and even physical safety.

The Risks of Online Secondhand Goods Trading Services: Almost all participants report using online platforms for secondhand goods trading on an everyday basis because they cannot afford new merchandise (P3, P5, P6, P13, P17, P22, P26, P28). Platforms like Vinted, Kleiderkreisel, or Ebay Kleinanzeigen connect a buyer and a seller of secondhand goods, offering a shipment or a personal pickup option, as well as an option to pay through the platform's own payment system or via PayPal, banking, and in cash. There is also the option to give away things for free. To use these platforms, participants must create an account, filling in personal information like the home or any other shipment address, telephone number and email as well as banking or banking app data. Sharing this information with strangers is usually based on the mutual trust that everybody will only use shared data to complete the trade in question and for no other reasons.

One person reported to only search for giveaway things that they pickup in person as they could never afford to buy anything through these platforms including shipment costs.

Table 1: Daily technology use reported by participants. "Old" and "new" as subjectively reported by participants.

	Smartphone	Laptop	PC	Tablet
Old	P1, P2, P5, P7, P16, P18, P20, P21, P23	P4, P10, P16, P21, P23	P16, P18, P21, P26, P28	P3, P16
Used	P19, P25	P3	-	-
Little storage	P7, P11, P20, P25	P21, P25	-	-
Broken	-	P21	P7	-
New	P15, P24, P28	-	P15, P19	P8, P17, P25

To them, this is also part of a security and privacy action: for picking up free handouts, they never expose their own personal information like banking data or their home address, which gives them increased anonymity, security, and privacy *because* they are poor:

> "*I: Do you pass on your bank account details? P: No, no bank account details. I only pick these things up. I: And then you just hand over cash? P: Yes. But I mostly look for things to give away. I'm unemployed, so there's not much to buy.*" — *P26*

Little Storage Space Forces Users into Cloud Computing: The use of old, broken, and pre-owned hardware (Section 5.1) may push users towards more frequent or thorough backups of their personal data (P3; P8) because they are afraid the hardware will break, or because the hardware has minimal storage (P9; P13). Participants expressed that they lack storage space on their smartphones and notebooks, forcing them to either delete data on a regular basis, to store data on external hard drives, or to use cloud services (P9; P13). Some participants perceived physical or offline storage as the best way to protect data from unwanted access—though other participants report not to use cloud systems at all due to safety reasons (P14, P16, P23, P27).

> "*I don't use cloud systems; I don't upload my personal data to iCloud or similar programs and service providers now. Yes, of course it's nice, but then Apple just has all your pictures all the time. And you don't know what they do with them. And why would you also upload the photos there?*" — *P14*

However, although they distrust cloud services like Google Cloud or iCloud, they report that physical hard drives are a financial burden, and so cloud services are the go-to opportunity to receive free or affordable extra storage (P6; P7; P9; P10; P18; P20; P25). This is why they choose to put their data in a cloud or simply do not disable the automatic cloud backup pre-set on their smartphones (P6, P18, P20, P25), but report that they would not use cloud services if they could afford it financially:

> "*If I had more money to buy hard drives, I would change to that and quit the cloud.*" — *P20*

Other interviewees state that the benefits of greater storage space outweigh the costs of potential privacy loss:

> "*My laptop is full, now I can put new stuff on it again. That's the only reason I did this.*" — *P6*

In the face of their mostly cheap and old hardware that does not have much storage space, opting into cloud services seems to be the only solution to store data. Additionally, other interviewees describe that their data is automatically backed up and stored by Google, whether it is private photos, photos of important documents, important files, or (artistic) work files, and that it is impossible or very complicated to shut down this automated backup (P18; P20; P22; P23; P26). Either they describe it as a burden because they cannot access their data offline (P20), or they wish for a "Google-free" phone that they cannot afford (P18):

> "*It would be cool to get a Google-free phone, at all, with a lot of storage space. There are people who can do that.*" — *P18*

> "*Well, my cell phone does that automatically. Yes, I turned this function on myself. And my photos are saved on my Google account. On Google Cloud. And if I don't have internet and want to open photos from 2015, 2016, that doesn't work. I always have to be connected to the internet because it's stored on my Google account.*" — *P20*

Participants' skepticism of cloud storage for privacy reasons is in line with prior work on user attitudes towards cloud storage [82, 83]. While it is beyond the scope of this paper to comment on the security and privacy practices of any one cloud provider, complete deletion [84] and isolation [85] of data in distributed systems are difficult due to data replication and shared hardware. Additionally, prior work shows that cloud UIs can be confusing, and lead users to improperly delete or retain data [86, 87].

5.3 Data: Loss of Personal Data Considered Low Risk but High Impact due to Poverty

Separate from software and hardware is *data*, and how poverty affects what people consider to be their assets (and non-assets), as well as how they perceive threats to their data privacy like data breaches, tracking, and identity theft. We find that participants, in general, consider their personal data as important assets, but in many cases assign it low value specifically because they themselves are poor. The sense that they will not be "worth" an attacker's time because they do not have expensive assets was pervasive. This betrays a potentially dangerous incomplete mental model about how and why data breaches occur: they may be targeted, and user-centric, but they also often occur en masse, by no fault of the user's own, as an online service is breached (and therefore the financial assets of the user are no consideration) [88, 89]. Yet participants explained that if they *did* experience a data breach, e.g., identify theft, the impact would be *high*, also directly because of poverty. Here, we report the *types* of data assets and non-assets that users defined, and discuss their perceived sensitivity and value; we discuss the feeling of "not much to get" further in Section 5.4.

Photos, Mailings, Messages: We find that participants report photos, mailings and messages as important and private data. They consider some photos low-value assets, or even non-assets, while others are considered high value assets. Participants report disuse of social media in response, in line with some prior literature and philosophical non-use [90].

> "*I have the feeling that there is a lot of sharing or oversharing. ... That's already a habit.*" — *P25*

Indeed, pictures showing children mark a threshold and are considered to be extremely sensitive content to avoid posting online (P26). The same applies to photos showing party pictures (P11) or nudes including faces (P20). Generally, oversharing posts and photos through social media was considered an undesirable tendency (P25). A sufficiently secure and private alternative for sharing sensitive photos either does not exist or does not feel usable to participants (e.g., it is not already used by their social group, it costs money, they are skeptical of it). We observe, however, that participants' use of self-deleting messages shows a positive example of a security and privacy feature addressing their concerns and being used.

Banking Data: All participants mentioned their online banking accounts to be important, but were ambivalent regarding the idea of losing their banking data or being scammed (P11; P19; P20; P21). While some participants described feeling safe because they do not have a lot of money and thus do not think of themselves as attractive targets, at the same time they fear losing all their money at once (P2; P3; P6; P11). This is directly related to poverty, as participants have exactly one (instead of multiple) bank accounts, and have no savings nor other financial fallbacks.

> "*I think that's very unlikely for me, because there's not much to get. For example, that someone has the access data for my PayPal account and then somehow steals money from me for small amounts or something.*" — *P3*

> "*Well, if someone stole all my money, I mean, it's not that much. But then of course I'd have a problem and then I'd have no more money. ”* — *P3*

Even though there are legal protections and insurances for the loss of data from a bank [91], and users would likely get their money back in a few days, it is reported to be a source of strong discomfort (P2; P3; P7; P8; P9; P11; P21; P28) because of the lack of financial fallback possibilities that those with higher (relative) income may not experience.

> "*So even if that could be arranged somehow, it's just not a situation I want to get into in the first place. Unfortunately, I only have one account and that's where most of the money is. And if that's gone, then it's not fun. Even if it's only a few days.*" — *P15*

Non-banks, such as PayPal, are not regulated in the same way, and thus a breach can lead to financial loss; however, they remain commonly used for purchasing items, e.g., from online swap/sale sites, and are also used between friends and partners. Interviewees reported PayPal-like phishing emails leading them to uninstall PayPal completely (P11; P21). One participant reported a friend for whom getting money back was impossible after the account has been hacked (P20):

> "*A few months ago, someone hacked into a friend of mine's PayPal account and stole a lot of money from her. And that made me feel pretty insecure about using PayPal. I think she contacted PayPal and they followed up on it. And they said it would take a few months. I don't know yet whether she got her money back.*" — *P20*

We observe that financial regulations *do* protect people from loss if their bank account is breached. However, people experiencing relative poverty may be unable to fulfill their everyday needs—e.g., buying food, paying rent—while they wait for the bank to return their money to their account. We also observe that the use of money-sharing apps, only some of which are regulated as banks, contribute to financial loss that relatively poor people cannot easily withstand, and we bookmark both as opportunities for improvements in technology and policy to protect poor users.

5.4 Adversaries and Risk Perception: States, Criminals, and Companies don't Come for Me

Complementary to hardware, software, and data *assets* and *non-assets* are *adversaries*. We now turn to the *actors* and *adversaries* in participants' threat models, as well as the level of risk that participants believed they posed to their previously defined assets. Participants define different adversaries including state regimes, criminals, and companies crawling data. While many express a high awareness of these adversaries as threats in general, at the same time they do not see themselves personally at risk. Reasons to personally feel safe included living in Germany, which is perceived to be a safe country, as well as not to possess financial means or sensitive data worth getting stealing (in line with their discussion of *non*-assets, in Section 5.3). These threat models may lead to a false feeling of safety. Also we find that participants report financial, emotional and time reasons prohibiting them from gathering more information about security and privacy that would enable them to better protect themselves.

Government Actors: Living in Germany is Perceived to be Safe: Some interviewees have expressed not to perceive any given government-related security and privacy risks while living in Germany. Drawing comparisons to other countries, like the persecution of LGBTQI+ people in Poland (P2), the political system in Iran (P20) or Russia (P12), and the strong social control systems in China (P16; P18), participants reported to feel free in Germany while performing tasks like critical journalism (P5), being unemployed (P16), or politically engaging to move freely through the internet (P18). Others voiced concerns about nation states like Russia influencing the votes in Germany, pointing out that incidents like these were at least publicly discussed (P9). This leads participants not to engage deliberately in security and privacy action like anonymizing their personal data or traces surfing the internet, as the following citation exemplifies. Asked whether they would take action to increase their online security or privacy, P12 replies:

> "*It would have to be something bad where I say: 'No. I can't go on; I have to make myself anonymous now.' In China or Russia, people do it because they know that their data is completely controlled, and here in Germany, at least I don't think that's the case, I think our data is free.*" — *P12*

The feeling of being safe and secure that is connected with living in a democratic constitutional country like Germany might lead to an inaccurate or incomplete assessment of personal security and privacy, as every government may unjustifiably gather personal information or violate digital security of its residents. Also, data gathered can have an unproblematic status now and become a threat in the future, e.g. when the political system undergoes substantial changes.

Targeted Attacks by a Non-State Criminal: Feeling Safe as There is Not Much to Get—Unless Something Happens: Participants generally felt well protected from targeted criminal attacks because of the simple fact that there is "not much to get" from them because they do not possess large amounts of money or important data or information (P13; P15; P19; P22; P23; P25; P27; P28). Participants hypothesized that cybercriminals would be more likely to target public figures, people with significantly more money, or people with substantial social media followings (P2; P8; P9; P14; P16; P17; P18; P23), assuming that "*if this data somehow gets to someone, they cannot do anything with it*" (P16).

Thus in general, we found that participants do not see the urgency or necessity to protect themselves better as long as nothing specific happened to them (P2; P3; P7; P10; P13; P18) — thinking that "*the probability that someone will attack*" would be "*one in a million*" (P28). On the other hand, some interviewees also refer to this perception as an "*illusion of security,*" letting them "*feel safe"* generally, but only "*as long as no one tells me, 'Oh, you've been hacked',*" or until an incident really happens.

Companies: Personalized Ads Lead to a Strong Feeling of Being Tracked: Participants had substantial concerns about online ad tracking and the invasion of their privacy (P10; P18), echoing prior work about user concerns with personalized ads [92]. However, some concerns were technically inaccurate (e.g., ad tracking very likely does not occur due to apps secretly listening via the phone's microphone [93]) and revealed inappropriate coping mechanisms e.g., only rejecting cookies, or changing their behavior in an irrational way:

> "*What actually bothers me is that the algorithm is now so blatant that there is this 'eye tracking' thing or whatever it's called. You can google it. And since then, I've been like no, I no longer look there. It actually stresses me out.*" — *P6*

Another interviewee protected themselves against tracking through rejecting all cookies which "*didn't help much*" (P2) and another put their "*phone on airplane mode during sex because I don't want my privacy to be exploited*" (P20). While these strategies may give them some protection, the myriad strategies that online trackers use for advertising content has extreme depth and will rarely be thwarted by one simple trick. We observe, at a high level, that participants are deeply uncomfortable with tracking, and also are ill-equipped to avoid it, both because of inaccurate mental models regarding how it happens, and because they cannot "buy" their privacy.

Getting personalized ads is often described in relation to big online companies like Instagram, Youtube, Amazon, and Google (P2; P14; P20) and is reported to fuel a strong discomfort due to personalized content being displayed without prior action: Eight participants believed private conversations were tracked by their smartphones (P2; P6; P7; P13; P20; P23;

P26; P27) as they have been shown personalized content after talking with a friend about a product without having actively interacted with the smartphone, e.g., googling for the product.

Some users think it is standard to be tracked by their smartphones, either worrying because they heard about it—"*You keep hearing rumors about how cell phone microphones listen. For example, if you talk about a certain product, you later get advertisements for it or something similar*" (P27)—or because they believe they experience it (P2; P23; P26):

> "*If you think about the fact that I'm talking to a friend on WhatsApp about, I don't know, let's say, foot cream, and then the advertising for foot creams pops up directly on social media. ... We only talked about it via WhatsApp. ... There was no other way. Interestingly enough, the advertising was then displayed to me on Amazon as well.*" — *P26*

We find that mostly Android and a few iOS users reported experiencing situations making them think they were being "eavesdropped" (P2; P6; P7; P20; P23; P26; P27, see: Table 4 in the Appendix). We observe that there is no evidence that modern apps listen for content to feed into advertising algorithms without being otherwise turned to "listen" mode [93].

Google as a Trade-Off: Out of 28 participants, 21 talked about Google unprompted, mostly reporting ambivalent feelings about it, which is why we choose to elaborate on that matter in more detail. Interviewees report using Google as a search engine, saying that 'googling something' is an integral part of their everyday technology use (P13; P16; P18). At the same time, participants voice a general feeling of unease using Google, because it is gathering and harvesting their data (P2; P3; P7; P12; P23; P25).

> "*I also know that companies like Meta and Google or whatnot make their profits by exploiting data. And I still support them, I'm basically giving them the data even though I know it and that bothers me.*" — *P7*

While all participants say that Google is very user friendly and has generally a high amount of usability, some of them are generally convinced that using Google is not safe (P7; P17; P23). Other participants express that leaving Google is the only option that would make their data safer and more private. One participant expresses complete abstinence from Google as an effective security and privacy practice: "*I don't have Google Play Store on my phone. I use a 'Shiftphone' and I have consciously tried not to use Google services*" (P4).

At the same time, leaving Google is reported to be a difficult endeavor, as using Google services is often described as a necessity on four levels: the technical level for Android smartphone users who have to use a Google account in order to use the Play Store (P23; P28). Second, interviewees report that it is very difficult to get rid of Google and shut Google services down, both because either Google trackers are enabled again or because they don't manage to shut off Google connectivity (P14; P15). Third, Google services are reported to be highly usable, participants express to be too 'lazy' to use something else as this would be more complicated (P22; P23) and fourth Google services are connected with many other services the interviewees use in their everyday technology use (P1; P18):

> "*I first tried to uninstall it, to see whether I can uninstall it ... uninstalling is not enough, because you are in this so to speak ... And I tried to write an email and there have been totally complicated answers ... I already talked to people who also have the problem. It's super hard to get out of Google again.*" — *P18*

Even interviewees who manage to shut down Google trackers on a technical level report that they are automatically re-enabled at some point again which one interviewee reports to have been "*annoyed by very much*" (P23). The default Google backup function leaves interviewees wondering why their data are automatically sent to Google which makes them feel uncomfortable and unsafe (P26).

Insufficient Financial, Emotional and Time Resources While Managing Uncertainty: All interviewees self-evaluate to lack deeper knowledge about digital security and privacy and state they could use improvement in knowledge, skill, and protective strategies. Participants connect financial, emotional, and time resources with their security and privacy behavior. Some describe never caring about security and privacy except "*for financial reasons or something like that*", for instance if their banking account would be at risk (P6). Other participants report not to *"have the energy"* to learn more about (P26) or to have *''too much on their plate*" to invest more time in security and privacy although they think that it would be important (P20; P25), as P25 explains below:

> "*I certainly have no good conscience about it, so it's not that I say I feel totally good or something! In the back of my head, I always think that it is actually not so good, but I have just other priorities in life somehow, than to put so much time into it, although it is super important, that is clear to me.*" — *P25*

The interviewees also give other emotional or mental reasons to desist security and privacy action. Many participants report not wanting to think too much about security and privacy as they fear to become "paranoid" about it (P2; P3; P4; P8; P10; P11; P14; P16): "*The more you read into it, the more you drift off into some paranoid conspiracy theories*" (P11). Other participants report not being able to discern whether they appropriately assess security and privacy issues they

read, hear, or know about (P3; P12; P13; P14) which leaves them with a feeling of unease and incompetence, wondering whether "*everything is actually that bad or just okay as it is* " (P12; also P3; P11; P13; P14). Another interviewee linked their lack of engagement with security and privacy directly to their financial situation: They stated that in order to inform themselves more about digital security and privacy, they would "*have to deal with things that I can't afford. And that makes me sad, so I don't do that*" (P26). While poverty is certainly not the only barrier to having an accurate and complete threat model and being able to match one's actions to that threat model, we thus observe, again, directly, that *poverty itself is a barrier to security and privacy*.

6 Discussion

Persistent social structures often prevent upward social mobility [94], especially in Germany [95]. Even for those leaving poverty, the effects of security and privacy practices adopted during times of poverty may persist (e.g., data being hard to remove from the cloud). Our findings, through 28 interviews with low-income users in Germany, show that poverty directly and indirectly impacts security and privacy needs, experiences, and mental models, and that poverty influences what is important to users in the context of digital security and privacy, and what technology and assets they use and seek to protect. We now synthesize key *technical* and *research* recommendations from our work, towards better supporting and understanding those experiencing poverty.

Securing the Use of Old and Second-Hand Devices As we found that the everyday security and privacy actions and practices of people living in relative poverty in Germany are often tied to the use of old, broken or pre-used hardware, we suggest to improve the security of old and second-hand device use. There is extensive prior work showing that old and used devices can be sources of potential security and privacy harms because users often do not properly sanitize their discarded devices, and there is no guarantee that even a wiped device is completely reset and e.g., malware free [96, 18, 17, 64, 65, 67, 70]. An already-used device may also lead to unwillingly sharing identification information like in taking over the Apple ID from a previous user who failed to properly uninstall their information, and certain hardware identifiers that may be used for (ad) tracking cannot (easily) be changed. Additionally, hardware and software ceases to be supported at some point [97, 98], and old devices will not be supported with security updates, leaving potentially exploitable vulnerabilities forever.

We urge manufacturers to expand the lifetime of security update availability, since deprecated operating systems and hardware disproportionately affect low-income users. As relying on old and used devices is standard among low income users, we also recommend developing and establishing usable practices for digitally sanitizing devices before use. We observe that to truly sanitize a device, the functionality must be implemented at the OS level rather than by a third party, and thus strong sanitization practices, with cross-OS usability and recognizability for users, requires coordinated industry support.

However, there are also other actors that may be able to support (or nudge) users and manufacturers into better sanitization practices: there is space for policy to require sanitization, or an agreement of non-sanitization, between old and new device owners, as well as a discussion of non-sanitized data. We also imagine that second hand goods trading platforms may play a role in enforcing and enabling sanitization.

Ensuring Cloud Security is (and Feels) Sufficiently Secure, Private, and Usable: Participants expressed that they use free cloud storage for data because physical (personally owned) hard drives are financially out of reach. However, some participants also expressed discomfort with storing their personal data on a corporately owned and managed cloud, uncomfortable with the access that gives the cloud provider to their personal data. We observe two key tensions that arise here. First, there is a tension between *free* and *not private* manufactured by the business model of free cloud storage. Second, it is tempting to simply recommend technology and policy that puts users in charge of their data when it is in the cloud (e.g., how GDPR allows users a right to be forgotten), yet we recognize that such technology and policy will inherently burden users who are already busy and may not have technical expertise. As our interviews show that people living in poverty are vulnerable at this point, because they *have to* opt into cloud services *and* do not have sufficient resources to ensure (or generate the feeling of) secure cloud use, we recommend researchers technologists and policymakers consider how to move towards improving *secure and usable free cloud services*, as a public utility. More concretely, for example, tools exist to encrypt one's data and move them to the cloud, but there remain open questions about their use, usability, and in-practice security and privacy properties.

Empowering Users With Accurate and Complete Threat Models: Prior work shows that financial poverty does not necessarily correlate with information-poverty or capability [99], and our data also demonstrates that low income users may very well be highly educated and possess a high amount of tech literacy. But this still is not enough to always have adequate security and privacy strategies implemented in their everyday technology use, not only because what users consider important assets they seek to protect is—at least in part—shaped by the scant hardware and software available to them. Also, we observe that poverty may make users feel a false sense of safety because there is "not much to get."

We thus remark on the importance of supporting users in developing accurate and complete threat models including, for example, an understanding of how data breaches happen *to companies* in addition to individuals [88, 89] and thus, for untargeted attacks, "not much to get" should not affect one's mitigation strategies. While a recommendation for user education ultimately puts the burden on users, we argue that it also empowers them to take collective, non-technical action for themselves: to pressure technologists, researchers, and policy-makers through democracy, to take legal action against those who mishandle data, and to boycott services that mistreat users without the intention of doing better. We observe, however, that the burdens of user education can be variable, and with proper design, we would hope they would be manageable.

Prior work has found that people learn cybersecurity behaviors and threat models socially, through their communities [100] as well as in their workplaces or school [62], and in apps [62, 101]. Thus, looking beyond social sources of cybersecuity advice [100], we turn to employer/school practices [62], apps [101], and any other sources of cybersecurity knowledge that people have access to. Prior work has found that IoT device manuals and support pages communicate cybersecurity advice [101], but IoT may be prohibitively expensive for those experiencing poverty, or, as our dataset showed, users may reject IoT for privacy cocnerns, but then also not learn new technical behaviors and mental models through the installation process.

More Work is Necessary to Understand and Alleviate the Impact of Poverty on Security and Privacy: Finally, we implore computer security and HCI researchers to continue to study poverty, particularly employing participatory and qualitative methods, and having an emphasis on doing research *with*, not *about* low income users. Despite tackling a topic that may seem "abstract," we observe that by asking people—experts in poverty through their lived experiences—*directly* about the effects of poverty, they told us *directly* what the effects were.

We also imagine numerous directions for technical and measurement research to measure and further elucidate the effects of poverty on security and privacy, as well as to support users with better technologies. In order to better support poor users, we must first understand the technical security and privacy properties of the platforms they use. Future work could measure and analyze the security and privacy properties of technology that poor people depend on, e.g., government services, second-hand goods trading platforms, third-party payment services. Mixed use device policies ("bring-your-own-device (BYOD) policies") may also be of interest. Such measurement and analysis will provide a basis on which to develop policy and technology that empowers users rather than puts them at risk and makes them feel discomfort.

We emphasize that anything that alleviates the burdens of poverty, including increasing access to security and privacy mechanisms and mental models, helps decrease the marginalization caused by poverty.

7 Conclusion

Although not only internet access and technology penetration but also poverty rates are growing, low income end users are not well studied but make up a growing set of end users with specific experiences, behaviors, and challenges in security and privacy. To address some of these challenges, and to elaborate on experiences, and strategies with security and privacy as well as on threat models low income users have, we conducted *28* in-depth, semi-structured interviews. Focusing on the everyday security and privacy actions and practices of users living in relative poverty in Germany, on the technology and assets they seek to protect, and on what they find important in the context of digital security and privacy, we find that our participants are subject to a series of possible security and privacy threats related to their low income. Because they rely on old, used, and broken devices, frequently engage in online second hand trading, possess little storage space, do not perceive themselves as attractive S&P targets, they may thus falsely feel safe, and do not have the financial, emotional, and time resources to improve their security and privacy, we offer recommendations to the research community, developers, and policy makers that can help better protect low income users and make security and privacy affordable to everybody.

Acknowledgements

We want to thank the anonymous reviewers and shepherd who gave us constructive feedback and helped us making this paper better. We thank the Max Planck Institute for Security and Privacy as well as The George Washington University for financial support. We thank Anna Lena Rotthaler, Marcel Fourné, and Christian Sperneac-Wolfer for their helpful comments to earlier versions of this paper. We want to thank all the the interviewees, as well as our colleagues and friends Clément Dreano, Marisa Kruchen, and Justus Pötzsch who piloted our study and gave constructive feedback.

Abstract

Afghanistan deployed biometric voter verification (BVV) machines nationally for the first time in the critical 2019 presidential election. Through the leading authors' unique backgrounds and involvement in this election, which facilitated interviews with 18 Afghan nationals and international participants who had an active role in this Afghan election, we explore the gap between the expected outcomes of the electoral system, centered around BVVs, and the reality on election day and beyond. We find that BVVs supported and violated the electoral goals of voter enfranchisement, fraud prevention, enabling public trust, and created threats for voters, staff, and officials. We identify technical, usability, and bureaucratic underlying causes for these mismatches and discuss several vital factors that are part of an election.

1 Introduction

Democracies today often involve technology in elections, e.g., to record votes, register voters or verify identity, transmit votes, and report results. Although computer technology is not *inherently* part of the electoral process, its use confers both massive benefits and potential vulnerabilities that must be carefully managed to preserve the integrity of the electoral process and to maintain public trust. The compromise or misuse of any technology involved in conducting an election has the potential to violate democratic goals and lead to political instability or an illegitimate government.

There has been significant work in the security and privacy community regarding electoral technologies, notably, about their hardware and software security properties (e.g., [71,79]), and about usability issues in practice (e.g., [51]), more details in Section 2. However, substantial questions remain about the use of (in)secure and (un)usable technologies in practice in electoral systems, especially in non-Western contexts.

In this work, we begin to fill a gap about the design and use of voter-facing technology in a non-Western context, following technical computer (in)security from its non-technical causes to its non-technical consequences in Afghanistan's 2019 presidential election. Before the 2019 presidential election, Afghanistan had experienced decades of armed conflict, political instability, and changing regimes, including civil war, the rise and fall of the Taliban, and fighting between the government and insurgent groups [36, 61]. Each election from 2004–2018 was marred with allegations of widespread and systemic fraud and disenfranchisement—multiple voting, ballot stuffing, and manipulation of voters or ballots [38, 42, 46, 73]. In 2009, for example, 1.3 million ballots were discarded as fraudulent, and after the 2014 presidential election, European Union election observers wrote that, after an audit by the United Nations and the US, "large scale fraud had been committed" [38]: some polling stations reported no data [38], while others reported orders of magnitude more votes than voters [42]. This combination of the electoral, political, and societal context made it particularly difficult, in 2019, to achieve a legitimate and trustworthy election in a young democracy that was simultaneously building or acquiring key physical institutions and infrastructure while facing significant domestic or international threats [94, 101].

To mitigate the systemic fraud in prior elections, the Afghan government deployed **biometric voter verification (BVV)** machines in the 2019 presidential election—the first time voter-facing technology had been employed in much of the country—requiring voters to pre-register before the election (without biometrics) and have their fingerprints and faces biometrically captured on election day (for post-processing deduplication) before casting a paper ballot. This process promised to enforce one vote per voter while making voting accessible to all [32]. Given Afghanistan's at-the-time fragile political state after decades of war and terrorism, many Afghans hoped the 2019 election would be a step towards political stability and further economic development. However, 2019's election day brought technical issues with voter verification and vote collection, causing disenfranchisement [27, 66], disputed votes, and political instability [2].

This research, led by a former Afghan Independent Election Commission (IEC)[1] employee, has the unique opportunity to study the deployment and use of these BVV machines during the 2019 Afghan presidential election. We focus on the introduction of BVV as the central and new element of the 2019 Afghanistan election, and as a critical electoral technology whose misuse or compromise led or could have led to technical security issues, voter disenfranchisement, fraud, and political instability. We explore the new technical ecosystem surrounding BVV as well as how it fit within Afghanistan's social, political, and environmental contexts, given that in hindsight we know that the electoral system did *not* function as intended. We ask: what happened, and *why*? What can we learn about technology, policy, and elections? We center our research around the research questions below, categorized in three broad topics:

- **The Biometric Voter Verification (BVV) ecosystem:** What were the goals when BVV was adopted? How was BVV integrated in the electoral process? In what ways did BVV machines work well, and what issues did they face?
- **Consequences:** What were the *consequences* of the BVVs on the electoral system? To what extent did the BVV ecosystem enable or prevent a democratic election?
- **Causes for issues and design alignments between BVVs and the electoral system:** *Why* (technically, politically, and administratively) was the BVV ecosystem designed, implemented, and deployed the way it was?

We address these topics through 18 semi-structured interviews with key international and Afghan election workers, a unique look into both technical issues and non-technical causes and consequences of those issues. Importantly, although our participants' expertise and direct experience with the election is a huge asset for our study, we are inherently limited by lack of direct access to other primary sources, such as BVV devices themselves, or their original design specifications. However, our interviews are informed by the first and second authors' own expertise: the first author is Afghan and worked for the Independent Election Commission during the 2019 election, and the second author is a member of the US armed forces, with a tour of duty in Afghanistan. We deeply reflect on our methodological decisions, our positionality as researchers, and the ethical implications of conducting this research in Section 3.

Through our interviews, we find three thematically emergent electoral goals for biometric voter verification to support—voter enfranchisement, fraud prevention, and maintenance and increase of public trust—and ground this research about biometric voter verification technology in a discussion of *how and why* it both supported and violated these goals in Afghanistan in 2019. Deciding *whether* these goals are met is *not* our aim as we analyze the complexity of our expert participants' knowledge and opinions. For example, some felt the BVVs enabled fraud—if poll workers allowed it—by using multiple fingers of the same voter. Other participants said the very existence of biometric technology deterred fraud. Both views can be true: BVVs may have enabled fraud in some ways, and prevented it in other ways.

We also find there were a number of technical mishaps and usability problems that caused cascading issues resulting in voter disenfranchisement. Some technical issues seem—from our perspective—straightforward, such as the fact that election workers had to set the time and date manually on the devices, leading to errors that contributed to 102,012 votes recorded as "out-of-time" and disputed for weeks [3]. Other technical issues seem less straightforward, yet extraordinarily impactful—such as the fact that the devices were not built to the usability requirements of the poll workers.

Contributions Through the expertise of the authors and qualitative analysis of interviews with experts involved in the 2019 Afghanistan election, our data offers insight to the computer security research community into the technical design alignments and misalignments of biometric voter verification, as well as their human causes and consequences. We hope that publishing these results will aid designers and practitioners of future electoral systems (technically and administratively). As we discuss in detail in Section 11, while it is unlikely that there will be a new election in Afghanistan in the immediate future, electoral systems in other countries may share societal, environmental, technical, and adversarial characteristics that mean that they can learn from how and why the use of biometric voter verification both supported and violated electoral goals in Afghanistan in 2019.

2 Related work

Use of biometric technologies in elections Fourty-eight countries have used biometrics in elections in the last 10 years [60], most commonly using fingerprints for voter registration, verification, or identification [106]. Fingerprints are focused on due to their high accuracy [103], uniqueness [93], and difficulty to falsify [25], with even identical twins having distinct fingerprints [62]. Adopting face matching along with fingerprint recognition can further increase biometric systems' accuracy [54]. However, the effectiveness of face matching is contingent upon the quality of the photographs and other checks [106]. Fingerprint verification accuracy is generally measured by equal error rate (EER), a comparison of false rejection and false acceptance rates [63], with the best algorithms having EERs below 0.1% and common algorithms having rates below 1% [22, 107]. Efforts to develop fingerprint biometrics for elections [6, 52, 64, 78, 98] continue to advance but differ significantly from Afghanistan in the

[1] During the Islamic Republic of Afghanistan (2004-2021).

use of Biometric Voter *Registration* [43]. Typically, biometric verification at the polls involves checking the voter's identity against a pre-existing database that includes previously collected biometrics [23]. However, Afghanistan used Biometric Voter *Verification* (BVV) technology to collect biometric data at the polls to later identify duplicate voters, and did not collect biometrics during voter *registration*. We explain the role of BVV in Afghanistan further in Section 6.

Other works related to biometric technology in elections have focused on the social, political, and economic challenges and implications of the use of biometric technology, specifically in non-Western countries [34, 37, 43, 45]. With a focus on Ghana's 2012 election, Debrah et al. found biometric technologies can benefit an election if the technologies are "robust ... [enough] to surmount election management challenges" [35]. Our work builds on this by exploring how election management challenges affected biometric technologies in Afghanistan.

Technical evaluations of election technology Foundational work in the security and privacy community has analyzed the security of various voting machines, finding potentially exploitable vulnerabilities, and usability issues [21, 39, 50, 71, 95, 95, 104, 105]. Both Wolchok et al. and Kohno et al. found issues caused by both the proprietary nature of the systems and an over-reliance on poll workers, both with regards to tasks and trust [71, 104]. Both recommend paper audit trails along with digital records and a move towards more open development. Halderman summarizes the importance of the technical security of voting machines: "*e-voting systems need to be engineered to a level of security quality far greater than that of typical information technology systems, on par with other kinds of critical infrastructure*" [50].

Other work has proposed design principles for voting machines to align with the Help America Vote Act [55]. Gritzalis proposed 15 voting system design principles aligned to US constitutional requirements to ensure that e-voting is free, equal, and secret while simultaneously being transparent and subject to public scrutiny [48]. Similarly, Molnar et al. proposed simple, reliable, and cost-effective ballot storage that is also tamper-evident, history-independent, and subliminal free [79]. Both works propose that voting machines must include audit-ability and traceability without compromising voter confidentiality or being so complex as to exclude voters.

Perceptions of election technology security Prior work has also examined user perceptions of both the security and usability of e-voting. Bederson et al. proposed that usability must be high priority and even 10% of a population having significant concerns about an election technology is unacceptable [17]. Furthermore, Oostveen and Besselaar found that trust in the machine itself is not enough and the people must trust both the officials running the election and the developer of the technology [82]. Expanding on this, de Jong et al. as well as Karola et al. cite the importance of experts' trust and evaluations as a factor in voters' confidence [33, 75]. More recently, Pomers et al. found that both voters and poll workers were more likely to be concerned with usability than with confidence in the system. Interestingly, however, they also found that poll workers were far more likely to be concerned with a lack of training [85]. Our paper builds on these important works about technical security properties of voting machines and perceptions of electronic voting by studying both in practice in Afghanistan in 2019.

Evaluations of electoral ecosystems Complementary to literature about technical security and privacy guarantees of voting machines, and user perceptions thereof, are holistic evaluations of *entire* electoral ecosystems. Bader examines the 2011 Russian legislative election and technology in elections known or perceived to have significant fraud. He found that technology reduced fraud not because of the inherent security, but because it automated vote counting and reduced human involvement [15]. Halderman evaluated challenges during the (US) Antrim County 2020 elections, finding significant failures in pre-election testing and poll workers erasing memory cards, cross-culturally echoing our findings (Sections 7 and 10) [51]. Halderman proposes that both usability and insufficiently defensive software design are at least partially to blame. Both Bader and Haldermann were specifically interested in the validity of the results of the elections and the impact of technology, whereas we are focused on the extent to which the technological processes including procurement, training, and use supported election goals including transparency, credibility, and fairness.

There are also significant works about the 2019 Afghan election, including many that focus on the political ramifications of the results and delays [1, 28, 30]. Johnson examines the 2019 presidential elections, proposing that the biometric technology could have made it simpler for a technologically savvy party to overcome another [66]. A thorough report by the US Special Inspector General for Afghanistan Reconstruction finds that the hasty implementation of technology may have exacerbated fraud and malpractice [94]. While both of these efforts address similar challenges that we identify, neither deeply examines the BVV and its impacts as they relate to the trust and transparency expectations for secure technology in an election. Furthermore, neither effort uses qualitative assessments or draws their conclusions and recommendations from this methodology.

3 Methodology

In order to explore the integration of BVVs into the 2019 Afghan election, we conducted semi-structured interviews with 18 participants familiar with them.

Participant selection and recruitment The lead author worked for the Independent Election Commission (IEC) during the election and leveraged his former professional contacts for recruitment. We recruited 18 individuals engaged in the 2019 Afghan election as part of Afghan civil society (3), the IEC (11), media (1), NGOs (2), and politics (4) (some had multiple affiliations). Four participants had expertise in IT; 13 were Afghan. Participants were ethnically diverse, with all three major Afghan ethnic groups represented. Not all Afghan participants were from Kabul; eight spoke Dari natively, and five spoke Pashto natively (all spoke Dari colloquially). One participant was recruited through another author's network as a member of the US military. The authors contacted potential participants over telephone, email, and E2EE messengers. At the conclusion of each interview, the interviewer asked for referrals to other potential participants.

Interviews We conducted semi-structured interviews from February 2022 until October 2022, with 11 interviews in Dari and 7 in English. The first author conducted all the interviews; the second author participated in four. Before each interview, we sent detailed information about the study and ourselves to participants (Appendix A). At the start of each interview, as part of our informed consent process, we went over the information that we had sent over email, and discussed risk mitigation, the interview medium (end-to-end encrypted video/audio), our data security protocols (encrypted external hard drive only accessible by the interviewers), and any of their safety concerns. Our first question during this consent process was whether they feel safe doing the interview. Our Institutional Review Board (IRB) waived documentation of consent because it would have created additional risk for participants.

We also emphasized that they were free to skip topics or questions. Additionally, we asked permission to record and told them they could ask us to stop recording at any point. Upon their confirmation, we began recording. Our interviews covered the following:

1. Experiences and challenges with **BVV adoption**
2. Political, administrative, legal and social **influences on and consequences of adoption**
3. **Security & privacy issues** during the election with BVVs
4. **Trust** in the electoral system (both personal and public)

We developed our interview protocol through several rounds of revision and a feedback session with an external expert on the 2019 elections who also has expertise in social science. Questions were open-ended (Appendix B has the full protocol) and interviews lasted 60 to 90 minutes. We stopped interviewing when interviews produced no new data, defining thematic saturation [47]. Thematic saturation has limitations in the context of qualitative work [83], and it is indeed possible that if we had not used thematic saturation as a measure of "doneness," or if we had defined it differently, our data could include more or different themes. The external expert later became a participant in the study, and thus knew the protocol in advance; the interview was structured such that knowledge of subsequent questions would be unlikely to influence responses to earlier questions.

Analysis Throughout data collection and analysis, we regularly discussed interviews and wrote memos. The lead author, a native Dari speaker, translated and transcribed all interviews. We then conducted thematic analysis, beginning by open coding and discussing broader themes [40]. The codebook iteratively coalesced through multiple rounds of discussions, open, and axial coding [20].[2] Then, two researchers independently applied the codebook to each transcript and checked their shared understanding, resolving disagreements and updating the codebook. They also regularly talked with a third researcher about their understanding of the codes and emergent themes. They iteratively applied the codebook until no new codes emerged and no new code applications occurred.

Ethical considerations Because the Taliban have threatened leadership of the former Afghan government [57], there is potential for harm to our participants, as well as ourselves and our loved ones, and any future elections that use a similar system. The rest of the team followed the lead of the first author regarding his own safety. However, the team worked with him to consider the possible risks and mitigations. The lead author feels that publishing this work will not substantially *add* to any potential harm he may face. Likewise, the lead author (and team) weighed the potential benefits and risks with this research and concluded that the potential benefits of an eventual publication outweighed the potential risks.

In accordance with the Menlo report, we attempted to maximize benefit and minimize harm, and protect and respect everyone involved with and/or affected by our research [16]. We obtained Institutional Review Board (IRB) approval from our institution. We did not pay participants in order to avoid creating institutional records, following the lead of prior work [31].

All interviews were conducted on Zoom. Despite known security flaws (as with many platforms), Zoom employs E2EE, and participants used their own trusted devices. Most importantly, participants—experts in their own safety within the context of the political situation—felt comfortable using the technology; this follows a standard of safety in prior work [11, 26, 31, 49].

We contacted approximately twice as many individuals as participants; of those who did not participate, some expressed safety concerns due to still being in Afghanistan. Once participants expressed safety concerns, we thanked them for the consideration and ended the conversation.

[2] Codebook available at https://osf.io/2ZQC8/

We present little demographic and recruitment information, and we redact information in quotes when participants discussed their specific role in the election. In doing so, we strove to make it extremely unlikely our participants will be identified from the data in this paper. Additionally, due to the nature of our contribution—i.e., the fact that they were largely discussing either *personal* anecdotes and perceptions, or publicly known events—we do not think that this publication will increase the harms they already face.

We disclosed our findings to the BVV vendor after acceptance and before publication, to enhance the security and usability of future products. We omit the name of the vendor, instead describing them as a European company, to avoid placing undue blame on them as opposed to other decision makers who are not named. We do not attempt to attribute fault to any one party, as an undesirable feature may either be a flaw in specification or implementation, and from our perspective, we cannot know the difference.

Methodological limitations Our research faced significant challenges due to the political shift in Afghanistan in August 2021 [88], when the Taliban took control of the country and disbanded the IEC [84], hindering our access to key IEC authorities, many of whom were either inaccessible or unwilling to participate due to safety concerns or perceived irrelevance to their field. Additionally, the IEC website, which contained valuable information about the election, was taken offline.

The validity of our study depends largely on the credibility of the participants' recollection and the precision of public sources of information; however, recall bias diminishes when participants recall specific events [19,81]. Additionally, different methodologies entirely could have produced new theories or richer results.

Researcher positionality Some of the authors have unique backgrounds that have enabled them to conduct this research. The first author, an Afghan native, was the Director of Information Technology (IT) for the IEC during the 2019 elections. The second author is a member of the US armed forces with tours of duty in multiple theaters, including Afghanistan. The first author's expertise and professional network enabled us to effectively conduct this research by recruiting participants that were directly involved with the adoption and implementation of the BVV technology in the 2019 election. Additionally, the first author's depth of knowledge and experience on this topic made this research possible by enabling deep and detailed conversations about advanced election mechanics with experts. The second author's experience, specifically in Afghanistan, offered valuable geopolitical insights that enriched our interview questions and perspectives.

In conducting our interviews, we were cognizant of the complex interplay of power dynamics, cultural sensitivities, and personal relationships. No researchers interviewed anyone over whom they had current or previous power. Our team's diverse backgrounds—spanning various cultural, linguistic, and professional domains—equipped us to navigate cultural, gender, age, nationality and other dynamics, and we sought to make participants comfortable, with some dynamics mitigated by pre-existing personal relationships.

The other authors have prior experience in security and privacy and HCI research, as well as specifically working with non-WEIRD and vulnerable populations. Some are American, including the senior author, but none have specific professional or personal experience or knowledge regarding Afghanistan. It is, however, relevant to acknowledge that our role as citizens of the country that had a presence in Afghanistan for two decades has certainly affected our development of this research. We have, accordingly, followed the lead of the Afghan first author regarding Afghan politics and history. Additionally, while we acknowledge the significant role the US and other nations have had in Afghanistan, including in the 2019 elections, the focus of this paper is *not* about their influence or the ramifications of it. We focus on telling this story from the Afghan perspective, though the international involvement is an integral part of that story.

4 The 2019 Afghan presidential election: adversarial actors and threats

The zeitgeist prior to the 2019 presidential election created significant threats. Understanding adversarial actors and the threat model under which the 2019 election was planned and conducted is critical to understanding *how* and *why* the electoral system operated (or failed to operate).

Adversarial actors There were significant adversarial actors in the 2019 election including the Taliban, individual politicians, internal threats, as well as foreign actors. The Taliban have historically opposed democratic processes [53], particularly elections [44]. They threatened and killed voters, staff and stakeholders during and after each election, and also attempted to destroy infrastructure [13,58,97]. In an election, political candidates can sometimes evolve into potentially adversarial actors. In previous elections, political candidates were accused of committing fraud including direct interference with the electoral process [9,56,89]. Such accusations continued into the 2019 election [76]. Additionally, there were nonspecific reports of foreign actors [4] with intention to carry out cyber-attacks on the IEC network, also echoed by four participants. While we consider international adversaries out of scope for this paper, their potential interference in an election cannot be ignored [90].

Threats to or during the 2019 election Threats during the election include voter de-anonymization, physical harm to both voters and officials, data compromise, as well as fraud

and corruption. We consider all of these, digital or not, computer security threats due to their influence on how people built and interacted with (or declined to use) the electoral system technology, and because they may occur due to misuse or compromise of computer systems.

Data compromise Adversaries may attempt to compromise data in order to identify voters or remove, add, or change votes. P7 explained: "*suppose adversaries gain access to confidential election-related data, they could sabotage the whole operation and undermine the credibility of the election and harm voters.*" Though our dataset (and news) does not indicate any systemic data compromise in the 2019 elections (contrary to prior elections [38, 67]), participants told stories of small scale data compromise, such as individuals voting multiple times, or data being deleted (discussed in Sections 7 and 8), as well as instances from the past elections.

Voter de-anonymization, physical violence and harm The Taliban disrupted polling with explosions [7], spread violence by threatening to amputate the fingers of voters who participated in the 2019 election [92], and seized BVVs in a potential attempt to realize this threat [68]. While no evidence points to the Taliban actually identifying voters whose biometric data was present on seized BVVs, these threats discouraged voters from voting [68]. As P13 noted, "*during the 2019 election, the Taliban seized some BVVs to identify participating voters. They destroyed the devices when found data is encrypted, which led to the invalidation of votes.*"

In addition to violence against voters, there was violence (and threats of violence) against election workers at all levels, from temporary field workers, to high-ranking officials [68]. Five participants told ten stories of either themselves, other election officials being marked for assassination via social media. Additionally, nine participants reported threats to themselves or their employees. Adversaries also attacked or threatened to attack either the devices or the BVV operators (poll workers) directly. P11 disclosed, "*Several biometric operators who received training were absent on the election day. When reach them out, they said that terrorist groups had identified and threatened them with fatal consequences if they took part in the election process.*"

Infrastructural damage Fourteen participants noted that infrastructure—electric, cellular, internet, and roads—were key supporting components of BVV, and therefore, were sources of vulnerability. Eight participants discussed adversarial attempts to undermine infrastructural integrity, including compromising, damaging and destroying telecommunications, transportation, and electrical infrastructure. P3 explained that "*the insurgent groups... threatened telecommunication companies to shut down their antennas on the election day otherwise they would destroy all their cell towers.*"

5 Electoral goals

Having first discussed Afghanistan's technical, environmental, political, and social contexts, and the threats and adversarial actors active during the election (Section 4), we can now turn to *electoral goals*, which are set *within* and *because of* the aforementioned contexts. This section overviews electoral goals with regards to the integration of BVV technology in the election as viewed by our participants; we return to these goals, and how they were both supported and violated by the implementation of the electoral system, in Sections 7 - 9. These goals are qualitatively drawn from our data and derived from our thematic analysis rather than prescribed by prior research; we do so because our participants discussed electoral goals throughout the interviews, and we find them a useful lens through which to understand biometric voter verification technology in 2019 Afghanistan.

Electoral goal 1: Everyone eligible to vote can cast a vote (enfranchisement). Voters must be able to safely participate and cast votes in the election, and must not be prevented from voting by the electoral system. Votes must also be accurately and securely stored, counted, and transmitted. Voting must also not put anyone at risk of harm, i.e. from the Taliban. Seventeen participants discussed voter enfranchisement, its importance to the election, or the role that it plays with regards to the end state of a successful election.

Electoral goal 2: Each voter may cast at most one vote; no non-voters may cast votes (anti-fraud). Due to Afghanistan's history with systemic and widespread election fraud, preventing, deterring, and detecting fraud was the impetus for the BVVs, in line with the United Nations' specification of a free and fair election [99]. Biometric technology promised to allow each voter to vote once and *only* once. Every respondent discussed fraud, with 15 participants specifically talking about fraud and anti-fraud measures related to the 2019 elections, while the other three respondents discussed the impact fraud and corruption had on the legitimacy of past elections.

Electoral goal 3: Increase public trust in the electoral system. A third goal of the biometric voter verification system was to build public trust in the electoral process—after decades of elections marred with fraud and instability—by providing undeniable accuracy and transparency. Seventeen of our participants highlighted the importance of trust, accuracy, and transparency in the relationship between the public, the election, and technology.

6 Biometric voter verification in Afghanistan

To achieve the goals described in Section 5—voter enfranchisement, anti-fraud, and public trust in the electoral system—despite the history of fraud and the challenging political, social, environmental, and technical contexts (Sections 1 and 4), Afghanistan's **Independent Election Committee (IEC)** partially tested a **Biometric Voter Verification (BVV)** system

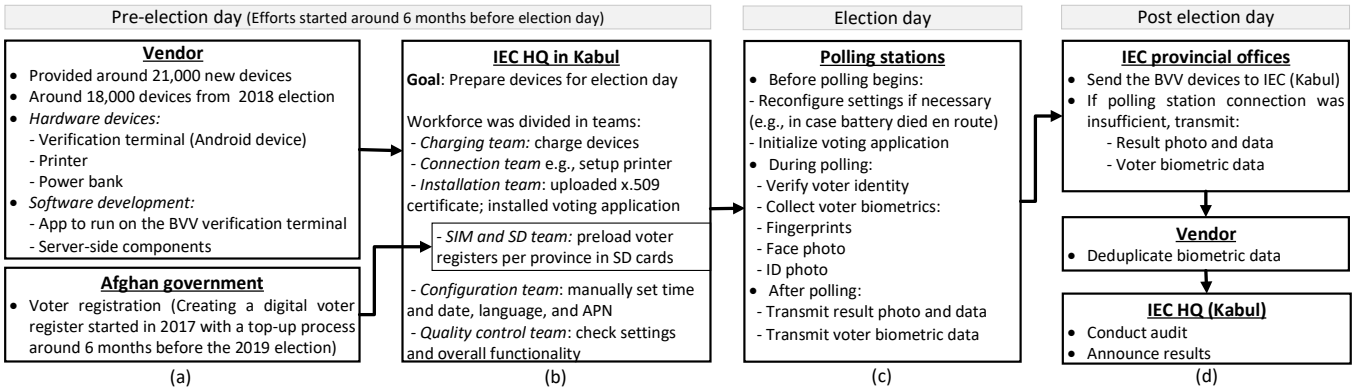

Figure 1: Integration of Biometric Voter Verification (BVV) into the Electoral System – A high-level overview of the BVV ecosystem at several key stages before, during, and after election day.

in the 2018 parliamentary election [45]. The following year—the 2019 presidential election—the IEC were mandated by law to deploy biometric voter verification for all voters [4].

The BVV used in the 2019 Afghan election included a *verification terminal* (a hand-held Android-based device with a camera and fingerprint sensor), a *sticker printer*, and a *power bank*. The printer generated QR codes that were attached to ballots. In this paper, we refer to the Android device as the BVV, and the printer and power bank perform supplementary tasks.

As a basis for understanding how BVVs supported and violated electoral goals, it is important to first understand how the devices were *supposed* to work in the electoral system, as well as what *actually* happened. The following subsections explore the consequences of the sometimes substantial gap between expectation and reality, referring to Figure 1, which summarizes the *intended* BVV development and function. While we cite public data for much of this section, we have also relied upon the first author's professional knowledge as former IEC Director of IT in 2019.

6.1 Pre-election period: Voter registration, BVVs sent to Kabul

Voter registration In Afghanistan, voter registration was historically inconsistent and error-prone because the country did not have a reliable national identification system to connect a person to a fixed address. The first voter registration process was conducted in 2004, giving 12 million people voter cards that included their name, province, and an optional photo. However, it was difficult to track the cards, and faced issues of over-registration and people registering for others [96, 108]. By 2014, the number of distributed voter cards exceeded the estimated number of eligible voters by at least 7.5 million [102].

The IEC therefore started registration anew in 2017, discarding the old registry entirely. From 2017 to 2018, the IEC registered 9.6 million voters (approximately a quarter of Afghanistan's entire population [24]). They used stickers on **Tazkiras** (national IDs) to hold voter information.

> **Reality: The voter registration database was flawed, meaning that not all who wished to cast votes could**. The new registry did not include voter photos and had errors, such as spelling issues with names (P4), duplicates if someone had more than one national ID, and missing voters [94]. Additionally, in 2019, the IEC announced that 400,000 "ghost voters" had been removed from the voter list due to duplication [66]. Nonetheless, nine participants noted that some of these removals led to voter disenfranchisement.

BVVs arrive in Kabul As shown in Figure 1(b), after the vendor had delivered the BVVs to Kabul, the devices required some setup, including charging the BVVs and power banks, installing a certificate from a server in the IEC data center, setting the time and date, installing the *voter verification application* developed by the vendor (via USB), and loading the proper province's voter registration data on SD cards.

The BVVs were then transported to polling centers, e.g., schools. Each polling center had multiple polling stations (booths), with one polling station per 300 registered voters, split by gender. Each polling station was allocated a single BVV, with one extra BVV sent to the entire polling center as a backup. In total, there were 39,000 BVVs deployed to 26,580 open polling stations out of total 29,586 polling stations [2].

> **Reality: Issues with device setup led to voter disenfranchisement**. Some BVVs arrived without charge [65]; others arrived with incorrect time and dates and were not fixed by poll workers [2]. These issues led to voters being unable to vote (on devices without charge) or cast votes being disputed [4].

6.2 Election day: Casting votes

Poll workers, temporary field employees, operated BVVs at each polling station. Before polling began, the poll worker

would activate the BVV app by scanning a QR code on the printed voter list.

When a voter arrived, the poll worker would enter the voter ID number in the BVV to check that the voter is registered for that polling center. Upon successful verification of the voter's ID, the poll worker would direct the voter to a specific polling station to cast their vote. BVVs captured the following information from each voter:

- **Fingerprints** of both index fingers
- A **photograph** of the voter's **face**, taken against a specific backdrop to confirm the location
- A **photograph** of the voter's **Tazkira (national ID)**, including the voter registration confirmation sticker from the most recent round of voter registration

A QR code (produced by the sticker printer) linking to this information was printed on a sticker and affixed to the back of the voter's ballot paper by the poll worker. Additionally, this sticker would contain polling center code as well as date and time of voting.

Moreover, poll workers had an *override* option available as part of BVV app to use at their discretion (P15), but any votes where voter verification was overridden were supposed to get checked by the vendor.

> **Reality: Technical, usability, and database issues prevented some voters from casting votes**. While many voters did cast votes, many encountered issues, from the poll workers incorrectly operating BVVs and either disallowing them to cast votes or deleting their votes, to voter registration that was tied to a different location, to technical issues with the BVVs leading their votes to be disputed or discounted [94]. (We discuss these issues through Sections 7, 8, and 9).

6.3 After election day: Results transmission, counting, and reporting

After election day, the process of reporting results began, including transmission, counting, and fraud detection.

Summarizing results at the polling station After polling closed, poll workers counted all completed biometrically validated ballots, and marked totals on a paper result sheet including the number of votes, used ballots, and votes for each candidate. During this process, several election observers and candidate agents watched, and all signed the paper to indicate the results sheet was accurate. Then, the poll worker took a photo of the results sheet using the BVV, and additionally entered the data from the results sheet into the voting app on the BVV itself. Thus, there were three copies of the summary data on the results sheet: the original paper copy, a photograph of the paper copy, and manually entered text in the BVV application. These three copies were necessary because "*there had been chances that this [results] form would be manipulated in transit. Capturing the result information digitally on the polling station would enable us to detect fraud*" (P2).

Transmission of results and voter biometric data After poll workers had tallied results and triplicated the data, the BVV devices, equipped with SIM cards, were supposed to transmit both biometric and result data using the cell network. Paper ballots and physical BVV devices were transported to provincial offices and on to Kabul.

> **Reality: Some BVVs were unable to transmit data due to a lack of sufficient cellular connection**. Additionally, the Taliban threatened telecommunication companies not to allow their antennas to be used on the election day [18]. Thus, instead, all BVV devices were transported to provincial offices and then to Kabul for data synchronization, though there were technical issues with data transfer [10] which led to political disputes [91].

Checking for fraud at polling station, in transmission, and amongst Kabul staff In order to account for manual error in results tabulation *as well as* adversarial staff members and poll workers or observers, there was a complex system using multiplicative data entry and comparison. Recall that poll workers and observers jointly produced three copies of a results summary: on paper, a photo of the paper on the BVV, and manually entered data on the BVV. To check for fraud at polling stations and in transmission, two randomly assigned staff members first compared the photograph of the results sheet and the data on the BVV; if the two did not match, a separate team corrected the digital file to match the photo, and noted the operators and polling stations involved (a process known as double-blind auditing). Separately, three staff members entered results summary data from each *paper* result sheet (in triplicate to account for manual errors and detect fraud, both at the polling station and amongst the data enterers). Finally, both sets of digital results summary files were compared programmatically. Flags anywhere along this process indicate that the polling station (and/or staff members) must be separately audited through a recount.

Checking for duplicate voters and final vote count Parallel to the above was the deduplication of voters, carried out by the vendor. After the biometric data from the BVVs was transmitted to the servers, the vendor identified duplicate voters based on fingerprints, face photographs, and voter IDs. Following deduplication, IEC removed all the duplicate votes in a special audit program (using the identifier in the form of a QR code to match them) and recounted the remaining votes. Finally, IEC announced the final result of the election as 923,592 (50.64%) for Ashraf Ghani, and 720,841 for Abdullah Abdullah (39.52%), with other candidates trailing [91]. Results were announced five months after the election, in stark contrast to the IEC's planned results timeline of 21 days [12].

7 Support and violation of electoral goal 1: Voter enfranchisement

Due to the gaps between the *design* of the BVV ecosystem, and the *implementation* and *reality* on election day, we are now poised to return to the three election goals from Section 5 and discuss, in depth, the specific technical issues that caused cascading security, privacy, safety, and election legitimacy issues. Throughout this section and the following two, we explore precisely how and why the BVV ecosystem both supported and violated the goals of **voter enfranchisement** (here), **anti-fraud** (Section 8), and **public trust in the electoral system** (Section 9). Our aim is not to judge whether each goal was achieved—and indeed, our participants, electoral experts themselves, often did not agree on high level questions of success or failure. Instead, we argue that through understanding the *technical factors* (including database, hardware, software, and usability issues) that led to both support and violation of the electoral goals, our results can help inform designers and implementers of future electoral systems. We note no factual contradictions between participants, but a healthy contrast in opinions about the support and violation of electoral goals, perhaps driven by participants' diverse professional backgrounds.

We begin with the ***electoral goal 1: Voter enfranchisement***: that everyone eligible to vote is able to cast a vote, that casting a vote has no repercussions for their or others' physical safety, and that their vote, once cast, is properly counted.

7.1 Supported: Voter participation and safety

1,929,333 votes were successfully cast on election day (86,226 later discounted as fraudulent) [14]. Although this number is substantially lower than votes cast in prior elections, votes *were* cast, and *some* of the lower voter turnout could have been to factors unrelated to the BVVs [94]. Four participants felt the very presence of BVVs increased voter participation because it felt safer, e.g., P16, who said that the use of BVVs "*encouraged other areas ...and different population groups to come and... vote for their president because they were hearing that it was safe... because of technology.*"

7.2 Violated: Some voters did not vote due to misalignments with cultural values or concerns about safety

There were multiple reports of people being unable to vote [7], and some constituents declined to vote because they feared for their physical safety. As discussed in Section 4, the Taliban threatened to amputate voters' fingers. In some instances, voters believed that the data recorded by the BVV could be traced back to them. P11 explained that "*people were told that if you participate in the election and register your biometric identities, later the Taliban will access to the database and identify your participation in the election and will cut your fingers. This created a big fear among the public not to participate in the election.*"

Some women could not vote due to the biometric verification process—taking pictures of voters' faces—did not align with their family's cultural values. P11 explained that "*in the conservative and male-dominant society like Afghanistan, men didn't allow their wives or daughters to be photographed.*" P13 added that "*introducing biometrics without having an adequate and proper awareness program in a conservative society was a cultural shock for them.*" Although many Afghan women *did* vote, it is notable that this technology precluded some from voting *by design*.

7.3 Violated: Some voters could not cast votes due to technical issues with BVVs

Distinct from people who *could* have voted but did not are those who *tried* to vote but could not due to technical issues. In addition to the issues with BVVs detailed here, inconsistencies in the voter registry (Section 6.1) meant that some voters were turned away, e.g., in P12's location at least, "*from every three voters, two voters were not in the list, despite they all registered and had valid voter stickers.*"

Unauthoritative timestamps resulted in votes being thrown out When voters cast votes, they were recorded, by the BVV, with the BVV's current timestamp, and any votes recorded before or after the official election operating time interval were supposed to be thrown out as fraud or potential fraud, as per Afghanistan's electoral laws [80]. However, recall that the time and date was set manually by central election workers, and again by some field workers if necessary. Seven participants mentioned that the manual process of setting the date and time resulted in some BVVs having timestamps with the wrong month (P8), entirely incorrect years (P2), or mixed up AM and PM (P2). P2 explained that as required by electoral law, "*those irregular voting were considered as fraud... Some devices dates were setup wrongly in 2029, so we can't say that it is fraud but likely mistake of the person who configured the device*" (P2). P2 continued, explaining that "*there were about 112,000*[3] *voters affected by the device timing issue*" (P2). These votes were part of the set of disputed votes in the post-election period; some were eventually counted [14].

Hardware design issues: power and climate Because "*in most of Afghanistan we didn't have electricity*" (P9), it was critical that the BVVs arrived with enough battery power to last a full day of voting. Four participants, however, said that devices sometimes arrived without charge at the polling centers. Despite devices being charged in Kabul before being shipped to polling centers, "*sometimes those machines, they*

[3] Official sources put the number of out-of-time votes at 102,012 [14].

charged it but they didn't turn it off... [so] sometimes when they opened it [at the polling centers], there was not enough charge" (P9). Sometimes, the battery did not last the entire day, and the devices were slow to charge: "*The BVV's battery couldn't last a full day of continuous use, and while poll workers used power banks, these also charged the device very slowly*" (P15). Complicating matters further, P18 recalled that BVVs became substantially slower in the heat, problematic given some provinces are extremely hot and lacked air conditioning in polling stations. P18 estimated that each voter took approximately three minutes in the extreme heat. At three minutes per vote, in the 10 hour voting period (7am to 5pm), a maximum of 200 people would have been able to vote. Because each polling station had a single BVV, and one polling station had 300 registered voters assigned to them, one third of the registered voters would have been unable to vote. Indeed, P18 said,"*if all the voters had participated in the elections, we would not have been able to collect the votes in the schedule set by the Election Commission, and election would turn to an uproar!*" P18 attributed this slow speed directly to "*the excessive hotness*."

7.4 Violated: Usability issues led to poll workers' mistakes and uncounted votes

Usability issues plagued the BVVs, with poll workers at times struggling to operate the devices due both to training and usability, preventing potential votes. Training did not sufficiently prepare poll workers to use the BVVs, as P12 observed: "*the biometric [poll] workers were not prepared and didn't have the enough knowledge to operate with the BVV devices*." Indeed, nine participants discussed how insufficient training and interface design left poll workers without clear procedures in case of device malfunction. P18 said that "*when several BVV devices stopped working... we did not know what to do... We asked the polling workers to put the memory of the failed device in a new device and resume polling, which later created a big challenge in data integrity.*" Understandably, poll workers who did this were trying to preserve the votes already cast, but likely were unaware that if the SD card was ever removed, a "security" feature of the BVV recorded this, and all votes previously cast on that SD card would not be counted. Corroborating this, P2 remarked, "*there were quite a number of biometric devices ... that displayed zero votes while transferring data to the server; however, there is evidence that people have come and voted in that station.*" We note that a technical design which requires the hardware to be paired and allows users to easily swap SD cards is a data integrity violation, similar to issues from the US 2020 election [51].

These technical oversights not only jeopardized data integrity but were further exacerbated by device usability. Eight participants described the usability of BVVs as complex. P11 noted "*even trained, educated biometric operators struggled with the biometric devices on election day due to the technology's complexity*." The insufficient information provided in the training was compounded by some poll workers' lack of formal education. The United Nations (UN) estimated that approximately 43% of Afghan adults were literate in 2018, a substantial increase over a decade prior [100], with more access to formal education and higher literacy rates in cities such as Kabul, and less in rural areas (education was open to all until 2021 [8]). Five participants mentioned this as an issue. P11 stated, "*The people in the villages were not educated enough to operate with the biometric device, so it was a big challenge.*" Also, P7 noted that "*most biometric workers in remote areas lacked sufficient education or learning skills, and some were too old to grasp the biometric device*."

8 Support and violation of electoral goal 2: Anti-fraud (only one vote per voter)

In tandem with the goal of every eligible voter being *able* to cast a vote was the goal for every voter to cast *only one* vote. Electoral fraud was rampant through Afghanistan's prior decades of elections, and the *deterrence*, *detection*, and *prevention* of fraud was thus a paramount goal in the design of the 2019 election.

8.1 Supported: Deterrence

Fifteen participants said the very existence of BVVs deterred fraud, e.g., P10: "*Afghan citizens knew that this biometric system was put in place ... from that perspective, it was successful ... [in] deterring people from trying to vote multiple times.*" Our data shows that BVV awarded fraud deterrence as the extent of fraud compared to historical numbers of fraudulent votes, e.g., ballot stuffing [42] in past elections, was trivial. P5 noted, "*In earlier elections, we have witnessed agents from warlords and gangsters forcing polling staff to do ballot stuffing in favor of their candidates, but BVV worked as a deterrent for the warlords this time.*"

8.2 Violated: Alleged duplicate votes

Although the BVV ecosystem *did* likely deter, prevent, and detect fraud attempts, it also malfunctioned in ways that may have allowed vote manipulation, though we cannot know the extent.

The IEC mandated that voters register and vote with both index fingers [59]. However, only *valid* fingers were registered, putting the onus on poll workers to ensure voters did not enter a second vote with a different finger because "*there was no mechanism to deny registering the rest of fingers*" (P17). Voters may have been allowed to vote with multiple fingers (and thus cast multiple votes) for multiple reasons, for example, if poll workers were fatigued or simply did not notice which finger the voter used, or if they were physically intimidated or threatened, or if they misunderstood their role (recall

from Section 6 that poll workers could manually override the voter verification process). We thus reemphasize that the technical and user interface designs—through mismatches with poll workers' abilities and understanding of technology, as well as with their intentions—may have allowed poll workers outsized power over the election outcome.

It is also possible that poll workers could also *intentionally* have enabled multiple votes. For example, P11 heard that "*some polling voters moved the biometric verification devices to unknown places on the election day and have attempted to register even their foot's toes in order to print the barcode and vote in the favor of their favorite candidate*." P3 explained that, politically, poll workers were valuable, and "*the candidates ... tried to influence the polling staff who were supposed to work with the biometric devices on the election day by any means of force, threatening, and/or bribe*."

8.3 Supported: Detection of fraudulent votes and vote manipulation

Through the parallel result audit process performed in Kabul (Section 6) and the deduplication of voter biometric data done by the vendor, thousands of votes were marked as suspicious (indicating vote manipulation by staff or in transit), and 86,226 determined, by the vendor, to be duplicate votes [94]. Both are design features of the BVVs: recall from Section 6 that the audit in Kabul was done through triplicate reporting of results (on paper, as a photo on the BVV, and as manually entered data on the BVV). As the deduplication of voter biometric data was also reliant on the BVV device and broader systems, we would be remiss to not discuss the details of biometric deduplication. P10 points out that biometric comparison involves setting a somewhat arbitrary (and likely unbiased) threshold for similarity that determines the number of duplicate fingerprints in the dataset: "*we have no way to fine-tune the system because the fingerprint is divorced from the identity of voters, so we can't go back and find out that our system really detected duplicates or did it just detect people with similar fingerprints.*" The breakdown of the votes invalidated by the vendor is reported as follow: 5,822 votes for having duplicate fingerprints, 47,527 for duplicate faces, 37,006 for duplicate voter numbers, and 5,141 for being uploaded twice, for a total of 86,226 duplicate votes being invalidated (numbers add up to more than 86,226 because 9,270 duplicates matched "multiple criteria") [3].

9 Support and violation of electoral goal 3: Increase public trust in the electoral system

Finally, we address the third overarching electoral goal: increasing public trust in the electoral system itself. Without public trust in the electoral system, the results of the election—and the new political leaders—may not be accepted [69].

We find that public trust was both supported and violated by technical design and implementation of the BVVs. We also find that the support and violation of other electoral goals—voter enfranchisement and anti-fraud measures—affected public trust: 13 participants expressed that experiences and stories of voter disenfranchisement decreased public trust.

9.1 Violated: Lack of public understanding about technical properties

Misinformation about the technical capabilities and (non)guarantees of the BVVs was widespread. Some participants attributed the public's misunderstanding to Afghan officials: P14 said that the "*IEC didn't have enough public awareness programs about the technology and how technology can commit transparency in the election... If you don't have enough knowledge about something you can't trust it.*"

9.2 Violated: Political instability fueled by slow data transmission

Substantial design and implementation issues slowed the transmission of data from BVV devices to servers, contributing to a period of political instability during which the two main candidates argued about who had won, before results were official. Preliminary results were promised in 21 days [87], but it actually took five months [86]. Here, we explore technical issues that contributed to these slow results.

Disputed votes caused by technical issues with BVVs One of the main issues during this period of political instability was the number of disputed votes, publicly reported as approximately 300,000 [94]. Some were cast at the wrong time, or even the wrong date (in the past or future), as discussed in Section 7.3. Others were from polling stations that had a suspiciously high discrepancy between votes cast and voter biometric data collected (should be 0 difference; a very small difference did not trigger a recount) [66].

While recounts on certain polling stations were conducted, the debate around whether to count suspicious votes continued. Significantly, many more of these votes were from the rural districts [66]. While we absolutely cannot speculate about the legitimacy of these votes, we observe the following: all BVVs were configured centrally (Figure 1(b)), including the time and date, but this was a manual process and some were likely misconfigured due to human error. We speculate that batteries in some devices draining on their way to the polling stations (either due to faulty batteries or not being turned off) resulted in a loss of setting, and that poll workers in the field had to reset the time and date for the devices that arrived without the proper time and date.

Poll workers did not promptly tabulate and send results Some poll workers did not follow the prescribed procedures to digitally enter votes and send results to the headquarters using BVV devices after polling concluded. P3 recalled a poll worker who "*did not take the photograph of the result form following the polling process as they were supposed to, which created a big technical challenge in the transmission of data.*" Participants mostly attributed this misuse to poor training and insufficient usability—a mismatch with the digital literacy skills of the workers. P14 recalled that, for some, this caused "*two hours of delay to configure and test the device.*" These issues echo problems that led to political disputes due to the improperly collected votes and voter data—that is, the BVVs did not match poll workers' technical experience.

The BVVs required connectivity that was not available in many rural polling centers In order to meet election timelines [87], the BVVs were designed to transmit results utilizing the cellular infrastructure. However, internet did not exist in many of the rural provinces to cover the polling centers. Indeed, 14 interviewees said that the BVV required infrastructure (e.g., cellular, electrical, internet) was not present.

P14 stated that *"the technology was not compatible with the local conditions of Afghanistan.... Many polling centers didn't have internet coverage in [the province of] Panjshir, so it created a challenge to transmit data over the internet on time from the polling centers."* Additionally, internet and cellular connectivity are dependent on electrical infrastructure. P16 explained: "*some of the challenges that we faced was just giving them enough fuel to run their generators to run their electricity so that they can have the free flowing internet to have communication equipment.*"

9.3 Supported: Improvement over the past

While the BVV ecosystem was certainly flawed, as discussed in other sections, 16 participants actually considered it, *on the whole*, a major step forward—especially with regards to reducing the electoral fraud that plagued prior elections. P6 observed that the 2019 election presented "*a lot of challenges but compared to the 2014 presidential election, there was a big improvement in terms of technology.*" P17 also generally observed that, in their opinion, "*technology is particularly important in improving the election transparency.*"

10 Underlying causes for malfunctions of the BVV ecosystem

Through the preceding discussions of support and violation for the overarching electoral goals (voter enfranchisement, anti-fraud, public trust), we have explored a variety of technical functionality, database, and usability issues. However, our expert participants went beyond specific technical malfunctions and mismatches, discussing the influence of non-technical administrative processes and roles on the *selection*, *design*, and *implementation* of the BVV ecosystem. Through this section, we identify how bureaucratic decisions that may seem non-technical can lead to design decisions and technical implications that have devastating consequences for security, privacy, safety, and election legitimacy. P17 explained: "*No doubt that the technology is particularly important in improving the election process; the selection of technology is more critical. Wrong selection of technology without consideration of the societal and political factors of a country may jeopardize the entire process.*"

Politicians and decision-makers were not well-informed about biometric and electoral technology Participants expressed that the election leadership were not always able to make informed decisions because they lacked foundational technical knowledge and appropriate technical counseling. P7 described that "*they thought that technology can make magic and can miraculously solve all the problems*." In a particularly egregious example, P10 recalled a meeting with an official who thought the BVV would know who they intended to vote for: "*he said, 'go to the thing, and you put your fingerprint on it, and the machine will already know how to vote'... in his mind he jumbled together biometrics and electronic voting and mind-reading, all of those system that somehow did magic for him.*" More generally, P9 explained that "*they thought if we look at the other countries, if we use technology in the election, maybe it will increase transparency and it will increase the speed of tally, votes and everything. But they have overlooked a few things in Afghanistan*."

The power imbalance between the vendor and the IEC regarding control of data Seven participants expressed that the vendor had too much power over electoral data, and the Afghan agency deploying the system (the IEC) had too little power (though we note that some of our participants are former IEC employees, and none represent the vendor). This control was not limited to the development of the software and hardware and deduplication of voters—P6 described that the vendor was also responsible for "*the configuration of the server [and had] access [to the] data*." P6 pointed out that this control was "*a ... national security issue because the election of a country was being managed by a company* outside *of the country.*" Control of electoral data being outside the country could either benefit or harm the security of the data, depending on the adversarial actors; P6 was "*not comfortable ... that a technology vendor, a commercial company has so much influence over the election technology.*" Compounding these issues was limited communication with the vendor during the actual election period: "*the company agreed to provide 24 hours service seven days a week*" (P15) but "*IEC and [the vendor] were communicating effectively with each*

other through emails only three days a week due to time and calendar differences between Afghanistan and [Europe]. If a technical problem would have arisen on Thursday, IEC had to wait four days until Monday to get a response..." (P4).

The lack of a consistent and pervasive national census obstructed the design of the electoral system Five participants explained how the absence of a national census inhibited the design and implementation of the BVV ecosystem. P8 said: "*if we want to change the election, we need to have an infrastructure in place, clear statistics, clear census in the country, without a clear census we can't have elections in Afghanistan.*" They went on to explain that one of the challenges in conducting such a census was political in nature, rather than purely logistical: "*the reason that we don't have census because there is a political aspect to it as well, because over the years many ethnic groups tried to have these narrative of majority, minority things ... so if we have a clear census that might change their narrative.*"

Vendor selection was influenced by politics Nine participants said that political parties had an inappropriate role in the selection of the vendor. P2 described that rather than a bidding process with multiple vendors,"*the choice of the vendor was initially proposed in a meeting during 2018 by Central Statistics Office and political parties seemed to agree with it.*" The incumbent "*supported this idea*" because the person suggesting it "*was from a trusted circle of the president*" (P17). P12 described the process as corruption: "*technology could work better if the corruption in the government was not a big issue. The president selected a company to implement biometric technology in Afghanistan that had no working background in the election area.*" While there may have been reasons "*due to shortage of timing [they] opted to go with the same vendor in 2019*" (P2), P7 felt that the vendor was selected without sufficient research, as an abuse of power: "*They have misused their power to impose the technology on IEC without researching it from all aspects.*" P8, P15, and P18 also said that the vendor was insufficiently familiar with both Afghanistan and electoral technology.

The limited timeframe to implement and deploy BVVs allowed bugs, design misconfigurations, and procedural errors to go unnoticed Ten participants discussed how the short amount of time between the 2018 and 2019 elections precluded thorough testing of the technology itself. P17 said "*the devices and the rest of the system arrived [from the vendor] exactly 28 days before the [2019] election.*" P17 continued, explaining how the short timeline led to usability issues that eventually violated electoral goals: "*We did not even have enough time to train staff to configure and prepare the devices to dispatch them to the provinces*" (P17). P15 estimated that six months would be appropriate for a testing period (rather than the 28 days that the IEC had with the updated devices): "*I wouldn't say it was fault of the IEC because I've seen a process of testing, auditing and certification. It takes at least six months. The commission didn't have this six months*" (P15).

11 Discussion and conclusion

Our findings show computer systems, database, and usability issues that marred the 2019 Afghan election, driven in part by administrative, political, and bureaucratic issues. Still, there was no consensus among our participants on whether the election was a "success" or "failure," or even whether the addition of the biometric technology was a "success" or "failure." Although our research uncovered flaws that disenfranchised voters and, to a lesser extent, allowed fraud and decreased public trust in the democratic system itself (Sections 7- 9), *some* participants felt there was a sense of *good enough for now*, given the history of extensive fraud.

While our research provides unique and broad visibility into the procedures and practices of adopting new election technology, we cannot say whether the integration of the biometric voter verification technology in the 2019 Afghan election was indeed "good enough for now" or "successful." Instead, we hope our research can provide a foundation for future conversations *before* a new election technology is adopted. It is unlikely that Afghanistan will hold elections while the Taliban are in power [74, 84], and thus the most direct application for our recommendations—for usable, trusted, safe, and secure elections *in Afghanistan*—is *currently* irrelevant, and so we cannot speculate about the context during Afghanistan's *next* election. However, biometric technologies are being increasingly adopted in electoral systems [5] and so it is important to understand how, why, and *whether* such a technology can be appropriate for any given country's democratic processes. Here, we offer high level recommendations to practitioners and designers of elections. These lessons echo general best practices, but, to use P9's words, it is absolutely critical to not "*overlook a few things*." That is, practitioners should draw lessons from our work based on the cultural, religious, environmental, historical, infrastructure, technical, political, societal, and adversarial characteristics that their country shares with Afghanistan:

- **Plan ahead:** It is important to ensure enough time for testing, evaluation, and modification of technology, as well as for training workers and physically deploying the technology. Election workers in Afghanistan had less than one month to deploy the technology, and the usability mismatch between some poll workers and the BVV technology suggests that training was insufficient (although we strongly recommend designing *first* to minimize usability gaps, and *second* to then fill those gaps with suitable training, aligning with human-centered design principles [29, 41, 77]). Our data also reveals other issues that might have been revealed

with more thorough time for evaluation cycles. Because testing, especially *in situ*, is certainly not an easy task, nor is it always possible, given that delaying an election is often not possible, we particularly emphasize its importance and the potential that sufficient time to test, certify, evaluate, modify, deploy, and integrate technology has to positively impact the credibility and integrity of an election.

- **Have full visibility and be cognizant of biases:** Our research demonstrates the impact limited technical knowledge has on the ability of decision makers to make informed decisions, e.g., the belief in Afghanistan that technology will create a trustworthy and trusted election, the IEC's forced reliance on the vendor for technical support, etc. It is important to have full visibility, understanding, and awareness. For example, it may benefit decision makers to have access to the underlying code, understand the abstract details of its functionality, be aware of any vulnerabilities and consequences that technology may have. Fulfilling this recommendation may be extraordinarily difficult given the limitations of human expertise and technical resources, but a decision-making team that holds the appropriate technical, legal, political, and sociological knowledge is critical to making both high and low level electoral technology design decisions. When decision makers don't have such expertise, we encourage hiring third party experts as guides, as well as independent testing and certification. Additionally, while it is impossible to be completely apolitical, decision-makers must be aware of their own biases, define goals ahead of time, and select the best technology for those goals [70].

- **Consider the context:** Our research demonstrates the impact of designers not fully accounting for the local deployment context. Consequently, it is important to understand and anticipate the specific challenges, cultural values, infrastructural limitations, and user educational level and expectations prior to deploying election technology. Our data shows numerous misalignments with local context, from the very use of facial biometrics disenfranchising some women, to the expectation that the BVVs would use the cell network to transmit data when there was no cell network present at some polling stations. While other work in this field has explored the importance of local context on the adoption and use of technology [31], our work additionally shows how it can be rife with tensions: for example, the very use of biometrics enfranchised some voters and disenfranchised others. We recommend, thus, that designers deeply understand the complexities of local cultural, environmental, social, political, and infrastructure context, and minimize tensions through design. Some tensions may be impossible to resolve fully through design, and hence it may be helpful to use ethics modeling to comprehensively surface and then navigate those tensions [70].

These recommendations apply to everyone working on an election—but we observe that they are most important for decision-makers with the power to affect vendor selection, to allow sufficient time for design, implementation, and deployment, and to gather complete contextual information. Having sufficient time, visibility, and context are important not only for a trust*worthy* election but also for a trust*ed* election.

Accordingly, once irreversible decisions are made, practitioners with less power over electoral design may find themselves working in suboptimal conditions, yet may still be able to both adhere to the above recommendations, and make further decisions within their purview. For example, a developer or manager with subject matter expertise may learn that designs do not adhere to cryptographic best practices, and should be able to affect change through the proper channels.

We strongly encourage practitioners to systematically consider how the application of certain design decisions *at scale*, *within the threat model of an election*, and *within the specific local context* affect the security properties of the "general case" of any given design decision. We include the following topics as starter conversations, inspired by speculative conversations within our research team during this work: linking biometric data to votes with sufficient theoretical and practical anonymity guarantees given the adversaries and size of the dataset; resiliency to network failure, disruption, and nonexistence; supply chain control and hardware security; poll worker training, manual labor, and repetitive processes as a source of potential error or insecurity.

Epilogue We conclude this paper with the *aftermath* of the 2019 election. By August 2021, following the U.S. military's exit after 20 years of presence in Afghanistan, the government collapsed and the Taliban took over Kabul [72], which consequently resulted in the dissolution of the IEC and its entire framework [84]. We cannot know what would have happened if the technology in the 2019 election had fully supported the electoral goals. Yet, achieving these goals might have paved the way for a different trajectory for the Afghan society.

Acknowledgements

We are grateful to Dalton Brucker-Hahn and Kailani Jones for their guidance in interview protocol development, and to Jeremy Epstein, Collins Munyendo, Alison Simko, and Karl Weintraub for their feedback on a draft of this paper. We also thank our anonymous reviewers and shepherd for their thoughtful and constructive comments. This work was supported by the National Science Foundation (NSF) Awards 2143393 and 2205171. Any opinions, findings and conclusions or recommendations expressed in this material are those of the authors and do not necessarily reflect the views of the NSF.

A Appendix – Consent information sent to participants before interview

We are academic researchers in security and privacy from the United States of America that want to understand the role of technology in the Afghan election system. We are not working for any government entities. Specifically, we want to understand where technology proved useful and where it fell short during the elections in Afghanistan. We want to understand the technology needs of election systems. Our goal is to present these technology-related needs to our community. This enables our community to work on providing better technological solutions for elections. Information about the research project/study:

- Our ultimate **purpose** is to develop better technical tools and communication mechanisms for elections.
- This is a **research** project conducted at the [Institution & PI].
- Activities and **procedures** to be followed:
  - **Duration**: Around one hour (an interview in English or Pashto about technologies used in the Afghan elections)
  - Audio recorded interview: YES or NO (it's your choice)
  - Recording the interview is OPTIONAL and you can ask us at any time to stop the recording. If you desire, your entire recording will be deleted at that point.
  - Name and specific personally identifiable information will not be recorded.
  - Recording the interview will allow us to focus only on talking with you, and having your exact words will greatly increase the quality of the data (recordings will not be shared outside the research group).
  - Recording will be hosted on the infrastructure of the [Institution name]. Access will be restricted to the research team and the recordings will be password protected.
  - Only the researchers that are part of this study will transcribe the interviews.
  - To mitigate future **risks**, your identifiable information will not be used or distributed for future research studies even if your identifiable information is removed.
  - It is possible, however, with internet communications, that through intent or accident someone other than the intended recipient may see your response.
  - In case you want to withdraw from the interview, your recording and the corresponding interview notes will be removed from our records.
- Publications will NOT include personally identifiable info.
- We will give you the option to review a draft of our research paper before it is published. Though we will remove all information we see as identifying, you may ask us to remove any additional information you feel may identify you.
- This study is **voluntary**: You have the option to refuse to answer any question. You have no obligation to participate and you may discontinue your involvement at any time.
- Although participation may not **benefit** you directly in the first instance, the information obtained from the study will help us gain a better understanding of how to develop better security and privacy solutions for election systems.
- Even though personally identifiable information will be removed, information about protests may be considered sensitive and, if this information is released and tied back to an individual, it could damage that individual's financial standing, employability, reputation, or cause social stigmatization or discrimination.

Participation in this effort indicates your willingness to take part in this study and that you are at least 18 years old. Should you have any questions about this project or your participation in it you may ask [PI name] [Institutional email]. If you have any questions about your rights as a research participant, you may call the Human Research Protection Program at [phone #] or [email].

Audio recording: YES NO

B Appendix – Interview protocol

Our semi-structured interviews varied slightly based on each participant's background. While all participants were asked questions in line with their expertise, participants with a comprehensive background of IT were queried more extensively to get more technical details. The interview protocol was influenced significantly by [31].

Consent Process:

- Introduction to researchers and research objectives.
- Oral overview of the consent form, covering:
  - Expected interview duration.
  - Voluntary nature of interview recording.
  - Ask to stop the recording at any point.
  - Assurances of anonymity and data protection.
- Any question, before we start the interview?

Preliminary Remarks (Post-Consent):

- Remind participant on maintaining their anonymity and confidentiality to share any stories freely with us.
- Confirm with participant to start the interview.

Interview Sections and Questions: Our question were structured into specific sections to comprehensively cover various aspects of electoral technologies. Each section was designed to include questions addressing security and privacy, and we encouraged participants to share their personal experiences and stories. Depending on their responses, we further explored each subsequent section. We also tried to skip some sections if participants didn't have any information on that or preferred not to answer.

Experience and Challenges:

- Which elections did you participate/have role in?
- What technologies did you experience during the 2019 election?
- How did you see technology being used during the election?
- What was your perspectives on adoption of biometrics technology in the 2019 election?
- What did you see as the challenges/benefits of technologies in 2019 Afghan election?

Perceived Political Influence:

- 2019 Afghan election had a lot of political tension, how, in your opinion, did the technology used in the 2019 election impact the political tension?
- Do you have any story that politics influenced selection or use of technology in the election 2019 to share with us?
- What impact, in your opinion, can political parties have influence on the improvement/impediment of electoral technology?
- If you could change the election process, how would you?

Societal and Administrative Impact:
- How did you see influence of non-technical staff, officials, stakeholders, observers in selection or use of technology?
- What organizations impacted the selection of technology?
- How did you see sharing information about election technologies with public during the 2019 election?
- What technology did you use to receive public information concerning the elections and its technologies?
- If social media was used, what type of information were posted about technology and infrastructure?
- How did you see the influence of social media on the election process and its technologies?

Relation to Training:
- Did you receive any training for using technology in the election?
- If yes, how did you use that training in the 2019 election? Was the training helpful or unhelpful? Why?

Trust Factors:
- What technologies are you aware of that were used in the Afghan elections prior to 2019?
- Did you see any improvement in the 2019 technical electoral systems in compare to technologies used in the past?
- Did you trust or distrust technology used in the election? Why?
- Did people trust the electoral technologies?
- Did technology improve credibility of the 2019 election?
- How can technology improve the credibility of future Afghan elections?

Voter Registration:
- What do you know about voter registration and voter lists?
- What technology were used in the voter registration? Was it effective? Why?
- What security approaches were in place to protect voter's data against manipulation?

Biometric Voter Verification:
- What brand, type, and model of biometric voter verification devices were used in the 2019 election?
- What hardware technology was used on the server-side?
- How the data were transferred from BVV devices to the Server?
- How does IEC check the integrity of data among BVV devices and the server while transferring the data?
- What procs were used to securely transfer the data to the server?
- How is the data stored on the BVV device and the server? What format? what type? Was it encrypted? What was the overall size? Who accessed the data?
- What security mechanisms were adopted to protect the voters' biometric data?
- How did the deduplication work?

Result Tabulation and Audit:
- What was the process to tabulate the result during the 2019 election (With all technical and security details)?
- What technologies are used during the result tabulation?
- How did you eval. the result tabulation process in the election?
- Were you involved in the audit process during the 2019 election? If yes, what IT systems were involved during the audit process? How did you see the process?

Result Transmission and Reporting:
- What data and how transmitted from the polling centers/stations particularly from places with no internet coverage?
- Who was permitted to transmit the data? How was the data received in the server side? What security factor was involved during transmission?
- What was the process for reporting results?
- What security procedures were leveraged to avoid data manipulations by attackers after the data was posted on the website?

Advanced Technical:
- What IT infrastructures were used in the headquarter and provinces in the 2019 election to deploy BVV?
- What election-related data do you define as confidential?
- What procedure did the IEC use to keep the confidential systems/data safe and secure?
- What backup mechan. does the IEC pactice to prevent data loss?

Security and Privacy:
- Have you noticed any fraudulent cases during the 2019 election?
- How did technology help in dtection/prevention of fraud?
- Did technology create any threat for your your colleagues during the 2019 election?
- What cybersecurity threats remained potential in 2019 election? Do you have any story about a cyber-attack that you would like to share with us?
- What security procedures/equipment were in place to prevent cyber or physical attacks on the infrastructure level?
- What was the influence of military groups against the Afghanistan gov. on the IT infrastructure in the 2019 election?

Conclusion:
- Is there anything else that you would like to add to this interview?
- Do you have any question for us?
- Could you refer us to other individuals who had a role in the election that may be interested in an interview?

Abstract

Understanding and managing data privacy in the digital world can be challenging for sighted users, let alone blind and low-vision (BLV) users. There is limited research on how BLV users, who have special accessibility needs, navigate data privacy, and how potential privacy tools could assist them. We conducted an in-depth qualitative study with 21 US BLV participants to understand their data privacy risk perception and mitigation, as well as their information behaviors related to data privacy. We also explored BLV users' attitudes towards potential privacy question answering (Q&A) assistants that enable them to better navigate data privacy information. We found that BLV users face heightened security and privacy risks, but their risk mitigation is often insufficient. They do not necessarily seek data privacy information but clearly recognize the benefits of a potential privacy Q&A assistant. They also expect privacy Q&A assistants to possess cross-platform compatibility, support multi-modality, and demonstrate robust functionality. Our study sheds light on BLV users' expectations when it comes to usability, accessibility, trust and equity issues regarding digital data privacy.

1 Introduction

Navigating information about how websites, mobile applications, digital services, and Internet-connected devices ("digital technologies" thereafter) collect, use, and share personal data is challenging. First, it is difficult to find privacy policies – the legal documents mandated by many privacy regulations that disclose data privacy practices [69]. Then, understanding the data practices disclosed in these privacy policies can be even more challenging due to their length, legal jargon, and vague language [42, 48]. Given how difficult it is in general for people to find and understand data privacy information, it is natural to wonder how accessible these tasks are for people who are blind or have low vision. According to the Cornell University Employment and Disability Institute's interpretation of the 2016 American Community Survey, more than seven million US adults (2.4%) have a visual disability [53]. This population often relies on assistive technology, such as screen readers and magnifiers, to access digital information. In this paper, we use positive affirming adjectives recommended by the US National Federation of the Blind [1] —"blind" and "low-vision" (instead of "visually-impaired")—to describe this population ("BLV people/users" thereafter).

Prior research shows that BLV people are particularly vulnerable to online security and security threats due to the lack of visual cues [6, 34]. Generally, digital technologies tend to have poor accessibility features to support their general information needs in the digital world [17, 40]. Therefore, it is critical to improve not only the usability but also the accessibility of security and privacy (S&P) tools. We seek to understand BLV people's needs in navigating the data privacy information regarding the digital technologies with which they interact. We also aim to inform the design of accessible privacy tools, enabling BLV users to have the same level of access to privacy information as sighted users [83].

Specifically, we want to explore BLV users' attitudes towards "privacy assistants", broadly defined in this paper as tools designed to help users navigate and/or manage digital data privacy [12, 16, 45]. Recently, there has been considerable research on developing privacy assistants that can answer users' privacy questions based on the content of privacy policies using natural language processing (NLP) techniques [32, 60, 62]. Inspired by these recent advances in privacy question answering and the increasing public interest in applications such as ChatGPT[2] built on Large Language Models, we particularly investigate the NLP-based privacy question answering assistants ("privacy Q&A assistants" thereafter) as a promising approach to improve accessibility and bridge potential privacy inequity for BLV users.

To this end, we conducted a qualitative interview study with 21 US BLV users of various digital technologies to investigate three research questions (RQs):

[1] The National Federation of the Blind. https://nfb.org/
[2] ChatGPT. https://chat.openai.com/

- *RQ1: How do BLV people perceive and mitigate data privacy risks associated with digital technologies?*
- *RQ2: What are BLV people's information (seeking) behaviors around data privacy?*
- *RQ3: What do BLV people expect from potential privacy Q&A tools for navigating data privacy information?*

By answering these RQs, this paper contributes:

- The first in-depth qualitative investigation into how BLV users perceive and mitigate data privacy risks and how they seek (if any) data privacy information.
- To the understanding of BLV users' expectations around functionality and accessibility for potential privacy Q&A assistants that inform them about data privacy.
- To the growing area of inclusive security and privacy (S&P), providing insights into designing accessible, usable, and equitable S&P tools for BLV users and beyond.

2 Background and Related Work

2.1 How BLV Users Access Information

BLV users primarily rely on screen readers (e.g., JAWS and NVDA software on computers, VoiceOver on Apple devices, Talkback on Android devices), a type of assistive technology that reads out aloud text on the device screen, to access digital information and utilize other digital technologies. Screen readers only function well when digital technologies and contents follow good accessibility practices. However, research [2, 3, 29] revealed that websites and mobile applications do not consistently adhere to accessibility standards such as the Web Content Accessibility Guidelines [35].

Recently, agent-based visual interpreter services, including Aira[3] and Be My Eyes[4] mobile apps, have gained traction among BLV users. These services connect BLV users with sighted human agents, who help them recognize objects and cope with everyday situations through the phone cameras. Similarly, artificial intelligence(AI)-based visual-aid apps like Seeing AI[5] that leverage device cameras to describe texts, objects, people, and environments are also on the rise, enabling BLV users to access certain information independently.

Meanwhile, computing researchers have explored novel technical solutions and interaction modalities to improve information access for BLV people. As smart home speakers and their built-in voice-based assistants (e.g., Amazon Echo devices with Alexa) gain popularity, voice user interfaces significantly improve information accessibility for BLV people [56]. Also, research advances in computer vision [27] and mixed reality [81, 82] have also opened new possibilities to convey visual information through other modalities. We broadly categorize these above-mentioned examples as assistive technology in this paper.

2.2 Privacy and Security for BLV Users

With growing recognition of the importance of accessibility and inclusiveness in privacy and security technologies [74], many research studies examined blind and low-vision users' privacy concerns and behaviors. Ahmed et al. [6]'s interview study revealed blind participants' unique privacy concerns in three environments: physical (e.g., eavesdropping), digital (e.g., privacy settings in social media), and the intersection of physical and digital (e.g., shoulder-surfing). To fulfill their privacy and security needs, Hayes et al. found that BLV users also rely heavily on their allies (e.g., family members, caregivers) to protect their privacy and security cooperatively [34]. Akter et al.'s survey study elaborated on BLV users' concerns regarding camera-based visual interpreter services, where volunteers answer their questions about photos or videos [7].

Though focusing on a different population, Hamidi et al.'s study revealed that the privacy and utility trade-offs of adaptive assistive technologies might be overlooked among older adults with pointing problems [31]. This suggests that users with accessibility needs may knowingly use assistive technologies or services that compromise their data privacy. Such divergence between privacy attitudes and behaviors is commonly known as the privacy paradox [25].

Another important body of work focuses on the usability and accessibility of security and privacy tools for BLV users. For example, Danoso et al. found that web authentication can be time-consuming to BLV users and pose significant challenges, such as accessing error messages [17, 18]. More importantly, these usability issues may result in BLV users' risky behaviors (e.g., not being able to identify phishing websites) or decisions that compromise security [52]. Such usability issues also impact how BLV users seek and access general information [9, 51, 70, 76]. A study investigating online information behaviors revealed the barriers for blind web users to assess the credibility of websites [1], highlighting the need to assist BLV users in verifying the credibility of online information. However, to our knowledge, there is no research focusing on BLV users' information behaviors for data privacy information, a type of information that is challenging even for sighted users to navigate and understand [55, 63, 69, 72]. Our study aims to explore this untrodden topic to understand the challenges faced by BLV users in navigating data privacy.

2.3 Privacy Question Answering (Q&A)

Data privacy information about digital technologies can be obtained through many channels from different sources. A primary source is the official privacy policies – the legal doc-

uments in which companies or organizations self-disclose the practices they engage in with user data. Despite being required in many regulatory regimes around the world, privacy policies are difficult to find [69] and even more difficult to understand due to their technical and legal jargon [50]. The time required to read them is also impractical for most users [54].

Thus a growing line of research has explored using natural language processing (NLP) techniques to extract salient information from privacy policies, which can empower users to take control of their data privacy in the digital world. Prior studies [8, 13, 14, 46, 57, 75] have successfully identified data practices within privacy policies to potentially enable easier navigation of privacy policy content. Kumar et al. [43] extracted opt-out choices from website privacy policies and presented them to users in a web browser extension, *Opt-Out Easy*. Prior research efforts [39, 71, 78, 79] also developed techniques to summarize the most salient aspects of privacy policies to present to end-users. However, other research has indicated that summarization approaches that are not tailored to the needs of individual users are unlikely to be effective at meaningfully informing people about the information in privacy policies [26, 58]. Consequently, in recent years, there has been considerable interest in developing assistants that will answer users' privacy questions, which would enable people to flexibly access information within privacy policies that are most pertinent to them. Harkous et al. [33] created *PriBots*, chatbots for communicating privacy practices to users based on questions asked by users on Twitter. Ravichander et al. [60] constructed a benchmark for privacy question answering systems, where they source answers from experts with legal training and provide systems based on pretrained language models to identify answers to these questions. Ahmad et al. [5] extracted segments from policies in the OPP-115 Corpus [75], recruited "skilled annotators" to construct questions based on these segments, and explored transfer learning-based approaches to provide answers to these questions.

Building on existing research efforts to automatically answer users' data privacy questions [59, 61], our study explores BLV users' expectations for similar privacy Q&A tools to assist them in navigating data privacy information.

3 Methods

3.1 Assumption and Method Justification

Informed by literature review and guidance from two blind consultants, this study assumes that BLV people face challenges in navigating data privacy information and they can benefit from accessible privacy tools like the privacy Q&A assistant. To account for the potential inaccuracy of this assumption, we carefully formulated our research questions (RQs) in an open-ended manner, as shown in Section 1).

We chose the qualitative interviewing method for its strengths in obtaining a deep understanding of participants' perceptions, attitudes, and experiences [10], which is well-suited for RQ1 and RQ2. Alternative methods to address RQ3 are prototype testing and evaluation with users, which are more beneficial during the late stages of software development [64]. Because there was little understanding of BLV users' needs around privacy Q&A, we decided not to present researcher-derived prototypes to avoid inaccurate assumptions about BLV users' preferences. Instead, we decided to ask participants to freely imagine a hypothetical "digital assistant", a technique used in prior privacy and security interview studies [12, 68, 77] to elicit their requirements and expectations. This technique is particularly advantageous for requirements gathering in the early stages of tool design [37].

3.2 Study Design and Research Ethics

We used the university-licensed Zoom software to conduct remote interviews in 2021 during the COVID pandemic. We sought advice from two blind consultants in our academic network to ensure all study procedures are culturally responsible. The first consultant provided us with best practices for recruiting BLV participants into research studies. The second consultant completed a mock-up interview and provided suggestions to improve the study materials. For example, we revised our study materials to accommodate varying technology literacy and the high unemployment rate among BLV people in the US. Then, we conducted a pilot interview with a blind friend to refine the wording of some interview questions and finalize all study materials.

Our study protocol was approved by the Institution Review Board (IRB) at Carnegie Mellon University with the permission to obtain informed consent verbally because our participants may have difficulty signing electronic documents. We emailed participants the IRB-approved consent form when we scheduled interviews because many BLV users prefer reading text via screen readers at a fast speed. When they joined the interview remotely, we asked if they had read the consent form. If yes, we read the study summary section of the consent form; if not, one researcher read the full consent form. Then we obtained their verbal consent before starting the audio recording. We also completed a research data sharing agreement after the first author joined the University of Vermont.

3.3 Interview Questions

We started each interview by asking the participant's preferred terminology to describe their vision status so that we could use their preferred terminology throughout the interview. We structured our interview questions based on the RQs, with additional baseline questions at the start and optional demographic questions at the end. We describe interview question design rationale below and provide them in Appendix A.

Baseline questions: We started with questions to establish a baseline of participants' technology use, understanding of

data practices, and attitude towards data privacy. During baseline questions, we provided them with plain-language definitions for "digital technologies", "data privacy", and "data practices" in the context of this study to ensure a shared understanding of these terminologies (see Appendix B). After providing the definitions, we asked about their general thoughts around data privacy because people's privacy attitudes are shown to impact their perceived risks [41].

RQ1: Risk perception and mitigation. We asked participants to describe the potential risks associated with the digital technologies that they use and optionally to compare the risk levels between general and assistive technology. We employed the critical incident technique [23] by asking participants to share their most memorable experiences (i.e., critical incidents) around data privacy in the past few months. Then, we asked a hypothetical dilemma question to understand how they would mitigate privacy risks if assistive technology engaged in data practices that they were uncomfortable with.

RQ2: Information (seeking) behaviors. Not assuming all participants actively seek data privacy information, we used "information behaviors" [9] to broadly describe how participants navigate, access, seek, and understand data privacy information. We first asked about the sources from which they obtain data privacy information and their perceived credibility of these sources. Then, we focused on their prior experience seeking data privacy information, if any. We noted if participants naturally mentioned privacy policies in their responses. If not, we prompted privacy policies as a source.

RQ3: Expectations for privacy Q&A tools. To minimize the bias towards privacy Q&A assistants as the researcher-introduced solution, we crafted the interview questions to emphasize participants' needs for privacy Q&A. We first introduced an imaginary privacy expert who can answer their data privacy questions for any digital technologies they use. Then, we let them assume this expert was a "digital assistant" and asked them to freely describe their expectations for this digital assistant without priming them with any information about how the assistant might function. After that, we probed further into detailed aspects of this hypothetical digital assistant, including modalities, developers, and information sources. Finally, we asked about their perceived benefits, concerns, and potential use cases.

Demographic questions: The interview ended with optional demographic questions. All participants answered these questions to provide us with data on sample diversity.

3.4 Recruitment and Data Collection

Recruiting BLV people into research studies requires trust-building, so we recruited participants through our personal contacts and the National Federation of the Blind. Our consultants cautioned us about the sampling bias towards BLV users who are already comfortable using digital technologies. To mitigate this, we included a phone number in the recruitment materials and provided accessible instructions for joining Zoom via the Internet or phone call.

Aiming to increase sample diversity, we included the following statement in all study recruitment materials: "We particularly welcome diverse perspectives from individuals who are less familiar with technology and who also belong to other underrepresented groups." When replying to study inquiries, we politely explain the rationale prioritizing participants from underrepresented groups. Many voluntarily shared their demographic information with us during inquiry, and those who were not chosen expressed their understanding. Besides the above-mentioned diversity consideration, we responded to potential participants primarily by their time of inquiry. We aimed for a sample size of around 20 by referencing prior qualitative studies with BLV participants [6, 17, 34, 56].

We recruited 21 self-identified blind or low-vision participants in the US: 2 from our personal connections with snowball sampling and 19 through the approved email solicitation of the National Federation of the Blind. To avoid the potential discomfort some people feel when realizing they are the first few participants in a study, we assigned the number P10 to the pilot participant and numbered the full study participants from P11 to P31. Note that we did not use data saturation [24] to determine the sample size due to the inherent difficulty recruiting BLV users. Instead, we set our sample size goal by referencing published qualitative studies with this population.

The first and second authors conducted the first four interviews together and slightly adjusted interview question wording through discussing the initial results with the research team. All remaining interviews were led by either the first or second author, with an optional secondary interviewer from the research team. We audio-recorded all interviews using Zoom after requesting participants to turn off their cameras during the interviews to ensure only audio was recorded. We compensated each participant with an accessible electronic gift card of 25 US dollars after the interview.

3.5 Qualitative Data Analysis

We collected audio recordings from 21 interviews ranging from 40 to 92 minutes in length (average was 65 minutes). We first leveraged Zoom's automatic transcription to generate initial transcripts and then manually reviewed all auto-generated transcripts for correctness according to the audio recordings. Then, the first author structured all transcripts with multi-level section headings according to RQs to ensure effective navigation of transcripts in the coding process. To rigorously assess the qualitative data, we combined both inductive and deductive coding approaches in our thematic analysis [11, 22]. Four team members with prior qualitative data analysis experience were involved as coders to ensure internal reliability. Our coding process included five steps: (1) The first author conducted the first round of inductive open coding and summarized emerging themes in the data; (2) The research team

discussed these themes with examples from the data and then create an initial codebook based on study RQs and themes identified in the first round coding. (3) The research team used the codebook to perform the second round of coding, where the first author and three co-authors (secondary coders) double-coded all transcripts; (4) The first authors discussed with three secondary coders individually to resolved all coding conflicts, which eliminated coder errors and further clarified a few codes. Inter-coder reliability measures are not necessary when coders reach full consensus [49]; (5) The first author performed additional axial coding and selective coding [73] to synthesize high-level meta-themes.

There is a growing recognition in the research community that the frequency of themes in qualitative research should not be interpreted quantitatively for generalization [20, 28]. Rather, the contribution lies in the identification of these themes and in-depth discussion of their implications. We report frequencies of themes and codes when appropriate, but also adopt a consistent terminology used by Zhang et al. [80] (Figure 1) to convey the relative prominence of themes. We archive our coded data including exact frequencies in Open Science Framework (see Appendix C).

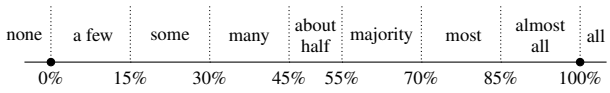

Figure 1: Our terminology to describe theme frequencies

4 Participants and Baseline Questions

4.1 Sample and Demographics

19 of 21 participants self-reported to be blind or legally blind, and two had low vision. Our sample is balanced across genders, age groups, and employment statuses (see Appendix D). We over-sampled non-white participants (N=8) compared to the US demographic distribution, while two participants voluntarily reported as members of the LGBTQ+ community. Our sample is biased towards people with high education levels as all participants had at least some college education. Overall, our sample is relatively inclusive and mitigates common sampling bias with the BLV population.

4.2 Participants' Technology Use

Almost all participants reported having used computers (N=20) and phones or tablets (N=21). Overall, we noticed an overall heavier reliance on mobile phones than computers. Specifically, two participants no longer use computers, citing the steep learning curve of computer screen readers and affordability considerations. 18 participants reported using various smart home devices, including smart speakers and other smart devices controlled through smart speakers. Participants also mentioned using Victor Stream devices (N=4) and Braille Displays (N=5), both of which are assistive output devices with narrow functionality and thus excluded from our analysis due to their limited data privacy implications.

Participants used two major categories of digital technologies on their devices: (1) **Assistive technology** that enables them to access various digital information, products, or services. All participants reported using screen readers on both computers (e.g., JAWS, NVDA) and mobile devices (e.g., VoiceOver, TalkBack). 18 participants used agent-based visual interpreter (VI) services, while 15 participants used AI-based visual-aid apps (e.g., Seeing AI). All participants also used voice assistants (e.g., Siri, Alexa) on their devices for accessibility. (2) **General technology** that broadly refers to all devices, websites, apps, and digital products or services.

Additionally, our participants reported using computers mostly for formal activities such as work, banking, and information seeking. In contrast, they used their phones and/or tablets for broader online activities, including shopping, banking, communication, entertainment, and social media. 12 participants explicitly mentioned using websites or apps for their banking needs, but a few reported not using any online banking for security reasons. Those who have smart speakers primarily use them for content, quick life help, and controlling other smart home devices.

4.3 Data Privacy Awareness and Control

All participants identified at least one type of personal data being collected and knew advertising was a major purpose for data collection. 19 participants knew that digital technologies' data practices are pervasive. 17 participants were aware of the existence of data privacy control options made available by digital technologies, many of whom reported having configured cookie settings, privacy settings, and app permissions.

However, nine participants expressed that the existing control options are ineffective. Additionally, eight participants mentioned using some broadly defined privacy-enhancing technologies, including more private browsers or search engines and virtual private networks (VPNs). In summary, our participants are generally aware of data privacy and engage in some privacy control behaviors, which is similar to a recent sample with sighted Internet users in the US [67].

4.4 Data Privacy Attitudes

Our participants expressed multi-facet attitudes towards data privacy and we summarize the key themes below.

Pervasive data practices and the hope for change. Participants described digital technologies' data practices as "pervasive" (N=9) and even "intrusiveness" (N=9). Some participants believed such data practices should be limited or hoped for better privacy notice and choice mechanisms.

Not concerned and resigned. Only two participants expressed explicit concerns about personal digital data privacy, while four were not concerned at all due to perceived low risks. Four participants expressed privacy resignation [19], as P18 said: *"It's very difficult to contain [data practices] no matter what message you try."*

Low data privacy expectations online and in daily life. Seven participants felt their online privacy was limited and two participants explicitly commented on their low privacy expectations as blind individuals, said P11:

"I think privacy is a very important thing...for blind people, we just don't get that privacy. There's nothing in my whole life that's private because being blind...somebody has to know everything to help me out with something."

Neutral or positive attitudes towards data practices. Seven participants were okay with reasonable use of their personal data such as "providing or improving service" but felt differently about targeted advertising. Such a difference may derive from participants' opinions towards the data economy, the phenomenon that users' personal data is exchanged for access to a service and that data may subsequently be shared or sold to other entities. For example, three participants have neutral views about the data economy, as explained by P17: *"We are a capitalist society so companies need to make money."* Three participants mentioned personal benefits from targeted advertising, such as knowing about useful products.

Overall, the data reported in this section highlights the fact that BLV users must rely on assistive technology or sighted people (either from personal lives or interpreter services) to access online information, use other digital technologies, and manage their everyday lives, which invisibly impact their privacy perceptions and behaviors. Our participants' privacy awareness and their diverse attitudes towards digital data privacy share many similarities with sighted users [4, 38, 67].

5 BLV Users' Risk Perception and Mitigation

5.1 Perceived Security and Privacy Risks

Our participants reported a broad range of security and privacy (S&P) risks with digital technologies beyond the definition of data privacy presented to them (detailed in Appendix B).

General technology security risks. 15 participants mentioned the risks around personal financial data (e.g., social security numbers, credit card numbers, banking information). Eight participants also mentioned data breaches that leak their sensitive data collected by legitimate companies, and some cited the Equifax data breach as an example. Notably, the above-mentioned risks are security risks, not necessarily data privacy risks. Our analysis showed that only seven participants clearly distinguished security risks from data privacy risks associated with data practices. During the interview, we intentionally did not interrupt participants when they talked about security risks beyond data privacy. Though not asked in our interview, six participants voluntarily shared their experience falling victim to financial crimes, from personal financial information being used by a neighbor to credit card numbers being stolen online. Our participants' experiences revealed their vulnerability to financial crimes. It is only natural for many participants to be more concerned about financial security than data privacy.

Visual interpreter services: agents and companies. 14 participants identified the agents working for visual interpreter (VI) services as a risk. P20 expressed her concern: *"When you call in, if they [agents] can't see it [the content to be interpreted] properly, they're supposed to ask permission before they snap a picture of it, but 99% of agents will just snap a picture without asking you first now. It's your credit card sitting there; They've got your information."*

Two participants pointed out the risks of how VI service companies store their personal data, as P24 explained: *"There is the potential of my privacy being exposed because even though your information is stored in the cloud...those can also be compromised, and they may not know in time to inform you or to even make a solution for it."*

Compared to VI services, participants were less concerned about privacy risks associated with AI-based visual-aid apps, as P17 said: *"Seeing AI is not a problem because that's my phone reading it back to me. But Be My Eyes and Aira, I'm concerned about using them because it's a live person who may be reading sensitive information."*

Expanded physical-digital risks. Some participants mentioned physical-digital privacy risks, including shoulder surfing and eavesdropping by people nearby. We found such physical-digital risks expanded to assistive technology and other scenarios. For example, P31 was concerned about using voice assistants in public: *"One of the things I think is a real downside of the audio and the speech recognition style controls like Siri and Echo devices is that it forces you to speak information out loud...and that's a risk all by itself...if you forget other people [are] around sometimes."* Similarly, P11 mentioned a new category of physical-digital risk with VI services, she said *"Not only [the agents], there are whoever happens to be in their houses...now they're all working from home, so you hear other people in the background, and I wonder, is this really secure?"*

Risks around data practices. Participants mentioned risks associated with various data practices regarding both general technology (N=7) and assistive technology (N=2). A few participants reported physical safety concerns related to location tracking, said P21: *"If the data that's being collected could be shared with people that I haven't consented to, or could reveal things like my location and personal information about where I live, or might be expected to be in that create safety concerns."* Additionally, two raised concerns about unwanted surveillance, either by governments or companies. For example, P22 said, *"data privacy issues now are becoming a political thing...if the wrong people figure out with your*

data you're not in the same political camp as they are", and pointed out the risk to civil liberty if being censored by digital technologies.

More concerned about general technology. Mid-study, we added a follow-up question asking participants to compare their stated data privacy risks between general technology and assistive technology. 10 out of 13 participants who answered this question were more concerned about privacy risks with general technology. A few explained their rationale that assistive technology is a "small market" thus less likely to be targeted by attacks. Also, some participants already mitigated assistive technology use (see section 5.2) and thus were less concerned. However, within assistive technology, VI services draw the highest level of concern, while screen readers are considered low-risk.

Critical incidents around data privacy. Our critical incident technique probed into the participants' recent experiences when they felt surprised, uncomfortable, or suspicious of certain data practices. 19 participants recalled at least one critical incident. Ten of them were surprised by unexpected features of certain apps or services, including Facebook's friend recommendations, auto-fill features on some websites, and Apple devices asking to share Wi-Fi passwords with contacts. Ten participants feel surprised or uncomfortable with targeted advertising, particularly by the speed and accuracy of these ads. Five of them specifically mentioned ads that appeared to be cross-platform, as P22 explained: *"I'm on Amazon, and I searched for something, I would expect them to show me [the same] sort of things later on. I expect that. I don't expect Facebook to show it to me. And I've seen that happen."* Additionally, many shared their experiences receiving unexpected spam/scam emails (N=5) or security incidents online (N=3). Most of these reported critical incidents made participants realize how pervasively various digital technologies collect, use, and share their personal data. However, many participants' responses reveal misconceptions or gaps in understanding about online behavioral advertising and cookies.

5.2 Mitigation of Perceived Risks

Primary strategy: adjusted technology use Adjusting their usage patterns of digital technologies is the most commonly mentioned risk mitigation strategy. Four participants adjusted their general technology use, including limiting their social media usage to preserve online privacy (P22) and choosing mobile banking apps over web-based banking interfaces for better security (P24). For assistive technology, ten participants mitigated the risks with visual interpreter services by intentionally not sharing sensitive information with Be My Eyes volunteers, as P13 said: *"With Be My Eyes...you do not use them to read credit cards to you that you got in the mail because your other one expired. Because they're not background checked, they're just people that really want to help...But with Aira, the agents are extensively trained; they're also background checked, and I think they're bonded or something, so I have had them read credit cards..."*

Such usage adjustments were not financially viable for all BLV users. A few participants in our study mentioned that cost is a key consideration when using agent-based VI services, as P14 explained: *" I take advantage of it [Aira's promotion]. You don't have to pay for it for [participating] stores that you go shopping, you can get access [to Aira] and it doesn't cost in places like Walgreen [store]. But I also use Be My Eyes...That's a free one you don't have to pay for. They are volunteers from all over the world."*

Discontinued use and non-use. Only five participants stopped using certain digital technologies or switching to alternatives out of privacy or security reasons. These include deleting accounts on e-commerce sites due to security concerns (P11), stopping using social media apps out of privacy concerns (P12, P14), switching to new browsers because Internet Explorer is no longer maintained for security (P30), and adopting non-Google search engines to limit data exposure online (P27). However, no participants reported stopping using any assistive technologies for privacy and security reasons. In contrast, seven participants chose the non-use strategy to avoid risks with digital technologies: For general technology, a few did not use online or mobile banking to reduce financial risks. For assistive technology, a few mentioned that they avoided using agent-based VI services.

Security and privacy practices. Ten participants reported adopting good privacy and security practices for risk mitigation, such as using more private search engines or browsers, configuring privacy settings or mobile app permissions, using strong passwords, and being cautious wherever personal data is requested. We also observed **varying levels of security and privacy knowledge**. A few tech-savvy participants understood the benefits of using relatively effective security and privacy tools such as virtual private networks (VPNs). For example, P27 was confident about his security practices: *"The security is so locked down around my credit cards that I think it takes an actual data breach to get them. I don't think it's through the privacy settings."* In contrast, many participants **only followed generic S&P advice**, and a few reported struggling with online privacy, including difficulty understanding how cookies work (P11). A few participants also shared their frustration when security impeded accessibility, said P18: *"I was doing [mobile] banking. I had someone put the app on [my phone], I could check my balance and inquiry transactions, but then they [the bank] changed it. every time you go on the site, you have to put a new password. The major problem is that I can't type it in. On the Apple phone, you can dictate everything except your password."*

Hypothetical dilemma with assistive technology. Our hypothetical dilemma question forced participants to weigh up between accessibility and privacy: 17 participants reported that problematic data practices would affect their willingness to use certain assistive technology. However, the attitude may

not stop them from using the assistive technology in such a dilemma. Only eight firmly stated that they would stop using that assistive technology, most of whom felt confident in finding good alternatives. Nine participants said it would depend on the risk level, as P19 explained: *"No matter what you do, we're still going to have a risk. It all depends on to what extent the information is shared and how it's being shared. "* It also depended on how heavily they rely on the assistive technology, as P18 said: *"It has to do with how much you need this device (technology). I'm totally blind, I don't have any vision at all, and I live alone. So my need for the device is greater than someone else who maybe has some vision or lives with somebody."* Specifically, some participants mentioned giving up or switching screen readers would be the most difficult, and a few could not switch due to the limited available alternatives. We notice that less technology-proficient participants were less likely to stop using or switch, said P11: *"It's always a concern, and if I found out that they did have a privacy (issue), they weren't really secure, or they were leaking information. it's hard to say, because if you are blind, you don't really have a whole lot of options. So do you take a chance and do it, or can you do without? Some things you just can't do without."*

Participants' responses revealed a high level of trust in assistive technology, with the exception of agent-based VI services. For example, P25 said: *"Especially with assistive technology, I operate with a very high level of trust. If they would do something that would erode my trust level, I would seriously consider changing things or making a complete switch to something different, if need be."*

6 BLV Users' Information (Seeking) Behavior

6.1 Information Sources and Credibility

Data privacy information sources. Participants reported various sources that they obtained data privacy information from. Reputable news outlets (e.g., TV, radio, and print news) were the most reported source (N=13), followed by various online sources (N=11) and interpersonal sources (N=11) including tech-savvy friends and technical experts in the BLV communities. A third reported obtaining data privacy information from privacy policies, terms of use, or user agreements. Six participants realized the existence of data practices based on their empirical experiences, such as receiving targeted and various spam/scam emails, to rationalize that their personal data was collected or shared by companies.

Assessing information source credibility. Almost all participants reported certain criteria or preferences when assessing the credibility of information sources. Our analysis revealed that **trust** played a critical role in their credibility assessment process. 15 participants believed **their trusted entities** could provide relatively credible information, including reputable news outlets and BLV organizations. Nine participants placed trust in **the people** disseminating the information, including tech-savvy friends and influencers in the blind community. A third of the participants reported sophisticated credibility assessment strategies, such as cross-referencing multiple sources and seeking primary sources.

6.2 Privacy Policies as Information Source

Experience with privacy policies. Eight participants mentioned privacy policies in their responses without prompts, and all participants said they heard about privacy policies before after the prompt. 17 participants reported that they have read at least a few privacy policies before, often when signing up for a new service or receiving privacy updates from companies. Only two participants read privacy policies due to the perceived importance of the contents. This result and 6.1 together indicate that privacy policies are an underutilized source by BLV users.

Credibility and usability of privacy policies. 15 participants considered privacy policies a credible source for data privacy information because they are the official disclosure of companies' data practices. A few pointed out caveats with its credibility because privacy policies "may change without notice" and "do not prevent security problems". The remaining six participants thought privacy policies were not credible, because they "lack accountability" and credibility can "vary by the companies". 11 participants described difficulty reading privacy policies due to their length and vague languages, as P19 elaborated: *"It's a lengthy legal document so it's not like an exciting read to begin with...I feel that they're very vague...just very open to interpretation."*

6.3 Seeking and Non-seeking

13 participants reported that they sought information regarding the data practices of digital technologies and the remaining eight participants did not, as detailed below. **Seeking data privacy information** Among 13 participants, eight actively looked for data privacy information multiple times, while five only mentioned one or two examples and admitted that rarely sought data privacy information unless they had a concern. 10 out of the 13 participants successfully found the data privacy information they were looking for, including clarification about data practices, confirmation of data practices mentioned elsewhere, available privacy controls, and detailed information of known data breaches. To our surprise, only three participants mentioned that their search outcome were less than satisfactory, citing challenges in finding relevant information (P11), exercising privacy controls (P12), and understanding privacy policies (P30). Regarding information-seeking strategies, Google searches (N=6) and reputable news outlets (N=6) were the most commonly mentioned. Three participants reported using non-Google search engines for "more neutral results". A few participants also consulted privacy policies or terms of use (N=3), expert opinion (N=2), and trusted persons

(N=2). In summary, participants who sought information on data privacy generally succeeded in their search.

Not seeking data privacy information. Among the eight participants who did not seek data privacy information, four reported that privacy was not a major concern to motivate their information seeking. However, the lack of concern may derive from certain **misconceptions around data privacy**, as one marginalized participant said: *"(I didn't seek information) because it doesn't affect me. I don't have any information that is that important, that I would be upset about them collecting the information....I mean they can do anything with the little bit of money I got in the bank; I don't think it's important to them. I think I'm so glad that I'm down on the socioeconomic totem pole and that my information is not that important to them. But I think there are people whose information is."* This data suggests misconceptions may lead to an inaccurate assessment of data privacy risks and a failure to establish the appropriate level of concern. Two participants thought it was not necessary. For example, P29, who has high technology literacy, felt that "not much has changed in the data privacy landscape." Another participant admitted that "fear" prevented her from seeking such information, as she explained: *"Information, mainly because it's a scary topic, like the more I know the less I want to be on the web."* Only one participant admitted that they did not seek such information due to the perceived difficulty because "it's time-consuming and difficult" (P31). In summary, **the lack of data privacy concern** reduced the necessity for participants to seek data privacy information, which is consistent with findings in 5.1 that data privacy risks were not participants' primary concern.

7 Expectations for Privacy Q&A Tools

To mitigate participant response bias, we avoided priming participants with the idea of privacy Q&A assistants by phrasing it as a hypothetical "digital assitant" (detailed in Section 3).

7.1 Expectations without Priming

19 participants described at least one expectation for the privacy Q&A assistant without priming, as detailed below.

Good functionality. Most participants expected good Q&A functionality, which means the assistant should provide high-quality (N=9) and up-to-date (N=3) answers to their privacy questions in plain language (N6), as P15 described: *"It would give answers to the questions we ask...in straight-out answers, it's not what we think it's [the data] going to be used for...No, it's gonna be, not assumptions, just cold hard facts."*

Accessibility by default. Two participants explicitly expected the assistant to be accessible for BLV people. The other participants' follow-up comments confirmed that they implicitly assumed the assistant would be accessible by default.

Advanced features. Many participants elaborated on several advanced features, such as providing "links to references" in support of the answers(N=2), providing "a general overview" (N=2), and incorporating a mechanism to verify data privacy information. Seven participants expected other advanced features, including attractive accent (assuming the assistant is voice-based), the capability to naturally interact with users, and personalized reminders of potentially risky data practices.

Three prefer privacy experts over digital assistants. P20 commented on the poor accessibility of other digital assistants: *"I prefer it to be a human assistant because digital assistants can only give you answers that it's programmed to give. When you have something like Aira involved, it's person to person contact. Digital assistant is not enough to answer the concerns of a blind consumer."* Our analysis revealed that all three participants had negative user experiences with digital assistants. For example, P17 vividly shared a frustrating experience with us and commented: *"I'm done dealing with digital assistants on several different websites."* This data indicates that prior negative experiences could impede BLV users' acceptance of digital assistants in the future.

7.2 Expectations for Privacy Q&A Assistants

Cross-platform and multi-modality. While six participants preferred the privacy Q&A assistant to be available on one device type (i.e, smartphones, computers), 15 participants hoped the privacy Q&A assistant would be cross-platform and cross-device, as P13 commented: *"probably all of them [the devices]...in whatever form or shape... but I think the assistant should be on all devices."*

Regarding the interaction modality of the privacy Q&A assistant, 15 participants want it to support both textual and auditory Q&A experiences. P26 explained his understanding of accessibility: *"I've always been interested in accessibility for the most people, so I would say both. By voice for people that are interested in something like that...but maybe a lot of people are deaf and unable to speak, so to have an alternative method like being able to type would definitely bring accessibility up a lot, and maybe even getting a response back in text for somebody that cannot hear."*

Interesting, three participants strongly preferred the non-verbal interaction modality due to the limited accuracy of dictation on their devices, as P28 explained: *"I'm more comfortable doing research by typing. I haven't had much success by voice searching on any device, I always prefer to type...[For answers, I prefer] text format that can be accessed by anyone, but with me, it would be the screen reader."* Notably, two participants pointed out **modality consistency** during their Q&A interaction – they would prefer to receive answers in the same modality as they asked questions.

Preferred information sources. Participants reported their preferred information sources from which the privacy Q&A assistant should gather information. 13 participants preferred information from the first-party companies, about which the privacy questions were asked. 11 participants wanted infor-

mation from the official legal documents including privacy policies and terms of use. Many participants also mentioned reputable news outlets (N=6), other online sources (N=7), and organizations like privacy watch groups (N=6), while a few wanted the assistant to also look for actual regulations (N=2) as well as ratings of companies' privacy practices (N=2). Notably, four participants would like the assistant to employ some verification mechanisms to "constantly vet sources" and "compare what the company's saying to actually what has happened." This indicates participants valued both credible information sources and mechanisms (e.g., [47, 84] to verify the sources.

Preferred developers. 16 participants would trust **nonprofit organizations** to develop the assistant because they are "neutral' and "have guiding purposes". Some cited Consumer Reports, the World Wide Web Consortium (W3C), and research universities as examples. 10 participants would trust **third-party companies** dedicated to developing the privacy Q&A assistant. Participants believed they had the technical capability but "no vested interest" in the data practices being questioned. Similarly, two participants preferred collaboration between two types of entities, as P31 said: *"Either a nonprofit and a third party working together, one with the tech and one with the ethics, or it could be a governmental entity working with a nonprofit."* Interestingly, two participants strongly preferred first-party companies (e.g., big tech companies). P19 specified that she would trust Apple to develop the assistant because she valued Apple's product quality and customer support, even if the company may not be completely neutral.

Participants also discussed the entities they would not trust to develop the privacy Q&A assistant. 12 participants distrusted **first-party companies** that also engage in data practices being questioned, citing that the assistant may not be neutral because the companies have vested interest in the data practices. **Governments** (N=10) were also unpopular due to participants' personal political opinions or their belief that governments cannot deliver good technology products.

7.3 Benefits, Concerns, and Use Cases

Assuming the privacy Q&A assistant was developed by their preferred developers, participants elaborated on the benefits, concerns, and use cases for the privacy Q&A assistant.

Benefits. 14 participants identified **easy access to trusted data privacy information** as a benefit. P13 explained: *"I don't have to be scurrying, like a little kitty cat over the Internet, to try to find this information as much. The assistant can read the boring information and then give me a snapshot of what it has found."* Three participants mentioned that using the assistant could increase their awareness of data practices, said P24: *" [Having] readily available, accurate information that was generated or produced by a group of people who have the knowledge...I, as a consumer, will be better informed about how my information is collected and shared. "* Some participants mentioned **benefits tied to their preferred developers**, including accessing neutral data privacy information (third-party companies or nonprofit organizations as developers) and enjoying highly-quality products (trusted first-party companies as developers). A few participants mentioned that the assistant can increase their confidence when dealing with businesses or making privacy decisions online. These results indicate that a privacy Q&A assistant would benefit BLV users in many ways, regardless of whether they sought data privacy information or not.

Concerns. Even with their preferred developers, participants still expressed concerns about the privacy Q&A assistant. Eight participants identified **the data practices of the assistant itself as a concern**, explained P24: *"The digital assistant is going to function like Siri or the smart speaker. Their constant availability accepting information via voice...because they're able to access more information and then that there might open up the channels for other people to have access to the information."* Note that our emphasis on data privacy in prior interview questions may have priming effect for this concern. A few participants worried about the **long-term neutrality** of the privacy Q&A assistant and the **quality of the answers** provided, said P14: *"There would definitely have to be checks and balances so that the digital assistant wouldn't morph into something that could be used against the purpose of its existence."* Only one participant explicitly voiced accessibility concerns from a blind user's perspective.

Use cases. 14 participants reported that they would most likely ask questions about data privacy **before starting to use a new or unfamiliar digital technologies**, including *"at the time of installing the app (P12)"* and *"when connecting with a merchant that I've not used before (P14)"*. Many participants said that they would like to use the privacy Q&A assistant to check the digital technologies they currently use (N=4), obtain proof for companies' data practices (N=4), and when there are updates to companies' data practices (N=3). Two participants said they would only use it **when there is a privacy concern**. Notably, two participants expressed strong enthusiasm towards using the privacy Q&A assistant, as P17 commented: *"[I would use it in] any place I have to put in something beyond my name. if I've got to put in my date of birth, my social security number, or any financial information linking any financial accounts to a certain company, I would definitely use that digital assistant to make sure that I know exactly what's happening with the data that I'm inputting."*

8 Discussion and Implications

8.1 Study Limitations

We acknowledge several limitations of this study. First, a purely self-reported interview study has its inherent methodological limitations. To increase data validity, we employed techniques [23] to help participants recall their experiences

and refined interview questions to evoke truthful answers.

Second, the qualitative interviewing method also restricted our sample. Though our sample size is on par or larger than prior security and privacy qualitative studies with BLV users, the findings may not generalize to all BLV users. Particularly, the US sample in this study cannot reflect the data privacy experience of BLV users worldwide, who may need to navigate more complicated consent procedures, such as the cookie banners mandated by the General Data Protection Regulation [15]. Nevertheless, compared to prior studies with BLV participants [6, 17, 34, 44, 56], we recruited a more diverse sample across age, gender, and race/ethnicity, which yielded more inclusive perspectives and uncovered disparities within this underrepresented user group.

Third, due to the study focus, our interview questions for RQ3 cannot escape the participant response bias towards NLP-based privacy Q&A assistants. This means our findings did not investigate other approaches that can also assist BLV users in navigating digital data privacy. To mitigate this researcher-induced bias, we did not explicitly mention "privacy Q&A assistant" or any NLP techniques in the interviews and carefully crafted our interview questions to focus on participants' needs and expectations for privacy question answering capabilities, as detailed in 3.3.

8.2 Mitigating Risks for BLV Users

Heightened risks for BLV users. Besides confirming prior research that BLV users face high security and privacy (S&P) risks when using digital technologies [6, 7, 52], this study revealed several **previously unstudied privacy risks**. Regarding VI services, we identify the privacy risks associated with VI companies' data practices and a new type of physical-digital risks caused by the VI agents' environment (5.1). BLV users are vulnerable to S&P risks because they de-prioritize S&P concerns when having to overcome accessibility challenges around digital technologies [52]. Our results further suggest participants' low levels of privacy concern (4.3) and certain misconceptions (5.1) may further expose them to heightened S&P risks.

BLV users' risk mitigation is insufficient. Our study is the first to articulate BLV users' risk mitigation strategies and behaviors. Our participants primarily mitigate perceived risks by adjusting how they use digital technologies (5.2). This is unique for assistive technology, including VI services, that some participants heavily relied on in their daily lives. With limited alternatives, BLV users *had to weigh between the essential utilities and risk mitigation*. We also found participants' risk perceptions affect their risk mitigation behaviors. For example, most participants considered AI-based visual-aid apps low-risk (5.1) because there seemed to be no human involvement. Such perception fails to consider S&P risks associated with these apps' data practices and their underlying algorithms. Our sample is skewed towards educated participants but their current risk mitigation strategies do not prevent them from many S&P risks.

Implications for mitigating S&P risks. Our findings indicate the importance of providing accessible information to BLV users to enable accurate assessment of S&P risks. This highlights the need for tools like privacy Q&A assistants. Specifically, compared to sighted users, BLV users tend to mitigate risks through behaviors, presenting both opportunities and challenges for S&P tools. The opportunities lie in the potential impact of significantly improving their S&P if they adopt effective tools. However, our results also identify several challenges: S&P tools should consider the unique risks faced by BLV users and their accessibility needs; these tools should be seamlessly integrated into their existing risk mitigation strategies without increased user burden.

8.3 Creating Inclusive Privacy Tools

This is the first study investigating BLV users' information behavior around data privacy information, which yielded novel findings on how they seek or do not seek such information (6.3) and how they assess information sources (6.1).

Generally successful information seeking outcomes. Different from prior research [51, 76], our participants who sought data privacy information were mostly successful and **reported little difficulty** during the process. Similarly, the main reason for not seeking such information was a lack of need or concern. However, it is impossible to know if those who claimed no need or concern fully understand the privacy risks or if they would feel the same way if they did. Regarding data privacy information sources, besides news outlets and privacy policies, interpersonal and BLV-specific channels are particularly important for BLV users.

Similar challenges but more patience with privacy policies. Our findings revealed how BLV participant felt and interacted with privacy policies (6.2), which is a major source for NLP-based privacy tools [33, 43, 61]. We found that BLV participants **face similar challenges as sighted users** in comprehending privacy policies [55, 63, 72] but generally consider privacy policies a credible source. Surprisingly different from sighted users, many participants **had the patience** to read through multiple privacy policies.

Implications for creating inclusive privacy tools. Our findings show that BLV users' information behaviors around data privacy exhibit both similarities and differences when compared to sighted users. Particularly, we did not find prevailing evidence that BLV users face more challenges when seeking data privacy information beyond accessibility considerations. This cautions researchers about inaccurate assumptions that they might bring into their research or tool development. Essentially, privacy tools should account for BLV users' information needs and align with their existing information behaviors. For instance, a search tool may not benefit those who seldom seek data privacy information but NLP-based privacy tools

capable of summarizing key information from privacy policies [39, 43, 78] can alleviate the usability frustrations for both sighted and BLV users. This calls for more research to understand underrepresented user groups' privacy perceptions and behaviors to design more inclusive privacy tools.

8.4 Strengthening Trust with BLV Users

Trust is a meta-theme that impacts BLV participants' technology selection and their approach to data privacy information.

Trust in entities and people. Participants' answers to the only trust-focused interview question (7.2) suggest that BLV users' trust in developers may impact their decision to adopt S&P tools. Our results showed that BLV users **distrust** big technology companies and governments to create transparent privacy tools. In contrast, they tend to trust companies that provide assistive technology and products with outstanding accessibility features (5.2 & 7.2). They also trust organizations and experts of the BLV community as well reliable friends and family members, because they believe these organizations and people have their best interests in mind.

Trust in risk and credibility assessment. BLV participants considered screen readers and AI-based visual-aid apps low-risk because these digital technologies do not directly expose data to strangers (human agents). Notably, our participants seemed to trust AI-based tools and did not express concerns about relying on these AI-based tools, potentially leading to overlooked AI-induced S&P risks. Additionally, in line with [34], we find that BLV participants' existing trust also impacts how they assess the credibility of data privacy information. The participants who did not use sophisticated credibility assessment criteria tended to believe information mostly from the people or channels they already trust(6.1).

Implications for building trust with BLV users. Trust is integral to BLV users' interactions with digital technologies, assessment of information credibility, and evaluation of S&P risks. S&P tools should establish trust with BLV users, where ensuring S&P tools' accessibility is an essential starting point. Collaborating with BLV organizations can further strengthen trust with BLV users. Moreover, under the backdrop that popular generative AI applications like ChatGPT often provide false answers [66], it is particularly crucial for tools like privacy Q&A assistants to build and strengthen trust with BLV and other marginalized users.

8.5 Expectations for Privacy Q&A Assistants

This is the first study exploring BLV participants' expectations for potential privacy Q&A assistants, enriching the growing research to design user-centered privacy assistants [12, 65, 68] with a focus on accessibility and the need of BLV users. While our participants may prioritize data security over data privacy(5.1), they clearly recognized the potential benefits of privacy Q&A assistants and expressed interest in them(7.3).

Rethinking accessibility. Our BLV participants expected the assistant to be **accessible by default**, meaning they could access the assistant across devices and platforms and via different modalities (7.2). Different from prior research showing that BLV users found voice-based apps particularly useful [56], our participants preferred interacting with the assistant in **multiple modalities**. Some also favored **textual input and output** so that they can ask more precise questions and obtain more comprehensive answers. This highlights the importance to extend existing NLP Q&A evaluations [21,30,62] to account for inputs from different modalities like speech.

The importance of quality and trustworthiness. Most participants implicitly assumed that the privacy Q&A assistant could provide high-quality answers to their privacy questions (7.1). Some also imagined advanced features to enhance answer credibility, including the ability to cross-reference sources and to verify data practices objectively. In addition, many participants generally emphasized the importance of having trustworthy assistants with their best interest in mind when providing answers. Given that three participants still prefer human experts due to prior negative experience with online chatbots, the assistants would need to provide high-quality and trustworthy answers to swing their perspectives.

Implications for privacy Q&A assistants. These findings underscore the significance of default accessibility for privacy Q&A assistants and broader S&P tools. To achieve optimal accessibility, developers should determine the best modality combination based on different user groups' accessibility needs [36], which typically supports multiple modalities. Moreover, BLV users' expectations for functionality drives their interest in privacy Q&A assistants. To meet such expectations, potential areas of research include applying NLP techniques to consolidate relevant information from both privacy policies and other credible sources (e.g., privacy regulations and news), and advancing verification mechanisms to validate the data practices disclosed in privacy policies.

8.6 Towards Equitable Privacy

Digital divide. The digital divide generally refers to unequal access to digital technology among populations. This was seen in several unemployed or racially minoritized participants. For example, one participant never learned to use computers due to the lack of affordable screen reader training (4.2) and another had to use the free but relatively risky VI services Be My Eyes due to financial considerations (5.2). We also observed that marginalized BLV participants in our sample heavily relied on mobile phones to access digital technologies. This directly increases the S&P risks faced by marginalized BLV users and limits their risk mitigation options.

Technology literacy. Our results reflected the inequality caused by disparities in technology literacy. A few participants enjoyed the security provided by paid privacy-enhancing technology like VPNs (4.2), while one marginal-

ized participant struggled with entering passwords on their iPhone that prevented them from using mobile banking(5.2).

Implications for S&P research. Our inclusive sample yielded perspectives on equity and inclusion even among BLV users. While technology alone cannot resolve the disparity in security and privacy resulting from societal factors, it is essential for the S&P community to acknowledge the presence of such inequality. We should actively work towards developing accessible, inclusive, and equitable S&P tools that can benefit the widest possible spectrum of users.

9 Conclusion

We presented an in-depth interview study aimed at understanding BLV users' data privacy risk perception and mitigation strategies, their information behaviors related to data privacy, and their expectations for privacy Q&A tools that could assist them in navigating data privacy information. This study yielded rich findings and implications around usability, accessibility, trust, equity, and S&P risk mitigation for BLV users and beyond. We want to conclude this paper with one participant's quote that uncovers the core value of accessibility:

> *"I know the survey [interview] is supposed to be for the blind...but really what you're talking about to me is a survey [interview] everybody should take...because I think what you're talking about [the privacy Q&A assistant]...will benefit everybody, and you know a lot of the cases in the community of people with disabilities, we try to find things that are going to benefit the whole populace."*

Acknowledgments

We want to thank our blind consultants Dr. Cynthia Bennett and Chancey Fleet for their invaluable advice and the National Federation of the Blind for their help with participant recruitment. This study is funded by the US National Science Foundation under the project "Automatically Answering People's Privacy Questions" (CNS-1914444 & CNS-1914486). A Interview Questions

We list all key interview questions and describe some (but not all) follow-up probing questions due to the page limit.

Baseline questions: (1) What electronic devices do you typically use to access digital information? (2) What assistive tools or technologies and other websites/apps/services do you use on this device? (for each type of device mentioned) (3) Do you know what types of personal data is collected when you

use these digital technologies on your devices? (4) Considering the extend of data practices discussed just now, what are your general thoughts about data privacy in regarding digital technologies?

RQ1: Risks perception and mitigation: (1) Please think about the digital tools/technologies that you use, can you think of some of the potential risks around your personal data privacy? (Follow-up questions about comparing risks between general technology and assistive technology). (2) *[Critical incident]* Please think about the past month when you used digital tools/technologies, were there any situations that you felt surprised, uncomfortable, or suspicious about how these tools/technologies use your personal data? (3) Have you ever stopped using a tool/technology or switched to an alternative tool/technology out of data privacy concerns? (4) *(Hypothetical dilemma question)* If you find out an assistive technology that you use handles your data in a way that you feel uncomfortable with, would it affect your willingness to use the technology?

RQ2: Information (seeking) behaviors: (1) How did you typically come across or get information about data privacy in the digital world? (follow-up questions: where, how, information sources , and perceived credibility of information sources) (2) Have you ever tried to find any information about data privacy? (If yes, follow up with where, how, and information sources; If not, ask why) (3) *(When participants did not mention privacy policies as a source)* Are you familiar with privacy policies? (follow up on perceived credibility for privacy policies)

RQ3: Expectations for Q&A tools: (1) You mentioned that you used [X]. Please imagine if there is an expert who can answer any questions around data privacy for [X]. What kinds of questions would you ask this expert about [X]? ([X] is a digital tool/technology mentioned by participants; up to 4 tools/technologies of different categories are asked here) — *Note: the data from this set of questions is not reported due to the scope and focus of this paper.* (2) Please imagine if the expert we discussed above is a digital assistant that can provide you with information around data privacy, how would you like the privacy assistant to be? (First, we let participants freely describe their imagined digital assistant without priming; then we asked follow up questions on preferred devices, modality, sources, developers, benefits, concerns, and use cases.)

B Definitions Given to Participants

Digital technologies: During this interview, I will use the general term "digital technologies" to refer to all the websites, apps, web services, and assistive tools/technologies that you mentioned. Does it sound okay to you?

Data practices: As you may know, when you use these digital tools/technologies on your devices, your personal data is often collected, used, or shared by these tools/technologies.
Data privacy: Data privacy concerns the handling of personal data by different entities, such as if the handling is appropriate and if it's in compliance with laws. The handling of personal data includes a variety of practices, such as how data is collected, used, or stored, whether data collectors share or sell the data to others. The focus of this interview study is data privacy with digital technologies, or digital data privacy.

C Coded Data

We archive the coded data in this Open Science Framework repository: https://doi.org/10.17605/OSF.IO/K9FV6

D Participants' Demographic Distribution

Gender		Education	
Female	52.4%	Some college	38.1%
Male	47.6%	College degree	33.3%
		Graduate degree	28.6%
Race/Ethnicity		**Age Group**	
White	61.9%	18–29	9.5%
Black	19.0%	30–39	19.0%
Asian	9.5%	40–49	19.0%
Hispanic	4.8%	50–59	28.6%
Mixed	4.8%	60–69	14.3%
		70+	9.5%
Employment Status			
Fully employed			23.8%
Partially employed			14.3%
Self-employed			9.5%
Unemployed			28.6%
Retired			19.0%
Homemaker			4.8%

Assessing Suspicious Emails with Banner Warnings Among Blind and Low-Vision Users in Realistic Settings

Filipo Sharevski
DePaul University

Aziz Zeidieh
University of Illinois Urbana-Champaign

Abstract

Warning users about suspicious emails usually happens through visual interventions such as banners. Evidence from laboratory experiments shows that email banner warnings are unsuitable for blind and low-vision (BLV) users as they tend to miss or make no use of them. However, the laboratory settings preclude a full understanding of how BLV users would realistically behave around these banner warnings because the experiments don't use the individuals' *own* email addresses, devices, or emails of *their* choice. To address this limitation, we devised a study with n=21 BLV email users in *realistic settings*. Our findings indicate that this user population misses or makes no use of Gmail and Outlook banner warnings because these are implemented in a *narrow* sense, that is, (i) they allow access to the warning text without providing context relevant to the risk of associated email, and (ii) the formatting, together with the possible actions, is confusing as to how a user should deal with the email in question. To address these barriers, our participants proposed designs to accommodate the accessibility preferences and usability habits of individuals with visual disabilities according to their capabilities to engage with email banner warnings.

1 Introduction

An inclusive human-centered security design needs to accommodate the considerations of three dimensions: (1) *security*, (2) *usability* and (3) *accessibility* [25, 26]. Accessibility refers to the means that address discriminatory aspects related to equivalent user experience for people with disabilities, allowing them to equally perceive, understand, navigate, and interact with technologies, as well as contribute equally without barriers [39]. Relative to usability, accessibility demands that any human-centered security design does not disproportionally impact people with disabilities [3]. Relative to inclusivity, accessibility also demands that everyone is involved to the greatest extent possible, that is, factoring not just for their disabilities, but also their basic capabilities (e.g., access to the Internet, computer literacy, economic situation, etc.) when designing security technologies [5, 8]. While the security and usability dimensions are well established, accessibility has seldom been considered in a security context. Take phishing emails for example — there are plenty of studies considering the security and usability of warnings among sighted users [11, 24, 33, 36], but only a few consider the accessibility aspect for blind and low-vision (BLV) users [15, 18, 40].

Evidence shows that BLV users struggle with answering a large number of emails and are unable to distinguish warning pop-ups in their browsers while accessing email clients [15]. When accessing their email clients in browsers, BLV users are left to infer themselves the actions available as a result of a browser phishing warning (e.g., button to abandon a phishing link) based on ambiguous wording, ultimately exposing them to a higher risk of ignoring the warning altogether and falling pray to a phish [18]. Heeding phishing email warnings in clients like Gmail is also mired in difficulties. As the warnings' implementation hardly corresponds with the habits of using assistive technologies (e.g. using shortcut keys to skip over elements in the email) nor includes the necessary HTML tags (e.g., link, heading) for proper parsing, BLV users often miss the warnings altogether [40].

While this evidence is important in advancing the accessibility dimension of any human-centered security design, it is nonetheless limited to laboratory settings where BLV participants use email clients/browsers controlled by the researchers and are exposed to a set of either common phishing emails [18] or pre-selected combination of phishing and legitimate emails [40]. This setup precludes from understanding how BLV users behave under realistic conditions where they assess emails sent to their *own* email address, use different email providers for work (e.g. Outlook) and private communication (e.g. Gmail), or check their email through an app, a browser, or both. The email stimuli are of little relevance to BLV users personally because none of the emails are addressed to them, the content might be outdated, or the topic of the email is unfamiliar or inapplicable to them. Also, BLV users encounter spam emails in addition to phishing ones as

another type of potentially harmful communication, for which email providers also offer banner warnings in their clients.

An assessment of suspicious emails in a realistic scenario where all of these limitations are addressed at once is rather challenging but not prohibitive as past studies have observed the daily tasks BLV individuals perform when accessing their email clients [15]. To contextualize this observation when suspicious emails and the associated banner warnings are included, both for phishing and spam messages, we crafted a specific scenario in our study where BLV individuals used their *own* email correspondence sent to their *own* address and accessed through a client, device, and assistive technology of their *own* choice to answer the following research questions:

- **RQ1:** How a) accessible and b) usable are the phishing or spam banner warnings offered by email providers for BLV individuals in determining the legitimacy and the actions they take about suspicious emails sent to their own email addresses?
- **RQ2:** Do BLV individuals adhere to banner warnings about suspicious emails and to what extent do they continue to pay attention to a banner warning after encountering it multiple times?
- **RQ3:** How do BLV individuals assess suspicious — phishing or spam emails sent to their own email addresses (i.e. what cues do they use to determine the emails' legitimacy and what actions they perform)?
- **RQ4:** What recommendations do BLV individuals have for improvements in accessibility, design, and usability of banner warnings about suspicious emails sent to their own email addresses?

We obtained approval from our Institutional Review Board (IRB) to conduct a study with a sample of n=21 BLV individuals (original approval for 20 participants or above) who are regular email users (recruited through a snowballing technique). We set to perform our observations over Zoom where participants were asked to perform a few tasks with emails of their choice during which they verbalized their steps and provided their experiences/opinions. Respecting the privacy of their personal email correspondence in the main inbox, the first task was to review several emails of their choice in their spam/junk folder with their assistive technology of choice and verbalize to us only the subject line and sender. Using this verbalization, we ensured that these emails were not dangerous (e.g., resembled standard spam or phishing) both by checking for pretext and formatting patterns found in databases of known spam/phishing emails [23] and using our own assessment experience. If we were uncertain, we asked the participant to proceed to the next one (during the debriefing, we advised them that it is best to delete it). We then asked the participants to open the email, assess the legitimacy of the email (with a baseline established beforehand, as described in Appendix B), and share with us what the most likely action they would perform on it (without actually clicking any links or downloading any attachments).

To ensure that participants encountered both phishing and spam banner warnings (which are more prevalent in the spam/junk folders than the main inbox), we secretly sent a *false positive* phishing email to their own email address (the one they used to sign up for the study) — an email that providers deem as "phishing," assign a phishing banner warning, and automatically put it in the spam/junk folder — but in reality the email is legitimate. Once we completed the assessment tasks, we asked our participants about their accessibility and usability design recommendations for the banner warnings as well as their real-life experiences with detecting and acting on phishing and spam emails in general.

Our findings indicate that the email banner warnings in the two most prominent email clients, Gmail and Outlook, are implemented in a *narrow* sense. The *narrow accessibility* means that BLV users are only offered a mere verbalization of the warning text without conveying the reason why the banner is applied, the personal risks of engaging with the email, and the possible corrective actions relative to the automatic decision to filter the email and apply the warning. The *narrow usability* means that the warnings were technically noticeable but with a confusing textual formatting that is disconnected from the accessibility dimension in conveying what the banners are supposed to achieve security-wise for users whose needs, so far, have been excluded or overlooked.

This *narrow* sense of accessibility and usability compliance was perceived as a barrier to a *broader, usable accessibility* that is inclusive to the needs, habits, and experiences of BLV users with suspicious emails. To address the barriers of the narrow accessibility and usability of the real-world email banner warnings, our participants proposed designs that (i) mark suspicious emails as early warnings and allow BLV users to "*learn why*" a particular email was marked; (ii) allow configurable ping tones both "*before*" and "*after*" the text conveying the marking; (iii) a comprehensible text that conveys the risk level of marked emails; and (iv) different-than-rectangular shapes, in addition to stark contrast/and colorblind accessible colors for individuals who use screen magnifiers.

Contributions Our work has three contributions toward an inclusive human-centered security design:

- A novel methodology for conducting experiments in realistic conditions with security and safety-inducing interventions for emails with users whose needs have been, so far, excluded or overlooked in the current designs;
- Evidence of barriers to secure email engagement in realistic conditions due to *narrow* accessibility and *narrow* usability implementations (i.e., disconnected designs that don't account for the BLV users' overall email experience or basic email literacy);

- Recommendations for *broader, usable accessibility* redesign of email banner warnings (or other security warnings, in general) that consider the accessibility needs, usability habits, and basic capabilities of BLV users.

2 Background and Related Work

2.1 Usable Security Warnings

Usable security warnings are interventions in the user interfaces that are placed *in situ* with the objective of raising users' awareness of potential phishing attempts during their primary course of action [11]. They usually come in a couple of variants, depending on whether they require user interaction or not. The first variant is *interactive* warnings that either force the attention of a user to a suspicious element like a link or attachment (usually within an email client) [24, 36] or offer options for users to "go back to safety" or "proceed to a website" (usually in a browser). Often, the interactive warnings come with additional informative messages that communicate the threats ahead in an effort to proactively raise awareness for future cases of phishing exposure. The second variant is *passive* warnings that attempt to indicate to a user an imminent phishing warning without interrupting their primary course of action either by highlighting a domain or chaining the color of a browser's address bar.

The evidence from user evaluations of both types of warnings suggests that users often ignore the passive warnings, but they tend to adhere to the interactive warnings [11], provided the wording is comprehensible and incorporates a design that prevents habituation (i.e. attenuation of a user interaction response with multiple exposures to a same warning) [33]. The adherence and phishing safety, however, does not come without a cost – usually, the forced attention is distracting, time-consuming, and tedious [38], especially with a high number of emails a user receives a day, and the element of fear increases with the repeated exposure to decisions to abandon a suspicious website [27]. There is also a difference in effectiveness whether the warning "friction" happens within an email client as a banner (the usual vector for delivery of phishing attacks [34]) or in a browser as a splash screen, with the later implementation being better preventing participants from reaching phishing websites [24].

2.2 Access to Usable Security Warnings

The evaluation of usable security warnings usually is done with *sighted* users or users who don't need an assistive technology to access the warnings. But the technologies that these warnings attempt to prevent from security failures necessitate a material access with technical capabilities and know-how, something that is not available or intrinsic to all users [19]. A digital divide thus exists between users [28] that disproportionately renders many of those without access and digital literacy to greater security and privacy risks [3, 4]. This "digital exclusion" often brings on, or exacerbates, the vulnerabilities of marginalized and underserved user groups [26].

Vulnerability in this context arises from the lack of access to resources or barriers to using a security or privacy technology in the way for which it is designed. These are "human vulnerabilities" and differ from the usual "cybersecurity vulnerabilities" (i.e., weaknesses in the technologies that result in security protections' failure [22]), though the notorious statement "humans are the weakest link" treats all users as the cybersecurity vulnerabilities. In response to this (mis)treatment, a user-centered security approach has been adopted [27, 41] and, accounting for the human vulnerabilities, an inclusive security approach has recently gained traction [37]. The latter approach brings the attention of evaluation, involvement, and empowerment of users with human vulnerabilities with security technologies, such as authentication [12], usable security warnings [18, 40], and misinformation [30].

The inclusion pertains to users with physical vulnerabilities (such as blindness, motor impairments, deafness, hearing loss, etc.), cognitive (such as memory loss, mental health conditions, etc.), financial vulnerabilities (such as unemployment, homelessness, etc.), and emotional (such as fear appeal, upsetting security and privacy experiences, etc.) [26]. We, in our work, were particularly interested in studying the exclusion of BLV users when designing usable security warnings that preclude access to people with visual disabilities. From a visual accessibility perspective, it appears that the design is driven towards "visual" frictions intended to enhance the security behavior of sighted users [9].

The objective of forcing attention, for example, is achieved by displaying (i) interactive warnings that appear when a user hovers over a phishing link; (ii) a banner between the email header and body; or (iii) a splash screen with an informative message that offers users the option to click back to safety or proceed to a website. In the first case, a sighted user has no problem hovering over a hyperlink in an email, but that is not the case for a BLV individual who relies on a screen reader to verbalize the contents of an email. In the second and third cases, the banner is often implemented in red color and contains signage like stop or exclamation mark signs to highlight the danger of phishing ahead. Red as a color holds little significance to a (color) blind person who is also unable to fully capture the warning signage when accessing the email in a text-to-speech fashion.

The promising utility of the interactive warnings comes short when it comes to accessibility as evidence further shows that the options for "going back to safety" or "proceeding to a website" are incongruent between different browser implementations and often confuse BLV users about what is the outcome of the interactive element in the warning [18]. The email banners warning equally suffer from inconsistency when it comes to standard and HTML presentations and though verbalized by screen readers, they make a very weak case of

adherence [40]. It's not that the accessibility is insufficiently or partially addressed when it comes to communicating the message of the warning — the design entirely omits to incorporate the email and browser habits of BLV users too.

Usability-wise, BLV users tend to escape from non-usable or inaccessible content by tabbing or scrolling down [35]. This user population usually "scans" a website with their ears by listening at a high speed and rapidly exploring the page by jumping directly to headings and links through heading lists or link lists provided by the screen reader [32]. Blind or low vision users often remember the "metadata" that needs to be skipped in order to reach their desired content on a website of their interest [35]. Also, rich, well-formulated textual content seems more credible to blind or low vision users even if the visual appeal seems suspicious to visually able users [1].

2.3 Usable Security Warnings and BLV Users

An evaluation of warnings about dangerous emails, so far, has mainly been performed relative to their accessibility [18, 40]. In [18], BLV users were shown an example of a phishing email sourced from a repository of common phishing emails [6] and informed that if a user clicks on the links inside the email, a standard browser warning will be displayed with a description of the phishing risk ahead and the options to abandon the link (e.g., "Go Back" button), proceed (e.g., "advanced" link), or learn more. Then, the users proceed to evaluate this warning with their own assistive technology by opening a researcher-controlled link in a browser of their choice.

Though this approach is certainly better than a laboratory set security warning evaluation, it has a couple of limitations. First, participants are shown an email that neither is addressed to them (i.e., to their *own* email address) nor the content is of significant relevance to them. While the emails, coming from Cornell University's repository [6], employ the known elements for luring victims (e.g., authority, scarcity, etc.), they usually use a pretext relevant to academic environments (e.g., a campus job offering, university account expiring, etc.), which might neither be of interest to participants nor would they be targeted with such emails. Second, these emails, if not filtered by default, usually invoke banner warnings in the email client of choice of the participants that precede the browser warnings. These banner warnings together with the email itself, even with a variable degree of accessibility, might dissuade a BLV user under realistic conditions from clicking the link and accessing the browser altogether.

An evaluation of email client warnings with BLV users was performed in [40]. Here, the emails were also selected from a phishing email repository and were spoofing three popular email senders including Google, Apple, and Hulu. The emails were placed in a Gmail account controlled by the researchers and opened in a Chrome browser, that was running in a virtual machine with a preloaded assistive technology of the choice of each participant. Participants accessed this setup remotely through Zoom (screen sharing and remote control function) and played the role of an assistant to help their manager process and review emails. The emails triggered an icon warning that displays a red question mark in the sender's avatar icon of the email and, on hovering over, pops up a short message: "Gmail couldn't verify [sender address] actually sent this message (and not a spammer)."

While this setup in [40] was created to test a baseline behavior that later would allow comparison with their implementation of inclusive email security indicators (a very commendable and welcomed contribution), it nonetheless has several limitations towards a realistic evaluation of email security warnings. As previously noted, the selection of the emails might not be relevant for the participants as they are not addressed to them personally. Next, many BLV people use Outlook or other email clients in addition to Gmail, and they might check their emails through their phone's applications in addition to a browser. A role-play scenario in which a BLV individual plays a manager's assistant might also be something that many of the participants are unfamiliar with or it might not represent their typical daily engagement with emails. Importantly, the icon tested in the baseline scenario differs from the email banner warnings that are usually triggered for both phishing (example shown in Figure 1) and spam (example shown in Figure 2, and tested neither in [18] nor in [40]) and contain much more a verbose text of the warning compared to the icon's alt text (particularly an important feature for users that rely on aural email access).

3 Study Methodology

Situating the study in realistic settings entailed a specific protocol that ensured our participants were not exposed to greater than minimal risk but also using mild deception to avoid priming them about exposure to real-world phishing and spam emails (the entire debriefing about this deception is given in Appendix D). Instead of exposing participants to phishing emails that weren't addressed to them or using a laboratory setup and a role play scenario for accessing these emails, we invited our participants to join a 45-minute, audio-only, recorded Zoom interview session where they can use their *own* device, their *own* email client, and their *own* assistive technology as they go about in their everyday lives with their *own* email address. We avoided asking them to go through their primary inbox for several reasons, namely because: (i) this might have constituted a greater than minimal risk of privacy invasion for which we did not have available safeguards to prevent; (ii) the probability that a participant will encounter a phishing or spam email with warnings during a brief sorting task of their inbox during the interview time is very low; and (iii) major email providers might display banner warnings, but automatically move untrustworthy emails to the spam/junk folder by default [14, 20].

To address this challenge, we decided to direct our partici-

pants to access several emails within their spam/junk folder. This would have constituted a priming to phishing/spam if we had done so at the beginning of the study, therefore, we asked them a couple of questions prior to starting efforts to frame the study in a broader suspicious email context. The first question was about how often our participants receive suspicious emails in their inbox folder (not caught by a spam/junk filter) and the second was about how often they encounter legitimate emails in their spam/junk folders. These answers allowed us to provide the opportunity to frame the subsequent request to sort several emails from the spam/junk folders as a task towards assessment of suspicious emails that are not expected to be phishing or spam by default just because they have been filtered as such by the email providers. Once in the folder, we allowed our participants to select any emails they wanted, but we had to ensure a higher probability that each participant would encounter phishing, spam, or both emails — with their associated client banner warnings attached by providers shown in Figure 1 and 2 (Gmail) and Figure 3 (Outlook), respectively — during the Zoom interview session.

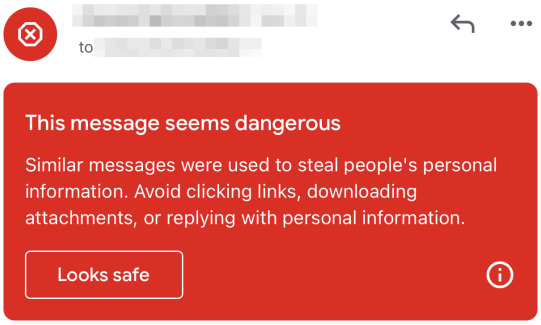

Figure 1: Gmail phishing warning banner

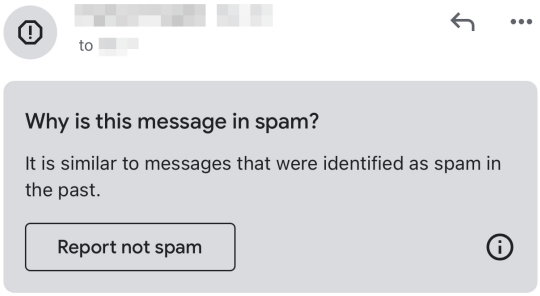

Figure 2: Gmail spam warning banner

While a prior check of multiple researcher-controlled email addresses revealed to us that encountering a spam email with the associated banner would not be a problem, that was not the case for encountering a phishing email in the participants' spam/junk folders. To ensure that this would happen for the

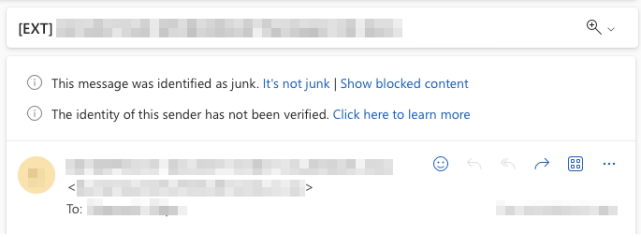

Figure 3: Outlook warning banner in the junk folder (note: Outlook uses the same for any untrustworthy email without distinction of the email type between phishing and spam)

purpose of the study, we have prepared a *false positive* phishing email that we knew the filters would assign a phishing or banner warning and move to the spam/junk folder. We decided to use a false positive phishing email, that is, an email which was *not* phishing but was classified as such anyhow in order to avoid exposing our participants to greater than a minimal risk with other, *true positive* phishing emails. This means the email could not cause any harm to BLV users as it did not contain any malicious attachments or links involving an unduly phishing risk (all links lead to legitimate Amazon Web Services (AWS) pages). As a *false positive* phishing email in our study we initiated an AWS account creation verification email, shown in Figure 4, directed on the day of participation to the participants' emails they used to sign up for the study (we didn't want to tip them off that something might be amiss if we sent the email right before their Zoom session).

We chose this email as we encountered it in our own spam/junk inboxes after we did a personal AWS initiation. We refer to it as "mild deception" as our participants did not know we were the ones that instigated the sending of this email to their addresses. We were fairly confident that the participants would already have spam and we were prepared to use the spam instance if needed, but we were less sure about them having phishing emails sitting in their spam/junk folders so we could also test the phishing warning banner variant. The AWS email was necessary to invoke a realistic scenario where our participants access a phishing banner warning assigned to an email because such an occurrence might not happen frequently enough to be reasonably observed as part of the participants' typical email engagement during the study. To ensure the AWS email will work for all participants (Gmail will assign the warning banner and put it in the spam/junk inbox), we created 10 different email accounts, sent the AWS email to them, and found that to be the case in all of them.

We were aware that the classification of untrustworthy emails was predicated on the individual's email correspondence and behavior, and we expected that we might encounter a case where the AWS email might not end up in participants' spam/junk folders. For those cases, we decided to proceed only with what they had in their spam folder as emails addressed to them without going to the main inbox or attempting

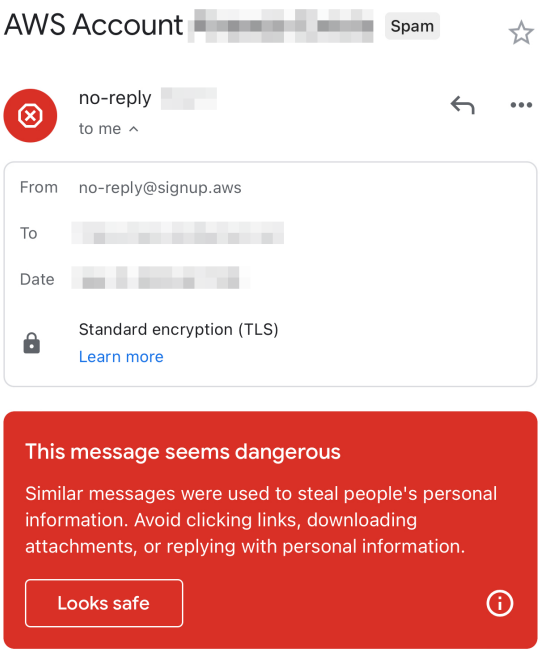

Figure 4: The *false positive* AWS sign-up email

to ask them to perform additional steps. The study has been approved by our IRB and we used an extensive debriefing (see Appendix D) in which we pointed out our methodology, discussed any surprises or events during the interviews where we felt participants might be in the line of phishing/spam harm in the future, and pointed participants to general email phishing resources if they wished to raise awareness on the subject. We believe that our overall methodological approach is appropriate because we strike a good balance between the acceptability/manageability of our participants to participate under realistic conditions while we grasp their real-time experiences with their personal email correspondence.

3.1 Participant Recruitment

For our recruitment, we followed Gerber's advice when doing usability and accessibility studies with blind and low vision people [13]. Accordingly, we recruited participants who use a screen reader, screen magnifier, or both, that regularly use web/email clients, and could obtain online information aurally without problems. They had to be individuals 18 years of age or older who had internet access on their own device, client, and browser and were English-speaking and literate. As one of the researchers is a legally blind individual, we recruited potential participants through snowballing where we partially sampled personal acquaintances and partially a pool of BLV participants that was recommended by one of our acquaintances. We used a formal email approved by our IRB (see Appendix A) to approach each of the potential participants. We arranged audio-only recorded Zoom interviews with interested respondents on a rolling basis, requesting that each participant has access to their preferred way of using emails and their assistive technology. The interviews lasted on average 45 minutes, and we compensated each participant with a $25 Amazon eGift Card ($525 in total).

3.2 Trust and Ethical Considerations

As this was a study in realistic settings and concerning the participants' own email addresses, it was important for us to establish trust and assurances about the goals of the study and the safeguard protections we had in place. Following the suggestions for considering the ethical aspects when doing research with blind or low vision individuals from prior work [16] we first obtained verbal consent both before we started the audio recording and afterward (to have evidence in our transcripts, but also to avoid creating a recording in case a potential participant does not consent, in which we would have thank them and closed the Zoom session). Next, we communicated that the goal of our study was to capture the "richness" of their experiences in realistic settings rather than the commonality of these experiences in laboratory settings. This is the reason, hence, why we are asking them to work with their own email address, client, and access technology. Here, we offered the option for them to choose not to participate and to choose which address they will use — as many of them have multiple email addresses (e.g., work, private, subscriptions). We noted they could select any email they wanted to communicate with us from their spam/junk inbox and they were free to stop and abandon any question at any point in time if they felt doing so. Prior to doing any of the tasks and the interview, we told them that they could ask us to stop the interview, stop the recording, or remove any answers or readings at any point in time.

Only after we received the participants' explicit permission that they were okay with proceeding with the study and accessing the spam/junk folder of their own email address, we commenced the audio-only recorded Zoom session and proceeded to complete the tasks and the interviews. Following the recommendations for doing usable security research with BLV users [29], we verbally notified each participant when we started each audio recording and we explicitly told them that they could take as much time as they needed to answer any question. We allowed them to verbalize the process, give comments, complaints, suggestions, and verbalize any other experience that was not necessarily with emails but other technologies (e.g., social media, passwords, software) in order to allow for them to fully express the natural behavior "surrounding" their daily interactions with email.

We also pointed out to our participants that they could act on the emails from the study as they ultimately wished (e.g., delete, move to inbox, report, etc.). After the we collected participants' answers, we verbosely debriefed the participants about the mild deception we used and that we were the ones

that initiated a *false positive* phishing email to their spam/junk email (if they received one or chosen to verbalize one during the study). We pointed out participants to general email phishing resources if they wished to further raise or check their awareness [7]. To ensure we obtained a correct understanding of their experiences and recommendations, we reviewed the main points we recorded during the interview and clarified any misunderstandings we might have. We also sent a draft of our paper to our participants for feedback.

We employed lengthy explanations to ensure our participants that we were not involved with the filtering nor with the formatting, verbalization, and accessibility implementations of the email banner warnings they saw during the study or in the past. We were also careful not to appear in favor nor support of particular types of warnings in order to maintain full researcher impartiality. We communicated that our ultimate goal is to create meaningful *inclusion* for BLV individuals when these banner warnings are present in their *own* email clients of choice. We pointed out that, this goal, however, doesn't prevent from misusing our findings or misinterpreting them in making compromises for accessibility or removing such support altogether, given the trend of big tech companies to do just that for cost saving reasons [17].

3.3 Data Collection

Initially, the interview transcripts from our Zoom sessions were not anonymized, but we removed any names and references to individual participants and deleted the audio recordings altogether. The transcripts, assigned only with a participant number in the order of participation, were stored on a secure server that only the researchers had access to. Each interview was done with open-ended questions, listed in the interview script (see Appendix B). Due to the nature of the study, not all the participants used a similar set of emails, and in some cases, the email providers either entirely filtered out the *false positive* phishing email (shown in Figure 4) or moved it to the main inbox without assigning any banner warnings.

We concluded our recruitment with a sample of 21 participants as we reached thematic/data saturation (i.e., we collected data up to the point where there were fewer surprises in the responses to the research questions and no more emergent patterns). As part of the debriefing process, participants were offered the option to withdraw from the study after finding out about the mild deception (i.e., the *false positive* phishing email) or no later than 30 days period after the data collection concluded (none of the participants exercised this option). The demographics, email setup, and the sample's visual profile, per the suggestion in [13], are all given in Table 1.

Gender				
Female 11	Male 9	**Non-Binary** 1		
Racial/Ethnic Self Identification				
White 14	Latinx 3	Asian 1	Black 1	Other 2

Table 1: Demographic Distribution

3.4 Data Analysis

Since we had to work with a degree of arbitrary selection of emails in our study, we asked our participants to provide lengthy responses to our questions and asked for further clarifications. With the collected data, we performed an inductive coding approach to identify frequent, dominant, or significant aspects of their answers. As suggested in [2], we first familiarized ourselves with the data as we had to manually revise each transcript to remove personally identifiable information. Next, we completed a round of open coding for arbitrarily selected two interviews to capture the participants' decision-making process around the tasks they performed in the study. Then we discussed the individual coding schemes and converged on an agreed codebook. We used this codebook to independently code the remaining interviews, reaching an *Inter-Rater Reliability* (IRR) of $k = 0.9$ (Cohen's kappa), which we deemed acceptable. The themes we identified respective to the research questions, were then discussed, interpreted, and example quotations were selected to represent each of the findings [10].

The coding was informed by a shared accessibility experience relative to what it means to pay attention when using a screen reader and the effort needed when accessing emails using assistive technology. This helped us resolve mismatches that usually arose from differences in familiarity with a particular screen reader or other assistive technology. The codebook (see Appendix C), thus, captured four main aspects: (i) *email banner warning accessibility and usability* i.e., codes related

to the accessibility and the phishing-avoidance utility of the email banner warnings; (ii) *email banner warning adherence and attention* i.e., codes related to the adherence and attention paid to the email banner warnings; (iii) *email assessment* i.e., codes pertaining to cues, criteria or rules of thumb used to determine the legitimacy of personal emails; and (iv) *accessibility and usability redesign* i.e., codes describing the participants' recommendations for accessibility and usability redesign of the email banner warnings towards a safer use of emails by blind or low vision users.

4 Results

As this was a study in naturalistic settings, participants had the opportunity to choose and select which and how many emails they would like to access and assess in their spam/junk folder. As previously mentioned, we initiated the *false positive* phishing email to each of the participants on the day of the Zoom session, but we were aware that it might not end up in their junk/spam inbox because of personalized filtering or because the participant might have deleted it before. Table 2 gives the breakdown of the number of emails, types, and banner warnings encountered by each participant.

P#	Gmail Spam	Gmail Phishing	Outlook Junk
P1	1	1	n/a
P2	1	1	n/a

Table 2: Personal Emails Used in the Study per Participant

4.1 Study Framing

Equally, as their sighted counterparts, BLV users do receive suspicious emails in their inbox folder (not caught by a spam/junk filter) – some of them receive a few a month, some of them rarely, and some of them all the time. These emails revolved either around "*password reset*" or a work-from-home opportunity where the email receiver is free to "*make their own hours and make $95 an hour*" (**P10**). The senders of these emails ranged from businesses, banks, insurance companies, and service providers to simply individuals from the perspective of "cognitive triggers" of phishing compliance, blind and low vision users are targeted with the *scarcity* and *reciprocity* pretexts, reinforced with *authority* as the alleged email initiator. In an attempt to trick spam/junk filters, phishing attacks sometimes contain only attachments, one of which is an image of what should have been the body of the email. This phishing tactic, for BLV users proves hardly efficient because, as **P21** put it, their "*screen reader was reading neither the sender nor the attachment content*, " which was a cue that the overall email was "*super phishy*." Interestingly, this might be a phishing case where BLV users, have an advantage, in the form of their screen reader, compared to sighted users.

A similar outcome was observed relative to the encounters of legitimate emails in BLV users' spam/junk folders. This happens regularly, and our participants stated that these are often important emails that they found following a "*check your spam folder*" reminder email in their main inbox, as participant **P11** noted. Without this reminder, participants complained that there is little to be done because "*marking these emails as 'not spam/junk'*" (**P11**) or "*putting these email addresses in the address book*" (**P4**) doesn't prevent them missing important correspondence. The problem is exacerbated when it comes to 2-Factor Authentication (2FA) because, according to participant **P12**, "*it delays their login, causing them to make additional phone calls*." Considering security protections from a broader usability perspective, this finding reveals that this machine-assisted design of filtering suspicious emails negatively impacts people with visual disabilities [3] as it induces a burden in using a second layer authentication as an enhanced protection.

4.2 Accessibility and Usability Evaluation

To address the gap in knowledge of how BLV users engage with email banner warnings under realistic conditions [18, 40], our first research question looked at the accessibility and usability of these warnings when applied to the participants' own emails by their preferred email provider.

4.2.1 Gmail *Phishing* Banner Warning

Out of the 19 participants that used Gmail, either on their phone or laptop, 14 received the *false positive* AWS email shown in Figure 4. One participant also received another phishing email in addition to the *false positive* AWS email (**P17**). The first thing we discovered was a discrepancy between the visual formatting in the friction and the formatting

delivered through a screen reader. Several participants mentioned that their screen reader uttered the word "*phishing*" before it read the sender and the subject line of the email, a feature not available for other assistive technologies such as screen magnifiers or otherwise in general (nor is the word phishing is found anywhere in the banner text). Usability-wise, participants didn't mention that this "hidden" accessibility feature of Gmail was much of a help because "*their attention is usually focused on the sender and the subject line*" (*P9*) and the "*phishing*" utterance was not an element they expect or are used to when reading emails.

Most of the participants using screen readers and all using magnifiers were able to access the Gmail phishing banner warning in a *narrow* sense, that is, they were able to hear the text of the warning or see the banner through magnification. But they also commented that "*it's not obvious [the banner] is a separate interactive element and there is no way to easily find it if you quickly went past it*" (**P9**). More importantly, the Gmail phishing banner did not address the accessibility in a *broader* sense, i.e., considering the usability and security aspects of these warnings – many participants missed or ignored them altogether when going through their emails. We had to explicitly point them back to the banners so they could go over again and access them again. This interactive drawback was also emphasized as a barrier precluding engagement with protections that should not disproportionately discriminate between sighted and BLV users.

Many of them, like participant **P3**, noted that they use their screen reader "*set on a much faster rate than a generally spoken text*" and, as such, they have no way of telling whether the banner warning text "*is part of the email's header or not*." Participants also commented on the lack of a literacy baseline that joins the accessibility and usability of the phishing banner warnings. For example, participant **P7** noted that the "*apprehension of the text is confusing*" because it doesn't say "*who's stealing my account or who's trying to steal my personal information*" or if "*somehow related to my other similar emails from Amazon*." Along these lines, Interestingly, here, participant **P3** even commented that the button "*looks safe*" means little to a user that *technically cannot use their sight to actually look*."

The nonintuitive accessibility was equally met with the nonintuitive usability of Gmail's phishing banner warning. Participants did mention that the additional text they heard '*give them like a little quick second to actually think what to do with an email*" (**P1**) or ""*delete the email straight away*" (**P2**), but they were aware that this *narrow* sense of usability is not sufficient to always induce a safe behavior. Participants, aware that "*Gmail doesn't always do a good job of filtering*" (**P3**), complained that they have to "*scroll through and come back a few times before deciding what to do with the email*." The lack of phishing warning literacy or an explicit agreement on what the banners are intended to achieve security-wise for users was also brought up as a barrier for a *broader, usable accessibility*. For example, the emphasis on "*danger*" without an explanation of what are the consequences of having your personal information stolen was perceived as an effort to elicit an "*emotional response*" (**P6**) without "*really communicating the severity of how harmful an email is*" (**P20**). This usability drawback, in turn, did not necessarily "*dissuade [them] from looking in each of those emails in detail*" (**P16**)

4.2.2 Gmail *Spam* Banner Warning

Participants, depending on the nature of the email, either accessed one, two, or three two spam emails with the warning banner from Figure 2. Here too, some of the participants missed the spam banner warnings and commented on the *narrow* sense of accessibility that precludes full user engagement with them. For example, **P18** noted that "*they are accessible as it's just text, but I kind of passed over them really quickly without paying much attention*." The absence of baseline literacy of how these help users was also pointed out as problematic. Here, participant **P21** commented that the "*warning is accessible, but the button 'report not spam' is confusing as it doesn't say to whom this report goes and whether the reporting will automatically unblock all future emails from this sender to never go to spam*." The *narrow* sense of accessibility was also present here, as participants "*often have to poke around to find what really is the beginning of the email message — the warning or the subject line*" (**P15**).

The nonintuitive usability of Gmail's spam banner warning was also brought up as an issue. The evolution of the spam warnings design – especially the wording that is intended to induce a safe behavior – wasn't helpful either, because "*previously [it] was saying to be careful with an email and now [it] just says why the email is in the spam*." (**P20**). Here, participant **P12** pointed to the confusing wording of the spam warning relative to the "similarity" reference inside: "*I understand [what it supposed to tell me], but it didn't make sense, because it's not something I've experienced before with my 'own' similar messages*." This usability drawback, similar to the Gmail phishing banner warning, did not "*dissuade*" the users to assess the email body nonetheless because "*the email might be something important to [them]*" (**P16**). This course or (in)secure action, in effect, was a result of the formatting of the warning's text itself (and the overall design) as it made the participants "*read the email anyhow to know whether to report it as spam or not*" (**P6**).

4.2.3 Outlook *Junk* Banner Warning

The participants that preferred the Outlook client did receive the *false positive* email from Figure 4 but the warning banner shown in Figure 3 was the same for it and for the other junk email that was in their folder. Overall, Outlook didn't fare any better than Gmail in enabling a *broader* accessibility for blind or low vision users that contextualizes the usability and

security of the "junk" email warnings towards a truly secure behavior under realistic conditions. Participant **P13** considered the Outlook banner warning in the context of what they habitually use in their main inbox, stating they "*have easily missed it or went pass through it because it appears after the email subject*" (unlike the Gmail's banners). The wording of the warning – as the main element of communication with users strictly dependent on aural guidance – showed to be a problem here too because it was "*too cumbersome and confusing in the first sentence and the follow-up link*" (**P13**) leaving users to wonder whether the email "*was or was not junk*." While the participants were able to navigate to the warning itself, this course of action didn't help them much because it did not preclude them from wondering *who* is the one that "*identified [an email they received] as junk*" – the provider, the email owner, or someone else (**P10**).

4.3 Adherence and Attention Evaluation

With the second research question we wanted to learn whether BLV users (i) adhere to banner warnings like this in general, and (ii) continue to pay attention to them after encountering them multiple times under realistic conditions. These aspects have been evaluated with sighted users in the past [11, 27], but have not been addressed in the previous work with BLV individuals [18, 40]. Participants confirmed they do adhere to the warnings mostly because they "*trust Gmail to filter the spam and phishing out for them*" (**P5**), even "*if there are instances when important correspondence has been sent to their spam inbox*" (**P21**).

But the trust-based adherence alone was not something that participants relied on when engaging with suspicious emails in their daily lives and instead relied on their "*own judgment*" (**P2**). Participants were wary that the implementation of the warnings wasn't catering to their accessibility needs (e.g., "*mentioning a 'danger' without clear danger ahead is confusing*"(**P4**)) or to their usability needs (e.g., the "'*report not spam' feature really doesn't solve the problem with one click and is ineffective of avoiding putting important emails in the spam folder time and again*" (**P4**)). The adherence exceptions that sighted users exhibited with security warnings [38] were also mentioned by the BLV participants in our study. Participants complained about the "*tediousness of getting legitimate emails from spam back to inbox*" (**P15**), which for a blind user is "*time-consuming*" (**P12**), and goes counter the intention of the warnings to help users get an "*intuitive sense*" of the phishing/spam risk ahead.

When it came to attention, we wanted to know whether the BLV users' interaction response attenuates with multiple exposures to the same warning. We couldn't use the same evaluation strategies for sighted users [33] so we asked the participants who accessed more than one spam (Gmail) or junk (Outlook) email about how attention-grabbing was the experience when they heard the warnings multiple times. Granted, we couldn't explicitly measure any "attenuation" effect, but we nonetheless uncovered the tendency of the BLV participants to avoid "*paying much attention to the warnings after the first one*" (**P21**). Their focus, instead, was "*more so to the subject and the sender to get the feeling if the emails are not actually spam*" (**P21**). Instead of heeding the warning each and every time, participants attention was driven towards finding a way to "*report an email to make sure that they don't get these emails again (automatically deleted)*" (**P19**) so they didn't have to deal with warnings altogether.

The narrow accessibility of warnings also played a role in the lack of attention to repeated warnings with our participants. The aural aspect of the warnings, unsupported by the color and signage for sighted users, makes them less attentive. The repetition of the warning text when using fast speed settings on a screen reader, according to participant **P18**, is of little to no help because "*keywords like 'spam' or 'phishing' are eclipsed by the convoluted text of the warning itself*" so the attention is shifted to the next email element instead. The narrow usability of the warnings, too, turned some of the participants to "*default being suspicious of certain emails in their junk folder*" and pay no attention to the warnings at all, regardless of any repeated exposure.

4.4 Suspicious Email Assessment Strategies

One of the most dominant cues of an email's untrustworthiness that our participants relied on was the aural inconsistency and grammatical errors resulting from typos, punctuation, and unexpected symbols. Our BLV participants pointed to their aural ability to spot misspellings, grammatical errors, typos, and inconsistencies in the use of symbols. The cues that the BLV participants in our study relied on – regardless of the presence or absence of warning banners – included "*random letters and numbers and 'weird' addresses*" (**P17**), "*grammatical errors*" (**P19**), and "*spelling errors, omitted letters, or extra letters*" (**P18**). Participants, like **P5**, noted that the aural cues of inconsistency make them distinguish between spam and other emails because "*spam seems to have a lot more punctuation or symbols instead of letters*."

The lack of warning context for BLV users, leaves them to rely on expected "*email narratives*" as a clue for potential phishing, spam, or junk emails. For example, participant **P16** mentioned that past experience accessing legitimate emails using assistive technologies helped them "*tell [when] the narrative sit right with [them]*" or not. The improbability of a request, for example "*an expired account, change of password, or attempted delivery*," was "*screaming of phishing*" – in the words of participant **P18** – because they knew when to change a password or what they have ordered. Here, the text of the warnings was of little help because the design is "*too general and doesn't mention examples such as passwords when it speaks of 'personal' information*" (**P9**). The banner warnings were irrelevant elements in detecting spam or phish-

ing when a request was inapplicable to the conditions of the participants. For example, participants **P11** shared that "*you know it's phishing or spam email when they try to sell you a car insurance but they don't know you can't drive a car*."

To the point of absent baseline literacy that joins the accessibility and the usability of the banner warnings, more than 70% of our participants mentioned they never received any formal training in phishing detection, including heeding warnings with accessible technologies. Those that did, mentioned a standard form of training like "*training modules, quizzes, and little scenarios asking 'should you open this email or not'*" (**P11**) that were not specifically considerate of the accessibility dimension of engaging with suspicious emails. This omission negatively affected our participants in reality as six of them disclosed they had been phishing or spam victims in the past. Participant **P8** said they fell for a phish and wondered whether a *broadly* accessible warning would have precluded them avoid an "*email requesting a change of the expiration date of a payment method*" because the phishing warnings shown in Figure 1 or Figure 3 don't explicitly refer to these details as 'personal information' nor to actions past 'clicking a link' such as changing expiration dates.

4.5 Design Input and Recommendations

Suspecting that the email banner warnings, in realistic conditions, might not particularly cater for aural reception and usability through assistive technologies, we asked our participants to share their preferences in how they would like to be warned about potential phishing spam or junk email. Past research with BLV users has successfully tested accessible warnings for screen readers that contain a bell sound, followed by a short introduction speech "warning! for details, press a shortcut key." [40]. The shortcut key, in turn, presented an overlay message that conveyed an overlay text of a general Gmail warning that urges users to be careful with the email message. Testing security warnings with suspicious content, though on social media instead of emails, blind and low vision users proposed several design options for placement of these warnings in order for them to be noticeable, comprehensible, and usable [30]. In agreement with the overlay warning approach from [40], these options included: (i) covers or banners that incorporate text that explains why the cover/banner is there in the first place and how the cover/banner content relates to a particular user's email/content; (ii) an audio signal or vibration that precedes the banner/content; and (iii) stark contrast, bold/large font, and standout colors that differ from the client/platform aesthetics so users dependent on magnifiers (or colorblind users) could notice the warning itself.

As we wanted to capitalize on the participants' immediate realistic experience with email banner warnings, in the four research questions we asked them to provide design input and recommendations that aim to address the interactive drawbacks they experienced through the tasks and reflections part of the previous research questions. Participants unanimously agreed that the current implementation of the real-life email banner warnings is accessible in *narrow* sense, i.e., it allows for a simple text-to-speech translation by a screen reader or presentation through a magnifier tool. Gmail's "*phishing*" utterance was seen as a potential opportunity to expand the accessibility in a *broader* sense, i.e., one that considers the usability and security aspects of the entire interactive warning experience for BLV people. For example, participants proposed replacing the "*phishing*" utterance with the wording "*Gmail marked this email as a phishing/spam; tab to see why*" (**P5**), and then on the tab action, a full warning "*explaining the features and the decision making of the particular email message that got it marked*."

The emphasis on explicitly "*tab to see why*" (**P15**), in participant **P9** view (and similarly to the shortcut key feature proposed in [40]), was to provide a baseline literacy that joins the accessibility and the usability of the phishing banner warnings. Participants reasoned a "*full transparency on filtering*" will help them better shape their engagement with emails in cases where Gmail/Outlook mistakenly apply (or omit) banners and puts the messages in a wrong inbox. Here, participant **P7** reasoned that if Gmail tells them that a "*mangled domain such as 'arnazon.com' instead of 'amazon.com' have been detected in this email*" then they would look for this cue for future emails, such as was the AWS *false positive* email we sent. sighted users, studies show, are able to benefit from such warning information [21]. A variant of the proposed warning alert that included a risk categorization level – akin to the defense readiness condition scale DEFCON – was proposed by participant **P7**. They reasoned that a "*numeric or categorization system*" would help BLV users "*quickly assess*" the email without the need to tab to the main warning.

An extended warning text preceding the email header as the one proposed above was particularly demanded by participants who had their screen readers on fast rate. Here, participant **P18** proposed adding a "*ping tone*, akin to the bell sound in [40], though not only *before* the warning, but also *after* it. In their view, the "*bookended*" warning alert will certainly get the attention of a blind user and make an "*immediate aural connection*" (**P7**) with the subsequent text of the warning. Here, participants like **P13** were aware that the alert should be "*a very short and somewhat unobtrusive sound, and also a configurable feature, so that [one] could enable/disable it or use your own sound*" as to prevent both non-adherence and habituation as a result of "*adding a second stream to the main aural stream of the screen reader*."

The interactive involvement of BLV users, past just presetting aural stream(s) as warnings, was also brought up as a potential improvement of the current elements. Making the banner warnings "*interactive elements*" with "*apprehensive text*" (**P3**) was seen as an improvement on the passive side of accessibility/usability so our participants recommended an active side too. Active for them was creating action elements

that were not just driven towards "*training the Gmail/Outlook filter*" (**P21**) (like the current "Looks safe," "Report not spam," and "It's not junk") but also helping them avoid both an immediate risk and the tediousness of future corrections. Here, participants felt it would be beneficial to have actions such as "*block this sender/subject*" (**P21**), "*delete email*," (**P3**), or "*move email to inbox*" (**P14**).

The low-vision participants, concordant with the recommendations and the ones noted in [30], stated that they would also benefit from a redesign that includes a "*relatable and comprehensible message*" (**P10**) in the banner text. Here, participants welcomed Gmail's choice to use distinguishing colors though they suggested using a pallet for colorblind users as the phishing warning banner, for example, comes in a stark red color. Participants also proposed an option to "*experimenting with a different shape than the rectangle*" (**P2**) so the captures the attention beyond the standardized angular design of email clients and the associated banners. This idea, in the view of participant **P14** who mentioned a new feature/shortcut of the JAWS screen reader called "smart glance," would equally help them quickly to "*areas that may stand out visually so it conveys those areas back to BLV users*."

5 Discussion

5.1 Accessibility and Usability Barriers

Our study aimed to uncover the accessibility and usability barriers in the engagement with the email banner warnings that BLV users experience under realistic conditions. These realistic conditions allowed participants to evaluate phishing, spam (Gmail), and junk (Outlook) emails with banners sent to their *own* emails instead of evaluating banners assigned to emails selected from phishing repositories [18, 40]. We also allowed participants to use their *own* device, their *own* client, and their *own* setup on assistive technology (including the speech rate or magnification ratio) instead of a setup where researchers control the device, the client, and the assistive technology for participation [18, 40]. As participants in reality might receive many emails with one type of banner warning (e.g., spam) and none of the others (e.g., phishing), we instigated a false positive email, that is a legitimate one that does not put participants at risk, to ensure they have both spam and phishing addressed to them. This allowed our participants to encounter email pretexts that pertain to their *own* email communication and not pretexts targeting mostly sighted users nor scenarios that might be unfamiliar to BLV users.

The Gmail and Outlook email banner warnings we evaluated in our study, designed for sighted users as visual frictions, did not account for the practice of many screen reader users to have a fast rate of text-to-speech translation, rendering the warning text in many cases of little use for them. In the Gmail phishing variant, the screen readers of our participants verbalized a "*phishing*" utterance that was assigned in addition to the warning. Appearing unexpectedly and sounding disjointed from the email (as it was followed by verbalization of the email header) it was also of little usability to our participants in deciding the nature of the email message ahead. The navigation was achieved with some effort, but participants would have preferred the banners (and utterances) to be implemented as intuitive interactive elements so they could better engage with the warning itself when sorting their email correspondence. The formatting of the banner warning text was also a barrier to our BLV participants because it confusingly asked them to nonetheless go through the email and decide if message the "looks safe," "report not spam," or indicate "it's not junk." This task, paired with the task of reverting incorrectly filtered emails, was deemed tedious by our participants and, in cases of 2-factor authentication emails, disadvantaged them to sighted users as it introduced a lot of timeouts.

Participants indicated that they do adhere to this narrow implementation of the email banner warnings, but nonetheless rely on their own judgment and use cues from the email header and body to decide how to proceed with a suspicious email. This judgment was based on aural or magnified "scanning" of the entire email [32], including the banners, which were scanned more so to *assess whether the warning banner was correctly applied to an email or not* (i.e., if an email was incorrectly labeled as spam). Here, our BLV participants enjoyed the advantage of avoiding phishing/spam emails that contained only attachments as their assistive technologies could not convey the content and thus led them to ignore these emails. As a strategy unique to BLV users, our participants pointed out cases of email pretext that included improbable or irrelevant requests contradicting their "human vulnerability" i.e., offering services that are offered mostly for sighted users.

Our participants didn't benefit much from the urgency of the warning because it left them wondering what was wrong with an email, what action to take, and whether the warning pertains to all of their email correspondence. For example, the Gmail phishing warning communicated danger, but the "basis" of that danger was unclear whether it related to "similar messages" the participant received or Gmail has noticed overall for all the Gmail users. The change of the warning sentence to a dialog with a question and answer for the Gmail spam banner variant was also confusing for our participants because of the absence of clear action of deleting the message instead of simply reporting it. Similarly for the Outlook wording, the inclusion of both junk/not-junk wording in subsequent sentences (with the latter actually being a link for "report not junk") and the lack of explicit reference as to who made the decision to "identify an email as junk" made it unclear how to act upon it.

5.2 Designing for Realistic Email Engagement

An adaptation towards usable accessibility when it comes to email banner warnings was successfully tested in [40] with

BLV participants. The implementation consisted of a bell sound, followed by a short introduction speech "warning! for details, press a shortcut key," which conveyed an overlay text of a general Gmail warning that urges users to be careful with the email message. This design, overall, achieved higher noticeability than the current Gmail designs. Participants who evaluated this adaptation also proposed redesigns that keep the audio warning, but instead of a shortcut key and an overlay text include just a warning text, either on the same page as the email header/body or replacing the email body. Some participants proposed using markers in the email list to help them distinguish ones needing further attention [40].

Our BLV participants based their recommendations relative to the interactive drawbacks they experienced through the tasks and reflections they performed in the study, as well as their past lived experiences, towards a "visceral" redesign of email banner warnings [31]. For example, participants proposed replacing the wording of the "*phishing*" utterance with a longer wording: "*Gmail marked this email as a phishing/spam; tab to see why*." This recommendation addresses for request for markers in the email list as an "early warning" proposed in [40] and might allow for higher noticeability of the warning (or we hypothesize so). The proposed adaptation of our participants allows for the full warning text to be implemented as either an overlay text, a text on the same page as the email header/body, or a text that replaces the email body. The linear tab action (and the equivalent action on a mobile device) could be configurable to allow users to choose the order where, in the order of email elements, the full warning will be read back to them (or not read at all).

Our participants also provided a design input to address the lack of comprehensibility and usability of the warning banners themselves, not just their *narrow* accessibility. Seeing "*why*" an email is marked as phishing, spam, or junk was deemed important for a BLV user as they can benefit from the banner warning not just for the email in question, but for other future emails, especially ones where Gmail/Outlook mistakenly apply (or omit) banners and put the messages in a wrong inbox. Transparently learning about automatic detection cues that they could also use, our participants felt that they could also benefit from nuanced formatting of the warning that helps them actively engage with emails. They proposed including a risk categorization level in the warning marker that would help BLV users "*quickly assess*" the email without the need to tab to the main warning.

The habits of using screen readers on "fast" were also considered in the design recommendations as participants saw the need for an alarm sound not just to notice the warning, but to grab and keep their attention. Here, our participants proposed adding a "*ping tone*" both before and after the warning marker. Aware of the disruptive nature of such an implementation (a concern also expressed by some of the participants in [40]), our participants thought it was also concerning from a habituation perspective as BLV users might increasingly ignore such a "*bookended*" warning alert after repeated exposure. To address this potential limitation, our participants proposed "*a very short and somewhat unobtrusive sound, and also a configurable feature, so that [one] could enable/disable it or use your own sound*."

Absent from the recommendations proposed in [40] was the redesign of the actions BLV users could take as part of the interaction with the warning. On this account, our participants requested creating action elements that were not just driven towards "*training the Gmail/Outlook filter*" for automated filtering (like the current "Looks safe," "Report not spam," and "It's not junk") but helping them avoid both an immediate risk and the tediousness of future corrections. For this, our participants proposed the inclusion of elements that allow to "*block this sender/subject*," "*delete email*," or "*move email to inbox*." Equally absent were the redesigns that cater to the needs of low-vision users that use screen magnifiers. Our low-vision participants contemplated a possible reformatting of the distinguishing banner colors to accommodate colorblind users with appropriate pallets as well as the use of "*different shapes than the rectangle*" for boxing the warning in order to achieve a higher noticeability beyond the standardized angular design of email clients and the associated banners.

5.3 Limitations

The realistic settings impose several limitations pertaining to our study. A limitation comes from the sample size that prevents generalization of the results to the entire population of BLV users, other email providers than Gmail and Outlook, and other devices than iOS iPhones, and Windows OS laptops. Another limitation is that we sampled English-speaking email users from the United States and used the email banner warnings in Gmail/Outlook in their English variant. Other language implementations of the warnings and the email client interface, as well as blind or low vision individuals from countries other than the US, might yield different results than ours. Aside from using only Gmail and Outlook (per our participant's own choice), a limitation comes from the fact that we used the implementation version of the respective banner warnings at the time of the study, that is, the first part of 2023. Future changes, adaptations, and improvements in the way Gmail and Outlook make their banner warnings accessible might render our results obsolete (which we sincerely hope will be the case soon). The current version of assistive technologies our participants used as part of the study could pose yet another limitation as any new features (e.g. advanced "smart glance") might transform how blind or low vision users access and use the email banner warnings, and with that, affect the overall findings.

A structural limitation is the choice of using the participants' spam/junk inbox instead of their own inbox. This research setup might have primed our participants with a hint that these emails were not to be trusted, even though

we took measures to minimize such a hint before participants did the tasks in our study. The priming, however, was a necessary compromise to introduce and test a novel methodology that brings experiments close to the real interaction with suspicious emails and away from laboratory settings (or settings that are not familiar or naturally occurring for participants, especially BLV users). We cannot fully generalize our results to BLV individuals' main inboxes because we were not permitted by our IRB to phish, spam, or tamper with Gmail/Outlook's filtering rules due to greater than the minimal risk to them. Another related limitation comes from the choice of the *false positive* email we used to initiate a phishing/junk warning. The particular sender and the email request itself might have contributed to a phishing tip-off in a greater capacity/effect than the warning itself. Other phishing emails might have yielded different results, but the only participant that received two phishing emails (**P17**) heeded the respective banner warnings in the same manner, giving at least a provisional validity to our findings in this respect.

Similarly, a limitation comes from the choice of spam/junk emails our participants arbitrarily selected in our study as any other message or an encounter with a legitimate email marked as spam/junk might have caused a different behavior around the banner warnings. Though we left our participants sufficient time and support to engage with the emails and the email banner warnings through the assistive technology of their choice, this might have not been insufficient for them to formulate a more informed expression about their overall suspiciousness assessment and ultimate decision about it. Despite all these limitations, and similar to qualitative studies in general, our study nonetheless provides rich accounts of BLV individual's' lived experiences with suspicious emails, which studies in laboratory settings hardly offer.

6 Conclusion

In this paper, we worked with 21 BLV email users to bridge the knowledge gap relative to how they experience, access, and use client warning banners for emails sent to their *own* email address. Our study reveals that BLV users access these banner warnings, but this access is not tailored to their needs, habits, and basic capabilities in realistic conditions. The non-intuitive usability of these banner warnings, thus, was experienced as a barrier to an equal security protection that sighted users enjoy by default. To address this exclusion, participants' own proposal was driven towards early warning alerts that include text and tones as well as comprehensible warning text that indicates the actual risk associated with each email that pertains specifically to them. We believe our results in realistic settings illuminate a compelling set of issues encountered by a population of email users dependent on assistive technologies, and as such, provide the locus for further inquiries that broadly consider the accessibility dimension of any inclusive human-centered security design.

A Recruitment Email

From: Researcher's Email
Subject: Research Study Participation
Date:
To: Potential Participant

Hello,

I am contacting you as you are my personal acquaintance and you are a low vision or blind person under the legal definitions [see the end of the email]. I have recently participated in a research study that was looking to learn more about how people with visual disabilities utilize email client interfaces through their assistive technologies. The study was conducted as an audio-recorded Zoom interview during which I was asked to arbitrarily select an email from my spam folder, access the subject line and the sender, and provide my experience with the way the email was presented in my email client.

I was asked to share personal information, such as age, gender, ethnicity/race, education, email use, and visual disability diagnosis. The research study was anonymous and I had the opportunity to skip any question that I wasn't comfortable answering. The study took around 45 minutes to complete and I was compensated with a $25 Amazon eGift Card.

If you are also interested in participating in this research study, please contact [redacted] over email at [redacted] or telephone: [redacted].

Low vision or blind person that is legally blind is defined as: Anyone with acuity of 20/200 or field-of-view of 20 degrees or less in the better eye with correction; low vision with acuity up to 20/70 and field-of-view larger than 20 degrees in the better eye with correction.

Best, Participant

B Interview Script

Announcement

This interview is being audio-recorded for research purposes. You may stop the recording at any time. Do you consent to being audio-recorded? Recording starts now.

Questions and Tasks

1. How often do you see suspicious emails in your inbox?
2. How often do you see legitimate emails in your spam folder?

   Note: A baseline of "suspicious" and "legitimate" is established, based on the the participant's interpretation of what they think is suspicious (or legitimate). In case this interpretation differs from the definition of phishing/spam suspiciousness/legitimacy [7], a brief explanation of "suspicious" and/or "legitmate" is provided. This is done as such to minimize the probability of priming participants for the subsequent tasks.

3. For the purpose of the study, could you please check your spam or junk folder. Can you please go over a few emails of your choice — one by one — you have received in this folder. For each, just open it and let your screen reader access the subject and the sender (or read the subject and the sender with your magnifier).

   Carefully open each of these emails and just review the contents. We would like to ask some questions about this particular experience:

4. Have you noticed anything unusual about these emails? Please specify in as much detail as you can.
5. Have you noticed any warnings, banners, notifications, or labels about these emails? Please specify in as much detail as you can.

6. How do these warnings, banners, notifications, or labels assist you in determining the legitimacy of the email they were substantiated to?
7. Do you usually adhere and/or plan to adhere to these warnings, banners, notifications, or labels when determining the legitimacy of the email they were substantiated to?
8. (optional) Did you payed particular attention to each of the warnings, banners, notifications, or labels you encountered while accessing the emails for this study?
9. What cues do you usually use to assess the legitimacy of emails, in general?
10. Have you received any phishing, spam, or suspicious email training?
11. Have you ever been a victim of a successful phishing or spam campaign? If you are comfortable, please share your experiences from this event(s).
12. What would you recommend about how these email **banner warnings** that you have encountered in the study should be made adequately accessible for blind or low vision individuals or individuals who use assistive technology like screen readers and screen magnification?
13. Anything else you want to add on this topic or your experience with warnings about emails?
14. Demographic Questions [Gender, Race/Ethnicity, Age, Education, Visual Self-Identification, Device, Provider, Client, Assistive Technology, frequency of email use]

C Codebook

Email Banner Warning Accessibility and Usability

- **Accessibility** Codes pertaining to the *accessibility* of the email banner warnings shown in Figure 1, 2, or 3.
  - **Not Accessible** The participant expressed that email banner warning is not accessible
  - **Accessible** The participant expressed that email banner warning is accessible
  - **Accessible with an extra cognitive effort** The participant expressed that email banner warning is accessible, but requires an extra cognitive effort to make sense of the warning text
- **Usability** Codes pertaining to the *usability* of the email banner warnings shown in Figure 1, 2, or 3.
  - **Usable** The participant expressed that email banner warning is usable
  - **Unusable** The participant expressed that email banner warning is not usable
  - **Partially Unusable** The participant expressed that email banner warning is partially usable, but it should be improved further

Email Banner Warning Adherence and Attention

- **Adherence** Codes pertaining to the *adherence* to the email banner warnings shown in Figure 1, 2, or 3.
  - **Not Adherent** The participant expressed that they did not adhere to the email banner warning
  - **Adherent** The participant expressed that they did adhere to the email banner warning
  - **Selectively Adherent** The participant expressed that they did selectively adhere to the email banner warning
- **Attention** Codes pertaining to the *attention* to multiple email banner warnings shown in Figure 1, 2, or 3.
  - **Payed Full Attention** The participant expressed that they did payed full attention to the email banner warning (individually/multiple encounters)
  - **Payed Partial Attention** The participant expressed that they did payed partial attention to the email banner warning (individually/multiple encounters)
  - **Payed No Attention** The participant expressed that they did not payed attention to the email banner warning (individually/multiple encounters)

Email Assessment, Training, and Past Experience

- **Email Assessment** Codes pertaining to cues, criteria or rules of thumb used to determine a legitimacy of an email.
  - **Aural Cues** The participant expressed that relied on aural cues such as grammatical inconsistencies, typos, misspellings, out-of-order symbols
  - **Logical Cues** The participant expressed that relied on logical cues such as the improbability of an email request
  - **Elements in the Email** The participant expressed that relied on cues in the email structure such as the subject, email sender, timestamp, and body without attachments
- **Email Training** Codes pertaining to training about spotting and dealing with suspicious emails;

  - **Didn't Receive a Formal Training** The participant expressed that they did not received a formal training about spotting and dealing with suspicious emails, including phishing and spam
  - **Received a Formal Training** The participant expressed that they received a formal training about spotting and dealing with suspicious emails, including phishing and spam

- **Email Phishing/Spam Past Experience** Codes pertaining to instances of phishing/spam victimization in the past;
  - **Fell victim of a phish/spam** The participant expressed that they did fell a victim of a successful phish/spam in the past
  - **Didn't fell victim of a phish/spam** The participant expressed that they did not fell a victim of a successful phish/spam in the past

Accessibility and Usability Banner Warning Redesign

- **Accessibility Improvements** Codes pertaining to accessibility improvements
  - **Popup/Cover** The participant recommends the banner warnings to be implemented as pop-ups or overlays to give a sufficient non-visual friction for them before they access the suspicious email
  - **Warning Sound** The participant recommends the banner warnings to be augmented with a sound alarm in order to give a sufficient audio friction for them before they access the suspicious email

- **Usability Improvements** Codes pertaining to usability improvements
  - **Severity/Risk Level Indicators** The participant recommends for the banner warnings to include severity/risk level indicators to better discriminate between various levels of threats and risk exposures based on the email type

D Debriefing

Thank you for participating in our research on how users who are low vision or blind experience and utilize email warnings. This study aimed to examine whether people pay attention to warnings as a cue before they proceed to the website or not. The emails you selected might be phishing, scam, or spam so we suggest you proceed with caution and better delete them. So far, no research exists on how low vision or blind users are experiencing and utilizing emails warnings under realistic conditions. This is why we asked you to select and examine one email from your spam/junk folder. The AWS email you reviewed as instantiated by us, the researchers, and the email is harmless – that is, it is actually sent by AWS but Gmail/Outlook assigned the phishing banner warning nonetheless (we refer to this email as "*false positive*." You can safely ignore or delete this email. There is no negative consequence to you nor your past, present, or future involvement and use of the AWS services.

It was necessary for the researchers to withhold this information from you regarding the purpose of the study to ensure that your actions and answers to questions accurately reflected your behavior under realistic conditions. Your participation in the study is important in helping researchers identify the best ways to address the accessibility of the warnings by email providers that are equally usable and result in safe behavior specifically for blind or low vision users. You have the option to option to withdraw from the study after finding out about the mild deception now or no later than 30 days period after the data collection concluded. We will anonymize your the transcript of the interview, and to be able to remove your entry from the data bank of our research interviews you might need to provide descriptions of answers and reference to the spam/junk emails you accessed in your inbox so we can attempt to uniquely match your interview (something that only you know and no other person could use to identify you in the data bank).

The final results of this study will be published in a peer-reviewed journal or conference. Your results will not be available individually and your participation will remain confidential. If you have any additional inquiries please contact [redacted]. If you have questions about your rights as a research subject, you may contact [redacted] in the Office of Research Services at [redacted]. You may also contact [redacted] Office of Research Services if your questions, concerns, or complaints are not being answered by the research team, you cannot reach them, or you want to talk to someone besides them.

INVALIDATE+COMPARE: A Timer-Free GPU Cache Attack Primitive

Abstract

While extensive research has been conducted on CPU cache side-channel attacks, the landscape of similar studies on modern GPUs remains largely uncharted. In this paper, we investigate potential information leakage threats posed by the caches in GPUs of NVIDIA's latest Ampere and Ada Lovelace generations. We first exploit a GPU cache maintenance instruction to reverse engineer certain key properties of the cache hierarchy in these GPUs, and then we introduce a novel GPU cache side-channel attack primitive named INVALIDATE+COMPARE that is designed to spy on the GPU cache activities of a victim in a timer-free manner. We further showcase the use of this primitive with two case studies. The first one is a website fingerprinting attack that can accurately identify the web pages visited by a user, while the second one uncovers keystroke data entered via a virtual keyboard. To our knowledge, these stand as the first demonstrations of timer-free cache side-channel attacks on GPUs.

1 Introduction

Over the years, dedicated graphics processing units (GPUs) have emerged as essential components in modern computer systems. On one hand, they are utilized to handle high-quality graphics rendering tasks, ensuring smooth frame rates with fine texture details and rich color depths. On the other hand, they provide the processing power required for executing a broad spectrum of compute-intensive applications, such as physical dynamics simulation and deep learning.

Undeniably, NVIDIA has established itself as the dominant player in the GPU market. In recent years, its products of the Ampere and Ada Lovelace generations (e.g., those in the RTX 30-/40-series) have been driving substantial revenue, thanks to their industry-leading performance and the high demand they enjoy across various sectors [13, 31, 44, 66].

However, despite the widespread adoption of these GPUs, their potential security issues, from the hardware perspective, have not been as thoroughly studied as those of CPUs. As an outstanding example, concerns about information leakage via CPU caches have received extensive research attention [2, 9, 10, 17, 25, 30, 47, 48, 51, 56, 69, 73], but similar problems are under-explored with respect to GPU caches. Since many tasks running on a GPU operate on sensitive information, such an oversight may lead to unanticipated security breaches.

Echoing the presumed implications, in this work, we aim to undertake a study on potential information leakage through caches in contemporary NVIDIA GPUs and demonstrate relevant side-channel attacks that compromise user confidentiality. Yet, to achieve this, several challenges specific to these GPUs need to be addressed.

The first challenge lies in the lack of knowledge about such GPU caches. To develop cache side-channel attacks, a level of understanding on certain properties of the cache is necessary (e.g., whether it is inclusive, exclusive, or non-inclusive and how its state can be deterministically manipulated). Although there exist a few reverse-engineering works on GPUs [20, 21, 33, 53, 71], most of them deal with obsolete models and all of them only concentrate on the cache structures without delving into the policies that dictate cache operations. Therefore, we must make efforts to bridge this knowledge gap.

The second one revolves around finding a reliable method to monitor GPU cache activities. Conventionally, CPU cache side-channel attacks exploit the timing discrepancies between cache hits and misses to infer cache access patterns. While the approach is largely successful, noise in timing measurements may degrade its effectiveness [2], which can also be an issue in the context of GPUs. Nevertheless, a more pronounced issue of using timers in GPUs is that unlike CPU timestamp counters, which increment in a frequency-invariant fashion [29], their GPU equivalents are susceptible to frequency shifts. This means that a cache hit at a high performance level may require as many cycles as a cache miss at a low level. For instance, an RTX 3080's frequency dynamically varies between 210MHz and 2100MHz, and at its peak frequency, an L2 cache hit takes about 530 cycles, while at around 550MHz, an L2 miss takes roughly the same amount. Certainly, the problems associated with timing can be bypassed if a timer-free attack primitive, similar to those for CPUs [2, 23, 74, 76], is available.

The third challenge stems from the manner in which GPUs handle the execution of concurrently running GPU programs. Unlike multi-core CPUs that allow multiple processes to run simultaneously, GPUs orchestrate the concurrent execution of programs using a time-sharing mechanism. The duration of a GPU time slice is long enough to accommodate a number of memory operations, and we observe that nearly all of the GPU cache sets are accessed within each time slice in common GPU workloads. As a result, merely deducing if a GPU cache set has been accessed or not is insufficient for mounting GPU cache side-channel attacks. We need an approach to extracting more fine-grained information from the GPU cache.

Taking advantage of a GPU cache maintenance instruction named `discard`, we have successfully addressed all of these challenges and formulated a novel, timer-free GPU cache side-channel attack primitive dubbed as INVALIDATE+COMPARE. Using this primitive, we demonstrate two side-channel attacks targeting the latest NVIDIA Ampere and Ada Lovelace GPUs. The first one is a website fingerprinting attack, similar to those described in [27, 38]. However, unlike these prior studies that exploited software flaws (already fixed) in GPU drivers, our attack is built on vulnerabilities of hardware cache, which is more difficult to thwart. The second attack we showcase is to infer specific keystrokes made by a user on a virtual keyboard. While it has been shown that typing on such a keyboard can be recovered via monitoring cache lines of graphics libraries on the CPU side [69], our attack reveals that such sensitive information can also be extracted from GPU cache. To our knowledge, these two case studies stand as the first timer-free cache side-channel attacks on GPUs.

The main contributions of this paper are:

- We leverage the incoherence among GPU L1 caches and the undocumented semantics of the `discard` instruction to form a new method for reverse engineering GPU cache properties. We show that the approach allows us to unveil certain key cache characteristics in the latest NVIDIA GPUs for the first time.
- We introduce INVALIDATE+COMPARE, which is a new GPU cache side-channel attack primitive and also the first of its kind to be timer-free. To put the primitive into action, we address challenges like how to synchronize cache monitoring steps with GPU context switching and how to measure fine-grained information regarding the degree of contention within a GPU cache set.
- We use the formulated attack primitive to conduct two case studies. In the first, we illustrate a highly accurate website fingerprinting attack that maintains its effectiveness over time, and in the second, we present a keystroke extraction attack against the OS's bundled virtual keyboard, showing its potential to steal a user's login password.

Responsible disclosure: We have disclosed our findings to NVIDIA, who has acknowledged our work.

2 Background

2.1 GPU Architecture

GPUs have transformed from specialized graphics rendering devices into highly programmable accelerators capable of executing a wide range of parallel workloads. The primary compute units in a modern GPU are called streaming multiprocessors (SMs), each of which comprises an array of simple cores. SMs are designed to execute groups of threads, referred to as warps, in a single-instruction multiple-thread (SIMT) fashion. In terms of NVIDIA GPUs, a warp consists of 32 threads. When multiple warps execute on an SM, they are scheduled by a hardware unit in the SM. In general, there are tens of SMs in a high-end GPU (e.g., NVIDIA RTX 3080 houses 68 SMs).

A GPU uses its on-board memory to hold data slated for processing. Such on-board GPU memory typically comprises several DRAM chips that are of special types tailored for high bandwidth (e.g., GDDR6). Each DRAM chip is connected with the GPU via a dedicated memory controller. Note that the GPU memory operates independently from the main memory on the CPU side and is managed in its own manner. Transferring data between the main memory and GPU memory is facilitated by the PCIe bus.

GPU memory access latency is very high (in fact much higher than that of main memory). To help counteract such significant latency, caches are used. A modern GPU usually has a two-level cache hierarchy. SMs have private L1 caches, a portion of which can be repurposed as scratchpad memory. All SMs share an L2 that serves as the last-level cache (LLC). In NVIDIA GPUs, the cache line size is 128B [22]. Similar to the CPU counterpart, the LLC of a GPU is also set-associative and physically tagged.

2.2 GPU Programming

GPUs can always be programmed using graphics rendering APIs (e.g., OpenGL [7] and Vulkan [6]). These APIs provide the framework for developing shaders, which are specialized GPU programs that dictate how graphics are generated and drawn on the screen. However, when using GPUs for broader computational tasks, a more general-purpose programming language is needed.

As a standard practice, NVIDIA GPUs are programmed with CUDA for general-purpose parallel computing [41]. In CUDA, GPU computational tasks are defined within functions known as kernels. When a kernel gets launched on a GPU, it is instantiated as a grid of thread blocks. Each thread block contains a number of threads and is assigned to an SM by the CUDA runtime for execution. The count of thread blocks and the threads in each block need to be specified upon launch.

While CUDA provides a high-level GPU programming paradigm, a low-level assembly-like language named Parallel

Table 1: GPU models tested in Section 3.

Grade	GPU Model	Generation	SM Cnt.	Memory Sz.	L2 Sz.†	Release
Consumer	RTX 3060	Ampere	28	12GB	3MB	Jan 2021
	RTX 3080	Ampere	68	10GB	5MB	Sep 2020
	RTX 4060	Ada Lovelace	24	8GB	24MB	May 2023
Server	A2	Ampere	10	16GB	2MB	Nov 2021
	A10	Ampere	72	24GB	6MB	Apr 2021

† Except for RTX 3080 whose L2 cache size is officially provided by NVIDIA [43], the data for the other models are sourced from TechPowerUp [62–65].

Thread Execution (PTX) can also be used to program NVIDIA GPUs [45]. PTX exposes more details about GPU internals and offers finer control over hardware resources. The `asm()` statements can be leveraged to embed arbitrary PTX code within a CUDA kernel function. Notice that PTX is not the actual assembly language used by NVIDIA GPUs. Instead, it plays the role of an intermediate representation, acting as an abstract ISA that is compatible across multiple generations of NVIDIA GPUs.

2.3 GPU Context

Regardless of the programming language or API being used, an instance of a GPU program in execution is referred to as a GPU context that is analogous to a CPU process. GPUs employ a time-sharing mechanism to concurrently run multiple GPU contexts. Basically, inside a GPU, there is a hardware scheduler that multiplexes the execution of GPU contexts by allocating each context a time slice. Within its time slice, a context can access available resources on the GPU.

Although an NVIDIA GPU does not support simultaneous execution of multiple contexts, a feature of the CUDA runtime named multi-process service (MPS), when enabled, can merge several running CUDA programs into a single GPU context for better resource utilization. By default, MPS is disabled and users typically do not turn it on. Therefore, in the usual setup, GPU contexts of running CUDA programs are time-sliced. Moreover, MPS is specific to CUDA and does not combine graphics rendering GPU contexts.

3 GPU Cache Characteristics

In this section, we explore the cache hierarchy in NVIDIA GPUs and uncover the key properties that pave the way for the construction of our new attack primitive. Both the exploration and the primitive hinge on the use of a special GPU cache maintenance instruction, which we shall present first in the following discussion.

3.1 The `discard` PTX Instruction

Undoubtedly, the security community has been familiar with the `clflush` instruction in x86 CPUs and the various cache side-channel attacks it enables [8, 10, 69, 73]. Essentially, this unprivileged instruction can be used to flush a cache line from all the cache levels in an x86 processor, and if the cache line is dirty, it also ensures that the contents in the cache line are written back to the main memory [16].

In NVIDIA Turing and earlier GPUs, no instruction similar to `clflush` is available. On the other hand, starting with the Ampere microarchitecture, NVIDIA has introduced a new PTX instruction named `discard` to facilitate removing cache lines. The syntax[1] of this instruction is as follows:

```
discard.L2   [addr], 128;
```

where the *addr* operand specifies a GPU memory address that needs to align on a 128-byte boundary. According to the official documentation [45], the semantics of the `discard` instruction is to invalidate any data in the address range [*addr*, *addr* + 128) cached in L2 without writing the data back to GPU memory.

Although it is not specifically mentioned in [45], given the fact that the cache line size is 128B in NVIDIA GPUs [22], we can deduce that `discard` operates on a single cache line. Notice that, similar to the CPU side, the GPU also employs paging-based virtual memory, and the address specified by the *addr* operand is a virtual one. Naturally, GPUs also require virtual-to-physical address translation, the details of which have been revealed in [78].

If we compare the semantics of the CPU's `clflush` and the GPU's `discard` instructions as described in their respective official documentations, we can identify two main differences. First, `clflush` removes the target cache line from the entire cache hierarchy, while `discard` is only mentioned to remove the cache line from L2, which is the LLC in a GPU. Second, it is important to highlight that `clflush` writes modified data in the removed cache line back to memory, whereas `discard` does not write any data back to memory, even if the target cache line is dirty. From this aspect, `discard` bears resemblance to the privileged `invd` instruction in x86.

3.2 Inclusion Policy

NVIDIA has never disclosed any information on whether the L2 cache in its GPUs is inclusive, exclusive, or non-inclusive. Because the load instruction `ld` brings data into both L1 and L2 caches by default [45], L2 must not be exclusive. Interestingly, it is mentioned in [45] that L1 caches are not coherent. We know that the main reason for having an inclusive LLC is to simplify the design of cache coherence protocols, and thus we speculate that L2 in NVIDIA GPUs is non-inclusive. To shed light on this matter and also understand more on the `discard`'s effects, we perform the following experiment illustrated in Figure 1.

Suppose there is a data block `B` in GPU memory whose initial value is 0. To begin with, we arbitrarily choose two SMs, `X` and `Y`, to load `B` into L2 as well as their own L1 caches.

[1] The exact syntax of this instruction is `discard{.global}.`*`level`* `[`*`addr`*`], `*`size`*`;`. Nevertheless, `.global` can be omitted, *`level`* can only be `L2`, and *`size`* can only be 128.

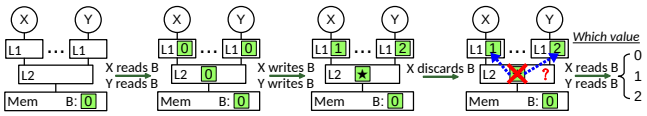

Figure 1: Experiment to further understand `discard` and determine if L2 is inclusive or non-inclusive. (★ is used to represent an indeterminate value, and Section 3.3 explains why it can happen.)

Next, we let `X` overwrite `B` with the value 1 and let `Y` overwrite `B` with the value 2. Since coherence is not maintained among L1 caches of SMs [45], the updates made by `X` and `Y` will be simultaneously kept in the corresponding L1 caches without invalidating each other. We then let `X` execute the `discard` instruction on `B` to remove it from L2. After that, we have `X` and `Y` read `B` again to examine which value each of them retrieves, respectively.

We conduct this experiment on multiple GPUs, which are listed in Table 1, including three very popular consumer-grade ones (e.g., RTX 3060) and two server-grade ones (e.g., A10). We observe a consistent result on all the GPUs, which is: `X` retrieves 0 and `Y` retrieves 2. From this result, we can draw the following conclusions. ❶ L2 in these GPUs is non-inclusive; otherwise, the removal of `B` from L2 should have enforced the invalidation of the corresponding cache line in `Y`'s L1. ❷ `discard` does not remove the target cache line from the entire cache hierarchy. Instead, it removes the cache line from L2 and also from the L1 cache of the SM issuing the instruction, which is not specified in the documented semantics. ❸ When an L1 cache miss occurs, the needed memory block is fetched from lower levels of the GPU memory hierarchy rather than the sibling L1 caches; if this were not the case, `X` should have obtained 2.

Notice that there is no mechanism in CUDA to synchronize concurrent execution on different SMs. To ensure that one SM will not perform an operation (e.g., `X` discards `B`) until the other SM has finished its required predecessor (e.g., `Y` modifies `B`), we insert a sufficiently large delay before the operation to enforce the intended ordering.

3.3 Write Policy

In the aforementioned experiment, it is clear that updates do not write through the whole cache hierarchy to the GPU memory (otherwise, `X` would not have retrieved 0). Nevertheless, we do not know how writes are handled between L1 and L2. To gain insight into this particular write policy, we conduct the procedure shown in Figure 2.

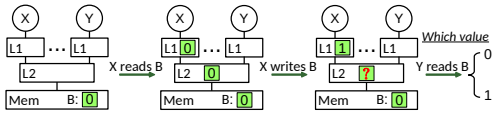

Figure 2: Experiment to check if L1 is write-back or write-through.

Similar to the study performed above, we utilize two SMs and a memory block with an initial value of 0. Instead of having both SMs read and modify `B`, here we only use `X` to do so. After `X`'s update, we let `Y` read `B` to check its value. (An auxiliary experiment in Appendix A also confirms that `B` has never been evicted from `X`'s L1 cache.) We find that `Y` always retrieves 1 regardless of the GPU and selected SMs.

This behavior is not surprising if considered from the CPU's perspective. However, as discussed earlier, a GPU's L1 caches are incoherent, and its L1 cache misses are serviced by L2 or GPU memory rather than by any sibling L1 caches. Therefore, such behavior manifests the fact that when `B` is written in L1, it is also updated in L2. In other words, the write policy employed by GPU L1 caches is *write-through*. (The whole write-through process should be atomic.) Surely, due to this design, if multiple SMs write to the same address concurrently, the final value in L2 depends on the order of these writes.

From our previous reasoning, it is not hard to deduce that L2 is a write-back cache. As a simple verification, after `X` writes 1 to `B`, we let `Y` sequentially access a very large array, and then have `X` use `discard` to invalidate `B`. When `X` reloads `B` from GPU memory, it obtains 1. If dirty cache lines in L2 were not written back to memory, `X` should have retrieved 0.

3.4 Write Allocation Policy

It is said that write-back caches often use the write allocate scheme (namely, when a write operation misses in the cache, the corresponding block is fetched and put in the cache for being updated), while write-through caches often use the no-write allocate scheme (namely, when a write operation misses in the cache, data is directly written to the lower level without being allocated space in the cache) [50]. Following the steps shown in Figure 3 and Figure 4, we can easily examine the write allocation policy used in GPU L1 and L2 caches, respectively.

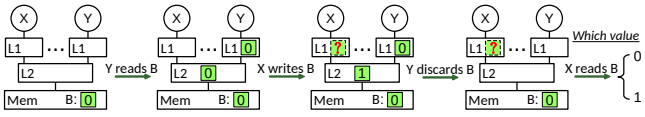

Figure 3: Experiment to examine the write allocation policy of L1.

As illustrated in Figure 3, `Y` loads `B` first, and then `X` writes 1 to `B`. In this case, `X` experiences an L1 cache miss when writing `B`. Subsequently, `Y` discards `B`, after which, `X` reads `B` to check its value. We find that the value read out by `X` is always 1. This observation indicates that L1, although write-through, employs the write allocate scheme; because if the no-write allocate one were used, `X` should have read `B` from GPU memory, which still has the initial value 0.

Similarly, as illustrated in Figure 4, we can engineer a situation where `X` will experience an L2 cache miss when it

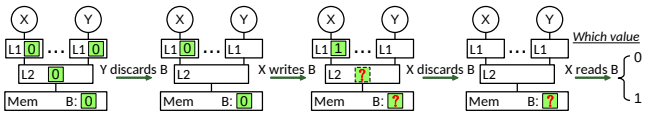

Figure 4: Experiment to examine the write allocation policy of L2.

modifies B. Despite a hit in L1, L2 always receives X's write operation due to the write-through property of L1. Thus, if L2 employs the no-write allocate policy, B in GPU memory will be updated; conversely, if L2 uses the write allocate scheme, B in memory will preserve its original value. To check if the value of B in GPU memory is updated, X can discard B first and then read it. We discover that L2 caches in all the tested GPUs use the write allocate scheme.

Exploiting timing differences between L1/L2 cache hits and misses, we can reach the same conclusions. Even though timing can be used for examining both inclusion and write allocation policies, we need to emphasize that it may not be easily used to infer the write policy.

3.5 L1 Cache Auto-Flushing

As outlined in Section 2.3, by default, GPU contexts are scheduled to take turns executing on the GPU. An interesting behavior we have noticed is that context switching automatically flushes all the L1 caches. The experiment shown in Figure 5 demonstrates this auto-flushing behavior.

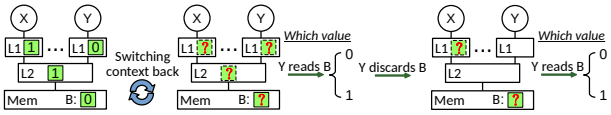

Figure 5: Experiment to demonstrate L1 cache auto-flushing.

At the outset, we prepare an incoherent cache hierarchy state in which B holds different values in the L1 caches of X and Y. This can be easily achieved by having Y load B first and then X write 1 to B. It is apparent that if B persistently resides in Y's L1 cache, Y will never see the value of B as 1. To induce GPU context switches, we create and execute a dummy CUDA program that has a PTX branch instruction infinitely looping on itself. Accordingly, the chance that L1 caches are evicted by other memory accesses is minimized. After the context is switched back, we find that Y, regardless of which SM it is, always sees the value of B as 1. This observation indicates that GPU context switching triggers L1 cache flushing.

To verify that GPU context switching does not flush L2 and write dirty cache lines back to memory, we subsequently let Y discard B, followed by a load operation on B. In this case, we find that Y retrieves 0, i.e., the original value of B. This implies the fact that L2 is not flushed; otherwise, Y should have consistently seen the same value no matter if discarding B was performed or not.

3.6 Associativity and Replacement

Due to its auto-flushing behavior, L1 will not pose challenges to cache side-channel attacks on GPUs, even though the LLC is non-inclusive. Consequently, we only focus on the L2 cache (i.e., the LLC) here for the sake of brevity.

Given a GPU, we begin by determining the associativity of its L2 cache. For this purpose, we derive a list of addresses $\{A_0, A_1, \cdots\}$ that are mapped to an identical L2 cache set (see Section 4.2 for the detailed procedure), and access them one-by-one to find how many of them the cache set can hold. For each GPU tested, we observe a peculiar behavior. ❶ If we access the addresses using only st, at most 7 of them can be kept in a cache set. ❷ If we access the addresses using only ld, up to 16 of them can be finally kept in a set. ❸ If we access the addresses using both ld and st, a cache set can still hold 16 blocks, but under certain access patterns, up to 8 can be brought in by st. Thus, we deduce that the associativity of L2 is 16 in NVIDIA GPUs, but a cache set's 16 ways are not used proportionately by loads and stores. We conjecture that NVIDIA aims to maintain a dirty cache line ratio $\leq$50% in its L2 design.

We further examine the dynamics of replacement within L2. When only st is used, we find that the replacement among the 7 dirty cache lines simply adheres to the LRU policy. Intriguingly, when only ld is used, replacements start appearing regularly as a cache set is being filled over 9 ways, but after all the 16 ways are occupied, the replacement behavior conforms to LRU (refer to Appendix B for more details).

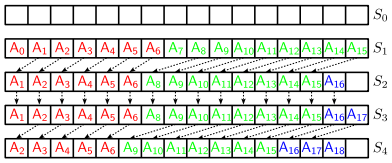

Figure 6: Priming an L2 cache set (writing $A_0, \cdots, A_6$ followed by reading $A_7, \cdots, A_{15}$) and then accessing other addresses.

Our attack primitive needs to prime cache sets while making certain cache lines in them dirty. Apparently, due to the limit on the number of dirty cache lines in a set, we cannot use st alone to achieve priming. In our case, we look to verify whether 7 stores followed by 9 loads, or 9 loads followed by 7 stores, can effectively populate a cache set, and we are also interested in the replacement behavior in response to new accesses after a cache set is populated.

Although filling an empty cache set with only ld requires more than 16 accesses (see Appendix B), we observe that a combination of 7 stores and 9 loads, adding up to 16 accesses, can effectively occupy an unused set. (The state S_1 in Figure 6 illustrates the case where 7 stores followed by 9 loads.) This implies that L2 may not manage dirty and clean cache lines in the same way.

When accessing new addresses after a cache set is filled

with 7 stores and 9 loads, we find an interesting phenomenon that the eviction patterns do not align with any known replacement policy, which is depicted in Figure 6. We can see that accessing A_{16} forces out not only the least recently used A_0 but also A_7. While A_7 has been accessed more recently than $A_1, \cdots, A_6$, it is the least recently read one via `ld`. Our hypothesis is that when the least recently used cache line is dirty and gets evicted, the least recently read one will also be evicted. The state transition from S_3 to S_4 in Figure 6 lends support to this hypothesis. Note that the opposite is not true. If the least recently used cache line is clean and becomes evicted, the least recently written one will not be evicted.

Despite the L2's unusual replacement behavior, we find that after cache lines in a primed cache set are evicted, the state can be reestablished by performing 7 stores and 9 loads again. This determinism suffices for the scope of this study, and the detailed analysis of its replacement policy is reserved for future research. Following standard nomenclature, the addresses corresponding to the 7 stores and 9 loads are said to form an eviction set, and these addresses are referred to as congruent.

4 INVALIDATE+COMPARE

Based on the learned properties of the GPU cache hierarchy, we formulate the INVALIDATE+COMPARE attack primitive for spying on a victim's GPU cache activity in a timer-free manner. Given an L2 cache set along with an eviction set $\{A_0, \cdots, A_6, A_7, \cdots, A_{15}\}$, the initial primitive consists of the following five steps:

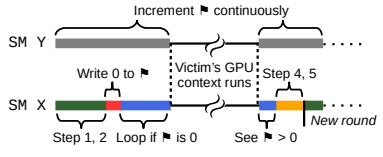
Step 1: Write new values to addresses $A_0, \cdots, A_6$.
Step 2: Read the values at addresses $A_7, \cdots, A_{15}$.
Step 3: Wait for the context to be switched away and back.
Step 4: Execute the `discard` instruction on A_0.
Step 5: Read the current value at A_0 for comparison.
- If it is the original value, the victim did not access the cache set during its running period.
- If it is the newly written value, the victim accessed the cache set during its running period.

The rationale behind the primitive is that if the victim fetched any data into the cache set, the dirty cache line corresponding to A_0 would have been evicted before we attempted to invalidate it and hence the value within it would have been committed to the memory; otherwise, no dirty cache lines were evicted and when the one associated with A_0 became invalidated, the value within it would be lost in accordance with the `discard`'s semantics. Therefore, the value at A_0 after performing the invalidation can accurately reveal if the cache set is accessed by the victim. (The reason for the initial two steps has been discussed above in Section 3.6.)

In this primitive, after Step 1 and 2 prepare the cache set state, in Step 3, the attacker shall wait for the victim to carry out some GPU computation. In other words, the attacker needs to wait for the victim's GPU context to get scheduled and later the attacker's GPU context will regain control again. Hence, this step in essence is the attacker awaiting her own GPU context to be switched out and then back in.

An SM is capable of simultaneously spying on multiple cache sets, each of which is monitored by a separate thread. For NVIDIA GPUs, a warp consists of 32 threads. When there are multiple warps executing on an SM, they are scheduled by a hardware scheduler unit. Considering the availability of tens of SMs in a GPU, we are able to monitor hundreds of cache sets in parallel.

It is important to highlight that the primitive *in its current form* is intended only for illustrative purposes to aid in comprehension, and may not have practical utility in real-world scenarios. This is because we notice that all (or most of) the L2 sets appear to be accessed after a GPU context switch. To make the INVALIDATE+COMPARE primitive useful, we need to refine it, which will be described later in this section.



4.1 GPU Context Switch Detection

An important question we have yet to address pertains to the realization of Step 3. More precisely, how can we find out that the execution of the GPU context has been preempted and then resumed? Here we propose two approaches, and both of them are effective for Ampere GPUs, but only the second one is suitable for GPUs in the Ada Lovelace generation.

In the first approach, we slightly relax the timer-free claim by allowing the use of `%clock64` that is the GPU's timestamp counter. (The measurement phase consistently remains timer-free.) Our approach, as depicted in Figure 7a, keeps cycling through a tight loop until an iteration takes more time than a specified threshold `T`. This is indicative of an event where the GPU context has been switched away and resumed in that iteration, since the looping time is very stable in the absence of context switching. Furthermore, `delta` can even help us capture useful temporal information regarding competition under the GPU scheduling.

```
1 prev = 0;
2 start = clock64();
3 do {
4   delta = clock64() - start;
5   if (delta - prev > T)
6     break;
7   prev = delta;
8 } while (1);
```

(a) First approach.

(b) Second approach.

Figure 7: How to detect if the context is switched away and back.

While this method is effective on Ampere GPUs, it does not function as intended on Ada Lovelace GPUs. We discover that, unlike the counter in Ampere GPUs, `%clock64` in Ada Lovelace ones (e.g., RTX 4060) does not represent an actual

clock; instead, it acts as a logical clock specific to each GPU context. Consequently, during a context switch, `%clock64` of one context does not increase to account for the execution time of other GPU contexts.

The second approach, which does not rely on the timestamp counter, is built on the L1 auto-flushing behavior and some other special properties of the GPU cache hierarchy. In this approach, aside from the SMs tasked with monitoring cache sets (dubbed as spy SMs), an additional SM is designated to continuously increment a flag variable. This flag variable should be mapped to a non-monitored set to prevent interference with the monitoring process. After a spy SM has finished the first two steps, it writes 0 to the flag and then repeatedly checks it until the value is no longer zero. Given the L1's incoherent and write allocate nature, copies of the flag variable with two different values reside in the L1 caches of the spy SMs and the SM dedicated to incrementing the flag variable. Because of the L1's write-through nature, each increment to the flag results in an immediate update in L2. It is not hard to see that the spy SMs cannot observe the updated flag in L2 until the copies residing in their own L1 caches are flushed due to context switching.

The second approach is visualized in Figure 7b, where `X` is a spy SM and `Y` is the SM responsible for incrementing the flag. Note that the effectiveness of the approach is not influenced by whether or not the flag is evicted from L2 during the execution of the victim's GPU context. Similar to the `delta` value in the first approach, the flag value here can also be used for capturing temporal information. We shall underscore that the second approach works well on GPUs in both Ampere and Ada Lovelace generations.

4.2 Eviction Set Construction

The problem of finding congruent addresses to form eviction sets for CPU caches has been studied extensively [2, 30, 59, 68]. In terms of our study, we adapt the commonly used method in [30] by replacing its timing-based eviction checking with the function shown in Algorithm 1. The principle of this timer-free checking is essentially the same as that of the primitive, namely, the written value will not survive unless the cache line has been evicted before the invalidation.

Notice that, due to the limitation on the number of dirty cache lines in an L2 cache set (as discussed in Section 3.6), we need to run the method multiple times with respect to different GPU memory chunks to accumulate sufficient congruent addresses. While this is just a minor issue, a trickier problem we encounter is that a large amount of online noise (e.g., introduced by time-sharing) may cause the finding process to fail. Certainly, if it were possible to derive eviction sets offline only once and subsequently use them directly for online attacks, these inconveniences could be eliminated. We confirm that such a "one and done" approach is feasible.

First of all, unlike CPUs where the memory configuration

Algorithm 1: Timer-free eviction checking function.

```
inputs  : An address a and a set of addresses S.
output  : If a can be evicted by S, true; otherwise, false.
function check_eviction(a,S):
    write 0xdeadbeef to a;
    for each address e in S do
        write an arbitrary value (e.g., 0) to e;
    execute the discard instruction on a;
    read the current value v at a;
    if v is equal to 0xdeadbeef then
        return true;
    else
        return false;
```

can be altered, the memory setup in a GPU is not only static but also identical for all instances of the same model. In other words, any given physical address will be mapped into the same L2 cache set on two GPUs of the same model (e.g., an ASUS RTX 4060 and a PNY RTX 4060). Second, we observe that NVIDIA drivers follow a pattern of allocating physically contiguous GPU page frames and maintain a consistent starting address for memory allocation; namely, there is minimal randomization involved in this allocation process. Therefore, we can construct eviction sets against a GPU offline and use them online.

We should emphasize that while the driver begins memory allocation at low physical addresses, we construct eviction sets using memory chunks at a relatively high address (e.g., `0x20000000` in our case studies). This strategy reduces the likelihood of other GPU contexts occupying our required page frames. At the onset of an online attack, by trying different sizes of padding prior to memory allocation and testing if the prepared eviction sets work, we can identify the right location. It is worth mentioning that each padding size is a multiple of the GPU page size, which is 2MB. This large stride allows the search process to be completed swiftly.

We have also tried to derive the mapping function from the constructed eviction sets for each GPU we experimented with. Unfortunately, we have not been successful in this endeavor. We observe that the number of L2 cache sets in all the tested GPUs is not a power of 2, and they cannot be addressed using a group of XOR functions. We leave the full reverse engineering of the mapping functions for our future work.

4.3 Primitive Revision

We have mentioned that the attack primitive requires revision because it lacks practical effectiveness in its present form. Even though it is theoretically sound, we identify two primary issues that prevent the primitive from yielding useful information. The first issue is the non-negligible spatial overhead introduced by GPU context switching. For example, on an RTX 3060, we observe that a number of L2 cache sets appear to have been accessed upon switching back, in spite of the

fact that the other context belongs to a minimal GPU program running merely a dummy infinite loop. Second, contrary to some prior cache side-channel attacks on CPUs, where the attacker can game the scheduler of the OS or hypervisor [10, 77], we have not found a viable method for exerting the same influence over the GPU scheduler. As shown in Figure 8, each time slice allocated to a GPU context is not short, making it very likely that the victim accesses most of, if not all, the L2 cache sets during this period. Hence, providing information solely on whether a cache set is accessed or not barely offers any useful insight into the cache activities of the victim.

To address this problem, we propose a revision to the last two steps of the primitive. Instead of just checking whether a cache set has been accessed, our revised primitive aims to measure the degree of contention in a cache set. Note that one key advantage of our timer-free primitive over the traditional PRIME+PROBE is its ability to easily pinpoint which of the first few cache lines in a set have been evicted. Capitalizing on this feature, we modify the last two steps of the original method to reformulate the primitive as follows:

Step 4: Execute the `discard` instruction on $A_0, \cdots, A_6$.
Step 5: Read the current value at $A_0, \cdots, A_6$ for comparison.
- If A_0 is not evicted (i.e., the old value), it is 0.
- If A_0 is evicted and A_1 is not, it is 1.

  ⋮
- If A_5 is evicted and A_6 is not, it is 6.
- If A_6 is evicted, it is 7.

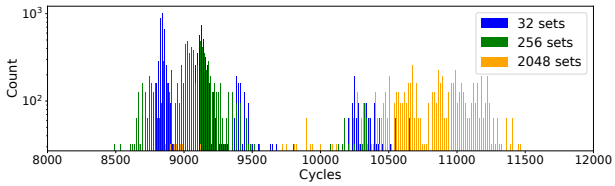
Essentially, rather than only carrying out the invalidation and comparison operations on A_0, we perform the invalidation operation across all seven addresses, $A_0, \cdots, A_6$, and identify the first one that is not evicted through comparison. We then use the position of the found address in the range to encode the intensity of contention in the corresponding cache set. For instance, if A_0 is not evicted, the intensity is encoded as 0 denoting the lowest, and if every one is evicted, the intensity is encoded as 7 denoting the highest.

Note that for heavy workloads, the contention intensity may always peak at its maximum of 7, which certainly does not convey much information. To enable capturing higher levels of contention in such cases, we can swap the order of Step 1 and Step 2, namely, we first read from $A_7, \cdots, A_{15}$ and then write to $A_0, \cdots, A_6$. In this variant, intensity 0 will be like an aggregate of all the original values from 0 to 7, while intensity 1 can be treated as an equivalent to a hypothetical previous intensity of 8, and so forth.

4.4 Execution Time v.s. Allocated Time Slice

Considering GPU context scheduling, it is crucial to examine whether the execution of the primitive can potentially exceed the allocated time slice before its completion. (If so, the effectiveness of attacks may be affected.) To this end, we compare the maximum duration needed to perform the primitive with the minimum time slice allocated to a GPU context.

As illustrated in Figure 7b, when the attacker's context is switched back, it first executes Step 4 and 5, followed by Step 1 through 3. Since Step 3 is just waiting to be scheduled away, the pertinent execution time is the cumulative time spent on Step 4, 5, 1, and 2. The worst-case scenario for this time occurs when all addresses of the eviction set are absent from the L2 cache, particularly in the revised primitive where all 7 stores need to be invalidated. Figure 8 shows the distributions of 10,000 execution times for the primitive on an RTX 3080. These times are measured in the worst-case scenario when monitoring 32, 256, and 2048 cache sets with 1, 8, and 64 SMs (i.e., each SM hosts one warp), respectively. We can find that all the times are less than 12,000 clock cycles, which is about 6μs. Since the steps of the attack primitive are executed immediately upon being rescheduled, as long as the allocated time slice exceeds 6μs, there is no concern about the primitive failing to complete.



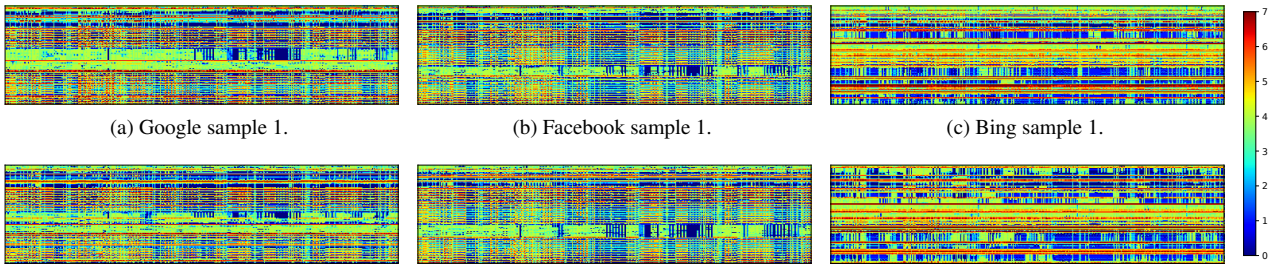


Figure 8: Distributions of primitive execution times on an RTX 3080 GPU. The y-axis uses a logarithmic scale.

Regarding the GPU context scheduler, we have not found any documentation providing information about its time slice length. Given the inevitable presence of scheduling overhead, we surmise that the time slice should not be less than 100μs. For an empirical validation, we run different GPU workloads and measure the allocated time slices in an approximate way (outlined in Appendix C). The analysis of the measured time slices reveals that only around 0.04% of them fall below 1ms, and among these, the shortest length observed is about 172μs. Therefore, we believe that the execution of the primitive can always complete successfully in each round.

5 Case Studies

We present two case studies to demonstrate the effectiveness of our INVALIDATE+COMPARE attack primitive. (Note that the reference to the attack primitive here corresponds to the revised version described in Section 4.3.) While the primitive is applicable to both consumer- and server-grade GPUs, the targets in these case studies are desktop applications, indicating that server-grade GPUs are not relevant to our scenarios. Accordingly, we perform the case studies using the consumer-grade GPUs listed in Table 1, namely the GeForce RTX 3060, 3080, and 4060.

(a) Google sample 1. (b) Facebook sample 1. (c) Bing sample 1.

(d) Google sample 2. (e) Facebook sample 2. (f) Bing sample 2.

Figure 9: Memorygrams corresponding to three commonly visited websites (the x-axis represents 512 cache sets of the RTX 4060 GPU, while the y-axis corresponds to time that progresses from top to bottom).

5.1 Threat Model

An attacker aims to extract certain sensitive information from a victim through their routine use of a personal computer. The victim's computer is equipped with an up-to-date NVIDIA GPU (that is in the Ampere or Ada Lovelace generation), where the latest driver and CUDA, with all disclosed vulnerabilities fixed, have been installed.[2] No special settings for the driver or CUDA are required (e.g., MPS may be turned on/off and the performance mode may be set as auto/fixed).

Similar to many other works [11, 19, 27, 38, 79], we assume that the attacker can run a piece of native code on the victim's computer with user-level privileges. Under this assumption, it is evident that the attacker has no problem retrieving any world-readable version information of software (e.g., the OS or web browser). While this native code setting may seem less consequential, we emphasize that its purpose is for showcasing the application of our primitive. A broader attack scenario will be discussed in Section 5.5.

We focus on two types of sensitive information here, which are website visits and virtual keystrokes. In the case study on stealing information about website visits, commonly referred to as website fingerprinting, we assume that the victim uses a modern web browser with default settings to regularly visit popular websites. The attacker can use the same browser to profile many possible ones to build a predictive model.

In the case study on retrieving keystrokes, we assume that the victim inputs data by tapping the visual keys of a virtual keyboard via a touchscreen or stylus. The virtual keyboard used by the victim is the default one of the corresponding OS. Once again, the attacker is assumed to be able to use the same virtual keyboard to build a predictive model.

5.2 Eviction Set Preparation

As a preparation step, we construct the eviction sets for the L2 cache of each GPU model offline. (See Section 4.2 for the reason of this process.) For each GPU model, we use a chunk of GPU memory, twice the size of the L2 cache, starting at the physical address `0x20000000` to identify the eviction sets. To demonstrate that the manufacturer has no bearing on this process, we tested two RTX 3080 GPUs from different brands (Founders Edition and Gigabyte) and two RTX 4060 GPUs, also from different vendors (MSI and PNY). Our results affirm that, given the same GPU model, the eviction sets remain consistent across vendors.

Note that, in terms of RTX 3060, we have identified 1152 distinct eviction sets for its L2 cache. This equates to 2.25MB (i.e., $1152 \times 16 \times 128\text{B} = 2.25\text{MB}$), not the size of 3MB as reported by TechPowerUp [64]. In the absence of NVIDIA's official documentation, it is unclear which size is the correct one. Nevertheless, this discrepancy does not impact the case studies we conduct. With respect to other models, the L2 sizes match the reported ones (e.g., we find 2560 eviction sets for RTX 3080's L2, which is exactly 5MB).

5.3 Website Fingerprinting

As our first case study, we demonstrate how to identify the web pages browsed by a user, essentially mounting a website fingerprinting attack. Information regarding website visits is typically viewed as significant to privacy, given its potential to reveal a person's sensitive aspects (e.g., political affiliations, health conditions, and special hobbies). Several prior studies have exploited vulnerabilities in NVIDIA drivers to achieve this objective [27, 38], but as the corresponding software flaws have been addressed, their approaches are no longer effective.

5.3.1 Investigation

Over time, a variety of website fingerprinting techniques have been proposed, like those in [1, 12, 14, 19, 47, 49, 52, 56, 67]. Among the existing techniques, several exploit information leakage over cache hierarchies. Ours bears a resemblance to these works (e.g., that of Oren *et al.* [47]), yet with differences. While their methods rely on a (high-resolution) timer to use primitives such as PRIME+PROBE to capture the CPU cache

[2] At the time of this writing, the latest GPU driver version is 535.113.01 and the latest CUDA version is 12.2.

behavior, we use our timer-free attack primitive to measure GPU cache contentions.

The potential to leverage the monitored GPU cache behavior for website fingerprinting arises from the fact that modern web browsers, like Chrome and Firefox, enlist the GPU's assistance for rendering web pages. In effect, when the GPU helps render a web page, the majority of its computational tasks are contingent upon the contents and design of that web page. For example, the rasterization process that converts web page elements (e.g., text, images, and vector graphics) into pixels happens entirely on the GPU, and the compositing process that assembles the separately rasterized layers of a web page into the final image for display is also performed by the GPU. Their workloads depend significantly on the contents of the web page being rendered and how it is designed.

Our website fingerprinting technique leverages contentions in GPU L2 cache sets. We find that during the rendering of a web page, nearly every cache set will be accessed by the browser's GPU context within each of its allocated time slices, but the number of used cache lines varies among different sets. The INVALIDATE+COMPARE primitive empowers us to capture this behavior since it measures the contention intensity within the monitored cache sets. Note that, as the rendering process can extensively occupy the L2 cache space, we choose to use the variant with reading 9 addresses first followed by writing 7 addresses.

Figure 9 demonstrates the traces of contention intensity in 512 cache sets of the RTX 4060 GPU when three popular websites are being browsed in Chrome. A trace shown in Figure 9 contains 128 INVALIDATE+COMPARE measurements. (Each measurement is a vector of 512 elements whose value range is from 0 to 7.) To follow the established parlance [47, 56], we also refer to these traces as memorygrams. It is apparent that such memorygrams can provide certain insights into the contention behavior of GPU cache during the web page rendering process. More importantly, it is not difficult to observe that such memorygrams can be utilized to effectively distinguish between these three websites.

5.3.2 Evaluation

We evaluate our technique against a set of 50 websites, which are detailed in Appendix D. These websites are popular in the English-speaking world and chosen according to Similarweb rankings. As the main purpose of this case study is to illustrate the practical use of our attack primitive, we believe that a closed-world setting will suffice at this point. (The major challenge in open-world settings is how to achieve reliable open set recognition, which falls outside the scope of this paper.) In addition, due to Chrome's dominant market share, we focus our evaluation solely on this browser. The OS used in our evaluation is Ubuntu 20.04.

For each website, we gather 100 memorygrams similar to the ones depicted in Figure 9. Regardless of the GPU model, we choose to let one SM monitor 64 L2 cache sets (i.e., two warps running on an SM). Due to the relatively small L2 sizes in RTX 3060 and 3080, we can monitor all of their cache sets using 18 and 40 SMs, respectively. However, there are 12,288 cache sets in an RTX 4060 GPU but only 24 SMs, and thus we just monitor 1472 of them using 23 SMs with the last SM used for context switching detection (see Section 4.1).

Each memorygram consists of the contention intensity measurements in 5 seconds. As we have 50 websites, our data set has 5,000 memorygrams in total. For the task of classifying memorygrams into respective websites, we use the standard DenseNet-121 model. To assess the performance of our website fingerprinting, we conduct a 5-fold cross-validation on our collected data set. For each fold, we determine its accuracy, precision, and recall. As all websites are treated equally in our evaluation, we employ macro-averaging when calculating precision and recall (see Appendix D).

Table 2: Results of the 5-fold cross-validation.

	Accuracy			Precision			Recall		
	Max.	Min.	Avg.	Max.	Min.	Avg.	Max.	Min.	Avg.
RTX 3060	98.9%	98.1%	98.4%	98.9%	98.1%	98.4%	99.0%	98.2%	98.5%
RTX 3080	99.3%	98.5%	98.9%	99.3%	98.5%	98.9%	99.4%	98.6%	98.9%
RTX 4060	99.5%	98.5%	99.0%	99.5%	98.5%	99.0%	99.5%	98.6%	99.0%

The results of the 5-fold cross-validation are presented in Table 2. From the results, we can observe that the accuracy in each fold on any GPU is >98% and the average accuracy over the 5 folds is >98% as well, which highlights the effectiveness of our website fingerprinting technique. Meanwhile, it is noted that both the precision and recall in each fold are also >98%, which indicates that when a memorygram is classified as belonging to a website, there is a >98% chance it is correct and when a memorygram originates from a website, there is a >98% chance it will be accurately recognized as such.

To substantiate that the underlying platforms will not affect the results as long as the same GPU model is used, we evaluate the fingerprinting performance using two separate computer machines, M_1 and M_2, whose configurations are specified in Table 3. Both of them are equipped with an RTX 3080 GPU. We highlight that the RTX 3080 GPU cards are of different brands (Gigabyte and Founders Edition).

Table 3: Computers equipped with different RTX 3080 cards.

Machine	GPU Brand	CPU	Motherboard	Main Mem.
M_1	Gigabyte	AMD Ryzen 5 5500	Asus Prime B450M-A II	16GB
M_2	Founders Ed.	Intel Core i3-10100	ASRock H570 Steel Legend	32GB

On the machine M_1, 100 memorygrams per website are collected, and a DenseNet-121 model is trained using these memorygrams. On the machine M_2, 20 memorygrams per website are collected, and we apply the trained model to classify such data. Figure 16 in Appendix E shows the resulting confusion matrix. In summary, the average accuracy is 97.7%, precision is 97.7%, and recall is 97.8%, when tested with 1,000 samples from M_2. It is evident that the results comparatively align with those of the 5-fold cross-validation.

In reality, most websites update their page content very frequently, often on a daily basis or even on an hourly basis. An interesting scenario to investigate is whether the model, once trained, can maintain its effectiveness in fingerprinting websites for a longer term. To assess this, we train a DenseNet-121 model with the initial 5,000 memorygrams of our RTX 3080. Subsequently, for each website, we gather an additional 10 memorygrams on the 3rd, 5th, and 7th days after the original data collection for testing. Figure 10 presents the results.

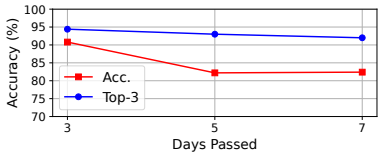

Figure 10: Results of effectiveness testing over time.

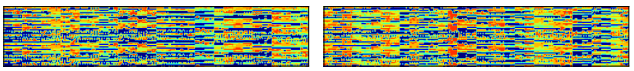
As anticipated, there is some degradation in performance, but it still maintains a substantial level of effectiveness. Even after one week, our accuracy can still reach 82.40%. Aside from trying to exactly fingerprint the websites, we evaluate its Top-3 accuracy as well, which remains high and relatively stable over time (around 93%). It is intriguing to see that for certain websites tending to update their contents frequently, such as YouTube and BBC, our model is still able to accurately identify them. Irrespective of frequent content changes on these websites, their overall page layout or structure does not alter as much. For example, the number and positions of pictures and/or videos are stable but only the materials shown by them are changed. Our conjecture is that this structural consistency is the main contributing factor to the model's fingerprinting effectiveness over time, as it can lead to similar web page rendering workload and patterns.

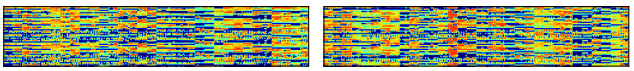
5.4 Virtual Keystroke Extraction

In the second case study, we aim to recover more fine-grained and sensitive information beyond merely website visit data. To this end, we focus on the keystrokes made by a user on a virtual keyboard (also known as an on-screen keyboard) and show that INVALIDATE+COMPARE enables us to steal them.



Note that using a virtual keyboard is not unusual in practice. For example, it is common and crucial among people with special needs (e.g., those with disabilities), and it is treated as a countermeasure against keyloggers (even though its effectiveness is debatable [40]). Moreover, with the proliferation of touchscreen-based laptops and monitors, virtual keyboards are becoming increasingly popular for day-to-day tasks. Major consumer-facing OSes all provide default virtual keyboards as an accessibility feature.

5.4.1 Investigation



In a GUI-based modern OS, its windowing system (e.g., X11 or Wayland in Linux) provides the protocol and mechanics for graphics rendering and input handling. Built on top of this, the desktop environment (e.g., GNOME or KDE) offers the GUI interface. (Roughly speaking, the desktop environment is an application running under a windowing system.) Usually, the default virtual keyboard bundled with the OS is an integrated feature of the desktop environment [5].

Windowing systems are often designed with considerations for efficient graphics rendering, and they generally attempt to avoid re-rendering the entire screen when only a small portion of the screen changes. Take X11 with the DAMAGE extension as an example.[3] (This extension is incorporated in nearly all display server implementations of X11, such as the widely used Xorg.) When a graphical element in an application running under this setup is modified, the DAMAGE extension identifies the affected region and marks it as "dirty". Compositing window managers compatible with X11 system will then focus on re-compositing only the "dirty" region of the surfaces to enhance efficiency.

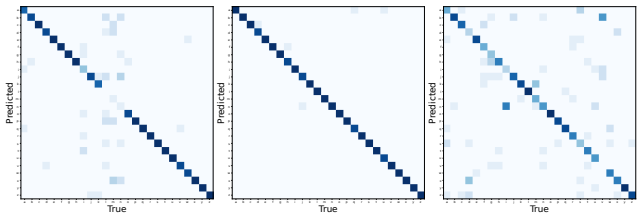
With respect to a virtual keyboard, when a key is activated, it normally exhibits certain local visual effects (e.g., shading the surroundings of the key). Consequently, the windowing system should focus on re-rendering only that particular area. Note that windowing systems typically leverage the power of GPUs for graphic rendering, and they also maintain various buffers in GPU memory, one of which in fact corresponds to the desktop environment. When a virtual keystroke is made, it is conceivable that only the parts of this buffer associated with the "dirty" regions (i.e., those affected by the keystroke) are accessed. This implies that distinct keys may access different GPU memory addresses. Therefore, we hypothesize that it is possible to produce distinguishable traces in the GPU cache when pressing different keys.

(a) Key 'a' sample 1. (b) Key 'b' sample 1.

(c) Key 'a' sample 2. (d) Key 'b' sample 2.

Figure 11: Reshaped memorygrams corresponding to pressing keys 'a' and 'b' on the GNOME virtual keyboard under the default X11 windowing system when an RTX 3080 GPU is used.

As evidence supporting our hypothesis, Figure 11 depicts two pairs of memorygrams generated on an RTX 3080 when pressing the letters 'a' and 'b' under the X11 windowing system. Note that the original memorygrams have a dimension of 5×2560, because we monitor 2560 L2 cache sets and the keystroke visual effect rendering induces about 5 GPU context switches. For clarity in visualization, we reshape them into



[3] The newer Wayland windowing system has the concept of "dirty" regions handling from the ground up.

50×256. Moreover, we have filtered the level 7 intensity to prevent visual clutter. While there are similarities among them, it shall not be hard to find that discernible and repeatable patterns do exist to classify these two keys.

5.4.2 Evaluation

We carry out our evaluations on a Linux platform running Ubuntu 20.04. By default, Ubuntu 20.04 uses X11 as its windowing system.[4] In terms of the desktop environment, we use the default GNOME coming with the OS.

The GNOME virtual keyboard displays only letters every time it is launched. As a first step, we investigate how accurately the memorygrams can be used to deduce the pressed letters. For this purpose, we collect 100 memorygrams for each letter, which are used to train a DenseNet-121 model. Given a GPU, the number of monitored cache sets and the number of warps on each SM are consistent with our previous case study. Subsequently, we capture another 10 memorygrams per letter for testing. The resulting confusion matrices are presented in Figure 12.

(a) RTX 3060. (b) RTX 3080. (c) RTX 4060.

Figure 12: Heat maps corresponding to the testing results based on memorygrams for ‘a’ to ‘z letters.

From the confusion matrices, we can observe that letters, in most cases, are distinguishable. The average accuracies for RTX 3060, 3080, and 4060 are 83.1%, 98.1%, and 67.7% respectively. In comparison, a random guess will yield an accuracy of just 3.8%. This disparity underscores the information leakage from GPU cache activities during the rendering of keystroke visual effects on the screen.

For the RTX 3060 GPU, we note a peculiar trend: the recognition performance for letters ‘l’, ‘m’, and ‘n’ is substantially lower than for the other letters. Conversely, the RTX 3080 outperforms both, delivering the best results. It is interesting to note that while RTX 3080 has a larger cache size than RTX 3060, it is significantly smaller than that of RTX 4060. However, the recognition performance of RTX 4060 is the lowest.

The lower performance of the RTX 4060 relative to the RTX 3060 and 3080 can be attributed to the fact that we only monitored 1472 cache sets for the RTX 4060, whereas all cache sets are monitored for the other two GPUs. While this configuration suffices for coarse-grained tasks like website fingerprinting, fine-grained tasks necessitate the selection of more appropriate cache sets. We believe that by identifying the most relevant ones, the performance on the RTX 4060 can be substantially improved.

To access the numbers, users have to utilize the switch key located at the bottom left, and when activated, the numbers replace the first row of 10 letters exactly. We aim to determine if the switch action and the numbers can be differentiated from the letters (especially those in the first row) using our memorygrams. To this end, we use 100 samples each for the letters, numbers, and both switching actions (to numbers and back to letters) to train a DenseNet-121 model, and another 10 samples for testing.

Considering the action of switching to or from numbers, our data set comprises 37 classes. For the GPUs RTX 3060, 3080, and 4060, the average accuracies achieved are 68.6%, 77.3%, and 67.3%, respectively. Intriguingly, despite the numbers and the letters from the first row occupying the same screen position, they are distinguishable to some extent. (The corresponding confusion matrices are given in Figure 15 in Appendix E.) We believe the distinguishability between characters, such as ‘p’ and ‘0’, is due to each being mapped to distinct buffer addresses in the GPU memory.

A further point of interest is the contrasting performance trends between the GPUs. While both RTX 3060 and 3080 exhibit a decrease in accuracy, the RTX 4060’s performance remains very consistent. This stability can be attributed to RTX 4060’s very large cache size, which has the capacity to house the entire frame buffer (even though we have not chosen the most appropriate ones).

Next, we evaluate if we can extract a user’s system login password entered via the virtual keyboard. For demonstration purposes, we select four commonly used and pwned passwords as listed by the National Cyber Security Centre [39]. These four passwords are given in Table 4.

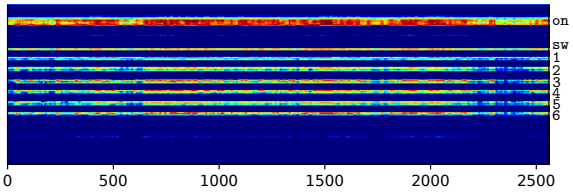


Figure 13: GPU L2 contention intensity trace, where the x-axis gives cache sets and the y-axis gives the time (derived from the recorded context switch times as stated in Section 4.1).

We capture the GPU L2 contention intensity traces when the victim is prompted to input their system login password. This scenario can occur frequently because, by default, Ubuntu, along with many other Linux distributions, goes to a black screen after 5 minutes of inactivity. Upon returning, the user is asked to provide the login credentials. Figure 13 illus-

[4] Although newer versions of Ubuntu, e.g., 22.04, have made Wayland the default windowing system, there are compatibility issues with NVIDIA GPUs. As a result, when NVIDIA GPUs are detected, the system will automatically switch back to X11.

trates a trace captured on an RTX 3080 GPU corresponding to the input of the password shown in the first entry of Table 4. From this trace, it is evident that the individual memorygrams can be readily distinguished. The topmost bar signifies the system's awakening from the black screen state, followed by the second bar which indicates the act of toggling the number/letter switch.

Table 4: Results of inferring four commonly used login passwords. A correct inference is denoted by ✓and an incorrect one is denoted by ✗. The symbol '@' indicates the action of switching between letters and numbers.

Password	Keystrokes	RTX 3060	RTX 3080	RTX 4060
123456	@123456	✓✓✗✗✓✗✓	✓✗✓✓✓✓✓	✓✓✗✓✗✓✓
qwerty	qwerty	✓✗✓✓✗✓	✓✓✗✓✗✓	✓✓✗✓✗✓
abc123	abc@123	✓✗✓✓✗✓✓	✓✗✓✓✗✓✓	✓✗✓✗✗✓✓
1qaz2wsx	@1@qaz@2@wsx	✓✗✓✗✓✓✓✗✓✗✓✓	✓✗✓✗✓✓✓✗✓✗✓✓	✓✓✓✗✓✓✓✓✗✗✓✓

For our evaluation, we employ a DenseNet-121 model, training it with 300 samples for each character. An analysis of Table 4 reveals that we can indeed decipher many segments of these passwords. A significant portion of the errors stems from the confusion between numbers and letters. The most reliably recognized keystroke is the switching between letters and numbers.

5.5 Discussion

A common limitation across both case studies is that they require the execution of native code with user-level privileges on the victim's machine. However, it is essential to note that such a condition is not always necessary for employing the primitive in some more practical scenarios. For example, we find that many major cloud service providers (e.g., Azure [34]) offer VMs powered by NVIDIA vGPUs, and in this context, our INVALIDATE+COMPARE primitive can be leveraged to facilitate cross-vGPU side-channel attacks without requiring native code execution on the victim's VM. Moreover, a number of companies have adopted virtual desktop infrastructures sharing high-end GPUs to support their daily business operations [42, 46], creating additional venues where the primitive can be used for potential side-channel attacks.

We should also mention that unlike website fingerprinting, the demonstrated virtual keystroke extraction is a more fine-grained attack, whose success greatly depends on whether the victim's on-screen keyboard uses the same GPU memory area as the one used by the attacker during profiling. While this is difficult to control when the GPU is actively in use, we have discovered that when the system is idle for a certain period, the X11 server reduces its usage of GPU physical memory to a fixed level. Upon activation, the system normally utilizes the same GPU memory area for the virtual keyboard, which creates a favorable scenario for the attacker to perform the keystroke extraction.

6 Countermeasures

To prevent the exploitation of our timer-free attack primitive, we propose several possible countermeasures. The first one is to simply disable the use of the `discard` instruction. To this end, we can directly remove the support for this PTX instruction in the compiler toolchain. However, this straightforward patch can be easily circumvented by altering instructions in the compiled binary files to match the encoding of `discard`. An alternative method is to enable the NVIDIA driver to inspect user programs for `discard` instructions and reject the launch of their kernels if detected. While such an in-driver defense raises the bar for attackers, it can still be bypassed by modifying instructions in GPU code pages at run time.

A more effective solution is to disable this instruction in hardware. Nevertheless, due to the lack of publicly accessible information, it is uncertain whether the instruction can be disabled via a GPU firmware update, or if a less desirable hardware modification is necessary. Even if a firmware update can achieve the objective, the potential ramifications for existing software still need to be determined.

As the root cause of the examined information leakage stems from observable contentions in the GPU L2 cache, the other mitigation direction we can work on is to seal off this source. Given the fact that GPU contexts cannot execute in parallel, our focus narrows to managing the serialized use of the L2 cache. One feasible way to achieve this is to let the runtime flush the contents in L2 every time GPU contexts are scheduled. While clean cache lines can be directly invalidated, dirty ones need to be written back to GPU memory. A primary concern with this approach lies in its potential impact on GPU performance. However, as L2 flushing is only triggered upon scheduling GPU contexts, an event that typically occurs on the millisecond level, our anticipation is that the performance degradation may be limited.

Additionally, given that eviction sets can be prepared a single time offline and then utilized across all future online attacks, it is undeniable that the task of an attacker is considerably eased. This convenience arises from the way NVIDIA drivers allocate GPU page frames, favoring physical contiguity and consistently starting the allocation from the same address. To neutralize this benefit for attackers, NVIDIA should consider introducing a degree of randomness into its drivers for GPU memory allocation.

7 Related Work

Extensive studies have been conducted on cache side-channel attacks in the past two decades, and the majority of them target cache hierarchies in CPUs like x86 and ARM [4, 32]. Overall, these studies exploit various attack primitives, which can be classified into eviction-based and flush-based types. PRIME+PROBE is the representative of the eviction-based attack primitives [48], and it can be used for leaking

information across domains established by browser sandboxes [47, 55], SGX enclaves [35, 54, 70], VMs [15, 17, 30], and even networks [25, 61]. In terms of flush-based primitives, FLUSH+RELOAD [10, 73] is the most notable one and has been employed in a number of attacks [9, 18, 24, 28, 69]. Flush-based primitives typically can offer finer leakage granularity than eviction-based ones, but they need to have shared memory with the victim. Our attack primitive, in spite of using a flush-like instruction on GPUs, is fundamentally eviction-based.

Traditionally, cache side-channel attack primitives require a high-resolution timer to distinguish between hits and misses. As exceptions to this rule, several timer-free ones have been devised, like PRIME+ABORT [2], DPRIME+DABORT [23], S^2C [74], and `mwait`-based primitives [76]. While these primitives target x86 and ARM CPUs, ours is developed for NVIDIA GPUs.

With GPUs becoming indispensable in modern computing, their security issues have garnered much attention. There have been works that examine website fingerprinting on GPUs [27, 38, 57, 60, 72, 75]. While some of them capitalize on software vulnerabilities present in device drivers [27, 38], others hinge on coarse-grained contention, whether over PCIe [57, 60] or on the rendering pipeline [72]. These studies largely sidestep delving into the GPU's microarchitectural intricacies, which is a primary emphasis of this paper.

On the other hand, techniques for keystroke extraction via GPUs have also been investigated [38, 60, 72]. These studies exploit the dependence of inter-keystroke timings on key distance and location to deduce which key is pressed [36, 58]. In contrast, our work is similar to approaches that leverage different cache activities to directly extract the keys [9, 69]. Moreover, a GPU keylogger that reads the keyboard buffer over PCIe bus has been described in [26].

Besides our work, there exist other studies on exploiting data caches of discrete GPUs for information leakage, all of which are built on the traditional PRIME+PROBE primitive [3, 37]. In [37], several covert channels for data exfiltration are constructed, but they require operation under MPS. In [3], other than covert channel attacks, an application fingerprinting case study is presented, albeit limited to only 6 applications. Note that restricting access to timers, or adding noise to them, which are used on CPUs, can also be applied to GPUs to mitigate such PRIME+PROBE-based attacks; however, these countermeasures will not affect attacks utilizing our timer-free primitive.

8 Conclusion

In this paper, we have unveiled certain previously-unknown characteristics of NVIDIA GPU caches for the first time and introduced a new GPU cache side-channel attack primitive. This new primitive enables effective spying on GPU cache activities without relying on timers. Capitalizing on this approach, we have successfully orchestrated website fingerprinting and keystroke extraction attacks on NVIDIA's latest Ampere and Ada Lovelace GPUs. To our knowledge, these represent the first timer-free cache side-channel attacks on GPUs. Our work highlights the need to scrutinize the information leakage possibilities within GPU caches against microarchitectural attacks.

Availability. The proof-of-concept implementation of our primitive, including the method for constructing GPU L2 cache eviction sets, is available at https://github.com/0x5ec1ab/invalidate-compare.git.

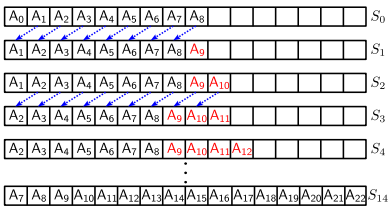
A Supplement to Write Policy Study

To confirm that B is never evicted from X's L1 cache in the experiment presented in Section 3.3 (see Figure 2), we proceed with the following three steps *after* Y *reads* B (recall that here Y always retrieves 1) – First, Y discards B. Next, Y reads B to check its value. Finally, X reads B to check its value.

We consistently observe that after Y executes the `discard` instruction on B, its subsequent read returns 0, as expected since B is now fetched from GPU memory. Notably, X consistently retrieves the value 1 for B. If B had been evicted from X's L1 cache, X would also retrieve 0, echoing Y's read value after invalidation of B. Therefore, this indicates that B remains in X's L1 cache throughout the experiment presented in Section 3.3.

B Replacements during Set Population

In the case where only `ld` is used, we surprisingly observe replacements in the course of filling a set, as illustrated in Figure 14. Starting from an empty cache set, we first read from 8 addresses (i.e., $A_0, A_1, \cdots, A_8$), reaching the state S_0. Interestingly, when loading from another address A_9, the cache line corresponding to A_0 is evicted, even though the cache set is only half full. However, when reading from A_{10}, no eviction occurs until the subsequent load. This process continues until the cache set reaches the filled state (i.e., the state S_{14}). After this point, the cache set's replacement behavior using `ld` aligns with the LRU policy. Notably, the initial replacement pattern does not match any known policy.



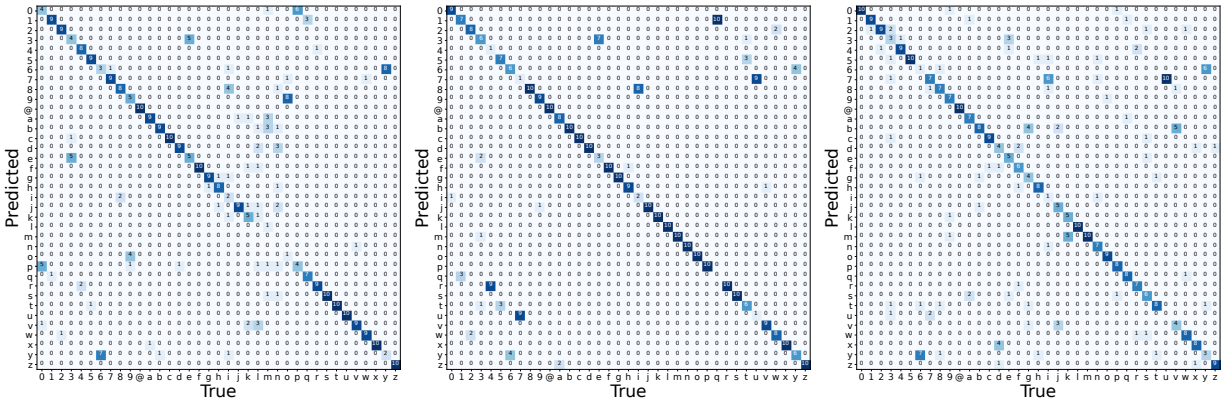


Figure 14: Populating an L2 cache set using `ld`.

Figure 15: Confusion matrix corresponding to the testing results based on memorygrams for 'a' to 'z letters, '0' to '9 numbers, and switch action between letters and numbers (shown as '@').

C Time Slice Measurement

We cannot determine the exact allocated time slices, but we can approximate them using the first context switch detection approach depicted in Figure 7a. The `delta` from this approach provides a tight upper bound for the allocated time slice. We assessed the time slices using this method across several applications, such as GPU benchmarks, neural network training, games, and web browsers. We have observed that GPU benchmarks and games tend to have large time slices. However, our primary concern is identifying the minimum time slice, which we find to be generated predominantly by web browsers.

D Website List

Table 5 lists the websites that are used in our evaluations on website fingerprinting. Since there are 50 websites, the macro-averaged precision is calculated as $\frac{1}{50}\sum_{i=1}^{50} P(i)$ and the macro-averaged recall is calculated as $\frac{1}{50}\sum_{i=1}^{50} R(i)$, where $P(i)$ and $R(i)$ represent the precision and recall for the i^{th} website, respectively.

Abstract

Application sandboxing is a well-established security principle employed in the Android platform to safeguard sensitive information. However, hardware resources, specifically the CPU caches, are beyond the protection of this software-based mechanism, leaving room for potential side-channel attacks. Existing attacks against this particular weakness of app sandboxing mainly target shared components among apps, hence can only observe system-level program dynamics (such as UI tracing). In this work, we advance cache side-channel attacks by demonstrating the viability of non-intrusive and fine-grained probing across different app sandboxes, which have the potential to uncover app-specific and private program behaviors, thereby highlighting the importance of further research in this area.

In contrast to conventional attack schemes, our proposal leverages a user-level attack surface within the Android platform, namely the dynamic inter-app component sharing with package context (also known as DICI), to fully map the code of targeted victim apps into the memory space of the attacker's sandbox. Building upon this concept, we have developed a proof-of-concept attack demo called ANDROSCOPE and demonstrated its effectiveness with empirical evaluations where the attack app was shown to be able to successfully infer private information pertaining to individual apps, such as driving routes and keystroke dynamics with considerable accuracy.

1 Introduction

In the past decade, Android has become the predominant mobile operating system and is boasting the largest market share in global smartphone sales volume [4]. With Android smartphones serving as ubiquitous personal handheld devices, countless personal private data (e.g., user email and contact list) and a variety of persistent identifiers (e.g., IMEI) are accessed and processed daily. The emergence of the Android ecosystem has also attracted numerous malicious attacks [12], a large portion of which either gain device control [13, 23] or steal private user information such as chats [37] and geographic locations [22]. To protect user privacy from unauthorized access, Android sandboxes user-space apps to prevent them from interacting arbitrarily with each other and the key system components. When first introduced in Android 5, the app sandboxing mechanism was implemented on top of the mandatory user-based access control of SELinux [43]. It inherits the UID/GID permission model of Linux and enforces each app to be run in an isolated process space by assigning a unique UID at installation time. By default, two isolated apps (without a pre-established trust relationship) cannot interact; any app is not allowed to access system components or resources without the corresponding permissions. Subsequent Android versions continued to improve their security mechanisms, e.g., Android 10 introduced Scoped Storage [14] which restricts an app's access to external storage.

Nevertheless, it has been shown in real-world practices that an app may circumvent Android's sandboxing and gain access to protected data without user consent, which is mostly achieved by means of covert or side-channel techniques. In particular, covert channels enable communication between two colluding apps so that one app can share its permission-protected data with another app lacking those permissions [27]. The research community has previously explored the potential for covert channels in Android using local sockets and shared storage [32], as well as other unorthodox means such as vibrations and accelerometer data [6]. However, typical covert channels can be easily detected by dynamic analysis, e.g., TaintDroid [15] and XManDroid [10]. Side channels, on the other hand, occur when there are alternate means to access the protected resource that is not audited by security mechanisms. Side-channel attacks take advantage of unintended leakage of information through features such as power consumption, electromagnetic emissions, timing, or even sound. The typical scenarios of side-channel attacks involve inferring sensitive data (e.g., encryption keys and

*Corresponding author

passwords) and private user information (examples including gender [33], identity [44], and even driving routes [35]). Attempts have also been made to exploit cache-based side channels for the purpose of breaching Android's app sandboxing. For instance, ARMageddon launched side-channel attacks on `libinput.so`, a system-shared library, to monitor keyboard presses [30]. Zhang et al. used the same strategy on another system-shared library, namely `libinputflinger.so` [50]. However, existing work only managed to exploit shared code across different processes due to Android's system architecture; in addition, these adversarial approaches are susceptible to various system factors and noises in practice [47], limiting their capabilities to rough estimations of what is happening at a coarse granularity.

In this paper, we propose ANDROSCOPE, a fine-grained side-channel attack that compromises the Android app sandboxing mechanism. Our attack leverages a user-level attack surface of the Android platform, namely the dynamic code loading mechanism using package context (DICI). Specifically, while the previous work explored the possibility of exploiting DICI in code reuse attacks [17], our investigation targets a more fundamental question, namely "*how code of another app is accessed by components within the current sandbox during* DICI", and find that *when an app attempts to invoke external methods via* DICI*, it loads the corresponding code files (belonging to the victim app) into the memory space of the attack app as a side effect*. We confirmed that this undocumented feature applies to all types of executables on the Android platform, including Dalvik Executable (Dex), ahead-of-time (AOT) compiled code, and third-party native libraries, and such code loading turns out to be successful even if the external invocation request is rejected (due to proper security measures). This observation thus enables carefully crafted cache-based side-channel attacks to completely break app sandboxing and permission-based access control, allowing a stealthy app to, for the first time, monitor detailed runtime behavior of other apps non-intrusively without any unusual privileges.

We tested the effectiveness of ANDROSCOPE on monitoring the method execution of a number of open-source apps and confirmed that ANDROSCOPE could effectively extract sensitive and app-specific user behavior. As two representative use cases, we demonstrate that ANDROSCOPE successfully infers driving routes taken by a navigation app and keystroke dynamics of a communication app. In conclusion, we make the following contributions.

- For the first time, we identified another layer of security threat exposed by Android's undocumented DICI mechanisms, which could lead to inter-app privacy leakage that bypasses Android's app sandboxing.
- We have implemented a proof-of-concept attack framework called ANDROSCOPE, which leverages the DICI vulnerability to conduct non-intrusive inter-app runtime behavior monitoring via the cache-based side channel with zero privilege. ANDROSCOPE shows its capability to directly probe a victim's private code, surpassing prior methods that relied on shared libraries and system APIs.
- We conducted a comprehensive evaluation on the effectiveness of ANDROSCOPE using real-world devices and apps, which confirmed the validity of DICI-based sandbox breach and suggested that the issue may be universal to all Android-based systems. The result also demonstrates that ANDROSCOPE addresses concerns about background noise as raised in previous approaches focused on the shared libraries and system APIs.

2 Background

2.1 Android App Sandboxing

App sandboxing is a fundamental security feature of the Android operating system, which helps protect the device and user data by isolating each app from both other apps and the rest of the system. This ensures that apps cannot interfere with each other's operations or access unauthorized resources and data. The construction of the app sandbox is based on three mechanisms, namely Discretionary Access Control (DAC) [11], Mandatory Access Control (MAC) [41], and the Android permissions [16] mechanism. Both DAC and MAC are inherited from Linux. Specifically, DAC restricts access to resources based on user and group identity. By assigning each application a unique UNIX user ID (UID) and a dedicated directory, Android runs each app in its own independent user space with the file system set up in a way that each app can only access its own data and resources. MAC further enforces finer-grained protections by dictating whether an in-process action is allowed based on a set of pre-defined policies concerning the security contexts (i.e., collections of security labels that classify resources) of the involved parties. Last but not the least, Android permissions control data sharing among apps of UIDs and system resources (such as camera, GPS, contacts, and etc.). An app must declare permissions in advance (or, in the case of dangerous permissions, explicitly) so that invocations can be granted.

Android's use of MAC policy has evolved over time to meet the increasing demands of mobile security. In the early versions of Android (before Android 4.3), it relied heavily on DAC and allowed apps to run with the permissions of the user who installed them. This provided only limited security as apps had broad access to the privileged resources. With the release of Android 4.3, SELinux was introduced as an additional layer of security, but the implementation was permissive by default, i.e., it logged policy violations but did not actively enforce policies. Android finally switched its SELinux to enforcing mode since Android 5 to actively enforce the pre-defined security policies.

2.2 Dynamic Inter-App Component Sharing with Package Context

The initial purpose of DICI is for inter-app communication so that one app can leverage resources from other apps during its execution. Listing 1 shows an example of DICI used in plugin implementation in the app with package name *kl.ime.oh*, which intends to invoke a method named `predict` that belongs to the `M` class of a Chinese keyboard plugin app called *klye.hanwriting*. Specifically, the API `createPackageContext` is called at Line 7 to create a context of *klye.hanwriting*. The second parameter of this API is known as flags, allowing developers to specify how should the package context be created, most notably:

- 0x0001 (*CONTEXT_INCLUDE_CODE*), allowing access to the code in the loaded package.
- 0x0002 (*CONTEXT_IGNORE_SECURITY*), ignoring any security restrictions. When it is enabled with *CONTEXT_INCLUDE_CODE*, code is loaded even if it unsafe to do so. features of the accessed resources.

```
1  public boolean loadHW() {
2      try {
3          if (M.i.getPackageManager().
               ↪ getPackageInfo(
4          "klye.hanwriting", DoneRec).versionCode
               ↪  < 19){
5              return false;
6          }
7          Class<?> loadClass = M.i.
               ↪ createPackageContext("klye.
               ↪ hanwriting", 3).getClassLoader()
               ↪ .loadClass("klye.hanwriting.M");
8          Class[] clsArr = new Class[3];
9          clsArr[DoneRec] = String.class;
10         clsArr[1] = Character.TYPE;
11         clsArr[2] = Integer.TYPE;
12         this.m1 = loadClass.getMethod("predict"
               ↪ ,clsArr);
13         ......
14         return true;
15     } catch (Throwable unused) {
16         return false;
17     }
18 }
```

Listing 1: Example of direct inter-app code invocation

In this example, the value 3 (0*x*0001|0*x*0002) enables both flags *CONTEXT_INCLUDE_CODE* and *CONTEXT_IGNORE_SECURITY* on loading the class *klye.hanwriting.M* on-the-fly. The method object is acquired with the class object containing it (Lines 9-13). Android first locates the APK file based on the package name provided, and then opens it and dynamically loads `classes.dex` into the current address space.

Despite the lack of explicit documentation, DICI is a legitimate mechanism used by various apps published on Google Play Store (see more details in Section 3.6). It is important to emphasize that *even if the method invocation fails (for valid reasons like lack of permissions), the file loading operations would have been completed as a side effect and would not be revoked as long as the initiating app is not terminated*. Our tests confirmed that this undocumented component sharing mechanism is viable on the most recent Android 14.

Existing work [17] pointed out that this mechanism can be used to plagiarize supposedly-protected functionalities, but the potential risk of side-channel attacks was overlooked. As a matter of fact, both `base.vdex` and `base.odex` are used by the Android Runtime for actual execution of apps, such that the overhead of repeatedly verifying and optimizing `classes.dex` can be avoided. With these observations, we investigate how the DICI mechanism could be used to launch side-channel attacks with the purpose of fully circumventing Android app sandboxing.

2.3 CPU Caches and Side-Channel Attacks

Program execution often has temporal and spatial locality, i.e., the most recently accessed memory addresses as well as nearby addresses are often accessed in the near future. To exploit locality, modern CPU architectures use caches to store recently accessed code and data. These caches are often organized into multiple levels with different sizes and access speeds. For example, on ARM CPUs, there are commonly two levels of caches L1 and L2, with L1 being faster and smaller while L2 being larger and slower. On multi-core CPUs, lower-level caches (L2) are often shared among multiple CPU cores. Modern caches are usually organized with an N-way associative table. The basic unit of memory allocation in a cache is called a line or cache line of a typical size of 64 bytes.

An adversary could infer secret information about a running program by observing its use of CPU caches, which is typically called cache side-channel attacks. Initially, cache side-channel attacks were performed on cryptographic algorithms [25, 26, 36, 40, 45]. Previous studies have explored different types of cache side-channel attacks: EVICT+TIME [38], PRIME+PROBE [38], FLUSH+RELOAD [48], and EVICT+RELOAD [19]. EVICT+TIME and PRIME+PROBE allow an adversary to determine which cache sets are used during the victim's computation and have been exploited to attack cryptographic algorithms [38]. In particular, in EVICT+TIME attacks, the attacker first causes the victim to run, preload its cache lines, and establish a baseline execution time. The attacker then evicts a cache line of interest and runs the victim code again, with a variation in execution time indicating that the line of interest was accessed. PRIME+PROBE attacks pre-load every cache line in the target cache set with its own memory blocks so that the adversary can make sure her future memory

accesses will be served by the cache unless some of the cache lines are evicted by the victim program during its execution. Therefore, her own cache misses will reveal the victim's cache usage.

FLUSH+RELOAD [48] allows an attacker to determine which specific instructions are executed and which specific data is accessed by the victim program. Specifically, in FLUSH+RELOAD attacks, the adversary shares some physical memory pages (e.g., through shared libraries and system components) with the victim. By issuing flush instructions on certain virtual address ranges, the adversary can flush the (physical) cache lines that correspond to this address range out of the entire cache hierarchy. Therefore, any future reading (RELOAD) of the cache lines will be slower because they are loaded from the memory unless they have been accessed by the victim. Since some ARM processors do not have a flush instruction, EVICT+RELOAD has been proposed by replacing the flush instruction in FLUSH+RELOAD by eviction. This paper makes use of FLUSH+RELOAD to trace the execution of an app in Android.

3 ANDROSCOPE

In this section, we first provide an overview of the proposed attack starting with the threat model. We then describe the individual components of the attack in detail.

3.1 Threat Model

In the attack scenarios assumed by ANDROSCOPE, the adversary's general goal is to passively eavesdrop behavior of another victim app. The adversary is assumed to be local, i.e., the attack process is co-located with the victim process on the same physical device, and are both executed within the same operating system environment. Nonetheless, the attack process is considered to be isolated from the victim by app sandboxing and is not allowed to break such isolation via any intrusive approaches. We assume that the physical device is a multi-core system, and the attack and victim processes can run simultaneously on different cores. The attack process can create a few threads that run continuously in the background, but cannot attempt to obtain root privileges or request any special permissions. The adversary could perform offline reverse engineering of the victim app and correlate the memory addresses of methods to be targeted by its runtime surveillance.

3.2 Overall Workflow

Rather than leaking system-wide information via shared code components as demonstrated in previous work, ANDROSCOPE is designed to monitor app-specific methods to circumvent the protection of app sandboxing. In particular, utilizing the DICI mechanism enables ANDROSCOPE to load

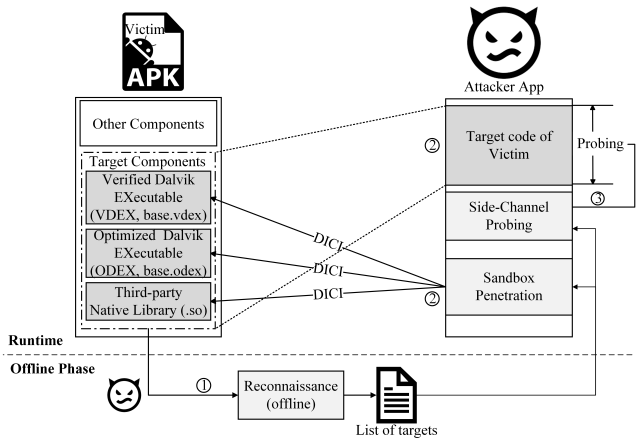

Figure 1: Overview of ANDROSCOPE

all the necessary executables of a victim app into the attacker's own memory space, creating a side-channel attack surface for the attacker process to probe any method of the victim as if observing it from inside using an endoscope (hence the name "ANDROSCOPE").

Figure 1 illustrates the overall workflow of the proposed attack. ANDROSCOPE consists of three phases to create an app-specific side-channel attack.

- **Phase 1: Reconnaissance (Section 3.3)** In order to detect sensitive information through side-channel probing, the adversary first determines which of the victim app's executable files are required and the offsets of the particular methods that are of interest. This is done offline with the adversary obtaining and conducting reconnaissance on the victim app's APK in advance.
- **Phase 2: Sandbox Penetration (Section 3.4)** With the reconnaissance results from Phase 1, the adversary deploys ANDROSCOPE (likely via a cover app with seemingly reasonable functionality) to detect whether the targeted victim app has also been installed. Upon a positive answer, ANDROSCOPE would leverage the DICI mechanism to load necessary code files of the victim app. This ensures that the ANDROSCOPE process shares physical code pages with the victim app of the DICI-loaded code files.
- **Phase 3: Side-Channel Probing (Section 3.5)** After the prior steps, the adversary finally launches side-channel probing of FLUSH+RELOAD to detect fine-grained traces of executions occurring within the victim app's code region, and thus gaining awareness of the sensitive runtime status of the victim.

To achieve the expected attack goal, a number of technical details are critical for the implementation of ANDROSCOPE. Note that our study was carried out on two smartphones as

Table 1: Experimental Devices

	Xiaomi Mi 11 Lite	Pixel 4a
Soc	Snapdragon 732G	Snapdragon 730G
Architecture	big.LITTLE	big.LITTLE
Processors	2x Kryo 470 Gold as big cores 6x Kryo 470 Silver as little cores	

listed in Table 1, which are both mounted with Qualcomm's ARMv8-A CPUs that adopt big.LITTLE architectures. Both devices have the cache line flushing instruction unlocked by default, making it available in user space.

3.3 Reconnaissance

Recall that the purpose of the reconnaissance phase is to determine which parts of a victim code are of interests in the side-channel attack. While the specific methods to be targeted can be selected via a careful manual analysis, the adversary must still be able to parse different types of executable files such that the linear address of these methods at runtime can be correctly resolved.

Today, the Android platform uses a runtime environment called Android runtime (ART) to execute methods in apps. ART uses ahead-of-time (AOT) compilation and, starting from Android 7.0, uses a combination of AOT, just-in-time (JIT), and profile-guided compilations. Specifically, before Android 8.0, an app is installed without any AOT compilation, but an Optimized Dalvik EXecutable (ODEX) named `base.odex` is generated with only Dalvik bytecode. When the device is idle and charging, a compilation daemon AOT-compiles frequently used code to machine code based on a profile generated during the first few runs, and inserts the instructions into the ODEX file. Starting from Android 8.0, however, ART stopped merging the DEX files into `base.odex` but introduced a VDEX file called `base.vdex` to store the copy of original DEX files. In addition, an increasing number of Android developers are incorporating third-party native libraries in their applications for code reuse, CPU-intensive tasks, and other purposes. According to the new runtime environment, the adversary therefore needs to parse all the aforementioned types of files so that the address of any potential targets of our attack can be obtained.

3.3.1 VDEX file Parsing

In order to obtain the target addresses of methods executed by the Dalvik Virtual Machine (DVM), we employ the vdexExtractor [5] utility for the parsing of VDEX files. vdexExtractor represents a command-line tool designed for the decompilation and extraction of Android Dex bytecode from VDEX files. These VDEX files are produced in conjunction with ODEX files during the optimization of bytecode by the dex2oat ART runtime compiler.

More specifically, we analyze the output file generated by vdexExtractor and extract the offset value (referred to as `vdex_offset`) corresponding to the method of interest based on its method name. It is worth noting that each method is subject to an additional fixed offset of 0x40 on our devices. The extra offset 0x40 is to account for a 4-byte magic number and a 4-byte version field at the beginning of the file. Consequently, the ultimate address utilized in the FLUSH+RELOAD attack is computed as follows: `vdex_base_address + 0x40 + vdex_offset`. Here, `vdex_base_address` is determined by examining the mapped location of `base.vdex` of the victim within the `/proc/self/maps` directory of the attacker.

3.3.2 ODEX file Parsing

We employ the oatdump utility to acquire the target offset, denoted as `odex_offset`, pertaining to a native-compiled method subject to AOT compilation. Furthermore, our investigation reveals the presence of a constant offset of 0x1000 (which corresponds to the ELF header page) that is uniformly applied to each native-compiled method on our devices. The ultimate address computation is achieved by summing the values of `odex_base_address`, which is ascertained by inspecting the mapped location of `base.odex` associated with the victim within the `/proc/self/maps` directory of the attacker, with 0x1000 and `odex_offset`.

3.3.3 Third-Party Native Library Parsing

Parsing a native library can be accomplished with ease by employing Executable and Linkable Format (ELF) analysis tools like objdump and readelf. These tools facilitate the retrieval of method offsets. In this paper, we make use of objdump to disassemble the native library and obtain the offset of the methods.

3.4 Sandbox Penetration

The most fundamental intention of Android's app sandboxing is to prevent any user process from accessing another process's private resources (e.g., code, data, config files). However, our observation on the undocumented DICI mechanism, especially regarding its side effect of dynamic code loading, puts a question mark on the effectiveness of app sandboxing.

Here we select `Organic Maps`, an open-source app from F-Droid, as an exemplary target to illustrate how DICI can be exploited to penetrate Android app sandboxing. Listing 2 shows the code snippet used for this mock attack testing, where the invocations at Lines 3 and 4 implement DICI in the exact same way as described in Section 2.2, only that the parameter `victimPackageName` is set to `app.organicmaps`, the package name of the victim app. We find that these two

```
pubic class MainActivity{
    public void LoadVictim(String victimPackageName, String victimClass, Optional<String> victimMethod
        ↪ ){
        Context ike = this.createPackageContext(victimPackageName,  Context.Context_INCLUDE_CODE |
            ↪ Context.CONTEXT_IGNORE_SECURITY);
        ClassLoader loader = ike.getClassLoader();
        /*only loading third-party native libraries needs to execute the following code*/
        Class utils = loader.loadClass(victimClass);
        Method method = util.getDeclaredMethod(victimMethod.get(), String.class);
        method.setAccessible(true);
        method.invoke(null,"/sdcard/Documents");
    }
}
```

Listing 2: Code snippet of attack app

```

Figure 2: Partial memory mapping of the attacker app with DICI

simple invocations are sufficient for the adversary to load all the VDEX and ODEX files of `Organic Maps` into the memory space of the attacker process. On top of this, we also find that by invoking Java methods that would eventually call a native method located in a particular third-party native library, the specific native library will be mapped to the attacker process as well. As shown in Lines 6 - 9 of Listing 2, we implemented such an invocation using the reflection mechanism with parameters `victimClass` and `victimMethod` set, respectively, to `app.organicmaps.MwmApplication` and `nativeSetSettingsDir`. The Java method referred by this particular reflection is known to eventually raise a Java Native Interface (JNI) call of the function `ToNativeString` in library `liborganicmaps.so`. Figure 2 presents part of the memory mapping of the ANDROSCOPE attack process after running the mock attack snippet. We can see that, beyond its own executable, all three code files of the victim `Organic Maps`, namely the `base.odex`, the `base.vdex`, and the `liborganicmaps.so`, have been mapped into the address space of the attacker app.

We repeated the same experiments for 1,000 apps downloaded from AndroZoo, a growing collection of Android applications from a few sources, including the official Google Play. The results indicate that ANDROSCOPE can successfully load the VDEX and ODEX files of all the tested apps by leveraging the DICI mechanism. In short, by using the DICI mechanism, ANDROSCOPE can directly load a victim's private code. This enables it to surpass prior methods relying on shared libraries and system APIs on resolution and resilience.

3.5 Side-Channel Probing

Compared to x86, ARM poses several technical challenges for cache side-channel attacks. For starters, not all ARM processors support the CLFLUSH instruction directly. However, ARM v8 offers instructions to flush data and instruction caches, allowing ANDROSCOPE to adopt an instruction sequence as given in Listing 3 to launch FLUSH+RELOAD attack.

```
// Cleans and Invalidates data cache by
    ↪ address to Point of Coherency
asm volatile ("DC CIVAC, %0" :: "r"(address));
// Ensures completion of the cleaning and
    ↪ invalidations
asm volatile ("DSB ISH");
// Synchronize the fetched instruction stream
asm volatile ("ISB");
```

Listing 3: Flush instruction in the FLUSH+RELOAD attack

Another challenge is that many ARM CPUs do not have a data-inclusive shared last-level cache (LLC). Green et al. [18] have also shown that there are other features in the ARM CPU implementation that make an attack more difficult. For instance, ARM devices implement inclusive and non-inclusive caches alike with both properties co-existing even in the same cache hierarchy. Fortunately, most ARM CPUs are cache-coherent. When a process accesses a cache line not currently cached in its own core, the CPU will try to fetch it from other cores in case other processes are accessing it. If successful, the resulting access will be much faster than accessing from

memory. This feature has been exploited in recent work [30] and in AndroScope as well.

One additional challenge is regarding the big.LITTLE architecture [31] adopted by many ARM CPUs consist of a System-on-a-Chip (SoC) made from two discrete computing clusters, one low-power group of cores and one high-power group. It appears that *only cores among big and LITTLE have the proper cache coherency protocol that can be exploited*, which requires the attacker and victim to be *on different classes of cores*. Further, we find it interesting that flushing takes significantly more time on the big cores (likely due to their cache replacement policy). As a result, AndroScope pins the attack threads on the "LITTLE" cores, both for performance consideration and also for reasons that high-value victim apps tend to exploit "big" cores for better user experiences.

Additionally, the existing threshold calibration method lacks reliability across devices from various manufacturers and models. Therefore, we have devised an adaptive strategy to accurately calculate the runtime cache hit/miss threshold on any given device. Specifically, we dynamically adjust the hit/miss threshold during runtime by monitoring the occurrence of false positives following a Flush+Reload operation. If the number of false positives exceeds a predefined threshold, we decrease the hit/miss threshold accordingly.

Last but not the least, given that side-channel probing is, after all, not a deterministic metric, we introduce a simple voting mechanism to improve the accuracy, which is by all means to monitor multiple addresses in the same method and come to the cache hit/miss conclusion according to the majority. Due to the minimum cache line size, we avoid monitoring more than one address in the same 64-byte code snippet. Moreover, our tests show that ARM CPUs tend to trigger the pre-fetching mechanism when a continuous segment of address space is accessed more than four times in a short period, causing any subsequent side-channel accesses to contribute nothing but false positives. Therefore, we also avoid probing more than four addresses of the same targeted method.

Note that for ARM processors that do not have a flush instruction, AndroScope makes use of the Evict+Reload approach [46] to carry out its cache side-channel attacks.

3.6 DICI in Real-World Apps

To understand the usage of DICI in real-world Android apps (a different experiment from that described in Section 3.4 where DICI was used by our attacker app), we utilize Soot [21] and FlowDroid [7] to construct and parse the call graph in 1,000 apps downloaded from AndroZoo, tracing how DICI is employed in the analyzed apps to gain insights into the prevalence and utilization of DICI. In summary, we find that DICI is used by 227 apps to load code in Google Mobile Services (GMS), including YouTube Kids[1], XPlayer[2], and QR & Barcode Scanner[3]. Additionally, we find that 412 apps call `createPackageContext` to obtain the context of other applications without loading the code, allowing them to access data stored in the *SharedPreferences* of other applications.

4 Evaluation

Now we present our experiences in applying AndroScope to attack two real-world applications, `Organic Maps` and `Briar`, for the purpose of inferring sensitive user behavior. The two victim applications are chosen due to them being primary targets of recent attacks, which enables us to compare with related work and reveal the unique offering of AndroScope in attack scenarios involving unauthorized, app-specific behavior inferring. Table 2 summarizes the prior work on the two applications as well as the new perspectives AndroScope offers. Although our attack scheme shares some common objectives with prior work, it offers two important unique properties. First, it does not require any specific permission, unlike prior work that leverages sensor readings. Second, it captures finer-grained behaviors of the targeted victim app in particular, unlike prior work that leverages system-level method invocations which include noise from other apps. The two apps also allow us to demonstrate our capability in monitoring all three types of victim code, including ODEX, VDEX, and native libraries.

To evaluate the extent and precision to which AndroScope can monitor app-specific behaviors across different app sandboxes, we implemented our scheme demo as a regular third-party app to carry out the mock attacks. In the following subsections, we go into details of each experiment and explain the specific target methods to be monitored, the intermediate results in detecting method executions, and the resulting overall capability in inferring user behaviors.

Recall that AndroScope monitors multiple addresses in one method and applies simple output voting to improve our accuracy of CPU cache side-channel monitoring. When attacking `Organic Maps`, our attack app leverages up to four targets within a single method at least four cache lines apart and uses an output voting threshold of three out of four; whereas for `Briar`, AndroScope uses up to three targets within a method at least two cache lines apart with an output voting threshold of two out of three. This is because that methods of `Briar` are generally shorter than those of `Organic Maps`. We further discuss such practical settings at the end of this section.

Table 2: Comparison with Previous Work on Inferring App Behavior

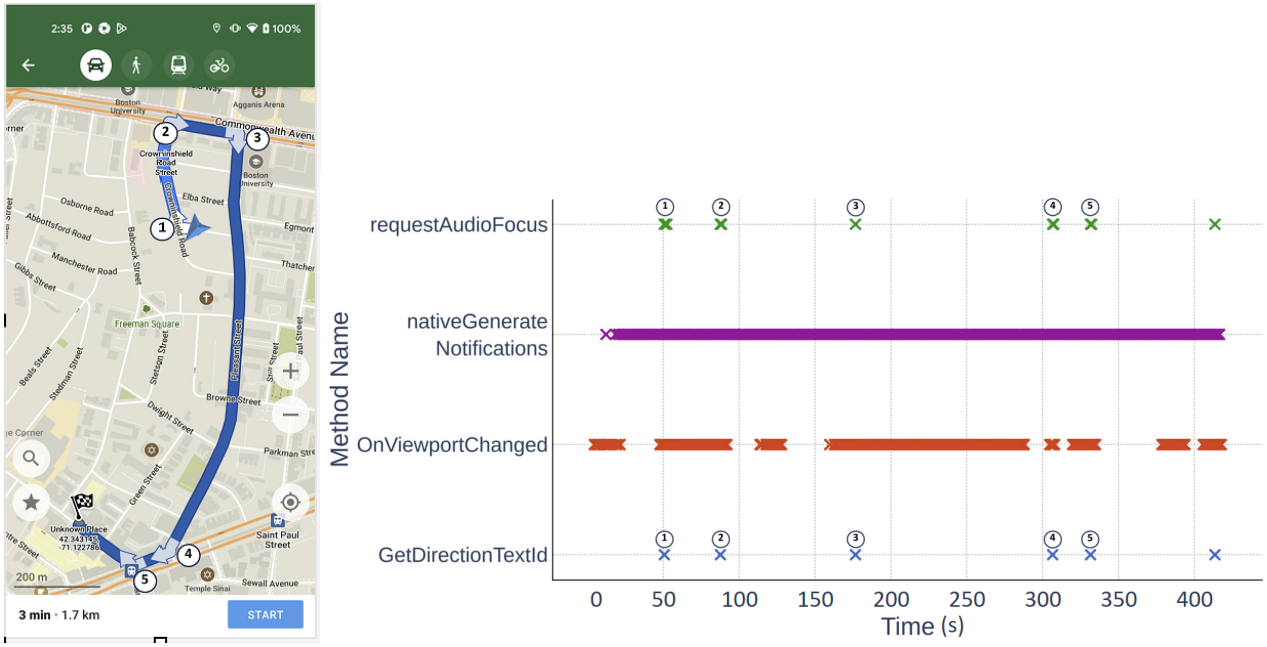
App		Organic Maps	Briar
Sensitive behavior to be inferred		Route taken in driving navigation	Keystroke dynamics in typing
Information leveraged	Prior work	Gyroscope, accelerometer, and magnetometer [35]	Timing of system-level method execution [30]
	AndroScope	Timing of app-level method execution	
		Methods from ODEX and native libraries	Methods from VDEX
Unique offering by AndroScope		• No permissions needed • Detecting start/end of navigation session	• No permissions needed • Detecting start/sending of a message

4.1 Inferencing Driving Routes

In this subsection, we investigate the potential of tracking users' mobility without explicitly requesting permissions to access the phone sensors or location services. More specifically, we demonstrate that AndroScope can accurately recover the route taken by the victim device user by tracing the execution of methods in the navigation app `Organic Maps`. Our observation is that when the vehicle approaches a turn, a turning notification audio will be played, and the detection of the execution of such audio-playing methods enables our attack app to recover the timestamps of each turning, which can be used to infer the route. Here we assume that the attacker has knowledge of the travel area of the victim (e.g., known to live in Boston) via other means such as analyzing IP addresses or social networks.

Monitored methods. We monitor driving-related methods encompassing route initiation, directional transitions, moments of immobility, and culmination. The primary objective of this study is to ascertain the effectiveness of AndroScope in elucidating the execution of these procedures. The details about these methods can be found in Table 3. Notably, the first three methods are intrinsic to a third-party native library, while the last method pertains to the ODEX file. When the vehicle approaches a directional change, both `GetDirectionTextId` and `requestAudioFocus` are invoked. In cases where vehicular motion is interrupted, for instance, at traffic lights, method `OnViewportChanged` is further scrutinized to determine whether the vehicle remains in motion along its designated route or is at a standstill. Lastly, method `nativeGenerateNotifications` serves the dual purpose of signaling the commencement and culmination of a driving session.

Implementation. Besides the technical details described in Section 3.4 and 3.5, our attack app leveraged the same algorithm proposed by Sensor [35] to process the logged cache hit timestamps for the selected methods and subsequently infer driving routes indicated by the gathered data. This design is to make our approach as comparable as possible with the previous work of the same attack purpose.



A sample route. Figure 3 illustrates an example of the tested driving route and its corresponding side-channel cache-hit timestamps for the monitored methods. The particular route had five turns (Figure 3a) which resulted in six cache hits for methods `GetDirectionTextId` and `requestAudioFocus`, out of which the first five indicated turns while the last one corresponded to an arrival notification. When the vehicle was stationary, we can see that there was no cache hit for method `OnViewportChanged`, whereas method `nativeGenerateNotifications` was always invoked. This enables us to deduct vehicle stationary time to arrive at a more accurate driving duration between two consecutive turns.

Intermediate results in detecting turnings. We randomly chose 33 routes in two cities, namely Boston and Waltham (provided by Narain et al. in their work of Sensor), and simulated the driving using Appium [1] by replaying the GPS coordinates along with the timestamps for both two devices Listed in Table 1. Result of AndroScope in correctly identifying the turns can be found in Table 4, where we report that our attack accurately identified the turns for 30 and 28 routes (out of 33) in Boston and Waltham respectively. Among the mistaken ones, AndroScope missed one turn for two routes and falsely identified an additional "turn" for one route in Boston. For Waltham, AndroScope identified one additional "turn" for three routes and failed to identify any turns for two routes. The timing of all correctly identified turnings, on the other hand, were all detected accurately.

Overall results in route reconstruction. We further demonstrate the effectiveness of AndroScope by reconstructing routes instead of solely focusing on the number of recoverable turns, utilizing other information obtained by AndroScope, such as timestamps between turns. To perform a fair comparison with Sensor, we remove the additional information Sensor has (e.g., angles of the route curve) and construct a setting with comparable inputs for Sensor and denote it as Sensor_OT. The percentage of routes that can be inferred by AndroScope, Sensor, and Sensor_OT are shown in Table 5, which indicate that the timestamps obtained by AndroScope can be used to effectively infer the route of driving compared to Sensor_OT. For example, 43% and 47% of routes can be inferred by AndroScope for mobile phones Xiaomi Mi 11 Lite and Pixel 4a respectively, while Sensor_OT can only infer 37% of the routes for Boston. For routes in Waltham, AndroScope can infer 64% of them

Table 3: Method to be monitored

Method Name	Description	Type
`GetDirectionTextId`	Indicates that the vehicle is approaching a turn	`liborganicmaps.so`
`OnViewportChanged`	Indicates whether the vehicle continues moving along the route or is stationary	`liborganicmaps.so`
`nativeGenerateNotifications`	Indicates that the navigation started and ended	`liborganicmaps.so`
`requestAudioFocus`	Indicates that the vehicle is approaching a turn	`base.odex`

(a) Route example

(b) FLUSH+RELOAD side-channel result

Figure 3: Route and FLUSH+RELOAD result.

for both mobile phones while SENSOR_OT can only infer 54% of them.

Comparison with Traditional Approach. We find that when a turn is approaching, the monitored method `requestAudioFocus` of `Organic Maps` eventually sends a request to the Android service `AudioManager` by invoking `android.media.AudioManager.requestAudioFocus` located in */system/framework/arm64/boot-framework.oat*. This file contains compiled code for core framework classes and methods provided by the Android framework and is shared across user processes. This means that in order to achieve the same attack described in this section like ANDROSCOPE, existing work regarding cache-based side-channel attacks against Android devices would have to probe the underlying system (framework) API as mentioned above to implicitly infer the navigation behaviors of `Organic Maps`. However, the audio focus mechanism provided by `AudioManager` serves a wide spread of different types of apps, such as `Spotify` and `WhatsApp`, enabling them to request exclusive or temporary control over the audio output of the device. As such, the execution of the aforementioned framework API alone can mean various types of events (other than navigation), e.g., viewing short videos or hearing voice messages, causing the existing Android side-channel work to be trapped in significant noise interference.

To give an illustrative example, we built a customized app called `NoiseApp` which is designed to continuously invoke `android.media.AudioManager.requestAudioFocus` in the background upon running (simulating music playing apps like `Spotify`). Then, in the presence of `NoiseApp`, the effectiveness of ANDROSCOPE is compared with the traditional Android side-channel approach which can only resort to framework API monitoring (utilizing the same FLUSH+RELOAD approach). The result showed that during the navigation of the same route in Figure 3, the compared traditional side-channel approach picked up a total of 12,089 cache hits for the targeted framework API, out of which 12,083 were actually “noises" contributed by `NoiseApp`; on the other hand, such noises had no impact on ANDROSCOPE because it observes the method `requestAudioFocus` within the code base of `Organic Maps` and is able to confirm the de-

Table 4: Routes distribution under ANDROSCOPE. *Correctly identified* means all identified turns correspond to ground truth. *Extra one* means ANDROSCOPE mistakenly identified one additional turn while *Miss one* means ANDROSCOPE misses one turn compared to ground truth. *Failed* means ANDROSCOPE cannot identify any turns at all.

City	Xiaomi Mi 11 Lite				Pixel 4a			
	Correctly identified	Extra one	Miss one	Failed	Correct identified	Extra one	Miss one	Failed
Boston	30	1	2	0	30	1	2	0
Waltham	28	3	0	2	28	3	0	2

Table 5: Percentage of routes that can be inferred by ANDROSCOPE, SENSOR, and SENSOR_OT

City	ANDROSCOPE		SENSOR	SENSOR_OT
	Xiaomi	Pixel 4a		
Boston	43%	47%	67%	37%
Waltham	64%	64%	93%	54%

tection with the observation on another in-app private method, namely `GetDirectionTextId`.

In conclusion, there are two main aspects in which ANDROSCOPE goes beyond existing work, including (1) ANDROSCOPE demonstrates the capability of directly probing a victim's private code, surpassing previous methods relying on system APIs; and (2) ANDROSCOPE dismisses concerns about background noise as raised in the existing approach.

4.2 Inferring Keystroke Dynamics

In this subsection, we demonstrate that ANDROSCOPE can be used to launch keystroke timing attacks as well. The high-level observation is that by monitoring the callback methods of keyboard pressing using our attack, an adversary could obtain precise timing of each key press, which could be subsequently used to infer the actual words and sentences typed. Our work differs from the prior work of ARMageddon [30] in that we monitor app-level methods instead of system-level methods, which not only eliminates noise introduced by other apps when they execute the same system-level method implementations, but also enables our attack to gain more knowledge on what is being input by the user (e.g., characters or spaces). In addition, the method-level difference also makes ANDROSCOPE immune to counter-measures like KeyDrown [42] which runs through the same code path in the shared library for all, fake and real, keystrokes.

Monitored methods. As depicted in Figure 4, `Briar` transforms the "send" icon into an attachment icon in the absence of text within the chat box, which is facilitated through the invocation of the `updateViewState` method. Simultaneously, the method `onTextIsEmptyChanged` is invoked whenever a transition occurs within the chat box, either from an empty state to a non-empty one or vice versa. Consequently, we leverage cache hit events associated with these two methods to signify the commencement and dispatch of a message. Furthermore, the act of entering a character or depressing the space bar triggers the execution of `onTextChanged` method, whereas method `countLeadingWhiteSpace` is executed exclusively when the current count of leading white spaces, measured from the cursor position to the last character typed, is zero.

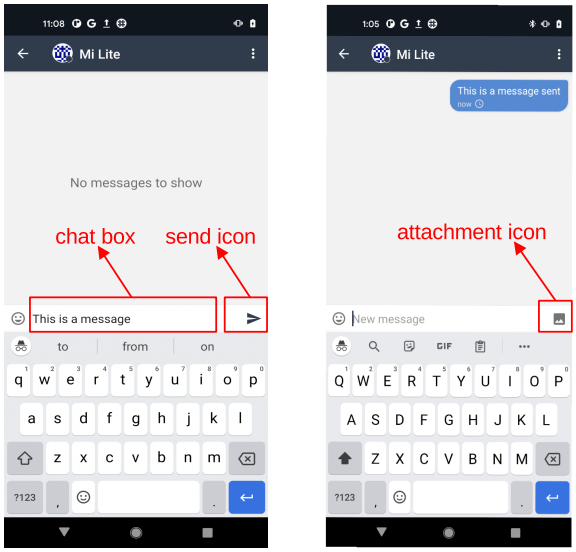


Figure 4: Example of the main page of Briar

As shown in Listing 4, `Briar` implements its own overloaded version of the `onTextChanged` function, which is called to notify that, within the parameter string *s*, the *count* characters beginning at *start* have just replaced old text that had length *before*. Specifically, if *isEmpty* is true (indicating that the text was previously empty), it checks whether the characters that were added (count) contain any leading whitespace characters (Lines 3 - 8). If there are non-whitespace characters among the added ones, it means the text is no longer empty. If *isEmpty* is false and *before* is greater than 0 (indicating that characters have been replaced), it checks from the beginning of the text (index 0) to see if the entire text consists of whitespace characters (Lines 8 - 15). Note that after a spacebar is pressed, the current Android system will set *offset* to zero. When subsequently the next letter is typed, function `countLeadingWhiteSpace` will not be executed.

Table 6: Method to be monitored in Briar

Method Name	Description	Purpose
`onTextIsEmptyChanged`	Gets called when the chat box changes from empty to non-empty or from non-empty to empty	Indicates the start of a message and the sent of a message
`updateViewState`	Updates the composite button functionality. When there is no text in the chat box, the button becomes an 'attachment' icon. When it is filled with text, the button becomes a 'send' icon	Indicates the start of a message and the sent of a message
`onTextChanged`	Gets called whenever a letter is typed, deleted, or when the space bar is pressed	Used together with method `countLeadingWhitespace` to determine the start of a new word.
`countLeadingWhitespace`	Counts the number of leading whitespaces from the current cursor position up until the last character typed	Used together with method `onTextChanged` to determine a space has been entered and indicates the start of a new word

```
1  public void onTextChanged(CharSequence s, int
       ↪ start, int before, int count) {
2      if (emptyTextAllowed || listener == null)
           ↪ return;
3      if (isEmpty) {
4          if (countLeadingWhitespace(s, start,
               ↪ count) < count) {
5              isEmpty = false;
6              listener.onTextIsEmptyChanged(false);
7          }
8      } else if (before > 0) {
9          // Characters have been removed or
               ↪ replaced - check from the start
10         int length = s.length();
11         if (countLeadingWhitespace(s, 0, length)
               ↪  == length) {
12             isEmpty = true;
13             listener.onTextIsEmptyChanged(true);
14         }
15     }
16 }
```

Listing 4: Code snippet of function onTextChanged

A sample message. For instance, consider the message "This is a message sent". Upon pressing the space bar following the word "This", the value of *offset* was set to zero. Subsequently, when the letter *i* was typed, in accordance with the established policy, the code lines in the else condition (Lines 10 - 13 of Figure 4) were not executed, thereby precluding the execution of the `countLeadingWhiteSpace` method. However, upon typing *s*, the value of *offset* became one since there was no white space immediately ahead of it, prompting the invocation of the `countLeadingWhiteSpace` method.

It is important to note that throughout this entire process, the `onTextChanged` method was consistently invoked. Consequently, these two methods were employed to ascertain the length of an individual word being typed. The method that we probed on Google Pixel 4a can be found in Table 6 and all four methods were located in the VDEX file.

The side-channel cache-hit result on these four methods is shown in Figure 5. We can see that AndroScope accurately identified the starting and sending time of a message from the cache hits obtained for methods `onTextIsEmptyChanged` and `updateViewState`. By analyzing the cache hit result for methods `onTextChanged` and `countLeadingWhitespace`, we can see that a cache hit on method `onTextChanged` and no hit on method `countLeadingWhitespace` can be used to indicate the first letter of a new word.

Results of keystroke timing detected We computed the inter-keystroke timing difference between the ground truths and AndroScope attacks with five human typing cases and 20 simulated (and replayed) typing cases, and the result is shown in Figure 6. We can see that the timing difference between the ground truth and our attack was trivial, indicating that the obtained cache-hit timestamps may be directly used as resources for keystroke timing attacks. More specifically, the average keystroke timing difference between the ground truth and our side-channel attack was only around 0.00005 seconds while the average time for inter-keystroke was around 0.25 seconds.

Comparison with Traditional Approach. Armageddon scans two addresses in the default AOSP keyboard, namely `Latin-IME.odex`, to showcase the capability of word length detection. This requires inspecting the memory mapping file (i.e., */proc/pid/maps*) of the system application `com.android.inputmethod.latin`. However, accessing files like */proc/pid/maps* which belong to another app's process requires root privilege (e.g., with a rooted Android device). The proposed approach, AndroScope, eliminates this requirement and does not need any additional permissions.

4.3 Flexibility of AndroScope

Now we further investigate the flexibility of AndroScope in probing the execution of a method under different configurations to better support the effectiveness of our approach. Specifically, we set the maximum number of addresses to be probed in a particular method to be five, and the minimum gap between two consecutive addresses be one cache line, two cache lines, and four cache lines, respectively. We tested 24

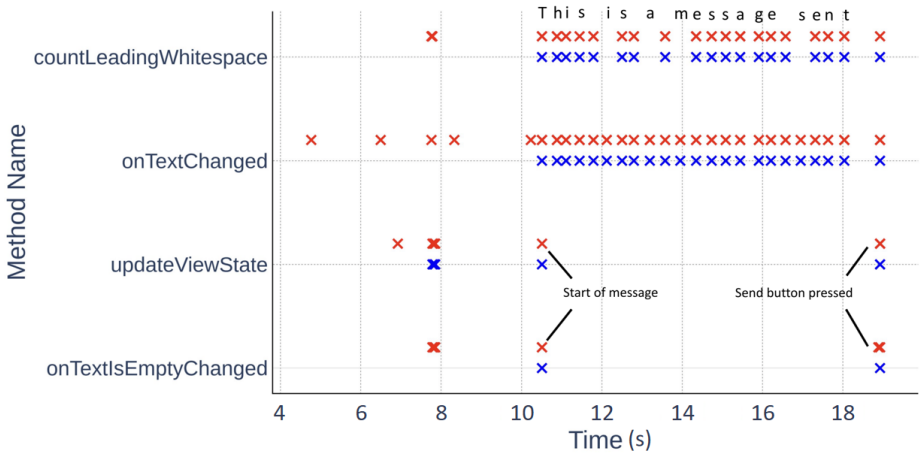

Figure 5: User input reference. The blue x is the ground truth obtained by instrumenting the app, which means the method is really executed. The red x means the cache hit.

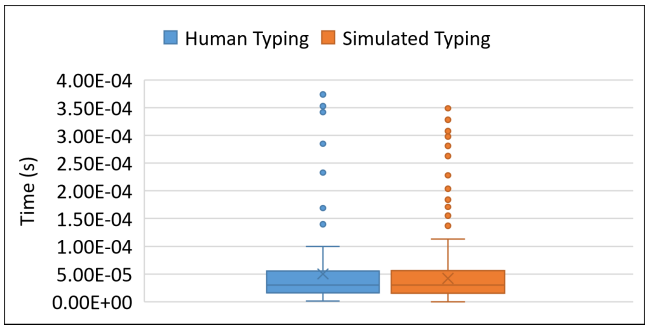

Figure 6: Keystroke time difference between side channel and ground truth

methods in the VDEX file, ODEX file, and third-party native library in apps `Dolphin` [2] and `Briar`, with the F1 score of AndroScope in identifying the execution of each method under different configurations shown in Figure 7. Here, "forward" means the monitored addresses are ordered from low to high, and AndroScope probes the lower one first; whereas "backward" means the addresses are ordered reversely and the higher address is probed first. We can see that although the F1 score differs from method to method[4], for most methods we can always find a configuration under which AndroScope can work with a satisfying accuracy. This indicates that when launching the proposed attack, an adversary is in fact quite flexible w.r.t. the detailed attack strategy, the technical arsenal, as well as the selection of target methods.

For certain methods, we observed suboptimal performance, notably in methods 4, 19, and 20. Several factors may contribute to this suboptimal performance, including but not limited to (1) The potential for cache pollution when a small method shares a cache line with a preceding large method; (2) Cases where a frequently executed method with a short duration may exceed the probing resolution capabilities of AndroScope; (3) Situations where multiple probed addresses share the same cache set, resulting in conflicts.

[4]The reasons of the relatively unstable results may include the prefetching mechanism, layout, and sequence of binary code in the address space, sizes of individual methods, starting/ending offset of a method from the nearest cache line boundary, and etc. We leave the more thorough investigation regarding this observation as a future work.

4.4 Performance Overhead

To evaluate the runtime overhead of AndroScope, we conducted experiments by running our attack app on a series of devices listed in Table 1, with it kept in the background for the whole period. We then used one of the most popular benchmarks, `Geekbench-6` [3], to assess the devices both with and without *appside* running. Specifically, `Geekbench` runs a series of tests on a processor and measures the time it takes for the processor to complete these tasks. The faster the CPU completes the tests, the higher the `Geekbench` score is.

We configured AndroScope to probe different numbers of addresses, namely 276, 151, and 104 addresses in Dolphin, and ran `Geekbench-6` 10 times to obtain the average score. As shown by the results presented in Figure 8, AndroScope reduced the benchmark scores respectively by 18.09%, 14.98%, and 12.78% for the Xiaomi Mi 11 Lite with the three experiment configurations. For the Pixel 4a, AndroScope decreased the benchmark score by 27.49% when probing 276 addresses and by 23.13% and 20.14% when probing 151 and 104 addresses. The overhead mainly comes from the side-channel probing. We expect such overhead to decrease when AndroScope is configured to probe its target addresses less frequently or when the attack is launched on more recent (and powerful) devices.

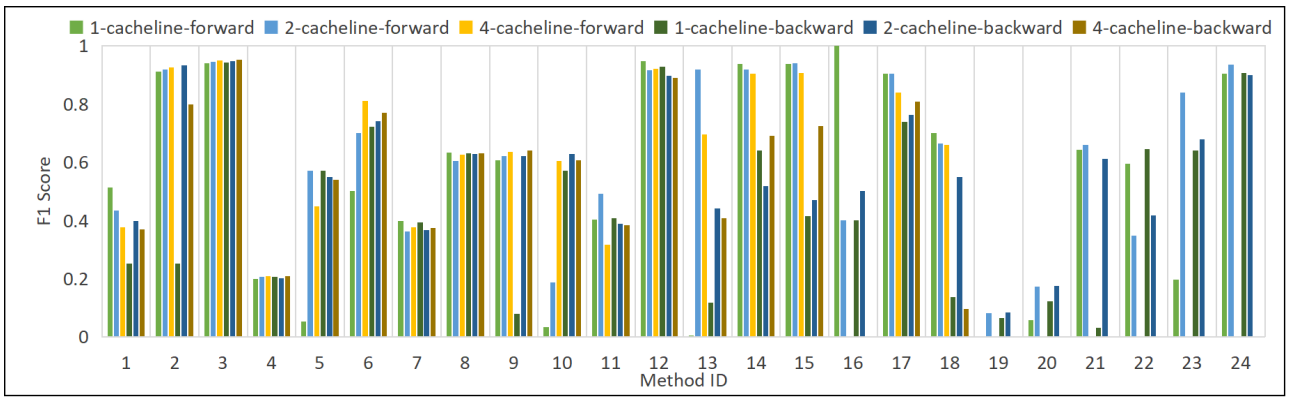

Figure 7: F1 score distribution under different configurations

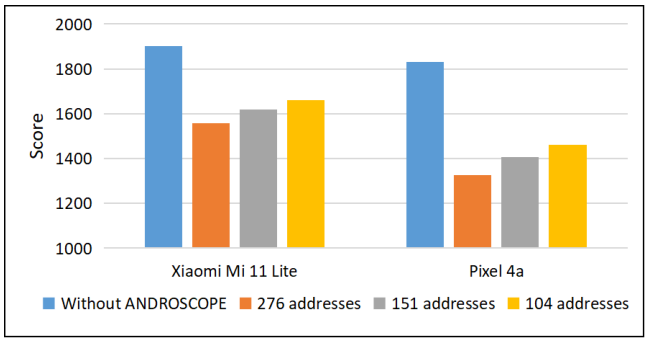

Figure 8: Performance of ANDROSCOPE evaluated with Geekbench Benchmark

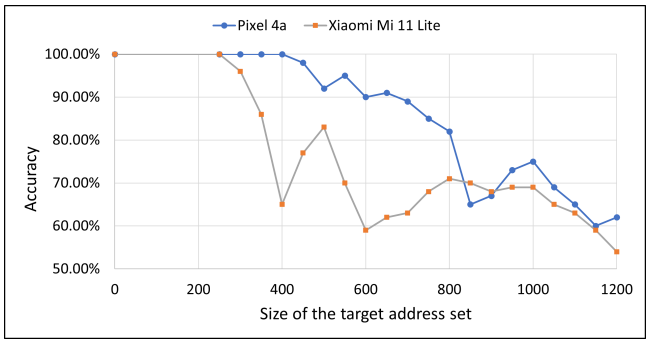

Figure 9: Throughput of ANDROSCOPE, where "0" for the size of ANDROSCOPE's target address set indicates that the subject app's button click was monitored.

4.5 Number of Concurrent Addresses Monitored

With this evaluation, we intend to demonstrate the capability of ANDROSCOPE in monitoring multiple code addresses simultaneously. Currently, our FLUSH+RELOAD component occupies one CPU core and conducts sequential polling on a given set of target addresses. Therefore, here we progressively increased the size of ANDROSCOPE's target address set (+50 a time until the total amount of targets reaches 1,200), with one particular address corresponding to a button click event of a subject app always included; then, the subject app was manually used with the being monitored button clicked for 100 times, to see how many of the clicks were identified. As can be found in Figure 9, the accuracy of our approach was maintained at 100% for Pixel 4a and Xiaomi Mi 11 Lite before the number of scanned target addresses reached 400 and 250, respectively. Beyond these thresholds, the accuracy decreased gradually until down to 62% and 54% respectively when ANDROSCOPE scans 1,200 target addresses simultaneously. It is important to highlight that the previous case studies on `Organic Maps` and `Briar` (Section 4.1and 4.2) only involve scanning 11 and five addresses, respectively. This underscores that scanning 400/250 addresses is sufficient in real attack scenarios to enable ANDROSCOPE to achieve full capability.

4.6 Countermeasures

There are several steps one could take to help mitigate the side-channel attack that we discover.

Firstly, DICI usage can be restricted in several ways. Android OS could introduce an enhanced access control mechanism by adding a declaration to the AndroidManifest file. This declaration would define which legitimate apps are allowed to use DICI or determine which specific parts of the code (such as classes) can be accessed by other applications through DICI. By doing so, Android developers and system administrators can exercise greater control over the scope and permissions of DICI usage, ensuring that sensitive data and functions are protected from unauthorized access.

We rely on reading the */proc/self/maps* file to gather vital details about the VDEX, ODEX, and third-party native libraries of victim apps that are mapped into the attacker's address space. Restricting access to this sensitive information significantly raises the complexity of the proposed attack.

We modify the Android kernel to enhance security by selectively omitting memory mapping information for files located in other apps' private directories. Specifically, we revise the `show_map_vma` routine in `task_mmu.c` to not display memory mapping information when the resolved package name does not match with the package name of the current task.

We also evaluated the runtime overhead of this countermeasure by running `Geekbench-6`. The corresponding scores with and without countermeasures are 1,840 and 1,863, respectively, demonstrating a negligible runtime overhead.

Another way to mitigate the FLUSH+RELOAD attack we proposed is to prevent physical memory sharing among apps. This can be achieved by implementing techniques like the *copy-on-access* method proposed by Zhou et al. [51]. With this approach, a state machine is employed to meticulously monitor the sharing of each physical page among distinct security domains, such as containers. Whenever a shared page is accessed by any security domain, an immediate page copy operation is triggered. This proactive measure serves as a strong defense against FLUSH+RELOAD attacks by disrupting the mechanism that attackers could exploit.

5 Related Work

5.1 Cache Side-Channel Attacks on ARM

Most of the existing work so far has focused on x86 processors. For ARM, we are aware of some papers that specifically explore the security of caches. ARMageddon [30] makes use of the flush instruction provided by ARM v8 to launch FLUSH+RELOAD attacks to probe user input. It also introduces PRIME+PROBE and EVICT+RELOAD attacks for ARM processors that do not have the flush instruction. Zhang et al. [50] give a systematic exploration of vectors for FLUSH+RELOAD attacks on ARM processors and use the FLUSH+RELOAD attacks to trace software execution. AutoLock [18] explores how the *AutoLock* feature found in some ARM processors could be used to thwart some cache timing attacks. It also shows how attackers can overcome the feature and perform EVICT+TIME and PRIME+PROBE attacks. TruSpy [49] analyzes timing cache side-channel attacks on ARM TrustZone and exploits cache contention between the normal world and the secure world to leak secret information from TrustZone protected code using PRIME+PROBE attack. Lee et al. [28] explore FLUSH+RELOAD attacks on the ARM FPGA by exploiting Accelerator Coherency Port (ACP) and iTimed [20] makes use of PRIME+PROBE and FLUSH+RELOAD to attack Apple A10 Fusion System-on-a-Chip (SOC). Wang et al. [46] make use of EVICT+RELOAD attacks to extract a user's password and PIN.

5.2 Side-Channel Attacks on Mobile Sensors

IMU sensor readings on mobile devices have been used to infer sensitive information too. Abdul Rehman et al. [24] proposed and developed an application on the Android platform that runs in the background and gathers information in accelerometer, gyroscope, and magnetometer to infer the keystrokes being typed. Some work [8, 34, 39] used the accelerometer sensor to infer password inputs. Sashank et al. [35] utilized the accelerometer, gyroscope, and magnetometer to infer the route of driving. However, these approaches are known to be very sensitive to random noise and heterogeneous human behavior patterns.

6 Discussion

6.1 Other Scenarios of ANDROSCOPE

In addition to monitoring method execution, ANDROSCOPE exhibits the capability to infer sensitive data. A notable illustration of this capability lies in the DICI mechanism, which may be employed to access data stored in the *SharedPreferences* of another application. *SharedPreferences* serves as a frequently utilized repository for storing key-value pairs, and this repository can encompass sensitive information [9, 29].

6.2 Limitations

Due to the nature of DICI, an app can add noises to ANDROSCOPE by invoking the monitored methods in the victim app. This potential for noise arises from the fact that other apps can inadvertently trigger the same methods that ANDROSCOPE is monitoring. Since we FLUSH+RELOAD multiple functions at the same time, the likelihood of these functions being called together by another app is very low. Hence, most background noise of this kind can be eliminated.

Secondly, a Java method will be compiled using the just-in-time (JIT) compiler and stored in a code cache if it is frequently executed. This optimization mechanism enhances the performance of the application by allowing frequently used methods to be readily available in compiled form. However, this code cache is specific to each individual application and is not shared between the attack and the victim apps. Consequently, ANDROSCOPE cannot be used to launch an attack against this type of method. We observe the activation of JIT compilation after methods have been executed more than 100 times. During periods of device idleness and charging, Android initiates the re-compilation of applications based on the aggregated profile generated during initial runs. At this stage, high-frequency methods are incorporated as native components within the ODEX file. Consequently, frequently executed methods may experience temporary inaccessibility when located inside the code cache due to JIT compilation. However, AndroScope regains access to such code

by patiently waiting and subsequently reloading the ODEX associated with the targeted application.

Thirdly, when an app targets Android 11 (API level 30) or higher and queries for information about other apps installed on a device, the system filters this information by default. In this case, the attacker needs to manually use the `<queries>` element in the manifest file to declare the need for package visibility, so that DICI can work. The `<queries>` element allows developers to specify which packages or components they need to access, granting their apps the necessary permissions to interact with these elements. It's a security measure introduced by Android to protect user privacy and data. While some application stores, like the Google Play Store, may remove the malicious app, attackers can employ various methods to install it, including through advertising and phishing.

7 Responsible Disclosure

We have responsibly informed Google about the risk posed by DICI regarding its potential to bypass Android app sandboxing and infer private information related to individual apps through cache-based side-channel attacks. Google informed us that they have completed their assessment on June 7, 2024, have determined that the issue is of moderate severity, and will pass it to their feature team to fix in an upcoming release. It remains unclear to us how this issue is to be fixed.

8 Conclusion

In this paper, we propose AndroScope, a side-channel attack scheme that fully circumvents the application sandboxing mechanism of Android by leveraging the DICI mechanism supported by the platform. The experimental results on a number of real-world apps showed that AndroScope can be used to successfully infer fine-grained user behavior by probing app-specific methods executed in the victim processes, with the attack app not conducting any intrusive operations, obtaining root privilege or requesting any unusual permissions.

Indirector: High-Precision Branch Target Injection Attacks Exploiting the Indirect Branch Predictor

Luyi Li* Hosein Yavarzadeh* Dean Tullsen

University of California San Diego

* Equal contribution joint first authors

Abstract

This paper introduces novel high-precision Branch Target Injection (BTI) attacks, leveraging the intricate structures of the Indirect Branch Predictor (IBP) and the Branch Target Buffer (BTB) in high-end Intel CPUs. It presents, for the first time, a comprehensive picture of the IBP and the BTB within the most recent Intel processors, revealing their size, structure, and the precise functions governing index and tag hashing. Additionally, this study reveals new details into the inner workings of Intel's hardware defenses, such as IBPB, IBRS, and STIBP, including previously unknown holes in their coverage. Leveraging insights from reverse engineering efforts, this research develops highly precise Branch Target Injection (BTI) attacks to breach security boundaries across diverse scenarios, including cross-process and cross-privilege scenarios and uses the IBP and the BTB to break Address Space Layout Randomization (ASLR).

1 Introduction

Modern processors include extensive support for predicting the outcome of control flow operations. As the potential for transient execution attacks [14, 19, 24, 29, 31, 32, 37, 52, 60, 69] has become apparent, these structures have become a favored target for direction poisoning [24, 29, 31, 52, 69] and target injection attacks [14, 31, 32]. Most of those attacks have been launched with limited knowledge of the actual structure of those predictors, and were thus forced to rely on heavyweight brute force algorithms to discover and create the type of aliasing necessary to launch an attack.

Of particular concern are Branch Target Injection (BTI) attacks, which dramatically open up the potential gadgets that can be employed to exploit a vulnerable branch instruction. These attacks exploit the structures responsible for predicting the target address of taken branches. In modern processors, those structures are the Branch Target Buffer (BTB), the Indirect Branch Predictor (IBP), and the Return Stack Buffer (RSB). This paper examines the first two (BTB and IBP), with particular focus on the IBP because it is the least documented and least understood of all the branch prediction structures.

Indirect branches are branches whose address is computed at runtime, with the address loaded from a register or memory. They can be used for switch and case statements, for calling functions passed as arguments, for object-oriented languages that can overload function calls, etc. While direct branches always have the same target (and are easily predicted with simple structures), accurate prediction of indirect branches requires capture of past history patterns [14, 31, 44, 49, 59, 69, 70], much like conditional branch predictors, and requires more complex structures.

For the first time in the literature, this work reveals exactly how the BTB and the IBP cooperate to make a prediction of indirect branches on Intel processors. It also reveals the precise structure of the IBP, including how history is captured, how that history is used to index the several tables of the IBP, how the tags are formed from the history and the branch address, how many bits of the target are stored and how many are assumed, and lastly, the size, associativity and structure of each table in the IBP.

This information enables several new, high precision attacks on the table itself – these include two new target injection attacks and a new technique to break ASLR. While these machines can capture nearly 400 bits of branch history (representing a huge search space), precise understanding of how that history is folded down to index one of the actual tables allows us to instead systematically probe only 512 sets, incurring no wasted computation – even in the cases where we must use brute force methods, for example in aliasing a branch of unknown address or history. Being able to launch these attacks with orders of magnitude greater efficiency has immense implications. Current mitigations against these attacks are heavyweight and costly. Ultimately, the frequency at which such mitigations need to be deployed is directly connected to the minimum runtime of a successful attack. Reducing the runtime of these attacks by orders of magnitude means that the perceived performance cost of these mitigations to the user can go from slightly noticeable to unpalatable,

and for all practical purposes render these solutions no longer viable for any but the most protected code.

Intel has provided several mitigation mechanisms aimed at protecting the BTB and IBP from different types of target injection attacks, which vary in goals, actual operation, and performance implications. These include Indirect Branch Restricted Speculation (IBRS) [8], Single Thread Indirect Branch Predictors (STIBP) [3], and Indirect Branch Predictor Barrier (IBPB) [7]. This work carefully deconstructs each of these mitigations on both pre-Spectre and post-Spectre Intel processors, and reveals for the first time in the literature the precise actions employed by each. Those actions vary by machine, and do not always correspond closely to their advertised goals. We also describe some surprising attack surfaces that remain uncovered by these mitigations.

Contributions. The contributions of this work are:

- It presents the first comprehensive analysis of the Indirect Branch Predictor and its interaction with the Branch Target Buffer in the recent Intel processor families, detailing the size, structure, and precise indexing and tagging hash functions of each table.
- It carefully analyzes mitigation mechanisms (IBRS, STIBP, and IBPB) designed to protect against BTB and IBP target injection attacks on both pre-Spectre and post-Spectre Intel processors, revealing for the first time in the literature the specific actions employed by each mechanism.
- It proposes iBranch Locator, an efficient and high-resolution tool capable of locating any indirect branch within the IBP without requiring prior history information about the branch. Using this tool, it introduces high-precision target injection attacks and successfully breaks address space layout randomization.

Outline. Section 2 provides background and related work. Section 3 delves into the analysis of the BTB and IBP structures. Section 4 deconstructs the Intel hardware defenses against BTI attacks. Section 5 introduces our attack primitive to extract the index and tag of any victim indirect branch. Section 6 describes our new target injection attacks. Section 7 discusses potential mitigations, and Section 8 concludes the paper.

Responsible Disclosure. We disclosed our findings to Intel before submitting to USENIX Security 2024.

2 Background and Related Work

This section provides relevant background information about the branch prediction mechanism in modern high-performance processors, focusing on Indirect Branch Predictors (IBP) and their role in providing target addresses for indirect branch instructions. We review state-of-the-art IBP structures, followed by a discussion of the most relevant research on branch-based side-channel attacks and mitigations.

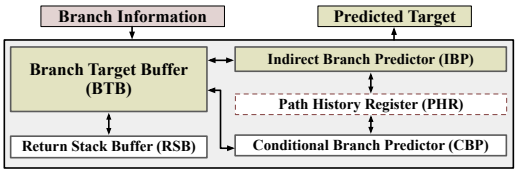

Figure 1: Branch Prediction Unit Internals in Modern CPUs.

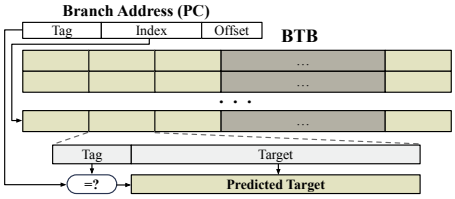

Figure 2: Overall Structure of the Set-Associative BTB.

2.1 Branch Prediction

The Branch Prediction Unit (BPU) plays a crucial role in modern high-performance processors by steering the processor front-end pipeline through the identification of branch instructions, their directions, and target addresses. To provide predictions for the variety of control flow mechanisms, the BPU incorporates various dedicated structures, as Figure 1 illustrates [2,14,24,29,31,38,70]. Among these are the Branch Target Buffer (BTB) [28], which predicts whether an instruction is a branch instruction and, if so, predicts the target address. Additionally, the Indirect Branch Predictor (IBP) [44] serves as a dedicated unit for predicting the target addresses of indirect (computing) branches—those whose targets reside in registers or memory. Furthermore, a Conditional Branch Predictor (CBP) [50,70] is employed to determine whether conditional branch instructions will be taken or not-taken.

Branch Target Buffer (BTB): The BTB keeps track of the recently executed target addresses of branch instructions and predicts the occurrence of future branch instructions along with their targets. Earlier research [2,5,23,27,41,58,59,74] reverse engineered the BTB structures of several modern CPUs, revealing that they each exhibit an almost identical cache-like set-associative structure (shown in Figure 2), albeit with varying sizes. In Section 3, we delve into a more detailed examination of the BTB's structure in high-end Intel processors.

Indirect Branch Predictor (IBP): In addition to the BTB, there is a dedicated unit specifically designed for predicting the target addresses of indirect branch instructions, known as the Indirect Branch Predictor (IBP) [44]. Indirect branches, also known as computed branches, differ from direct branches

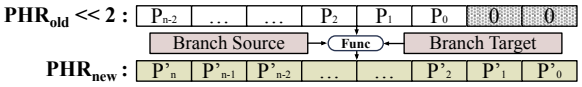

Figure 3: PHR Update Process: (1) PHR is first left-shifted by 2 bits and then (2) combined with branch and target addresses via a *Function*, detailed in Appendix A.

in how they determine the next instruction to execute. Instead of specifying the target address directly, indirect branches rely on a value stored in a register or memory location, which is calculated at runtime. This approach enables dynamic control flow patterns, such as switch-case statements in high-level languages. Predicting the target address of these branches is challenging because they may have multiple targets, and cannot be simply predicted by the BTB (which captures a single address). Consequently, a dedicated unit, such as the IBP, is necessary to accurately predict their target addresses.

The state-of-the-art IBP design in the literature is known as Indirect Target Tagged GEometric length (ITTAGE) [49] predictor, which uses history-based structures [39, 48, 50] to predict the targets of indirect branches. This prediction is made based on the global history which captures the record of executed branch instructions within the processor. There exist two forms of global history: the first is the Global History Register, or GHR - inserting 1 when a branch is taken and 0 when it is not. The second form is the Path History Register, or PHR, where updates are influenced by one or more bits in the branch source and/or target address. The ITTAGE predictor comprises a tagless base predictor responsible for delivering a default prediction along with a set of (partially) tagged predictor components, each indexed through independent functions of the global history and the branch address.

Path History Register (PHR): In 2018, Spectre attacks [31] revealed the potential for exploiting CBP or BTB/IBP mispredictions, coupled with speculative execution, for malicious purposes. Fundamentally, Spectre attacks capitalize on branch mispredictions to execute code that can lead to the leakage of sensitive data. Specifically, they reverse-engineered some structures of the IBP designed for Haswell architecture including the global history (PHR). They found that the PHR tracks taken branches and gets updated using the corresponding branch and target addresses, as Figure 3 illustrates. We summarize the latest findings (based on [69, 70]) about the PHR update policy in Appendix A, and verify that these findings still hold true for more recent Intel processors not covered in earlier studies.

It is important to highlight that some earlier studies [14] claimed the existence of only one BTB with different indexing schemes. Nonetheless, our reverse engineering work unveils that the IBP incorporates a distinct and separate structure, a topic we will delve into in Section 3.

2.2 Branch-based Side Channel Attacks

We categorize branch-based side-channel attacks into two main types based on the specific BPU structure they target:

Direction based attacks: These attacks [19,22,24,31,52,69] aim to extract or manipulate the control flow of a victim process by analyzing or influencing the CBP state. The most representative attack is Spectre v1 [31]. This can reveal confidential information or steer the victim's execution towards unintended paths.

Target based attacks: These attacks attempt to directly hijack and/or extract the victim's control flow by poisoning entries in the BTB and/or IBP. Early research on branch-based vulnerabilities primarily targeted the BTB [9–11]. These attacks demonstrate a timing side channel based on BTB capacity. Following the initial BTB-focused research, Evtyushkin et al. [23] leveraged BTB collisions to bypass Kernel Address Space Layout Randomization (KASLR) by colliding entries between an unprivileged user process and privileged kernel code. Similarly, Lee et al. [34] exploited BTB collisions to infer the control flow of victims.

More recently, in Spectre v2 [31], also called Branch Target Injection (BTI), the attacker trains the target predictors (BTB and/or IBP) so that the victim program speculatively jumps to a chosen disclosure gadget. Through speculative execution of the instructions within the gadget, the attacker gains access to the victim's confidential data, subsequently transferring it via the data cache [26, 56, 68] or other covert channels [17, 22, 45, 47, 65, 76].

Similar to Spectre v2, Barberis et al. [14] introduce Branch History Injection (BHI), a cross-privilege BTI attack. Since the branch target entries are isolated between kernel and user, Spectre v2 is difficult to directly apply in a cross-privilege scenario, targeting a kernel branch. This work finds that the branch history state (PHR) is still shared across privilege levels. Therefore, the attacker manipulates the branch history in user space and further misleads a kernel indirect branch to a prepared malicious kernel gadget during speculation. In a concurrent study, InSpectre Gadget [64] demonstrates a native Spectre-v2 exploit targeting the Linux kernel on recent-generation Intel CPUs, leveraging the latest BHI variant [14].

2.3 Defenses Against Branch-based Attacks

The broadest defense against contention-based side-channel attacks involves partitioning the targeted unit across various processes or domains [35, 54, 71]. This principle also extends to general defenses against other BPU attacks [25, 42, 62, 70, 75, 78]. Another approach is to simply flush the target predictor state when context switching [7, 53, 62]. An alternative defense utilized by sensitive code, such as cryptographic libraries, is constant-time programming [15, 21]. This strategy removes secret-dependent branches. However, it's rarely adopted in general-purpose code due to its high overhead.

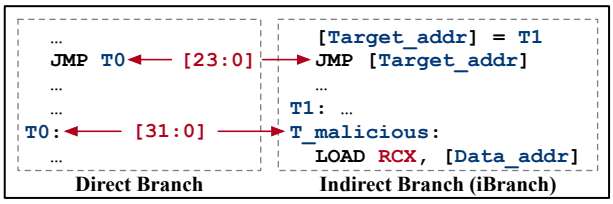
To mitigate Spectre-style attacks targeting either the direction predictor (CBP) or the target predictors (BTB and IBP), several defense strategies have been proposed [3,4,6–8,19,70]. These include inserting fences in programs [30, 40, 51, 61], speculative load hardening [20], or artificial data dependencies [43] near branches, measures to restrict the impact of speculation on structures such as the cache [12, 46, 66, 67], limitations on speculative execution when handling sensitive data [55], and even alterations to CPU design to enable safe speculation [13, 36, 63, 72, 73]. Retpoline [4, 6] is a mitigation technique designed by Google to counter Spectre v2 attacks. It works by altering how indirect branches are handled in code, introducing a trampoline code sequence that traps any potential mis-speculation into an infinite loop until the actual address is resolved and popped from the return stack buffer (RSB). Intel has proposed several hardware defenses against target injection attacks, including IBRS [8], STIBP [3] and IBPB [7]. We will elaborate on them in Section 4.

3 Analysis of Indirect Branch Prediction

In this section, we present a detailed analysis of our reverse engineering efforts on branch target prediction mechanisms in modern Intel processors. This includes reverse engineering the detailed structures of the Branch Target Buffer (BTB) and the Indirect Branch Predictor (IBP) in multiple high-end Intel CPUs. For brevity, we focus on *Raptor Cove* microarchitecture in the text, and only summarize the important information for other microarchitectures.

3.1 Branch Target Buffer (BTB)

The Branch Target Buffer (BTB) plays a crucial role in steering modern CPUs' front-end by not only identifying the branch instructions but also predicting their target addresses. Earlier research [2, 23, 27, 31, 34, 58, 59, 74, 76] reverse engineered the BTB structures of several modern CPUs. Zhang et al. [74] revealed the mapping policy and the associativity of the BTB, showing that the instruction address of the branch is divided into tag, index, and offset fields to lookup the BTB. Numerous studies [23, 28, 31, 74, 76] confirmed that the BTB only stores lower bits of the target address, rather than the entire 48-bit virtual address. The predicted target address is subsequently formed by concatenating these lower bits with the higher bits of the branch address. We replicate these experiments on the recent *Raptor Cove* and *Gracemont* microarchitectures and find consistent results with previous studies, which is summarized in Table 1. In modern CPUs, the BTB not only stores the target address but also records various metadata pertaining to branch instructions, such as branch type and core ID. In the subsequent discussion, we delve into our new observations regarding this information stored within the BTB entries.



Model	i7-6770HQ	i9-12900 (P-core) i7-13700K (P-core)	i9-12900 (E-core) i7-13700K (E-core)
μArch	Skylake	Raptor (Golden) Cove	Gracemont
Address Type	Virtual	Virtual	Virtual
Index	PC [13:5]	PC [14:5]	PC [14:5]
Tag	PC [29:22] $\oplus$ PC [21:14]	PC [23:15]	PC [24:15]
Associativity	8	12	5
Capacity (Entry)	4K	12K	5K
Target Length (Bit)	32 (Long) / 10 (Short)	32	32 (Long) / 10 (Short)
Predicted Target	{PC, BTB}		

Table 1: Fundamental BTB Details Across Various CPUs.

3.1.1 Branch Type in BTB

In x86 architecture, there are various types of branching instructions including: conditional branch, direct unconditional branch, indirect branch, call, and ret. The BTB needs to record the branch type for each branch instruction since different branch prediction mechanisms (CBP, IBP, or RSB) are used for different branch instruction types. To verify this in Raptor Cove microarchitecture, we create a scenario comprising two branch instructions of different types but sharing the same lower 24 bits of the branch address (thus exhibiting aliasing in the BTB). Subsequently, we measure the branch misprediction rate for both instructions. Our findings reveal that when two branches of different types have distinct target addresses, a misprediction rate of 100% occurs. This suggests that these branches are utilizing the same BTB entry, resulting in inaccurate predictions. However, when they share identical target addresses (lower 32 bits), as expected, no misprediction arises.

Based on this result, we explore whether a direct branch can inject a malicious target into the BTB entry and mislead an aliased indirect branch to speculatively execute it, because the correct target of the indirect branch will not be resolved until the Execution stage. As Listing 1 shows, the indirect branch has only one target. Single-target indirect branches only use the BTB for prediction, which will be explained in Section 3.3. During normal execution, the malicious target is never reached. In order to measure whether the instructions in the malicious target are executed, we introduce a load instruction within it. Before this, we flush the data associated with this instruction out of the cache. After the victim execution, we reload the data to determine if it has been cached. We also flush the correct target of the indirect branch to create a large-enough speculation window. We find that the data associated with the load instruction never gets cached, indicating that the load instruction is never speculatively executed. However, we observe that both the malicious target and the subsequent instruction are cached in the instruction cache. This suggests that these instructions are speculatively fetched and maybe decoded, but are somehow being prevented from executing speculatively. We also tested other types of branches (e.g. conditional branches) to see if they could inject a malicious target into the BTB entry and mislead the aliased indirect branch, and we confirmed that they cannot. Conversely, if both branches are indirect ones, we see cached data (specu-

Listing 1: Microbenchmark Pseudo-Code for Injecting Targets with Different Branch Types. The dashed frame means these are multiple branches in the same thread. The arrow represents specific bits of their virtual addresses are identical. In a single test, they are executed in order from left to right.

lative execution). Thus, there is at least one bit in the BTB metadata that differentiates indirect branches from other types of branches. We believe that in the former scenario (different branch types), speculative execution does not occur due to the presence of the Branch Address Calculator (BAC) unit in the decode stage, along with the BTB bit identify branch type. This unit ensures that the BTB prediction aligns with the actual decoded branch type. This unit empowers modern CPUs to detect potential branch mismatches earlier in the pipeline, well before the target is resolved in the execution stage.

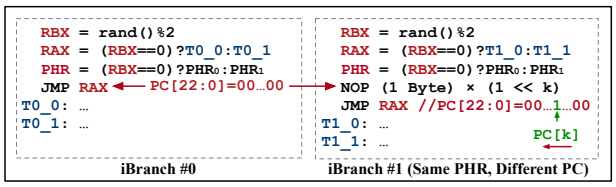
Observation 1. The BTB features a 'Branch Type' bit to aid branch prediction. Since different branch types may alias in the BTB, this check serves to verify that the indirect branch prediction from the BTB aligns with the actual type.

3.1.2 Core-ID in BTB

Modern Intel CPUs support simultaneous multi-threading (SMT) [57], which virtualizes a single physical core into two logical (SMT) cores. Since there is only one BPU per physical core, we aim to determine whether the BTB is shared or statically partitioned between SMT cores. To do that, we create two SMT threads: $Thread_0$ with M direct branches and $Thread_1$ with N direct branches. All branches share the same BTB index but have different tags. Subsequently, we measure the number of BTB entries that can be allocated to each SMT thread. We observe that when $M+N \leq 12$ (where $M,N \in 0,1,2,\ldots,12$), no branch mispredictions occur. This suggests that there are no constraints on the number of entries per set available to each SMT thread and there is no SMT-based static partitioning in place.

Building upon this, we repeat the experiment in Listing 1 but this time the aliased branches run on different SMT cores and have the same branch type. We find that these two branches do not alias in the BTB and no mispredictions occur. This suggests that the BTB stores some information about the core-ID or thread-ID or process-ID. Through exhaustive testing across various scenarios—cross-SMT context, cross-process, and cross-thread—we ascertain that aliasing is possible only if two branches are in the same SMT virtual core, implying that only the core-ID is recorded for each branch instruction in the BTB. This finding also explains why BTB mistraining disappears in cross-SMT scenarios mentioned in BunnyHop [76].

Observation 2. Core-ID is recorded and used as part of the tag in the BTB. When two aliased branches reside on the same SMT virtual core, they can share the same BTB entry, even in a cross-thread or cross-process scenario.



3.1.3 Privilege Level in BTB

In addition to our new findings, we also confirm prior findings, including the fact that there is a *Privilege Level* field in each BTB entry so that the kernel and the user cannot share entries in the BTB [14, 76]. The "Privilege Level" field behaves similarly to the "Branch Type" field. Aliased branches in different privilege levels lead to speculative fetch but not execution.

3.2 Indirect Branch Predictor (IBP)

The Indirect Branch Predictor (IBP) is a dedicated unit designed to predict the target addresses of indirect branches as they can jump to various places within the program. Many recent studies [14, 27, 31, 58, 59, 74] have revealed that indirect branch prediction in modern CPUs relies not only on the branch address but also on the global history, dubbed as Path History Register (PHR) or Branch History Buffer (BHB). Some studies [14, 74] argue that the indirect branch prediction mechanism lacks a distinct structure and is instead implemented through multiple indexing functions to the BTB. Other studies, such as an Intel patent [44] and Uzelac's reverse engineering of the Intel Pentium M processor [58], provide evidence supporting the existence of a separate structure dedicated to predicting indirect branches. Furthermore, the ITTAGE predictor proposed by Seznec et al. [49] in 2011 also features its own distinct structure separate from the BTB, as discussed in Section 2. Since the structure of the IBP within Intel CPUs is completely undocumented, we begin with a small set of assumptions. Specifically, we assume that the IBP adopts a TAGE-like structure, consisting of multiple tagged tables indexed by varying lengths of the global history (PHR). These tables are utilized to store the target addresses of indirect branches.

Prior works [14, 27, 31, 58, 59, 74] show that the IBP is indexed by the global history (PHR). Additionally, recent works [69, 70] have shown complete details of the structure and update policy of the PHR used for the CBP.

Listing 2: Microbenchmark Pseudo-code for Recovering the Number of PC Bits Involved in the IBP.

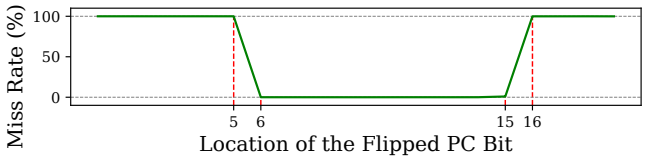


Figure 4: Misprediction Rate of when the Position of Flipped PC bit Varies.

To study the structure, size, and the update policy of the PHR in the IBP, we run a set of similar experiments to those discussed in Half&Half [70]. Our results show that the PHR used in the IBP has the same update policy as the CBP. On *Raptor Cove*, the PHR records the global history of the last 194 taken branches, which means its size is $194 \times 2 = 388$ bits in total because each update shifts it to the left by 2 bits. Building on this, we can set the PHR to any arbitrary value through a carefully aligned series of 194 direct branches, as demonstrated in a recent study [69].

3.2.1 Index and Tag Inputs

First, we explore how many bits of the branch address (PC) are used in the IBP lookup (in addition to the PHR). As shown in Listing 2, there are two indirect branches, each with two targets. The branch targets are determined by a random binary input, each correlated with a specific PHR value. We keep all lower bits of branch addresses identical except for one bit, which we systematically brute force to determine when these two branches collide within the IBP. We measure the misprediction rate for these cases to identify the collision point. Figure 4 illustrates that the miss-rate remains consistently near 0% when the flipped bit pertains to PC[15:6]. However, it increases at other locations. This finding suggests that when PC addresses of the branches differ in PC[15:6], the IBP can effectively distinguish between them and accurately predict their target addresses.

Observation 3. PC[15:6] is used as input (index and/or tag) to the IBP, which differs from the BTB that uses PC[23:0].

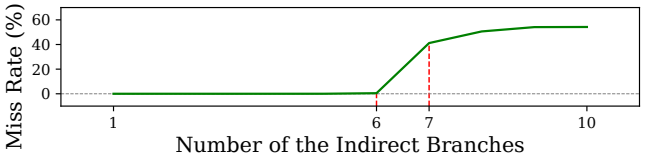

Figure 5: Misprediction Rate when the Number of Indirect Branches with the Same PHR Value Varies.

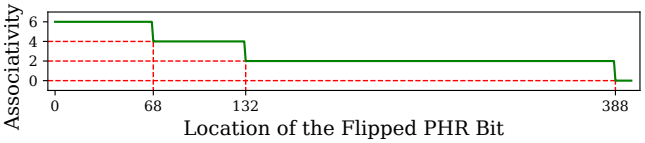

Figure 6: Associativity of the IBP when the Position of Effective PHR bit Varies.

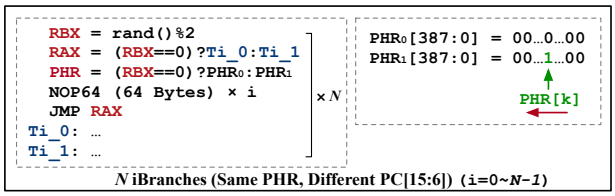
3.2.2 Associativity



As introduced earlier, the ITTAGE predictor has multiple set-associative tables, each table indexed with a different length of global history. We investigate if the IBP in Intel processors has a similar structure. First, we seek to determine how the PC is used in IBP lookup and hence determine if it is used in tag and/or index. To do that, we create a scenario where there are N indirect branches with the same PHR but different PCs (bits[15:6]). We increase the number of branches and measure the miss-rate for them.

For a K-way associative structure, once the number of branches exceeds K, the miss rate shows a steep rise, as a single set lacks empty entries to capture the $(K+1)^{th}$ branch and must replace an old branch, leading to a misprediction.

We exhaustively test all the combinations of PC[15:6] values and our results (See Figure 5) show that the IBP can predict up to only 6 branches even as we change PC[15:6] values. This suggests that the PC bits are not used in the index but used as **tag** and the IBP has a set-associative structure with a maximum associativity of 6, indexed by the PHR.

Next, we want to find whether the associativity varies with the effective PHR length. In Listing 3, all N indirect branches have the same PHR setup: PHR_0 is set to 0 while PHR_1 is modified during each test by incrementally shifting a single bit from LSb to MSb. Each branch has a unique PC[15:6] (tag) to avoid entry sharing. We test enough permutations of PC [15:6] (giving us same index, different tags) to exhaust the associativity of that set and start seeing mispredicts. We find the associativity does vary, depending on where in the PHR the one-bit difference exists between the PHR_0 and PHR_1. When the difference is in a lower bit, there are six entries available to record a branch target. When it is in the middle of the PHR, there are four; when the difference is in a high bit (distant correlation), there are only two.

These results, then, shown in Figure 6, indicate that the IBP consists of three tables, each a 2-way set associative structure.

Listing 3: Microbenchmark Pseudo-Code for Recovering the IBP Associativity.

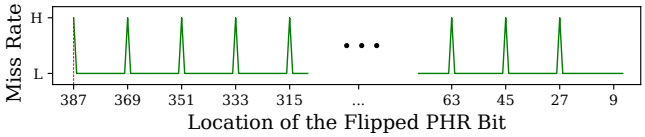


Figure 7: Position of Odd PHR Bits Folded with PHR[387] in the Index Hash Function.

The first table is indexed by the global history of the last 34 branches, i.e. the lowest 68 bits of the PHR. The second table uses the last 66 branches' history (PHR[131:0]). And the last table uses the entire global history (PHR[387:0]).

Observation 4. The IBP on *Raptor Cove*, like ITTAGE, features a set-associative structure with three tables, each being 2-way set associative indexed with different global history lengths.

3.2.3 Index Hash Function

Next, we find the index hash function for each table in the IBP, using the last table as an example. We use two groups of indirect branches. The first group consists of a single branch with the highest bit in the PHR, i.e. PHR[387], set to 1, while the remaining bits are 0. The second group contains $N(N = 2,4,6)$ indirect branches, each using a cleared PHR with a single bit set to 1. Inspired by prior studies [69, 70] on the CBP, the PHR odd and even bits might be folded separately. Therefore, we start by focusing initially on just the odd bits in the PHR. During the test, the location of the set bit of the second group shifts from PHR[387] to PHR[1] with a step of 2. N starts at 2, then changes to 4 when the flipped bit is in PHR[131:68] — this range is within the history span of the second table but not the first. Finally, N increases to 6 when the flipped bit falls within the range of all three tables.

When the bit in the second PHR is not folded with bit 387, we expect a low misprediction rate as the first branch will map to a different set than the second group of branches. When the bits are folded together in the index function, they map to the same index and there will be an eviction, causing a branch misprediction. Figure 7 shows a noticeable spike at some locations. This identifies bits folded with PHR[387]. Moreover, they are spaced uniformly, with an interval of 18 bits. Changing the flipped bit in the first branch maintains this folding pattern, with a fixed distance of 18 bits. However, none of the lowest 8 odd bits are folded with any higher bits. No matter what these 8 bits are, when their higher PHR bits match or differ by an interval of $18*i(i=0,1,2,\ldots)$, they map to the same set. This indicates the lowest 8 odd bits are not used in the index. However, the IBP is still able to distinguish the PHR states with just these lowest bits set, because they are used as tag, which will be discussed in Section 3.2.4. Similarly, the even bits also exhibit this folding function with each other.

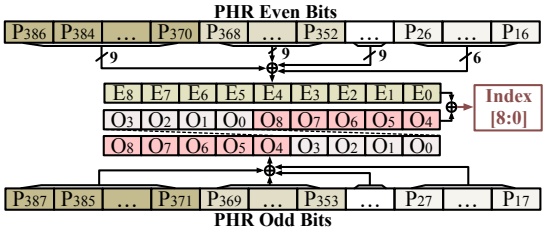

Figure 8: 9-bit Index Hash Function for the Last IBP Table.

Finally, we aim to understand how the odd and even bits are combined to form the final index. We conduct similar experiments to investigate this, with one branch group only setting odd bits and another group only setting even bits. The final index hash function is illustrated in Figure 8. First, all odd and even bits are folded into two 9-bit values respectively. Next, the 9-bit value generated by the odd bits is rotated 5 bits to the left and then folded with another 9-bit value to generate the final index. The remaining two tables in the IBP also employ the same index hash function (but on fewer PHR bits).

Observation 5. Each IBP table is indexed with a 9-bit index, generated from a dedicated hash function folding together the odd and even bits in the PHR.

3.2.4 Tag Hash Function

Because the IBP tables are all set associative, we know they must be tagged structures. We first investigate if, and how, the PHR factors into the tag formation. Take two indirect branches with the same PC[15:6] as an example. Their PHRs are set to all zeroes except PHR[k] and PHR[$k+18*i$] respectively. k is an odd number here. Based on the index hash function both branches use the same IBP set. From Section 3.2.2 we already know that PC[15:6] impacts the tag for the IBP. If the PHR is not used as tag, we will observe misprediction because it is a IBP hit scenario for both branches and leads to entry aliasing. However, the result shows that misprediction only occurs when $i = 0$ or 11, indicating the PHR is used as tag but with a different folding distance than the index.

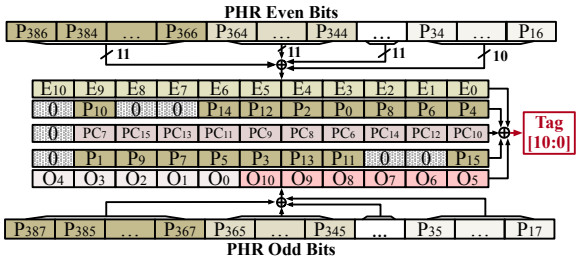

Figure 9: 11-bit Tag Hash Function for the Last IBP Table.

Mispredictions only happen when the PHRs are equivalent under a 198-bit distance folding. Further, a 198-bit tag seems unlikely.

Prior works [39] on the predictor tag design offer us some insights. There are indications that the tag hash function uses a different folding distance of 22. The least common multiple of 18 and 22 is 198, in line with the observed folding pattern. We verify this assumption by setting bits PHR[k] and PHR[$k+22*j$] for the first branch and PHR[$k+18*i$] and PHR[$k+18*i+22*j$] ($k=2n+1, n=8,9,10,\ldots$) for the second. A high misprediction rate occurs again under this PHR configuration because the two branches share the same IBP index under a 18-bit distance folding and the same tag under another 22-bit distance folding, causing them to share the same IBP entry. We run similar experiments on the even bits and find the same folding pattern.

It remains possible that PC[15:6] is also folded with the PHR to generate the final tag. Consider two branches with their PHR states set at PHR[k] and PHR[$k+18$] ($k=2n+1$). These two branches map to the same IBP set but differ in their PHR tag folding pattern. During testing, PC[15:6] of one branch is kept fixed at 0. In the other branch, it is placed at an address where a single bit is set (and that bit is varied in subsequent experiments). The misprediction rate spikes in a specific case, indicating both branches have the same IBP tag. This confirms that PC[15:6] is folded with the PHR, rather than concatenated to the PHR tag to form the final tag. PHR even bits are also folded with PC[15:6]. By comparing the patterns of how odd and even bits are folded with PC[15:6] respectively, through exhaustive search, it can be inferred that there is also a rotation-shift between the odd and even bits.

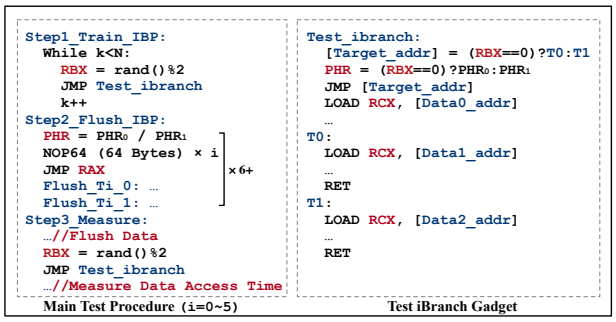
The final tag hash function is shown in Figure 9. The other two tables also utilize this same folding algorithm. Thus, for the lower 16 PHR bits that are not used in the IBP index, we find that they are used in the IBP tag but not involved in the 22-bit distance folding with the higher PHR bits. There is a different folding pattern for them as shown in the figure.

Observation 6. PHR is used to calculate the tag for IBP entries, using a different folding distance with the index hash function. For generating the final tag, PC[15:6] is also involved (See Figure 9).

3.2.5 Target Address in IBP

The final step is to recover how the target address is stored in the IBP. To do that, we create a scenario with two indirect branches with identical PC[15:6] and PHR state, plus aliased targets in lower bits. The first branch, i.e. the attacker branch, has a load after each of its targets.

We begin by executing the attacker indirect branch multiple times to ensure that the poisoned target addresses are stored in the related IBP entries. Before the victim indirect branch, we flush its target address from the cache to create a large speculation window. The measurement shows that the victim branch has a near 100% misprediction rate and the target data of the loads are cached, indicating that it speculatively jumps to the attacker branch's target. This result persists even when the number of identical bits in their targets increase to 47. This observation suggests that the IBP stores absolute 48-bit target addresses (because the poisoned branch target matches all 48 bits of the aliased branch). This is in contrast to the BTB which constructs full addresses from 32-bit partial stored addresses.



Observation 7. Unlike the BTB, the IBP stores the full 48-bit absolute target address.

3.2.6 Core-ID in IBP

From Section 3.1.2, we already know that the BTB records Core-ID on both *Skylake* and *Raptor Cove* architectures. We conduct a series of similar experiments, employing indirect branches to ascertain the presence or absence of a *Core-ID* field in IBP entries. In the *Skylake* architecture, we find that indirect branches across SMT cores can share the same entry in the IBP, which suggests that there is no *Core-ID* field in IBP entries. In contrast, in the *Raptor Cove* architecture, akin to the BTB, all entries in the IBP are tagged with the SMT core-ID. Our findings indicate that there is not a distinct partitioning between the cores (each can fill a set or be fully evicted from a set). Hence, contention-based side channel attacks (on IBP) remain feasible across SMT cores, whereas direct injection attacks are not viable within the IBP between two SMT cores (except on Skylake). However, all threads that run on the same logical (SMT) core have the same core-ID. As long as the attacker and the victim share the same SMT core, the attacker can still inject malicious targets into the victim's IBP entries and mislead its indirect branches to a disclosure gadget.

3.2.7 Privilege Level in IBP

In order to study the indirect branch prediction in higher privilege levels, e.g. kernel code, we create a custom *system call (syscall)*, which includes a single indirect branch. In the user space, we create an aliased indirect branch with identical PC[15:6] and PHR states as the one in the kernel. In the

Listing 4: Microbenchmark Pseudo-code for Testing Prediction under BTB Hit + IBP Miss. The test iBranch gadget is called at step 1 and step 3 in the main test.

Skylake architecture, we observe that there is no *Privilege Level* field in IBP entries, enabling the potential for user-level target injection attacks into the kernel. In contrast, in the *Raptor Cove* microarchitecture, we observe that these two indirect branches cannot occupy the same entry in the IBP, even if they have identical PC and PHR values. This suggests the presence of a *Privilege Level* field in IBP entries, which prevents aliasing across different privilege levels. However, there remains a potential attack surface when both the attacker and the victim run on the same SMT core and share the same privilege level.

3.3 IBP and BTB Interactions

As discussed above, both BTB and IBP record information about indirect branches. The question arises: which makes the final prediction for an indirect branch? Intel's patent on indirect branch prediction [44] offers us some hints. As listed in the following, there are four combinations of BTB and IBP outcomes in total. We will disclose the prediction under each scenario.

BTB Hit + IBP Hit: To investigate whether the target prediction originates from the BTB or IBP, we deliberately poison both structures for a specific victim indirect branch and observe side effects for the potential misdirected paths. As expected, our findings indicate that the prediction indeed comes from the IBP for multi-target indirect branches in this case. For single-target indirect branches, the prediction originates from the BTB.

BTB Hit + IBP Miss: We explore this situation with one indirect branch, as shown in Listing 4. After training the IBP to record its targets, we issue more than 6 indirect branches in the same set to evict it from the IBP, creating an IBP miss upon next execution. Finally, we execute the test branch again and measure its misprediction rate. With random binary input, we observe a 50% miss rate instead of 100%, indicating the BPU still makes predictions despite the IBP miss. Moreover, for each misprediction, both *Data1* and *Data2* are cached, but

BTB State	IBP State	BPU Prediction	Predicted Target	Speculation?
Hit	Hit	IBP (MT) / BTB (ST)	IBP[47:0] / {PC, BTB}	Y
Hit	Miss	BTB	{PC, BTB}	Y
Miss	Hit	None	Next Instruction	N (Only Fetching)
Miss	Miss	None	Next Instruction	N (Only Fetching)

Table 2: Indirect Branch Prediction Policy under Different BTB/IBP States (MT: Multi-Target indirect branch; ST: Single-Target indirect branch).

Data0 is not. Therefore, we infer that the prediction comes from the BTB. Since the BTB entry is only able to hold one target, we observe an overall 50% miss rate when the correct target alternates between T0 and T1 under a random input.

BTB Miss + IBP Hit: To test this scenario, step 2 is replaced with 12+ direct branches in the same BTB set to evict the test branch, resulting in a BTB miss upon next execution. The misprediction rate is always 100% in step 3, indicating instructions at some other locations might be speculatively fetched or even executed. The Intel developer manual [1] suggests that the next instruction right after the branch might be speculatively executed if the BTB lacks information about the branch. However, measurement shows that *Data0* is never cached, but the first load instruction is always brought into I-Cache. This indicates that instructions after the branch enter the front-end, but likely are flushed when the decoder recognizes a branch not in the BTB. There is no indication that the IBP is accessed in this case.

BTB Miss + IBP Miss: In this case, the result is the same as above. The execution of the indirect branch will be stalled until the target is resolved. These results confirm that the CPU only identifies the existence of branch instructions based on their BTB states.

3.4 IBP Overall Structure

So far, we have successfully reverse-engineered most of the structural details of the IBP in Intel's recent processors, as well as the prediction mechanism for indirect branches. Figure 10 depicts the ITTAGE structure of the IBP. The indirect branch prediction policy is summarized in Table 2. We believe these analyses will aid the security community in better understanding how and why prior injection attacks work, at the microarchitectural level.

4 Analyzing Intel Hardware Security Measures Against BTI Attacks

Intel has introduced various defense mechanisms aimed at safeguarding processors against malicious exploitation of BPU structures, particularly speculative execution attacks. Although official websites and documentation sources such as [3, 7, 8] outline the usage and applicable scenarios of these defenses, they offer limited insight into their implementation

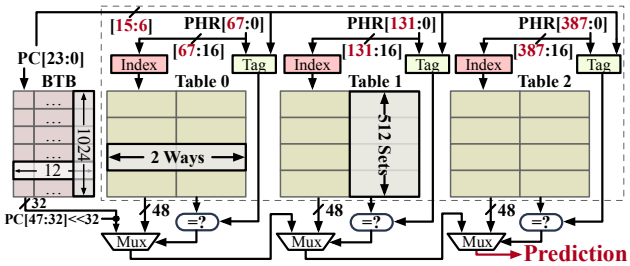


Figure 10: Overall IBP Structure in *Raptor Cove*.

μArch	Defense	IBRS	STIBP	IBPB
Skylake	BTB	Disable iBranch	None	Flush All Types
	IBP	Disable	Disable	Flush
	Behavior	Mode	Mode	Event
	Granularity	Physical Core	Physical Core	Physical Core
Raptor (Golden) Cove	BTB	Flush iBranch	Flush iBranch	Flush iBranch
	IBP	None	None	Flush
	Behavior	Event	Event	Event
	Granularity	SMT Core	SMT Core	SMT Core

Table 3: Impacts of Intel Hardware Defenses on BTB/IBP.

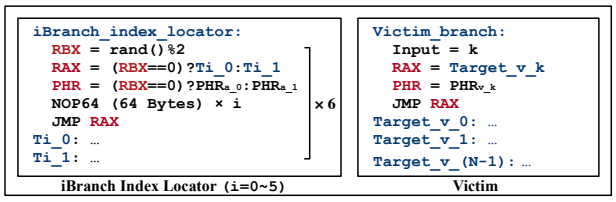
and the specific microarchitectural states affected by them. In this section, our goal is to delve into the inner workings of these defense mechanisms, focusing particularly on Indirect Branch Restricted Speculation (IBRS), Single Thread Indirect Branch Predictors (STIBP), and Indirect Branch Predictor Barrier (IBPB). Previous studies [16, 19] have analyzed the overall performance overhead of these defenses. However, none have revealed the specific changes that occur in the BTB and IBP states upon activating these defenses. We examine these defenses in two microarchitectures: *Skylake* (2015) and *Raptor Cove* (2022). Comparing these two architectures can also illustrate the evolution of Intel processors in terms of hardware security, as the former was launched before the Spectre attack, whereas the latter was introduced well after.

To uncover the changes to the BTB and IBP for each defense mechanism, we carefully design microbenchmarks that allow us to track the presence and absence of particular BTB and/or IBP entries across a series of events.

IBRS: We first start with IBRS, which protects against branch injection by lower-privileged attackers. On *Raptor Cove*, our tests show that IBRS is a singular event, in which indirect branch entries are flushed from the BTB. Direct and conditional branches are not flushed. The IBP microbenchmark further shows that the IBP is not cleared and retains all branch targets. Interestingly, then, IBRS has no special function which addresses cross-privilege sharing. This is consistent with Section 3.2.7 that shows that the privilege-level identifier has already prevented cross-privilege IBP injection in the general case, without any special mitigation. Intel seems to describe this as the "Enhanced IBRS mode (eIBRS)" [8], which is an "always on" mitigation.

On the Skylake architecture, our experiments yield similar results for direct and conditional branches, which are not flushed. However, for indirect branches, the outcomes differ significantly. Upon issuing the IBRS, every indirect branch incurs both BTB and IBP misses, even upon repeated execution. This suggests that, on Skylake, the IBRS behaves more like a "mode" than an "event" – once activated, both the BTB and the IBP are entirely disabled, providing no target prediction for indirect branches. After IBRS is disabled, we are able to continue to successfully access prior IBP entries, indicating neither the BTB or IBP are flushed when IBRS is invoked.

STIBP: STIBP was introduced with a goal of preventing victim poisoning by attackers on a co-located SMT logical core. On *Raptor Cove*, the results are identical to the IBRS: only BTB entries for indirect branches are flushed, without flushing the IBP. This also aligns with Section 3.2.6 showing that cross-SMT protections are in place by default.



On *Skylake*, STIBP does not flush the BTB entries at all. For indirect branches, we find some unexpected behavior. We can successfully predict single-target indirect branches, but not multiple-target branches. This indicates that the IBP is disabled, but the BTB indirect branch entries are not flushed and the BTB is used to generate indirect branch predictions. Thus, STIBP operates as a special mode of operation (that gets turned on and off) and not a distinct flush event – and in fact the IBP is not flushed.

IBPB: IBPB is intended to prevent attackers from poisoning indirect branches on the same logical core. On *Raptor Cove*, we find that the IBPB flushes all the BTB entries of indirect branches, similar to the IBRS and STIBP. However, IBPB also flushes the IBP entries. On *Skylake*, we find that IBPB flushes the entire BTB and the entire IBP. In summary, IBPB is a stricter and more thorough defense than the other two, and can be applied in a wider range of attack scenarios. However, this comes at the cost of the highest performance overhead (of the *Raptor Cove* mitigations).

Furthermore, we find that *Raptor Cove* allows each of these defenses to be applied per SMT core. When defenses are activated on one SMT context, the branch prediction for the other context remains unchanged. However, on *Skylake*, both SMT contexts are affected. All our discoveries regarding Intel hardware defenses are summarized in Table 3.

5 iBranch Locator

Previous branch target injection (BTI) attacks require extensive efforts to create branch history aliasing between the attacker and the victim branch. For instance, Spectre v2 requires the attacker to execute multiple aliased branches alongside the victim to replicate identical history patterns [31]. BHI uses a few branches to brute-force the history, requiring thousands of attempts to achieve aliasing [14]. Consequently, in this section, building upon our new, much deeper understanding

Listing 5: Pseudo-code of iBranch Index Locator for Extracting the IBP Index of the Victim Indirect Branch. The solid frame means the branches are in separate processes. They are launched simultaneously.

of the IBP structure, we propose iBranch Locator, an efficient and high-resolution tool to locate any indirect branch within the IBP, without the need to know any prior history information before the branch. In this tool, the locating process is divided into two steps: first finding the IBP index and then searching for tag aliasing. Utilizing this tool, two injection attacks can be easily mounted with precision, which will be presented in Section 6.

5.1 iBranch Index Locator

The first step is to find the IBP set where the victim's indirect branch is located. Namely, we need to extract the index of the victim entry. To distinguish which set the victim branch uses, iBranch Index Locator conducts an associativity test during the victim's execution, using an eviction-based contention technique.

As Listing 5 shows, it has 6 indirect branches with the same PHR setup and different PC[15:6] to fully use an IBP set. The victim contains an indirect branch with multiple targets, each correlated to a PHR state, meaning that each target is stored in a different IBP entry. iBranch Index Locator runs on a different SMT core so the real associativity can be measured more accurately without the possibility of entry sharing with the victim; however this can be easily adapted to other sharing scenarios. PHR_{a_0} is fixed to 0 while PHR_{a_1} is changed during each trial. Since the PHR is folded into a 9-bit index, 512 attempts are needed at most. The misprediction rate of the 6 locator branches is measured. If the victim branch uses a specific IBP entry, an increase in the misprediction rate under a certain PHR_{a_1} will be observed. On some older machines like *Skylake*, the IBP is indexed by an 8-bit value, so we only need 256 attempts.

As the example in Figure 11 illustrates, during the 512 trials, the misprediction rate rises at 184 and 384. This result indicates that the victim indirect branch is recorded in two different IBP sets, each corresponding to a target. In this example, `Target_v_0` is stored in the 184th set, and `Target_v_1` is in the 384th set.

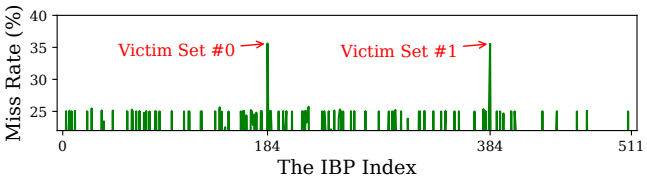


Figure 11: Misprediction Rate of the Indirect Branches in iBranch Index Locator. Spikes corresponds to the victim sets.

5.2 iBranch Tag Locator

iBranch Index Locator does not extract the entire PHR, only the index (the 9-bit value derived from the 388-bit PHR). Locating the victim entry requires not only the index but also the tag, making it more challenging, particularly since we have shown the tag hash function differs from the index hash.

So the second step of iBranch Locator is to search for tag aliasing. We can again do a brute force search for the 11 bits by only controlling the PHR, but it requires a large effort to create index and tag aliasing at the same time. Based on the tag hash function revealed in Section 3.2.4, it can be largely simplified by the fact that 10 of the 11 bits are xored with PC bits to create the tag. Thus, iBranch Tag Locator can permute the relevant PC bits (with 1024 branches) and need only toggle two PHR bits (which create the same index but a different Tag[10]) to complete the search of all 2048 tag permutations. For instance, to toggle Tag[10], PHR[34] can be toggled. To maintain the same IBP index as the victim, PHR[$34+18=52$] should also be flipped. On *Skylake*, we find the IBP tag is 7 bits, requiring much fewer attempts to successfully find the tag.

Different from iBranch Index Locator, iBranch Tag Locator needs to run on the same SMT core with the victim, because entry sharing will only occur when they share core-ID. Figure 12, shows a related experiment, where we seek to create IBP entry collision between the victim and locator branches. It only succeeds when we permute the PC bits to replicate the tag of the victim. We again see two hits, at two PC values, indicating the victim branch has two targets and occupies two IBP entries.

Therefore, iBranch Locator empowers us to successfully uncover the IBP entry of the victim branch, with at most 512+2048 trials on *Raptor Cove* and 256+128 trials on *Skylake*. It can also disclose other exploitable information about the victim branch, such as the number of targets it may jump to. Moreover, it is immune to address randomization techniques, such as ASLR and KASLR. iBranch Locator is still capable of extracting the location when the victim is running with a randomized branch address and targets. Last but not least, it supports cross-privilege detection starting from user space: iBranch Index Locator can be launched in user space to extract a kernel indirect branch's IBP index, then iBranch Tag Locator might run in an unprivileged eBPF program to

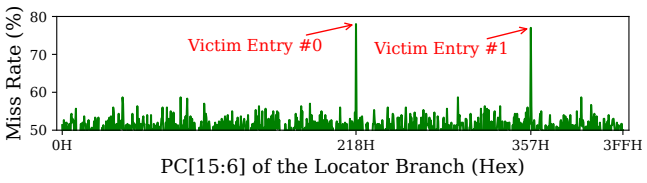

Figure 12: Misprediction Rate of the Locator Branch under Different PC[15:6]. Spikes indicate that tag aliasing is found.

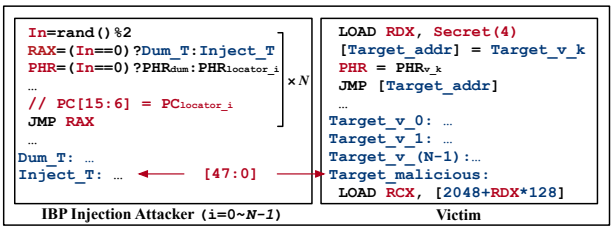
recover the tag.



Despite the advantages offered by iBranch Locator, it has limitations. In this form, it cannot distinguish a target indirect branch from other indirect branches in the victim; however, indirect branches are far less common in many executables and identifying a few (or even many) false positives is still far better than prior brute force methods.

6 High-Precision Target Injection Attack

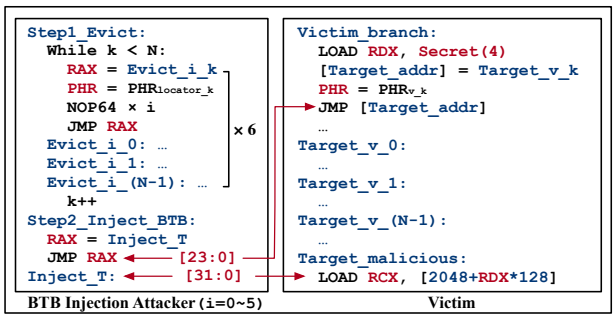
Using iBranch Locator, we introduce two distinct types of high-precision branch target injection attacks directed at indirect branches. The first type of attack poisons the victim's IBP entry. This attack offers a very wide range of attack possibilities due to the full-length target being stored within the IBP. The second type of attack directly injects malicious targets into the victim's BTB entry, which can be done more quickly once iBranch Index Locator has successfully recovered the IBP index, without the need for tag searching. In contrast to previous target injection attacks [14], our attacks do not require any prior history information of the victim. Additionally, it is efficient in identifying aliasing, which is a common challenge in this domain. Moreover, even with ASLR enabled, we propose a new method to break the randomized bits of the victim branch address. This makes injection attacks still feasible in the cross-process scenario.

Attack Model: The attacker and the victim are two processes on the same SMT (logical) core. The victim contains an indirect branch with multiple targets, each correlated to a specific PHR state. We assume that there is a secret-dependent malicious load which is never reached by the victim during normal execution, similar to the gadget exploited by Spectre v1 [31]. The main goal of the attacker is to leverage iBranch Locator to inject malicious targets and mislead the victim to speculatively leak confidential information in microarchitectural states, e.g. cache. The attacker uses methods like Flush+Reload [68] to extract the cache state. Therefore, we assume that the attacker and the victim use a shared memory.

Experimental Setup: All the experiments described in this section are conducted on an Intel i7-13700K performance core (Raptor Cove) with IBRS and STIBP enabled. The operating system used is Ubuntu 20.04.6 LTS, running an unmodified Linux kernel version 5.15.89.

Listing 6: Proof-of-concept Pseudo-code of the IBP Injection Attack. Two processes run on the same SMT core.

6.1 IBP Injection Attack



Equipped with iBranch Locator, the attacker is able to locate any victim IBP entry and inject an arbitrary target address. Our attack requires the following steps.

Step 1. Locate victim entries by iBranch Locator: The attacker first launches iBranch Locator to extract both the IBP index and tag of the victim entries, detailed in Section 5. For an N-target victim, iBranch Locator extracts $PHR_{locator\_i}$ as index and $PC_{locator\_i}$ as the corresponding tag $(i = 0, 1, ..., N-1)$.

Step 2. Inject IBP with multi-target indirect branch: Listing 6 shows the attacker process, including N indirect branches and 2 targets in total. For each branch, the first target is the `Dum_T` correlated with a dummy PHR state, which generates a different index from the victim. The second is `Inject_T` which is identical with the malicious target in the virtual address, correlated with $PHR_{locator\_i}$. The PC[15:6] of the i-th branch is also set to $PC_{locator\_i}$, causing entry sharing with the victim's i-th target. The multi-target branches (even if the first target is only seen once) ensure the attacker uses IBP prediction and records targets into the related IBP entries. As a result, the attacker successfully injects the malicious target into all N victim entries.

Result analysis: We use Flush+Reload [68] to detect load execution and thereby extract the secret value. The result shows shared data at address `2560` has a noticeably higher hit rate than other locations in the Reload stage, indicating the secret is $(2560-2048)/128 = 4$. The injection success rate achieves 97.4% on our *Raptor Cove* machine.

Comparison to Prior Works: In summary, the IBP injection can mislead an indirect branch to any address in the address space. Compared to Spectre v2 [27, 31], our attack bypasses the need for prior knowledge of victim branch history. Compared to Branch History Injection (BHI) [14], our injection, equipped with better knowledge of the IBP implementation, is more precise as it can locate the victim branch's entries accurately at a microarchitectural level. So while we also use brute force methods, we are precisely searching the exact structures rather than the entire possible branch history; thus requiring, in many cases, orders of magnitude fewer trials.

Listing 7: Proof-of-concept Pseudo-code of the BTB Injection Attack. Two processes run on the same SMT core.

6.2 BTB Injection Attack

Next, we introduce a more efficient target injection attack, with only iBranch Index Locator needed. In this attack, the attacker indirect branch can inject malicious targets into the victim's BTB entry and mislead it via BTB prediction. Listing 7 and the following description demonstrate the attack steps.

Step 1. Evict the victim from IBP: First, the attacker uses 6 or more indirect branches to evict the victim branch from the IBP. This can be easily achieved by setting the eviction branches' PHR states to $PHR_{locator}$, as extracted from iBranch Index Locator. This creates a BTB Hit + IBP Miss scenario for the victim, ensuring the BTB will source its next target prediction.

Step 2. Inject BTB with single-target indirect branch: As observed in Section 3.1.1, branches with the same PC[23:0] share the same BTB entry. Further, if they have identical branch types, speculative fetching and execution will occur. Therefore, our attacker leverages this feature to inject and mislead the victim branch. As step 2 in Listing 7 shows, the aliased attacker branch has only one target, aliased (low 32 bits) with the malicious load. Therefore, after IBP eviction, the attacker injects the malicious target into the victim's BTB entry. A single-target indirect branch gets the BTB prediction and records its target in the BTB, so it is used here to ensure the victim's BTB entry gets overwritten each time.

Result analysis: Figure 13 shows the average cache hit rate of all shared memory locations in the Reload stage for each of three scenarios. With both IBP eviction and BTB injection, the secret '4' can be successfully extracted. However, with only IBP eviction, the cached data disappears, indicating the BTB entry has not been injected by the attacker. BTB injection alone also fails, because the victim's prediction comes from the IBP rather than the BTB. The injection success rate is 97.2% on our *Raptor Cove* machine.

Comparison to Prior Works: This BTB injection attack against the IBP is more efficient than previous injection attacks [31], requiring at most 512 trials in iBranch Index Locator. The injection can be carried out instantly after the attacker gets the IBP index of the victim. Moreover, this attack can also be applied in a cross-privilege scenario: iBranch Index Locator and IBP eviction can be launched in user space, and then an unprivileged eBPF program that includes an aliased indirect branch can inject the malicious target into the BTB, similar to the method described in Branch History Injection (BHI) [14].

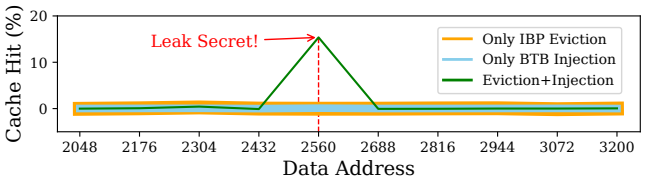


Figure 13: Cache Hit Rate of All the Shared Memory Locations in the Reload Stage.

6.3 Breaking ASLR and Enabling Injection

Most target injection attacks are ineffective under a cross-process scenario with ASLR enabled, as address randomization makes it challenging for attackers to create aliasing with malicious gadgets in the victim process, especially for IBP injection that requires full 48-bit target aliasing with the gadget. Several prior works [18, 23, 76] proposed methods to break ASLR. In this section, we develop a new method to break it inside the BTB, enabling BTB injection in the presence of ASLR, with relatively few attempts.

Step 1. Recover PC[23:12] from BTB associativity: In the first step, we aim to break PC[14:12] of the victim indirect branch. We use a similar idea to iBranch Index Locator, which extracts information from associativity tests. We prepare 12 direct branches with the same BTB index, i.e. PC[14:5], to measure BTB associativity. Because the ASLR only randomizes bits higher than the 12th, we need at most 8 trials to locate which BTB set the victim is in. This successfully uncovers PC[14:12], which is all we need to create index aliasing.

To create the BTB injection attack, we also need to establish tag aliasing. To break the BTB tag (PC[23:15]), we use a test direct branch with the same PC[14:0] as the victim, then brute-force the tag. We measure the misprediction of another 11 eviction direct branches mapping to the same set. Based on Observation 1, when the test direct branch has the same PC[23:0] as the victim, they share a BTB entry and thus the misprediction of the 11 eviction branches is low. Otherwise, the test branch uses a different entry from the victim, causing evictions and thus mispredictions within the 11 branches. In our experiments, we have managed to locate the BTB entry of the victim consistently and recover PC[23:12].

Step 2. Recover PC[31:24] from BTB injection: BTB

injection attacks require aliasing in the lower 32 bits of targets. As the offset between the malicious gadget and victim is fixed, the lower 23 bits of the gadget are known. We only need to brute-force bits 31-24, requiring 256 total trials. iBranch Index Locator is immune to ASLR as mentioned before, so IBP eviction remains effective. Successful BTB injection will occur for a certain Target[31:24], breaking partial ASLR (bits 31-12) and enabling effective target injection against indirect branches at the same time.

The results show that we can achieve a 96.5% success rate of breaking ASLR on *Raptor Cove*. To sum up, we need 8+512+256=776 attempts at most to break partial ASLR. Previous works inject targets into the IBP, which stores the entire 48-bit target and this makes injection difficult with ASLR enabled, because breaking all the randomized bits (from the 13th to 48th bit) needs tremendous effort (over 10M brute-forcing attempts). However, with our method and BTB injection, the attack is still practical with ASLR enabled.

7 Mitigation Strategies

In this section, we discuss the potential mitigation strategies for Branch Target Injection (BTI) attacks.

Mitigations from CPU Vendors: As discussed in Section 4, the Indirect Branch Prediction Barrier (IBPB) is the most strict defense available on the newest CPUs and mitigates any out-of-place target injection attack if used properly. To the best of our understanding, Linux opts to automatically activate the IBPB during context switches between different users. The default policy in the latest Linux version, termed "IBPB: conditional," only activates IBPB during transitions to *SECCOMP* mode or tasks with restricted indirect branches in the kernel. Consequently, IBPB activation is infrequent in both user and kernel spaces due to the significant performance overhead (up to 50% [19]). It is not a viable mitigation for frequent domain crossings (browsers, sandboxes, and even kernel/user) – plus the fact that the OS does not use it in the most frequent domain transitions by default.

However, even with this measure in place, when an attacker exploits intra-process poisoning, injection opportunities persist. Therefore, a potential mitigation strategy could involve triggering the IBPB during context switches between all processes – actually in all transitions between different security domains, where it is anticipated that those security domains may influence and/or leak information to another. This could represent a very high overhead for systems with low-level management of short threads, such as microservices or FaaS, if they even had the opportunity to employ IBPB (since they carefully avoid kernel calls between user-level switches). In general, relying on this mitigation would indeed necessitate the operating system triggering frequent IBPBs, resulting in significant overhead.

Secure BPU Design: Section 3 highlights that Intel has already integrated new fields such as *Core-ID* and *Privilege Level* into their recent Indirect Branch Predictor (IBP) design. This inclusion aims to prevent aliasing between indirect branches originating from different SMT cores and different privilege levels, respectively. However, this still leaves potential attack surfaces within the same-core and/or same-privilege scenarios. For future BPU designs, a more complicated tag should be considered to provide more fine-grained isolation across security domains [42, 62, 77]. Additional measures, such as employing encryption or randomization in entry allocation and index generation policy [25, 33, 75, 77, 78], are also suggested.

8 Conclusion

This paper presents the first comprehensive analysis of the Indirect Branch Predictor (IBP) and the Branch Target Buffer (BTB) structures in high-end Intel CPUs. This work also analyzes the inner workings of Intel hardware defenses against Branch Target Injection (BTI) attacks, including IBPB, IBRS, and STIBP, shedding light on their mechanisms and the affected structures upon activation. Expanding on these findings, it demonstrates precise Branch Target Injection (BTI) attacks, showing the continued feasibility of BTI attacks in specific scenarios such as cross-process situations. Leveraging this, it also exploits the IBP and BTB to break Address Space Layout Randomization (ASLR).

Appendix

A Path History Register (PHR)

As described in Section 2.1, the Path History Register (PHR) keeps track of past taken branches and gets updated with both branch source and target addresses. The general PHR update process is:

- **Step 1:** The old PHR value is left-shifted by 2 bits, with the lowest bits padded with zeros.
- **Step 2:** The left-shifted PHR is further combined with the latest taken branch's source and target addresses through a certain function (depicted in Figure 14) to form the new PHR value.

Table 4 summarizes basic PHR information for *Skylake*, *Raptor (Golden) Cove* and *Gracemont* microarchitectures. On *Skylake* and *Gracemont*, the IBP uses the past 29 branches' history for prediction while the CBP uses 93 branches [70]. In contrast, *Raptor (Golden) Cove* uses the same PHR length for both IBP and CBP, which is 194 branches. As shown in Figure 3, each update left-shifts the PHR by 2 bits. Therefore, the total bit size of the PHR is the product of the number of branches and 2. The bits of the branch source and target addresses used for update are also summarized in Table 4.

μArch	PHR size (IBP)	PHR size (CBP)	Source Addr. Input	Target Addr. Input
Skylake	29 * 2	93 * 2	[18:3]	[5:0]
Raptor (Golden) Cove	194 * 2	194 * 2	[15:0]	[5:0]
Gracemont	29 * 2	93 * 2	[11:0]	[3:0]

Table 4: PHR size used for IBP and CBP prediction, and branch source and target bits involved in PHR update.

Figure 14 illustrates the detailed PHR update function. First, specific bits of the branch and target addresses are XORed together to form a branch trace. This XOR pattern differs based on microarchitecture. The branch trace is then XORed with the left-shifted PHR to form the new PHR.

These results are consistent with the results shown in [70] and [69], but extended to also include the branch history length used for the indirect branch prediction.

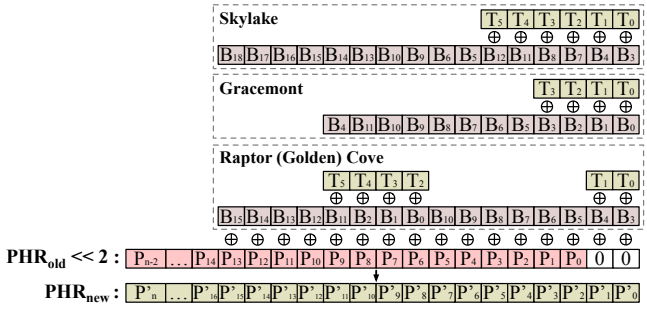

Figure 14: PHR Update Function for *Skylake*, *Raptor (Golden) Cove* and *Gracemont*. B_i represents the i-th bit of the branch source address. T_i is i-th bit of the target address.

Intellectual Property Exposure: Subverting and Securing Intellectual Property Encapsulation in Texas Instruments Microcontrollers

Marton Bognar, Cas Magnus, Frank Piessens, Jo Van Bulck

DistriNet, KU Leuven, 3001 Leuven, Belgium

Abstract

In contrast to high-end computing platforms, specialized memory protection features in low-end embedded devices remain relatively unexplored despite the ubiquity of these devices. Hence, we perform an in-depth security evaluation of the state-of-the-art Intellectual Property Encapsulation (IPE) technology found in widely used off-the-shelf, Texas Instruments MSP430 microcontrollers. While we find IPE to be promising, bearing remarkable similarities with trusted execution environments (TEEs) from research and industry, we reveal several fundamental protection shortcomings in current IPE hardware. We show that many software-level attack techniques from the academic TEE literature apply to this platform, and we discover a novel attack primitive, dubbed *controlled* `call` *corruption*, exploiting a vulnerability in the IPE access control mechanism. Our practical, end-to-end attack scenarios demonstrate a complete bypass of confidentiality and integrity guarantees of IPE-protected programs.

Informed by our systematic attack study on IPE and root-cause analysis, also considering related research prototypes, we propose lightweight hardware changes to secure IPE. Furthermore, we develop a prototype framework that transparently implements software responsibilities to reduce information leakage and repurposes the onboard memory protection unit to reinstate IPE security guarantees on currently vulnerable devices with low performance overheads.

1 Introduction

Memory isolation is a fundamental building block for security, safety, and privacy in computing systems; it protects secret keys, personal data, intellectual property, and other sensitive information. On high-end systems, the operating system provides isolation using established hardware features such as memory management units (MMUs) and CPU privilege levels. Recent years have also seen the rise of trusted execution environments (TEEs) shipped by major processor vendors, such as Intel SGX [13] and TDX [29], AMD SEV [5], and ARM TrustZone [4], which provide hardware-backed isolation even in the presence of a compromised operating system. Still, low-end embedded devices, omnipresent in the Internet of things (IoT), often lack established memory isolation primitives [26] due to stringent demands on manufacturing costs and power consumption. In response to these unique challenges, a line of specialized, embedded TEE research prototypes [9,15,18,32,41,42] has been developed. However, these TEE designs all require custom hardware changes and are, hence, incompatible with off-the-shelf IoT microcontrollers that often only offer a coarse-grained and error-prone memory protection unit (MPU) [24].

There is a clear demand for specialized IoT memory protection mechanisms, as also evidenced by the inclusion of diverse hardware security features with varying degrees of sophistication by embedded device manufacturers [4, 6, 10, 36–38, 48, 51, 52]. In this paper, we study an advanced example, the Intellectual Property Encapsulation (IPE) technology found in some popular, ultra-low-power MSP430 microcontrollers by Texas Instruments (TI). Interestingly, we find that IPE holds remarkable similarities to general-purpose TEEs in that it offers enclave-like, hardware-level isolation of arbitrary code and data, protecting from read or write access from *anywhere* outside of the encapsulated memory area, including the embedded operating system and even JTAG hardware debuggers [55, 61]. Unlike academic prototypes, IPE technology has been readily available in off-the-shelf devices since 2014 [55, 58], predating most academic works and several commercial technologies. IPE technology has been advertised to protect high-value proprietary code and sensitive data such as cryptographic keys [57, 60, 61]. Moreover, IPE has been used as a critical enabling technology for several recent academic security systems [17, 33, 34]. However, despite IPE's potential and widespread availability, no critical analysis has yet been conducted to properly understand the guarantees and limitations of this security technology.

This paper performs such an analysis: we study TEE attack literature and comparable research prototypes [15, 18, 41, 42] to assess the security level offered by off-the-shelf IPE tech-

nology against software adversaries with arbitrary code execution on the device. Our findings paint a promising but currently disappointing picture. The lack of clear documentation makes it difficult to identify the exact security guarantees and attacks prevented by IPE. Furthermore, inadequate compiler toolchain support considerably increases the burden on developers and the likelihood of introducing unintentional interface sanitization vulnerabilities [69].

Most concerningly, we discover several hardware shortcomings that make it impossible to securely isolate application code and data with IPE on current devices. First, we discover *controlled* `call` *corruption*, a novel critical vulnerability in IPE's memory access control logic, allowing an attacker-controlled `call` instruction to overwrite arbitrary protected memory locations. In our root-cause analysis, we attribute this behavior to the pipelined CPU architecture and show that at least two related open-source TEE implementations [41, 42] took measures to avoid similar flaws in their access control logic. Second, we show how the lack of enforcing a single entry point into the encapsulated IPE area, standard in comparable single-address-space TEE designs [13, 18, 32, 41, 42], opens the door to code-reuse attacks [35, 49]. Third, we demonstrate that IPE's lack of enforcing atomic execution [18, 41, 42] or protecting the register state [13, 15, 30, 32, 71] upon interrupts allows to leak or modify CPU registers at arbitrary points during execution. In practical proof-of-concept demonstrations, we show how these attack primitives – individually and in potent combinations – allow us to bypass the IPE security objectives, i.e., confidentiality and integrity of encapsulated code and data.

Finally, we challenge assumptions [8, 16, 75] that deterministic MSP430 platforms would be less vulnerable to microarchitectural side-channel attacks. Specifically, inspired by attack research on popular high-end TEEs, including Intel SGX and AMD SEV, we experimentally show how IPE software adversaries can induce measurable cache timing differences [39] by manipulating CPU clock speed, reconstruct instruction timings via interrupt latency [71], and mount novel controlled-channel attacks [25, 77] through the MPU.

Building on our comprehensive attack analysis, we propose both hardware and software countermeasures. First, inspired by research prototypes [15, 18, 41, 42] on the open-source openMSP430 [20] processor, we formulate concrete refinements for IPE's hardware-level memory access control logic. Next, we contribute a software framework, inspired by established TEE software development kits [28, 41, 69], to improve on TI's rudimentary toolchain [61] by using a source-to-source translator and hardened entry and exit assembly stubs to automatically transform a developer-annotated C program and transparently safeguard IPE software transitions. Moreover, we extend this framework to secure currently vulnerable devices against our attacks by repurposing the onboard MPU to overlay an additional layer of fine-grained, execution-aware protection over the IPE memory area, reinstating the security guarantees of IPE against software adversaries (without JTAG access) with minimal performance and code size impact.

Contributions. In summary, our main contributions are:

- Analyzing the security guarantees offered by IPE technology in off-the-shelf TI MSP430 microcontrollers, uncovering important vulnerabilities in current hardware, including the novel *controlled* `call` *corruption* attack.
- Showing that side channels from prior research can be adapted to leak information from vulnerable IPE code.
- Building practical, software-exploitable attack primitives and end-to-end attack demonstrations that completely bypass IPE confidentiality and integrity guarantees.
- Contributing hardware and software mitigations to improve security, including a software framework that transparently sanitizes IPE programs and mitigates our attacks on current hardware by utilizing the MPU.

Responsible disclosure. We disclosed our findings, including proof-of-concept exploits, to TI on April 20, 2023. After thorough analysis and successful reproduction of our attacks, TI issued a security advisory [65] for the *controlled* `call` *corruption* with a CVSS score of 7.1 (high). TI also fed back our findings to their internal design teams to ensure improved security practices for future devices and included our MPU approach as a suggested mitigation for current devices. TI currently considers the other issues out of scope, defining the goal of IPE as blocking the direct readout of encapsulated memory via the CPU or JTAG and not as preventing an attacker from indirectly inferring code or secrets. In this paper, we clearly show, however, that such indirect exposure is practical using our attack primitives.

Availability. To facilitate future research on IPE, our source code, including our attacks, the software framework, and the evaluation, is available at https://github.com/martonbognar/ipe-exposure/.

2 Background and problem statement

2.1 MSP430 microcontrollers

The widely used [19] line of MSP430 microcontrollers, developed by Texas Instruments, is targeted at low-cost, ultra-low-power applications, such as vehicle ECUs and key fobs [56]. These microcontrollers feature a single address space without virtual memory or processor privilege levels and exhibit deterministic timing behavior, allowing their use in real-time systems. Over time, the 16-bit MSP430 instruction set and the devices received several extensions, such as an address space extension to 20 bits, direct memory access (DMA) capabilities, and security features such as an AES accelerator and an elementary MPU. More recently, TI has shipped millions of

MSP430 microcontrollers with non-volatile FRAM memory technology [58, 59], equipped with the IPE security feature described in the following subsection.

Memory protection unit (MPU). The most rudimentary mechanism to enforce isolation on the FRAM MSP430 devices is the MPU [55]. It allows partitioning the address space into three regions at 1 kB boundaries with separate access control permissions for each region. The MPU configuration registers are protected by fixed "passwords", allowing to safeguard the memory partitions against accidental read, write, or execute accesses originating from code, DMA, and JTAG. The access control of the MPU is not program-counter-dependent, and while setting a configuration bit makes its configuration immutable, a device reset deactivates the protection entirely.

Research TEEs on openMSP430. Supported by the simplicity and popularity of the MSP430 instruction set, and the availability of the near-cycle-accurate openMSP430 [20] open-source softcore implementation, the MSP430 platform has been an attractive target for developing academic prototypes, among others TEEs [15, 18, 41, 42]. These systems employ a lightweight, program-counter-based access control mechanism [53] to seclude a contiguous memory region from external software accesses: additional hardware-level circuitry enforces that only when the program counter is inside the protected address range, access to protected memory is allowed.

2.2 Intellectual Property Encapsulation (IPE)

The security feature studied in this work is Intellectual Property Encapsulation, widely available since 2014 [58] in the MSP430FR58xx, MSP430FR59xx, and MSP430FR6xx families of TI microcontrollers. In short, IPE isolates a region of the address space from all outside accesses. In the following, we elaborate on IPE's design and precise security features based on several technical documents [54, 55] and whitepapers [57, 61, 64] released by TI, anticipating and contextualizing some of the attack primitives explored in depth in Section 3. Given the striking resemblance of IPE to (embedded) TEE designs, we structure the discussion based on requirements explicitly identified to realize enclave isolation [53].

Memory isolation. The most fundamental building block for trusted execution is that untrusted code should not be able to read or modify the data of the protected module. To this end, IPE includes hardware-level access control logic, schematized in Figure 1, that is strikingly similar to the program-counter-based access control mechanism [53] used in many embedded TEEs [18, 32, 41, 42]. The device user's guide [55] explains unambiguously that "*only program code executed from the IPE-segment can access data stored in this segment*" and multiple TI documents [57, 60, 61] explicitly recommend using IPE to protect secret keys and configuration data. One important difference to many other TEEs is that, as hinted by the name, *Intellectual Property* Encapsulation, this technology is meant to protect code in addition to data. Hence, IPE protects a unified contiguous address range for both code and data, whereas research prototypes commonly separate executable code and (non-executable) data. Finally, IPE is limited to isolating a single "enclave", similar to simpler designs [11, 15, 18, 42], whereas more advanced TEEs [32, 41] provide support for multiple, mutually distrusting enclaves.

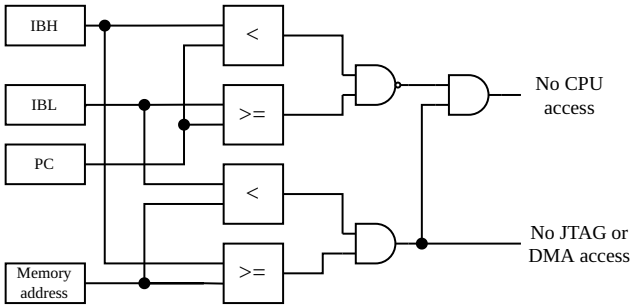

Figure 1: IPE access control logic [55]. IBH and IBL refer to the high and low boundaries of the IPE region.

Two explicitly documented [55] exceptions for the protection are that IPE cannot protect the fixed memory locations for the interrupt vector table (IVT) and that the first 8 bytes of IPE memory are reserved for a configuration data structure, called `ipe_init_struct`, and, hence, code executed from here cannot access the rest of the IPE region. This structure stores the boundaries of the IPE region along with other settings and a checksum, and is used by the boot process, explained next.

Minimal trusted computing base (TCB). The compelling feature of TEEs is that their security guarantees only rely on the correct functioning of the enclave code itself, the hardware, and possibly part of the boot process, not on the operating system or any other privileged software on the platform.

In line with this definition, IPE only requires trusting the hardware and a minimal part of the boot process. On startup, an immutable piece of trusted TI firmware ("bootcode") initializes the IPE region boundary registers by reading the `ipe_init_struct`. This process allows IPE software to dynamically reconfigure its boundaries across resets. However, `ipe_init_struct` also includes an odd-bit-interleaved parity checksum, such that the bootcode can detect any accidental corruptions and erase all memory to avoid unintentional exposure of IPE secrets. Crucially, once the trusted bootcode finishes, the IPE boundary hardware registers are locked, and the processor's program-counter-based access control logic protects the IPE region from *any* later direct accesses, including from the privileged MSP430 bootstrap loader (BSL), which was previously leveraged to extract firmware [21, 22].

While IPE does not explicitly support software attestation, commonly found in TEEs, the trusted bootcode can be considered an effective root of trust. That is, after IPE is first initialized in a secure environment, e.g., in the factory or before deploying the microcontroller to end users, stakeholders can assume that across system reboots the IPE code and data will remain persistent (via the non-volatile FRAM technology) and protected (via IPE).

Controlled entry points. If the protected module can be invoked at any location, its behavior will become unpredictable, posing a risk of inadvertent secret leakage through *code-reuse attacks* [49]. To avoid this issue, invocation should only happen at defined entry functions, as implemented in embedded [15, 18, 32, 41, 42] and high-end TEEs [13].

We found that TI's documentation is unclear about restricting execution to defined entry points. The device user's guide [55] writes: "*to execute code from the IPE-segment, branch into that segment or call functions stored in that segment*". At least one document [54] describes IPE as protecting against "*any read, write, or execute access*", implying that execute access can be disabled for part of the IPE region. Of course, completely disabling execute permissions would make the IPE section useless, as no code in the module could be invoked, which also means that the protected data could never be accessed. Another TI white paper [64] used to hint more explicitly towards defined entry points: "*execution of this portion of memory can be limited to specific callback functions that are defined at the time the IPE module is enabled*".[1] However, we experimentally demonstrate in Section 3.2 that the current IPE hardware access control logic does *not* enforce entry points, giving rise to capable code-reuse attacks.

Interrupts and real-time guarantees. To prevent the corruption or leakage of CPU register values, some embedded TEE designs disable interrupts during enclaved execution [18, 41, 42, 53]. However, it is important to note that embedded devices are often used for real-time, safety-critical applications where timely handling of interrupts is crucial, and allowing enclaves to arbitrarily hold on to the CPU may be unacceptable. Thus, more advanced TEEs like Intel SGX and many embedded research prototypes [2, 11, 15, 32, 68] support interruptible enclaves via a hardware-level secure interrupt mechanism that transparently saves and restores enclave register contents when transitioning to and from the untrusted interrupt service routine (ISR). Interestingly, early versions of AMD SEV, before the introduction of SEV-ES [30], did not feature such a mechanism and were vulnerable as a result [73]. As we will demonstrate in Section 3.3, IPE also does not include a secure interrupt mechanism, nor forcibly disables interrupts in hardware.

[1] Following our disclosure process, TI updated this document to reflect the offered security features better.

Table 1: Results of our IPE security analysis, listing software-driven architectural and side-channel attack primitives from prior TEE research or contributed by us *(new)*. Symbols indicate whether the attack primitive can break IPE confidentiality (**C**✗) and integrity (**I**✗) guarantees directly (●) or indirectly (◐). Positive results are highlighted.

Attacker model and scope. The device user's guide [55] describes IPE as a feature protecting an address range from accesses originating from any code outside this region. In addition to protection against software adversaries with arbitrary code execution, IPE also blocks DMA requests by peripherals and JTAG accesses by the debugger [55]. The FRAM technology used for IPE also has physical features specifically aimed at thwarting physical attackers with microscopy, voltage manipulation, and radiation capabilities [57].

To scope our work, we consider only software-exploitable attacks in our analysis. Specifically, in line with the standard threat model assumed by academic TEEs for embedded devices [9, 15, 18, 32, 41, 42], we consider a capable software adversary with arbitrary code execution on the device, but place physical attacks out of scope. Studying physical attacks against IPE and validating the relevant security measures is orthogonal to our analysis and left as future work.

3 Attack primitives

This section presents the attack primitives we discovered and reproduced, most of which build on existing TEE attack literature. Table 1 summarizes our results, where we distinguish between attack primitives that *directly* break confidentiality or integrity of IPE memory or register contents, and primitives that *indirectly* impact these properties through confused-deputy code gadgets or side channels. The table also includes two relevant negative results that we describe in Appendix A.

All attacks in this section have been implemented on proof-of-concept code based on TI's official example IPE project [62] and experimentally validated on the following actively manufactured TI boards: MSP-EXP430FR5994, MSP-EXP430FR5969, EVM430-FR6047, MSP-EXP430FR6989.

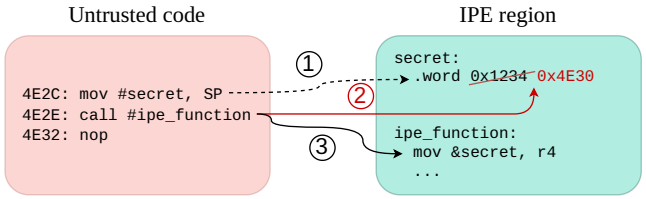

Figure 2: Principle of the controlled `call` corruption exploit.

3.1 Controlled `call` corruption

The processor's access-control logic must protect IPE memory against both explicit and *implicit* accesses. One example of the latter is the processor's interrupt logic, which pushes the interrupted instruction's address and the value of the status register on the stack. In this scenario, we found that even if the attacker manipulates the stack pointer to point to IPE memory, the access rights are correctly enforced, and the interrupt logic will not write to the IPE region. Another example is the `call` instruction, which pushes the called function's return address on the stack. Crucially, we found that the access control rules are not always correctly enforced for this instruction.

Figure 2 explains how to exploit this vulnerability. The attacker, executing from an untrusted region, first ① points the stack pointer inside the IPE region. Next, when executing a simple `call` instruction, ② the processor writes the return address of the function call (i.e., the address of the instruction below `call`) to the stack. As the stack pointer currently points inside IPE, data or code inside the protected region could be overwritten by the (known) return address if the access rules are not correctly enforced. Indeed, in our experiments, we found that this write access is incorrectly allowed in a specific scenario; ③ when the target of the `call` (i.e., the function being called) lies inside the IPE region.

This vulnerability gives the attacker a very strong primitive: arbitrary locations inside the IPE region, chosen by setting the stack pointer value, can be overwritten by a known value, i.e., the address of the instruction following the `call`.

Choosing corruption values. Attackers using the controlled `call` corruption primitive can overwrite code and data locations inside IPE. The exact written value is the return address of the `call` and, thus, depends on the location of the attacker code. For certain attacks, e.g., when overwriting secret keys, inserting a known arbitrary value is sufficient.

In other cases, however, the attacker may want to insert concrete values, such as the machine code of an assembly instruction. If the attacker had control over the entire address space, they could place the `call` instruction anywhere, inserting arbitrary values. In reality, however, the attacker is limited in the available locations. Table 2 lists the different memory segments, and Table 3 lists a subset of the instruction encodings on MSP430 (we refer to the user's guide [55] for the complete list). The attacker can execute code from the entirety of the RAM and FRAM sections, except for regions protected by the MPU or IPE. Depending on the size and location of these restricted regions, the attacker can encode different binary instructions in the written value, as seen by comparing the two tables. A possible complication is that some instructions in MSP430 consist of multiple words, e.g., representing integer literals or memory addresses.

Many of these challenges can be overcome depending on the goal of the attacker: alternative instructions may be inserted as gadgets to leak information (e.g., `add` instead of `mov`), instructions with indirect addressing modes (using addresses stored in registers) can be used to avoid having to insert additional literal values. Additionally, the 20-bit MSP430X instruction set used by our target microcontroller features a `calla` instruction that jumps to 20-bit target addresses and writes the 20-bit return address to the stack as a zero-extended 32-bit value, covering two 16-bit words. This way, values can be inserted as either the lower 16 bits of a 20-bit address or the zero-extended upper 4 bits, making it possible to insert a broader range of values. We, therefore, want to stress that merely overlapping the IPE region over a specific part of the address space (e.g., covering all the `mov` instructions) is decidedly *not* a sufficient defense against this attack.

Table 2: Address space of our target devices. Segments marked with a ✓ are writable and executable by the attacker unless protected by the MPU or IPE.

Segment	Address range	RWX
FRAM	0x4400 – 0x13FFF	✓
RAM	0x1C00 – 0x23FF	✓
Information memory	0x1800 – 0x1AFF	✗
Bootloader	0x1000 – 0x17FF	✗
Peripherals	0x0000 – 0x0FFF	✗

Table 3: A subset of instruction encodings on MSP430, falling in the RAM (*italic*) or FRAM ranges (cf. Table 2).

Encoding	Inst	Encoding	Inst
0xFxxx	and	0x8xxx	sub
0xExxx	xor	0x7xxx	subc
0xDxxx	bis	0x6xxx	addc
0xCxxx	bic	0x5xxx	add
0xBxxx	bit	0x4xxx	mov
0xAxxx	dadd	*0x3xxx*	*jmp, jl, jge, jn*
0x9xxx	cmp	*0x2xxx*	*jc, jnc, jz, jnz*

Vulnerability root-cause hypothesis. Given that this exploit only works when the `call` target lies inside the IPE region, we suspect the vulnerability is caused by incorrectly performing the access control check on the updated program

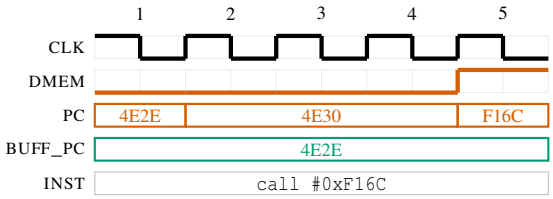

Figure 3: Changes to the program counter (PC) during a call on openMSP430. During the instruction's execution, the program counter changes twice, in the 2nd and 5th clock cycles. Sancus [41] and VRASED [42] buffer the PC (BUFF_PC) for accurate program-counter-based access control.

counter. During the execution of the call instruction, the program counter changes to the target address, and the return address is written to the stack. This write will be subject to the access control of IPE. If, however, the program counter is updated before the access control check, this check will succeed when the target of the call is inside the IPE region.

This hypothesis is supported by an additional finding: as explained in Section 2.2, the first 4 words of the IPE region, storing ipe_init_struct, should not have access to the rest of the protected region. We experimentally confirmed that an instruction executing from the last word of the struct can access the IPE region. This incorrect behavior could again be explained by the program counter being updated too early, this time simply moving to the next instruction before the check. In the pipelined MSP430 design, the processor fetches the next instruction while executing the current one, explaining why the value of the program counter would change early.

The openMSP430 [20] two-stage pipeline behaves very similarly, and this open-source processor allows the inspection of its internal signals. Figure 3 shows the evolution of the program counter during the execution of a call instruction. The program counter updates multiple times during the instruction's execution, first to fetch an additional word from memory (the target address of the call), then to change to the jump target while the instruction is still executing. The DMEM signal shows that the memory bus is active in the last cycle, where the return address is written to the stack, making it logical that the flawed access control check happens then.

Attack on modified Sancus. Building on the previous finding on openMSP430, we illustrate that the identified access-control flaw is not just a one-off bug in TI's proprietary IPE implementation, but represents a more fundamental consideration for program-counter-based access control in pipelined CPU designs. To this end, we examined two mature and popular open-source TEE designs, Sancus [41] and VRASED [42], which feature similar program-counter-based access control logic and are built on openMSP430. We found that both Sancus and VRASED include explicit patches[2] to avoid this issue in their hardware-level access control logic. Figure 3 shows how a new stable BUFF_PC signal is introduced that buffers the program counter of the currently executing instruction until its last cycle, such that access control is performed accurately for the full duration of the instruction. We theorize that these patches were introduced to prevent instructions on protection boundaries from being prematurely granted access to protected data, similar to the experiment with ipe_init_struct. To show the applicability of the controlled call corruption, we manually removed the buffered program counter from Sancus, effectively reverting the protection to that before the patch. With this modification, we experimentally validated in simulation that attackers from outside a Sancus enclave could indeed use the controlled call corruption primitive to corrupt data inside the enclave in the same way as on IPE.

3.2 Arbitrary jumps to IPE code

As explained in Section 2.2, arbitrary jumps to code in the protected region lead to a known class of code-reuse attacks. We experimentally validated that – in contrast to other TEEs, such as Intel SGX [13], Sancus [41], or VRASED [42] – IPE indeed does not enforce an entry point to its code, allowing untrusted code to jump to arbitrary locations in IPE. Interestingly, TI's ARM-based MSP432 microcontrollers did enforce a mechanism similar to entry points in their IP protection [63] but have been discontinued [66], leaving the MSP430 line as the only active one supporting IPE. However, compared to traditional return-oriented programming (ROP) [49], the attacker on IPE is thwarted, as the code of the IPE region is also confidential. This makes finding useful gadgets more difficult, similar to blind ROP attacks on TEEs [35].

```
1 mov #source, r13
2 mov #dest, r14
3 mov 0(r13), 0(r14)
```

Listing 1: IPE code gadget copying secure data.

We first demonstrate an elementary proof-of-concept with this attack primitive assuming knowledge of the protected code but discuss the possibility of leaking IPE memory without this assumption in the following subsection. Consider the code in Listing 1, copying a word of data from one protected location to another with the mov 0(r13), 0(r14) instruction. This instruction takes the value from memory at the address contained in the r13 register and stores it to the address taken from r14. While under normal operation these registers are set up with the correct, secure addresses, this instruction can be attacked with our primitive and used as a universal read or write gadget. By setting the registers r13 and r14 in untrusted code to point to a location inside and outside IPE respectively, then jumping directly to this instruction

[2] For Sancus, we could pinpoint the fix to a commit bcc746a dated Oct 23, 2012. For VRASED, this fix is similarly included in the initial release commit d2d316c dated May 15, 2019.

(line 3), it will unknowingly copy data or code from inside IPE to an unprotected outside location.

3.3 Arbitrary interrupts in IPE code

Section 2.2 explained that interrupting protected code without protections can lead to leaking or modifying the values of CPU registers. We experimentally validated that IPE does not offer such protection, and this class of attacks can be carried out by implementing a malicious ISR and overwriting an IVT entry (which remains writeable even if placed within IPE boundaries [55]). Our attack was again conducted on the code of Listing 1, this time interrupting the execution before the instruction on line 3 after the intended addresses are written to `r13` and `r14`. We overwrite the addresses in `r13` and `r14` inside the ISR, then resume execution to IPE, which will again unintentionally leak the secret values to unprotected memory.

TI discusses interrupt handling in multiple documents, none of which offer a fix for these attacks. While TI's example code [62] does not disable interrupts, it clears the register state at the end of its execution. This is insufficient, as an attacker can interrupt the code before the register state is cleared and read out the registers. A different TI document [61] mentions interrupts as an attack vector and recommends disabling interrupts during IPE execution. There are different issues with this recommendation. First, it is not explained how to disable interrupts, and the `dint` (disable interrupts) instruction leaves non-maskable interrupts enabled, which could also be used for this attack. Second, using the previous arbitrary jump primitive, attackers could simply jump over the instructions disabling interrupts at the start of IPE code.

Blind attacks. The proofs-of-concept for the interrupt and the arbitrary jump primitive relied on the attacker knowing the location of a universal read gadget in the victim code. There are many such instructions, such as the `pop rx` instruction, which pops the last word from the stack into a register. This instruction is commonly emitted by compilers in function prologues and epilogues and is always present in code using stack operations, e.g., function arguments or local variables.

More generally, even if the code is protected, instructions may be reconstructed by observing the state changes they cause. In prior work, Schink and Obermaier [47] reconstructed code on MSP432 devices with IP protection enabled by interrupting individual instructions and observing their state changes. We, hence, anticipate that such an automated disassembler, augmented with the side-channel information described in the following section, could also be constructed for MSP430 IPE. Our attacks currently make such an effort unnecessary, as they allow the leakage of the entire IPE region.

Table 4: Evaluation of the side channels used in a covert-channel setting on MSP430FR5969. The extrapolated speeds are calculated for the maximum frequency of 16 MHz.

Side channel	Cycles to leak 16 bits	Extrapolated speed
FRAM cache patterns	1473	173 kbps
Instruction latencies	750	341 kbps
MPU access violations	475	538 kbps

3.4 IPE side-channel leakage

In addition to the attack primitives providing architectural leakage, we investigated the applicability of microarchitectural side-channel primitives from the TEE attack literature. We experimentally validated the presence of three different sources of side-channel leakage from IPE code, showing the relevance of these attacks on MSP430. For each side channel, we built and evaluated a proof-of-concept covert channel on the MSP430FR5969 to demonstrate how secrets can leak from the IPE region to untrusted code without shared memory, summarized in Table 4. While the control-channel setups rely on a cooperating victim, our examples show how deterministic and straightforward the channels are, making them also relevant in a classical attack scenario. In the following subsections, we describe these side channels in more detail and give some countermeasures that can limit the leakage from IPE. Importantly, the established defense against these types of side channels is writing data-oblivious (constant-time [3] or balanced [8, 75] code), avoiding any secret-dependent state changes in the microarchitecture. We only discuss different, specific defenses against the given side channels, possibly involving proposed hardware changes.

3.4.1 FRAM cache access patterns

Side-channel description. Cache attacks are one of the most well-known microarchitectural attacks in the literature. They have been extensively demonstrated on Intel SGX [23, 39], but, to the best of our knowledge, MSP430 microcontrollers were not considered vulnerable to fine-grained, cache-based access pattern leakage [8, 16, 75]. However, the FRAM MSP430 microcontrollers with IPE feature a small cache (2-way set-associative with two sets and 64-bit lines) to speed up accesses to FRAM [55]. This cache improves performance when the processor operates at frequencies above 8 MHz, in which case the CPU needs to insert wait cycles for FRAM reads unless they are served from the cache.

These differences in the timing of FRAM accesses can be observed accurately and deterministically on MSP430 thanks to the following properties. First, the attacker can configure the operating frequency of the core from untrusted software [55], forcing the insertion of wait cycles for cache misses. The attacker can also interrupt the execution of IPE after each instruction, similar to CacheZoom [39] or SGX-Step [70], and measure the cache state using a cycle-accurate timer. Fi-

```
configure_frequency();
↯ prime_cache();
    if (secret[0] == 1) touch(line1);
    if (secret[1] == 1) touch(line2);
↯ secret[1:0] = probe_cache();
```

Listing 2: Pseudocode of the cache covert channel.

```
setup_isr();
    if (secret[1:0] == 0b00) inst1;
    if (secret[1:0] == 0b01) inst2;
    if (secret[1:0] == 0b10) inst3;
    if (secret[1:0] == 0b11) inst4;
↯ secret[1:0] = measure_time();
```

Listing 3: Pseudocode of the instruction-timing channel.

nally, the instruction timings are deterministic, and, unlike in higher-end systems [23], there is no noise in the cache state due to parallel processes.

Proof-of-concept setup. Listing 2 shows the pseudocode of our covert channel setup, based on the Prime+Probe [44] technique. The victim, depending on the value of two secret bits, accesses two variables that fall into different cache sets, which we reverse-engineered to be determined by the 4th least significant bit of the address. The *attacker* sets up two interrupts (↯) that execute before and after these accesses. The first ISR, executing from RAM to avoid polluting the FRAM cache, primes the cache state by filling it with attacker-controlled values. Afterward, the victim performs the conditional accesses that can evict two lines from the cache. The *attacker*'s second interrupt hits after the conditional accesses, at which point the cache state can be probed and the two secret bits can be reconstructed based on which of the *attacker*'s values were evicted from the cache. Due to the IPE code executing from FRAM, its code accesses will also evict lines from the cache, limiting the number of cache lines that can be used for data transmission. In our proof-of-concept, we limit the executing code to two cache lines, leaving the two other lines for transmitting information. We successfully transmitted a secret word in a total of 1473 clock cycles (including both attacker and victim code), translating to an extrapolated bandwidth of 173 kbps at the maximum frequency of 16 MHz.

Mitigations. Hardware defenses include cache partitioning between trusted and untrusted code [14] or flushing the cache between context switches. Importantly, merely running the IPE code at a lower frequency is an insufficient defense, as we have observed that the cache state was kept updated at low clock speeds, making it possible to recover the cache state by increasing the frequency after the IPE's execution.

3.4.2 Instruction timings through interrupt latency

Side-channel description. Interrupt latency attacks were first demonstrated on Intel SGX and Sancus platforms [71] and later extended to VRASED [7] and AMD SEV [74]. These attacks derive the execution time of individual instructions by measuring the time taken for interrupt handlers to fire, as the processor first waits for the current instruction to complete before handling a pending interrupt request.

Our device is very similar to the openMSP430-based [20] Sancus and VRASED, having deterministic instruction timings and a cycle-accurate timer. Apart from having an extended instruction set [55], the most interesting difference on our device is the presence of the FRAM cache, which also influences the timing of instructions accessing memory. This means that interrupt-latency attackers can distinguish IPE load instructions that hit or miss the cache, similar to prior attacks on Intel SGX [71].

Proof-of-concept setup. Listing 3 shows our covert channel setup, similar to the cache setting. In this case, the victim executes instructions with different execution times depending on the secret bit values. The *attacker* times an interrupt (↯) to the start of the secret-dependent instruction's execution and derives the leaked secret bits based on the delay before its ISR starts executing. In our setup, we encode two bits of information in instructions that take 1-4 cycles to execute. This setup leaks a secret word in a total of 750 cycles, resulting in an approximate bandwidth of 341 kpbs at the maximum frequency of 16 MHz.

Mitigations. If interrupts could be securely disabled during the execution of IPE code, this attack would be mitigated. The design of Sancus_V [11] shows that with hardware support, it is possible to create provably secure interrupt handling that does not leak timing information. Alternatively, careful hardware-software co-design, such as AEX-Notify [12] on recent Intel SGX platforms, may thwart the attacker's ability to precisely interrupt victim enclaves.

3.4.3 MPU-based controlled channel

Side-channel description. One of the first attacks on TEEs involved abusing the privileged operating system's control over untrusted page tables, coining the term controlled-channel attacks [77]. Particularly, based on the page faults generated by the application running in the enclave, its memory access patterns could be reconstructed, which in turn might allow the reconstruction of its secret data.

While the MSP430 microcontrollers do not feature an advanced MMU or virtual memory paging, we show that a similar idea can be applied using the onboard MPU. On MSP430, the MPU can divide the address space into three regions at 1 kB boundaries with different access rights. The IPE access rules do not override MPU rules [55], so code within IPE can

```
setup_mpu();
    if (secret[0] == 1) touch(segment1);
    if (secret[1] == 1) touch(segment2);
    if (secret[2] == 1) touch(segment3);
; secret[2:0] = probe_mpu();
```

Listing 4: Pseudocode of the MPU-based covert channel.

still be denied from accessing data or executing code if the target address falls within an MPU segment with restricted permissions. By partially overlapping MPU segments with the IPE region and observing when an MPU violation occurs, an attacker can track when certain parts of the IPE memory are accessed. Similarly to the original controlled-channel attack, this can leak information about the location of the executing code or the data it is operating on.

Proof-of-concept setup. Our covert channel in Listing 4 follows a similar pattern to the previous setups. This time, the *attacker* sets up three MPU regions, all without write permissions, before launching the IPE code. The IPE code accesses the three regions depending on the secret value, encoding three bits of information. After the victim's execution, the *attacker* checks the MPU violation flags, similar to monitoring page table metadata on Intel SGX [72], to see which of the three regions has a write violation, reconstructing the secret bits. Encoding three bits of information in each iteration leaks a secret word in 475 cycles, translating to a bandwidth of 538 kbps at the maximum frequency of 16 MHz.

Mitigations. The MPU configuration can be made immutable until a reset occurs [55] by setting a lock bit. Code in the IPE region could either configure the MPU to be in a known benign state at the start of its execution and lock it or validate that it is already locked and in a configuration that will not interfere with the IPE's execution or leak information. Alternatively, the hardware could conceivably be changed to ignore MPU access rights while the IPE code executes.

4 End-to-end attacks

This section demonstrates multiple end-to-end attacks to extract secret data and code from IPE using our architectural attack primitives. Our applications are based on TI's IPE example project [62], which developers are likely to build on when writing their code. We successfully reproduced the attacks on all four analyzed devices.

4.1 Overwriting sensitive data

Our first end-to-end attack scenario overwrites a secret key stored in IPE to demonstrate how an integrity violation can lead to loss of confidentiality. The TI example code loads a secret key into the AES accelerator of the device for demonstration purposes. We extended this code to perform encryption on a secret plaintext string stored in IPE memory, the result of which is then written to a public variable.

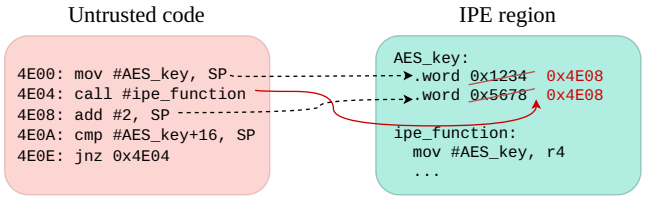

Figure 4: Using a controlled `call` corruption to overwrite a secret AES key in IPE memory.

For this attack, we use a controlled `call` corruption to overwrite the AES key with a known value, gaining the ability to decrypt the resulting ciphertext. Overwriting the key assumes knowledge of its location, which, while part of the attacker model of many other TEEs, is not necessarily a capability on IPE, as the code is also protected. Nevertheless, the boundaries of the IPE region are visible to the attacker, and the default TI linker script places data at the end of the region, opening the door to a brute-force attack.

Figure 4 shows the basic idea of the attack. The attacker code first points the stack pointer to the (assumed) location of the AES key and calls an IPE function, which, through a controlled `call` corruption, will overwrite the first word of the key with the known return address. This process can be repeated for each word of the key (shown by the second dashed arrow), after which the full key will be overwritten with the same return value and, as we have shown experimentally, all output ciphertexts can be trivially decrypted.

4.2 Leaking the entire IPE region

While the previous attack can already pose a threat to real applications, it relies on two assumptions: the attacker knows (or can find) the location of some secret information, and that the corruption of this information leads to violating the security guarantees of IPE. In the following generic attacks, we go further; we leak the entire IPE region's memory without relying on *any* assumptions about the code or data.

4.2.1 Variant 1: Inserting a leaky gadget

For the arbitrary jump and interrupt examples in Section 3, we rely on a known instruction in the IPE region that can leak data to unprotected memory. With the controlled `call` corruption, this requirement is lifted, as the attacker can insert such an instruction inside the protected region. For example, to insert the `mov 0(r15),r12` instruction with machine code `0x4F2C`, we need to place the `call` instruction at the memory location preceding `0x4F2C`, as the value inserted by the attack is the return address, the address following the `call`.

After performing the corruption, we utilize the other attack primitives to jump directly to the inserted instruction with `r15` pointing to a protected location, then read out the leaked value from `r12` after the inserted instruction executes. The attack could also be orchestrated without relying on the other attack primitives, e.g., by encoding absolute addresses in the inserted instruction.

To mitigate any information loss from overwriting unknown IPE values, we can choose to insert the instruction at the end of the IPE region, as the region is aligned to 1 kB boundaries, leaving some protected memory unused. Overwriting the `ipe_init_struct` at the start of the region is an even better option, as this only contains public values.

4.2.2 Variant 2: Removing IPE protection

The `ipe_init_struct` data structure enables an even more interesting attack. The user's guide mentions the possibility of reconfiguring the IPE boundaries dynamically [55], a feature that is not supported on comparable systems such as Sancus or VRASED. This reconfiguration happens on a reset if `ipe_init_struct` is updated with new boundary addresses and a valid checksum (invalid data leads to a mass erase).

Building on the previous exploit, we perform another end-to-end attack where we overwrite `ipe_init_struct` to move the boundaries of the protection. This is done by first inserting an arbitrary write gadget inside the IPE region (we chose `0x4FAE = mov 0(r15), 0(r14)`), and then using this instruction to overwrite `ipe_init_struct` one word at a time, taking care to also write a valid checksum for the modified configuration. Locating the currently active `ipe_init_struct` is trivial, as its address is stored at a fixed location [55]. After overwriting the boundaries to different values, we reset the device, which will update the IPE configuration and completely expose the original protected region, which can now be read out in full.

5 Hardware mitigations

This section proposes hardware mitigations to our architectural attack primitives inspired by related academic systems.

5.1 Single entry point and secure interrupts

Many TEEs [13, 18, 32, 41, 42] enforce a single entry point for protected regions to prevent code-reuse attacks that could bypass isolation. Such a modest change in the hardware would rule out most code gadget abuse attacks while only requiring limited extra resources. Specifically, compared to the existing IPE hardware circuitry in Figure 1, only a new internal hardware register `PREV_PC` is needed to buffer the previous value of the program counter (`PC`), plus additional comparators to ensure that when the current `PC` lies inside the protected IPE range, it is either the single entry point address or `PREV_PC` already pointed inside IPE [41, 53]. Furthermore, existing applications could be transparently recompiled with our framework (cf. Section 6) to securely multiplex several software entry points through a single hardware-level entry point.

While it is possible to disable interrupts during the execution of enclaves from hardware as it is done in some embedded TEEs [18, 42], an enforced single entry point also makes it possible to disable interrupts in a non-bypassable way from enclave software. Alternatively, if interruptible and resumable IPE execution is desired, e.g., to ensure real-time guarantees, the hardware can be extended with support to securely save and clear registers upon interrupts, safeguarding the confidentiality and integrity of the register state from the untrusted ISR. In Sancus$_V$ [11], the hardware cost of this mechanism when synthesized to an FPGA was 260 slice registers (+21%) and 142 slice LUTs (+5%), where most of the overhead comes from a shadow register file in the processor. This could be further reduced by storing the values securely in memory [2, 13, 15, 32, 68] (e.g., on the protected IPE stack).

5.2 Controlled `call` corruption mitigation

As discussed in Section 3.1, the likely cause of the controlled `call` corruption is performing the access control check on an updated program counter value, which we have shown may also affect the openMSP430 core [20]. While we do not have access to the design of the proprietary TI microcontrollers, we suspect that a defense that properly buffers the program counter register, similar to Sancus and VRASED, could be straightforwardly applied to mitigate our attacks.

To estimate the cost of this mitigation, we compare two versions of Sancus: the current upstream version (commit `d83a5207`) and the modified version on which we demonstrated our attack in Section 3.1 by reversing the buffered program counter defense. We synthesized both versions for the Xilinx XC6SLX25-2FTG256 FPGA at 20 MHz using the Xilinx ISE 14.7 tool. Based on this analysis, applying the mitigation incurs an overhead of 20 slice registers, from 3078 to 3098 (less than 1% increase), while slightly decreasing the number of necessary slice LUTs from 5628 to 5613.

6 Software mitigations

This section presents our software framework, which helps secure IPE applications on both future devices with mitigations for our attacks and currently deployed hardware. While TEEs like Sancus [41] and Intel SGX [28] provide mature toolchains to help enforce software requirements to achieve the security guarantees of the system, TI only offers an automated setup of the IPE boundaries based on developer annotations via their CCS IDE [61] and an example IPE project [62] demonstrating best practices. This lack of support motivated our framework, which, in addition to using the MPU to reinstate most security guarantees of IPE on current devices with vulnerable

hardware, offers compiler toolchain support to automatically prevent information leakage from sensitive programs, also providing utility on future devices with hardware fixes for our attack primitives. Our mitigation design, like IPE itself, focuses only on preserving the confidentiality and integrity of IPE memory and register contents, placing availability and real-time guarantees out of scope.

Our framework consists of a collection of assembly and C code files and a source-to-source translation script. The developer is responsible for adding intuitive `IPE_ENTRY`, `IPE_FUNC`, and `IPE_DATA` C preprocessor annotations in the source code to define the (entry) functions and data objects that are to be protected. This source file can then be applied to our translator script, which will generate additional assembly stubs and a slightly modified C source code, all of which compiled together will produce a protected binary. As the source files and the changes generated by the translator script are minimal, they can be subjected to manual security analysis or symbolic validation efforts [1] in future work.

6.1 Secure entry and exit stubs

Similar to the Sancus toolchain [41] and the Intel SGX SDK [28], we support a (non-nested) secure function call abstraction, where *ecall*s represent context switches from untrusted code to IPE and *ocall*s refer to calls from secure IPE code to untrusted code. Our framework automatically inserts dedicated assembly stubs whenever the control flow enters or leaves the protected code to sanitize low-level CPU registers and switch between call stacks, known sources of unintentional information leakage [7, 69]. These stubs, shown in orange in the first section of Table 5, are protected by IPE.

In addition to low-level assembly stubs, our framework includes a small C library with support functions for securely validating that a given pointer lies outside the IPE region and for constant-time comparison. These functions can help prevent known issues demonstrated earlier on MSP430 microcontrollers, such as inadvertently leaking secrets through unchecked pointers [69] or timing side channels [7, 21].

IPE ecalls. For each `IPE_ENTRY` function, the translator assigns a logical EID and generates an `ecall_stub` placed in untrusted memory with the name of the original function (to preserve compatibility with other code). This untrusted stub transparently invokes the single protected `ipe_entry` entry point, passing the logical EID in a defined register, ensuring that third-party code calling the entry functions will be vectored correctly through the single entry point. The translator, furthermore, automatically generates an `ecall_table` in IPE memory. This table, indexed by the EID, stores the addresses of the ecall functions and a bitmap indicating which registers hold return values and should thus not be cleared on exit.

The single entry point `ipe_entry` performs multiple security-critical tasks. First, it disables all (maskable and non-maskable) interrupts and switches to a known secure stack in IPE memory. The assembly logic then decides if the IPE code previously performed an ocall, in which case it restores the saved register state and resumes IPE execution. Otherwise, the stub vectors to the ecall function address retrieved from `ecall_table[EID]`. Upon return from the protected function, the remainder of the assembly code clears all registers except those containing a return value, switches back to the untrusted stack, and returns to untrusted code.

Table 5: Assembly stubs provided or generated by our framework. Orange entries in the first section are protected by IPE (and also by the MPU when untrusted code is executing). Blue entries in the second section are only protected by the MPU. Black entries in the last section are not protected.

	Stub	# instances	Size	Cycles
IPE + MPU	`ipe_entry`	global	76 B	63
	`ipe_ocall`	global	60 B	51
	`ocall_stub`	per ocall fn	20 B	25
	`ecall_table` entry	per ecall fn	6 B	-
MPU only	`_system_pre_init`	global	72 B	28/42
	`_system_post_cinit`	global	36 B	28
	`reset_into_ipe`	global	66 B	49
	`ipe_ocall_cont`	global	72 B	54
	`ecall_ret`	global	68 B	51
	`new_reset_isr`	global	120 B	45/62
	Interrupt vector table (`IVT`)	global	-	-
	Untrusted `ecall_stub`	per ecall fn	12 B	16

IPE ocalls. For each untrusted function called from IPE code, the translator generates an `ocall_stub` in IPE memory and redirects the call site there. This stub vectors to a single `ipe_ocall` exit point, passing the address of the untrusted function to be called and a bitmap indicating argument register usage. The `ipe_ocall` stub will securely exit IPE by clearing unused registers and switching to the untrusted stack before vectoring to the called function.

TI example code and toolchain limitations. As a comparison, the TI example project [62] only includes inline assembly to demonstrate register clearing before returning from an ecall but does not provide any guidance for ocalls. Furthermore, we found that the inline assembly code does not clear the value of the MSP430 status register, which contains sensitive information on whether the previous branch was taken, potentially leaking secret information for non-constant-time programs. More worrisomely, the TI example code offers no guidance on sanitizing the stack pointer, which could lead to severe confused-deputy memory corruption or leakage [7, 69].

Finally, we found that the compiler – both GCC and TI's proprietary MSP430 compiler – may silently include calls to built-in runtime helper functions, such as `memset` or software-emulated numerical operations. By default, these functions re-

Table 6: Timeline (top to bottom) of MPU-based protection showing the initialization of the device and a subsequent execution consisting of an ecall followed by an ocall. Device resets disabling the MPU are highlighted.

Executing function	MPU

side in untrusted memory, even when called from IPE. Hence, any such compiler-generated calls would inadvertently transfer control to the attacker and allow to expose arguments and inject arbitrary return values through CPU registers. It is well-known that compilers that are not aware of security objectives of code can introduce serious vulnerabilities [50], and this is a particularly dangerous illustration of that problem. Therefore, we developed a script in our framework that runs before the linker and intercepts any relocations to such compiler-inserted functions, transparently redirecting them to trusted, intra-IPE counterparts offering the required functionality.

6.2 MPU-based isolation

To protect currently deployed devices with no mitigations against our architectural attack primitives, we leverage the MPU in our framework. This allows reinstating the security guarantees of IPE at the cost of increasing the TCB with the hardware MPU and security-sensitive code protected by the MPU: a few stubs and the IVT (cf. blue entries in Table 5).

Preventing controlled `call` corruption. Our framework dynamically disables write access in the MPU over the IPE region when untrusted code is executing, preventing the corruption of protected values by untrusted `call` instructions.

Table 6 shows the evolution of the MPU protection for an execution consisting of an ecall with a single ocall. During the first boot after flashing, `_system_pre_init` sets up our reset vector handler `new_reset_isr` in the IVT. Following the initialization of global variables, this one-time setup finishes with `_system_post_cinit` enabling and locking the MPU configuration, then calling the untrusted `main` function.

When untrusted code calls (via `ecall_stub`) or returns to (via `ipe_ocall_cont`) the IPE region, the protected `reset_into_ipe` stub is called, which saves all register values and triggers a software brown-out reset. Upon such a reset, the MPU is disabled, and the CPU executes the reset vector, `new_reset_isr`. This reset vector re-enables the secure MPU configuration unless a persistent flag is set, indicating that the untrusted code requested an ecall. In this case, the MPU is not enabled and `ipe_entry` is directly invoked from the reset vector after restoring the previously saved register values to support passing arguments or return values from untrusted code to IPE ecall functions. Two additional stubs, `ipe_ocall_cont` and `ecall_ret`, enable and lock the MPU configuration before calling or returning to untrusted code.

Single entry point and interrupts. In addition to restricting reads and writes to the sensitive MPU region, we also remove execute privileges from this region. By restricting the execute permissions, we prevent attackers from being able to jump to arbitrary points inside the protected region. To launch the protected code, untrusted code needs to call `reset_into_ipe` as explained before, which our framework automatically handles in the generated entry stubs.

Once the previous fixes are in place, and code injection or reuse attacks are not possible, interrupts can be disabled from software in `ipe_entry` before the protected code executes. Even if not all non-maskable interrupt sources can be disabled, the MPU-protected IVT entries can be set to trusted interrupt handlers that prevent register values from being exposed.

6.3 Limitations

Our framework has a few prototype limitations that we believe could be addressed with further engineering effort in future work. For instance, we currently only support automatically generating stubs for functions that only pass basic primitive data types as arguments and return values in registers.

A more fundamental limitation of using the MPU is that we inherit a weaker attacker model than IPE. That is, while JTAG can be, and often is deactivated on devices sold to end users [22], if it is enabled, JTAG can easily bypass our defense if execution is halted during `new_reset_isr` before the MPU protection is enabled and locked, which disables JTAG accesses. This is in contrast to IPE, which is enabled earlier in the boot process before the debugger can attach. Furthermore, our design requires using two of the three MPU regions to protect the original IPE code and our stubs. Due to the `IVT` residing in the middle of the address space (near `0xFFFF`), the MPU protection also reduces the available storage for untrusted code and data, as only one MPU region can have no protection, and this region cannot contain the `IVT`.

We use software-induced brown-out resets to remove the MPU protection, which also comes with limitations. These

resets may add non-deterministic delays, making them inappropriate in certain hard real-time settings. They also clear peripherals and configuration settings (e.g., the processor frequency), making it necessary to manually move the required setup code to a section (e.g., `ipe_entry`) that executes before the protected code on each reset. However, both the FRAM and the RAM contents are preserved on resets, and our framework handles the saving of register contents.

Disabling interrupts for the duration of IPE execution and handling them afterward, as is done currently in our framework, might also be unacceptable in real-time settings. If real-time handling of interrupts is desired, our design could conceivably be extended to handle interrupts securely instead of disabling them. This would require adding a trusted interrupt handler to all IVT entries, which first enables the MPU protection and cleans the execution state, then invokes the untrusted ISR. The downside of this approach is that after the untrusted ISR's execution, IPE needs to be resumed through `reset_into_ipe`, causing a reset.

6.4 Evaluation

To evaluate the security and performance of our framework, we ported a representative embedded enclaved application, VRASED's memory attestation [42] using the HACL* cryptographic library [78], to the MSP-EXP430FR5969 board.

Security. To validate the security guarantees of our framework, we first implemented the attestation in IPE, following TI's guidelines and example project [62]. We then used an attack chain with the three architectural primitives to leak the secret attestation key, very similar to Section 4.2.1. After applying our framework to the application, we observed that the key could no longer be leaked. We also validated that each of the three primitives is individually mitigated by running more self-contained examples with our framework. The MPU protection for overwriting, reading, or executing the protected region is active during the execution of untrusted code and causes a device reset when the controlled `call` corruption or the arbitrary jump primitive is attempted. Interrupts are also disabled during execution of the secure attestation code, in line with VRASED's original requirements [42], and interrupting the code at the start (before interrupts are disabled) does not leak information. More rigorous or formal testing of the security of our framework is left as future work.

Microbenchmarks. To assess the individual overhead contributions of the different components introduced by our framework, we performed a series of microbenchmarks. First, Table 5 provides the binary size and execution times[3] of all stubs provided or generated by our framework, which are deterministic and minimal. A more important measurement is the time taken for the brown-out resets that need to be induced before executing trusted code. Table 7 shows these measurements for each of our devices. In our experimental setup, the target device was performing brown-out resets in a loop, sending a GPIO signal on each iteration to a dedicated MSP-EXP430FR5969 performing the timing measurement. While these timings are not entirely deterministic and might depend on physical properties, we see that, in all our experiments, the reset times were fast and very consistent.

[3] For stubs containing a branch, both possible execution times are listed.

Table 7: Mean duration of software-induced brown-out reset on tested devices ($n = 100$), calculated from cycle counts of the measuring device. Note that due to the frequency of the measuring device, the granularity of our timer is 0.0625 µs.

Device	Reset duration	Standard deviation
MSP-EXP430FR5969	347.3 µs	0.109 µs
MSP-EXP430FR5994	428.5 µs	0.095 µs
EVM430-FR6047	581.4 µs	0.099 µs
MSP-EXP430FR6989	383.9 µs	0.107 µs

Macrobenchmark. As an end-to-end benchmark, we also measured (using the above method) the average execution time of attesting the entire RAM (2 kB). Running at 8 MHz, the attestation takes 497.0777 ms ($n = 100, \sigma = 0.0149$) with only IPE protection, similar to the figure reported in the original paper (450.15 ms for 4 kB) [42]. Using our framework to protect this vulnerable implementation, the execution time increases to 497.7123 ms ($n = 100, \sigma = 0.0182$), an overhead of 634.6 µs (0.13%), which corresponds to the two resets required (the initial ecall, then returning from an ocall) as shown in Table 6. This result shows that, as is common with TEEs, the overhead of our framework seems to closely correspond with the number of context switches between the enclave and the untrusted world.

7 Related work

7.1 Code protection on microcontrollers

While this paper focused on IPE, in the following, we summarize other code protection or isolation features on currently manufactured microcontrollers.

Arm TrustZone. Arm TrustZone [4,45], introduced in 2004 and predating most other code protection and TEE technologies, isolates secure and non-secure software on 32-bit devices using support from the hardware, which maintains a security state and propagates it for bus operations, making peripherals also aware of the current security level.

Microchip CodeGuard. Microchip CodeGuard [36, 37], introduced in 2006, offers more comprehensive protection

than IPE on a similar class of devices. CodeGuard allows the flash code memory to be partitioned into three segments, called Boot, Secure, and General. These segments can also claim exclusive access over parts of the device's data memory, enabling the isolation of dynamic data. At the highest security setting, CodeGuard also enforces entry points, making only the first 32 instructions of the Boot and Secure regions executable from outside. Finally, interrupts are also secured. If a Boot segment is defined, only this segment has access to the IVT. Furthermore, if an interrupt is triggered during the execution of the Boot or Secure regions, the device first vectors to a special ISR in these regions that can clean the register and memory contents before invoking untrusted code.

Flash protection. Multiple vendors offer read and write protection of program code on embedded devices. While useful in certain scenarios, these solutions cannot offer the isolation guarantees outlined in this paper, as they do not protect application data. Microchip Selective Code Protection [38] separates program memory into blocks and can restrict read and write accesses to these, allowing read access to constant values to code from the same block. Armv7-M and v8-M processors are equipped with eXecute-Only-Memory (XOM) [6], which disallows read and write access to specific code regions. Certain Arm-based ST microcontrollers also feature global read protection (RDP) and sector-granular write protection, but importantly, RDP only disallows reads from debug interfaces, not user code [52]. Some ST devices also feature proprietary code read-out protection (PCROP), which is a sector-granular protection of sensitive code from read and write accesses, also from untrusted user code [51].

7.2 Attacks on code protection technologies

While not as actively researched as high-end TEEs, some code protection technologies have already been the subject of security analysis, exposing their vulnerabilities to different classes of attacks. Half-blind attacks [22] exploit the bootloader through a memory safety vulnerability in application code to extract protected code from MSP430 microcontrollers. Obermaier and Tatschner [43] completely remove the protection on ST's RDP [52] by downgrading the security level of the device and bypass the access control check on the debugger through a race condition. They also discovered that SRAM contents are readable for a debugger while stepping through code protected by RDP, potentially revealing the firmware when a CRC or hash value is calculated over it, storing intermediate values in SRAM.

This last exploit joins a line of work reconstructing protected firmware based on visible execution state changes. The first such attack [10] bypasses code protection on Cortex-M-based Nordic Semiconductor devices. This technique relies on finding indirect load instructions by single-stepping the protected code with the debugger, setting each register to a memory address and examining the register bank after the instruction. Once a load instruction is found, this is used to leak the entire firmware. Schink and Obermaier [47] performed similar attacks on other Cortex-M-based microcontrollers implementing XOM [6]. Their approach uses values in both memory and registers (and proposes using side-channel information) to recover all instructions without relying on load instructions to leak the firmware. They performed the attack on ST PCROP [51] and NXP FAC [48] (now deprecated) by using a debugger to single-step, and on MSP432's IP protection by using interrupts to execute instructions in isolation. In addition, they found implementation issues and load gadgets that can straightforwardly leak the firmware, similar to the attack on Nordic devices [10]. Finally, in concurrent work, RIPencapsulation [46] develops and evaluates a framework using a similar approach on MSP432 and MSP430 IPE.

8 Conclusion

This paper presented the first in-depth security analysis of the IPE security technology found in popular, off-the-shelf TI MSP430 microcontrollers. While this technology is promising and bears a striking resemblance to embedded TEE research prototypes that have been widely studied in recent years, we discovered multiple crucial issues in current IPE hardware and software. Among other attacks inspired by the attack literature, we showcased the novel controlled `call` corruption, which may critically undermine the security guarantees of systems relying on IPE as a secure key storage or intellectual property protection mechanism. To demonstrate the practicality of our attack primitives, we presented proof-of-concept exploits and end-to-end attacks.

Based on our thorough root-cause analysis and the design of similar TEE research prototypes, we formulated actionable hardware-level mitigations for next-generation hardened IPE microcontrollers. Furthermore, we contributed a practical, end-to-end framework that automates software security responsibilities on existing and future IPE devices at low overheads and provides security guarantees similar to IPE using the onboard MPU on existing devices.

Acknowledgments

A Negative results: Inapplicable attacks

Some attacks from high-end or embedded TEEs have turned out not to apply to the microcontrollers in our analysis. Most notably, embedded MSP430 microcontrollers are not optimized for high performance and do not come equipped with advanced microarchitectural features, such as out-of-order execution and branch prediction that give rise to the potent line of transient execution attacks, which has critically affected high-end TEEs like Intel SGX [67]. Below, we summarize two non-trivial negative results that we found unexploitable from software in our analysis.

A.1 Voltage fault injection

While voltage fault injection attacks, also performed on MSP430 [21] and other TI microcontrollers [76], have traditionally required physical access and are thus out of scope for our analysis, on certain systems it is also possible to control the frequency and voltage of the system through software interfaces. On Intel SGX, changing the voltage through these interfaces could compromise the confidentiality and integrity of enclaves through fault injection, even leading to leaking cryptographic keys from enclaves [31, 40].

The only related configuration setting our microcontroller exposes to software is the frequency of the device. Fault injection could occur by running the device at a high frequency, requiring wait states for the FRAM, but omitting this configuration step. However, the device implements a protection mechanism against this attack and resets the device upon such misconfiguration, avoiding fault injection [55]. In addition, the device contains additional measures against physical attacks [57], including voltage attacks, but these are out of scope for our software-based analysis.

A.2 Direct memory access (DMA) contention

A recent side-channel attack demonstrated on openMSP430-based TEEs uses contention between the CPU and DMA devices to measure the memory activity of enclaves [7, 8]. While on our device, it is possible to schedule DMA transfers from software (putting it in scope for our analysis), due to the DMA implementation on TI's devices, this attack is not possible in its current form. The side-channel attack exploits subtle timing differences caused by contention when DMA transfers and CPU activity happen in parallel, whereas on TI devices, DMA transfers happen while the CPU is disabled in low-power mode and not executing code [55].

AutoFHE: Automated Adaption of CNNs for Efficient Evaluation over FHE

Abstract

Secure inference of deep convolutional neural networks (CNNs) under RNS-CKKS involves polynomial approximation of unsupported non-linear activation functions. However, existing approaches have three main limitations: 1) *Inflexibility:* The polynomial approximation and associated homomorphic evaluation architecture are customized manually for each CNN architecture and do not generalize to other networks. 2) *Suboptimal Approximation:* Each activation function is approximated instead of the function represented by the CNN. 3) *Restricted Design:* Either high-degree or low-degree polynomial approximations are used. The former retains high accuracy but slows down inference due to bootstrapping operations, while the latter accelerates ciphertext inference but compromises accuracy. To address these limitations, we present AutoFHE, which automatically adapts standard CNNs for secure inference under RNS-CKKS. The key idea is to adopt layerwise mixed-degree polynomial activation functions, which are optimized jointly with the homomorphic evaluation architecture in terms of the placement of bootstrapping operations. The problem is modeled within a multi-objective optimization framework to maximize accuracy and minimize the number of bootstrapping operations. AutoFHE can be applied flexibly on any CNN architecture, and it provides diverse solutions that span the trade-off between accuracy and latency. Experimental evaluation over RNS-CKKS encrypted CIFAR datasets shows that AutoFHE accelerates secure inference by 1.32× to 1.8× compared to methods employing high-degree polynomials. It also improves accuracy by up to 2.56% compared to methods using low-degree polynomials. Lastly, AutoFHE accelerates inference and improves accuracy by 103× and 3.46%, respectively, compared to CNNs under TFHE.

1 Introduction

MLaaS, machine learning as a service, is a rapidly growing market with many commercial offerings like Amazon Web Services (AWS), Google Google Cloud Platform (GCP), and Microsoft Azure. Its growth has been driven by the widespread success of deep learning on many tasks like vision [15, 24], language [14, 56], games [49, 51], science [17, 28], and many more. Figure 1 shows a typical MLaaS scenario. The Cloud (Alice) holds deep learning models, while the customer (Bob) has private data and requests service from Alice. Bob wants to protect his private data and does not want Alice to learn sensitive information. On the other hand, deep learning models, including *neural architectures* and *trained weights*, are properties of Alice. Alice spends considerable efforts to design neural architectures, like ResNets [24], ViT [15], and MLP-Mixer [55] and consumes huge computational resources to search for novel neural architectures [39, 60] or train network weights [22, 57].

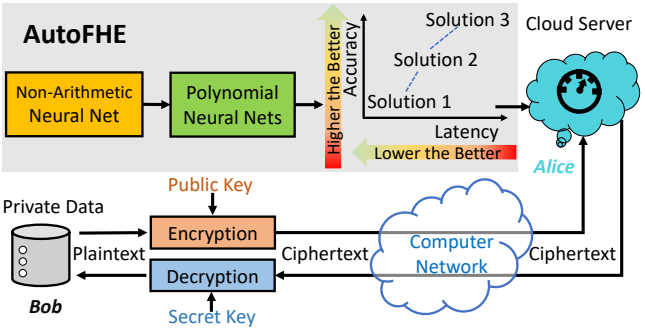

Figure 1: AutoFHE can automatically adapt the standard CNN with non-linear activations into a set of polynomial CNNs that span the trade-off between accuracy and latency for ciphertext inference. AutoFHE solutions can be deployed on the Cloud server to satisfy a range of customer requirements.

Homomorphic Encryption (HE): Secure inference of deep learning models under leveled homomorphic encryption (LHE) [6, 20, 41] or fully homomorphic encryption (FHE) [18, 33, 34] is a promising approach for resolving security concerns between Bob and Alice in the context of MLaaS. FHE enables us to evaluate a circuit with arbitrary depth, including modern deep CNNs [33]. Figure 1 shows secure

inference of CNNs under FHE. First, Bob generates a public key to encrypt his private data and sends Alice the ciphertext. Second, Alice applies neural networks to process the ciphertext input, yielding an encrypted result. Finally, Bob uses the secret key to decrypt the encrypted result. Under FHE, Bob cannot learn Alice's neural architectures and weights, while Alice is also not exposed to Bob's data or the outcome.

Polynomial CNNs: Non-arithmetic activation functions, such as $\mathrm{ReLU}(x) = \max(x, 0)$, are a core component of modern CNNs, aiding in learning non-linear decision boundaries between classes. For example, residual networks (ResNets) [24] are composed of Conv-BN-ReLU triplets [24]. Since FHE only supports *multiplications* and *additions*, ReLU must be replaced by polynomial approximations to evaluate CNNs under FHE. Existing methods to generate polynomial CNNs fall into two categories; *manual design of low-degree and high-degree polynomial approximations*.

(1) A number of approaches adopt low-degree (typically ≤ 3) polynomials [6, 12, 20, 41, 42, 45, 46] to substitute non-arithmetic activation functions and *train* the resultant polynomial neural networks *from scratch*. For instance, CryptoNets [20], LoLa [6] and Delphi [45] employ a simple quadratic activation function x^2. Faster CryptoNets [12] exploit more accurate low-degree approximation $2^{-3}x^2 + 2^{-1}x + 2^{-2}$. SAFENet [42] adopts $a_1x^3 + a_2x^2 + a_3x + a_4$ or $b_1x^2 + b_2x + b_3$ and HEMET [41] uses $ax^2 + bx + c$. After low-degree polynomials are plugged into networks like ResNets both *network weights* and *polynomial coefficients* are trained from scratch using stochastic gradient descent (SGD). However, polynomial layers often lead to unstable training since they may dramatically amplify activations during forward propagation and gradients during backward propagation. For example, gradient explosion was observed in prior works [42, 45]. As such, low-degree approaches suffer from a *dilemma*. On the one hand, since low-degree polynomials cannot precisely approximate ReLU, polynomial networks have to be trained from scratch and suffer from poor prediction accuracy. On the other hand, using a higher degree polynomial approximation of ReLU leads to training instability due to exploding gradients. In either case, low-degree approaches achieve lower accuracy than ReLU networks, *e.g.* on CIFAR-10 HEMET [41] and SAFENet [42] report 83.7% and 88.9% Top-1 accuracy, respectively. To mitigate gradient explosion, AESPA [46] normalized the outputs of each polynomial basis separately, leading to improved predictive accuracy.

(2) A few approaches use high-degree polynomials to approximate ReLU precisely. So, high-degree approaches do not need to train polynomial networks from scratch and can inherit weights from pretrained ReLU networks. One representative polynomial approximation of ReLU is Minimax composite polynomials [32, 36]. By expressing ReLU as $\mathrm{ReLU}(x) = x \cdot (0.5 + 0.5 \cdot \mathrm{sgn}(x))$, a composite polynomial is used to approximate $\mathrm{sgn}(x)$. The approximation of ReLU is defined as $\mathrm{AppReLU}(x) = x \cdot (0.5 + 0.5 \cdot p_\alpha(x)), x \in [-1, 1]$. $p_\alpha(x)$ is the composite Minimax polynomial, and α quantifies approximation precision, *i.e.*, $|p_\alpha(x) - \mathrm{sgn}(x)| \leq 2^{-\alpha}$. Given $x \in [-B, B]$, the scaled AppReLU is defined as $B \cdot \mathrm{AppReLU}(x/B)$, with a precision of $B \cdot 2^{-\alpha}$. However, high-degree polynomials consume many multiplicative levels and require numerous bootstrapping operations, leading to a high computational burden. MPCNN [33], the state-of-the-art approach for secure inference of CNNs under RNS-CKKS, adopts Minimax composite polynomials with a precision of $\alpha = 13$. By choosing to approximate each ReLU function with high precision, MPCNN results in prediction accuracy that is comparable to ReLU networks. However, the same high-degree AppReLU replaces all ReLUs and consumes $\sim$ **50**% levels. The ciphertext quickly exhausts levels and uses bootstrapping to refresh the zero-level ciphertext before every AppReLU layer (refer to Figure 2). As such, the homomorphic evaluation architecture needs to be customized for each CNN architecture. Moreover, bootstrapping operations consume $>$ **70**% of inference time (refer to Table 5) and result in prohibitively high latency.

Motivation: We propose AutoFHE to address the above-mentioned limitations of existing methods for secure inference of CNNs. It is based on layerwise mixed-degree polynomials and a hybrid of approximation and training methods. The goal is to **Auto**matically generate polynomial CNNs and associated homomorphic evaluation architecture spanning a trade-off front of accuracy and latency under **FHE**.

(1) LAYERWISE MIXED-DEGREE POLYNOMIALS: A plausible solution to decrease the computational burden of secure inference is to assign layerwise mixed-degree polynomials to different ReLUs across a network based on the observation that different layers in a network have varying degree of sensitivity to approximation errors. SAFENet [42] demonstrated that mixed-degree polynomials can exploit layerwise sensitivity. However, current mixed-degree search frameworks are limited in two aspects. i) *small search space*: *e.g.* SAFENet only provides two polynomials, degree 2 and degree 3. The small search space cannot include all possible solutions from low-degree to high-degree polynomials. ii) *scalarization of multiple objectives*: a weighted sum is used to balance multiple objectives [42, 45]. However, this approach requires a pre-defined preference to weigh the different objectives. So, they cannot generate diverse solutions to meet different requirements in a single optimization run.

(2) HYBRID OF APPROXIMATION AND TRAINING: Precisely approximating ReLU allows MPCNN to achieve the state-of-the-art ciphertext inference accuracy. Low-degree approaches train polynomial CNNs from scratch to compensate for loss in accuracy. We posit that by taking advantage of approximation and training, we can inherit weights from ReLU networks and fine-tune polynomial networks to adapt learnable weights to layerwise mixed-degree polynomials. In principle, such a design can allow for high ciphertext inference accuracy while reducing latency.

However, realizing the above goals presents multiple chal-

lenges. The design space, which includes layerwise mixed-degree polynomials and the associated homomorphic evaluation architectures in terms of placement of bootstrapping operations, is prohibitively large for effective manual design. Therefore, in this paper, we advocate for automated optimization of the joint polynomial and homomorphic architecture.

Contributions: We outline our contributions from two perspectives, *design* and *system*.

From a *design* perspective, our contributions are,

1. FLEXIBILITY: We jointly search for polynomial approximation and a compatible homomorphic evaluation architecture (placement of bootstrapping operations) so we can automatically adapt *any* convolutional neural networks for secure evaluation over FHE.

2. OPTIMAL APPROXIMATION: We approximate the end-to-end function represented by the CNN instead of a standalone non-linear activation function. This allows us to exploit the varying sensitivity of different layers to approximation error, and obtain polynomial approximations with high accuracy and efficient evaluation over FHE.

3. SEAMLESS DESIGN: We allow for layerwise mixed-degree polynomials, which enables us to find a range of models that span the accuracy and latency trade-off.

From a *system* perspective, our contributions are,

1. SEARCH SPACE: We design search space to include all possible low-degree and high-degree polynomials to enable us to discover better solutions.

2. SEARCH OBJECTIVE: We formulate the search problem as a multi-objective optimization. We automatically generate diverse polynomial networks spanning the trade-off front between accuracy and latency in a single optimization run.

3. SEARCH ALGORITHMS: We propose combining search and training algorithms to search over large search spaces efficiently, optimize coefficients of arbitrary polynomials, and fine-tune layerwise mixed-degree polynomial networks. Specifically, we propose:

   - *MOS*, a multi-objective search algorithm to search for solutions within a large search space.
   - *R-CCDE*, a gradient-free search algorithm to optimize coefficients of composite polynomials.
   - *PAT*, a fine-tuning algorithm that adapts network weights to polynomial activations.

Experimental Results on encrypted CIFAR datasets show that AutoFHE has a better trade-off of accuracy and latency compared to high-degree and low-degree approaches under RNS-CKKS. Compared to high-degree MPCNN [33], AutoFHE accelerates inference by $\mathbf{1.32\times \sim 1.8\times}$ while improving accuracy by $\mathbf{+0.08\% \sim 0.3\%}$ on CIFAR10. AutoFHE speeds up inference by $\mathbf{1.1\times \sim 1.4\times}$ while increasing accuracy by $\mathbf{+0.36\% \sim 0.75\%}$ on CIFAR100. Compared to low-degree AESPA [46], AutoFHE improves ciphertext accuracy by $\mathbf{+2.56\%}$ and $\mathbf{+2.44\%}$ based on ResNet32 and ResNet44 backbones on CIFAR10 with similar latency. Furthermore, we compare the accuracy-latency trade-off of networks across two FHE schemes, namely RNS-CKKS and TFHE. Specifically, we compare AutoFHE networks designed for RNS-CKKS with REDsec [18], which is designed for TFHE. We observe that AutoFHE improves accuracy by $\mathbf{+10.06\%}$ and $\mathbf{+3.46\%}$ compared to REDsec BNet_S and BNet, respectively, while simultaneously reducing the corresponding latency by $\mathbf{24\times}$ and $\mathbf{103\times}$, respectively.

2 Preliminaries

RNS-CKKS: The full residue number system (RNS) variant of Cheon-Kim-Kim-Song (RNS-CKKS) [8, 10] is a leveled homomorphic encryption (LHE) scheme for approximate arithmetic. Under RNS-CKKS, a ciphertext $\boldsymbol{c} \in \mathcal{R}_{Q_\ell}^2$ satisfies the decryption circuit $[\langle \boldsymbol{c}, sk\rangle]_{Q_\ell} = m + e$, where $\langle \cdot, \cdot \rangle$ is the dot product and $[\cdot]_Q$ is the modular reduction function. $\mathcal{R}_{Q_\ell} = \mathbb{Z}_{Q_\ell}[X]/(X^N+1)$ is the residue cyclotomic polynomial ring. The modulus is $Q_\ell = \prod_{i=0}^{\ell} q_\ell$, where $0 \le \ell \le L$. ℓ is a non-negative integer, referred to as *level*, which denotes the capacity of homomorphic multiplications. sk is the secret key with Hamming weight h. m is the original plaintext message, and e is a small error that provides security. A ciphertext has $N/2$ slots to accommodate $N/2$ complex or real numbers. RNS-CKKS supports homomorphic addition and multiplication:

$$\begin{aligned} \text{Decrypt}(\boldsymbol{c} \oplus \boldsymbol{c}') &= \text{Decrypt}(\boldsymbol{c}) + \text{Decrypt}(\boldsymbol{c}') \approx m + m' \\ \text{Decrypt}(\boldsymbol{c} \otimes \boldsymbol{c}') &= \text{Decrypt}(\boldsymbol{c}) \times \text{Decrypt}(\boldsymbol{c}') \approx m \times m' \end{aligned} \tag{1}$$

Bootstrapping: LHE only allows a finite number of homomorphic multiplications, with each multiplication consuming one level due to rescaling. Once a ciphertext's level reaches zero, a bootstrapping operation is required to refresh it to a higher level and allow more multiplications. The number of levels needed to evaluate a circuit is known as its *depth*. RNS-CKKS with bootstrapping [7] is an FHE scheme that can evaluate circuits of arbitrary depth. It enables us to homomorphically evaluate deep CNNs on encrypted data. Conceptually, bootstrapping homomorphically evaluates the decryption circuit and raises the modulus from Q_0 to Q_L by using the isomorphism $\mathcal{R}_{q_0} \cong \mathcal{R}_{q_0} \times \mathcal{R}_{q_1} \times \cdots \times \mathcal{R}_{q_L}$ [4]. Practically, bootstrapping [7] homomorphically evaluates modular reduction $[\cdot]_Q$ by first approximating it by a scaled sine function, which is further approximated through polynomials [7, 35]. Bootstrapping [4] has four stages: ModRaise, CoeffToSlot, EvalMod, and SlotToCoeff. Bootstrapping incurs a lot of

key switching operations (KSO), which are the most time-consuming operation on the RNS-CKKS scheme [33]. The refreshed ciphertext has level $\ell = L - K$, where K levels are consumed by bootstrapping [4] for polynomial approximation of modular reduction.

Threat Model: In this paper, we assume the same threat model as prior works under HE, like HEMET [41], MPCNN [33], REDsec [18]. As discussed in the MLaaS scenario, a customer uploads encrypted data to a Cloud server and requests ML services. The Cloud uses neural networks to process the ciphertext without decryption and send back an encrypted result. Only the customer holds the secret key and can decrypt the encrypted result. The Cloud cannot learn sensitive information from the customer's data and the result. The customer is also not exposed to the Cloud's neural networks, including architectures and weights.

3 AutoFHE

Given a neural network $g(\boldsymbol{a}, \boldsymbol{\omega}_0(\boldsymbol{a}))$ with architecture $\boldsymbol{a}$ and *pretrained*[1] weights $\boldsymbol{\omega}_0(\boldsymbol{a})$ and M ReLU layers, AutoFHE generates polynomial networks on a trade-off front by maximizing accuracy and minimizing latency. For a given architecture $\boldsymbol{a}$ during the search, every solution is represented by a triplet of variables $\boldsymbol{S}(\boldsymbol{a}) = (\boldsymbol{D}(\boldsymbol{a}), \boldsymbol{\Lambda}(\boldsymbol{a}), \boldsymbol{\omega}(\boldsymbol{a}))$. We will drop the architecture $\boldsymbol{a}$ from hereon for ease of notation. $\boldsymbol{D}$ is the degree vector of all EvoReLU layers, $\boldsymbol{\Lambda}$ is the coefficients of all EvoReLU layers, and $\boldsymbol{\omega}$ are the trainable weights of the neural network which are initialized with $\boldsymbol{\omega}_0$ and fine-tuned for adaptation to the layerwise mix-degree polynomials. We will assign each solution with the minimization objective $\boldsymbol{o}(\boldsymbol{S}) = \{1 - \mathrm{Acc}(\boldsymbol{S}), \mathrm{Boot}(\boldsymbol{S})\}$. $1 - \mathrm{Acc}(\boldsymbol{S})$ is the validation error, and $\mathrm{Boot}(\boldsymbol{S})$ is the number of bootstrapping operations. Note that the accuracy and the number of bootstrapping operations depend on all the variables $\boldsymbol{S}$. For instance, appropriately adapting the network weights $\boldsymbol{\omega}$ could allow us to use lower-degree polynomial approximations of the activation functions, which reduces the required number of bootstrapping calls.

AutoFHE is a search-based approach which comprises of three main components: *search space* (Section 3.1), *search objective* (Section 3.2) and *search algorithm* (Section 3.3). We describe each of these in detail next.

3.1 Search Space

EvoReLU is a genetic polynomial function used to replace the non-arithmetic ReLU function. We model it as follows,

$$y = \mathrm{EvoReLU}(x) = \begin{cases} x, & d = 1 \\ \alpha_2 x^2 + \alpha_1 x + \alpha_0, & d = 2 \\ x \cdot (\mathcal{F}(x) + 0.5), & d > 2 \end{cases} \quad (2)$$

[1] In our paper, *pretrained* neural networks especially refer to neural networks with ReLU activation.

where $\mathcal{F}(x)$ is a composite polynomial with K sub-polynomials $f_k^{d_k}$ with degree d_k and seeks to approximate $0.5 \cdot \mathrm{sgn}(x)$ for $d > 2$.

$$\mathcal{F}(x) = (f_K^{d_K} \circ \cdots \circ f_k^{d_k} \circ \cdots \circ f_1^{d_1})(x), 1 \le k \le K \quad (3)$$

The total degree of $\mathcal{F}(x)$ is $\prod_{k=1}^{K} d_k$, and consequently the degree of EvoReLU is $d = \prod_{k=1}^{K} d_k + 1$. For $d > 2$ the **multiplicative depth** of EvoReLU is $1 + \sum_{k=1}^{K} \lceil \log_2(d_k + 1) \rceil$ when using the Baby-Step Giant-Step (BSGS) algorithm [4, 35] to evaluate composite polynomial $\mathcal{F}(x)$. For $d = 1$ and $d = 2$, the multiplicative depth is 0 and 2, respectively.

EvoReLU is modeled to allow for *automatic* discovery of common solutions in the literature for improving the latency of inference on ciphertexts. For instance, for $d = 1$, $\mathrm{EvoReLU}(x) = x$ is equivalent to removing the corresponding ReLU layer through pruning [27, 42, 45]. Similarly, for $d = 2$, $\mathrm{EvoReLU}(x) = \alpha_2 x^2 + \alpha_1 x + \alpha_0$ is equivalent to using low-degree approximations of ReLU through quadratic functions [6, 12, 20, 41, 42, 45]. Finally, for $d > 2$, $\mathrm{EvoReLU}(x) = x \cdot (\mathcal{F}(x) + 0.5)$ is equivalent to high-degree polynomial approximations [32, 33] of ReLU. In this case, EvoReLU bears similarity to the Minimax composite polynomial in Lee *et al.* [33, 36]. However, the objective for optimizing the coefficients differs significantly. While Lee *et al.* [33, 36] seek to approximate a single ReLU function precisely, our goal is to jointly optimize all EvoReLU functions in a neural network $\boldsymbol{a}$ to approximate its corresponding function $g(\boldsymbol{a}, \boldsymbol{\omega})$.

For the quadratic version of EvoReLU, we allow the coefficients α_0, α_1, and α_2 to differ *channel-wise* when fine-tuning polynomial CNNs. Such a design improves performance and makes optimizing model weights $\boldsymbol{\omega}$ more stable. For this case, we also introduce a BatchNorm layer after the quadratic EvoReLU for recentering and reshaping the distribution of output activations. We can integrate the BatchNorm parameters into the polynomial coefficients. So, there is no extra consumption of multiplicative levels.

We **represent** the composite polynomial $\mathcal{F}(x)$ by its degree vector $\boldsymbol{d} = \{d_k\}_{k=1}^{K}, d_k \in \mathbb{N}$. Each sub-polynomial $f_k^{d_k}(x)$ as a linear combination of Chebyshev polynomials of degree d_k,

$$f_k^{d_k}(x) = \frac{1}{\beta_k} \sum_{i=1}^{d_k} \alpha_i \mathrm{T}_i(x) \quad (4)$$

where $\alpha_i \in \mathbb{R}$ and $\beta_k \in \mathbb{R}$. $\mathrm{T}_i(x)$ is the Chebyshev basis of the first kind, α_i are the coefficients for linear combination, and scaling parameter β_k is a parameter to scale the output. The coefficients $\boldsymbol{\alpha}_k = \{\alpha_i\}_{i=1}^{d_k}$ control the polynomial's shape, while β_k controls its amplitude. A composite polynomial with the degree vector $\boldsymbol{d}$ has learnable parameters:

$$\boldsymbol{\lambda} = \{\boldsymbol{\alpha}_1, \beta_1, \cdots, \boldsymbol{\alpha}_k, \beta_k, \cdots, \boldsymbol{\alpha}_K, \beta_K\} \quad (5)$$

A neural network with M ReLU activations needs M EvoReLU polynomial activations. $\boldsymbol{D} = \{\boldsymbol{d}_1, \boldsymbol{d}_2, \cdots, \boldsymbol{d}_M\}$ is

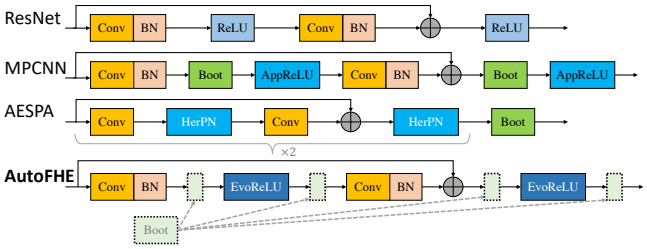

Figure 2: Homomorphic evaluation architectures for Residual Networks (ResNets). 1st row: standard Conv-BN-ReLU triplet [24]. 2nd row: MPCNN [33] which uses high-degree polynomials. 3rd row: AESPA [46] which uses low-degree polynomials. 4th row: The proposed AutoFHE, which uses layerwise mixed-degree polynomials. Dashed rectangles indicate the plausible locations where bootstrapping can be placed. Both EvoReLU and the placement of bootstrapping operations are searched.

the degree vector of all EvoReLUs and the corresponding coefficient parameters are $\mathbf{\Lambda} = \{\boldsymbol{\lambda}_1, \boldsymbol{\lambda}_2, \cdots, \boldsymbol{\lambda}_M\}$.

Homomorphic Evaluation Architecture refers to the placement of ConvBN, polynomial, and bootstrapping. In MPCNN, AppReLU depth is 14, ConvBN depth is 2, and the remaining levels after bootstrapping are $L-K=16$. So, bootstrapping is placed after every AppReLU and ConvBN (Figure 2). AESPA [46] uses degree 2 Hermite polynomial (HerPN) with depth 2 to replace ReLU and Batchnorm. Therefore, every 4 Conv-HerPN should be followed by one bootstrapping operation (Figure 2). In AutoFHE, EvoReLU is layerwise and mixed-degree. The multiplicative depth of EvoReLU varies layer by layer. AutoFHE introduces a flexible evaluation architecture where bootstrapping can be called after ConvBN or EvoReLU (Figure 2). The flexible evaluation architecture of AutoFHE can better fit layerwise mix-degree EvoReLU.

Linear Scaling: Since the domain of Chebyshev polynomials and bootstrapping is $[-1,1]$, we need to scale the ciphertext to $[-1,1]$ before Chebyshev polynomials and bootstrapping and reverse it after Chebyshev polynomials and bootstrapping. To avoid consuming levels, scaling is integrated into other operations. In MPCNN, the polynomial neural network with AppReLU can be roughly regarded as *piece-wise linear* due to high precision approximation of high-degree AppReLU. MPCNN estimates domain of AppReLU using the training dataset and uses the maximum number of all AppReLU domains to scale down input images by $\times 1/B$ and scale up ciphertext in the fully connected layer by $\times B$. In AESPA, HerPN uses degree 2 Hermite polynomial and does not need to scale input of HerPN. However, the input of bootstrapping should be scaled to $[-1,1]$. The domain $[-B,B]$ of each bootstrapping can be estimated on the training dataset, then integrate $\times 1/B$ into the previous HerPN and integrate $\times B$ into the next Conv layer. In AutoFHE, bootstrapping can be

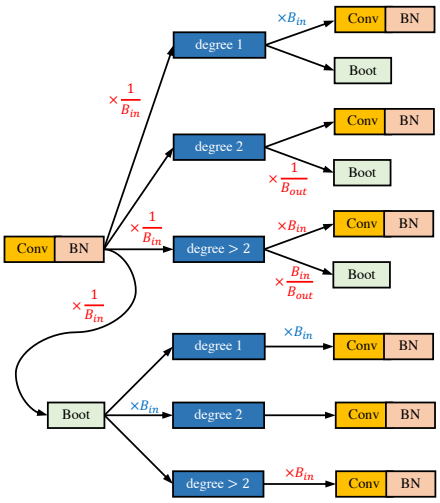

Figure 3: Scaling in AutoFHE. Color Key: integrate scaling into previous operation; integrate scaling into next operation.

placed before EvoReLU and after EvoReLU. So, we need to estimate domain $[-B_{in}, B_{in}]$ and range $[-B_{out}, B_{out}]$ of each EvoReLU on the training dataset. Figure 3 shows possible scaling scenarios in AutoFHE. We can integrate scaling into the previous or next operation. Specifically, we can multiply convolutional weight, batch norm weight and bias, and polynomial coefficients by the scaling constant. The scaling operation is conducted in plaintext and will not introduce either extra level consumption. With the scaling EvoReLU can now be expressed as,

$$\text{EvoReLU}(x) = \begin{cases} x, & d=1 \\ \alpha_2 x^2 + \alpha_1 x + \alpha_0, & d=2 \\ x \cdot (\mathcal{F}(x/B) + 0.5), & d>2 \end{cases} \quad (6)$$

Search Space: Our search space includes the number of sub-polynomials (K) in our composite polynomial, the choice of degrees for each sub-polynomial (d_k), and the coefficients of

Backbone	#ReLUs	Dimension of $\boldsymbol{D}$	Search Space Size
ResNet20	19	114	10^{80}
ResNet32	31	186	10^{130}
ResNet44	43	258	10^{180}
VGG11	10	60	10^{42}

Table 2: Search space of AutoFHE for ResNet and VGG.

the polynomials $\mathbf{\Lambda}$. Table 1 shows each variable's options. Note that choice $d_k = 0$ corresponds to an identity placeholder, so theoretically, the composite polynomial may have fewer than K sub-polynomials. Furthermore, when the degree of $(p_k^{d_k} \circ p_{k-1}^{d_{k-1}})(x)$ is less than or equal to 31 (maximum degree of a polynomial supported on RNS-CKKS [32, 36]), we merge the two sub-polynomials into a single sub-polynomial $p_k^{d_k}(p_{k-1}^{d_{k-1}})(x)$ with degree $d_k \cdot d_{k-1} \leq 31$ before computing its depth. This helps reduce the size of the search space and leads to smoother exploration. Table 2 lists the number of ReLUs of our backbone models and the corresponding dimension and size of search space for $\boldsymbol{D}$. Searching for layerwise EvoReLU is a challenging high-dimensional optimization problem within a vast search space.

3.2 Search Objective

AutoFHE formulates the search problem as *a multi-objective* optimization

$$\begin{aligned} \min_{\boldsymbol{D}} \quad & \{1 - \mathrm{Acc}_{val}\left(g\left(\boldsymbol{\omega}^* \mid \boldsymbol{D}, \mathbf{\Lambda}(\boldsymbol{D})\right)\right), \mathrm{Boot}(\boldsymbol{D})\} \\ \text{s.t.} \quad & \boldsymbol{\omega}^* = \arg\min_{\boldsymbol{\omega}} \mathcal{L}_{train}\left(g\left(\boldsymbol{\omega} \mid \boldsymbol{D}, \mathbf{\Lambda}(\boldsymbol{D})\right)\right) \\ & \mathcal{L}_{train} = (1-\tau)\mathcal{L}_{CE} + \tau\mathcal{L}_{KL} \end{aligned} \tag{7}$$

where $g(\boldsymbol{\omega})$ is a neural network with M activation layers and the trainable network weight $\boldsymbol{\omega}$. The outer multi-objective minimization formulation $\min_{\boldsymbol{D}} \{1 - \mathrm{Acc}_{val}\left(g\left(\boldsymbol{\omega}^* \mid \boldsymbol{D}, \mathbf{\Lambda}(\boldsymbol{D})\right)\right), \mathrm{Boot}(\boldsymbol{D})\}$ for $\boldsymbol{D}$ is to *maximize* the validation accuracy Acc_{val} as well as *minimize* the number of bootstrapping operations. The coefficient vector $\mathbf{\Lambda}$ is formulated as a function of $\boldsymbol{D}$. In Equation 7, Acc_{val} is the Top-1 accuracy on a validation dataset *val*, Boot is the number of bootstrapping operations. To determine the number of bootstrapping operations, we count the level consumption of all EvoReLU's to determine where we need to call bootstrapping. By minimizing the number of bootstrapping operations, we search for the placement of bootstrapping and minimize the wasted levels. For example, consider that we have a ciphertext with a level equal to 2, but the next operation consumes 10 levels. We must waste 2 levels and call bootstrapping to refresh the ciphertext first. AutoFHE can minimize the wasted levels by adjusting the depth of EvoReLU. $\{\boldsymbol{D}_i, \mathbf{\Lambda}_i\}$ has its corresponding network weight $\boldsymbol{\omega}_i$ that can compensate errors introduced by layerwise EvoReLU $\{\boldsymbol{D}_i, \mathbf{\Lambda}_i\}$. We initialize $\boldsymbol{\omega}_i$ with the weight $\boldsymbol{\omega}_0$ from the pretrained ReLU network and then fine-tune the network $g(\boldsymbol{\omega}_i)$ to minimize the training loss $\mathcal{L}_{train}(\boldsymbol{\omega}_i)$ on the training dataset. In summary, the objective in Equation 7 guides the search algorithm to i) explore layerwise EvoReLU, including its *degrees* and *coefficients*; 2) discover the placement of bootstrapping to work well with layerwise mixed-degree EvoReLU; 3) trade-off validation accuracy and inference latency to return diverse polynomial networks.

The training loss $\mathcal{L}_{train}$ used to optimize the weight $\boldsymbol{\omega}$ is $(1-\tau)\mathcal{L}_{CE} + \tau\mathcal{L}_{KL}$, where $\mathcal{L}_{CE}$ is the cross-entropy loss and $\mathcal{L}_{KL}$ is the Kullback–Leibler (KL) divergence loss. τ is a predefined parameter to balance CE and KL loss. In Equation 7, we omit the variable of $\mathcal{L}_{train}$. Given EvoReLU $(\boldsymbol{D}, \mathbf{\Lambda})$, the variable is weight $\boldsymbol{\omega}$. The KL loss computes the distance between distributions of logits of the polynomial network and the ReLU network. We introduce the KL loss because it can push the output of the polynomial network close to the ReLU network. It can be regarded as knowledge distillation (KD) [25]. We transfer knowledge from the ReLU network to polynomial networks.

3.3 Search Algorithms

3.3.1 Multi-Objective Search

Multi-Objective Optimization: Given two solutions with minimization objectives $\boldsymbol{o}_1, \boldsymbol{o}_2 \in \mathbb{R}^d$, we want to minimize all items of $\boldsymbol{o}_1$ and $\boldsymbol{o}_2$. If $\boldsymbol{o}_{1,i} \leq \boldsymbol{o}_{2,i}, \forall i \in \{1, 2, \cdots, d\}$ and $\boldsymbol{o}_{1,j} < \boldsymbol{o}_{2,j}, \exists j \in \{1, 2, \cdots, d\}$, $\boldsymbol{o}_1$ *dominates* $\boldsymbol{o}_2$ [13, 52]. It means $\boldsymbol{o}_1$ is better than $\boldsymbol{o}_2$. It is denoted as $\boldsymbol{o}_1 \prec \boldsymbol{o}_2$. A set of solutions $\boldsymbol{O} = \{\boldsymbol{o}_i\}_{i=1}^{N}$ can be grouped into sub-sets, $\{\boldsymbol{o}_i\}_{i=1}^{N_1}$, $\{\boldsymbol{o}_i\}_{i=1}^{N_2}$, $\cdots$, corresponding to the 1st trade-off front, the 2nd trade-off front and so on. Solutions within the same trade-off front are not dominated by each other. The 1st trade-off front dominates the 2nd trade-off front, and so on.

MOS: Figure 4 and Algorithm 1 show our **M**ulti-**O**bjective **S**earch framework for AutoFHE. MOS is an evolutionary search algorithm to solve the multi-objective optimization in Equation 7. It maintains a population of solutions distributed on trade-off fronts of accuracy and the number of bootstrapping operations. We crossover and mutate solutions to improve every generation's trade-off fronts, as shown in Figure 4. During the search, we define the population size, namely the number of solutions, N. These N solutions may be grouped into multiple trade-off fronts, which can improve exploration ability during search. We design operations to search for layerwise mixed-degree polynomials:

① SELECT: Solutions of the current population are first grouped to different trade-off fronts by non-dominated sorting [13]. Solutions on the same trade-off front have the same fitness. The 1st trade-off front has a higher fitness than the 2nd trade-off front, and so on. We apply the tournament selection [21] to improve the diversity of offspring. Specifically, we randomly select three solutions from the current population and keep the solution with the highest fitness. We choose N' solutions from the current population to build the offspring. In our paper, we set $N' = 6N$.

② CROSSOVER enables network-level information exchange. As shown in Figure 4, we randomly and uniformly exchange EvoReLU layers between two solutions

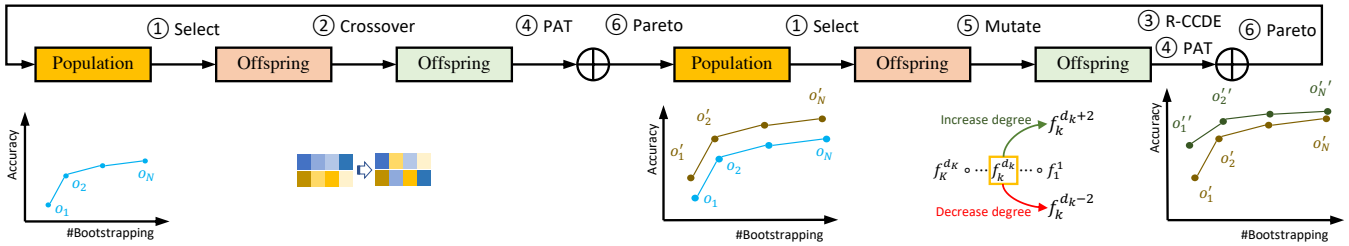

Figure 4: Multi-objective search of AutoFHE.

Algorithm 1: MOS

Input : Pretrained Network $g(\boldsymbol{\omega}_0)$, population size N, offspring size N', number of generations T, training dataset Train, mini-validation dataset Minival;

Output : Trade-off front $\{\boldsymbol{D}_i, \boldsymbol{\Lambda}_i, \boldsymbol{\omega}_i\} \Rightarrow \boldsymbol{o}_i, 1 \le i \le N$;

for $t \leftarrow 1$ **to** T **do**

$\{\boldsymbol{D}_j, \boldsymbol{\Lambda}_j\}_{j=1}^{N'} \leftarrow \texttt{Select}(\{\boldsymbol{D}_i, \boldsymbol{\Lambda}_i, \boldsymbol{o}_i\}_{i=1}^{N})$;

$\{\boldsymbol{D}'_j, \boldsymbol{\Lambda}'_j\}_{j=1}^{N'} \leftarrow \texttt{Crossover}(\{\boldsymbol{D}_j, \boldsymbol{\Lambda}_j\}_{j=1}^{N'})$;

$\{\boldsymbol{\omega}'_j\}_{j=1}^{N'} \leftarrow \texttt{PAT}(\{\boldsymbol{\omega}_0; \boldsymbol{D}'_j, \boldsymbol{\Lambda}'_j\}_{j=1}^{N'}, \text{Train})$;

$\{\boldsymbol{o}'_j\}_{j=1}^{N'} \leftarrow \texttt{Eval}(\{\boldsymbol{D}'_j, \boldsymbol{\Lambda}'_j, \boldsymbol{\omega}'_j\}_{j=1}^{N'}, \text{Minival})$;

$\left\{\boldsymbol{D}'_j, \boldsymbol{\Lambda}'_j, \boldsymbol{\omega}'_j\right\} \Rightarrow \boldsymbol{o}'_j, 1 \le j \le N'$;

$\{\boldsymbol{o}_i\}_{i=1}^{N} \leftarrow \texttt{Pareto}(\{\boldsymbol{o}_i\}_{i=1}^{N} \cup \{\boldsymbol{o}'_j\}_{j=1}^{N'})$;

$\{\boldsymbol{D}_i, \boldsymbol{\Lambda}_i, \boldsymbol{\omega}_i\} \Rightarrow \boldsymbol{o}_i, 1 \le i \le N$;

$\{\boldsymbol{D}_j, \boldsymbol{\Lambda}_j, \boldsymbol{\omega}_j\}_{j=1}^{N'} \leftarrow \texttt{Select}(\{\boldsymbol{D}_i, \boldsymbol{\Lambda}_i, \boldsymbol{\omega}_i, \boldsymbol{o}_i\}_{i=1}^{N})$;

$\{\boldsymbol{D}'_j\}_{j=1}^{N'} \leftarrow \texttt{Mutate}(\{\boldsymbol{D}_j\}_{j=1}^{N'})$;

$\{\boldsymbol{\Lambda}'_j\}_{j=1}^{N'} \leftarrow \texttt{R-CCDE}(\{\boldsymbol{D}'_j\}_{j=1}^{N'})$;

$\{\boldsymbol{\omega}'_j\}_{j=1}^{N'} \leftarrow \texttt{PAT}(\{\boldsymbol{\omega}'_j; \boldsymbol{D}'_j, \boldsymbol{\Lambda}'_j\}_{j=1}^{N'}, \text{Train})$;

$\{\boldsymbol{o}'_j\}_{j=1}^{N'} \leftarrow \texttt{Eval}(\{\boldsymbol{D}'_j, \boldsymbol{\Lambda}'_j, \boldsymbol{\omega}'_j\}_{j=1}^{N'}, \text{Minival})$;

$\left\{\boldsymbol{D}'_j, \boldsymbol{\Lambda}'_j, \boldsymbol{\omega}'_j\right\} \Rightarrow \boldsymbol{o}'_j, 1 \le j \le N'$;

$\{\boldsymbol{o}_i\}_{i=1}^{N} \leftarrow \texttt{Pareto}(\{\boldsymbol{o}_i\}_{i=1}^{N} \cup \{\boldsymbol{o}'_j\}_{j=1}^{N'})$;

$\{\boldsymbol{D}_i, \boldsymbol{\Lambda}_i, \boldsymbol{\omega}_i\} \Rightarrow \boldsymbol{o}_i, 1 \le i \le N$;

(parents) to generate two new solutions. However, new solutions cannot inherit weights from parent solutions because weights are adapted to the parent's layerwise mixed-degree polynomials. So, we initialize weights with pretrained weights and then fine-tune new solutions.

③ R-CCDE optimizes EvoReLU coefficients.

④ PAT fine-tunes new polynomial CNNs.

⑤ MUTATION is to locally explore EvoReLU. We randomly increase or decrease the degree to smoothly change polynomials, as shown in Figure 4. We randomly increase or decrease the degree of a sub-polynomial of EvoReLU with predefined probabilities.

⑥ PARETO refers to non-dominated sorting and crowding distance sorting [13]. We apply Pareto to select N solutions from both population and offspring ($N+N'$ solutions) to build a new population (N solutions).

3.3.2 R-CCDE

Coevolution: The composite polynomial used by EvoReLU is: $y_1 = f_1^{d_1}(x|\boldsymbol{\alpha}_1, \beta_1), \cdots, y_K = f_K^{d_K}(y_{K-1}|\boldsymbol{\alpha}_K, \beta_K)$. The forward architecture of the composite polynomial, $x \mapsto y_1 \mapsto y_2 \cdots \mapsto y_{K-1} \mapsto y$ is suitable for *coevolution* [43, 44, 58] and provides a natural *decomposition*. We can sequentially adjust every sub-polynomial to push the output y close to the target non-arithmetic function. Given the degree $\boldsymbol{d}$, the learnable parameter of EvoReLU $\boldsymbol{\lambda} = (\boldsymbol{\alpha}_1, \beta_1, \cdots, \boldsymbol{\alpha}_K, \beta_K)$ is grouped into $\{\boldsymbol{\alpha}_1\}, \{\beta_1\}, \cdots, \{\boldsymbol{\alpha}_K\}, \{\beta_K\}$. The coefficient $\boldsymbol{\alpha}$ controls the shape of the sub-polynomial output, while the scaling parameter β controls the amplitude. We sequentially update $\{\boldsymbol{\alpha}_k\}$ followed by β_k, $1 \le k \le K$, since i) sub-polynomials close to input will have a larger effect on the output, and ii) it is easier to learn coefficients by decoupling the amplitude from the coefficients.

Differentiable Evolution: The EvoReLU variables $\{\boldsymbol{\alpha}_k\}_{k=1}^{K}$ and $\{\beta_k\}_{k=1}^{K}$ are in the continuous space. We adopt a simple yet effective search algorithm to optimize these variables. Differentiable evolution (DE) [48] only uses the *difference* between solutions to optimize continuous variables. Given the following minimization problem in the continuous space

$$\boldsymbol{x}^* = \arg\min_{\boldsymbol{x}} \mathcal{F}(\boldsymbol{x}) \tag{8}$$

where $\boldsymbol{x} \in \mathbb{R}^d$ and $\mathcal{F}$ is the minimization objective. DE maintains a set of solutions $\boldsymbol{X} = \{\boldsymbol{x}_i\}_{i=1}^{N}, \boldsymbol{x}_i \in \mathbb{R}^d$. The mutation, crossover, and selection of DE are defined as:

$$\begin{aligned}
&\text{Mutation: } \boldsymbol{v} = \boldsymbol{x}_i + F \cdot (\boldsymbol{x}_j - \boldsymbol{x}_k), 1 \le i, j, k \le N \\
&\text{Crossover: } \boldsymbol{u}[t] = \begin{cases} \boldsymbol{v}[t], & \mathcal{U}(0,1) \le CR \\ \boldsymbol{x}_i[t], & \text{Otherwise} \end{cases}, 1 \le t \le d \\
&\text{Selection: } \boldsymbol{u} = \begin{cases} \boldsymbol{u}, & \mathcal{F}(\boldsymbol{u}) \le \mathcal{F}(\boldsymbol{x}_i) \\ \boldsymbol{x}_i, & \text{Otherwise} \end{cases}
\end{aligned} \tag{9}$$

Algorithm 2: R-CCDE

Input : Composite polynomial $\mathcal{F}(x) = (f_K^{d_K} \circ f_{k-1}^{d_{k-1}} \circ \cdots \circ f_1^{d_1})(x)$ with parameters $\boldsymbol{\lambda} = \{\boldsymbol{\alpha}_1, \beta_1, \cdots, \boldsymbol{\alpha}_k, \beta_k, \cdots \boldsymbol{\alpha}_K, \beta_K\}$, target function $q(x)$, number of generations T, scaling decay γ;
Output : Context vector $\boldsymbol{\lambda}^* = (\boldsymbol{\alpha}_1^*, \beta_1^*, \cdots, \boldsymbol{\alpha}_k^*, \beta_k^*, \cdots, \boldsymbol{\alpha}_K^*, \beta_K^*)$;
Initial : $\boldsymbol{\lambda}^* \leftarrow \texttt{LHS}\,(\sum_{k=1}^K d_k + K)$

for $t \leftarrow 1$ **to** T **do**
  for $k \leftarrow 1$ **to** K **do**
    $\boldsymbol{\alpha}_k^\star \leftarrow \arg\min_{\boldsymbol{\alpha}_k} \mathcal{L}_{\mathcal{F},q}(\boldsymbol{\alpha}_k|\boldsymbol{\lambda}^*)$ s.t. $\boldsymbol{\alpha}_k|\boldsymbol{\lambda}^* = (\boldsymbol{\alpha}_1^*, \beta_1^*, \cdots, \boldsymbol{\alpha}_k, \cdots, \boldsymbol{\alpha}_K^*, \beta_K^*)$;
    $\boldsymbol{\lambda}^* \leftarrow (\boldsymbol{\alpha}_1^*, \beta_1^*, \cdots, \boldsymbol{\alpha}_k^\star, \cdots, \boldsymbol{\alpha}_K^*, \beta_K^*)$;
    $\beta_k^\star \leftarrow \arg\min_{\beta_k} \mathcal{L}_{\mathcal{F},q}(\beta_k|\boldsymbol{\lambda}^*) + \gamma \cdot \beta_k{}^2$ s.t. $\beta_k|\boldsymbol{\lambda}^* = (\boldsymbol{\alpha}_1^*, \beta_1^*, \cdots, \beta_k, \cdots, \boldsymbol{\alpha}_K^*, \beta_K^*)$;
    $\boldsymbol{\lambda}^* \leftarrow (\boldsymbol{\alpha}_1^*, \beta_1^*, \cdots, \beta_k^\star, \cdots, \boldsymbol{\alpha}_K^*, \beta_K^*)$;

where $F \in \mathbb{R}$ is the scaling factor, $CR \in \mathbb{R}$ is the crossover rate, and $\mathcal{U}(0,1)$ is the uniform distribution between 0 and 1. Equation 9 shows a simple strategy to update solutions by only using difference. First, mutation updates $\boldsymbol{x}_i$ with the scaled difference $F \cdot (\boldsymbol{x}_j - \boldsymbol{x}_k)$. Then, we randomly select items from $\boldsymbol{v}$ or $\boldsymbol{x}_i$ to generate a new solution $\boldsymbol{u}$. Finally, we evaluate $\mathcal{F}(\boldsymbol{u})$ and use $\boldsymbol{u}$ to replace $\boldsymbol{x}_i$ if $\mathcal{F}(\boldsymbol{u}) \leq \mathcal{F}(\boldsymbol{x}_i)$. DE only uses difference and does not suffer from gradient exploding. It maintains a set of solutions and is not sensitive to initialization.

R-CCDE: We propose **R**egularized **C**ooperative **C**oevolution **D**ifferentiable **E**volution, called R-CCDE, to search for parameters of EvoReLU$(x, \boldsymbol{\lambda}; \boldsymbol{d})$, namely $\boldsymbol{\lambda} = \{\boldsymbol{\alpha}_k, \beta_k\}_{k=1}^K$. The scaling parameters $\{\beta_k\}_{k=1}^K$ are used to adjust the amplitude of sub-polynomials during the search. After the search, $\{\beta_k\}_{k=1}^K$ will be used to scale $\{\boldsymbol{\alpha}_k\}_{k=1}^K$ and obtain coefficients of polynomials. The decomposition makes the search easier by decoupling the shape and amplitude of polynomials. We detail the implementation of R-CCDE in Algorithm 2. R-CCDE takes as input a composite polynomial $\mathcal{F}(x) = (f_K^{d_K} \circ f_{k-1}^{d_{k-1}} \circ \cdots \circ f_1^{d_1})(x)$ with parameters $\boldsymbol{\lambda} = \{\boldsymbol{\alpha}_1, \beta_1, \cdots \boldsymbol{\alpha}_k, \beta_k \cdots \boldsymbol{\alpha}_K, \beta_K\}$. Because EvoReLU is defined as $y = \text{EvoReLU}(x) = x \cdot (\mathcal{F}(x) + 0.5)$ in Equation 3, we use the composite polynomial $\mathcal{F}(x)$ to approximate $q(x) = 0.5 \cdot \text{sgn}(x)$. We set the number of generations and the scaling decay parameter to T and γ, respectively. The objective function $\mathcal{L}_{\mathcal{F},q}(\cdot)$ is the ℓ_1 distance between the composite polynomial $\mathcal{F}(x)$ and the target function $q(x)$. R-CCDE maintains a *context vector* [44] $\boldsymbol{\lambda}^* = (\boldsymbol{\alpha}_1^*, \beta_1^*, \cdots, \boldsymbol{\alpha}_K^*, \beta_K^*)$ as the best solution so far. $\boldsymbol{\lambda}^*$ is initialized via Latin hypercube sampling (LHS). In Algorithm 2, $\boldsymbol{\alpha}_k$ and β_k $1 \leq k \leq K$ are optimized using DE sequentially and alternatively. In generation t, given the k-th position, we optimize $\boldsymbol{\alpha}_k$ as

$$\begin{aligned} \boldsymbol{\alpha}_k^\star &= \arg\min_{\boldsymbol{\alpha}_k} \mathcal{L}_{\mathcal{F},q}(\boldsymbol{\alpha}_k|\boldsymbol{\lambda}^*) \\ \text{s.t.} \quad \boldsymbol{\alpha}_k|\boldsymbol{\lambda}^* &= (\boldsymbol{\alpha}_1^*, \beta_1^*, \cdots \boldsymbol{\alpha}_k, \cdots, \boldsymbol{\alpha}_K^*, \beta_K^*) \end{aligned} \tag{10}$$

where $\boldsymbol{\alpha}_k$ is a variable, while other $\boldsymbol{\alpha}$'s and β's are fixed. A candidate solution of $\boldsymbol{\alpha}_k$ is plugged into $\boldsymbol{\lambda}^*$. Then, we evaluate the candidate solution $\boldsymbol{\alpha}_k$ by evaluating $\mathcal{L}_{\mathcal{F},q}(\boldsymbol{\alpha}_1^*, \beta_1^*, \cdots, \boldsymbol{\alpha}_k, \cdots, \boldsymbol{\alpha}_K^*, \beta_K^*)$. We adopt DE to solve the single-objective optimization problem in the continuous space. We maintain a set of candidate solutions of $\boldsymbol{\alpha}_k$, namely $\boldsymbol{X} = \{\boldsymbol{x}_i\}_{i=1}^N, \boldsymbol{x}_i \in \mathbb{R}^{d_k}$. Mutation, crossover, and selection defined in Equation 9 are applied to update solutions in $\boldsymbol{X}$. Then, the best solution in $\boldsymbol{X}$ is assigned to $\boldsymbol{\alpha}_k^\star$. We use $\boldsymbol{\alpha}_k^\star$ to replace $\boldsymbol{\alpha}_k^*$ in the context vector $\boldsymbol{\lambda}^*$ to update $\boldsymbol{\lambda}^*$

$$\boldsymbol{\lambda}^* = (\boldsymbol{\alpha}_1^*, \beta_1^*, \cdots \boldsymbol{\alpha}_k^\star, \cdots, \boldsymbol{\alpha}_K^*, \beta_K^*) \tag{11}$$

In summary, i)$\{\boldsymbol{\alpha}_k\}_{k=1}^K$ and $\{\beta_k\}_{k=1}^K$ *separately* maintain their sets of solutions that are optimized by DE; ii) the *context* vector $\boldsymbol{\lambda}^*$ is not only the best solution so far. It allows different variables to share information. When evolving $\{\beta_k\}_{k=1}^K$, the objective introduces a *regularization* term

$$\begin{aligned} \beta_k^\star = \arg\min_{\beta_k} & \underbrace{\mathcal{L}_{\mathcal{F},q}(\beta_k|\boldsymbol{\lambda}^*)}_{\ell_1 \text{ Distance}} + \underbrace{\gamma \cdot \beta_k{}^2}_{\text{Regularization}} \\ \text{s.t.} \quad & \beta_k|\boldsymbol{\lambda}^* = (\boldsymbol{\alpha}_1^*, \beta_1^*, \cdots, \beta_k, \cdots, \boldsymbol{\alpha}_K^*, \beta_K^*) \end{aligned} \tag{12}$$

where $\gamma \cdot \beta_k^2$ is the regularization term and γ is the scaling decay parameter. Without the regularization $\gamma \cdot \beta_k^2$, we observe $\{\beta_k\}_{k=1}^K$ prefers *large* numbers. Because $p_k^{d_k}(x) = \frac{1}{\beta_k} \sum_{i=1}^{d_k} \alpha_i \text{T}_i(x)$, large $\{\beta_k\}_{k=1}^K$ numbers can make the composite polynomial *numerical stable* because the polynomial output is scaled to a small number. However, it is hard to distinguish different solutions of $\{\boldsymbol{\alpha}_k\}_{k=1}^K$. By introducing the regularization term $\gamma \cdot \beta_k^2$, DE prefers large numbers in earlier generations and gradually reduces β_k. Therefore, DE is not biased toward solutions with large β_k numbers. We use R-CCDE to optimize coefficients of quadratic and high-degree EvoReLU. For quadratic EvoReLU in Equation 2, α_2 is obtained by R-CCDE and $\alpha_1 = 0.5$, $\alpha_0 = 0$.

3.3.3 Polynomial-Aware Training

Replacing ReLU with EvoReLU in pretrained neural networks injects *minor* approximation errors, which leads to

performance loss. Fine-tuning can mitigate this performance loss by allowing the learnable weights (e.g., convolution or fully connected layers) to adapt to the approximation error. However, backpropagation through EvoReLU easily leads to exploding gradients since the gradients may be amplified exponentially due to many composite polynomials. From Equation 2, high-degree EvoReLU can precisely approximate ReLU, while ReLU pruning (degree 1) and quadratic EvoReLU (degree 2) have a larger approximation error. For low-degree EvoReLU (degree ≤ 2), we can use SGD to compute gradients because they do not amplify gradients. For high-degree EvoReLU (degree > 2), we can use gradients from the original non-arithmetic ReLU function for *backpropagation*. Specifically, during *the forward* pass, EvoReLU injects slight errors captured by the training loss. During the *backward* pass, we bypass high-degree EvoReLU and use ReLU to compute gradients to update the weights of the linear trainable layers. We refer to this procedure as **P**olynomial-**A**ware **T**raining (PAT). PAT is inspired by STE [3] and QAT [26], which uses two different functions for forward- and back-propagation. PAT is defined as:

$$\frac{\partial \text{EvoReLU}(x)}{\partial x} = \begin{cases} 1, & d = 1 \\ 2\alpha_2 x + \alpha_1, & d = 2 \\ \partial \text{ReLU}(x)/\partial x, & d > 2 \end{cases} \tag{13}$$

4 Experiments

Datasets: We benchmark AutoFHE on CIFAR10 and CIFAR100 [31]. Both datasets have 50,000 training and 10,000 validation images at a resolution of 32×32. CIFAR10 has 10 classes, while CIFAR100 includes 100 classes. The validation images are treated as private data and used only for evaluating the final networks. To guide the search process, we randomly select 10,000 images from the training split as a *minival* [53] dataset and use the Top-1 accuracy on the minival dataset to optimize Equation 7. In addition, PAT uses the training split to fine-tune polynomial networks. Finally, as our final result, we report the Top-1 accuracy on the encrypted validation dataset under RNS-CKKS.

Parameters: (1) TRAINING PARAMETERS: We train ReLU networks (used by MPCNN and AutoFHE) and AESPA using SGD optimizer with batch size 128, epochs 200, learning rate 0.1, momentum 0.9 and weight decay 0.0005. We use a cosine learning rate scheduler. We clip gradients to 1 when we train polynomial networks (AESPA or AutoFHE). **(2)** SEARCH PARAMETERS: For MOS, we set the number of generations to 10. Population size is proportional to the number of variables. We set population size to 10, 20, 30 and 40 for VGG11, ResNet20, ResNet32 and ResNet44, respectively. The offspring size is $6\times$ as the population size. When we mutate a polynomial, its degree is decreased by -2 with a probability of 0.5 and is increased by $+2$ with a probability of 0.3. For R-CCDE, we set the search domain of $\boldsymbol{\alpha}$ to $[-5,5]$ and that of β to $[1,5]$. We use the set of 20 solutions for optimizing β. For $\boldsymbol{\alpha}$, we set the number of solutions equal to $20\times$ the number of variables. We set both the scaling factor F and the crossover rate CR to 0.5. We set the scaling decay to $\gamma = 0.01$ and the number of iterations to 100. We run R-CCDE 10 times with different random seeds and retain the best solution. **(3)** FINETUNING PARAMETERS: To fine-tune AutoFHE polynomial networks, we train them using PAT with batch size 128, learning rate 0.02, momentum 0.9, weight decay 0.0005, and KL weight $\tau = 0.9$. We clip gradients to 1. During the search, to quickly estimate the accuracy of polynomial networks, we set epochs to 5. After the search, we set epochs to 90 and use the cosine annealing learning rate scheduler. **(4)** CRYPTOGRAPHIC PARAMETERS: We followed MPCNN to set the same cryptographic parameters [33] of RNS-CKKS for MPCNN, AESPA and AutoFHE. The cyclotomic polynomial uses degree $N = 2^{16}$. The Hamming weight of the secret key is 192. The ciphertext level is $L = 30$, while bootstrapping uses 14 levels ($K = 14$). Base modulus, special modulus, and bootstrapping modulus are set to 51 bits, while default modulus is set to 46 bits [33]. The cryptographic parameters satisfy *128-bit security* [9, 33].

Method	Venue	Scheme	Polynomial	Layerwise	Strategy	Arch
MPCNN [33]	ICML22	CKKS	high-degree	×	approx	manual
AESPA [46]	arXiv22	CKKS	low-degree	×	train	manual
REDsec [18]	NDSS23	TFHE	n/a	n/a	train	manual
AutoFHE	USENIX24	CKKS	mixed	✓	adapt	search

Table 3: AutoFHE and baselines. AutoFHE, MPCNN and AESPA use fixed-point arithmetic under RNS-CKKS, while REDsec adpots ternary neural networks under TFHE.

Hardware and RNS-CKKS Library: (1) SEARCH: On one NVIDIA RTX A6000 GPU, the search process for ResNet-20/32/44 and VGG11 on CIFAR10 took 44 hours, 64 hours, 88 hours, 13 hours, respectively. The search for ResNet32 and VGG11 on CIFAR100 took 67 and 12 hours, respectively. To accelerate R-CCDE, we use 100 CPU threads of AMD EPYC 7502 32-core processor. **(2)** FHE INFERENCE: We evaluate latency under FHE on the publicly available Amazon AWS instance, r5.24xlarge, which has 96 CPU threads and 768 GB RAM. We build C++ implementation of AutoFHE under RNS-CKKS on top of MPCNN using Microsoft SEAL library [50]. We adopt MPCNN implementations of Conv, BN, Downsample, AvgPool, and FC layers.

Baselines: We compare the proposed AutoFHE with two recent state-of-the-art approaches under RNS-CKKS, high-degree polynomial and approximation-based approach MPCNN [33] and low-degree polynomial and training-based approach AESPA [46], as shown in Table 3. We also benchmark against REDsec [18] under TFHE to compare different FHE schemes.

RNS-CKKS BASELINES: MPCNN uses high-degree

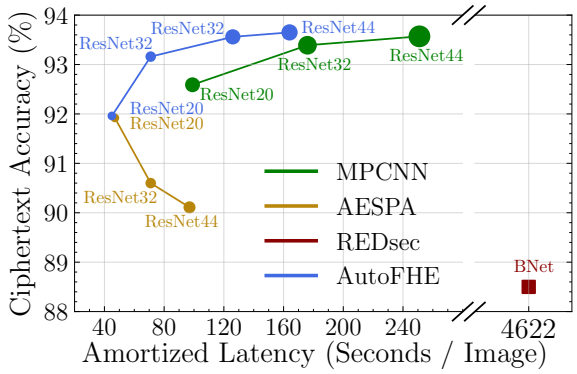

Figure 5: Comparison of trade-offs between ciphertext accuracy and amortized latency on encrypted CIFAR10. The latency is evaluated on Amazon AWS r5.24large using 96 threads. RNS-CKKS approaches take 96 encrypted images as input, while REDsec processes one image at a time. Circle size is proportional to the number of bootstrapping operations.

Minimax composite polynomial approximation of ReLU and reports high ciphertext accuracy (refer to Appendix A). AESPA applies degree 2 Hermite polynomial to replace ReLU, which reduces the multiplicative depth of polynomials and greatly reduces the consumption of bootstrapping. Because AESPA was originally proposed under secure MPC, we implement AESPA under RNS-CKKS (refer to Appendix B). We use the same training parameters for MPCNN, AESPA and AutoFHE. We estimate scaling parameters of MPCNN on training datasets: 21.26 (ResNet20), 21.99 (ResNet32), 17.80 (ResNet44), 29.82 (VGG11) on CIFAR10 dataset and 63.40 (ResNet32) and 54.97 (VGG11) on CIFAR100.

TFHE BASELINE: The fast fully homomorphic encryption scheme over the torus (TFHE) [11] provides very fast bootstrapping by using bootstrapped binary gates. REDsec applies efficient ternary networks (TNNs) under TFHE. REDsec reports performance of BNet$_S$ and BNet on CIFAR10 under CPU TFHE [54]. BNet$_S$ and BNet observe ciphertext accuracy 81.9% and 88.5%, and latency 1,081 and 4,622 seconds per image on CIFAR10 dataset on AWS r5.24large instance using 96 CPU threads [18]. The TFHE cryptographic parameters used by REDsec satisfy 128 bits of security [18]. Please note that REDsec uses a different parallel acceleration strategy. REDsec takes advantage of all 96 CPU threads to process one encrypted image, while RNS-CKKS approaches allocate one thread to each image. Therefore, REDsec has the same latency and amortized latency. When we evaluate the latency of AutoFHE, MPCNN and AESPA on AWS r5.24large, we input 96 encrypted images using 96 CPU threads. The amortized latency is $\frac{1}{96}\times$ as the latency under RNS-CKKS. So, the amortized latency of REDsec and RNS-CKKS approaches is comparable.

4.1 AutoFHE under RNS-CKKS

Trade-offs under FHE: Figure 5 shows trade-offs between ciphertext accuracy and amortized latency on CIFAR10 dataset. We benchmark the performance of ResNet and VGGNet backbones on CIFAR10 and CIFAR100 datasets, as shown in Table 4. For TFHE baseline REDsec, it reported 81.9% ciphertext accuracy with latency 1,081s per image and 88.5% ciphertext accuracy with latency 4,622s per image on CIFAR10 [18]. We have the following observations:

RNS-CKKS *vs* TFHE

Neural networks under RNS-CKKS significantly outperform those under TFHE in terms of both ciphertext accuracy and latency.

From Figure 5, REDsec shows lower ciphertext accuracy because ternary neural networks (TNNs) enormously compress models [38] compared to real-valued models used by RNS-CKKS approaches. Real-valued networks have much better representation learning ability than TNNs. In secure inference of neural networks, REDsec has to evaluate millions to billions of gates [18]. Although evaluating one gate is very fast (10 $\sim$ 13 ms) [18] on TFHE [54], the latency of the whole network is still extremely high. The most efficient solution (ResNet20 with 5 bootstrapping operations) of **AutoFHE** reports **91.96**% ciphertext accuracy and **45s** latency. Compared to REDsec BNet$_S$ and BNet, AutoFHE improves ciphertext accuracy by **+10.06**% and **+3.46**%, respectively, while being **24**× and **103**× faster in terms of amortized latency.

High-Degree *vs* Low-Degree *vs* Mixed-Degree

High-degree polynomials are suitable for shallow and deep neural networks but suffer from high latency. Low-degree polynomials can effectively accelerate ciphertext inference but at the cost of a significant drop in accuracy. Mixed-degree layer-wise polynomials (AutoFHE) lead to a significantly better trade-off between accuracy and latency.

From Figure 5 and Table 4, we observe that high-degree MPCNN is able to preserve plaintext accuracy although it consumes more levels (14) for AppReLU. Since MPCNN focuses on approximating the ReLU function, it can use weights from ReLU networks and does not suffer from exploding activations and gradients in the forward and backward passes of data through the network. In summary, MPCNN is a plug-in approach with high accuracy and high latency. Low-degree AESPA reduces level consumption of each polynomial by 12 compared to MPCNN. AESPA polynomials only consume 26% and 22% of the bootstrapping operations in MPCNN for ResNet and VGG, respectively. However, AESPA achieves this at the cost of large drops in accuracy, 0.7% $\sim$ 3.6% on

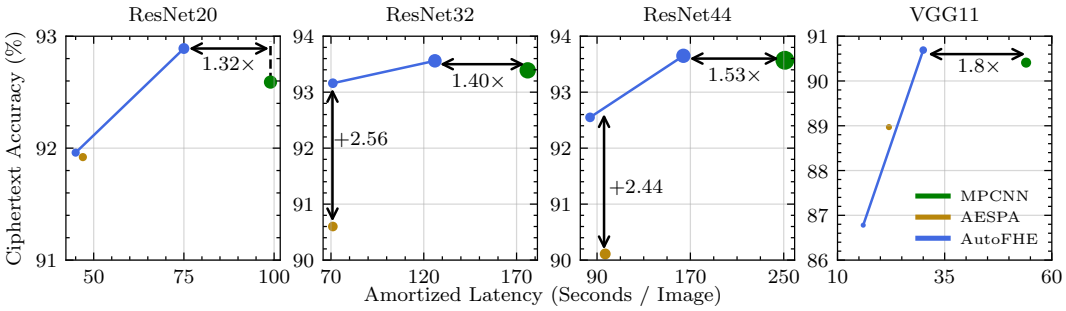

Figure 6: Trade-offs between ciphertext accuracy and amortized latency of ResNet and VGG backbones on CIFAR10.

Table 4: AutoFHE under the RNS-CKKS scheme. Latency for 96 images is evaluated on AWS r5.24large using 96 threads. Amortized latency is the average latency of each image. We report the ciphertext accuracy of 10,000 encrypted validation images. For CIFAR10, we select two solutions with different bootstrapping for each backbone network. Color key: highest ciphertext accuracy; lowest (amortized) latency; smallest number of bootstrapping operations.

Table 5: Latency of operations under the RNS-CKKS scheme. We report the mean and standard deviation of latency of 96 images in Table 4. Linear layers include Conv, BN, Downsample, AvgPool, and FC.

CIFAR10 and 1.7% ∼ 2.4% on CIFAR100 compared to the corresponding plaintext backbone models.

AutoFHE takes advantage of layerwise mixed-degree polynomials to reduce bootstrapping consumption while maintaining high accuracy. From Figure 6 and Table 4, AutoFHE shows a better trade-off between ciphertext accuracy and latency than MPCNN and AESPA. Compared to MPCNN on CIFAR10, **AutoFHE** accelerates encrypted image inference by **1.32×** ∼ **1.8×** while improving accuracy by **+0.08%** ∼ **0.3%** in comparison to MPCNN. Similarly, on CIFAR100, **AutoFHE** speeds up inference by **1.1×** ∼ **1.4×** while increasing accuracy by **+0.36%** ∼ **0.75%**. From Figure 6, compared to AESPA, AutoFHE improves ciphertext accuracy by **+2.56%** and **+2.44%** for ResNet32 and ResNet44

backbones on CIFAR10 with similar amortized latency. However, AESPA's low-degree polynomials lead to an increasing drop in accuracy with model depth. This starkly contrasts with plaintext models, where deeper models are known to improve performance. AutoFHE can improve performance with depth while maintaining the same latency as AESPA. As such, we observe from Figure 5 and Table 4 that AutoFHE enjoys a much better trade-off between accuracy and latency.

In summary, the challenge of navigating the vast joint design space of polynomial approximations of non-linear activation functions and homomorphic evaluation architectures limits manual approaches like MPCNN and AESPA to simplify solutions like approximating non-linear activation functions and uniform placement of bootstrapping operations. In contrast, AutoFHE algorithmically navigates the design space and identifies solutions that significantly *pareto dominate* manual approaches in accuracy, latency, or both.

Approximation *vs* Training *vs* Adaptation

High-precision function approximation can preserve plaintext accuracy without training, while low-precision function approximation with training leads to a loss in accuracy. AutoFHE is a hybrid method that inherits the representation learning ability of ReLU networks and adapts the network's learnable weights to layerwise polynomials.

On the one hand, MPCNN has a drop in accuracy of $0.07 \sim 0.15\%$ and $0.22 \sim 0.69\%$ compared to plaintext backbone models on CIFAR10 and CIFAR100, respectively. This demonstrates that high-degree polynomials still introduce slight approximation errors. On the other hand, AESPA has a significant drop in accuracy, especially for deeper networks, which was also observed by AESPA's authors [46]. The results demonstrate that the representation learning ability of (low-degree) polynomial neural networks is inferior to ReLU networks [37]. Unlike AESPA, AutoFHE inherits the representation learning ability from ReLU networks by using pretrained weights and transferring knowledge. Furthermore, we fine-tune polynomial networks using very small learning rates to adapt learnable network weights to layerwise mixed-degree polynomial EvoReLU. Therefore, AutoFHE can achieve the *high-accuracy* of ReLU networks and the *low-latency* of low-degree polynomial networks. As such, compared to MPCNN and AESPA, AutoFHE improves both prediction accuracy and reduces inference latency over all ResNet and VGG backbones.

Operations under RNS-CKKS: Table 5 shows the latency of different operations under RNS-CKKS. AppReLU is a high-degree polynomial, so its evaluation latency is higher than degree 2 HerPN. The latency of EvoReLU is roughly between AppReLU and HerPN. Low-bootstrapping solutions of AutoFHE further speed up evaluation of polynomial compared to HerPN, *e.g.* ResNet32 with eight bootstrapping, ResNet44 with eight bootstrapping and VGG11 with one bootstrapping. In MPCNN, bootstrapping dominates latency with $74 \sim 77\%$ of total inference time. In AESPA, linear layers and bootstrapping operations consume similar runtime.

The latency of AutoFHE is similar to AESPA for low-bootstrapping solutions and to MPCNN for high-bootstrapping solutions. Linear operations of MPCNN are faster than AESPA and AutoFHE since they are being evaluated at a lower level. For example, MPCNN ConvBN always takes level 2 ciphertext as input. The evaluation of low-level ciphertexts is faster than high-level ciphertexts. For AESPA and AutoFHE, polynomial activations (HerPN and EvoReLU) have smaller multiplicative depth, and their linear operations take ciphertexts at higher levels as input. From Table 5, we observe that i) AutoFHE can effectively accelerate neural network inference on RNS-CKKS by removing time-consuming bootstrapping operations; ii) Layerwise mixed-degree EvoReLU effectively explores how to reduce the multiplicative depth of polynomials and further decrease consumption of bootstrapping operations.

4.2 Layerwise AutoFHE

Depth Distribution: To analyze the layerwise mixed-degree EvoReLU discovered by AutoFHE, we study (see Figure 7) the distributions of multiplicative depth for different backbones on CIFAR10. In contrast to the uniform allocation used by MPCNN and AESPA, the optimal layerwise allocation of EvoReLU discovered by AutoFHE is highly non-uniform. Such a distribution is challenging to design manually, thus further motivating the need for automated design of layerwise mixed-degree polynomial approximations of activation functions. From the distribution in Figure 7, we identify the following design principles that can guide the design of polynomial neural networks under RNS-CKKS.

Observation 1

Low and high bootstrapping solutions share a similar distribution of multiplicative depth.

In Figure 7, we provide two solutions with low and high bootstrapping operations for each backbone. These two solutions share similar depth distributions. Specifically, high-degree polynomials are preferred in the same layers of low and high bootstrapping solutions.

Observation 2

Depth distribution is linearly scalable.

Consider the depth distributions of VGG11(4) and ResNet20(5), ResNet20(11) and ResNet32(19) in Figure 7.

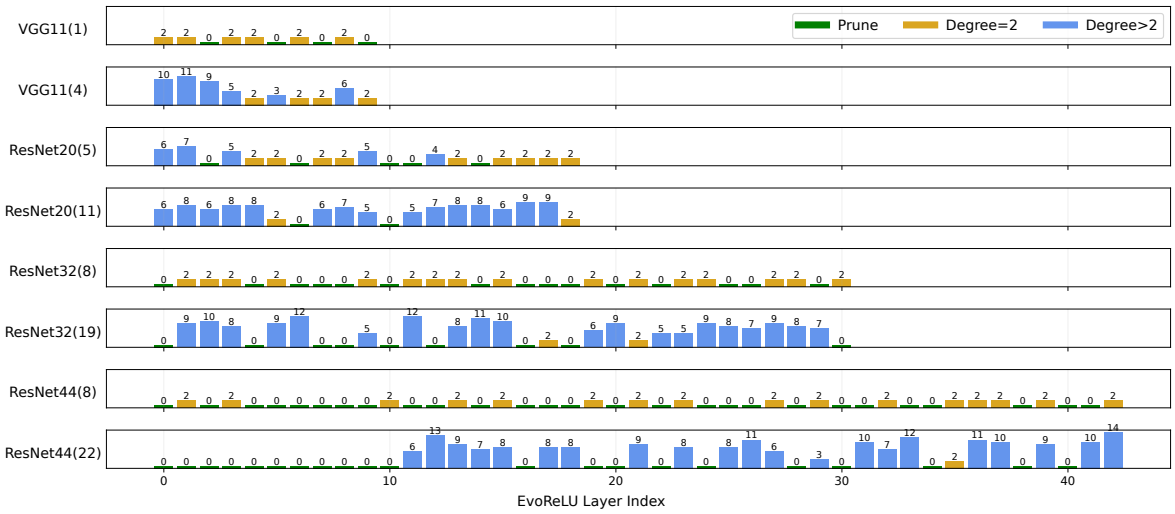

Figure 7: Multiplicative depth of layerwise mixed-degree EvoReLU layers.

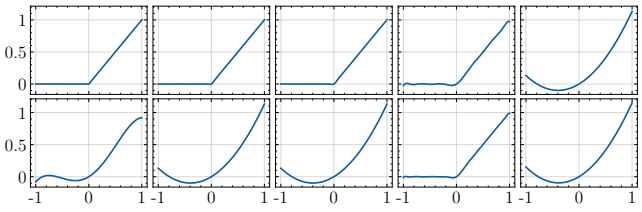

Figure 8: EvoReLU functions of AutoFHE for VGG11 with 4 bootstrapping operations. The top row shows EvoReLU for layer $0 \sim 4$, and the bottom row shows layer $5 \sim 9$.

They have different numbers of layers. If we scale their distributions horizontally to match the number of layers, their depth distributions are very similar. This demonstrates that the number of layers and position of activations are the most important factors affecting the sensitivity of layerwise approximation. Therefore, the depth distributions are linearly scalable to the neural network's depth.

Observation 3

Consecutive linear layers can be integrated into a single operation to reduce multiplicative depth.

Many networks have consecutive linear (depth 0) layers, especially ResNet44(22). In this case, it is possible to integrate successive linear layers into a single linear layer, which decreases the multiplicative depth and removes bootstrapping operations. Table 5 demonstrates that reducing linear operations is an effective way to further accelerate inference.

Layerwise EvoReLU: Figure 8 shows layerwise mixed-degree EvoReLU functions for VGG11 with 4 bootstrapping operations. High-degree EvoReLU functions can precisely approximate ReLU, *e.g.* layer 0, 1 and 2. Medium-degree EvoReLU functions (layer 3, 5, 8) observe oscillation but still are very close to ReLU. Degree 2 EvoReLU is a quadratic function and introduces more approximation errors compared to high-degree and medium-degree functions. For high-degree and medium-degree polynomials, input will be scaled to $[-1,1]$ so we can prevent exploding activations. Figure 8 qualitatively shows that high-degree and medium-degree EvoReLU functions can precisely approximate ReLU, and we can use gradients of ReLU in PAT to prevent exploding gradients during backpropagation. Since degree 2 EvoReLU has a relatively big approximation error, we use SGD rather than approximate gradients from ReLU (refer to Equation 13).

5 Related Work

In this paper, we focus on secure inference under FHE. Secure multiparty computation (MPC) is an alternative approach for secure inference [19, 29, 30, 40, 42, 45, 47]. It is usually employed in a hybrid protocol involving both MPC and HE. MPC primitives include secret sharing, Yao's garbled circuits [2, 59], and Beaver's multiplicative triples [1], *etc.* For example: (1) Gazelle [29] adopts packed additively homomorphic encryption (PAHE) to evaluate linear layers (Conv and FC layers) and garbled circuits to evaluate non-linear layers (ReLU and MaxPooling layers). (2) Delphi [45] uses Garbled circuits to evaluate ReLU, and Beaver's multiplicative triples to evaluate the polynomial approximation x^2 of ReLU. (3) Iron [23] employs the Brakerski-Fan-Vercauteren (BFV) scheme [5, 16] for matrix multiplication. Non-linear operations, like SoftMax, GELU, and LayerNorm, are evaluated through secret sharing.

Secure MPC-based approaches for secure inference must carefully consider the trade-off between computation and communication [29] since both the customer and the Cloud

perform computations. In some practical scenarios, sufficient communication and computing resources on the client side may not be available. Pure FHE-based approaches provide customers a *fire-and-forget* [18] service, where they are not involved in the computations and simply wait for the encrypted result. However, FHE-based approaches may have higher latency and memory footprint than secure MPC approaches.

In terms of polynomial neural networks, FHE approaches have to replace *all* ReLU activations with polynomials since FHE only supports multiplications and additions. Secure MPC approaches usually replace only a fraction of ReLUs to reduce online communication and computation costs and retain a few ReLU layers to preserve accuracy, *e.g.* Delphi [45] and SAFENet [42]. These approaches, however, only use low-degree polynomials and observe a significant drop in accuracy when most ReLU activations are replaced. AutoFHE can also be employed for secure MPC schemes by changing the search objective from the number of bootstrapping operations to online communication or computation costs of secure MPC.

6 Conclusion

Non-interactive end-to-end inference of homomorphically encrypted ciphertext images over convolutional networks is an attractive solution for mitigating the security and privacy concerns of cloud-based MLaaS offerings. Adapting CNNs for inference over FHE ciphertexts presents several challenges, including the optimal design of polynomial approximations of non-linear activation functions and associated homomorphic evaluation architecture. Existing solutions primarily rely on manual designs, which are neither scalable nor flexible enough to be applied to any architecture and cater to the needs of different MLaaS customers.

To overcome these challenges, this paper introduced AutoFHE, an automated approach for adapting any convolutional neural network for secure inference under RNS-CKKS. It is a multi-objective search algorithm that generates a set of polynomial networks and their associated homomorphic evaluation architecture under FHE by trading off accuracy and latency. It exploits layerwise mixed-degree polynomial activations across different layers in a network and jointly searches for placement of bootstrapping operations for evaluation under RNS-CKKS. We designed a custom search space for layerwise mixed-degree polynomials and adopted multiple objectives for optimization. We also proposed a combination of search and training algorithms, including multi-objective search algorithm *MOS*, composite polynomial coefficient optimization method *R-CCDE*, and polynomial aware network training strategy *PAT*. We extensively evaluate AutoFHE on ResNets and VGGNets over encrypted CIFAR datasets. Compared to high-degree MPCNN, AutoFHE accelerates inference by $1.32\times \sim 1.8\times$. Compared to low-degree AESPA, AutoFHE improves accuracy by up to 2.56%. Finally, models under RNS-CKKS (AutoFHE) accelerate inference by $103\times$ and improve accuracy by 3.46% compared to models under TFHE (REDsec).

Our results demonstrate the effectiveness of automated search-based algorithms in navigating the large search space of adapting convolution neural networks for inference over FHE ciphertexts and discovering networks that Pareto-dominate manually designed ones. In summary, an integrated and automated design of polynomial approximations and homomorphic evaluation architecture is an effective and flexible approach for seamlessly adapting CNNs for inference on FHE ciphertexts.

A MPCNN under RNS-CKKS

MPCNN [33] is the state-of-the-art framework for homomorphically evaluating deep CNNs on encrypted data under RNS-CKKS with high accuracy. Its salient features are as follows.

(1) COMPACT PACKING: All channels of a tensor are packed into a single ciphertext via multiplexed packing. Furthermore, multiplexed parallel (MP) convolution was proposed to process the ciphertext efficiently. Multiplexed packing can effectively avoid wasting slots due to strided convolutions.

(2) HOMOMORPHIC EVALUATION ARCHITECTURE: To refresh zero-level ciphertexts, bootstrapping operations are placed after every ConvBN (as shown in Figure 2), except for the first one. This hand-crafted homomorphic evaluation architecture for ResNets is determined by the choice of cryptographic parameters, the level consumption of operations, and ResNet's architectures.

(3) APPRELU: It replaces all ReLUs with the same high-degree Minimax composite polynomial [32, 36] of degrees $\{15,15,27\}$. By noting that $\mathrm{ReLU}(x) = x\cdot(0.5+0.5\cdot\mathrm{sgn}(x))$, where $\mathrm{sgn}(x)$ is the sign function, the approximated ReLU (AppReLU) is modeled as $\mathrm{AppReLU}(x) = x\cdot(0.5+0.5\cdot p_\alpha(x)), x\in[-1,1]$. $p_\alpha(x)$ is the composite Minimax polynomial. The precision α is defined as $|p_\alpha(x)-\mathrm{sgn}(x)|\le 2^{-\alpha}$. AppReLU is expanded to arbitrary domains $x\in[-B,B]$ of pre-activations in CNNs by scaling it as $B\cdot\mathrm{AppReLU}(x/B)$. B can be estimated on the training dataset.

(4) CRYPTOGRAPHIC PARAMETERS: MPCNN sets $N = 2^{16}$, $L = 30$ and Hamming weight $h = 192$. Base modulus, special modulus, and bootstrapping modulus are set to 51 bits, while default modulus is set to 46 bits. These cryptographic parameters satisfy 128 bits of security [9].

(5) MULTIPLICATIVE DEPTH: The multiplicative depth of Bootstrapping (i.e., K), AppReLU, ConvBN, DownSampling, AvgPool, FC layers are 14, 14, 2, 1, 1, 1 respectively. Statistically, when using MPCNN to homomorphically evaluate ResNet-18/32/44 on CIFAR10 or CIFAR100, AppReLUs consume $\sim 50\%$ of total levels, and bootstrapping operations consume $> 70\%$ of latency.

B AESPA under RNS-CKKS

AESPA [46] proposes HerPN to replace ReLU and Batchnorm. HerPN is the approximation of ReLU using Hermite polynomials followed by basis-wise normalization. The Hermite approximation is $f(x) = \sum_{i=0}^{\infty}\hat{f}_i h_i(x)$ where normalized probabilist's Hermite polynomial $h_i(x) = H_n(x)/\sqrt{n!}$ and coefficient $\hat{f}_i = \int_{-\infty}^{\infty} f(x)\overline{h_i(x)}e^{-x^2/2}$. Given tensor $\boldsymbol{x}\in\mathbb{R}^{N\times C\times H\times W}$, HerPN is defined as:

$$f(\boldsymbol{x}) = \boldsymbol{\gamma}\sum_{i=0}^{d}\hat{f}_i\frac{h_i(\boldsymbol{x})-\boldsymbol{\mu}_i}{\sqrt{\boldsymbol{\sigma}_i^2+\varepsilon}}+\boldsymbol{\beta} \tag{14}$$

where mean $\boldsymbol{\mu}_i\in\mathbb{R}^C$ and standard variance $\boldsymbol{\sigma}_i\in\mathbb{R}^C$ are computed over output of each Hermite polynomial, $h_i(\boldsymbol{x})$. $\boldsymbol{\gamma}\in\mathbb{R}^{\mathbb{C}}$ and $\boldsymbol{\beta}\in\mathbb{R}^C$ are learnable parameters. AESPA uses the first three Hermite bases, *i.e.*, $d = 2$. Hermite bases and coefficients are:

$$h_0(x) = 1 \qquad h_1(x) = x \qquad h_2(x) = \frac{x^2-1}{\sqrt{2}} \tag{15}$$

$$\hat{f}_0 = \frac{1}{\sqrt{2\pi}} \qquad \hat{f}_1 = \frac{1}{2} \qquad \hat{f}_3 = \frac{1}{\sqrt{4\pi}} \tag{16}$$

HerPN can be cast as a second-degree polynomial to reduce multiplicative depth, namely:

$$f(\boldsymbol{x}) = \frac{\boldsymbol{\gamma}}{\sqrt{8\pi(\boldsymbol{\sigma}_2^2+\varepsilon)}}\boldsymbol{x}^2+\frac{\boldsymbol{\gamma}}{2\sqrt{\boldsymbol{\sigma}_1^2+\varepsilon}}\boldsymbol{x}+\boldsymbol{\beta}+ \boldsymbol{\gamma}\left[\frac{1-\boldsymbol{\mu}_0}{\sqrt{2\pi(\boldsymbol{\sigma}_0^2+\varepsilon)}}-\frac{\boldsymbol{\mu}_1}{2\sqrt{\boldsymbol{\sigma}_1^2+\varepsilon}}-\frac{1+\sqrt{2}\boldsymbol{\mu}_2}{\sqrt{8\pi(\boldsymbol{\sigma}_2^2+\varepsilon)}}\right] \tag{17}$$

From Equation 17, the depth of HerPN is 2. Hence, 4 Conv-HerPN layers should be followed by one bootstrapping operation. AESPA was originally proposed for secure MPC [46]. Our paper adopts AESPA as a low-degree baseline under RNS-CKKS. We design the homomorphic evaluation architecture of AESPA under RNS-CKKS as shown in Figure 2. We build its C++ implementation on top of MPCNN by using its implementations of Conv, BN, Downsample, AvgPool, and FC layers.

Fast and Private Inference of Deep Neural Networks by Co-designing Activation Functions

Abstract

Machine Learning as a Service (MLaaS) is an increasingly popular design where a company with abundant computing resources trains a deep neural network and offers query access for tasks like image classification. The challenge with this design is that MLaaS requires the client to reveal their potentially sensitive queries to the company hosting the model. Multi-party computation (MPC) protects the client's data by allowing encrypted inferences. However, current approaches suffer from prohibitively large inference times. The inference time bottleneck in MPC is the evaluation of non-linear layers such as ReLU activation functions. Motivated by the success of previous work co-designing machine learning and MPC, we develop an activation function co-design. We replace all ReLUs with a polynomial approximation and evaluate them with single-round MPC protocols, which give state-of-the-art inference times in wide-area networks. Furthermore, to address the accuracy issues previously encountered with polynomial activations, we propose a novel training algorithm that gives accuracy competitive with plaintext models. Our evaluation shows between 3 and 110× speedups in inference time on large models with up to 23 million parameters while maintaining competitive inference accuracy.

1 Introduction

The rapid development of increasingly capable machine learning (ML) models has resulted in significant demand for products like machine learning as a service (MLaaS). In this scenario, big tech companies with vast computing resources train large machine learning models and provide users with query access. The major pitfall with MLaaS is that it requires clients to submit potentially sensitive queries to an untrusted entity. A promising solution to this problem is to employ cryptography to ensure the queries and inferences are hidden from the model owner. Secure inference is an active field of research with many solutions and different threat models as summarized in a recent SoK [32]. The challenge is that despite recent advances, the inference times are still prohibitively large compared to plaintext inferences.

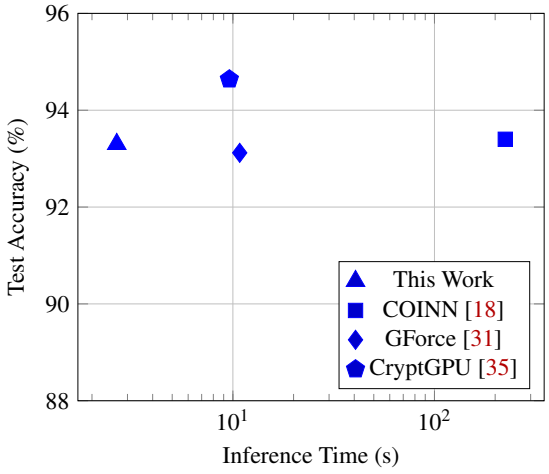

Figure 1: Summary of the inference time in seconds vs. test accuracy for each state-of-the-art approach on the CIFAR-10 dataset in the WAN (100 ms roundtrip delay).

This work focuses on reducing the runtime of secure inference on image data, under realistic network conditions, while maintaining classification accuracy. We consider the two-party setting using multi-party computation (MPC), where the server holds the modified ML model, and the client holds the data to query the model. Recent state-of-the-art works in this space employ various co-design approaches to reduce the inference time [32]. For example, COINN co-designs ML models optimized for quantization with efficient MPC protocols tailored to the custom models [18]. COINN substantially compresses the model and makes numerous optimizations to the architecture to achieve fast inferences. Another example is GForce, which tailors the cryptography needed for ML to high-speed GPU hardware [31]. By offloading vast

*Equal contribution

amounts of work to the pre-computation phase, they are able to achieve state-of-the-art runtime and accuracy in secure inference [31]. Similarly, CryptGPU [35] modifies the CrypTen framework [22] to run efficiently on the GPU and give state-of-the-art inference times in wide area networks. However, despite making major steps towards practical inference, none of these works remove a crucial bottleneck in secure inference: the non-linear layers.

It is well known that the non-linear layers are the bottleneck of secure inference [12, 13, 18, 29]. This is because secure computation on arithmetic shares is optimized for multiplications and additions, instead of non-linear layers such as ReLU activation functions or MaxPool layers. In order to compute these non-linear functions, expensive conversions between different types of MPC protocols are required. Specifically, in more realistic network settings with high latency, the inference time is substantially degraded due to each conversion taking many rounds of communication. This problem is particularly prevalent in deep neural networks (DNNs), where a non-linear activation separates each of the many linear layers.

This work addresses the non-linear layers by taking a co-design approach between the activation functions and MPC. We take the approach of replacing classic ReLU activation functions with a polynomial approximation during training and inference to avoid conversions altogether. Previous work has considered this approach but with limited success [12]. We propose two modifications to make this approach practical. First, we develop and evaluate new single-round MPC protocols that give the fastest evaluation of polynomials to date. The challenge with using polynomials is they severely impact model accuracy [12, 18, 29]. Previous work could not successfully train DNNs with more than 11 layers due to exploding gradients [12]. Thus, our second contribution is tailoring the ML training process to ensure high accuracy and stable training using polynomials. Our approach utilizes a new type of regularization that focuses on keeping the input to each activation function within a small range. We achieve close to plaintext accuracy on models as deep as ResNet-110 [16] and as large as a ResNet-50 on ImageNet [10] (23 million parameters). The combination of these approaches yields a co-design with state-of-the-art inference times and the highest accuracy for polynomial models.

We compare our work with three solutions representing the state-of-the-art approaches in secure inference according to Ng and Chow [32]. We summarize our results in Figure 1. Combining the single-round MPC protocols with our activation regularization achieves significantly faster inference times than all other solutions. Specifically, our solution is faster than CryptGPU by 4×, GForce by 5×, and COINN by 40× on average in wide area networks. Our approach also scales to large models on ImageNet with a 110× speedup over COINN, 14× speedup over Cheetah, and a 3× speedup over CryptGPU. Furthermore, our inference accuracy remains competitive with all other solutions. CryptGPU often gives slightly higher accuracy as it can evaluate any plaintext model (albeit slower than our work). Thus, the challenge for future work is to further close the ML accuracy gap between plain and polynomial models.

2 Background

2.1 Multi Party Computation

Secure multi-party computation (MPC) allows a set of parties to jointly compute a function while keeping their inputs to the function private. We focus on a variant of MPC which performs operations over shares of the data [5]. We use $[[s]] = [[s]_A, [s]_B]$ to denote that the value of s is shared among participants, where $[s]_A$ is the share held by party A and $[s]_B$ by party B. Arithmetic MPC protocols utilize a linear secret sharing scheme, such as an additive secret sharing scheme to compute complex circuits using combinations of additions and multiplications. Given constants v_1, v_2, v_3 and shares of values $[[x]], [[y]]$, one can locally compute

$$v_1[[x]] + v_2[[y]] + v_3 = [[v_1 \cdot x + v_2 \cdot y + v_3]] \quad (1)$$

to obtain shares of the value $v_1 \cdot x + v_2 \cdot y + v_3$. For multiplication, one can use Beaver's trick to multiply using a single round of communication between parties [4]. Specifically, we assume a triplet of random numbers a, b, c (called a Beaver triplet) was generated such that $a \cdot b = c$ and secret shared among all parties ahead of time (typically in an offline pre-computation phase). Then the parties compute $[[x \cdot y]]$ by first locally computing $[[a + x]] = A$ and $[[b + y]] = B$ and reconstructing A and B so that both parties have them in plaintext. This reconstruction is the single round required. Using these values, the parties compute the result locally as $[[x \cdot y]] = A[[y]] + (-B)[[a]] + [[c]]$, using the linearity property in equation 1.

Arithmetic MPC protocols are limited to basic multiplications and additions. Thus, for computing non-linear operations such as comparisons, other techniques such as converting to binary secret shares or using Yao's garbled circuits are common [9]. A binary secret sharing scheme is an arithmetic scheme carried out bitwise in the ring $\mathbb{Z}_2$. Specifically, the difference is that we first decompose x into its bits and have a separate arithmetic share of each bit. By maintaining this bitwise structure, operations such as XOR or bit shifts are trivial. We describe how to use a binary and arithmetic secret-sharing scheme together to compute non-linear functions in Section 3.3.

2.2 Neural Network Inference

We consider DNN classifiers with domain $\mathcal{X} \subseteq \mathbb{R}^d$ and range $\mathcal{Y} \subseteq \mathbb{R}^c$. DNN classifiers consist of a sequence of layers, each performing either a linear or a non-linear operation. The

ResNet [16] architecture we consider is composed of (i) convolutional, (ii) fully connected, (iii) pooling, (iv) batch normalization, and (v) ReLU layers. All layers are linear, except for $\text{ReLU}(x) = \max(x, 0)$ and max pooling (that can be replaced with average pooling). To classify an input x, a classifier h, passes the input sequentially through each layer. Upon reaching the last layer, the prediction is obtained by taking $\arg\max_{i \in \{1..c\}} h(x)_i$, where we call h the logit function for a classifier $h : \mathcal{X} \rightarrow \mathcal{Y}$. Our work is tailored to securely perform the inference phase. Specifically, for an encrypted input x we compute the encrypted output $h(x)$ of the logit function. However, to achieve improvements during inference, our work requires modification to the training phase that generates h.

3 Problem Setup and Motivation

3.1 Problem Setup

We follow the same threat model as prior work for two-party secure inference [18, 22, 29, 31]. Specifically, we follow the two-party client-server model where the server has a machine learning model (a DNN) they have trained (with our technique), and the client holds private data upon which they would like to make an inference. Like Delphi [29], our work assumes the server uses a modified training procedure. The server's input to the protocol is the weights of their trained model, which they do not want to leak to the client (due to intellectual property or protecting their MLaaS business [36]). The client has a private input (typically an image) they would like to classify using the model but do not want to leak this input or the prediction to the server. That is, the MPC function can be written as $f(\text{image}, \text{model}) = (label, \emptyset)$. Following previous work [18, 22, 29, 31], we consider the semi-honest model [15, §7.2.2], where adversaries do not deviate from the protocol but may gather information to infer private information. Also, in line with previous work, we assume the model architecture is known to both parties. This includes the dimensions and type of each layer, parameters such as field size used for inference, and the mean and standard deviation of the training set [22].

Our goal is to reduce the inference time as much as possible. We are willing to incur a small degradation in accuracy to achieve practical runtimes. For example, in the streaming setting, applications like spam detection are runtime-critical (a small accuracy trade-off can be tolerated to make it feasible). Since all the protocols we compare with contain pre-computation, we focus on the online phase for fair comparison. Furthermore, the online time determines the latency, which we focus on reducing in this work. We build from CrypTen [22], which does not implement pre-computation and rather assumes a third-party dealer for Beaver triplets. However, in practice, the server and client could generate the Beaver triplets in a pre-computation phase using off-the-shelf protocols [21, 33].

3.2 Privacy During Model Training

We focus only on the inference phase of machine learning. However, the privacy of the training process and training data is an orthogonal but essential problem. We recommend that the data owner take appropriate steps to protect the privacy of the model, such as training using differential privacy [2] or rounding the output of the inference. Furthermore, during training, care should be taken to protect against threats such as model stealing, which can be launched using only the inference result [19]. To summarize, the model owner learns nothing other than the fact a query was made. We ensure only the inference is revealed to the client; however, ML attacks that only require black box query access [19] must be defended against during the training process. Since we focus the effects of MPC on the runtime and accuracy of ML inference, we did not conflate this comparison with additional privacy preserving training goals. Any privacy-preserving technique would add a similar overhead (e.g., reducing the accuracy) to all approaches we evaluate.

3.3 Motivating the Co-Design of Activation Functions

It has been well established in the literature that activation functions such as ReLU are the bottleneck in MPC-based secure inference, taking up to 93% of the inference time [12, 13, 18, 29]. The reason for this is that current approaches use different types of MPC protocols for a model's linear and non-linear layers [18, 20, 22, 29, 31]. The linear layers are typically computed using standard arithmetic secret-sharing protocols tailored for additions and multiplications. The non-linear layers are computed using garbled circuits or binary secret share-based protocols. The bottleneck in wide area networks is typically the conversions between these protocols as they require a large number of communication rounds. A typical DNN architecture has many linear layers, each followed by a non-linear layer resulting in a prohibitively large number of conversions.

Consider CrypTen, a PyTorch-based secure ML library, as a baseline approach [22]. CrypTen uses binary shares to evaluate boolean non-linear layers such as ReLUs and MaxPooling layers. Specifically, all linear layers are computed using standard multiplication and addition protocols over arithmetic shares. To compute $[[ReLU(x)]]$ at each layer, $[[x]]$ is first converted to binary shares using a carry look-ahead adder. Once in binary shares, CrypTen extracts the sign bit to compute $[[x > 0]]$ (a local operation). The sign bit, $[[x > 0]]$, is then converted back to arithmetic shares (trivial for a single bit) and multiplied with $[[x]]$ to get $[[ReLU(x)]]$. The problem with this approach is that each conversion takes $O(log(L))$ communication rounds. Taking into account the additional round needed for multiplication, we observe nine communication rounds per ReLU in practice (under 64-bit precision). Re-

cently, more sophisticated MPC protocols have been proposed that reduce the number of rounds needed for comparisons in arithmetic shares [6, 7] or reduce the cost of binary share conversions [11]. However, even if one were to implement these protocols in CrypTen, the number of rounds needed for non-linear layers would still outweigh the number needed for linear layers.

Motivated by this bottleneck, several works have focused on either reducing the number of ReLUs or replacing ReLUs altogether [12, 13, 20, 24, 29, 30]. One approach is to approximate each ReLU with a high degree polynomial [12, 24]. The advantage of using polynomials is that polynomials can be computed using arithmetic shares, thus removing the need for expensive conversions and improving the total inference time. A significant challenge with polynomials is maintaining model accuracy [12, 13, 18, 20, 29].

Thus, this work aims to provide a secure inference protocol with state-of-the-art inference time and accuracy in realistic networks with high latency. To do this, we take a co-design approach to balance accuracy and fast inference time. In Section 4, we develop MPC protocols that achieve the fastest evaluation of polynomials to date, assuming a modified ML architecture. In Section 5, we tailor the ML training procedure to achieve high accuracy using this modified architecture.

4 Faster Evaluation of Polynomials

In this section, we evaluate the speed-up of replacing ReLU's with a naive polynomial approximation. We then develop our single-round protocols and show that they drastically reduce the activation function evaluation time in wide area networks.

4.1 The Polynomial Advantage

To highlight the speed-up of polynomials over standard ReLUs, we first evaluate the runtime of a single layer with 2^{15} ReLU activation functions in Figure 2. (See Section 6 for more implementation details.) First, we plot an unmodified version of CrypTen (using CryptGPU [35]) with the conversion to binary shares. Next, we replace the ReLU with a degree four polynomial fitted using least squares polynomial regression (see Section 5 for the details). We can see that using polynomials in off-the-shelf CrypTen is much faster across all network speeds than the default mixed arithmetic and binary protocol. This difference becomes more pronounced as we add more network delay or scale to deeper models with more ReLUs.

Despite the significant speed-up, naively computing a polynomial is still expensive in MPC with a non-trivial number of communication rounds. For example, Horner's method (an iterative approach to evaluating polynomials) uses $O(n)$ communication rounds (where n is the degree of the polynomial). However, most MPC libraries (including CrypTen) use the square-and-multiply algorithm for exponentiation, followed

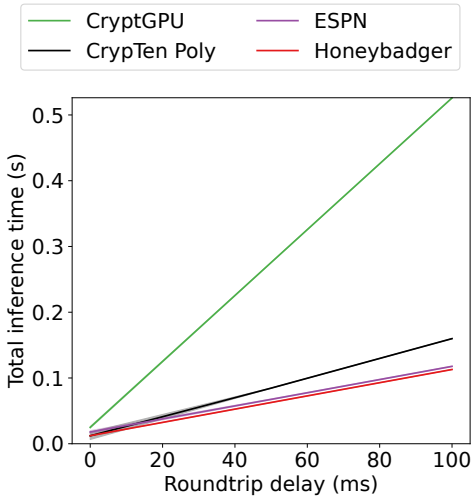

Figure 2: Benchmarking the secure evaluation of ReLU activation functions using various approaches. The x-axis is the network delay in ms and the y-axis is the mean runtime in seconds averaged over 20 runs with the shaded area representing the 95% confidence intervals.

by multiplying and summing the coefficients locally. The square-and-multiply algorithm requires $O(log(n))$ multiplications (and thus rounds) in MPC. In practice, the default square and multiply implementation in CrypTen uses two rounds per ReLU for a degree four polynomial. To increase the advantage of using polynomial activation functions even further, we develop a new single-round protocol for evaluating polynomials in MPC.

4.2 ESPN: Exponentiating Secret Shared Values using Pascal's triangle

We present our single-round, highly parallelizable protocol ESPN for computing high-degree polynomials. The fundamental idea is utilizing the binomial theorem (Pascal's triangle) to achieve faster exponentiation. We begin by describing our protocol for raising a number $[[x]]$ to the power k, in MPC (see Algorithm 1 for an overview). Using the additive secret sharing scheme, the exponentiation corresponds to $(x_A + x_B)^k$ where x_A represents the first party's share and x_B represents the second (such that $x_A + x_B = x$). The binomial theorem expands this expression as:

$$x^k = (x_A + x_B)^k = \sum_{i=0}^{k} \binom{k}{i} x_A^{k-i} x_B^i \tag{2}$$

We observe that, for each i in the sum, party A can compute $\mathbf{a}_i = x_A^{k-i}$ without needing to communicate with party B (Alg. 1 line 4). Similarly, party B can compute x_B^i without communicating with party A (Alg. 1 line 5). Finally, $\binom{k}{i}$ can be computed by any party (or pre-computed ahead of time).

For simplicity, we assign the computation of $\binom{k}{i}$ to party B. Thus party B computes $\mathbf{b}_i = \binom{k}{i} x_B^i$.

Once each party has computed their respective vectors, we multiply $\mathbf{a}_i \cdot \mathbf{b}_i$ for each i in parallel (Alg. 1 line 6). We carry out this multiplication using standard MPC protocols in one round. To use these multiplication protocols, each party must have a share of the input. We use a trivial additive secret sharing, where the other party inputs zero as their share to the protocol (Alg. 1 line 2). Finally, after the multiplication, the sum of the binomial theorem can be efficiently computed with no communication (Alg. 1 line 7).

Algorithm 1 Exponentiation Protocol for 2-party additive secret-sharing

1: **procedure** $Exp([[x]], k)$
2: $\quad \mathbf{a} = [[\mathbf{0}^k]]$, $\mathbf{b} = [[\mathbf{0}^k]]$ ▷ Initialize shares
3: $\quad$ **for** $i = 0 : k$ **do**
4: $\quad\quad$ Party A computes: $\mathbf{a}_i = \mathbf{a}_i + x_A^{k-i}$
5: $\quad\quad$ Party B computes: $\mathbf{b}_i = \mathbf{b}_i + \binom{k}{i} x_B^i$
6: $\quad \mathbf{p} = BeaverMultiply(\mathbf{a}, \mathbf{b})$ ▷ Parallel Multiplication
7: $\quad s = \sum_{i=0}^{k} \mathbf{p_i}$ ▷ $s = \mathbf{a} \cdot \mathbf{b}$
8: $\quad$ **return** s ▷ secret-shares of x^k

4.3 Polynomial Evaluation with ESPN

Floating Point Considerations. Our initial description of ESPNconsiders the integer domain for simplicity. Extending to floating point values is straightforward but requires rescaling (a standard practice in fixed-point arithmetic). We use CrypTen's two-party, local truncation protocol to ensure we do not incur additional rounds. However, there is a negligible chance of an incorrect result from this truncation protocol due to wrap-around in the ring. Specifically, the probability of an incorrect result when truncating x is $\frac{|x|}{2^L}$ where 2^L is the size of the ring [22, Appendix C.1.1]. This implies that x must be small compared to the ring for this fast truncation protocol to be correct.

Polynomial Evaluation Protocol. Using our exponentiation protocol, we show how to compute high-degree polynomials efficiently in a single round. We overview the protocol in Algorithm 2. First, in parallel, we compute all needed exponents using Algorithm 1. We recall that to ensure the correctness of truncation, we must ensure all intermediate values remain small. For simplicity, we define small to be that no intermediate scale becomes larger than twice the working precision p. We show the complete failure probability calculations of Algorithm 2 in Appendix E.

To ensure the values remain small after exponentiation, we create multiple scaled-down copies of the input x, proportional to each exponent we need to calculate. To compute x^i we first scale x down by $2^{-\bar{s}}$ where $\bar{s} = \lceil (i-2)p/i \rceil$) and p is the current working precision of x (line 5). $\bar{s}$ is chosen such that 2^p becomes approximately $2^{2p/i}$ after scaling and thus approximately 2^{2p} after exponentiation by i. These are approximations as not all values of i divide $(i-2)p$, so there is some error from taking the ceiling. To account for the additional factor of approximately two, we do an additional rescaling after each exponentiation in line 7. This rescaling incorporates $\bar{s}$ (which includes the ceiling function) to ensure all values are scaled back to 2^p. Finally, after computing all powers, we can locally multiply the result by the coefficients (public values) and sum in line 8. We give a complete proof of correctness for Algorithm 1 and 2, including the truncation operator in Appendix E.

Algorithm 2 Polynomial Evaluation Protocol for 2-party additive secret-sharing

1: **procedure** $Poly([[x]], \alpha, n)$
2: $\quad \mathbf{p}_1 = x$
3: $\quad$ **for** $i = 2 : n$ **do** ▷ In parallel
4: $\quad\quad$ Let $\bar{s} = \lceil (i-2)p/i \rceil$ ▷ Scale down factor
5: $\quad\quad x_i' = x \cdot 2^{-\bar{s}}$ ▷ Scale down before Exp
6: $\quad\quad \mathbf{p}_i = Exp(x_i', i)$ ▷ From Algorithm 1
7: $\quad\quad \mathbf{p}_i' = \mathbf{p}_i * 2^{-p*(i-1)+\bar{s}\cdot i}$ ▷ Scale down after Exp
8: $\quad y = \alpha_0 + \sum_{i=1}^{n} \alpha_i \cdot p_i'$ ▷ Locally dot product
9: $\quad$ **return** y ▷ Secret-shares of $f(x)$

Hyperparameter Restrictions. While Algorithm 2 is designed to keep intermediate values small, multiple hyperparameters determine the protocol's effectiveness. Using results from Appendix E (namely the max of Theorem E.2 and Theorem E.3), we get that the probability of failure for a given truncation is bounded by

$$Pr[\text{Truncation Failure}] \leq \frac{2^{n(\lceil \log_2 \lambda \rceil + 1) + 2p}}{2^L}. \quad (3)$$

For our experiments, we use CrypTen, with $L = 64$ [22] and a default working precision of $p = 16$. Assuming default values of $n = 4$ and $\lambda = 5$ we get a failure probability bound of 2^{-16}. However, this is a pessimistic upper bound since we consider the worst-case input of ± 5. Conversely, in our experiments, we find that the distribution of inputs follows an approximately Laplace distribution as shown in Appendix C. Thus, we observe a much smaller empirical failure probability.

While our default parameters were experimentally chosen to give high classification accuracy (Section 6, shows a minor degradation over plaintext accuracy), it is unclear if these values are optimal. For example, one approach to reducing the failure probability is to decrease p from 16 to 10-bit (which gives a failure probability of 2^{-28}). However, the trade-off is that the intermediate x_i' values will be truncated severely. For instance, with $n = 4$, x_i' will be truncated to 5-bits. We find that this loss of precision is too significant to simulate a

ReLU function accurately. Similarly, while a higher degree polynomial might better approximate a ReLU, a higher degree will negatively affect both the failure probability and the precision loss of x'_i. Future work could conduct an extensive hyperparameter search of all parameters to find the optimal trade-off. However, as we see in Section 6 (Tables 2-5), this would *at most* yield a 0.5% increase in encrypted classification accuracy (PyTorch vs. CrypTen accuracy), for the worst model and dataset.

Evaluating Algorithm 2. In Figure 2, we plot this approach alongside the previous approaches to evaluate the runtime. ESPN incurs slightly more overhead in the LAN setting; however, it scales significantly better (the confidence intervals do not overlap) to wide area networks that can be expected in practice.

4.4 Alternative Single Round Protocol: HoneyBadger

Like ESPN, Lu et al. give a single round protocol for exponentiation in MPC [28]. Despite focusing on a completely different problem (anonymous communication), they provide an MPC protocol of independent interest for exponentiation, which we also utilize in our work. They take a very different approach to our work that yields different trade-offs. Instead of the binomial theorem, their work utilizes the following factoring rule

$$x^k - r^k = (x-r)\sum_{i=0}^{k-1} x^{k-i-1} r^i \tag{4}$$

where r is a random secret-shared number derived during pre-computation. We assume each party has a share of x and a share of r^i for $i \in \{1,\ldots,k\}$ before beginning the protocol (instead of the more common Beaver triplets). The first step in the protocol is to compute and reveal $x-r$ (x blinded by r), which uses a single round. Once revealed, this value becomes a public constant C. After some algebraic manipulation of (4), Lu et al. obtain a recursive formula for $x^i r^j$ given below.

$$[[x^k r^j]] = [[r^{k+j}]] + C\sum_{i=0}^{k-1} [[x^{k-i-1} r^{i+j}]] \tag{5}$$

Using dynamic programming, the parties can then compute any power ($x^k r^0$) using only additions of previously computed terms and powers of r. To compute polynomials using this protocol, we simply swap the call to *Exp* in line 6 of Algorithm 2.

The advantage of Lu et al.'s protocol is that the communication is small (only the opening of $x-r$). The primary disadvantage is that the protocol requires a modified pre-computation phase, which is as difficult to pre-compute securely as the original problem (it is exponentiation). On the contrary, our binomial protocol uses standard Beaver triplets commonly found in MPC frameworks. There are well established protocols for efficiently computing these triplets, and the parties may already have them due to the popularity of Beaver's trick. A more minor disadvantage of Lu et al.'s solution is that, while the protocol requires very little communication, it is not locally parallelizable as each dynamic programming step depends on the previous one. In contrast, our entire protocol can be executed in parallel.

We also consider the runtime of using HoneyBadger in Figure 2. We emphasize this is a runtime-only evaluation. Without our training algorithm in Section 5, none of the polynomial-based solutions can attain usable accuracy. We find that ESPN and HoneyBadger perform similarly in practice, with HoneyBadger gaining a slight advantage in very low network delay. Due to the pre-computation trade-offs, we will evaluate both approaches for the remainder of this work.

5 PILLAR: Polynomial Activation Regularization

Our initial benchmark in Section 4 showed a significant speedup when replacing ReLU functions with polynomials implemented using ESPN and HoneyBadger. However, a notable challenge neglected thus far is that replacing a ReLU with a polynomial can drastically reduce the accuracy of the model [12, 18]. This section discusses the causes of the accuracy degradation and describes our mitigation techniques. Finally, we give empirical results showcasing the high accuracy of our modified training procedures across various architectures and datasets.

5.1 The Problem with Polynomial Activation Functions

Escaping Activations. The first step in replacing an activation function with a polynomial is to design a polynomial that closely approximates the original function. A common approach for this is the least-squares polynomial fitting. In this approach, a table of values is created for the polynomial over a small discretized range of values. This creates a system of equations for the polynomial coefficients that can be solved with least squares. The challenge with this approach is that, outside of this range, the polynomial no longer resembles the original activation function and often diverges rapidly. This leads to a problem called escaping activations, first identified by Garimella et al. [12]. If one naively swaps a ReLU for its polynomial approximation, all weights will become infinite within a few training epochs. We give an example of this degradation in Figure 3. We can see that, without modifying the training procedure, a polynomial can completely destroy the accuracy.

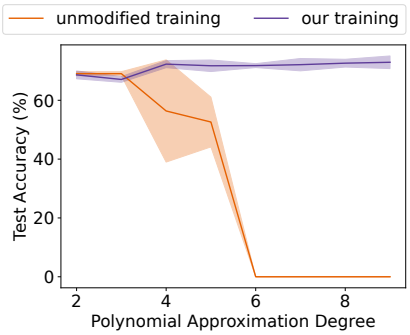

Figure 3: Accuracy of a 2-layer convolutional network trained with varying degrees for the polynomial activation function.

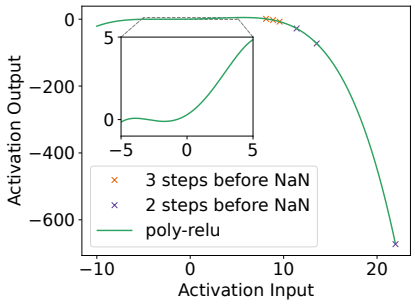

Figure 4: Illustrating the escaping activation problem for the two layers convolutional network.

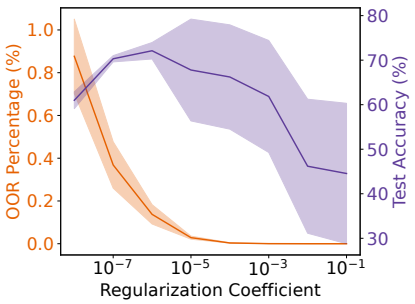

Figure 5: The effect of the regularization coefficient, β on model accuracy and out-of-range ratio for $\gamma = 10$

To illustrate the problem more clearly, we conduct an experiment using a polynomial of degree four fitted on the range $[-5,5]$ (λ=5) as the activation function for a three-layer model on CIFAR-10 [23]. In Figure 4, we plot this polynomial activation function and the ℓ_∞-norm of the input and output to each activation function. We note that, with no modification (except replacing ReLUs with polynomials), the weights of this model become undefined within approximately three epochs of training. First, we note the divergent behaviour of the polynomial outside the fitted range. Second, we observe the effect of the divergence on the outputs of the activation function. Specifically, we wait until the model weights become undefined (NaN in Python) and then observe the behaviour leading up to the explosion. We can see that three steps before the model weights become undefined (NaN), the input values of each activation are out-of-range, but the outputs still behave similarly to a ReLU. However, in the next iteration (two steps before NaN), a single value in the first layer goes too far out of range. This causes a ripple effect for the other two layers, creating an extremely large output (approx -2000) in the final activation function. This large value creates a large gradient, and after another iteration of training, the values become so large that the gradients (and weights) become undefined (NaN). We find that minimizing the classification loss alone is not enough to keep the model in range as the gradients explode before decreasing the loss.

Truncated Polynomial Coefficients. An additional challenge is that we will evaluate the fitted polynomial in a finite ring with limited precision. This significantly impacts the polynomial coefficients, which tend to be relatively small, especially for the higher-order terms. Specifically, these small coefficients can get truncated to zero in limited precision, which causes the polynomial to diverge even inside the fitted range. We give an example of this in Appendix C.

5.2 Defining PILLAR

Our approach, which we call PILLAR, is the combination of the components we describe in this section. Activation function regularization is our primary approach for mitigating escaping activation functions. However, to scale to larger models, we find that the additional steps of clipping, regularization warm-up, and adding batch normalization are beneficial.

Quantization-Aware Polynomial Fitting. We begin by solving the problem of truncated polynomial coefficients. To address this, we fit the polynomial with the precision constraint in mind. We do this by using mixed integer non-linear programming. Let X be the set of all values between $[-\lambda,\lambda]$ in p-bit precision (the domain we want to fit on). First, we generate $Y = ReLU(X) \cdot 2^p$, a table of values for a standard ReLU scaled up by the precision. Scaling the output of the ReLU allows us to work in the integer domain (similar to fixed point arithmetic). We then compute a matrix B where each column is the different powers of X used in a polynomial ($B = [X^0, X^1, X^2, \ldots]$).

Next, we solve the system $AB = Y$ for A using mixed integer linear programming with $A \in [-2^p - 1, 2^p - 1]$ to get the coefficients A that minimize the error between the polynomial AB and the ReLU values Y. Finally, we scale the resulting coefficients down by 2^p. We note that $A \in [-2^p - 1, 2^p - 1]$ corresponds to coefficients being bounded by $[-1,1]$ after we scale down. We empirically choose $p = 10$ for all polynomials during the ML training. As we observe in Appendix C, our quantized polynomial fitting addresses the problems of exploding activations within the range. However, the issue of going out-of-range requires additional treatment.

Activation Regularization. Following the observations of Section 5.1 and Garimella et al. [12], it is clear that minimizing the classification loss alone is not sufficient to pre-

vent escaping activations. Garimella et al. proposed QuaIL, a method that trains one layer of the model at a time, focusing not on classification accuracy but the similarity of the layer to a standard ReLU model [12]. QuaIL showed much better accuracy than naive training but only scaled to models with at most 11 layers.

In our work, we address the cause of the problem directly by regularizing the input to each activation function during training. We add an exponential penalty to the loss function when the model inputs out-of-range values to the polynomial activation function. Let x be the input to the activation function, and λ_{reg} be the upper bound of the symmetric range $[-\lambda_{reg}, \lambda_{reg}]$ in which we would like the input to be contained. Then, we define our penalty function as

$$p(x) = \left(\frac{x}{\lambda_{reg}}\right)^{\gamma} \tag{6}$$

where γ is a large even number (to handle negative values) determining the severity of the penalty. We find that values between six and ten work best in practice, with $\gamma = 10$ being the default in our experiments. This penalty function gives negligible penalties (less than 1) for $|x| < \lambda_{reg}$ and rapidly grows (in the degree of γ) as $|x| > \lambda_{reg}$.

We aggregate $p(x)$ over I, the set of inputs to all activation functions, by taking the average over each activation layer in the model. After aggregation, we scale the penalty using a regularization coefficient β and add it to the existing cross-entropy loss function of the model ℓ_c. Specifically, the modified loss function ℓ' is defined as:

$$\ell'(\cdot) = \ell_c(\cdot) + \frac{\beta}{K} \sum_{x \in I} p(x) \tag{7}$$

where K is the number of activation layers in the model. This allows us to tune the importance of classification loss vs. the cost of going out-of-range.

Clipping. Although activation regularization teaches the model not to go out-of-range over time, the model still needs to avoid going to infinity during the early stages of training. Thus, during training, we apply a clipping function to the input of the activation function such that if any input goes out of range, it is truncated to the range's maximum (or minimum) value. This clipping function does not affect the penalty as it is applied after the penalty function has been computed. We emphasize that this clipping function is only used during training and is removed during inference. The intuition is that the model should learn not to go out-of-range during training and thus no longer requires this clipping function during inference. Additionally, we find that setting the λ_{reg} of the penalty to be smaller than the range used for polynomial fitting (and clipping) can yield even better results. This is because the polynomial will be accurate for a larger range outside of the range the model was regularized to stay inside, allowing an extra buffer in case of failure during inference.

Dataset	Model	Plain Accuracy ± CI	
		ReLU	PILLAR
Cifar10	MiniONN	91.2 ± 0.17	88.1 ± 0.26
	VGG 16	92.6 ± 0.16	90.8 ± 0.11
	ResNet18	94.7 ± 0.09	93.4 ± 0.14
	ResNet110	92.8 ± 0.27	91.4 ± 0.18
CIFAR-100	VGG 16	70.9 ± 0.17	66.3 ± 0.22
	ResNet32	68.4 ± 0.46	67.8 ± 0.32
	ResNet18	76.6 ± 0.07	74.9 ± 0.14
ImageNet	ResNet50	80.8	77.7

Table 1: Plain-text Accuracy of PILLAR (5 runs).

Regularization Warm-up. We find the minimum requirements for successfully training a model with polynomial activation functions are activation regularization and clipping. However, for larger models, the penalty term can be extremely large in the first few epochs (until the model learns to stay in range). In some cases, the loss can become infinite due to our regularization penalty. To address this challenge, we adopt a regularization scheduler for the first four epochs that slowly increases both γ and β to the values used for the rest of the training. Empirically, the following schedule works well and avoids infinite loss. We let $\gamma' \in \{4, 6, \ldots, \gamma, \gamma, \ldots\}$ and $\beta' \in \{\beta/100, \beta/50, \beta/10, \beta/5, \beta, \beta, \ldots\}$.

BatchNorm Layers. Garimella et al. also investigated using normalization to help prevent the escaping activation functions [12]. They proposed a min-max normalization approach where each layer's minimum and maximum values are approximated using a weighted moving average of the true minimum and maximum. These values are frozen during inference. Garimella et al. observed that this approach alone was insufficient, as activations still escaped the range during inference. We observe this operation is similar to the batch norm layer commonly added to ML models. The main difference is that the mean and standard deviation of the batch are used to normalize the layer instead of the minimum and maximum values. By fixing the approximation of the mean and standard deviation during inference (following CrypTen [22]), this operation is very efficient in MPC. We study the effect of BatchNorm in Appendix A. We find that batch norm layers considerably improve the accuracy of PILLAR. This is an intuitive result as batch normalization helps to keep each layer's output bounded and thus reduces the work of our regularization function.

Summary of PILLAR We refer to PILLARas the combination of all components described in this section. We note that the clipping and regularization warm-up components are used (only during training) to enable regularization by preventing the model from going to infinity. The regularization

component ensures that the model will stay in range during inference. All three of these components play a crucial role in the success of PILLAR, as removing any of them will result in a model with unacceptable accuracy (due to infinite weights or escaping activations). The batch norm is the only optional component, which we give a small ablation study over in Appendix A.

5.3 Measuring PILLAR's Effectiveness

The Regularization Coefficient. To show the effect of our regularization and coefficient β, we conduct an experiment using the same three-layer model on CIFAR-10 from Section 5.1. In Figure 5, the left y-axis gives the out-of-range ratio (OOR), defined as the ratio of activation function inputs that were not within the interval $[-5,5]$. The right y-axis is standard classification accuracy, and the x-axis varies the regularization coefficient β. We observe that when the coefficient, β, is small, the model goes out-of-range often and thus has poor accuracy. As we increase β, the out-of-range ratio decreases, and accuracy increases. However, if we increase the coefficient too much, the accuracy decreases again.

End-to-end Accuracies. We evaluate PILLAR across a range of different models and architectures considered in related work [18,31,35]. We summarize the results in Table 1. We include the accuracy of a model trained with standard ReLUs as a baseline. All results are averaged over five random seeds, and we show the 95% confidence interval. The only exception is ResNet50 on ImageNet, where we only train a single model due to the size of the dataset. We defer to Section 6 for the details of the experimental setup. We note that these results are using PyTorch with no cryptography or quantization. We give a complete evaluation using MPC in Section 6 where quantization has an effect. Table 1 provides preliminary evidence that our polynomial training approach yields high accuracies competitive with state-of-the-art ReLU models across a range of models and datasets.

6 Evaluation of Co-Design

In this section, we provide an end-to-end comparison of our co-design against state-of-the-art solutions in secure inference. We evaluate the performance of PILLAR and Algorithm 2 using both ESPN and HoneyBadger as they offer different trade-offs in the type of pre-computation needed and the size of the communication. We determine the state-of-the-art works following a recent SoK by Ng and Chow [32]. Specifically, we consider three solutions on the Pareto front of latency and accuracy as determined by Ng and Chow. These works are COINN [18], GForce [31] and CrypTen (CryptGPU) [22,35]. We also evaluate Cheetah [17], a recent work not included in the SoK. We will evaluate the metrics of latency (or runtime of a single sample) and encrypted accuracy. We additionally evaluate the communication and number of rounds in Appendix D. We begin with the experimental setup, then evaluate both metrics (runtime and accuracy) against each related work. Section 6.2 evaluates the ResNet-18 architecture, which gives our state-of-the-art performance. Section 6.3 evaluates the VGG-16 architecture, the only architecture GForce evaluates. Section 6.4 considers other ResNets and the MiniONN architecture following COINN. Finally, in Section 6.5, we evaluate ImageNet against Cheetah, COINN, and CryptGPU.

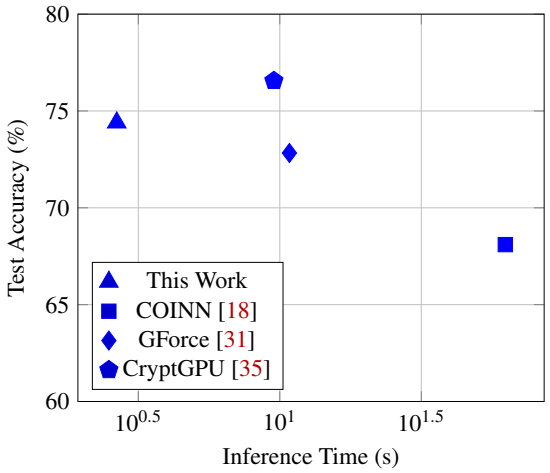

Figure 6: Summary of the inference time vs accuracy for each state-of-the-art approach on the CIFAR-100 dataset in the WAN (100 ms roundtrip delay).

Results Summary. We plot a summary of the accuracy and inference time for CIFAR-100 in Figure 6. For both datasets (recall Figure 1), we observe that our work always gives the solution with the fastest inference time by a statistically significant amount. In terms of accuracy, our work is competitive with the state-of-the-art, but CryptGPU is always the most accurate as it can infer unmodified plaintext models. Our solution is faster than CryptGPU by 4×, GForce by 5×, and COINN by 18× on average in wide area networks. Our accuracies are competitive with state-of-the-art and plaintext solutions and stay stable (no escaping activations) with models containing up to 110 layers and 23 million parameters.

6.1 Experimental Setup

We develop an experimental setup that follows as closely as possible to the works we compare to [18, 31, 35]. We use CIFAR-10/100 [23] and ImageNet [10], the same common benchmark datasets as related work. Our model architectures include: MiniONN [26], VGG [34], and ResNets [16]. This covers models of depth 7 to 110 layers with the number of trainable parameters ranging from 0.2 to 23 million.

Implementation Details. All experiments are run on a machine with 32 CPU cores @ 3.7 GHz and 1 TB of RAM with two NVIDIA A100 with 80 GB of memory. We simulate network delay by calling the sleep function for the appropriate time whenever the client and server communicate. We simulate the LAN with 0.25 ms roundtrip delay and the WAN with 100 ms, following COINN [18]. We additionally evaluate a real WAN using AWS instances in Section 6.6. All experiments (except ImageNet) are repeated over multiple random seeds, and we report the mean and 95% confidence interval as shaded areas.

For all related work, we run our own benchmarks of their code unmodified. While results for ResNet32 and MiniONN appear in the Cheetah paper, there was no source code for these models so we only evaluate Cheetah on ImageNet. To use CryptGPU in practice, one must first train a model in PyTorch. For ImageNet, PyTorch provides pre-trained models. However, we will need to train a model for all other architectures and datasets. We simply use the same configurations as our PolyRelu models but with standard ReLUs. We include all source code to reproduce our results [1].

Hyperparameters. We introduce five new hyperparameters associated with our techniques: polynomial degree (n), polynomial approximation range (λ), polynomial regularization range (λ_{reg}), polynomial regularization coefficient (β), and polynomial regularization exponent (γ). The default values for each are decided by extensive grid searches. These parameters primarily affect the accuracy and not the inference time, except for the polynomial degree (n), which has a minor effect on the communication size (but not the rounds). We found the optimal quantization-aware polynomial degree (n) to be 4. We found that higher degrees than four increase the failure probability of truncation with minimal accuracy gains (Section 4.3). Conversely, lower degrees give lower accuracy (as shown in Figure 3). The polynomial used in all evaluations is: $0.31445312 + 0.5x + 0.15625x^2 - 0.00292969x^4$.

For all models and datasets, we found a value of $\gamma = 10$ performs well as it introduces a strong enough incentive for PolyReLU inputs to stay in range (smaller values did not) while keeping penalization for values in range practically 0 (if an input x is within range, then $\frac{x}{\lambda_{reg}} < 1 \Rightarrow (\frac{x}{(\lambda_{reg})^{10}} \sim 0)$. Larger values than this often lead to an infinite penalty term. We found that a polynomial approximation range $\lambda = 5$ provides a good compromise between regularization and quantization. We found that smaller values of λ destroy the accuracy during training, and larger values use too much precision, increasing the failure probability. The optimal polynomial regularization range (λ_{reg}) and polynomial regularization coefficient (β) vary per model and dataset, although we found $\lambda_{reg} = 4.8$ (slightly tighter than $\lambda = 5$) and $\beta = 5 \times 10^{-5}$ to be good default values. We use $p = 10$ during ML training, but revert to CrypTen's default precision of $p = 16$ during inference in a 64-bit ring.

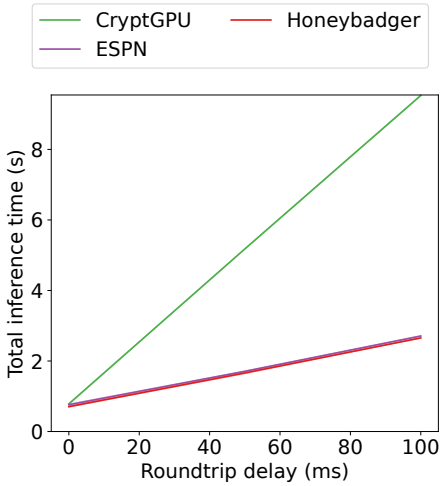

Figure 7: ResNet-18 evaluation on CIFAR-100 (20 runs).

We used Stochastic Gradient Decent as the optimizer with a learning rate of 0.013 as the default. This includes a Cosine Annealing Learning Rate Scheduler with Linear Learning Rate Warmup of 5 epochs and decay 0.01. We use a weight decay of either 10^{-4} or 5×10^{-4} and a momentum of 0.9. We used a default batch size of 128 and set the default number of Epochs to 185. For some models, we tuned the learning rate, number of epochs, and regularization coefficient to achieve a slightly higher accuracy. We detail hyperparameters in our source code repository.

6.2 ResNet-18 Architecture

In this section, we use a ResNet-18 architecture as it is the architecture that yields the best inference time and accuracy over all CIFAR-10 and CIFAR-100 experiments. For this comparison we focus on CryptGPU, which has been shown to be a state-of-the-art solution [32]. CryptGPU (or CrypTen) [35] serves as a baseline in all our comparisons including those against GForce and COINN in Sections 6.3 and 6.4. Neither COINN nor GForce support the ResNet-18 architecture evaluated in this section.

Inference Time. We measure the inference time of a single input image over varying network delays. The results are given in Figure 7. We include the result for CIFAR-100 and omit the plot for CIFAR-10 as it displays similar trends. We observe that both PILLAR + HoneyBadger and PILLAR + ESPN outperform CryptGPU with statistical significance across all roundtrip delays (as the shaded area does not overlap). In the WAN (100 ms), this corresponds to a 4× speedup over CryptGPU. Furthermore, we find HoneyBadger and ESPN perform similarly as observed in Section 4, with PILLAR + HoneyBadger having a slight advantage.

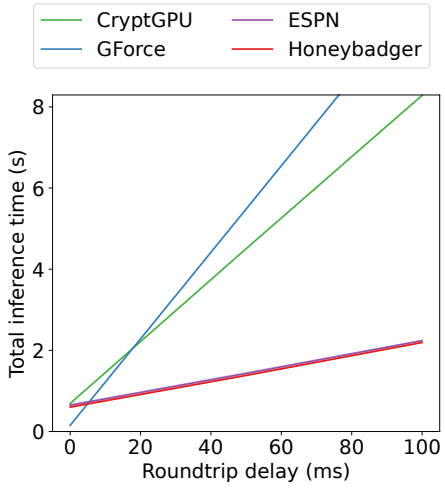

Figure 8: VGG-16 evaluation on CIFAR-100 (20 runs).

Accuracy. We measure the accuracy of the models on the testing set both in plain (using PyTorch) and encrypted (using CrypTen). We give the result in Table 2. First, we observe the plain and encrypted accuracies are very similar, indicating that quantization has a minor effect despite not considering this in training. We find that CryptGPU and PILLAR give similar accuracies, with CryptGPU performing slightly better, as is to be expected since they use unmodified activation functions. However, we argue this slight loss in accuracy is well justified by the significant decrease in inference time.

Dataset	Technique	Plain Acc	Enc Acc
CIFAR-10	PILLAR	93.4 ± 0.14	93.3 ± 0.22
	CryptGPU	94.7 ± 0.09	94.6 ± 0.10
CIFAR-100	PILLAR	74.9 ± 0.14	74.4 ± 0.31
	CryptGPU	76.6 ± 0.07	76.6 ± 0.13

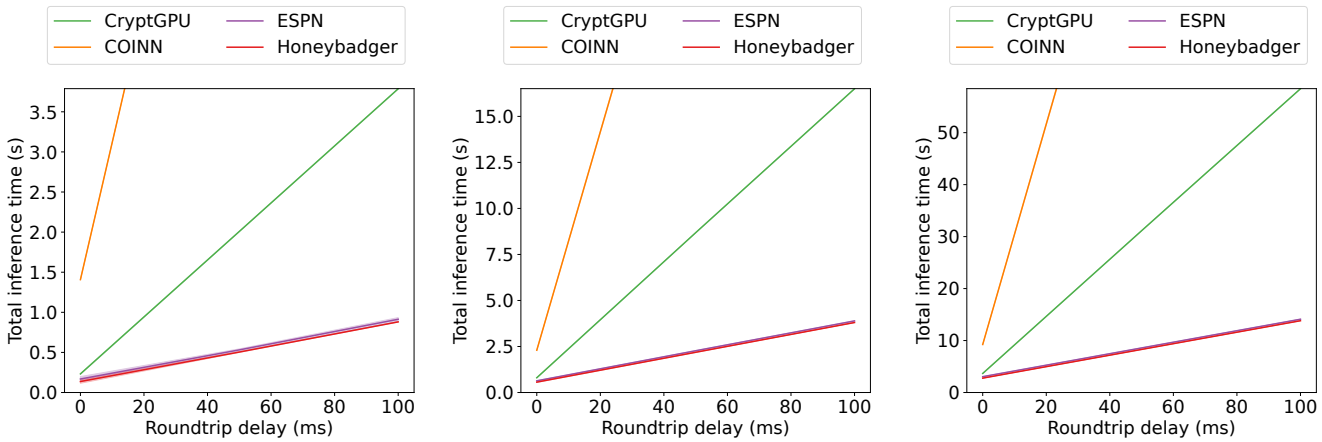
Table 2: ResNet-18 accuracy comparison (5 runs).

6.3 VGG-16 Architecture

In this section, we compare with GForce, the current state-of-the-art as shown by Ng and Chow [32]. GForce focused on a modified VGG-16 [34] architecture and compared it to all other works (including those using different architectures). For completeness, we evaluate the VGG-16 architecture using our techniques, and CryptGPU although we note that the ResNet-18 architecture outperforms VGG-16 in both inference time and accuracy. COINN [18] does not give results for VGG-16, so we exclude it from this section.

Inference Time. Since our work aims to reduce the rounds needed by binary non-linear layers, we replace the MaxPool layers in the VGG-16 with AvgPool for all solutions (including CryptGPU and GForce). We give the inference times over various delays in Figure 8. First, we note that GForce significantly outperforms all other solutions in the LAN. However, for more realistic high latency networks (>5ms roundtrip delay), we observe our solutions significantly outperform GForce (5× speedup in WAN). Once again, our solutions outperform CryptGPU for all network delays.

Encrypted Accuracy. We recall that we swap the MaxPool layers for AvgPool layers in the inference time evaluation. This comes at a cost to accuracy for the VGG architecture. Thus, to give the best scenario possible for GForce, we consider the accuracy of GForce with MaxPools and our work with AvgPool. We give the results in Table 3. As expected, GForce outperforms our work in accuracy (due to the MaxPools); however, only by a few percentage points. We train CryptGPU to use AvgPool and find it also loses a few percentage points, confirming our hypothesis that a MaxPool is necessary for high accuracy in VGG-16. We emphasize that our ResNet-18 result outperforms GForce's VGG result in inference time and accuracy. Furthermore, ResNets are a more popular and compact architecture due to skip-connections.



Dataset	Technique	Plain Acc	Enc Acc
CIFAR-10	PILLAR	90.8 ± 0.11	90.8 ± 0.14
	CryptGPU	92.6 ± 0.16	92.5 ± 0.16
	GForce	-	93.12
CIFAR-100	PILLAR	66.3 ± 0.22	66.3 ± 0.32
	CryptGPU	70.9 ± 0.17	70.8 ± 0.13
	GForce	-	72.83

Table 3: VGG-16 accuracy comparison (5 runs).

6.4 Other Architectures

While GForce is the current state-of-the-art, COINN is a competitive solution that evaluates ResNet architectures. Thus, we also evaluate the same configurations as COINN. This includes the smaller MiniONN architecture, a ResNet-32, and a ResNet-110. We exclude GForce from this evaluation as they only evaluate VGG-16 models.

Inference Time. We again swap all MaxPool layers for AvgPool in our work, and CryptGPU but leave COINN unmodified. We give the results in Figure 9. We observe that, over each of the three increasingly large architectures, the trends are similar and proportional to the number of parameters (0.2, 0.5, and 1.7 million parameters for MiniONN, ResNet-32, and ResNet-110, respectively). Across all architectures and network delays, our work outperforms COINN by a statistically significant amount (18× on average in WAN). We once

(a) MiniONN on CIFAR-10 (b) ResNet-32 on CIFAR-100 (c) ResNet-110 on CIFAR-10

Figure 9: Evaluating the various COINN architectures (20 runs).

again outperform CryptGPU in all evaluations[1] with a 4× speed up on average in the WAN.

Encrypted Accuracy. We give the results in Table 4. We observe that PILLAR is competitive with related work in all models, although we remark that, once again, our ResNet-18 models outperform all others. We also note that, while COINN does quantization-aware training, PILLAR does not and still only loses a small amount of accuracy in encryption vs. plaintext.

Dataset/Model	Technique	Plain Acc	Enc Acc
CIFAR-10 / MiniONN	PILLAR	88.1 ± 0.26	87.9 ± 0.46
	CryptGPU	91.2 ± 0.17	91.2 ± 0.16
	COINN	-	87.6
CIFAR-10 / ResNet-110	PILLAR	91.4 ± 0.18	91.4 ± 0.25
	CryptGPU	92.8 ± 0.27	92.7 ± 0.26
	COINN	-	93.4
CIFAR-100 / ResNet-32	PILLAR	67.8 ± 0.32	67.8 ± 0.47
	CryptGPU	68.4 ± 0.46	68.5 ± 0.45
	COINN	-	68.1

Table 4: Accuracy comparison on the various architectures considered in COINN (5 runs).

6.5 Scaling to ImageNet

In this section, we evaluate the scalability of our approach on the ImageNet dataset using a ResNet-50 architecture with 23 million parameters. This architecture was previously too large for training with polynomial activation functions [12]. We compare our approach to Cheetah, COINN and CryptGPUand exclude GForce as they do not consider ImageNet.

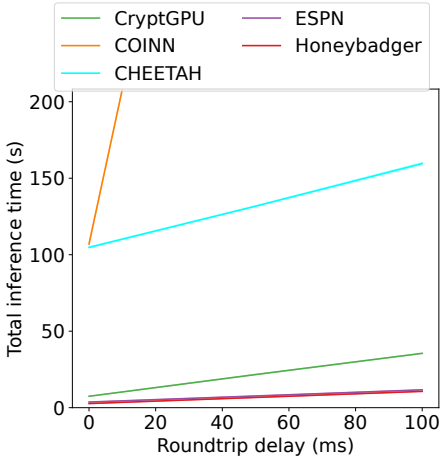


Figure 10: ImageNet evaluation on ResNet-50 (20 runs).

Inference Time. We plot the inference time in Figure 10. We observe a significant reduction over Cheetah and COINN across all network delays. We outperform Cheetah by 39× in the LAN (0.25 ms) and 15× in the WAN (100 ms). Over COINN, we observe a 28× reduction in the LAN and a 90× reduction in the WAN. Compared to CryptGPU we find that PILLAR + HoneyBadger is the fastest in all network delays by 3× on average. PILLAR + ESPN is slightly slower in the LAN, but once again outperforms CryptGPU in the WAN.

[1] All of which are statistically significant except MiniONN in LAN where the confidence intervals overlap slightly.

Dataset / Model	ESPN	HoneyBadger	CryptGPU
CIFAR-10 / ResNet-110	49.3 ± 0.1	49.0 ± 0.1	242.5 ± 0.9
CIFAR-10 / ResNet-18	15.3 ± 0.2	12.9 ± 0.1	48.9 ± 0.1
CIFAR-100 / ResNet-18	15.4 ± 0.2	12.9 ± 0.1	48.9 ± 0.5
CIFAR-100 / ResNet-32	14.1 ± 0.1	14.0 ± 0.1	75.4 ± 1.6
ImageNet / ResNet-50	153.9 ± 1.0	104.9 ± 0.8	268.67 ± 1.3

Table 6: Real World WAN evaluation. We report total inference time in seconds.

Encrypted Accuracy. We present a summary of the accuracies in Table 5. We note that Cheetah [17] did not measure accuracy in either their code or paper so we omit them from this comparison. We observe a much higher encrypted accuracy for PILLAR compared to COINN and thus, our solution is Pareto dominant. For CryptGPU, we use a pre-trained PyTorch model with state-of-the-art accuracy. Therefore, as expected, CryptGPU has an accuracy 3% higher than the model we trained from scratch. We note that with a higher degree polynomial, we were able to train a 79.2% polynomial model. However, this model is not possible to infer in the 64-bit field used by CrypTen (as higher degrees need more precision by equation 10). We discuss future directions to further improve this result in Section 7.

Technique	Plain Acc	Enc Acc
PILLAR	77.7	77.3
CryptGPU	80.8	80.8
COINN	-	73.9

Table 5: ImageNet accuracy comparison (1 run).

6.6 Real WAN Evaluation

This section gives benchmarks for ESPN, HoneyBadger, and CryptGPU [35] in a real WAN. We use two AWS EC2 `g4dn.metal` instances, one in the Ohio data centre and one in Frankfurt, Germany. Each machine has 96 cores, 384 GB of memory, 100 GB/s network bandwidth, and a NVIDIA T4 GPU. In practice, we measured 10.8MB/s bandwidth between the two instances. We run all the ResNet architectures and summarize the results in Table 6. We repeat each experiment 20 times and report the mean and 95% confidence intervals. We observe similar trends to the simulated WAN used in previous experiments. Namely, ESPN and HoneyBadger perform similarly in runtime for most models. The exception is larger models like ResNet50, where the bandwidth limits impact ESPN more than HoneyBadger. In all cases, CryptGPU is significantly outperformed by both approaches.

7 Discussion

Our experimental evaluation in Section 6 showed our algorithms significantly outperform all related work in WAN inference time. While state-of-the-art compared to other polynomial training approaches, PILLAR still incurs a minor accuracy degradation compared to standard models with ReLUs. We posit a few directions for future work to further close this gap between polynomials and ReLUs.

Quantization. Note that aside from our quantization-aware polynomial fitting described in Section 5, we have made no efforts to reduce the effects of quantization. COINN developed training algorithms to help the model be robust to the overflow and quantization present in MPC [18]. An interesting future work would be to combine the COINN methods with PILLAR to see if further accuracy gains are possible.

Precision. By using CrypTen as our backend, we were limited to a 64-bit ring for cryptographic operations. As discussed in Section 4.3, this precision determines the degree and range of polynomials we can use (due to either the failure probability of truncation or severe truncation of intermediate values). Interesting future work is to increase this precision to enable higher-degree polynomials and study the performance-accuracy trade-off. Our initial results on ImageNet show that we can train up to a degree eight polynomial without suffering escaping activations. However, we could not increase the ring size to study the effect of higher degrees on inference time.

MaxPools. We recall that a MaxPool layer requires comparisons and, thus, expensive conversions to binary shares (like ReLUs). Therefore, we replaced all MaxPools with AvgPool layers. However, in some architectures, such as VGG-16 [34], we found that swapping MaxPool for AvgPool degraded accuracy by up to 6%. Finding an efficient MaxPool alternative for architectures like VGG is important for future work. However, since the ResNet models give high accuracy using AvgPool layers we did not pursue this issue further.

8 Related Work

This work focuses on achieving state-of-the-art run time and accuracy in two-party secure inference. We measure this objective by evaluating against the current state-of-the-art as determined by a recent SoK by Ng and Chow [32]. Namely, we compare to COINN [18], GForce [31] and CrypTen [22, 35] in Section 6 as they represent the Pareto front according to Ng and Chow [32]. Another potential candidate on the Pareto front is Falcon [25], with low latency and accuracy [25]. We did not evaluate Falcon as the accuracy drop was too significant (over 10% [32]). Furthermore, GForce is shown to

outperform Falcon in both latency and accuracy, and we outperform GForce [31]. For a complete list of other works not on the Pareto front, we defer to Ng and Chow's work [32]. Notably, many works consider different threat models or use different approaches, such as homomorphic encryption. We leave extending our polynomial activation functions to these settings for future work. For the remainder of this section, we discuss works with a similar approach to ours that are not state-of-the-art or not evaluated by Ng and Chow [32].

Replacing or Reducing ReLU's. It has been established that the non-linear functions such as ReLU are the bottleneck for secure computation [12, 13, 18, 29]. Several works initially focused on reducing the number of ReLU activations, optimizing for the best trade-off between accuracy and runtime [13, 20]. A faster approach is to replace all ReLU's entirely using polynomial approximations [12]. In Section 5, we discussed the most recent work in this space, Sisyphus [12]. While making significant progress toward training models with polynomial activations, Sisyphus could not overcome the escaping activation problem for models with more than 11 layers. Before Sisyphus, there were a handful of works on smaller models that typically focus on partial replacement (some ReLU's remained) [14, 29, 30]. An interesting exception from Lee et al. used degree 29 polynomials in HE but suffered prohibitively high runtimes [24]. Our work is the first to make high-accuracy polynomial training feasible (without escaping activations) in deep neural networks.

A notable recent work is PolyKervNets [3]. Inspired by the computer vision literature, PolyKervNets remove the activation functions and instead exponentiate the output of each convolutional layer [3]. The problem with this approach is that, similar to polynomial activation functions, the exponents make the training unstable. Aremu and Nandakumar note that exploding gradients prevent their approach from scaling to ResNet models deeper than ResNet18 (using degree 2 polynomials). Furthermore, PolyKervNets only allow for a single fully connected layer which reduces the accuracy of the models. Conversely, PILLAR scales to deeper models such as ResNet110 and much higher degrees. Moreover, we achieve significantly better plaintext accuracy on ResNet-18 (93.4 vs 90.1 on CIFAR-10 and 74.9 vs 71.3 on CIFAR-100).

Polynomial Evaluation in MPC. Our work focuses on co-designing the activation functions with cryptography by using polynomials. However, the problem of computing polynomials in MPC is of independent interest and has also been studied in the literature. The state-of-the-art in this space is HoneyBadger, as discussed in Section 4. Other notable works include the initial inspiration for HoneyBadger from Damgård et al. [8]. This early approach conducts exponentiation by blinding and reconstructing the number to be exponentiated so the powers can be computed in plaintext [8]. Building off this idea, Polymath constructs a constant round protocol for evaluating polynomials focused on matrices [27]. However, HoneyBadger outperforms Polymath by reducing both the rounds and the number of reconstructions to one.

9 Conclusion

In this work, we co-designed the ML and MPC aspects of secure inference to remove the bottleneck of non-linear layers. PILLAR maintains a competitive inference accuracy while being significantly faster in wide area networks using novel single round MPC protocols (ESPN and HoneyBadger). Our state-of-the-art inference times motivate future work to further improve the ML accuracy of polynomial activations in DNNs.

A Evaluation of BatchNorm with Polynomials

	Without BatchNorm	With BatchNorm
Normal Relu	88.77 ± 0.11	90.05 ± 0.16
PolyRelu	82.99 ± 0.42	87.37 ± 0.13

Table 7: Comparing the effect of BatchNorm on MiniONN model.

To study the effect of a batch norm layer on our training process, we train a standard ReLU model and a model with polynomial activations both with and without batch norm layers. We use the MiniONN architecture and give the results averaged over three random seeds with 95% confidence intervals in Table 7. We find that batch norm layers improve both models. However, the improvement due to using batch norm is significantly greater when using polynomial activation functions. This is an intuitive result as batch norm helps keep each layer's output bounded and thus reduces the work of our regularization function.

B Evaluation of Sigmoid with Polynomials

	ReLU	Sigmoid
Standard Activation	94.7 ± 0.08	90.2 ± 0.11
Polynomial Approx.	93.4 ± 0.16	85.9 ± 0.11

Table 8: Comparing the effect of the activation function on a ResNet18 model.

In this work, we focus on the ReLU activation function, the default in common architectures such as ResNets [16]. Another reason we focus on ReLU is that it gives better accuracy than alternatives like Sigmoid. In this section, we highlight this accuracy advantage by the accuracy of a ResNet18 model with different activation functions. In Table 8, we evaluate

both ReLU and Sigmoid with and without using polynomial approximation. In all cases, we use the ResNet18 architecture with default parameters given in Section 6.1, we note the polynomial is of degree $n = 4$. The results are averaged over five random seeds and shown with 95% confidence intervals. We find that ReLU consistently outperforms Sigmoid with and without using polynomial evaluations. However, the accuracy of Sigmoid decreases more, relative to ReLU, when using polynomial approximation. This result further motivates our use of ReLU. We leave further investigation of Sigmoid and other activations for future work.

C Quantization Aware Polynomial Fitting

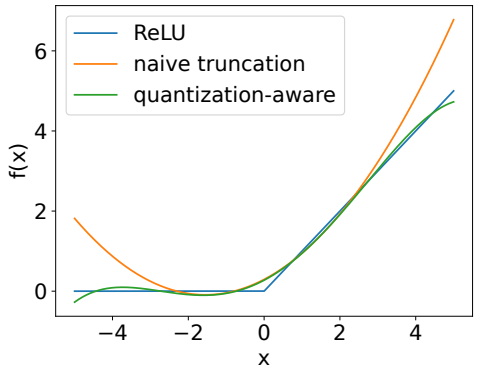

Figure 11: The effect of truncation on a polynomial activation function.

In Figure 11, we plot the polynomial approximation with and without our quantize-aware fitting approach described in Section 5.1. First, we plot the polynomial approximation after truncation and see that it diverges from a true ReLU. We also plot our quantized polynomial fitting and show that it addresses the problems of exploding activations within the range.

Polynomial Input Distribution After Regularization We plot the histogram of the input to all activation functions of a ResNet 18 model on CIFAR-10 in Figure 12.

D Communication and Rounds Benchmark

We study two additional evaluation metrics of rounds and communication in this section. Recall that the number of rounds significantly affects the protocol latency over WAN. The communication affects each round's throughput, depending on the network bandwidth. In Table 9, we summarize the communication in GB and the number of rounds (shown in parenthesis) for our work and the related work we compare to in Section 6. We note that both COINN and GForce do not

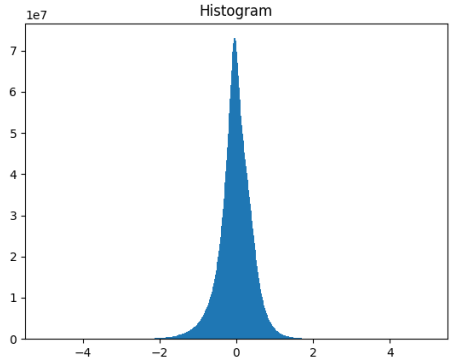

Figure 12: Polynomial Input Distribution of ResNet18 on CIFAR10.

log the communication or rounds in their code base. Thus, we report their communication numbers from the corresponding tables in the papers (COINN [18, Table 3] and GForce [31, Table 7]). Neither work evaluates the number of rounds.

In all cases, ESPN and HoneyBadger significantly dominate all evaluated related work in the number of rounds with a $3-5\times$ improvement. The communication of ESPN and HoneyBadger is significantly less than COINN, approximately the same as CryptGPU, and more than GForce and Cheetah. Our HoneyBadger solution has approximately $2\times$ the communication of Cheetah, but Cheetah has $10\times$ the rounds; thus, in practice, HoneyBadger gives much better performance as shown in Section 6. GForce has an impressively low communication online (50MB) due to offloading 20GB of communication to an offline phase. Once again, despite having higher communication, we recall that both ESPN and HoneyBadger dominate related work in runtime in the WAN (as shown in Section 6).

E Correctness Proofs

We begin by proving the correctness of Algorithm 1.

Theorem E.1. *Given an input* $[[x]] = x_A + x_B$ *and exponent* k, *Algorithm 1, correctly returns* $[[x^k]]$.

Proof. We begin with party A. In line 4, they compute their share of the vector $\mathbf{a}$ where $\mathbf{a}_i = x_A^{k-i}$ (since $\mathbf{a}$ was initialized to zero and the for loop iterates over each entry of $\mathbf{a}$ exactly once). Similarly, in line 5, party B computes their share of $\mathbf{b}$ where $\mathbf{b}_i = \binom{k}{i} x_B^i$. We recall that party B's share of $\mathbf{a}$ is the zero vector, and similarly for party A's share of $\mathbf{b}$ Then, the vector $\mathbf{p}$ is obtained by multiplying $\mathbf{a}$ and $\mathbf{b}$ element wise in line 6. Thus, $\mathbf{p}_i = \mathbf{a}_i \cdot \mathbf{b}_i = x_A^{k-i}\binom{k}{i}x_B^i$. The final step (line 7), simply sums $\mathbf{p}$. Therefore,

$$s = \sum_{i=1}^{k} \mathbf{p_i} = \sum_{i=1}^{k} \binom{k}{i} x_A^{k-i} x_B^i \tag{8}$$

Table 9: Evaluation of communication in GB and the number of rounds (shown in parenthesis).

which applying the binomial theorem (2) gives $(x_A + x_B)^k = [[x^k]]$. □

Given the correctness of Algorithm 1, we now prove the correctness of Algorithm 2. To begin, we bound the failure probability of each truncation step in Algorithm 2.

Theorem E.2. *Consider computing a degree n polynomial fitted to the range $[-\lambda, \lambda)$. Let the global precision (size of the ring) be L-bit and the working precision of each value be p-bit. Then, the truncation in line 5 of Algorithm 2, fails (The local division of $[[x]_A, [x]_B] * 2^{-\bar{s}} \neq [[x * 2^{-\bar{s}}]]$) with probability at most*

$$Pr[\textit{Line 5 Failure}] \leq \frac{2^{\lceil \log_2 \lambda \rceil + 1 + p}}{2^L}. \tag{9}$$

Proof. Consider the first truncation of Algorithm 2 in line 5. The input to this truncation is x which we assume is contained in the range $[-\lambda, \lambda)$ with a working precision of p-bits. Therefore, the size of x is $2^{\lceil \log_2 \lambda \rceil + 1}$ in the integer part and 2^p in the decimal part. Which gives, $|x| \leq 2^{\lceil \log_2 \lambda \rceil + 1 + p}$. Given that we are working in a L-bit ring and the probability of failure of the truncation protocol is bounded by $|x|/Q$ where Q is the ring size [22], the result follows. □

Theorem E.3. *Consider computing a degree n polynomial fitted to the range $[-\lambda, \lambda)$. Let the global precision (size of the ring) be L-bit and the working precision of each value be p-bit. Then, the truncation in line 7 of Algorithm 2 fails (The local division of $[[x]_A, [x]_B] * 2^{-p*(i-1)+\bar{s}\cdot i} \neq [[x * 2^{-p*(i-1)+\bar{s}\cdot i}]]$) with probability at most*

$$Pr[\textit{Line 7 Failure}] \leq \frac{2^{i(\lceil \log_2 \lambda \rceil + 1) + 2p}}{2^L}. \tag{10}$$

where i is the power of x being truncated ($i \leq n$).

Proof. Consider the truncation in line 7 of Algorithm 2. The input to this truncation is the output of the previous truncation in line 5, raised to the power i. We assume the previous truncation was correct. Then after the truncation,

$$|x'_i| = \frac{2^{\lceil \log_2 \lambda \rceil + 1 + p}}{2^{\lceil (i-2)p/i \rceil}} \leq \frac{2^{\lceil \log_2 \lambda \rceil + 1 + p}}{2^{(i-2)p/i}} \tag{11}$$

for $i \in \{2, \ldots, n\}$, where the inequality holds because $(i-2)p/i$ is positive. After applying the exponentiation by i we get $|\mathbf{p}_i| \leq 2^{i(\lceil \log_2 \lambda \rceil + 1) + 2p}$. Given that we are working in a L-bit ring and the probability of failure of the truncation protocol is bounded by $|x|/Q$ where Q is the ring size [22], the result follows. □

Theorem E.4. *Given an input $[[x]] = x_A + x_B$ and polynomial coefficients α, Algorithm 2, correctly returns the polynomial evaluation $[[\sum_{i=0}^{n} \alpha_i \cdot x^i]]$ except with probability.*

$$Pr[\textit{Alogrithm 2 Fails}] \leq \frac{\sum_{i=2}^{n} \left(2^{i(\lceil \log_2 \lambda \rceil + 1) + 2p} + 2^{\lceil \log_2 \lambda \rceil + 1 + p}\right)}{2^L}.$$

Proof. First, prove correctness assuming the truncation operators are correct (then we will account for the probability of failure). We begin by proving that $\mathbf{p'_i} = x^i$ for $i \in \{1, \ldots, n\}$ after line 7. We note that x is actually $x * 2^p$ due to the fixed point encoding. $\mathbf{p_1}$ follows trivially. For $i \in \{2, \ldots, n\}$, we work backwards, from line 7 to line 4 expanding the definition of $\mathbf{p'_i}$

$$\begin{aligned}
\mathbf{p'_i} &= \mathbf{p}_i * 2^{-p*(i-1)+\bar{s}\cdot i} && (12)\\
&= (x'_i)^i * 2^{-p*(i-1)+\bar{s}\cdot i} && (13)\\
&= (x \cdot 2^p \cdot 2^{-\bar{s}})^i * 2^{-p*(i-1)+\bar{s}\cdot i} && (14)\\
&= x^i \cdot 2^p && (15)
\end{aligned}$$

where the first lines, up to (14), come from the substitution of lines 7 through 5, respectively. The remaining step follows from basic algebra.

Finally, we bound the failure probability of the algorithm. The truncation steps in line 5 and line 7 each introduce a possibility of wrap around error. Each truncation is executed $n-1$ times. Thus, applying the bounds derived in Theorem E.2 and Theorem E.3 for each i in the for loop, the total failure probability follows. □

OblivGNN: Oblivious Inference on Transductive and Inductive Graph Neural Network

Abstract

Graph Neural Networks (GNNs) have emerged as a powerful tool for analysing graph-structured data across various domains, including social networks, banking, and bioinformatics. In the meantime, graph data contains sensitive information, such as social relations, financial transactions, and chemical structures, and GNN models are IPs of the model owner. Thus, deploying GNNs in cloud-based Machine Learning as a Service (MLaaS) raises significant privacy concerns.

In this paper, we present a comprehensive solution to enable secure GNN inference in MLaaS, named OblivGNN. OblivGNN is designed to support both *transductive* (static graph) and *inductive* (dynamic graph) inference services without revealing either graph data or GNN models. In particular, we adopt a lightweight cryptographic primitive, i.e., function secret sharing, to achieve low communication and computation overhead during inference. Furthermore, we are the first to propose a secure update protocol for the inductive setting, which can obliviously update the graph without revealing which parts of the graph are updated. Particularly, our results with three widely-used graph datasets (Cora, Citeseer, and Pubmed) show that OblivGNN can achieve comparable accuracy to an Additive Secret Sharing-based baseline. Nonetheless, our design reduces the runtime cost by up to 38% and the communication cost by 10× to 151×, highlighting its practicality when processing large graphs with GNN models.

1 Introduction

A growing emphasis has been placed on the development of Graph Neural Networks (GNNs) due to their power of analysing complex graph-structured data. GNNs are adopted in various domains (e.g., social networks [17], banking [67], bioinformatics [68]). Due to the popularity of GNNs, Machine Learning as a Service (MLaaS) has started to support GNN training and inference service [1, 4, 35]. Enterprises deploy GNN models in MLaaS for known benefits like scalability, reduced infrastructure maintenance, and convenient deployment.

Despite great advantages, deploying GNNs in an untrusted environment raises privacy concerns. On the one hand, collecting training graphs and building a GNN model often requires a large amount of human, computing, and economic resources [2, 66], and thus a model owner expects strong protection of its training graphs and GNN model against unauthorised access. On the other hand, GNNs' inference needs both model parameters, graph structure and node feature information, and sometimes graph data is sensitive by nature [67], such as users' financial transactions, and private friendships.

To ensure data confidentiality for machine learning in MLaaS, previous efforts have been made to construct privacy-preserving machine learning (PPML) protocols over encrypted data and models [16, 19, 28, 38–40, 44–46, 49, 51, 52, 56, 58]. However, those studies are designed for Convolutional Neural Networks and Recurrent Neural Networks, and are not tailored for GNNs. Although recent studies [14, 50, 59] designed to secure graph data in GNNs, they lack support for *full protection* of graph structures and feature information under the diverse settings of GNN deployment.

Practical GNN applications [17, 18, 27] demand that the inference should be conducted with both static graphs (*transductive*) and dynamic graphs (*inductive*). In this paper, we consider the node classification task which is the most representative task in GNN applications. In the transductive setting, the graph used in training and inference is the same. The classification labels for all nodes are generated during training, and the client directly queries the node ID to get the inference result. However, in the inductive setting, the inference graph is different from the training graph. Both the graph structure and node features can be updated before inference.

On the one hand, existing work reveals certain information about graph structures, such as the maximum node degree in SecGNN [59] and the range of node degree in CryptoGCN [50]. On the other hand, they do not support the inference in the inductive setting, where the graph needs to be securely updated. Specifically, directly updating the graph (e.g., adding new nodes or modifying the node features) will reveal the access to the encrypted graph. Such access could be

exploited to infer the graph structure, which has been demonstrated in leakage attacks against encrypted graph processing protocols [21].

Another issue is that the existing PPML designs for GNNs suffer from high computational and communication overhead given the large size of the graph and the high dimension of node features. For example, some work [14, 50] adopts heavy cryptographic primitives like FHE which can hardly scale for large matrix multiplication. Therefore, it is challenging to enable privacy-preserving inference over encrypted graphs and GNN models under transductive and inductive settings in a secure and efficient manner.

1.1 Summary of Techniques

We propose OblivGNN, which brings the following capabilities: 1) full protection on the graph structure data during inference; 2) enabling oblivious inference under *transductive* and *inductive* settings; 3) ensuring reduced, constant interparty communication during secure computation.

Full Protection on Graph Structure during Inference. As mentioned above, existing secure GNN designs [14, 50, 59] reveal the access pattern or partial graph information to achieve practical performance. To fully protect the graph structure in the GNN inference process, we observe that the native matrix multiplication can naturally hide the graph's structural information. However, the existing techniques [5, 23] for secure matrix multiplication encounter high computational and communication overhead.

To enable a low-cost secure matrix multiplication process, we resort to a lightweight cryptographic primitive, named function secret sharing (FSS) [6]. FSS provides an efficient way to conduct oblivious additions/multiplications with low computation and communication costs. Moreover, this technique can be used to realise practical oblivious secure activation functions [52], which makes it a perfect candidate for our application scenario. However, there are two main challenges when combining FSS primitives in GNN. First, FSS schemes, e.g., Distributed Point Function (DPF) [6] and arithmetic FSS gates [13] (Section 2.2) are designed to enable dedicated functionalities. This requires meticulous combinations of those schemes for specific GNN functions, e.g., matrix multiplication, and activation functions (Section 4.2.3), in a seamless and secure way. Moreover, unlike ASS-based designs that rely on independent randomness, the FSS-based design follows a circuit fashion that requires the gates (FSS keys) to be connected correctly for specific functions. Hence, it is also challenging to design a proper mechanism (Section 4.2.1) for generating/storing FSS keys correctly.

In OblivGNN, we carefully integrate different FSS functionalities together to enable secure and efficient matrix multiplication. Furthermore, the secure matrix multiplication protocol is customised to seamlessly integrate with the FSS-based secure activation functions, which guarantees a secure and access-pattern hiding (*oblivious*) inference process.

Support *Transductive* and *Inductive* Inference. The aforementioned design enables OblivGNN to conduct inference under the transductive setting, i.e., inference on static graphs. However, it is also crucial to support inferences on a graph with updated node information (*inductive* setting) to enable full GNN functionality in real-world applications [17, 18, 27].

Dynamic graphs are crucial in real-world application scenarios (i.e., *inductive* inference setting). However, the graph update operations entitle accessing individual nodes and nodes' features to perform the update. Such operations result in access pattern leakage if unprotected and can be exploited to recover/perturb the graph structure and reveal/perturb graph attribute information. Therefore, to protect the above leakage when supporting the dynamic graph in GNN inference, we develop secure oblivious update algorithms for OblivGNN. The proposed algorithms leverage the specific instantiation of FSS (DPF [6]) to update server-side sub-graphs into existing graphs without revealing which parts of the graph are updated. Our design ensures that the updated graph can be used as the input of the inference process directly, and thus enable OblivGNN to support oblivious GNN inference service on dynamic graphs.

Contributions. We present OblivGNN, a lightweight and oblivious GNN inference service. OblivGNN provides:

- **Fully support secure GNN inference:** We have devised the first oblivious GNN inference framework that supports both *transductive* and *inductive* settings, facilitating the protection of the inference and dynamic graph update operations (node insertion and graph update).
- **Obliviousness with Semi-honest Security:** We formally prove that the OblivGNN offers obliviousness under the semi-honest security assumption. Our proof successfully demonstrates the protection of the graph data, the graph update and clients' enquiry. A detailed exposition can be found in Appendix A.
- **Efficiency:** We have devised effective and oblivious protocols tailored specifically for fully oblivious GNN models to support both static and dynamic graphs. In three datasets, OblivGNN achieves a lower runtime cost compared to traditional ASS-based secure GNN, and it is scalable towards large dataset. To be specific, the baseline uses 11.05 minutes, while the OblivGNN uses only 6.83 minutes in the largest graph dataset (Pubmed with the size of 19717 nodes and 500 features). In the inter-server communication cost, OblivGNN achieved an average improvement of 93× among the three datasets.

2 Preliminary

This section introduces the graph neural networks and cryptographic tools used in OblivGNN. The notations are summarised in Table 1.

2.1 Graph Neural Networks

Node Classification via GNNs. Graph neural network (GNN) is a neural network architecture specifically designed to analyse graph-structured data. There are various graph analytics tasks enabled by GNNs. OblivGNN considers the most widely used one, i.e., graph convolutional networks (GCNs) [33] for node classification task. Specifically, let $\mathcal{G} = (\mathbf{A}, \mathbf{F})$ be an attributed graph, where $\mathbf{A} \in \{0,1\}^{n \times n}$ denotes the graph structure, and $\mathbf{F} \in \mathbb{R}^{n \times c}$ denotes the node features. Suppose the graph contains a number of n nodes with c-dimension of the feature vector, e.g., the $\mathbf{F}[i] \in \mathbb{R}^{1 \times c}$ is the feature vector for node i. Given the nodes i labelled with respective $\mathbf{Z}_1$, a GNN node classification task aims to classify a node with a label based on both graph structure and node features.

GNN model formulation. We now formulate the GCN model architecture for node classification. Intuitively, GCN is organised in a pipeline, where each layer aggregates the features of a current node and its adjacent nodes (neighbours), followed by a non-linear activation function. A two-layer feed-forward GCN for node class predictions is formally defined as:

$$\mathbf{Z}_1 = \text{Softmax}(\hat{\mathbf{A}}\text{ReLU}(\hat{\mathbf{A}}\hat{\mathbf{F}}\mathbf{W_0})\mathbf{W_1}), \tag{1}$$

where $\hat{\mathbf{A}}$ is an $n \times n$ normalised adjacency matrix corresponding to graph structure; $\hat{\mathbf{F}}$ is an $n \times c$ normalised feature matrix. The weight matrices $\mathbf{W_0}, \mathbf{W_1}$ contain trainable parameters of GCN model. Softmax and ReLU are two non-linear activation functions. We follow standard GCN inference and refer the reader to the work from Kipf and Welling [33] for the details of training and normalization.

Transductive & Inductive GNNs. At a high level, GNN for node classification comprises two learning settings: transductive and inductive. The training process for both transductive and inductive settings is identical. The main difference is attributed to the dynamism of the underlying graphs. In the *transductive setting*, the graph used during both training and inference remains unchanged. In an MLaaS setting, the server can pre-generate the inference results for all nodes at the training time, and directly return inference results to any consequent queries at the inference time.

In the *inductive setting*, the graphs used for training and inference are different. This is because of the appearance of new nodes/graphs that would connect to existing nodes in the inductive inference. In an MLaaS setting, when a client submits new nodes or existing nodes with updated features for queries, the server should update the corresponding adjacency matrix and feature matrix with these newly submitted nodes before proceeding with the inference. The dynamism of the inductive setting makes it better suit real-world scenarios where the graph is employed during training to involve updates, such as new node insertions or graph updates, before the inference process [17, 18, 27].

b	Party number $b \in \{0,1\}$
P_b	Party P_0, P_1
m	Total number of output classes
h_l	Size of weight matrix in layer l
L	Number of classes
$\mathbf{A}^*$	Adjacency matrix for subgraph
$\mathbf{F}^*$	Feature matrix for subgraph
$\mathbf{A}'$	Masked adjacency matrix
$\mathbf{F}'$	Masked feature matrix
$\hat{\mathbf{A}} = \{\hat{A}_0, \ldots\}$	Normalised adjacency matrix
$\hat{\mathbf{F}} = \{\hat{f}_0, \ldots\}$	Normalised feature matrix
$\mathbf{N} = \{\text{N}[0][0], \ldots\}$	Padded neighbouring nodes matrix
$\mathbf{E} = \{\text{E}[0][0], \ldots\}$	Padded neighbouring edge matrix
$\mathbf{AF} = \{af_0, \ldots\}$	Aggregated matrix
$\mathbf{Z}_l = \{z_l[0], \ldots\}$	Result on layer l before activation

Table 1: Notation

2.2 Function Secret Sharing

A two-party function secret sharing (FSS) [6, 13] splits a function f into succinct function shares. It guarantees that each function share reveals no information about f. When the function shares are evaluated at a given point x, the combination of the evaluations is equal to $f(x)$. OblivGNN resorts to two FSS constructions 1) distributed point functions (DPF [6]) and 2) arithmetic FSS [13]. We now give their formal definitions.

DPF for Equality Test. $\mathsf{DPF.Equa}(\llbracket x \rrbracket)$ aims to evaluate whether a secret value x inputted to a point function equals to 0. Such that,

$$\mathsf{Eval}^{=}(k_0^{=}, x') + \mathsf{Eval}^{=}(k_1^{=}, x') = \begin{cases} y = 1 & \text{if } x' = \gamma \\ 0 & \text{otherwise.} \end{cases}$$

During key generation, the client takes random value $\gamma \in \mathbb{Z}_{2^\ell}$ and runs $\mathsf{KeyGen}^{=}(1^\lambda, \alpha = \gamma, \beta = 1)$ to produce k_b for two parties. During evaluation, given a secret value $\llbracket x' \rrbracket_b = \llbracket \gamma \rrbracket_b + \llbracket x \rrbracket_b$ is additively masked by $\gamma \in \mathbb{Z}_{2^\ell}$. Parties exchange $\llbracket x' \rrbracket_b$ to reveal the masked x'. Each party P_b evaluates the DPF $\mathsf{Eval}^{=}(k_b, x')$ to produce secret shared $\llbracket y \rrbracket_b$, which would be reconstructed to have $y = 1$ only if $x' = \gamma$ (i.e., $x = 0$).

DPF for Comparison. $\mathsf{DPF.Comp}(\llbracket x \rrbracket)$ works in a similar way. Such that,

$$\mathsf{Eval}^{<}(k_0^{<}, x') + \mathsf{Eval}^{<}(k_1^{<}, x') = \begin{cases} y = 1 & \text{if } x' \leq \gamma \\ 0 & \text{if } x' > \gamma \end{cases}$$

Given a point function compares if x is less/equal to 0. the client runs $\mathsf{DPF.Comp}$'s key generation on $\alpha = \gamma$ and $\beta = 1$ to produce k_b. During DPF evaluation, party P_b evaluates the DPF $\mathsf{Eval}(k_b, x')$ on masked x and produces secret shared $y = 1$ if $x' \leq \gamma$ (i.e., $x \leq 0$). Otherwise, it is evaluated to $y = 0$ if $x' > \gamma$ (i.e., $x > 0$). Note that in both constructions, the DPF key generation is independent of the computation; it thus can be generated offline at random and stored in a key pool. For

Algorithm 1: FSS Multiplication $\mathsf{FSS.Mul}(x'_1, x'_2)$

Multiplication Gate ($\mathsf{KeyGen}^{\times}$, $\mathsf{Eval}^{\times}$)

$\underline{\mathsf{KeyGen}^{\times}(1^{\lambda}, r_1^{in}, r_2^{in}, r^{out})}$

1) Sample random number $\tau_0, \tau_1 \in \mathbb{Z}_{2^\ell}^{in}$, where $\tau_0 + \tau_1 = r_1^{in}$.
2) Sample random number $\rho_0, \rho_1 \in \mathbb{Z}_{2^\ell}^{in}$, where $\rho_0 + \rho_1 = r_2^{in}$.
3) Sample random number $\xi_0, \xi_1 \in \mathbb{Z}_{2^\ell}^{in}$, where $\xi_0 + \xi_1 = r_1^{in} \cdot r_2^{in} + r^{out}$.
4) Let $k_b = \tau_b \parallel \rho_b \parallel \xi_b$, where $b \in \{0,1\}$.
Return: $(k_0^{\times}, k_1^{\times})$.

$\underline{\mathsf{Eval}^{\times}(b, k_b^{\times}, x'_1, x'_2)}$

1) Parse $k_b^{\times} = \tau_b \parallel \rho_b \parallel \xi_b$.
Return: $b \cdot (x'_1 \cdot x'_2) - x'_1 \cdot \rho_b - x'_2 \cdot \tau_b + \xi_b$.

ease of demonstration, we omit the security parameter in the key generation KeyGen routine.

FSS Multiplication Gate The FSS multiplication gate aims to secretly calculate the arithmetic function $g^{\times}(x_1, x_2) := x_1 \cdot x_2$ with masks r_1^{in}, r_2^{in}, i.e., $(x_1 + r_1^{in}) \cdot (x_2 + r_2^{in})$. The two routines in FSS multiplication gate are denoted as $\mathsf{KeyGen}^{\times}$ and $\mathsf{Eval}^{\times}$. We define the FSS multiplication evaluation process such that, $[\![x_1 \cdot x_2 + r_{out}]\!]_b \leftarrow \mathsf{FSS.Mul}(x'_1, x'_2)$. The formal algorithm is in Algorithm 1.

FSS Addition Gate. The FSS addition gate aims to secretly calculate masked $g^{+}(x_1, x_2) := x_1 + x_2$ with masks r_1^{in}, r_2^{in}, i.e., $(x_1 + r_1^{in}) + (x_2 + r_2^{in})$ non-interactively. The two underlying routines in FSS addition gate are denoted as KeyGen^{+} and Eval^{+}. We define the FSS addition evaluation process such that, $[\![x_1 + x_2 + r_{out}]\!]_b \leftarrow \mathsf{FSS.Add}(x'_1, x'_2)$. The formal algorithm is in Algorithm 2.

2.3 Additive Secret Sharing

Additive secret sharing (ASS) [3] *shares* a secret value $x \in \mathbb{Z}_{2^\ell}$ into two additive secret shares $[\![x]\!]_0 + [\![x]\!]_1 \equiv x \pmod{2^\ell}$ by sampling random values $[\![x]\!]_0 \in_R \mathbb{Z}_{2^\ell}$ and $[\![x]\!]_1 = x - [\![x]\!]_0$. Let P_0 and P_1 be two parties involved in the computation. Each of them holds secret shares $[\![x]\!]_b, b \in \{0,1\}$. To *reveal* a secret, P_{1-b} sends its share $[\![x]\!]_{1-b}$ to P_b who computes $x = [\![x]\!]_0 + [\![x]\!]_1$. Given two secret values x and y shared among parties. Arithmetic operations are evaluated by ASS as follows. Addition $[\![z]\!]_b = [\![x]\!]_b + [\![y]\!]_b \pmod{2^\ell}$ can locally computed by P_b. Multiplication $[\![z]\!] = [\![x]\!] \cdot [\![y]\!] \pmod{2^\ell}$ is assisted by Beaver's multiplication technique [5].

3 System Overview

In this section, we introduce OblivGNN's system architecture, threat model and security guarantees.

Algorithm 2: FSS Addition $\mathsf{FSS.Add}(x'_1, x'_2)$

Addition Gate (KeyGen^{+}, Eval^{+})

$\underline{\mathsf{KeyGen}^{+}(1^{\lambda}, r_1^{in}, r_2^{in}, r^{out})}$

1) Sample random number $\xi_0, \xi_1 \in \mathbb{Z}_{2^\ell}^{in}$, where $\xi_0 + \xi_1 = r^{out} - (r_1^{in} + r_2^{in})$.
2) Let $k_b^{+} = \xi_b$, where $b \in \{0,1\}$.
Return: (k_0^{+}, k_1^{+}).

$\underline{\mathsf{Eval}^{+}(b, k_b^{+}, x'_1, x'_2)}$

1) Parse $k_b^{+} = \xi_b$.
Return: $x'_1 + \xi_0$ and $x'_2 + \xi_1$.

3.1 System Architecture

Figure 1 shows OblivGNN's system architecture, which has three entities: *model owner*, *client*, and two cloud *servers*.

- Model owner possesses a GNN model and wishes to leverage OblivGNN to enable an oblivious inference without revealing the model (i.e., training graph and model weights).
- Client is the querier who requests an oblivious node classification by making queries to OblivGNN. It submits node ID (transductive) and/or graph (inductive) to OblivGNN and receives inference results without revealing its private query.
- Two cloud servers in different trust domains obliviously execute the inference on both transductive and inductive GNNs, without seeing the model from the model owner and the query from the client in cleartext.

OblivGNN Workflow. OblivGNN has two settings of oblivious GNN inferences: Oblivious *Transductive* and Oblivious *Inductive*. Oblivious *Transductive* offloads the graph and model weights to the cloud servers in secret-shared format and only supports client queries to infer an existing node. Oblivious *Inductive*, on the other hand, supports updating the graph that has been already offloaded to the clouds. Both settings support OfflineGen, OblivAgg, and OblivAct, while Oblivious *Inductive* further supports OblivUpdate. Only OfflineGen is invoked by the model owner, all others are executed by the two cloud servers. Both settings are under OblivGNN's system framework and can be smoothly switched between each other. From a high-level point of view, Oblivious *Transductive* and Oblivious *Inductive* operate as follows.

Oblivious *Transductive*:

- OfflineGen: Given a ring $\mathbb{Z}_{2^\ell}$, mask and secret share the adjacency matrix $\hat{\mathbf{A}}$, feature matrix $\hat{\mathbf{F}}$, model weights $\mathbf{W_0}$ and $\mathbf{W_1}$ to two servers, and generate randomnesses.
- OblivAgg: Each party evaluates the matrix multiplications over the shared matrices, i.e., $[\![\hat{\mathbf{A}}]\!]_b \times [\![\hat{\mathbf{F}}]\!]_b \times [\![\mathbf{W_0}]\!]_b$ for the first layer, and $[\![\hat{\mathbf{A}}]\!]_b \times [\![\mathrm{ReLU}(\hat{\mathbf{A}}\hat{\mathbf{F}}\mathbf{W_0})]\!]_b \times [\![\mathbf{W_1}]\!]_b$ in the second layer, without revealing them.
- OblivAct: Each party uses the shares from the OblivAgg to perform oblivious ReLU, Softmax and Argmax.

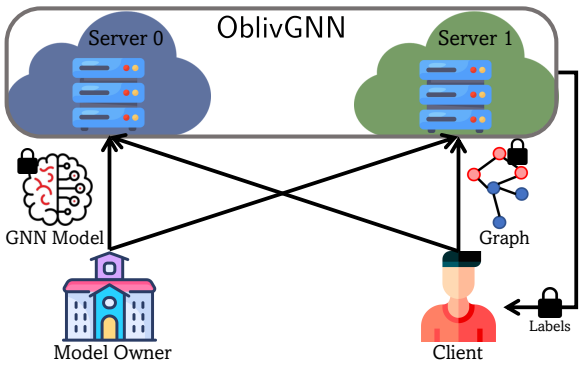

Figure 1: System Architecture of OblivGNN.

Oblivious *Inductive* works in a similar way to Oblivious *Transductive* yet additionally supports oblivious update OblivUpdate, therefore we only describe the above here.
Oblivious *Inductive*:

- OblivUpdate: Upon receiving the new node information $[\![\hat{\mathbf{A}}^*]\!]_b$ and $[\![\hat{\mathbf{F}}^*]\!]_b$, update the shares on each party to include the newly added nodes and updated node features.

3.2 Threat Model

We consider our system to be a secure cloud-based GNN inference service that protects both data privacy and data access pattern (*obliviousness*). Similar to the prior outsourced PPML schemes [16, 39, 46, 52], two servers execute the proposed protocol collaboratively and compute the inference result in secret shares. During the process, each server only observes computations over random numbers and cannot learn any model information, inputs or inference results [41].

We now describe the threat model and security scope of OblivGNN. OblivGNN operates in a semi-honest two-party setting following the works [28, 38, 44, 46, 51, 52], guaranteeing its users' data privacy if the adversary controls only one server. In particular, we assume that several non-colluding adversaries compromise one server at most. These adversaries do not deviate from the protocol but will try to infer input/model information based on their processed data/pattern. Prior works [16, 46, 52] indicate that two-party collusion can be prevented by making it costly or infeasible by placing two servers in different clouds or countries/jurisdictions. The laws/conflict of interest stop collusion [29] effectively. Furthermore, even in a semi-honest non-colluding adversary model, the compromised server can still observe the access pattern when accessing the graph (i.e., updating the graph matrices and the client inquiry). As stated in [21], the graph access pattern can be exploited even in an encrypted graph.

3.3 Security Guarantees

The GNN model owner outsources the GNN model and graph data to two servers for GNN inference service. During the process, the adversary can obtain the entire view of the OblivGNN protocol execution on the compromised server and analyse it. Nonetheless, all private information from the GNN model owners, including the adjacency matrix, feature matrix and model weights will not be revealed during inference.

In OblivGNN, the access pattern is protected (therefore named oblivious) from potential semi-honest adversarial attacks when accessing and updating the original graph. The access pattern protection also ensures the security of clients' interactions, e.g., the clients' inquiries when accessing and retrieving the inference outcomes.

4 PROTOCOL

We start by describing the strawman approach in Section 4.1. We then describe our OblivGNN in Section 4.2. We show and discuss our protocols in Algorithm 3, 5 and the complete protocols are shown in Algorithm 7 and Algorithm 8.

4.1 Strawman Approach

A naive solution to enable oblivious GNN inference can be achieved with the arithmetic secret sharing scheme. In particular, we leverage the following steps to obliviously evaluate Equation 1 from Section 2.1 to enable the *transductive* inference (Oblivious *Transductive*):

- $\mathsf{OfflineGen}(\mathbb{Z}_{2^\ell}, \hat{\mathbf{A}}, \hat{\mathbf{F}}, \mathbf{W_0}, \mathbf{W_1})$: The model owner shares the adjacency matrix $\hat{\mathbf{A}}$, feature matrix $\hat{\mathbf{F}}$, model weights $\mathbf{W_0}$ and $\mathbf{W_1}$ over the given ring $\mathbb{Z}_{2^\ell}$. Then, the model owner sends the shares of $[\![\hat{\mathbf{A}}]\!]_b$, $[\![\hat{\mathbf{F}}]\!]_b$, $[\![\mathbf{W_0}]\!]_b$, $[\![\mathbf{W_1}]\!]_b$ to Server b.
- $\mathsf{OblivAgg}(\mathbb{Z}_{2^\ell}, [\![\hat{\mathbf{A}}]\!]_b, [\![\hat{\mathbf{F}}]\!]_b, [\![\mathbf{W_0}]\!]_b, [\![\mathbf{W_1}]\!]_b)$: In the background, the model owner continuously generates beaver's multiplication triples, shares them over the given ring $\mathbb{Z}_{2^\ell}$, and sends them to Server b. With triples, two servers jointly compute the matrix multiplication with ASS additions [3] and Beaver's Triples [5] based multiplications.
- $\mathsf{OblivAct}(\mathbb{Z}_{2^\ell})$: The strawman approach leverages the approximation techniques [32] to approximate the Rectified Linear Unit (ReLU) and softmax to a polynomial. Then, two servers evaluate the activation functions with ASS and beaver's triples over $\mathbb{Z}_{2^\ell}$.

We can further enable oblivious *inductive* inference (Oblivious *Inductive*):

- $\mathsf{OblivUpdate}(\mathbb{Z}_{2^\ell}, [\![\hat{\mathbf{A}}]\!]_b, [\![\hat{\mathbf{F}}]\!]_b)$: When the client or the model owner performs updates on the graph by inserting nodes and updating features, they directly modify the adjacency matrix $\hat{\mathbf{A}}$ and feature matrix $\hat{\mathbf{F}}$. Then, those matrices are shared over $\mathbb{Z}_{2^\ell}$ and sent to the servers.

The above design is fully oblivious. Because all the above-mentioned operations (i.e., matrix multiplications, polynomial

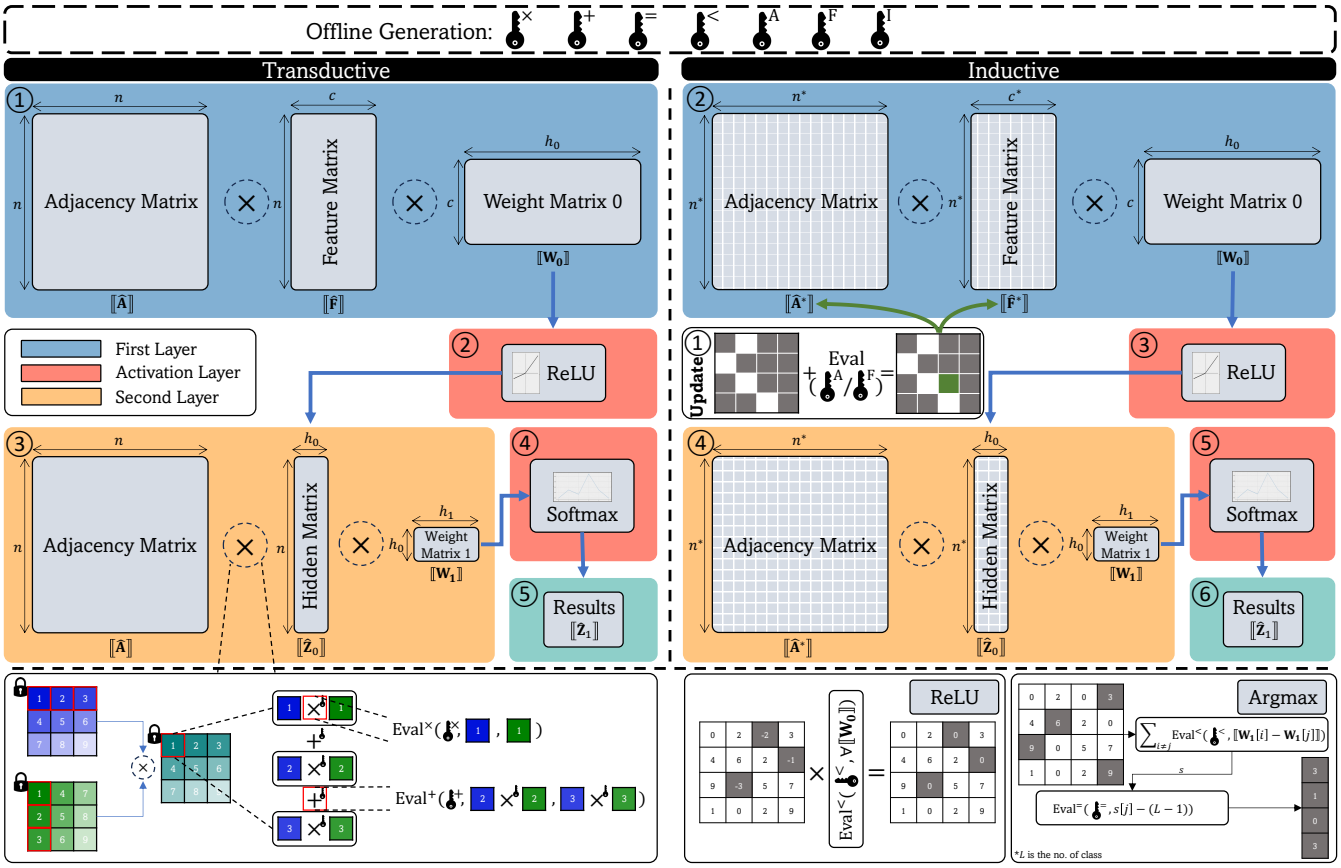

Figure 2: Protocol Overview of OblivGNN

evaluations, and graph updates) always execute the same process regardless of the input in the view of two servers. However, we noticed two problems: 1) the runtime/communication costs were significant due to adopting Beaver's Triple in aggregation. 2) to update obliviously, the communication cost of re-uploading the updated graph is significant. To address the above issues, we propose the OblivGNN approach.

4.2 OblivGNN Approach

To address the above two problems: we use Arithmetic FSS to save the significant runtime and communication costs due to adopting Beaver's Triple in aggregation (1). We adopt DPF to update obliviously with reduced communication cost (2).

Our focus has been primarily on executing secure GNN inference on the static graph (i.e., transductive setting). However, it is important to note that nodes and features may require updates in practice. We will discuss how OblivGNN approach facilitates the oblivious graph updates, limits the graph information leakage and substantially improves efficiency. Details are elaborated in the subsequent sections, and an illustration is provided in Figure 2.

Overview. The OblivGNN's oblivious inference operates as follows. In the *offline phase*, the model owner generates randomnesses to mask the normalised adjacency matrix, normalised feature matrix, and model weights. The randomnesses are also used to form the FSS keys pool, for all multiplication and addition pairs in oblivious matrix multiplication between the above matrices. The graph matrices are then split into secret shares using ASS from Section 2.3. In the inductive setting, the client or the model owner prepares the DPF keys for graph update, according to the updated subgraph's adjacency and feature matrix on the client side.

In the *online phase*, the model owner secretly shares the masked normalised adjacency matrix, feature matrix and the model weight matrices to both servers. Each party then performs oblivious aggregation by revealing the masked matrices and securely aggregating the neighbouring features for each node. The aggregated results then go through the first layer activation function, oblivious ReLU. As shown in Figure 2, the aggregation process will repeat with the oblivious softmax activation function for the second layer.

After two layers, the inference results are stored as secret shares in both parties. The client can then enquire the result(s) with specific node(s) ID. We will elaborate on each other the above protocol in the following sections.

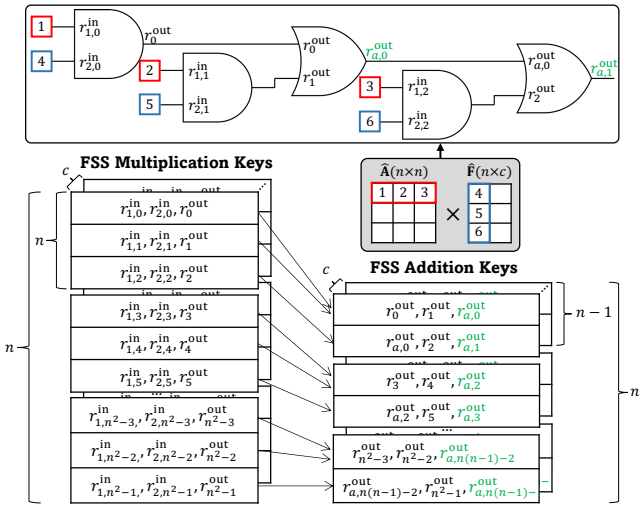

Figure 3: FSS Multiplicative and addition gates Chaining between Adjacency and Feature Matrix in OblivGNN

4.2.1 Oblivious Aggregation

The oblivious aggregation entitles the collection of information from nearby nodes. To protect the access pattern in aggregation, we employ matrix multiplication which linear accesses all nodes to naturally hide the access pattern.

To build secure matrix multiplication algorithms for oblivious aggregation, we leverage the FSS multiplication and addition gate, inspired by the works of Boyle et al. [7, 13].

FSS Circuit Chaining. To enable secure matrix multiplication, we should enable the secure dot product operation between each row and column of the matrix. While this is easy to be achieved with ASS, we realise that it is not straightforward to realise with FSS. This is because the FSS-based arithmetic operations consider a specific operation as a gate, which has randomnesses associated with the input and output wires of the gate (see Section 2.2). As a result, when calculating multiple arithmetic operations with FSS, it generates a circuit structure, where the randomness associated with the output wire of a gate, will be the randomness used by the input wire of the next gate.

In Figure 3, we provide an illustrative example for the dot product between one row and one column of the matrix. As shown in the figure, the dot product process will be converted to a circuit with FSS multiplication and addition gates. For each gate, three randomnesses $(r_1^{in}, r_2^{in}, r^{out})$ are selected and associated with the input/output wires of the gate, respectively (see Algorithm 1 and 2). For multiplication randomnesses, they can be selected independently since the multiplications in dot product are independent. However, the randomnesses for addition gates are correlated because they sum up the multiplication results to get the final result. More specifically, the randomnesses associated with the input wires of the addition gate are the randomnesses associated with the output wires of the previous multiplication gate or addition gate.

Without loss of generality, in the given example, when computing the dot product of the first row of $\hat{\mathbf{A}}$ and the first column of $\hat{\mathbf{F}}$, the multiplication of $\hat{\mathbf{A}}[0][i] \times \hat{\mathbf{F}}[i][0]$ for $i \in [0,2]$ are done with three independent sets of the randomnesses $(r_{1,i}^{in}, r_{2,i}^{in}, r_i^{out})$. When summing the multiplication outputs for the final dot product result, the circuit however requires to use the output wire randomnesses of prior gates that cascade to the addition gate. This covers two scenarios: The first one is that the addition gate is adding two outputs from multiplication gates ($\hat{\mathbf{A}}[0][0] \times \hat{\mathbf{F}}[0][0] + \hat{\mathbf{A}}[0][1] \times \hat{\mathbf{F}}[1][0]$ in our example), so it leverages r_0^{out} and r_1^{out} as the input wire randomnesses.

Following the above procedure, one can obtain a list of chained FSS keys that enable dot product operations for fixed-size vectors (the rows and columns of matrices) and thus can be readily used to support matrix multiplication.

The total number of arithmetic FSS keys depends on the size of the dataset. In Figure 2, there will be $n \times (nc + ch_0 + nh_0 + h_0h_1)(\mathrm{O}(n^2c))$ number of keys generated for FSS multiplication gate. And $(n-1) \times (nc + ch_0 + nh_0 + h_0h_1)(\mathrm{O}(n^2c))$ number of keys generated for FSS addition gate.

FSS Key Pool Generation. From the above, we observe that FSS keys are input-independent and solely rely on uniform randomnesses. This observation allows a similar pooling technique for Beaver's Triple [5], i.e., given the matrix sizes, the model owner can generate a large number of FSS keys following the above chaining process. Moreover, the model owner can distribute them to two servers in an offline phase for efficient matrix multiplications, while performing on-the-fly key pooling like in [46] to meet the query demands.

Aggregation functions. With the above FSS keys and pooling mechanism, two servers can conduct oblivious aggregation with matrix multiplication. In the aggregation function, two servers will have shared matrices $[\![\mathbf{X}]\!]_b$ and $[\![\mathbf{Y}]\!]_b$ and want to multiply them together. To bootstrap the computation, the model owner sends the FSS keys for one matrix multiplication to two servers. Also, he/she extracts the input wire randomnesses of multiplication gates to form two mask matrices $\mathbf{R_1}$ and $\mathbf{R_2}$ with the same sizes as $[\![\mathbf{X}]\!]_b$ and $[\![\mathbf{Y}]\!]_b$. These two mask matrices will be shared as additive secret share matrices $[\![\mathbf{R_1}]\!]_b$ and $[\![\mathbf{R_2}]\!]_b$ and sent to two servers to mask the corresponding elements in $\mathbf{X}$ and $\mathbf{Y}$, respectively.

Upon receiving the shared mask matrices and the FSS keys, two server first compute $[\![\mathbf{X'}]\!]_b = [\![\mathbf{X}]\!]_b + [\![\mathbf{R_1}]\!]_b$ and $[\![\mathbf{Y'}]\!]_b = [\![\mathbf{Y}]\!]_b + [\![\mathbf{R_2}]\!]_b$. Then, they exchange their local shares of $[\![\mathbf{X'}]\!]_b$ and $[\![\mathbf{Y'}]\!]_b$ to recover the masked $\mathbf{X'}$ and $\mathbf{Y'}$. With masked matrices, two servers can directly compute FSS-based multiplications and additions without interactions, and get $\mathbf{Z'} = \mathbf{X} \times \mathbf{Y} + \mathbf{R_{out}}$ at the end of the execution. In Algorithm 3, we provide the oblivious aggregation process in details. Note that the oblivious aggregation can be used to support the linear layer aggregation functions in each layer of GNN.

Algorithm 3: Oblivious Aggregation OblivAgg

Input: Shared matrices $[\![\mathbf{X}]\!]_b$ ($m \times n$ elements) and $[\![\mathbf{Y}]\!]_b$ ($n \times c$ elements)
Output: Masked aggregated results $\mathbf{Z}'$
Model Owner (FSS Key Pooling):
1) Generate $\mathbf{R_1}$ with $m \times n$ randomnesses, $\mathbf{R_2}$ with $n \times c$ randomness, and $\mathbf{R_{out}}$ with $m \times c$ randomness.
2) For $i \in [0, m-1]$,
3) For $j \in [0, c-1]$,
4) Initialise temp $r^{\times}_{out}$ and r^{+}_{out} arrays.
5) $\mathsf{KeyGen}^{+}(1^{\lambda}, r^{\times}_{out}[0], r^{\times}_{out}[1], r^{+}_{out}[0])$.
6) For $k \in [0, n-1]$,
7) $\mathsf{KeyGen}^{\times}(1^{\lambda}, \mathbf{R_1}[i][k], \mathbf{R_2}[k][j], r^{\times}_{out}[j])$.
8) $\mathsf{KeyGen}^{+}(1^{\lambda}, r^{+}_{out}[k-1], r^{\times}_{out}[k+1], r^{+}_{out}[k])$, if $k \in [1, n-3]$.
9) $\mathsf{KeyGen}^{+}(1^{\lambda}, r^{+}_{out}[n-3], r^{\times}_{out}[n-1], \mathbf{R_{out}}[i][j])$.
10) Share $\mathbf{R_1}$, $\mathbf{R_2}$ and $\mathbf{R_{out}}$ as $[\![\mathbf{R_1}]\!]_b$, $[\![\mathbf{R_2}]\!]_b$ and $[\![\mathbf{R_{out}}]\!]_b$.
Send $[\![\mathbf{R_1}]\!]_b$, $[\![\mathbf{R_2}]\!]_b$ and $[\![\mathbf{R_{out}}]\!]_b$ and FSS keys to P_b.
Party P_b:
1) Mask the shares of $[\![\mathbf{X}]\!]_b$ as $[\![\mathbf{X}']\!]_b = [\![\mathbf{X}]\!]_b + [\![\mathbf{R_1}]\!]_b$ and $[\![\mathbf{Y}]\!]_b$ as $[\![\mathbf{Y}']\!]_b = [\![\mathbf{Y}]\!]_b + [\![\mathbf{R_2}]\!]_b$.
2) Exchange shares with P_{1-b} to recover $\mathbf{X}'$ and $\mathbf{Y}'$.
3) For $i \in [0, m-1]$,
4) For $j \in [0, c-1]$,
5) Set vector $[\![\mathbf{Temp}]\!]_b$.
6) For $k \in [0, n-1]$,
7) $[\![\mathbf{Temp}[k]]\!]_b = \mathsf{FSS.Mul}(\mathbf{X}'[i][k], \mathbf{Y}'[k][j])$.
8) Exchange shares with P_{1-b} to recover **Temp**.
9) For $k \in [0, n-1]$,
10) $[\![\mathbf{Z}'[i][j]]\!]_b = \mathsf{FSS.Add}(\mathbf{Z}'[i][j], \mathbf{Temp}[k])$.
11) Exchange shares with P_{1-b} to recover $\mathbf{Z}'[i][j]$.
return $\mathbf{Z}' = \mathbf{Z} + R_{out}$.

4.2.2 Oblivious Graph Update

DPF Update Key Generation. During the update phase, some entries of the adjacent and feature matrices will be updated to new values. We note that if we directly update the matrix, it reveals the access pattern on the graph matrices and has the potential to disclose the underlying graph structure.

OblivGNN employs the DPF to hide the access pattern in graph updates. In particular, two sets of the key will be generated to implement two modifications, i.e., the connections relations change on the adjacency matrix and the feature updates on the feature matrix. Algorithm 4 demonstrates how to use the above two information with their location information. The algorithm extracts the updated node location (v_{i^*}) from the updated subgraphs $\mathbf{A}^*$ and $\mathbf{F}^*$. Then, it generates n DPF keys to update the v_{i^*} location of each row on the adjacent matrix, and c DPF keys to update the v_{i^*} location of each column on the feature matrix. Those keys will be sent to two servers to let them update their local shares of the adjacent matrix and the feature matrix, respectively.

Algorithm 4: DPF Update Key Generation UpdateKeyGen

Input: Updated subgraph $\mathbf{A}^*$ and $\mathbf{F}^*$
Output: k_b^{A}, k_b^{F}
1) Initialise $k_b^{\mathrm{A}}, k_b^{\mathrm{F}} \leftarrow \{\}$.
2) Extract the target node v_{i^*} for the update.
3) For $i \in [0, n-1]$, ; `// loop column`
4) $k_b^{\mathrm{A}}[i] \leftarrow \mathsf{KeyGen}(v_{i^*}, \mathbf{A}^*[v_{i^*}][i] - \mathbf{A}[v_{i^*}][i])$.
5) For $i \in [0, c-1]$, ; `// loop column`
6) $k_b^{\mathrm{F}}[i] \leftarrow \mathsf{KeyGen}(v_{i^*}, \mathbf{F}^*[v_{i^*}][i] - \mathbf{F}[v_{i^*}][i])$.

Algorithm 5: Oblivious Graph Update OblivUpdate

Input: New node adjacency and feature information $\hat{\mathbf{A}}$ and $\hat{\mathbf{F}}$, Graph Update DPF keys k_b^{A} and k_b^{F}
Output: Shares of updated adjacency matrix $[\![\hat{\mathbf{A}}]\!]_b$ and updated feature matrix $[\![\hat{\mathbf{F}}]\!]_b$
Party P_b:
1) For $i \in [0, n-1]$, ; `// loop column`
2) For $j \in [0, n-1]$, ; `// loop row`
3) $[\![\hat{\mathbf{A}}[j][i]]\!]_b = [\![\hat{\mathbf{A}}[j][i]]\!]_b + \mathsf{Eval}(k_b^{\mathrm{A}}[i], j)$.
4) For $i \in [0, c-1]$, ; `// loop column`
5) For $j \in [0, n-1]$, ; `// loop row`
6) $[\![\hat{\mathbf{F}}[j][i]]\!]_b = [\![\hat{\mathbf{F}}[j][i]]\!]_b + \mathsf{Eval}(k_b^{\mathrm{F}}[i], j)$.

Graph Update. With the DPF keys, two servers can easily update the graph with Algorithm 5. Specifically, to update the adjacency matrix, each server evaluates the given n DPF keys with inputs from $[0, n-1]$, and set the corresponding cell in each row to the evaluate output. By doing this, the connection of the updated point is changed while the access pattern of this update is hidden as the update scans the entire adjacency matrix. Similarly, each server can update the feature matrix by evaluating the given c DPF keys with inputs from $[0, n-1]$, and accumulates the evaluate output to corresponding cell in each column. Since the keys for the feature matrix update are generated by leverage the difference between new feature value and old one ($\mathbf{F}^*[v_{i^*}][i] - \mathbf{F}[v_{i^*}][i]$). The update process will replace the old feature with the new one, without revealing which node is updated.

Node Insertion. When inserting a new node, the model owner/client can directly shares the new node into two servers. Then, two servers can directly expand the adjacency (from $n \times n$ to $(n+1) \times (n+1)$) and feature (from $n \times c$ to $(n+1) \times c$) matrices and attach the shares to the expanded row/column. This process will not affect OblivGNN's security because the matrix size is not protected in OblivGNN.

However, since the matrix is expanded to fit the new node, the FSS pooling requires to be expanded accordingly to support the matrix multiplication with new matrix size. Fortunately, as stated in Section 4.2.1, the matrix multiplication can be seem as a series of independent dot products, thus we do not need to re- generate the FSS pooling to meet the computation requirement. Instead, we design a FSS key pooling

Algorithm 6: FSS Pooling Expansion PoolExpand

Input: Expanded $\mathbf{R_1}$ with $(m+1)\times(n+1)$ randomnesses, $\mathbf{R_2}$ with $(n+1)\times c$ randomness, and $\mathbf{R'_{out}}$ with $(m+1)\times c$ randomness; Original $\mathbf{R_{out}}$ with $m\times c$ randomness.

Model Owner:

1) For $i \in [0, m-1]$,
2) For $j \in [0, c-1]$,
3) Initialise temp $r^{\times}_{out}$ values.
4) $\mathsf{KeyGen}^{\times}(1^{\lambda}, \mathbf{R_1}[i][n], \mathbf{R_2}[n][j], r^{\times}_{out})$.
5) $\mathsf{KeyGen}^{+}(1^{\lambda}, \mathbf{R_{out}}[i][j], r^{\times}_{out}, \mathbf{R'_{out}}[i][j])$.
6) For $i \in [0, c-1]$,
7) Initialise temp $r^{\times}_{out}$ and r^{+}_{out} arrays.
8) $\mathsf{KeyGen}^{+}(1^{\lambda}, r^{\times}_{out}[0], r^{\times}_{out}[1], r^{+}_{out}[0])$.
9) For $j \in [0, n]$,
10) $\mathsf{KeyGen}^{\times}(1^{\lambda}, \mathbf{R_1}[m][j], \mathbf{R_2}[j][i], r^{\times}_{out}[j])$.
11) $\mathsf{KeyGen}^{+}(1^{\lambda}, r^{+}_{out}[j-1], r^{\times}_{out}[j+1], r^{+}_{out}[j])$, if $j \in [1, n-2]$.
12) $\mathsf{KeyGen}^{+}(1^{\lambda}, r^{+}_{out}[n-2], r^{\times}_{out}[n], \mathbf{R'_{out}}[m][i])$.
13) Share $\mathbf{R_1}$, $\mathbf{R_2}$ and $\mathbf{R'_{out}}$ as $[\![\mathbf{R_1}]\!]_b$, $[\![\mathbf{R_2}]\!]_b$ and $[\![\mathbf{R'_{out}}]\!]_b$.

Send $[\![\mathbf{R_1}]\!]_b$, $[\![\mathbf{R_2}]\!]_b$ and $[\![\mathbf{R'_{out}}]\!]_b$ and FSS keys to P_b.

expansion algorithm (see Algorithm 6) to assist this process.

For the existing nodes (i.e., nodes labeled with 0 to $m-1$), the algorithm calculates the FSS key for the multiplications of newly added nodes and features, and then create a FSS key for additions that sums the previous output at $\mathbf{Z}'[i][j]$ (masked by original $\mathbf{R_{out}}[i][j]$) and the new multiplication result into the same place that masked by expanded output mask matrix $\mathbf{R'_{out}}[i][j]$ (line 1-5). For the new node, the algorithm re-runs the pooling algorithm for it (line 6-12), which generates the FSS keys for value in $\mathbf{Z}[m][i], i \in [0, c-1]$.

Following the graph update, the servers initiate a single secured forward propagation, as outlined in Equation 1, using the updated $\hat{\mathbf{A}}$ and $\hat{\mathbf{F}}$. This process culminates in the generation of inference results for all nodes, including the newly inserted node, and stored within the result matrix $\mathbf{Z}$.

Remark. We can hide the graph size by padding the adjacency and feature matrix to 2^{ℓ} and use DPF to obliviously write the sub-graph information to the padded matrices. Moreover, a prominent feature of the update phase is that we use the DPF key to achieve a sub-linear complexity for both the communication and computation costs. In specific, the DPF key can compress a vector of n elements to $\lceil \log_2 n \rceil$ size and allow the vector to be recovered with $\lceil \log_2 n \rceil$ evaluations. In the experiment, we demonstrate that the update cost increases in the logarithm scale while the matrix size increases linearly.

4.2.3 Oblivious Activation Functions

Taking inspiration from Théo et al. [52], we employ the DPF equality test and comparison protocol to construct activation functions (i.e., ReLU, Softmax and Argmax). We provide a concise description of the DPF equality test (DPF.Equa) and the DPF comparison protocol (DPF.Comp) in Section 2.2. Subsequently, we demonstrate how these protocols can be employed in constructing activation functions.

We note that DPF.Comp has an opposite relationship (i.e., outputs 1 when input ≤ 0) to ReLU, therefore, we describe the oblivious bit flip protocol OblivBitFlip as follows.

1) $[\![\mathfrak{b}]\!]_0 = \mathsf{Eval}(k_0, [\![z]\!]_0)$, $[\![\mathfrak{b}]\!]_1 = \mathsf{Eval}(k_1, [\![z]\!]_1)$
2) $[\![\mathfrak{b}']\!]_0 = 0 - [\![\mathfrak{b}]\!]_0$, $[\![\mathfrak{b}']\!]_1 = 1 - [\![\mathfrak{b}]\!]_1$
3) $\mathfrak{b}' = [\![\mathfrak{b}']\!]_0 + [\![\mathfrak{b}']\!]_1 = 1 - ([\![\mathfrak{b}]\!]_0 + [\![\mathfrak{b}]\!]_1) = 1 - \mathfrak{b}$

Oblivious ReLU. We now use the aforementioned DPF.Comp to build the oblivious ReLU activation function. We describe the formal OblivReLU protocol on a $n \times c$ masked matrix $[\![\mathbf{X}]\!]_b$ as follows.

1) Each P_b exchanges its local share and recovers $\mathbf{X}$.
2) Each P_b receives $n \times c$ DPF.Comp keys.
3) Each P_b invoke received DPF keys to run DPF.Comp against each element in the aggregated matrix.
4) Each P_b invoke OblivBitFlip on DPF output $[\![\mathfrak{b}'[i][j]]\!]_b, i \in [0, n-1], j \in [0, c-1]$.
5) Each P_b outputs shared matrix that $[\![\mathbf{X}'[i][j]]\!]_b \leftarrow [\![\mathfrak{b}'[i][j]]\!]_b \times X[i][j]$

Oblivious Softmax. We develop the oblivious softmax function OblivSoftmax, inspired from the research by Mohassel et al. [46] and Keller et al. [31]. By removing the intricate power calculations in the MPC domain and leveraging the previously established low-interactive OblivReLU, we substitute the softmax function with the following function:

$$[\![\hat{\mathbf{z}}[i]]\!]_b := \begin{cases} \frac{\mathsf{OblivReLU}([\![z]\!]_b)}{\sum_i \mathsf{OblivReLU}([\![z[i]]\!]_b)}, & \text{if } \sum_i \mathsf{OblivReLU}([\![z[i]]\!]_b) > 0 \\ 1/L, & \text{otherwise} \end{cases} \tag{2}$$

To ensure the obliviousness when evaluating the above equation, we rely on the implementation in MP-SPDZ [30] to obliviously compute the division via garbled circuit. Moreover, the branching conditions are replaced with oblivious if, i.e., the equations for all conditions will be evaluated, but the condition will be used as an oblivious selector $((a\&condition)|(b\&\neg condition))$ to obtain the final result.

Oblivious Argmax. This function lets each party P_b find the location of the largest element in array z with L element.

We use DPF.Equa and DPF.Comp to formally construct the Oblivious Argmax (OblivArgmax) protocol below.

1) Each P_b: $[\![s[j]]\!]_b \leftarrow \sum_{i \neq j} \mathsf{DPF.Comp}([\![z[i] - z[j]]\!]_b)$
2) Each P_b: $[\![z'[j]]\!]_b \leftarrow \mathsf{DPF.Equa}([\![s[j] - (L-1)]\!]_b)$

The protocol checks whether $z[i] \leq z[j]$ for each $i \neq j$ and sums the check results into $s[j]$. Then, we can use a DPF.Equa key to check if $s[j] = (L-1)$, which means DPF.Comp for $z[i] \leq z[j]$ returns 1 for all $L-1$ elements, and thus be the largest element. The OblivArgmax protocol returns an array z', which only has shared '1' at the position with the largest element and '0' in other places.

Algorithm 7: Full Protocol of *transductive* OblivGNN

Model Owner:

1) Model Owner secret-shares the matrices $\hat{\mathbf{A}}, \hat{\mathbf{F}}, \mathbf{W_0}, \mathbf{W_1}$ to party P_b.
2) Model Owner create FSS pools for:
   $\mathsf{OblivAgg}([\![\hat{\mathbf{A}}]\!]_b, [\![\hat{\mathbf{F}}]\!]_b)$,
   $\mathsf{OblivAgg}([\![\hat{\mathbf{A}}\hat{\mathbf{F}}]\!]_b, [\![\mathbf{W_0}]\!]_b)$,
   $\mathsf{OblivAgg}([\![\hat{\mathbf{A}}]\!]_b, [\![\mathsf{ReLU}(\hat{\mathbf{A}}\hat{\mathbf{F}}\mathbf{W_0})]\!]_b)$,
   $\mathsf{OblivAgg}([\![\hat{\mathbf{A}}\mathsf{ReLU}(\hat{\mathbf{A}}\hat{\mathbf{F}}\mathbf{W_0})]\!]_b, [\![\mathbf{W_1}]\!]_b)$.

Party P_b:

1) 1st Layer: P_b runs:
   $[\![\hat{\mathbf{A}}\hat{\mathbf{F}}]\!]_b \leftarrow \mathsf{OblivAgg}([\![\hat{\mathbf{A}}]\!]_b, [\![\hat{\mathbf{F}}]\!]_b)$,
   $[\![\hat{\mathbf{A}}\hat{\mathbf{F}}\mathbf{W_0}]\!]_b \leftarrow \mathsf{OblivAgg}([\![\hat{\mathbf{A}}\hat{\mathbf{F}}]\!]_b, [\![\mathbf{W_0}]\!]_b)$,
   $[\![\mathsf{ReLU}(\hat{\mathbf{A}}\hat{\mathbf{F}}\mathbf{W_0})]\!]_b \leftarrow \mathsf{OblivReLU}([\![\hat{\mathbf{A}}\hat{\mathbf{F}}\mathbf{W_0}]\!]_b)$
2) 2nd Layer: P_b runs:
   $[\![\hat{\mathbf{A}}\mathsf{ReLU}(\hat{\mathbf{A}}\hat{\mathbf{F}}\mathbf{W_0})]\!]_b \leftarrow$
   $\mathsf{OblivAgg}([\![\hat{\mathbf{A}}]\!]_b, [\![\mathsf{ReLU}(\hat{\mathbf{A}}\hat{\mathbf{F}}\mathbf{W_0})]\!]_b)$,
   $[\![\hat{\mathbf{A}}\mathsf{ReLU}(\hat{\mathbf{A}}\hat{\mathbf{F}}\mathbf{W_0})\mathbf{W_1}]\!]_b \leftarrow$
   $\mathsf{OblivAgg}([\![\hat{\mathbf{A}}\mathsf{ReLU}(\hat{\mathbf{A}}\hat{\mathbf{F}}\mathbf{W_0})]\!]_b, [\![\mathbf{W_1}]\!]_b)$.
3) For $i \in [0, n-1]$,
   $[\![\mathbf{Z}[\mathbf{i}]]\!]_b \leftarrow$
   $\mathsf{OblivSoftmax}([\![\hat{\mathbf{A}}\mathsf{ReLU}(\hat{\mathbf{A}}\hat{\mathbf{F}}\mathbf{W_0})\mathbf{W_1}[\mathbf{i}]]\!]_b)$.
   $[\![\mathbf{Z}'[\mathbf{i}]]\!]_b \leftarrow \mathsf{OblivArgmax}([\![\mathbf{Z}[\mathbf{i}]]\!]_b)$.
4) Recover masked $\mathbf{Z}'[\mathbf{i}]$.

Client:

1) For a targeted node v_{i^*}, generate the query DPF key $k_b^{\mathrm{Q}} \leftarrow \mathsf{KeyGen}(v_{i^*}, 1)$ and send to P_b.

Party P_b:

1) For $i \in [0, h_1 - 1]$,
2) For $j \in [0, n-1]$,
3) $[\![\hat{\mathbf{r}}[j]]\!]_b \mathrel{+}= \mathsf{Eval}(k_b^{\mathrm{Q}}, i) \times Z'[j][i]$.
4) **Return $[\![\hat{\mathbf{r}}]\!]_b$ to Client**

Client:

1) Recover $\hat{\mathbf{r}}$, de-mask it and get the inference result.

Remark. The DPF keys used in the activation function can also be pooled in advance. Particularly, both the OblivReLU and OblivArgmax require the DPF keys to check whether the input is < 0, while OblivArgmax needs additional keys to check whether the input is $= L-1$. Since the above-mentioned values are input-independent, we can create a DPF pool to keep those keys the same as in OblivAgg.

4.2.4 Putting It Together

Having examined all essential components of the proposed Oblivious Graph Neural Network (OblivGNN), we are now prepared to integrate these elements into cohesive protocols. The complete protocols are presented for both *transductive* and *inductive* settings in Algorithm 7 and 8, respectively.

At the end of the protocol execution, two servers obtain a masked $n \times h_1$ matrix (the full graph classification results)

Algorithm 8: Full Protocol of *inductive* OblivGNN

1) Model Owner/Client sends newly added node as additive shares to P_b.
2) Model Owner/Client runs PoolExpand to update FSS key pool
3) Model Owner/Client runs $\mathsf{UpdateKeyGen}(\mathbf{A}^*, \mathbf{F}^*)$ and send k_b^{A}, k_b^{F} to P_b.
4) P_b attaches new node into original $\mathbf{A}$ and $\mathbf{F}$.
5) P_b runs $\mathsf{OblivUpdate}(k_b^{\mathrm{A}}, k_b^{\mathrm{F}})$ to update the graph
6) Run the transductive protocol in Algorithm 7 to get the inference result.

from the OblivArgmax. The client uses a DPF key generated with the targeted node ID to retrieve the inference result.

Security. It is intuitive to see that OblivGNN achieves the required security level. First, the aggregation process is a secure version of matrix multiplication, which will access all elements in the matrix, and thus oblivious. Moreover, non-linear functions, including ReLU, Softmax, Argmax and graph update, are implemented with DPF. This ensures that even if the same input is given for those functions, the DPF scheme will randomise it, so the adversary who controls one server cannot know the actual input. On the other hand, those DPF-based functions will perform a linear scan over the entire input domain (e.g., all elements in the feature matrix for node update), hiding the access pattern against the adversary on one server. In Appendix A, we formally define the real/ideal game for each protocol and provide a detailed security analysis.

Efficiency. From the Table 2, it is clear that the OblivGNN achieved a remarkable imporvement in efficiency. First, by adopting the FSS multiplication and addition gate, these cryptographic techniques have effectively addressed the challenges of communication overhead and computational efficiency while providing inherent protection to access pattern. The adaptation of arithmetic FSS gates also limited the graph information (e.g. maximum neighbouring n) leakage compared to [14, 50, 59]. Therefore, making OblivGNN feasible and efficient for real-world applications involving large-scale graphs and sensitive data.

5 Implementation and Evaluation

In this section, we have implemented OblivGNN, based on the proposed protocols. We now present the experimental settings and results in this section.

5.1 Setup

Platform. Our system is developed in both Python and C++. We have deployed the OblivGNN using the MP-SPDZ secure framework [30]. The computational environment is a server with 3.70GHz Intel(R) Xeon(R) E-2288G CPU, 64GB RAM and 128GB external storage running Ubuntu 20.04.5 LTS.

	Communication Cost	Computational Cost
Baseline	$16 \cdot O(n^2 \cdot m)$	$(2 \times T_{\text{Sub}} + 4 \times T_{\text{Mul}} + 3 \times T_{\text{Add}}) \cdot O(n^2 \cdot m)$
OblivGNN	$8 \cdot O(n^2 \cdot m)$	$(2 \times T_{\text{Sub}} + 4 \times T_{\text{Mul}} + 3 \times T_{\text{Add}}) \cdot O(n^2 \cdot m)$

Table 2: Theoretical Complexity: communication and computational cost between baseline and OblivGNN in online phase. v is a full-domain evaluation parameter (see Section 5.3). T_{Mul} is the time cost for single multiplication, T_{Add} is the time cost for single addition, T_{Sub} is the time cost for single subtraction.

Dataset	Nodes	Feature	Edge	Classes
Cora	2708	1433	5429	7
Citeseer	3327	3703	4732	6
Pubmed	19717	500	44338	3

Table 3: Dataset Statistics

The experiment was conducted in two phases: the offline phase and the online phase. Each phase is conducted within two different settings, i.e., transductive and inductive settings.

Dataset. The OblivGNN system is designed to be compatible with a variety of graph datasets, provided they adhere to the correct data structure. For our experiments, we selected three widely recognized and trusted graph datasets: Cora, Citeseer and Pubmed. A summary of the statistical characteristics of these graph datasets is presented in Table 3 below.

Baseline. In our experiments, we employed our strawman approach, using ASS for aggregation and approximation for activation, as the baseline approach.

Our evaluation results are presented in the following sections. We will begin by providing the microbenchmark statistics of our protocol in Section 5.2, followed by detailed comparisons of runtime, communication, latency, graph update cost and accuracy in Section 5.3.

5.2 Microbenchmark

Runtime. In this subsection, we perform a comprehensive runtime analysis, comparing the detailed runtime cost between the OblivGNN and the baseline approach. The detailed figures are shown in Figure 4. The microbenchmark evaluation is segmented into four distinct sections, focusing on the runtime comparison between the linear layer and non-linear layer across the two aforementioned layers.

The first and second layer linear comparison centres around the dimensions between the normalised adjacency matrix $\hat{\mathbf{A}}$ and normalised feature matrix $\hat{\mathbf{F}}$. As evident from the data presented in 4a and 4c, our optimised oblivious matrix multiplication algorithm, denoted as OblivAgg, yields a notable decrease in the runtime compared to the baseline approach. In the baseline, the initial layer of Cora, Citeseer, and Pubmed exhibits runtimes of 14.34, 25.8, and 73.18 seconds, respectively. In contrast, in OblivGNN we proposed, these runtimes have been notably reduced to a mere 4.92, 4.75, and 5.72 seconds for three datasets, respectively. Moreover, the second layer also faces a significant reduction in runtime. In the baseline setup, the runtime for the second layer of three datasets is 496.03, 643.824 and 11252.50 seconds respectively, while it is merely 2.53, 2.90 and 1.64 seconds in the OblivGNN setup. Given the distinct sizes of these matrices across various datasets, the associated runtimes naturally vary.

The runtime comparison between activation layers is notably evident in 4b, the OblivReLU function exhibits a significant reduction in computation time compared to the baseline approach. In the baseline approach, the runtime for ReLU for three datasets is 10.1072, 12.612 and 75.1263 seconds. In contrast to the baseline approach, the OblivGNN setup achieves a mere 0.99, 1.22 and 8.73 seconds respectively. Furthermore, the runtime (Figure 4d) significantly benefited from the improved MPC-friendly OblivSoftmax (Section 4.2.3). The strawman approach achieves 149.01, 159.52 and 509.45 seconds respectively in runtime, while the OblivGNN achieves 126.00, 132.40 and 393.83 seconds respectively.

Communication. In this subsection, we conduct a breakdown analysis of the communication time between OblivGNN and the baseline. Similar to the previous runtime microbenchmark, we analyse the communication cost in each layer.

The advantages observed in the first (Figure 5a) and second (Figure 5c) linear layers benefit from the integration of the low-communicative FSS addition and multiplication in the OblivAgg. Regarding the first linear layer, the highest communication reduction appears in the Pubmed dataset where the first linear layer reduced from 102.95MB to 31.30MB. The first linear layer for the other two datasets reduced from 209.35MB and 469.71MB to 98.88MB and 80.76MB. This trend of notable reductions is also observed in the second linear layer. The FSS-based matrix multiplication incurs noteworthy reductions in communication costs between servers and therefore, benefits both runtime and communication cost.

As evidenced in the first non-linear layer (Figure 5b), ReLU benefits from integrating DPF in the OblivReLU. The employment of DPF requires minimal inter-server communication in oblivious ReLU, OblivReLU. As evidenced in Figure 5b, the communication reduction in three datasets is 2.08MB to 0.26MB, 2.56MB to 0.36MB and 15.17MB to 1.89MB. The reduction of communication overheads is achieved while fortifying the protection of the access pattern inherent to the ReLU activation function. As shown in Figure 5d, the oblivious softmax OblivSoftmax is also advantaged by these adaptations. The communication cost for OblivSoftmax are reduced from 90.26, 95.47 and 295.03MB to 84.47, 88.97 and 263.58MB respectively among three datasets.

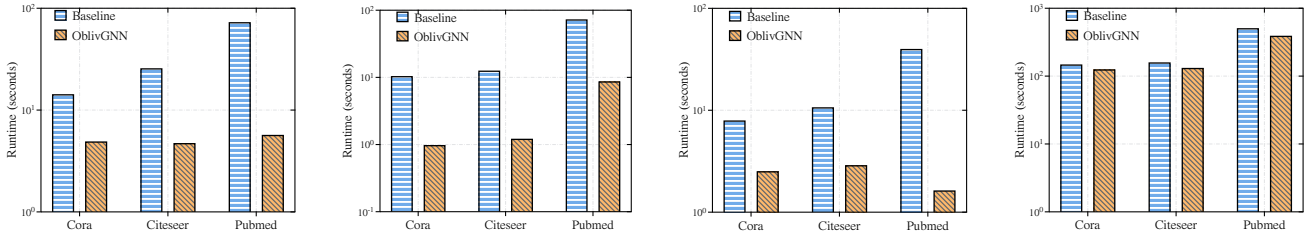

Figure 4: Microbenchmark Runtime: the layer-by-layer comparison between baseline and OblivGNN using three graph datasets in the log scale, in the unit of seconds(s).

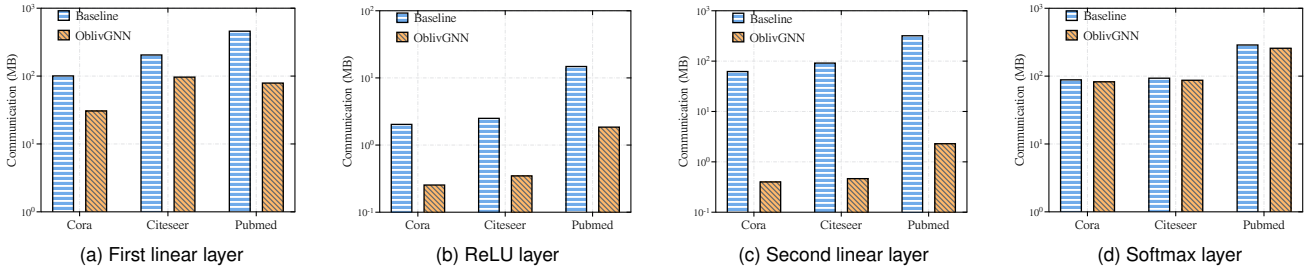

Figure 5: Microbenchmark Communication: the layer-by-layer inter-server communication comparison between baseline and OblivGNN using three graph datasets in the log scale, in the unit of MegaBytes (MB).

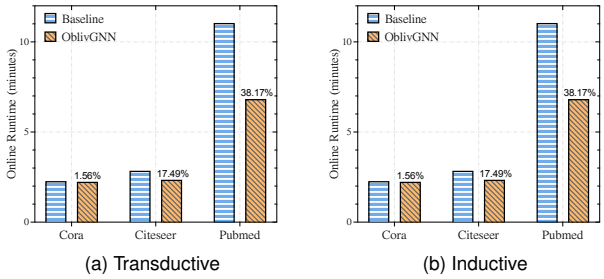

Figure 6: Runtime Comparison: the comparison between OblivGNN and baseline in three datasets, under transductive and inductive settings in the unit of minutes.

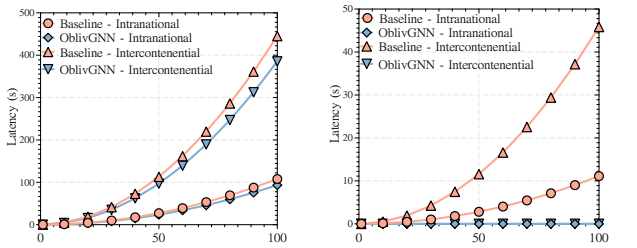
5.3 System

Runtime. This subsection discusses the runtime cost under both transductive and inductive settings. The online runtime comparisons are shown in Figure 6a and 6b.



In Cora, Citeseer and Pubmed datasets, we observed substantial improvements in inference time, amounting to 1.56%, 17.49% and 38.17%, respectively. This notable enhancement in the performance of OblivGNN can be largely attributed to our innovative OblivAgg algorithm. We identified that the most time-consuming operation during GNN inference, particularly between the adjacency matrix and the feature matrix, involves matrix multiplication. Consequently, by employing FSS multiplication and addition gates, inspired by Boyle et al. [13], as opposed to additive secret shares, we achieved substantial time savings compared to the multiplication operation employed in additive secret sharing, which relies on Beaver's triple [5]. The overall cost (offline+online) varies between datasets, using Cora as an example, the total time of the baseline is 136.57 seconds, while for OblivGNN is 200.09 seconds. In Pubmed dataset, the total time for baseline is 662.97 seconds, while the OblivGNN achieves 410.06 seconds.

Communication. The analysis of communication costs is categorized into two scenarios: communication between the model owner and servers, and communication between servers. We will discuss each of the techniques below and the influences on communication cost.

The communication between the model owner and the servers involves transmitting two crucial information: graph information and key pools. To elaborate further, the graph information includes the adjacency matrix, feature matrix and weight matrix. Additionally, the key pools include the FSS key pool and the DPF key pool for oblivious secure computation. It is noteworthy that an equal volume of graph information is transmitted, thereby we note that the communication cost of graph information remains constant compared with the baseline and plaintext. Furthermore, it is important to note that the FSS and DPF key pool generated in the offline phase vary according to datasets. As demonstrated in Figure 3, the size of the FSS keys depends on the overall size of the graph (using Cora dataset as an example, the DPF key size is 32.23 MB and the FSS key size is 459.89 TB). Similarly, the size of DPF keys is directly affected by two primary factors: the size of the subgraph and the total number of inquiries.

	Baseline	**OblivGNN**
Cora	34.21	**0.29**
Citeseer	61.81	**0.41**
Pubmed	16.33	**1.65**

Table 4: Communication Cost Comparison between servers: the comparison between three baselines with three different graph datasets, in the unit of GB.

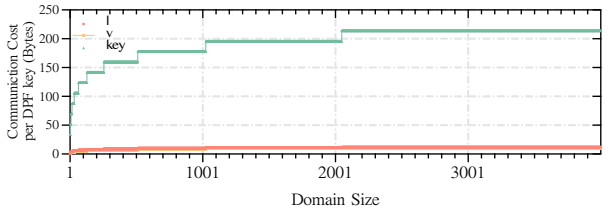
(a) Overall Intranational and Intercontinental Latency

(b) Intranational and Intercontinental Latency in Linear Layers

Figure 7: Latency: the latency comparison between OblivGNN and baseline under intranational (65 ms) and intercontinental (268 ms) server geographic settings.

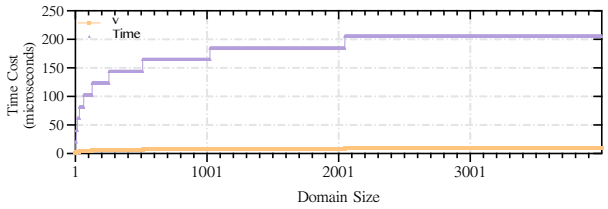
Table 4 provides a breakdown of the communication cost between servers.[1] Notably, the communication cost between servers is reduced when compared to the baseline, with a reduction range from 10× to 151×. This reduction benefits from the substitution of Beaver's triples with the non-interactive arithmetic FSS gates. The primary communication cost incurred in this process involves the revelation of the masked expressions $\hat{\mathbf{A}} + r_1^{in}$ and $\hat{\mathbf{F}} + r_2^{in}$. The adoption of non-interactive arithmetic FSS gates notably reduces inter-server communication expenses, thereby directly influencing the inference runtime, as shown in Figures 6a and 6b.

Latency. Here, we delve into two geographic scenarios concerning the spatial distribution of servers. The first scenario is an intra-national setup, where we presume the servers to be geographically situated within a country, such as the east and west coasts of America. The second scenario is an intercontinental setup, where we consider the servers as geographically distributed across separated continents, such as West America and East Asia. According to Google Cloud Inter-Region Latency and Throughput [42], the current intra-national latency is 65 ms and the intercontinental latency is 268 ms. We show our results in the Figure 7a and 7b.



As shown in Figure 7b, the linear layer latency in OblivGNN is consistent, contrasting with the exponential growth shown in the baseline approach. However, the overall latency shown in Figure 7a suggests that the OblivGNN has a similar trend as the baseline approach. The reason can be found in Figure 5d, where the OblivSoftmax layer in OblivGNN demonstrates lower but similar communication cost as the baseline approach. It is caused by the oblivious if (if_else) in the MP-SPDZ framework [30], which uses multiplexer (MUX) on bit in arithmetic circuits to determine the conditional selection on numbers. The use of garbled circuit to implement the oblivious selection (if $\sum_i \mathsf{OblivReLU}(\llbracket z[i] \rrbracket_b) > 0$ or otherwise) dominates the cost of OblivSoftmax and leads to a similar trend in overall latency. However, we also notice that due to the consistent growth in OblivGNN linear layer, OblivGNN is more scalable towards larger graphs compared to the baseline approach. We leave the optimisation of activation functions as future work.

Graph Update Cost. In this subsection, we will concentrate on the discussion of graph update costs. For the node insertion without modifying the current node connections and feature attributes, the communication cost will be the appended adjacency matrix plus the appended feature matrix. For instance, if the client or the model owner wants to add $n^{\#}$ (where $n^{\#} = n^* - n$) number of new nodes to the graph, the adjacency matrix will incur a communication cost of $2 \times n^{\#}$ and the feature matrix will incur $n^{\#} + c$. However, access pattern leaks if the model owner or the client have the opportunity to use their own proprietary graphs to update the original graph under the inductive setting. As described in Algorithm 5, DPF keys are employed to protect the access pattern from leakage. DPF keys $k^{\mathrm{A}}_{b\in\{0,1\}}$ and $k^{\mathrm{F}}_{b\in\{0,1\}}$ are generated and evaluated to update the adjacency matrix and feature matrix during the inference stage. Consequently, the time and communication costs will be directly related to the number of nodes that are inserted. We provide a summary of the full-domain DPF key generation evaluation [6] as follows.



The size of the DPF keys varies depending on the dataset. We assume that the DPF key generation and evaluations are carried out within the domain of $\mathbb{Z}_{2^a}$, where a is calculated by $\lceil \log_2 n \rceil$ and n is the number of nodes in the dataset. For Cora and Citeseer dataset, there are 2708 and 3327 nodes respectively, therefore $a = \lceil \log_2 2708 \rceil = \lceil \log_2 3327 \rceil = 12$, while Pubmed has 19717 nodes, thus $a = \lceil \log_2 19717 \rceil = 15$. The a will be used in the key length calculation.

To expedite the evaluation process, we employ full-domain DPF evaluation, a technique introduced in [6]. Full-domain evaluation incorporates an optimisation called early termination. Such optimisation allows the evaluation process to halt at 2^v rather than continuing until 2^a, resulting in a speedup of 2^{a-v}. The DPF keys have a key length as follows: $18 \times (v+1) + 16$, where $v = \lceil a - \log_2(\frac{\lambda}{\log_2 |\mathbb{Z}_{2^\ell}|}) \rceil$, in the unit of bytes. λ (security parameter) is 128, and $\mathbb{Z}_{2^\ell}$ (output group) is 2^{32}. The value of v for each of the three datasets can be calculated as follows. As demonstrated in Figure 8a, both the Cora and Citeseer datasets share the same value of $a = 12$. Consequently, the values of v for these datasets are determined to be 10, resulting in a single DPF key size of

[1] The communication cost for baseline Pubmed is too big and leads to counter overflow. This blocks us from getting the precise result, which should be the highest among all three datasets due to its size. Nonetheless, the current result has shown a huge communication cost save with OblivGNN.

(a) Node/Feature Update Key Size

(b) Node/Feature Update Time Cost

Figure 8: Node/Feature Update cost: Comparison of communication cost and time cost according to the domain size.

0.214 KB. On the other hand, the Pubmed dataset has $v = 13$, which translates to a key size of 0.268 KB. As depicted in Figure 8b, the average time required for a full-domain DPF evaluation is 206 microseconds for Cora and Citeseer, and 249 microseconds for Pubmed.

Accuracy. We now discuss the accuracy comparison across three datasets between OblivGNN and baseline model, considering both transductive and inductive settings.

Table 5 provides a comprehensive comparison across three widely-accepted datasets: Cora, Citeseer, and Pubmed (refer to Table 3 for dataset details). Each dataset is evaluated in both transductive and inductive settings. The unsecured plaintext test serves as the benchmark for comparison. The plaintext achieves the highest accuracy results, with the highest in the transductive Cora (87.82%) and lowest in inductive Citeseer (74.77%). The baseline approach and OblivGNN achieve similar levels of accuracy. The baseline achieved the highest accuracy in transductive Cora (81.92%) and the lowest in inductive Citeseer (72.96%). While the OblivGNN achieved 83.76% in transductive Cora and 72.97% in inductive Citeseer. Considering the significant reduction in runtime cost, communication cost and latency, OblivGNN demonstrates a noticeable advantage compared with the baseline.

6 Related Works

Privacy-Preserving Machine Learning. Previous works in PPML [9, 16, 19, 28, 38, 44–46, 49, 51, 52, 56, 58] have primarily focused on Convolutional Neural Networks [48] and Recurrent Neural Networks [55]. Their primary objective is protecting users' data while enabling machine learning tasks (i.e., classification, prediction) on sensitive data. The existing solutions face limitations in processing and preserving the privacy of graph-structured data for GNNs tasks.

Despite the presence of previous works in the field of PPML, there are attempts to design secure GNN services. Notably, SecGNN [59] introduced the first system designed to support secure GNN training and inference services in a cloud environment. Moreover, CryptoGCN [50], introduced a secure GNN model that optimised matrix operations to substantially reduce computational overheads.

However, existing secure GNN solutions [14, 50, 59, 65] still exhibit limitations, such as the lack of support for *inductive* setting (dynamic graphs) and high computational/communication overheads. While LinGCN [14] minimises the computational/communication overheads, expensive cryptographic tools still pose challenges in cost.

Graph Neural Networks. GNNs have attracted significant attention in recent years due to their potential for handling complex graph-structured data in machine learning. Gori et al. [24] first introduced the concept of GNNs, and subsequent studies [10, 22, 36, 54] contributed to the development of Recurrent Graph Neural Networks (RecGNNs). Spectral-based Convolutional GNNs emerged by the introduction of spectral convolution methods for graphs [8], inspiring subsequent studies [11, 33]. NN4G by Micheli et al. [43] led to the emergence of Spatial-based Convolutional GNNs [20, 25, 57, 64].

Inference Attacks against GNNs. Inference Attacks, such as stealing and membership inference attacks, pose significant dangers to data privacy and model security in GNNs. Model stealing attacks (MSA) [61] reverse-engineer the GNN model by exploiting query access or its predictions. Membership inference attacks (MIA) [60] in GNN target to identify whether specific nodes [12] or links [26] were part of the training graph based on the model's behaviour [62]. Note that such attacks are marked orthogonal to typical PPML works [19, 38, 44, 52, 56] that aim to protect models/inputs/results during computation, and consider inference from computation results out of scope.

Some works [15, 47, 53] have shown that DP naturally provides defence against MIA. If DP noises(e.g., perturbation on graphs and/or gradients) are added during the training phase, the methods are complementary to OblivGNN. For customised DP-based methods such as Kolluri et al. [34], it requires careful adaption in OblivGNN, as those methods also modify the GNN model architecture. For MSA, watermarking techniques [63] were proposed to detect the stolen GNN models. As watermarks are injected during the training phase, OblivGNN can also readily support those defences. However, watermarking is limited to the detection of stealing without proactive defence.

7 Conclusion

We present OblivGNN, a lightweight and low-communicative/computational oblivious system designed for securing transductive and inductive inference on GNNs, in the semi-honest two-server setting. We emphasise the

	Plaintext		Baseline		OblivGNN	
	Transductive	Inductive	Transductive	Inductive	Transductive	Inductive
Cora	87.82%	83.95%	81.92%	80.44%	83.76%	81.92%
Citeseer	76.13%	74.77%	74.93%	72.96%	75.53%	72.97%
Pubmed	85.12%	84.71%	82.60%	83.49%	83.24%	83.65%

Table 5: Accuracy Comparison: the comparison between three baselines with three different graph datasets, under transductive and inductive settings.

significance of this work and highlight the existing research gap between current PPML models and plaintext GNN models. OblivGNN contributes a set of comprehensive algorithms that enable OblivGNN to perform oblivious and low-interactive inference on both *transductive* (static graphs) and *inductive* (dynamic graphs) settings. Finally, we proceed to implement OblivGNN using the MP-SPDZ framework and evaluate its performance against the baseline model on three prominent datasets: Cora, Citeseer, and Pubmed. Through extensive experiments, we showcase promising results achieved by OblivGNN.

A Security Analysis

A.1 Security Definition

Definition A.1 (FSS Security)**.** *We say that the (*$\mathsf{KeyGen}^{=}$, $\mathsf{KeyGen}^{<}$, $\mathsf{Eval}^{=}$, $\mathsf{Eval}^{<}$*) as defines above, is a FSS scheme if it satisfies the following requirements:*

Security: *For each* $b \in \{0,1\}$*, there is a Probabilistic Polynomial Time (PPT) algorithm Simulator* $\mathcal{S}_b$*, such that for polynomial-size all-prefix function with sequence* $((\alpha,\bar{\beta})_\lambda)_{\lambda\in\mathbb{N}}$ *and polynomial size input sequence* α_λ*, the outputs of the following experiments* Real *and* Ideal *are indistinguishable:*

- Real_λ : $(k_0,k_1) \leftarrow \mathsf{KeyGen}(1^\lambda,(\alpha,\bar{\beta})_\lambda)$*; Output* k_b*.*
- Ideal_λ : *Output* $\mathcal{S}_b$*.*

A.2 Security Proof

We employ a simulation framework [37] based on multiparty computation (MPC) to establish the security assurances of OblivGNN. Within this framework, we consider a probabilistic polynomial-time (PPT) adversary denoted as $\mathcal{A}$, who possesses the ability to statically compromise one of the two servers. In the influence from $\mathcal{A}$, the corrupted server is permitted to act as a semi-honest entity, implying that it may acquire knowledge while adhering to the protocol's specifications. To streamline the clarity of our proof, we assume that the client behaves honestly.

To prove security under the simulation paradigm entails the definition of two distinct worlds: the real world, where

the protocol is executed by trustworthy parties, and an ideal world, where an ideal functionality denoted as $\mathcal{F}$ accepts inputs from the involved parties and produces the desired output for the relevant party. The adversary $\mathcal{A}$ monitors the interactions on compromised servers through the protocol execution. To ensure the adversary $\mathcal{A}$ cannot differentiate between the real world and the ideal world, we introduce a simulator, denoted as $\mathcal{S}$. The simulator $\mathcal{S}$ imitates messages between the model owner, honest server, client and the corrupt server in the real world. It is important to note that the simulator $\mathcal{S}$ only interacts with the adversary $\mathcal{A}$ and ideal functionality $\mathcal{F}$. If the adversary $\mathcal{A}$ cannot distinguish between the ideal world and the real world with the messages provided by ideal functionality $\mathcal{F}$ using the defined leakage, we consider our protocol to be secure.

Ideal Functionality $\mathcal{F}$. We first define our ideal functionality $\mathcal{F}$ to be a graph neural network and provide the graph data inference service as follows:

1) $\mathsf{OblivAgg}(k^{\times}, k^{+}, \hat{\mathbf{F}}, \hat{\mathbf{A}})$: $\mathcal{F}$ performs aggregation between $\hat{\mathbf{A}}$ and $\hat{\mathbf{F}}$ by employing the FSS keys, $k^{\times}, k^{+}$.
2) $\mathsf{OblivReLU}(k^{<})$ and $\mathsf{OblivSoftmax}(k^{<})$: $\mathcal{F}$ performs OblivReLU and OblivSoftmax on the aggregated graph data and repeats for the second layer.
3) $\mathsf{OblivUpdate}(k^{\mathrm{A}}$ and $k^{\mathrm{F}})$: $\mathcal{F}$ performs OblivUpdate using the DPF keys (k^{A}) to update the adjacency matrix and the DPF keys (k^{F}) to update the feature matrix.
4) $\mathsf{OblivArgmax}(k^{=}, k^{<})$: $\mathcal{F}$ performs OblivArgmax using the DPF keys $k^{=}$ and $k^{<}$ to calculate the most possible class and store the result.

We allow the ideal functionality $\mathcal{F}$ to leak the following information. 1) the size of the graph information (e.g., the total number of nodes, the feature size), 2) the model size (e.g., the weight sizes), 3) the number of FSS and DPF keys, 4) the FSS and DPF key size.

Definition A.2. *Let Π be a protocol for secure Graph Neural Network (GNN) inference service, which takes input Q from the model owner and client. The trustworthy party Π provides the functionality modelled by the above-defined ideal functionality $\mathcal{F}$. The adversary $\mathcal{A}$ observes the view from the corrupted server while the protocol runs. Let $\mathsf{View}^{\mathrm{Real}}_{\Pi(Q)}$ denote the view from $\mathcal{A}$ in real world. Let $\mathsf{View}^{\mathrm{Ideal}}_{\mathcal{S},\mathsf{Leak}(\mathcal{F}(Q))}$ denote the simulated view generated by Simulator $\mathcal{S}$ for $\mathcal{A}$. For all non-uniform PPT algorithms $\mathcal{A}$ with λ as security parameter, there exists a PPT algorithm $\mathcal{S}$ such that:*

$$\Pr[Q \leftarrow \mathcal{A}(1^{\lambda}); b \in \{0,1\}, \mathcal{A}(\mathsf{View}_b, Q) = b] \leq \frac{1}{2} + \mathrm{negl}(\lambda)$$

where $\mathsf{View}_0 = \mathsf{View}^{\mathrm{Real}}_{\Pi(Q)}$, $\mathsf{View}_1 = \mathsf{View}^{\mathrm{Ideal}}_{\mathcal{S},\mathsf{Leak}(\mathcal{F}(Q))}$

Theorem A.1. *According to the Definition A.2,* OblivGNN *is secure when evaluating the inputs from the ideal function $\mathcal{F}$.*

Proof. We will initiate our proof by describing the construction of the simulator $\mathcal{S}$ in the context of the ideal world. Our approach adheres to the hybrid models described in [37], assuming the sub-protocols gradually replacing the protocols in the real world. As long as it is demonstrated that all the sub-protocols are proven to be indistinguishable from the real world, it is then conclusively proven that OblivGNN is secure.

Simulator Construction. Assuming that the P_0 is the corrupted party. Upon receiving inputs Q and known leakage $Leak(\mathcal{F}(Q))$, the simulator $\mathcal{S}$ performs as follows:

1) On receiving $(Leak(\mathcal{F}(Q)))$ from $\mathcal{F}$: $\mathcal{S}$ conducts DPF and FSS key generation, considering the leakage $\mathcal{L}$.
2) On receiving $(k^{\times}, k^{+}, \hat{\mathbf{F}}, \hat{\mathbf{A}})$ from $\mathcal{F}$: $\mathcal{S}$ conducts random number sampling for the matrix, considering the received matrix size. It maintains a local copy and simultaneously conveys a duplicate to $\mathcal{A}$.
3) On receiving $k^{<}$ from $\mathcal{F}$: $\mathcal{S}$ samples random numbers for matrices after ReLU and Softmax, ensuring the output size aligns appropriately. Following this, $\mathcal{S}$ transmits the share of the sampled matrix for P_0 to $\mathcal{A}$.
4) On receiving k^{A} and k^{F} from $\mathcal{F}$: $\mathcal{S}$ employs random number sampling to create updated graph matrices. The dimensions of these updated matrices are contingent on the size of the original matrices and the number of keys received. $\mathcal{S}$ then forwards the P_0's share of the updated sampled graph matrices to $\mathcal{A}$.
5) On receiving $k^{<}$ and $k^{=}$ from $\mathcal{F}$: $\mathcal{S}$ samples random numbers for matrix after Argmax. The matrix size depends on the input matrix size. $\mathcal{S}$ then sends share of P_0 to $\mathcal{A}$.

We now dive into the proof that the above-generated views from $\mathcal{S}$ are indistinguishable between the real world and ideal world with the security parameter λ through the following hybrids $\mathcal{H}0 ... \mathcal{H}3$.

Hybrid 0. We initiate the hybrid with the real world.

Hybrid 1. Simulator $\mathcal{S}$ replaces the FSS $k^{\times}, k^{+}$, DPF keys $k^{=}$ and DCF keys $k^{<}$ with the output from the above-defined FSS, DPF and DCF simulators $\mathcal{S}_{\mathrm{FSS}}$, $\mathcal{S}_{\mathrm{DPF}}$ and $\mathcal{S}_{\mathrm{DCF}}$ from model owner. Based on the security analysis of FSS, DPF and DCF schemes, it implies that the probability of $\mathcal{A}$ can distinguish between $\mathcal{H}0$ and $\mathcal{H}1$ is $\mathrm{negl}(\lambda)$.

Hybrid 2. Simulator $\mathcal{S}$ replaces the DPF keys k^{A}, k^{F} and k^{Q} with the generated DPF keys based on real graph matrices for OblivUpdate, client inquiry from client. Based on the security analysis of DPF schemes, the probability of $\mathcal{A}$ can distinguish between $\mathcal{H}1$ and $\mathcal{H}2$ is $\mathrm{negl}(\lambda)$.

Hybrid 3. Simulator $\mathcal{S}$ replaces adjacency matrix $\mathbf{A}$ and feature matrix $\mathbf{F}$ with the simulated graph matrices. The probability of $\mathcal{A}$ can distinguish between $\mathcal{H}2$ and $\mathcal{H}3$ is $\mathrm{negl}(\lambda)$.

This concludes the proof for Theorem A.1. It is proven that $\mathcal{A}$ with the views cannot distinguish between the real world and ideal world, except with the probability $\leq \frac{1}{2} + \mathrm{negl}(\lambda)$.

MD-ML: Super Fast Privacy-Preserving Machine Learning for Malicious Security with a Dishonest Majority

Abstract

Privacy-preserving machine learning (PPML) enables the training and inference of models on private data, addressing security concerns in machine learning. PPML based on secure multi-party computation (MPC) has garnered significant attention from both the academic and industrial communities. Nevertheless, only a few PPML works provide malicious security with a dishonest majority. The state of the art by Damgård *et al.* (SP'19) fails to meet the demand for large models in practice, due to insufficient efficiency. In this work, we propose MD-ML, a framework for Maliciously secure Dishonest majority PPML, with a focus on boosting online efficiency.

MD-ML works for n parties, tolerating corruption of up to $n-1$ parties. We construct our novel protocols for PPML, including truncation, dot product, matrix multiplication, and comparison. The online communication of our dot product protocol is one *single* element per party, *independent* of input length. In addition, the online cost of our multiply-then-truncate protocol is *identical* to multiplication, which means truncation incurs *no* additional online cost. These features are achieved for the *first* time in the literature concerning maliciously secure dishonest majority PPML.

Benchmarking of MD-ML is conducted for SVM and NN including LeNet, AlexNet, and ResNet-18. For NN inference, compared to the state of the art (Damgård *et al.*, SP'19), we are about 3.4–11.0× (LAN) and 9.7–157.7× (WAN) faster in online execution time.

1 Introduction

Machine learning (ML) is increasingly being applied in a wide variety of application domains. For instance, Neural networks (NN) have been extensively used in applications such as image and speech recognition, natural language processing, and financial forecasting. Although being a powerful tool that has been used to revolutionize various fields, ML is a data-driven approach, requiring a significant amount of data to train the models. This inevitably raises privacy concerns with regard to the data being used. The vast amount of personal data required for ML training creates opportunities for misuse and mishandling of sensitive information. As such, privacy-preserving techniques should be employed to ensure the privacy of the data being used. Besides model training, another dilemma of ML applications exists in inference services, where a company that owns a model provides ML inference services to customers. The company does not want to give out the model directly while the customers consider their data as private information and do not want to reveal it to others. Towards this, secure multi-party computation (MPC) is used to realize privacy-preserving machine learning (PPML) [40], addressing the dilemma of privacy concerns in ML.

MPC [20, 53] allows a set of mutually distrusting parties $P_1,\ldots,P_n$ to jointly compute a function $y = f(x_1,\ldots,x_n)$, where P_i holds its private input x_i. On a high level, MPC has the following security properties: (1) privacy—no set of t corrupted parties can learn more information than the output of the computation, and (2) correctness—no set of t corrupted parties can cause incorrect output.

The security of MPC can be formulated by requiring that execution of the protocol can be simulated and proven to be equivalent to the execution by a trusted third party [4, 36]. The assumed capabilities of an adversary can then be used to classify the level of security. Two of the most important security metrics are: (1) whether the adversary is assumed to be *semi-honest* or *malicious*, and (2) the number of parties the adversary is assumed to corrupt, more concretely, *honest majority* if the adversary can only corrupt less than 50% of the parties, and *dishonest majority* if it can corrupt 50% or more of the parties. With respect to the first security metric, a semi-honest adversary is assumed to honestly follow the protocol but tries to learn secret values (by analyzing the transcript of messages that it received and its internal state), whereas a malicious adversary is allowed to perform arbitrarily during the execution (*e.g.*, sending incorrect values). Malicious security (*i.e.*, security against a malicious adver-

*Corresponding authors.

sary) is more desired, providing stronger security guarantees, With respect to the second metric, dishonest majority is more desired as it enables two-party computation, and provides stronger collusion-resistance guarantees in multi-party computation.

Semi-honest PPML protocols have been successful in several previous works [6, 7, 27, 30, 39, 45, 49, 50, 52] in which efficiency has been significantly improved since the initial work [40]. Maliciously secure honest majority PPML protocols have also been developed with some success [51], some achieving fairness [6, 46] or guaranteed output delivery (GOD) [12, 28] in this security model.

Nevertheless, in real-world scenarios, the parties can be malicious or even collude to break the privacy of the data and the correctness of the results. In such cases, considering semi-honest or maliciously secure honest majority models does not perfectly satisfy the security requirements. The promotion of *maliciously secure dishonest majority* security model will significantly enhance the deployability of PPML.

Despite the success and efficiency achieved in semi-honest and malicious honest majority PPML, only a few works have explored PPML protocols considering the strong *maliciously secure dishonest majority* security model. Damgård *et al.* [15] pioneered this field by designing new cryptographic primitives and demonstrating their applications in decision trees and support vector machines (SVM) inference.

However as shown by Dalskov *et al.* [11], there is still a huge performance gap between protocols in the maliciously secure dishonest majority model and other weaker models, with the former being 1–3 orders of magnitude slower. For instance, [11] shows that the maliciously secure dishonest majority protocol in [15] is 277 times slower than the honest majority in MobileNet V1 1.0_224 inference, due to high communication costs. This limits the applications to larger ML models such as convolutional neural networks (CNNs).

It is worth noting that although Dalskov *et al.* [11] also consider malicious security with a dishonest majority, the underlying protocols remain the same with [15]. The quantization technique they consider is out of the scope of this paper. To the best of our knowledge, no follow-up work has improved the efficiency of PPML in this security model.

This work—We propose MD-ML, a framework providing fast, **M**aliciously secure, **D**ishonest majority pp**ML**. We focus on minimizing online communication costs and boosting online efficiency.

1.1 Our Contributions

We summarize our contributions below. For ease of reference, the term "SPD$\mathbb{Z}_{2^k}$+" is adopted to denote the state of the art by Damgård *et al.* [15], since their protocols are based on the SPD$\mathbb{Z}_{2^k}$ protocol [9].

Efficient Protocols for PPML. We extend the circuit-dependent preprocessing technique of TurboSpeedz [3] to the ring $\mathbb{Z}_{2^k}$, achieving the online communication of 1 ring element per party for each multiplication gate. Moreover, we construct our novel protocols for PPML, including (*cf.* Table 1):

Table 1: Comparison of theoretical online communication cost with SPD$\mathbb{Z}_{2^k}$+ [15]

Online comm. of	Ours	SPD$\mathbb{Z}_{2^k}$+
Multiplication	1	2
Vector dot product†	1	$2m$
Matrix multiplication‡	hw	$2hmw$
Matrix multiplication with truncation‡	hw in 1 round	$hw(2m+1)$ in 2 rounds

† Vector length is m.
‡ Sizes of matrices are $h \times m$ and $m \times w$.

- Multiplication with truncation (§4.1): Truncation is needed after each multiplication in fixed-point arithmetic (FPA), which is crucial for applications in ML. We integrate truncation operation with multiplication *without* any additional online communication cost. To the best of our knowledge, this feature is achieved for the *first* time in maliciously secure dishonest majority model.

- Vector dot product (§4.2): For vector dot product, we achieve the online communication of only one *single* element per party, *independent* of input vector length. To the best of our knowledge, this feature is achieved for the *first* time in maliciously secure dishonest majority security model.

- Matrix multiplication (§4.2): For multiplication of matrices with sizes $h \times m$ and $m \times w$, online communication cost is hw ring elements per party. This is $2m\times$ improvement over SPD$\mathbb{Z}_{2^k}$+ [15] which requires $2hmw$ elements online communication for each party.

- Secure Comparison (§4.3): To enable computing non-linear functions of ML models, we refine the existing mask-and-compare technique [15, 38] in the context of circuit-dependent preprocessing, and propose our efficient secure comparison procedure.

UC-secure PPML. Our framework works for any n parties, allowing malicious corruption of any $n-1$ parties. We rigorously show the security of all of our protocols in the UC framework [4], for the first time in maliciously secure dishonest majority PPML literature.

Implementing and Benchmarking. We implement our protocols and building blocks to show the practicality of our constructions in PPML. We carry out extensive benchmarks

on SVMs and NNs, in particular CNN models such as ResNet-18. The results show significant efficiency improvement of our constructions over the state of the art. For CNN inference, we are about 3.4–11.0× (LAN) and 9.7–157.7× (WAN) faster in online execution time compared to SPD$\mathbb{Z}_{2^k}$+ [15]. The highlights are summarized in Table 2.

Table 2: Improvement over SPD$\mathbb{Z}_{2^k}$+ [15] in terms of online execution time and communication for ML model inference

Model	Time		Comm.
	LAN	WAN	
SVM	4.3–12.8×	3.4–13.6×	1.9–2.1×
LeNet	3.4–9.2×	9.7–31.7×	2.0–2.9×
AlexNet	8.0–11.0×	93.3–157.7×	9.8–23.8×
Resnet-18†	25.8 s	362.9 s	4.15 GB

† ResNet-18 inference are not carried out for SPD$\mathbb{Z}_{2^k}$+, we instead provide performance of our MD-ML framework here.

1.2 Technical Overview

Throughout the paper, our protocols are divided into an input-independent preprocessing phase and an online phase, similar to many other works [9, 14]. We use the circuit-dependent preprocessing technique to improve efficiency. The main idea is to introduce some extra random values (in addition to multiplication triples [2]) in the preprocessing phase. Then the opening of some values, which would have to be done round-by-round in the online phase, can be moved to and batched in one round in the preprocessing phase.

We start from the TurboSpeedz [3] protocol, which introduces circuit-dependent preprocessing over a finite field $\mathbb{F}$. We extend the circuit-dependent preprocessing technique to the ring $\mathbb{Z}_{2^k}$. The motivation is that (1) when implementing on modern CPUs, computations over the ring $\mathbb{Z}_{2^k}$ runs faster [15], and (2) protocols PPML-specific operations (*e.g.*, truncation, comparison) are easier to design and implement over the ring $\mathbb{Z}_{2^k}$.

Then we design our novel protocols for PPML. While TurboSpeedz [3] is restricted to only arithmetic circuits (*i.e.*, only considers addition and multiplication of integers), we show that by using circuit-dependent preprocessing technique the online efficiency of PPML can be significantly improved.

To extend circuit-dependent preprocessing to the ring $\mathbb{Z}_{2^k}$, notice that TurboSpeedz [3] uses the SPDZ-sharing [13, 14] as the underlying secret-sharing scheme. It turns out that replacing it with the SPD$\mathbb{Z}_{2^k}$-sharing suffices. We further introduce some optimizations to reduce online computation and storage. We also analyze the security of the protocols to prove them UC-secure.

Then, to construct our novel protocols for PPML, note that for every secret value $[x]$, the parties obtain a secret-shared value $[\lambda_x]$ from the circuit-dependent preprocessing phase, and open $\Delta_x = \lambda_x + x$ in the online phase.

- For truncation, we integrate the truncation operation into multiplication. We observe that the $[\lambda]$-values can be used both in the opening of Δ-values and in the truncation pairs. We make the online cost of multiplication-then-truncation operations identical to that of multiplications.
- For vector dot product, instead of executing the multiplication procedure for each underlying element multiplications, we sample only one random $[\lambda]$-value for the result, and require communicating only one ring element, regardless of vector length.
- For comparison of secret values, we adopt the mask-and-compare approach [15, 38]. By circuit-dependent preprocessing, we push the opening of the masked value to the preprocessing phase to reduce communication rounds.

In order to establish the UC-security of our protocols, we integrate all of the aforementioned procedures into a preprocessing protocol Π_{PrepPPML} and an online protocol $\Pi_{\mathsf{OnlinePPML}}$. By defining the corresponding functionalities as $\mathcal{F}_{\mathsf{PrepPPML}}$ and $\mathcal{F}_{\mathsf{OnlinePPML}}$, we proceed to conduct the security proofs.

Finally, it is worth noting that several recent works [18, 45] also uses circuit-dependent preprocessing. In particular, ABY2.0 [45] also achieves constant online communication for dot product. We briefly discuss these works and compare them with our constructions in §3.3.

1.3 Other Related Work

MPC-based PPML. SecureML by Mohassel *et al.* [40] is the first to consider MPC-based PPML. The protocol makes use of the ABY framework [16] and is capable of training and inference on small NNs. ABY3 by Mohassel *et al.* [39] considers the 3-party case for both semi-honest and malicious security. ASTRA by Chaudhari *et al.* [6] improves this by proposing faster online protocols for malicious security. BLAZE by Patra *et al.* [46] proposes maliciously secure protocols that support inference of neural networks with fairness security. SWIFT by Koti *et al.* [28] achieves GOD security for both 3PC and 4PC PPML, and Tetrad [30] further improves efficiency for 4PC with the same security. Falcon by Wagh *et al.* [51] shows the feasibility of training large CNNs in malicious security settings. CryptGPU by Tan *et al.* [49] and Piranha by Watson *et al.* [52] implements MPC-based PPML on GPU, further enhancing efficiency. Dalskov *et al.* [11] studies secure evaluation of quantized neural networks (QNN). Keller *et al.* [26] extends the MP-SPDZ framework [23] to

implement faster secure deep learning training. For a more comprehensive survey of PPML, we refer the readers to [41].

The SPDZ-line of work. A major pillar in maliciously secure dishonest majority MPC is the SPDZ-line of work. The SPDZ protocol by Damgård *et al.* [13, 14] introduces an innovative secret-sharing scheme based on message authentication codes (MACs) and a series of protocols to enable MPC over a finite field $\mathbb{F}$. MASCOT by Keller *et al.* [24] improves the offline phase of SPDZ by replacing the expensive homomorphic encryption and zero-knowledge proofs with oblivious transfer. Overdrive by Keller *et al.* [25] further improves the efficiency of the offline phase by using global zero-knowledge proofs and BGV encryption. Concurrently with Overdrive, the SPD$\mathbb{Z}_{2^k}$ protocol by Cramer *et al.* [9] overcomes the hurdle of only being able to do maliciously secure dishonest majority MPC over a finite field. Overdrive2k by Orsini *et al.* [44] extends Overdrive to the ring $\mathbb{Z}_{2^k}$ by introducing a special packing technique for BGV encryption. Escudero *et al.* [19] achieve a lower amortized communication complexity for MPC over $\mathbb{Z}_{2^k}$ by exploiting Galois rings. For a more comprehensive survey of the SPDZ-line of work, we refer the readers to [43].

1.4 Organization of This Paper

In §2 we introduce notations, state the security model used in the paper, and give background on the SPD$\mathbb{Z}_{2^k}$ secret-sharing scheme. In §3 we give our protocols for arithmetic circuits over the ring $\mathbb{Z}_{2^k}$. In §4 we give efficient building blocks for PPML including multiplication with truncation, vector dot product, and comparison. We show how to build SVMs and NNs in §5. We benchmark our MD-ML framework and compare it with the state of the art in §6, and conclude in §7.

Appendices. Appendix A contains the functionalities. Appendix B contains the procedures. Appendix C contains the protocols.

2 Preliminaries

2.1 Notation

For an integer L, we denote by $\mathbb{Z}_L$ the set of integers $\{0,1,\ldots,L-1\}$, and use $\lambda \xleftarrow{\$} \mathbb{Z}_L$ to denote that λ is uniformly random in $\mathbb{Z}_L$. For a vector $\vec{x}$, denote by $\vec{x}[i]$ the i-th element of $\vec{x}$. The dot product of $\vec{x}$ and $\vec{y}$ is denoted by $\vec{x}\cdot\vec{y}$. For a k-bit integer λ, we explicitly use $(\lambda_0,\ldots,\lambda_{k-1})$ to denote the bit decomposition of λ where λ_0 is the least significant bit. This notation is employed to differentiate the individual bits of λ from other subscripts. Denote by $(x<y)$ the comparison result of x and y, *i.e.*, $(x<y)=1$ if $x<y$, $(x<y)=0$ otherwise. Table 3 summarizes the notation we use in this paper.

Table 3: Notation used throughout this paper

$P_1, P_2, \ldots, P_n$	Parties performing secure computation
$\mathbb{Z}_L$	The set of integers $\{0,1,\ldots,L-1\}$
$\lambda \xleftarrow{\$} \mathbb{Z}_L$	λ is uniformly random in $\mathbb{Z}_L$
$\vec{x}\cdot\vec{y}$	Dot product of vectors $\vec{x}$ and $\vec{y}$
$\vec{x}[i]$	The i-th element of vector $\vec{x}$
$(\lambda_0,\ldots,\lambda_{k-1})$	the bit decomposition of λ
$(x<y)$	Comparison result of $x<y$
$[x]$	SPD$\mathbb{Z}_{2^k}$ arithmetic share of x (§2.3)
$[x]_2$	SPD$\mathbb{Z}_{2^k}$ binary share of $x \in \mathbb{Z}_2$ (§2.3)
k, s	Concrete parameters for SPD$\mathbb{Z}_{2^k}$ (§2.3)

2.2 Security Model

Our protocols work with n parties, and we consider security against a malicious, static adversary corrupting up to $n-1$ parties. In this context, "malicious" denotes that the corrupted parties may deviate arbitrarily from the protocol (*e.g.*, send incorrect values), and "static" denotes that corruption may only take place before protocol starts and remains fixed throughout protocol execution.

We prove our security statements in the universal composition (UC) framework of Canetti [4], where security is argued by the indistinguishability of an ideal world, modeled by a *functionality* (denoted by $\mathcal{F}$ with some subscript), and the real world, instantiated by a *protocol* (denoted by Π with some subscript). Protocols can invoke *procedures* (denoted by π with some subscript), which are like protocols but not intended to instantiate a functionality. Instead they are used as subroutines inside other protocols that instantiates some functionality.

2.3 The SPD$\mathbb{Z}_{2^k}$ Secret-sharing Scheme

We briefly recall the SPD$\mathbb{Z}_{2^k}$ secret-sharing scheme [9] in this section, which enables n parties to compute over the ring $\mathbb{Z}_{2^k}$ for any k (*e.g.*, $k=64$ for arithmetic circuits and $k=1$ [15] for boolean circuits). The main idea is that the parties carry out computations over the ring $\mathbb{Z}_{2^{k+s}}$, where $\sigma = s - \log s$ is the statistical security parameter, but security and correctness is only guaranteed modulo 2^k.

Definition of SPD$\mathbb{Z}_{2^k}$ secret-sharing scheme $[\cdot]_{2^k}$. Assume each party P_i (for $i=1,2,\ldots,n$) holds a uniformly random additive share $\alpha^i \xleftarrow{\$} \mathbb{Z}_{2^s}$ of a secret global MAC key $\alpha = \sum_{i=1}^n \alpha^i \bmod 2^{k+s}$. An element $x \in \mathbb{Z}_{2^k}$ is $[\cdot]_{2^k}$-shared if each party holds $x^i \in \mathbb{Z}_{2^{k+s}}$ and $m_x^i \in \mathbb{Z}_{2^{k+s}}$, where $x = \sum_{i=1}^n x^i \bmod 2^k$ is the element being shared, and $m_x = \sum_{i=1}^n m_x^i \bmod 2^{k+s}$ is the MAC, such that $m_x = (\sum_{i=1}^n x^i)\cdot\alpha \bmod 2^{k+s}$. We denote $[x]_{2^k} = \big((x^1,\ldots,x^n),(m_x^1,\ldots,m_x^n)\big)$. We abbreviate $[x]_{2^k}$ as $[x]$ when 2^k is a large integer (*e.g.*, $k=64$) and the context is

clear.

Linear combination of $[\cdot]$-sharing. The linear combination of secret-shared values can be locally computed by the parties. For instance, given secret-shared values $[x] = \left((x^1,\ldots,x^n),(m_x^1,\ldots,m_x^n)\right)$, $[y] = \left((y^1,\ldots,y^n),(m_y^1,\ldots,m_y^n)\right)$ and public constants a,b,c, the linear combination $[z] = a[x] + b[y] + c$ can be computed as $[z] = \left((z^1,\ldots,z^n),(m_z^1,\ldots,m_z^n)\right)$ where P_i locally computes $z^i = \begin{cases} ax^1 + by^1 + c, & \text{if } i = 1 \\ ax^i + by^i, & \text{if } i \neq 1 \end{cases}$ and $m_z^i = am_x^i + bm_y^i + c\alpha^i$ for $i = 1,\ldots,n$.

Opening $[\cdot]$-shared values and checking the MAC. To open $[x]$ so that all parties learn x in the clear, each party P_i use a random shared value $[r]$ to mask the upper s bits of x, getting $[\tilde{x}] = [x] + 2^k[r]$. Denote P_i's share and MAC share on $[\tilde{x}]$ by $\tilde{x}^i$ and $m_{\tilde{x}}^i$. Each party P_i broadcasts its own $\tilde{x}^i$ (but not $m_{\tilde{x}}^i$) and, upon receiving the values from other parties, computes $x = \sum_{i=1}^n \tilde{x}^i \bmod 2^k$. To ensure correctness, the MAC $m_{\tilde{x}}$ should be checked, but can be deferred and batched with other opened values. Procedure π_{MACCheck} of [9] takes as input a set of opened values and verifies the MACs of all the values, with failure probability negligible in s. For completeness, π_{MACCheck} is provided in Appendix B.1.

3 Efficient Protocols for Arithmetic Circuits

In this section, we provide our protocols for computing arithmetic circuits (*i.e.*, additions and multiplications) over the ring $\mathbb{Z}_{2^k}$. We extend the circuit-dependent preprocessing technique of TurboSpeedz [3] to MPC over the ring $\mathbb{Z}_{2^k}$. In §3.1 we provide a concise overview of the TurboSpeedz protocol. In §3.2 we propose our modifications and optimizations, then formally present our protocols and state the security theorems. It is worth noting that several recent works [18, 45] also uses circuit-dependent preprocessing. Thus, in §3.3 we discuss the techniques of ABY2.0, and explain why these techniques fails in the security model we concern.

3.1 An Overview of TurboSpeedz

The TurboSpeedz protocol [3] uses the SPDZ-sharing (denoted by $\langle\cdot\rangle$) as its underlying secret-sharing scheme. The SPDZ-sharing is the same as the SPD$\mathbb{Z}_{2^k}$-sharing (§2.3, denoted by $[\cdot]$), except that the secret data, the MAC key, and the sharings are from a finite field $\mathbb{F}$, instead of the ring $\mathbb{Z}_{2^{k+s}}$.

The protocol is divided into a circuit-dependent preprocessing phase and an online phase. Denote by x,y,z, *etc.* the wires in the circuit. The parties are assumed to have the following circuit-dependent preprocessing material: for every wire z in the circuit, the parties have a shared value $\langle\lambda_z\rangle$. If z is not the output of an addition gate, then λ_z is a uniformly random value. If z is the output of an addition gate with input wires x,y, then λ_z is defined (recursively) as $\lambda_z = \lambda_x + \lambda_y$. In addition, for each multiplication gate parties are assumed to have a shared multiplication triple $(\langle a\rangle, \langle b\rangle, \langle c\rangle)$ and values δ_x, δ_y, where $c = ab$, $\delta_x = a - \lambda_x$, $\delta_y = b - \lambda_y$.

Then, in the online phase, for a secret value x on wire x[1], parties are assumed to hold $\langle x\rangle$ and are required to learn $\Delta_x = x + \lambda_x$ in the clear. For an addition gate with input (x,y), it is clear that the parties can compute $\langle z\rangle = \langle x\rangle + \langle y\rangle$ and $\Delta_z = \Delta_x + \Delta_y$ locally. For a multiplication gate with input x,y, to get the result $\langle z\rangle$, the parties can compute the output as $\langle z\rangle = (\Delta_x + \delta_x)(\Delta_y + \delta_y) - (\Delta_y + \delta_y)\langle a\rangle - (\Delta_x + \delta_x)\langle b\rangle + \langle c\rangle$. This is correct since $\Delta_x + \delta_x = (x + \lambda_x) + (a - \lambda_x) = x + a$, and similarly $\Delta_y + \delta_y = y + b$, hence for the right-hand-side of $\langle z\rangle$ we have: $(\Delta_x + \delta_x)(\Delta_y + \delta_y) - (\Delta_y + \delta_y)a - (\Delta_x + \delta_x)b + c = (x + a)(y + b) - (y + b)a - (x + a)b + ab = xy = z$. Finally, to retain the knowledge of Δ-values, parties compute $\langle\Delta_z\rangle = \langle z\rangle + \langle\lambda_z\rangle$ and open it to get Δ_z.

3.2 Our Protocols

For our protocols, to enable computation over the ring $\mathbb{Z}_{2^k}$, we find that changing the underlying secret-sharing scheme from SPDZ-sharing ($\langle\cdot\rangle$) to SPD$\mathbb{Z}_{2^k}$-sharing ($[\cdot]$) suffices. However, the security of the protocols needs to be re-analyzed, as will be done later in this section.

Further optimizations can be introduced. In the aforementioned procedure, for a multiplication gate with output wire z, parties have to compute $[z]$, followed by computing $[\Delta_z] = [z] + [\lambda_z]$ and opening Δ_z. Patra *et al.* have noted in ABY2.0 [45] that it is unnecessary for the parties to compute and store the value $[z]$. Instead, only $[\Delta_z]$ is needed. This also holds for addition gates, where parties only need to compute $\Delta_z = \Delta_x + \Delta_y$ locally, without computing and storing $[z]$. We adopt this optimization and save 2 ring elements of storage in the online phase per wire per party.

We note that it is imperative for the parties to retain the knowledge of the $[\lambda]$-values corresponding to each wire during the preprocessing phase. Subsequently, during the online phase, for each gate the parties must compute and open the Δ-values associated with the output wire of that gate, based on the Δ-values of the input wires. This requirement holds true for all of the protocols proposed in §3 and §4.

For the preprocessing protocol, we rely on the SPD$\mathbb{Z}_{2^k}$ preprocessing functionality $\mathcal{F}_{\mathsf{Prep}}$ [9] for generating randomness. $\mathcal{F}_{\mathsf{Prep}}$ has three commands: Triple for generating a multiplication triple, Rand for generating a random shared element for all the parties, and Input for generating a random shared element $[r]$, where r is known by exactly one party in the clear. The formal definition of $\mathcal{F}_{\mathsf{Prep}}$ is given in Appendix A.1.

We are now ready to present the arithmetic-circuit preprocessing protocol $\Pi_{\mathsf{PrepArith}}$. The goal of $\Pi_{\mathsf{PrepArith}}$ is to generate the following material for the circuit: (1) a shared $[\lambda]$-value for each wire, (2) a shared multiplication triple for each multiplication gate, and (3) two public δ-values for each

[1] Note that we do not distinguish between the wire and its value, like the SPDZ-line of work [9, 14, 24].

multiplication gate. The above features are captured by the functionality $\mathcal{F}_{\mathsf{PrepArith}}$, which is described in Appendix A.2 due to space constraints. The protocol $\Pi_{\mathsf{PrepArith}}$ is presented below.

Protocol 1: $\Pi_{\mathsf{PrepArith}}$

The parties proceed in topological order of the circuit.
Input: For each input wire x of party P_i, parties call $\mathcal{F}_{\mathsf{Prep}}$.Input to get $([\lambda_x], \lambda_x)$ where λ_x is known to P_i in the clear, and all parties hold the sharing $[\lambda_x]$.
Add: For an addition gate with input wires x, y and output wire z, all the parties locally compute $[\lambda_z] = [\lambda_x] + [\lambda_y]$.
Multiply: For a multiplication gate with input wires x, y and output wire z, parties do the following:

1. Call $\mathcal{F}_{\mathsf{Prep}}$.Triple to get a multiplication triple $([a], [b], [c])$.
2. Locally compute $[\delta_x] = [a] - [\lambda_x]$ and $[\delta_y] = [b] - [\lambda_y]$.
3. Call $\mathcal{F}_{\mathsf{Prep}}$.Rand to get $[\lambda_z]$, where $\lambda_z \xleftarrow{\$} \mathbb{Z}_{2^k}$.

Now the parties have $[a], [b], [c], [\lambda_z], [\delta_x], [\delta_y]$ for a multiplication gate.
Output: Parties open the shared $[\delta]$-values for every multiplication gate to get them in the clear, then run π_{MACCheck} to check the MACs on values that are opened. If π_{MACCheck} aborts then the parties abort. Otherwise the protocol completes without failure.

The goal of the online protocol $\Pi_{\mathsf{OnlineArith}}$ is to let parties interactively obtain the Δ-values for each wire in topological order, and obtain the final output on their secret inputs, using the preprocessed material obtained in $\Pi_{\mathsf{PrepArith}}$. We capture these features in functionality $\mathcal{F}_{\mathsf{OnlineArith}}$, which is described in Appendix A.2 due to space constraints. The protocol $\Pi_{\mathsf{OnlineArith}}$ is presented below.

Protocol 2: $\Pi_{\mathsf{OnlineArith}}$

Initialize: Parties call $\mathcal{F}_{\mathsf{PrepArith}}$ with the circuit to get the δ-values, the shared $[\lambda]$-values, and the multiplication triples for each gate.
Then, parties proceed in topological order.
Input: For P_i to share its input value x, P_i computes and broadcasts $\Delta_x = x + \lambda_x$, then all parties store Δ_x.
Add: For an addition gate with input wires x, y and output wire z, parties locally compute $\Delta_z = \Delta_x + \Delta_y$.
Multiply: For a multiplication gate with input wires x, y and output wire z, all parties do the following:

1. Locally compute $[\Delta_z] = (\Delta_x + \delta_x)(\Delta_y + \delta_y) - (\Delta_y + \delta_y)[a] - (\Delta_x + \delta_x)[b] + [c] + [\lambda_z]$.
2. Open Δ_z to get Δ_z in the clear.

Output: To output the value on wire x, all the parties do the following:

1. Locally compute $[x] = \Delta_x - [\lambda_x]$ and open x in the clear.
2. Run π_{MACCheck} on all the values that have been opened so far. If π_{MACCheck} aborts then parties abort. Otherwise the output x is correct.

Now we state the security of our protocols. The proofs of the following theorems are given in the full version.

Theorem 1. *The protocol $\Pi_{\mathsf{PrepArith}}$ securely implements the functionality $\mathcal{F}_{\mathsf{PrepArith}}$ against a static, malicious adversary corrupting up to $n-1$ parties in the $\mathcal{F}_{\mathsf{Prep}}$-hybrid model.*

Theorem 2. *The protocol $\Pi_{\mathsf{OnlineArith}}$ securely implements the functionality $\mathcal{F}_{\mathsf{OnlineArith}}$ against a static, malicious adversary corrupting up to $n-1$ parties in the $\mathcal{F}_{\mathsf{PrepArith}}$-hybrid model.*

3.3 Comparison with Other Works

3.3.1 Comparison with ABY2.0

ABY2.0 by Patra *et al.* [45] also uses the circuit-dependent preprocessing technique to evaluate arithmetic circuits in *semi-honest two-party* computation. It is the state-of-the-art mixed-circuit framework in this security model. ABY2.0 achieves less communication in the preprocessing phase and the protocols are more concise. Nevertheless, the techniques of ABY2.0 cannot be directly applied to maliciously secure dishonest majority MPC, as demonstrated below.

ABY2.0 works similar as us: for a multiplication gate with input wires x, y and output wire z, the parties are assumed to have the sharings of circuit-dependently preprocessed values $\lambda_x, \lambda_y, \lambda_z$. The definition of these λ-values are the same as ours. However, instead of letting the parties have a multiplication triple (a, b, c) (which are independent of the λ-values), ABY2.0 let the parties hold a sharing of λ_{xy}, where $\lambda_{xy} = \lambda_x \lambda_y$ (*i.e.*, $(\lambda_x, \lambda_y, \lambda_{xy})$ forms a multiplication triple). This is done by having the parties execute a semi-honest triple generation protocol on inputs λ_x, λ_y.

This does not work for maliciously secure dishonest majority MPC, even if the underlying secret-sharing scheme of ABY2.0 is replaced by the SPD$\mathbb{Z}_{2^k}$-sharing. The triple generation protocol in malicious setting [9] cannot take two determined values (λ_x, λ_y in the above case) and output their product, since it involves a random linear combination step that randomizes the input values to ensure privacy in the presence of a malicious adversary.[2] Hence, the techniques of ABY2.0 cannot be directly applied to our protocols.

[2] Although the product of two determined values *can* be computed using a random triple, this incurs high communication cost and round complexity.

3.3.2 Discussions on flexible corruption

In another line of work, Goyal *et al.* [21] uncover the benefits of allowing flexible corruption wherein the corruption threshold is $t = n(1-\varepsilon)$ for a constant $0 < \varepsilon < 1/2$, as opposed to the conventional dishonest majority threshold of $t = n-1$ (n is the number of parties). Unlike most MPC protocols (including this work) where global communication grows linearly with n, the (amortized) global communication in [21] remains bounded by a constant, regardless of the growth of n. Subsequently, Escudero *et al.* [18] reduce this constant for the online phase by using the circuit-dependent preprocessing technique.

It is natural to explore the applicability of these techniques to our protocols for improved performance. However, the aforementioned works rely on packed Shamir secret-sharing, which is currently limited to arithmetic circuits over a moderately large finite field. Adapting these techniques for PPML necessitates either (1) extending packed Shamir secret-sharing to the ring $\mathbb{Z}_{2^k}$, or (2) devising ML operations (truncation, comparison, *etc.*) for packed Shamir secret-sharing over a finite field $\mathbb{F}$. Several works have been dedicated to both avenues. Regarding (1), Abspoel *et al.* [1] and Cramer *et al.* [10] propose techniques to transform Shamir secret-sharing to $\mathbb{Z}_{2^k}$. As for (2), Liu *et al.* [37] propose new truncation and comparison protocols for Shamir secret-sharing over $\mathbb{F}$. Nevertheless, these works primarily consider *non*-packed Shamir secret-sharing, leaving uncertainty regarding the compatibility and concrete efficiency of these techniques for packed Shamir-secret sharing. This issue is left as an open problem.

4 Building Blocks for Machine Learning

In this section, we further exploit the circuit-dependent preprocessing technique, and develop our novel building blocks for privacy-preserving machine learning. These include multiplication with truncation (§4.1), vector dot product (§4.2), and secure comparison (§4.3). We show that all of these building blocks benefit from circuit-dependent preprocessing, resulting in less online communication cost. In §4.4 we analyze the security and discuss the reactiveness of our constructions.

4.1 Multiplication with Truncation

Most of the computations in machine learning involve operating over decimals. To represent decimal values, we make use of fixed-point arithmetic (FPA). Values are represented as signed two's complement over the ring $\mathbb{Z}_{2^k}$ [40], with the most significant bit being the sign bit, and d least significant bits being the fractional part. Note that the computations are still carried out in $\mathbb{Z}_{2^{k+s}}$, but we only care about the values of the lower k bits. In FPA representation, the number of fractional bits doubles after each multiplication, therefore the multiplication result needs to be divided by 2^d (*i.e.*, truncate the last d bits) to avoid overflowing the ring $\mathbb{Z}_{2^k}$.

We provide a brief overview of existing truncation techniques. In ABY3 [39], the protocol involves generating shared random values $([r'],[r])$ in the preprocessing phase, where $r = r'/2^d$ (referred to as a truncation pair). During the online phase, parties compute and open $z'+r'$, followed by local computation of $[z] = (z'+r')/2^d - [r]$ to obtain the desired result. This approach requires one round of communication for multiplication and an additional round for truncation.

Subsequent works such as ABY2.0 [45], Swift [28], Tetrad [30], and MPClan [29] optimize the online cost of truncation by integrating it into the multiplication process. Instead of opening the intermediate result after multiplication and opening the final result after truncation, the intermediate result is masked with the random $[r']$ from the truncation pair and opened. This integration of the opening of masked value into the multiplication procedure helps reduce communication costs.

Inspired by the aforementioned techniques, we observe that in the multiplication procedure of $\Pi_{\mathsf{OnlineArith}}$, where $\Delta_{z'} = z' + \lambda_{z'}$ is opened, it is possible to locally truncate it to obtain $\Delta_z = \Delta_{z'}/2^d$. Assuming the parties possess $[\lambda_z]$ such that $\lambda_z = \lambda_{z'}/2^d$, it follows that $z = \Delta_z - \lambda_z = \Delta_{z'}/2^d - \lambda_{z'}/2^d = z'/2^d$, thereby completing the truncation. The crucial point is that $([\lambda_{z'}],[\lambda_z])$ not only functions as random masks in $\Delta_{z'}$ and Δ_z, but also serves as a truncation pair.

In order to generate the pair $([\lambda_{z'}],[\lambda_z])$ in the preprocessing phase, we no longer rely on $\mathcal{F}_{\mathsf{Prep}}.\mathsf{Rand}$ as in $\Pi_{\mathsf{PrepArith}}$. Instead, we utilize the functionality $\mathcal{F}_{\mathsf{edaBits}}$ for edaBits generation [17] to obtain the $(k-d)$-bit value $[\lambda_z]$ and a d-bit value $[u]$. Then $[\lambda_{z'}]$ can be locally computed as $[\lambda_{z'}] = 2^d \cdot [\lambda_z] + [u]$. The formal definition $\mathcal{F}_{\mathsf{edaBits}}$ is given in Appendix A.4. The procedure $\pi_{\mathsf{MultTrunc}}$ is described below.

Procedure 1: $\pi_{\mathsf{MultTrunc}}$

For a multiply-then-truncate gate with input wires x, y and output wire z, to multiply x, y and truncate the result by d bits:

Preprocessing phase:

1. Parties call $\mathcal{F}_{\mathsf{Prep}}.\mathsf{Triple}$ to get $([a],[b],[c])$.
2. Parties compute $[\delta_x] = [a] - [\lambda_x]$, $[\delta_y] = [b] - [\lambda_y]$ and open δ_x, δ_y.
3. Parties call $\mathcal{F}_{\mathsf{edaBits}}$ on input $(k-d)$ to get $[\lambda_z]$ and its bit decomposition $\{[\lambda_{z,i}]_2\}_{i=0}^{k-d-1}$.
4. Parties call $\mathcal{F}_{\mathsf{edaBits}}$ on input d to get $[u]$ and its bit decomposition $\{[u_i]_2\}_{i=0}^{d-1}$.
5. Parties locally compute $[\lambda_{z'}] = 2^d \cdot [\lambda_z] + [u]$.

Online phase:

1. Parties locally compute $[\Delta_{z'}] = (\Delta_x + \delta_x)(\Delta_y + \delta_y) - (\Delta_y + \delta_y)[a] - (\Delta_x + \delta_x)[b] + [c] + [\lambda_{z'}]$.
2. Parties open $\Delta_{z'}$ to get $\Delta_{z'}$ in the clear.
3. Parties locally compute $\Delta_z = \Delta_{z'}/2^d$.

Online communication cost. In the online phase of procedure $\pi_{\mathsf{MultTrunc}}$, each party is only required to broadcast a single ring element. This communication cost is *identical* to that of multiplication in $\Pi_{\mathsf{OnlineArith}}$. Therefore, truncation is essentially performed at *no* additional online communication cost. To the best of our knowledge, this feature is achieved for the *first* time in maliciously secure dishonest majority PPML protocols.

Correctness. For the correctness of $\pi_{\mathsf{MultTrunc}}$ we have the following proposition.

Proposition 3. *In the procedure* $\pi_{\mathsf{MultTrunc}}$*, if* $xy \le 2^\ell$ *for some* $\ell < k$*, then with probability at least* $1 - 2^{\ell-k}$ *it holds that* $z = \lfloor xy/2^d \rfloor + v$ *for some* $v \in \{0,1\}$.

Proof. We use the notations in $\pi_{\mathsf{MultTrunc}}$ and let $z' = xy = \Delta_{z'} - \lambda_{z'}$. Denote by $\mathsf{Carry}_k(x,y)$ the k-th carry bit when adding x and y. Since $\Delta_{z'} = (\lambda_{z'} + z') \bmod 2^k$, it holds that $\Delta_{z'} = \lambda_{z'} + z' - 2^k u$ with $u = \mathsf{Carry}_k(\lambda_{z'}, z')$. Also, we have $(\Delta_{z'} \bmod 2^d) = (\lambda_{z'} \bmod 2^d) + (z' \bmod 2^d) - 2^d v$ with $v = \mathsf{Carry}_d(\lambda_{z'}, z')$. Since for all positive integers x it holds that $\lfloor x/q \rfloor = (x - (x \bmod q))/q$, we can see that z satisfies

$$
\begin{aligned}
z = \Delta_z - \lambda_z &= \lfloor \Delta_{z'}/2^d \rfloor - \lambda_z = \frac{\Delta_{z'} - (\Delta_{z'} \bmod 2^d)}{2^d} - \lambda_z \\
&= \frac{\lambda_{z'} + z' - 2^k u - (\lambda_{z'} \bmod 2^d) - (z' \bmod 2^d) + 2^d v}{2^d} - \lambda_z \\
&= \frac{\lambda_{z'} - (\lambda_{z'} \bmod 2^d)}{2^d} + \frac{z' - (z' \bmod 2^d)}{2^d} - 2^{k-d}u + v - \lambda_z \\
&= \lambda_z + \lfloor z'/2^d \rfloor - 2^{k-d}u + v - \lambda_z = \lfloor z'/2^d \rfloor - 2^{k-d}u + v,
\end{aligned}
$$

hence the error is $-2^{k-d}u + v$. Since $u = \mathsf{Carry}_k(\lambda_{z'}, z') = (\lambda_{z'} + z' \ge 2^k)$, the probability that $u = 1$ is the probability that $\lambda_{z'} \ge 2^k - z'$. Moreover, since $z' < 2^\ell$ and $\lambda_{z'}$ is uniformly random in $\mathbb{Z}_{2^k}$, this probability is upper bounded by $2^{\ell-k}$. □

4.2 Vector Dot Product

In this section, we show that the online communication of vector dot product can be made *independent* of the vector size. This has been achieved in either semi-honest setting [45] or malicious setting with an honest majority [8, 39]. To the best of our knowledge, no previous works have achieved similar results in maliciously secure dishonest majority model.

For convenience we allow the $[\cdot]$ notation for vectors, *i.e.*, $[\vec{\lambda}]$ indicates that each element of the vector $\vec{\lambda}$ is $[\cdot]$-shared.

For a dot product gate with input vectors $\vec{x}, \vec{y}$ of length m, the goal of the procedure $\pi_{\mathsf{DotProduct}}$ is to compute the output on wire z where $z = \vec{x} \cdot \vec{y} = \sum_{i=1}^m \vec{x}[i]\vec{y}[i]$. A trivial way is to execute m multiplications in $\Pi_{\mathsf{OnlineArith}}$ for each underlying multiplication, but this results in online communication linear in vector length m.

We now show how to make online communication independent of vector length. Observe that in preprocessing phase parties do not need to generate the random shares $[\overrightarrow{\lambda_z}[i]]$ for each multiplication in the dot product. Instead, only a single random share $[\lambda_z]$ is needed for the final result. Then in the online phase, parties locally compute and sum up the products before masking with $[\lambda_z]$ to get $[\Delta_z]$. Finally, parties open Δ_z to retain knowledge on Δ_z. For details, see our dot product procedure $\pi_{\mathsf{DotProduct}}$ below.

Procedure 2: $\pi_{\mathsf{DotProduct}}$

For a dot product gate with input vectors of length m on wires $\vec{x}, \vec{y}$:

Preprocessing phase:

1. Parties call $\mathcal{F}_{\mathsf{Prep}}$.Rand to get $[\lambda_z]$ where $\lambda_z \xleftarrow{\$} \mathbb{Z}_{2^k}$.
2. Parties call $\mathcal{F}_{\mathsf{Prep}}$.Triple m times to get m triples, obtaining $[\vec{a}], [\vec{b}], [\vec{c}]$, where $([\vec{a}[i]], [\vec{b}[i]], [\vec{c}[i]])$ is an individual multiplication triple obtained in the i-th call of $\mathcal{F}_{\mathsf{Prep}}$.Triple.
3. Parties compute $[\overrightarrow{\delta_x}] = [\vec{a}] - [\overrightarrow{\lambda_x}]$, $[\overrightarrow{\delta_y}] = [\vec{b}] - [\lambda_y]$ and open $\overrightarrow{\delta_x}, \overrightarrow{\delta_y}$.

Online phase:

1. Parties locally compute $[\Delta_z] = \sum_{i=1}^m \Big((\overrightarrow{\Delta_x}[i] + \overrightarrow{\delta_x}[i])(\overrightarrow{\Delta_y}[i] + \overrightarrow{\delta_y}[i]) - (\overrightarrow{\Delta_y}[i] + \overrightarrow{\delta_y}[i])[\vec{a}[i]] - (\overrightarrow{\Delta_x}[i] + \overrightarrow{\delta_x}[i])[\vec{b}[i]] + [\vec{c}[i]] \Big) + [\lambda_z]$.
2. Parties open Δ_z to get Δ_z in the clear.

Online communication cost. For length-m vector dot product, SPD$\mathbb{Z}_{2^k}$+ [15] requires communication of $2m$ elements for each party in the online phase, while we only require 1 *single* element for each party, which is *independent* of input vector length m. To the best of our knowledge, this feature is achieved for the *first* time in maliciously secure dishonest majority MPC.

Matrix multiplication. Since matrix multiplication consists of vector dot products, it benefits from our constructions. Concretely, to multiply a secret $h \times m$ matrix by a secret $m \times w$ matrix, SPD$\mathbb{Z}_{2^k}$+ [15] requires online communication of $2mhw$ ring elements per party, while we require only hw ring elements, which is $2m\times$ improvement.

Dot product and matrix multiplication with truncation.

The *dot-product-then-truncate* procedure $\pi_{\mathsf{DotProductTrunc}}$ can be constructed similarly as $\pi_{\mathsf{MultTrunc}}$. We describe the details of $\pi_{\mathsf{DotProductTrunc}}$ in Appendix B.2. In addition, matrix multiplication with truncation also benefits from $\pi_{\mathsf{DotProductTrunc}}$. The property that truncation requires no additional online communication cost still holds. Concretely, for length m vector dot product with truncation, our construction requires only 1 ring element of online communication per party in 1 round, whereas SPD$\mathbb{Z}_{2^k}$+ [15] requires $2m+1$ elements in 2 rounds. For size $h \times m$ and $m \times w$ matrix multiplication followed by truncation, our construction requires hw ring element of online communication per party in 1 round, whereas SPD$\mathbb{Z}_{2^k}$+ [15] requires $hw(2m+1)$ elements in 2 rounds. We improve online communicate cost by a factor of $2m+1$ and save one round of communication.

4.3 Secure Comparison

Many non-linear functions used in machine learning (*e.g.*, ReLU, MaxPool) involve comparison operations. The goal of secure comparison is to perform comparison operations on secret-shared data, ensuring that the output remains secret-shared as well.

We first consider comparing a secret-shared value $[x]$ with public value 0 to get $[z]$ where $z = (x < 0)$. The mask-and-compare technique, proposed by Damgård *et al.* [15] and Makri *et al.* [38], works as follows. In the preprocessing phase, the parties call $\mathcal{F}_{\mathsf{edaBits}}$ to get a shared random mask $[r]$ and its bit decomposition $\{[r_i]_2\}_{i=0}^{k-1} = ([r_1]_2, \ldots, [r_{k-1}]_2)$. In the online phase, the parties compute $[c] = [x] + [r]$ and open c in the clear, then use a bit-wise comparison circuit π_{BitLT} to compare the public value c and the secret-shared bits $\{[r_i]_2\}_{i=0}^{k-1}$, obtaining $[z]_2$ where $z = (c < r) = (x + r < r) = (x < 0)$. Finally, $[z]_2$ is converted to $[z]$ using a bit-to-arithmetic conversion functionality $\mathcal{F}_{\mathsf{B2A}}$. The procedure for standard bit-wise comparison π_{BitLT} is described in Appendix B.3, and the bit-to-arithmetic conversion functionality $\mathcal{F}_{\mathsf{B2A}}$ is described in Appendix A.4.

Now we develop our LTZ (less-than-zero) procedure π_{LTZ} in the context of circuit-dependent preprocessing. Parties have input $[\lambda_x], \Delta_x$ where $\Delta_x = \lambda_x + x$ and wish to obtain $[\lambda_z], \Delta_z$ where $z = (x < 0)$ and $\Delta_z = \lambda_z + z$.

To apply the mask-and-compare technique, the parties must open the value $[c] = [x] + [r] = \Delta_x - [\lambda_x] + [r]$. Let $\delta_x = r - \lambda_x$, observe that $[\delta_x] = [r] - [\lambda_x]$ can be computed and opened in the preprocessing phase. Consequently, $c = \Delta_x + (r - \lambda_x) = \Delta_x + \delta_x$ can be computed *locally* in the online phase. This approach effectively shifts the opening of the masked value to the preprocessing phase. Furthermore, if there are multiple LTZ gates in the circuit, then the opening of these values can be batched in a single round, saving communication rounds. For details, see the LTZ procedure π_{LTZ} described below.

On the use of the additional random mask $[r]$. Unlike the multiplication-then-truncation procedure in §4.1, where $[\lambda]$-values are utilized as truncation pairs, we do not reuse $[\lambda_x]$ for the mask-and-compare approach. The reason for this is that the bit-wise comparison procedure π_{BitLT} requires the knowledge of shared bit decomposition of the random mask. However, since the value $[\lambda_x]$ is determined prior to the preprocessing phase of π_{LTZ}, obtaining the shared bit decomposition of λ_x requires an expensive protocol [5]. Hence, we resort to generating an additional random mask $[r]$ using the relatively cheap $\mathcal{F}_{\mathsf{edaBits}}$.

Procedure 3: π_{LTZ}

For an LTZ gate with input wire x, to get the comparison result $z = (x < 0)$ on wire z:

Preprocessing phase:

1. Parties call $\mathcal{F}_{\mathsf{edaBits}}$ on input k to get $[r]$ and its bit decomposition $\{[r_i]_2\}_{i=0}^{k-1} = ([r_1]_2, \ldots, [r_{k-1}]_2)$.
2. Parties compute $[\delta_x] = [r] - [\lambda_x]$, then open δ_x.
3. Parties call $\mathcal{F}_{\mathsf{Prep}}$.Rand to get $[\lambda_z]$ where $\lambda_z \xleftarrow{\$} \mathbb{Z}_{2^k}$.

Online phase:

1. Parties call $\pi_{\mathsf{BitLT}}(\Delta_x + \delta_x, \{[r_i]_2\}_{i=0}^{k-1})$ to get $[z]_2$.
2. Parties call $\mathcal{F}_{\mathsf{B2A}}$ on input $[z]_2$ to get $[z]$.
3. Parties locally compute $[\Delta_z] = [\lambda_z] + [z]$.
4. Parties open Δ_z to get Δ_z in the clear.

Further optimization for the preprocessing phase. If procedure π_{LTZ} is to be executed right after procedure $\pi_{\mathsf{MultTrunc}}$, which is often the case in neural networks (*e.g.*, ReLU function after matrix multiplication), then the preprocessing phase can be further optimized. Note that the bit decomposition $([\lambda_{x,0}]_2, \ldots, [\lambda_{x,k-1}]_2)$ is already known in the preprocessing phase of $\pi_{\mathsf{MultTrunc}}$, hence it can serve as the random mask in the mask-and-compare approach, and $[r]$ is no longer needed. In the online phase, the paries replace the first step with $\pi_{\mathsf{BitLT}}(\Delta_x, \{[\lambda_{x,i}]_2\}_{i=0}^{k-1})$. Correctness holds since $(x < 0) = (\Delta_x - \lambda_x < 0) = (\Delta_x < \lambda_x)$. As a result, the call to $\mathcal{F}_{\mathsf{edaBits}}$ and the opening of δ_x is no longer needed.

Comparison of two secret values. To compare two secret values on wires x, y and obtain secret $(x < y)$ on wire z, the parties can simply invoke π_{LTZ} on input $(x - y)$.

Online communication cost. The online phase involves an opening of a $(s+k)$-bit ring element, an opening of a $(s+1)$-bit ring element (in $\mathcal{F}_{\mathsf{B2A}}$), and an invocation of π_{BitLT} on length-k inputs, which has $2k-2$ AND gates in $\log k$ rounds. Hence online communication cost for each party is $2(2k-2)(s+1) + (s+1) + (s+k) = 4ks + 5k - 2s - 3$ bits.

4.4 The Full Protocol

To formally state and prove the security of the procedures proposed above, we integrate them into a preprocessing protocol Π_{PrepPPML} and an online protocol $\Pi_{\mathsf{OnlinePPML}}$. They are put in Appendix C due to space constraints, and we briefly describe them below.

The preprocessing protocol Π_{PrepPPML} consists all of the components of $\Pi_{\mathsf{PrepArith}}$, in addition to the preprocessing phases of procedures $\pi_{\mathsf{MultTrunc}}$, $\pi_{\mathsf{DotProduct}}$, and π_{LTZ}. Similarly, the online protocol $\Pi_{\mathsf{OnlinePPML}}$, consists all of the components of $\Pi_{\mathsf{OnlineArith}}$, along with the online phases of procedures $\pi_{\mathsf{MultTrunc}}$, $\pi_{\mathsf{DotProduct}}$, and π_{LTZ}.

We define the corresponding functionalities $\mathcal{F}_{\mathsf{PrepPPML}}$ and $\mathcal{F}_{\mathsf{OnlinePPML}}$, they are described in Appendix A.3.

Now we state the security of our protocols. The proofs of the following theorems are given in the full version.

Theorem 4. *The protocol Π_{PrepPPML} securely implements the functionality $\mathcal{F}_{\mathsf{PrepPPML}}$ against a static, malicious adversary corrupting up to $n-1$ parties in the ($\mathcal{F}_{\mathsf{Prep}}$,$\mathcal{F}_{\mathsf{edaBits}}$)-hybrid model.*

Theorem 5. *The protocol $\Pi_{\mathsf{OnlinePPML}}$ securely implements the functionality $\mathcal{F}_{\mathsf{OnlinePPML}}$ against a static, malicious adversary corrupting up to $n-1$ parties in the ($\mathcal{F}_{\mathsf{PrepPPML}}$,$\mathcal{F}_{\mathsf{B2A}}$)-hybrid model.*

On the reactiveness of our protocols. Our constructions make use of circuit-dependent preprocessing, hence parties cannot modify circuit structure during the online phase. Nevertheless, our functionalities and protocols are reactive, in the sense that input gates and output gates are allowed in the midst of the circuit. Parties can learn partial outputs from the output gates before providing new inputs (which may depend on the outputs) to the input gate.

5 Applications to Machine Learning

In this section, we show how to apply privacy-preserving techniques to two types of popular ML models: SVMs and NNs, on top of our constructions in §3 and §4.

5.1 Support Vector Machines

SVMs are widely used for classification purposes. They can serve as binary classifiers or be extended to handle multiple categories. Concretely an SVM is a function $f : \mathbb{R}^n \to \mathbb{Z}_q$ defined as

$$f(\vec{x}) = \underset{i\in\{1,\ldots,q\}}{\operatorname{argmax}} \left(\mathbf{W}[i]\cdot\vec{x}+\vec{b}[i]\right)$$

where n is the dimension of the feature space and q is the number of categories. The input is $\vec{x} \in \mathbb{R}^n$. The matrix $\mathbf{W} \in \mathbb{R}^{q\times n}$ and the vector $\vec{b} \in \mathbb{R}^n$ are the parameters. Note that $\mathbf{W}[i]$ denotes the i-th row of $\mathbf{W}$.

To implement SVM inference, notice that it consists of only matrix multiplication and comparison operations, which can be efficiently implemented using the corresponding procedures $\pi_{\mathsf{DotProduct}}$ and π_{LTZ} in §4.

5.2 Neural Networks

We mainly focus on the inference of convolutional neural networks (CNN), which consists of fully connected layers, convolution layers, batch normalization layers, pooling layers, and activation functions. We assume familiarity with these concepts and refer the readers to a standard deep learning textbook (*e.g.* [42]) for details.

Linear layers. Fully connected layers, convolution layers, and batch normalization layers are linear layers, hence can be implemented using vector dot product.

Pooling layers. We consider two common kinds of pooling layers: max pooling and average pooling. Average pooling can be implemented using the addition and multiplication procedure, and max pooling needs comparison operations, which are accomplished by procedure π_{LTZ}.

Activation functions. We mainly consider the ReLU function $\mathrm{ReLU}(x) = \begin{cases} x, & \text{if } x > 0 \\ 0, & \text{otherwise} \end{cases}$. For LeNet [34] we replace the legacy tanh function with ReLU since this enables faster training [32] and is easier to compute. To compute ReLU, notice that $\mathrm{ReLU}(x) = (x > 0)\cdot x = (1-(x<0))\cdot x$, parties can invoke π_{LTZ} on input x followed by multiplying $(1-(x<0))$ by x to obtain the result.

6 Evaluations

6.1 Experiment Setup

We implement our protocols in C++.[3] To compare with the state of the art SPD$\mathbb{Z}_{2^k}$+ [15], we implement the evaluations for SPD$\mathbb{Z}_{2^k}$+ in the MP-SPDZ framework [23]. Although both SPD$\mathbb{Z}_{2^k}$+ and MD-ML support multi-party computation, we mainly focus on 2PC scenario in the evaluations.

Execution environment. All of the experiments in this paper are performed on two cloud servers running Ubuntu 22.04 LTS. Both servers are equipped with 16 vCPUs and 32 GB of RAM. We consider two different network settings, LAN and WAN. The network parameters are simulated using the Linux `tc` command. The bandwidth between the parties are 10 Gbps (LAN) and 100 Mbps (WAN), respectively. The round-trip time (rtt) are 0.1ms (LAN) and 100ms (WAN), respectively.

Concrete parameters. Parameters $s = k = 64$ are used for the SPD$\mathbb{Z}_{2^k}$ secret-sharing scheme [9] in the evaluations of both MD-ML and SPD$\mathbb{Z}_{2^k}$+ [15]. For fixed point arithmetic in MD-ML, we use $d = 20$ for the number of fractional bits.

[3] Available at https://github.com/NemoYuan2008/MD-ML.

Datasets and ML models. The datasets used are MNIST [35], CIFAR-10 [31], Tiny ImageNet [33], and ImageNet [47]. The ML models used are SVM, LeNet [34], AlexNet [32], and ResNet-18 [22].

Metrics. We measure the total communication including all the messages sent by the paries (including TCP/IP headers, *etc.*). We measure the end-to-end execution time including the time of computation and network communication. The improvement factor of MD-ML over SPD$\mathbb{Z}_{2^k}$+ is included in the tables.

6.2 Microbenchmarks on the Building Blocks

6.2.1 Benchmarks of the online phase

We benchmark the online phase of the following building blocks for both MD-ML and SPD$\mathbb{Z}_{2^k}$+:

- Dot product of vector length 65536 (Table 4).
- Secure comparison (LTZ) of a batch of 65536 secret values (Table 4).
- Matrix multiplication of different sizes (Table 5).
- Tensor 2D convolution of different sizes (Table 6).

The execution time and communication costs of the online phase are measured and listed in the tables. Note that truncation operations are included in the benchmarks of multiplication, since they are needed in the application of PPML. The time and communication cost for the input phase is also included in the statistics.

The experimental results demonstrate the significant superiority of our efficient vector dot product and truncation protocols. Concretely, for linear operations (including convolution), we are 4.0–20.0× faster in LAN, 6.0–73.5× faster in WAN, and 1.7–8.8× more communication-efficient compared to SPD$\mathbb{Z}_{2^k}$+.

6.2.2 Benchmarks of the preprocessing phase

We benchmark the preprocessing phase of the following building blocks for both MD-ML and SPD$\mathbb{Z}_{2^k}$+ (Table 7):

- Dot product of vector length 65536.
- Multiplication with truncation of a batch of 1024 values.
- Secure comparison (LTZ) of a batch of 1024 values.

These correspond to the procedures $\pi_{\mathsf{DotProduct}}$, $\pi_{\mathsf{MultTrunc}}$, and π_{LTZ} from §4. Truncation and comparison operations are evaluated in a batch of 1024, aligning with the batch size of 1024 used in the edaBits generation implemented in the MP-SPDZ framework [23].

As shown by Table 7, the preprocessing cost of $\pi_{\mathsf{MultTrunc}}$ and π_{LTZ} are nearly the same as SPD$\mathbb{Z}_{2^k}$+, while the preprocessing cost of our vector dot product procedure is slightly higher than SPD$\mathbb{Z}_{2^k}$+. The reason is that parties need to generate the $[\lambda]$-values and open the δ-values in addition to the multiplication triples. This increase is very minimal compared to the significant efficiency enhancement of the online phase.

6.3 Benchmarks on ML models

We implement the following evaluations for online benchmarking:[4]

- SVM inference on the MNIST, CIFAR-10, and Tiny ImageNet datasets with both MD-ML and SPD$\mathbb{Z}_{2^k}$+ (Table 8).
- LeNet inference on the MNIST, CIFAR-10, and Tiny ImageNet datasets with both MD-ML and SPD$\mathbb{Z}_{2^k}$+ (Table 9).
- AlexNet inference on the CIFAR-10, Tiny ImageNet, and ImageNet datasets with both MD-ML and SPD$\mathbb{Z}_{2^k}$+ (Table 10).
- ResNet-18 inference on the CIFAR-10 dataset with MD-ML (Table 11).

The communication and the running time of the online phase are measured in both LAN and WAN settings.

Significant improvement of MD-ML over SPD$\mathbb{Z}_{2^k}$+ is observed from the tables. For LeNet inference, we are 3.4–9.2× faster in LAN, 9.7–31.7× faster in WAN, and 2.0–2.9× more communication-efficient. For AlexNet inference, we are 8.0–11.0× faster in LAN, 93.3–157.7× faster in WAN, and 9.8–23.8× more communication-efficient. For ResNet-18 inference on CIFAR-10, we are capable of completing the online phase of inference in 25.8s in LAN and 363.9s in WAN.

As the size of the neural network and dataset increases, we observe significant enhancements in online efficiency, owing to the utilization of our constant-communication dot product protocol and various efficient building blocks.

6.4 Accuracy

Table 12 compares the inference accuracy on MNIST dataset obtained by our MD-ML framework and by plaintext computation, using pre-trained SVM and LeNet models.

The primary sources of errors encountered in MD-ML can be attributed to the following factors: (1) the utilization of fixed-point arithmetic, (2) the introduction of errors through probabilistic truncation, and (3) the errors arising from comparison operations. The experimental results indicate that these errors are acceptable, with our relative error being 0.153%–0.435% compared to plaintext computation.

[4] In practice SVM and LeNet are not capable of classification of relatively large datasets such as Tiny ImageNet. Our objective in conducting the respective experiments is to showcase the performance of both frameworks.

7 Conclusion

In this work, we introduce MD-ML, a framework for maliciously secure dishonest majority PPML. We have developed a series of efficient building blocks such as dot product, multiplication with truncation, and comparison. We have significantly improved the performance in terms of online communication cost compared to SPD$\mathbb{Z}_{2^k}$+ [15]. Finally, we demonstrate the practicality and effectiveness of our constructions by implementing SVM, LeNet, AlexNet, and ResNet with MD-ML. We believe that MD-ML will promote the real-world applications of maliciously secure dishonest majority MPC and PPML.

There are several potential future directions for our research: (1) exploring the benefits of flexible corruption (§3.3.2), and (2) improving the efficiency of our constructions using orthogonal optimizations such as hardware acceleration.

Acknowledgment

We would like to thank the anonymous reviewers of USENIX Security 2024 for their valuable comments. This work was supported in part by the National Key Research and Development Project 2020YFA0712300, and National Natural Science Foundation of China (Grant No. 62272294).

A Functionalities

A.1 SPD$\mathbb{Z}_{2^k}$ Preprocessing Functionality

Functionality $\mathcal{F}_{\mathsf{Prep}}$ is taken from [9] and is described below.

Functionality 1: $\mathcal{F}_{\mathsf{Prep}}$

Input: On input (Input, P_i) from all parties, sample random $r \xleftarrow{\$} \mathbb{Z}_{2^k}$ and generate $[r]$. If P_i is corrupted, instead let the adversary choose the sharing $[r]$. Then send r to P_i, and distributes the sharing $[r]$ to all parties.
Triple: On input (Triple) from all parties, sample two random values $a, b \xleftarrow{\$} \mathbb{Z}_{2^k}$, compute $c = ab \bmod 2^k$, generate $[a], [b], [c]$, and distributes the sharings $[a], [b], [c]$ to all parties.
Rand: On input (Rand) from all parties, sample random value $r \xleftarrow{\$} \mathbb{Z}_{2^k}$, generate $[r]$, and distributes the sharing $[r]$ to all parties.

A.2 Our Functionalities for Arithmetic Circuits

We provide formal definitions of our functionalities for arithmetic circuits (§3) in this section.

Functionality 2: $\mathcal{F}_{\mathsf{PrepArith}}$

Input: On input $(\mathsf{Input}, P_i, id)$ from the parties, where id is a fresh, valid identifier for the input wire of P_i, the functionality samples $\lambda_x \xleftarrow{\$} \mathbb{Z}_{2^k}$ and generates $[\lambda_x]$. If P_i is corrupted, instead let the adversary choose $[\lambda_x]$. Then, the functionality stores $(id, [\lambda_x])$. Finally, the functionality sends λ_x to P_i and distributes $[\lambda_x]$ to all parties.
Add: On input $(\mathsf{Add}, id_1, id_2, id_3)$ from the parties, the functionality retrieves (if present in memory) the values $(id_1, [\lambda_x]), (id_2, [\lambda_y])$ and stores $(id_3, [\lambda_z])$ where $\lambda_z = \lambda_x + \lambda_y$.
Multiply: On input $(\mathsf{Multiply}, id_1, id_2, id_3)$ from the parties, the functionality retrieves (if present in memory) the values $(id_1, [\lambda_x]), (id_2, [\lambda_y])$. The functionality then samples $a, b, \lambda_z \xleftarrow{\$} \mathbb{Z}_{2^k}$, computes $c = ab$, generates $[a], [b], [c], [\lambda_z]$, and distributes them to the parties. Finally, the functionality computes $\delta_x = a - \lambda_x, \delta_y = b - \lambda_y$ and stores $(id_3, [\lambda_z])$ and δ_x, δ_y.
Output: The functionality sends all the stored δ-values to the adversary, then waits for a message Abort or $\mathsf{Proceed}$ from the adversary: if it sends Abort then the functionality aborts, otherwise the functionality sends the δ-values to the parties.

Functionality 3: $\mathcal{F}_{\mathsf{OnlineArith}}$

Initialize: Receive (init, k) from all parties.
Input: On input $(\mathsf{Input}, P_i, id, x)$ from P_i and input (Input, P_i) from other parties, where id is a fresh identifier, store (id, x).
Add: On input $(\mathsf{Add}, id_1, id_2, id_3)$ from all the parties (where id_1 and id_2 are present in memory), retrieve (id_1, x), (id_2, y) and store $(id_3, x+y)$.
Multiply: On input $(\mathsf{Mult}, id_1, id_2, id_3)$ from all the parties (where id_1, id_2 are present in memory), retrieve $(id_1, x), (id_2, y)$ and store (id_3, xy).
Output: On input (Output, id) from all the parties (where id is present in memory), retrieve (id, y) and output it to the adversary. Wait for an input Proceed or Abort from the adversary. If this is Proceed then send y to all parties, otherwise abort.

A.3 Our Functionalities for PPML

We provide formal definitions of our functionalities for PPML (§4) in this section.

Functionality 4: $\mathcal{F}_{\mathsf{PrepPPML}}$

Functionality $\mathcal{F}_{\mathsf{PrepPPML}}$ has the same commands as $\mathcal{F}_{\mathsf{PrepArith}}$, in addition to the following:
MultTrunc: On input $(\mathsf{MultTrunc}, id_1, id_2, id_3)$ from all parties, retrieve (if present in memory) the values $(id_1, [\lambda_x]), (id_2, [\lambda_y])$. Then, sample $a, b, \lambda_z \xleftarrow{\$} \mathbb{Z}_{2^k}$, compute $c = ab$, generate $[a], [b], [c], [\lambda_z]$, generate the shared bit decomposition $([\lambda_{z,0}]_2, \ldots, [\lambda_{z,k-1}]_2)$, generate $\{[\lambda_{z',i}]\}_{i=d}^{k-1}$, and distribute all of the above sharings to the parties. Finally, compute $\delta_x = a - \lambda_x, \delta_y = b - \lambda_y$, store $(id_3, [\lambda_z])$ and δ_x, δ_y.
DotProduct: On input $(\mathsf{DotProduct}, id_1, id_2, id_3)$ from all parties (where id_1, id_2 are present in memory which represent vectors of equal length m), retrieve (if present in memory) the values $(id_1, [\overrightarrow{\lambda_x}]), (id_2, [\overrightarrow{\lambda_y}])$. Then, sample $\vec{a}, \vec{b}, \xleftarrow{\$} \mathbb{Z}_{2^k}^m$ and $\lambda_z \xleftarrow{\$} \mathbb{Z}_{2^k}$, compute $\vec{c}$ such that $\vec{c}[i] = \vec{a}[i]\vec{b}[i]$. Then, generate $[\vec{a}], [\vec{b}], [\vec{c}], [\lambda_z]$, and distributes them to the parties. Finally, compute $\overrightarrow{\delta_x} = \vec{a} - \overrightarrow{\lambda_x}, \overrightarrow{\delta_y} = \vec{b} - \overrightarrow{\lambda_y}$, store $(id_3, [\lambda_z])$ and $\overrightarrow{\delta_x}, \overrightarrow{\delta_y}$.
LTZ: On input $(\mathsf{LTZ}, id_1, id_2)$ from all parties (where id_1 is present in memory), retrieve (if present in memory) the value $(id_1, [\lambda_x])$. Then, sample $r \xleftarrow{\$} \mathbb{Z}_{2^k}$, generate and distribute $[r]$ to the parties. Then, compute $\delta_x = r - \lambda_x$ and store δ_x. Finally, sample $\lambda_z \xleftarrow{\$} \mathbb{Z}_{2^k}$, generate and distribute $[\lambda_z]$ to the parties, and store (id_2, λ_z).

Functionality 5: $\mathcal{F}_{\mathsf{OnlinePPML}}$

Functionality $\mathcal{F}_{\mathsf{OnlinePPML}}$ has the same commands as $\mathcal{F}_{\mathsf{OnlineArith}}$, in addition to the following:
MultTrunc: On input $(\mathsf{MultTrunc}, id_1, id_2, id_3)$ from all parties (where id_1, id_2 are present in memory), retrieve $(id_1, x), (id_2, y)$ and store $(id_3, xy/2^d)$.
DotProduct: On input $(\mathsf{DotProduct}, id_1, id_2, id_3)$ from all parties (where id_1, id_2 are present in memory which represent vectors of equal length), retrieve $(id_1, \vec{x}), (id_2, \vec{y})$ and store $(id_3, \vec{x} \cdot \vec{y})$.
LTZ: On input $(\mathsf{LTZ}, id_1, id_2)$ from all parties (where id_1 is present in memory), retrieve (id_1, x) and store $(id_2, (x < 0))$.

A.4 Functionalities for edaBits and B2A

Functionality $\mathcal{F}_{\mathsf{edaBits}}$ is taken from [17].

Functionality 6: $\mathcal{F}_{\mathsf{edaBits}}$

On input $(\mathsf{edaBits}, \ell)$ from all parties, sample uniformly random values $(r_0, \ldots, r_{\ell-1}) \in \mathbb{Z}_2^\ell$, compute $r = \sum_{i=0}^{\ell-1} 2^i r_i$, generate $\{[r_i]_2\}_{i=0}^{\ell-1}$ and $[r]$, then distributes the sharings to all parties.

Functionality $\mathcal{F}_{\mathsf{B2A}}$ is a standard conversion functionality.

Functionality 7: $\mathcal{F}_{\mathsf{B2A}}$

On input $(\mathsf{B2A}, [x]_2)$ from all parties, compute $x \in \{0,1\}$ according to $[x]_2$, then generate $[x]$ and distribute the sharing $[x]$ to all parties.

B Procedures

B.1 MAC Checking

The procedure π_{MACCheck} is taken from [9]. It relies on a coin tossing functionality $\mathcal{F}_{\mathsf{Rand}}$ to sample public random values for the parties.

Procedure 4: π_{MACCheck}

Procedure π_{MACCheck} takes as input a set of opened values $(x_1, x_2, \ldots, x_t)$ and checks the correctness of the corresponding MACs. Let x_i^j, m_i^j, α_i^j be P_j's share, MAC share and MAC key share for x_i.

1. Parties call $\mathcal{F}_{\mathsf{Rand}}$ to sample public random values $(r_1, r_2, \ldots, r_t) \xleftarrow{\$} \mathbb{Z}_{2^s}^t$ and compute $y = \sum_{i=1}^t r_i \cdot x_i \bmod 2^{k+s}$.
2. Each Party P_j computes $m^j = \sum_{i=1}^t r_i m_i^j$ and $z^j = m^j - \alpha^j \cdot y$, then it commits to z^j.

3. Parties open their commitments and verify that $\sum_{i=j}^{n} z^j = 0 \pmod{2^{k+s}}$. If the check fails then parties abort.

The failure probability of π_{MACCheck} is negligible in s, as stated in the following theorem.

Theorem 6 ([9, Theorem 1]). *Assume α is uniformly random to the adversary, if procedure π_{MACCheck} passes, then the values accepted by the parties are correct, except with probability at most $2^{-s+\log(s+1)}$.*

B.2 Dot Product with Truncation

We describe our dot-product-then-truncate procedure below.

Procedure 5: $\pi_{\mathsf{DotProductTrunc}}$

For a dot-product-then-truncate gate with input vectors of length m on wires $\vec{x}, \vec{y}$, to compute dot product and truncate the result by d bits on output wire z:

Preprocessing phase:

1. Parties call $\mathcal{F}_{\mathsf{Prep}}$.Triple m times to get m triples, obtaining $[\vec{a}], [\vec{b}], [\vec{c}]$, where $([\vec{a}[i]], [\vec{b}[i]], [\vec{c}[i]])$ is an individual multiplication triple obtained in the i-th call of $\mathcal{F}_{\mathsf{Prep}}$.Triple.
2. Parties compute $[\overrightarrow{\delta_x}] = [\vec{a}] - [\overrightarrow{\lambda_x}]$, $[\overrightarrow{\delta_y}] = [\vec{b}] - [\lambda_y]$ and open $\overrightarrow{\delta_x}, \overrightarrow{\delta_y}$.
3. Parties call $\mathcal{F}_{\mathsf{edaBits}}$ on input $(k-d)$ to get $[\lambda_z]$ and its bit decomposition $\{[\lambda_{z,i}]_2\}_{i=0}^{k-d-1}$.
4. Parties call $\mathcal{F}_{\mathsf{edaBits}}$ on input d to get $[u]$ and its bit decomposition $\{[u_i]_2\}_{i=0}^{d-1}$.
5. Parties locally compute $[\lambda_{z'}] = 2^d \cdot [\lambda_z] + [u]$.

Online phase:

1. Parties locally compute $[\Delta_{z'}] = \sum_{i=1}^{m} \Big((\overrightarrow{\Delta_x}[i] + \overrightarrow{\delta_x}[i])(\overrightarrow{\Delta_y}[i] + \overrightarrow{\delta_y}[i]) - (\overrightarrow{\Delta_y}[i] + \overrightarrow{\delta_y}[i])[\vec{a}[i]] - (\overrightarrow{\Delta_x}[i] + \overrightarrow{\delta_x}[i])[\vec{b}[i]] + [\vec{c}[i]] \Big) + [\lambda_{z'}]$.
2. Parties open $\Delta_{z'}$ to get $\Delta_{z'}$ in the clear.
3. Parties locally compute $\Delta_z = \Delta_{z'} / 2^d$.

B.3 Bit-wise Comparison

The bit-wise comparison procedure π_{BitLT} is taken from [15]. The procedure uses a circuit $\pi_{\mathsf{Carry}}(x, \{[y_i]_2\}_{i=0}^{k-1}, u)$ to compute the carry bit of an addition between two integers $x, y \in \mathbb{Z}_{2^k}$, when the initial carry-in bit is $u \in \{0,1\}$. A circuit with $2k-2$ AND gates can be constructed using standard methods, and we refer to the CarryOutCin circuit described in [48].

The π_{BitLT} procedure is described below, we denote it as $\pi_{\mathsf{BitLT}}\left(x, \{[y_i]_2\}_{i=0}^{k}\right)$.

Procedure 6: π_{BitLT}

Input: A public value x, and the shared bit decomposition $\{[y_i]_2\}_{i=0}^{k-1} = ([y_0]_2, \ldots, [y_{k-1}]_2)$ of value y.
Output: A shared value $[z]_2$ where $z = (x < y)$.
The Procedure:

1. Parties set $[y'_i]_2 = 1 - [y_i]_2$ for $i = 0, 1, \ldots, k-1$.
2. Parties set $[z]_2 = 1 - \pi_{\mathsf{Carry}}(x, \{[y'_i]_2\}_{i=0}^{k-1}, 1)$.

C Protocols

We describe our full preprocessing protocol Π_{PrepPPML} and online protocol $\Pi_{\mathsf{OnlinePPML}}$ for PPML (§4) below.

Protocol 3: Π_{PrepPPML}

The parties proceed in topological order.
Input: Same as in $\Pi_{\mathsf{PrepArith}}$.
Add: Same as in $\Pi_{\mathsf{PrepArith}}$.
Multiply: Same as in $\Pi_{\mathsf{PrepArith}}$.
MultTrunc: Parties execute the preprocessing phase of $\pi_{\mathsf{MultTrunc}}$, the opening of the δ-values can be deferred and batched in the Output phase.
DotProduct: Parties execute the preprocessing phase of $\pi_{\mathsf{DotProduct}}$, the opening of the δ-values can be deferred and batched in the Output phase.
LTZ: Parties execute the preprocessing phase of π_{LTZ}, the opening of the δ-values can be deferred and batched in the Output phase.
Output: Same as in $\Pi_{\mathsf{PrepArith}}$.

Protocol 4: $\Pi_{\mathsf{OnlinePPML}}$

Initialize: Parties call $\mathcal{F}_{\mathsf{PrepPPML}}$ with the circuit to get the δ-values, the shared $[\lambda]$-values, and the multiplication triples for each gate.
Then, parties proceed in topological order.
Input: Same as in $\Pi_{\mathsf{OnlineArith}}$.
Add: Same as in $\Pi_{\mathsf{OnlineArith}}$.
Multiply: Same as in $\Pi_{\mathsf{OnlineArith}}$.
MultTrunc: Parties execute the online phase of $\pi_{\mathsf{MultTrunc}}$.
DotProduct: Parties execute the online phase of $\pi_{\mathsf{DotProduct}}$.
LTZ: Parties execute the online phase of π_{LTZ}.
Output: Same as in $\Pi_{\mathsf{OnlineArith}}$.

Accelerating Secure Collaborative Machine Learning with Protocol-Aware RDMA

Zhenghang Ren[1], Mingxuan Fan[1], Zilong Wang[1], Junxue Zhang[1], Chaoliang Zeng[1], Zhicong Huang[2], Cheng Hong[2], and Kai Chen[1,3]

Abstract

Secure Collaborative Machine Learning (SCML) suffers from high communication cost caused by secure computation protocols. While modern datacenters offer high-bandwidth and low-latency networks with Remote Direct Memory Access (RDMA) capability, existing SCML implementation remains to use TCP sockets, leading to inefficiency. We present CORA[1] to implement SCML over RDMA. By using a *protocol-aware* design, CORA identifies the protocol used by the SCML program and sends messages directly to the remote party's protocol buffer, improving the efficiency of message exchange. CORA exploits the chance that the SCML task is determined before execution and the pattern is largely input-irrelevant, so that CORA can plan message destinations on remote hosts at compile time. CORA can be readily deployed with existing SCML frameworks such as Piranha with its socket-like interface. We evaluate CORA in SCML training tasks, and our results show that CORA can reduce communication cost by up to 11× and achieve 1.2× −4.2× end-to-end speedup over TCP in SCML training.

1 Introduction

Secure Collaborative Machine Learning (SCML) provides solutions to protect privacy in machine learning tasks [21, 30, 44, 55]. SCML enables multiple individuals or organizations to perform model training or prediction collaboratively with their private data and get higher-quality results without compromising privacy. However, SCML faces high communication cost [41, 44, 58, 70] because it adopts communication-intensive protocols such as Secret Sharing (SS) and Oblivious Transfer (OT) as basic building blocks.

The widely deployed datacenters have brought opportunities to accelerate SCML. On one hand, it has been a common practice to store datasets and deploy machine learning tasks in a datacenter. The tenants within a datacenter will get better models if they collaboratively train on their datasets. On the other hand, datacenters provides high-performance computing and network facilities essential to train models. However, when performing SCML tasks, the datacenter network is not fully utilized because the implementation of SCML protocols is mainly based on TCP sockets, which is inefficient due to cost in host network stack [16]. Remote Direct Memory Access (RDMA), as a more efficient networking technology, is generally available in datacenters [26], yet remains to be integrated with SCML frameworks.

The communication cost consists of the time spent in the network protocol stack and the time for data propagation on the wire. While existing works accelerate SCML communication by configuring the transport layer protocol [12, 50] or reducing communication complexities [13], RDMA can speed up communication by offloading network stack to RDMA Network Interface Controller (RNIC), bringing better latency and bandwidth than kernel TCP.

However, accelerating SCML with RDMA still faces the following challenges:

- Current SCML frameworks usually use hybrid protocols [15, 31, 41–43, 48, 69]. But RDMA is unaware of the protocols, so messages are mixed in the staging buffer on receiving side which requires extra costs of demultiplexing the messages to multiple protocols' buffers.
- For the same protocol conducted by multiple parties, the communication patterns may differ across parties because the parties are different entities and have different runtime configurations, such as segmentation sizes, which require the extra cost of partitioning or concatenating messages.
- New SCML frameworks are still emerging with different protocols and communication patterns. Manually demultiplexing messages of multiple protocols is not scalable in new SCML frameworks.

We present CORA to address the above challenges with the following observations: 1) SCML tasks are data-parallel with each element in the input matrix processed by the same

[1]CORA: secure Collaborative machine learning Over RdmA

protocol. 2) The communication pattern of protocols will not change with the input, i.e., for each protocol used in SCML, it yields the same communication pattern [35] for different elements in the input matrix. 3) SCML tasks have high-level descriptions such as Domain Specific Languages (DSL) and APIs [33, 69], which provide the input's length and adopted protocols (§2.3). These opportunities enable us to demultiplex messages belonging to multiple protocols at compile time.

With the above observations, CORA tackles the challenges with the following designs:

- For the challenge of demultiplexing messages of hybrid protocols, CORA sets up a dedicated buffer for each protocol used in SCML. With the observations 2 and 3, CORA can identify the remote receiving buffer with the current task and adopted protocol. For example, when performing a convolution with SS protocol, the sender writes messages to an agreed buffer that is used to store SS messages specifically.

- For the challenge of heterogeneous communication patterns, CORA assigns offset addresses for the messages in the protocol buffers. With the observations 1 and 2, we know that the communication pattern is determined, so the address of the message will not change with input. The receiver can get the message directly from the corresponding offset without extra cost.

- For the challenge of applying CORA in new SCML frameworks, CORA relies on the observation 3 that current SCML frameworks have high-level descriptions of SCML tasks, including model structure and input length. CORA only requires the backend protocol to implement the layers in the SCML model. These features are commonly available in recent SCML frameworks.

We implement CORA as an independent module. Developers can use CORA in existing SCML frameworks without much effort because the interfaces are similar to the socket. It consists of three parts: 1) A Parser that extracts the SCML layers and adopted protocols as part of the protocol contexts to identify the current protocol. 2) A Planner that assigns starting addresses for the protocols to store messages. 3) Basic communication primitives that encode the current protocol in RDMA operations so that the receiver side knows the protocol context and addresses of arrived messages.

We thoroughly evaluate CORA in machine learning tasks, and the key results are as follows:

- In SCML building blocks, such as machine learning layers, CORA achieves $1.8\times - 7.2\times$ speedup over TCP.

- In SCML training tasks including SecureML [44], LeNet [36], VGG16 [51], and AlexNet [34], CORA achieves $1.2\times - 4.2\times$ speedup over TCP.

- In SCML inference tasks, CORA achieves $1.2\times - 2.0\times$ speedup over TCP.

- CORA reduces the communication cost in the model training tasks by up to $11\times$. The communication cost is no longer the bottleneck after using CORA.

To summarize, this paper makes two main contributions: First, we are among the first to use RDMA to accelerate SCML tasks, and we improve the efficiency of using RDMA for SCML tasks with CORA, a protocol-aware design of RDMA. Second, we integrate CORA into existing SCML frameworks and show the performance benefit of CORA.

2 Background

2.1 Secure Collaborative Machine Learning

SCML is mainly built on top of Secure Multi-party Computing (MPC) protocols, which enables a group of entities such as individuals or companies to jointly evaluate a function without revealing sensitive input to other parties. SCML combines various of different protocols, such as Oblivious Transfer (OT), Secret Sharing (SS), Garbled Circuits (GC), and Homomorphic Encryption (HE) to perform machine learning tasks. Recent efforts have achieved success in optimizing SCML in terms of computational efficiency [58], communication [45], versatility [33], and ease of use [69].

However, communication is still one of the major overheads in SCML due to the usage of MPC protocols [41, 44, 58, 70] and large amounts of training data. Studies have shown that communication is the bottleneck in both training and inference tasks of SCML [41, 44, 45].

Recent works such as ABY3 [43], Fantastic Four [19], Sharemind [11], and PrivPy [37] have enabled deploying SCML in a datacenter. For example, ABY3 enables three non-colluding servers to collaboratively perform machine learning tasks in a datacenter. An arbitrary number of parties can generate secret sharings of their data and distribute them to the servers. The privacy of data is guaranteed as long as at most one of the three servers is compromised.

Datacenters have high-performance interconnects with hundreds of Gbps bandwidth and a few microseconds latency. However, existing SCML frameworks fail to fully utilize the network facilities because of the inefficient TCP network [16]. During sending and receiving, it consumes lots of CPU cycles to process TCP packets, which bounds the maximum bandwidth [27, 39, 63] and harms computing performance. These problems motivate us to deploy SCML over RDMA network which bypasses CPU during data transmission.

2.2 Remote Direct Memory Access

RDMA enables direct access to a remote computer's memory without involving either side's operating system. It achieves

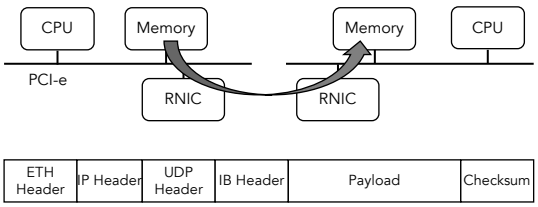

Figure 1: Overview of data transmission in RDMA network and RDMA packet format (RoCE v2).

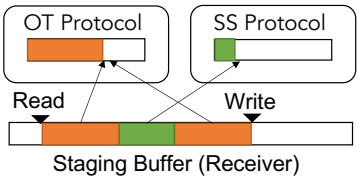

Figure 2: Illustration of the cost brought by the staging buffer because of multiple protocols and fractioned messages.

high bandwidth and low latency with zero-copy data transfer [64] and hardware-based network protocols in RNICs, which bypasses operating systems and CPUs during data transmission.

An overview of RDMA network is shown in Figure 1. A memory region on the remote host is registered and authorized to be directly accessed by RNICs without extra copy. When sending data, the RNIC possesses the full network stack to transmit the packets without involving CPUs. Moreover, RDMA packets have negligible overhead in headers compared to existing network protocols. For example, RoCE v2 [4], as one of the standard RDMA packet formats, is built on top of UDP protocol with an extra IB header (12 Bytes).

With offloaded network stack and zero-copy networking, RDMA outperforms traditional networks on both latency and bandwidth and has been widely deployed in datacenters. Moreover, RDMA brings chances to accelerate SCML for the following reasons:

- SCML frameworks intensively use sockets to send/receive data which triggers a context switch between user space and kernel space and interrupts the CPU when handling the received data. RDMA offloads the API to user space, and the program gets received data with a notification generated by RDMA hardware, which improves the utilization of CPU cycles.
- TCP requires copying the data to kernel buffers for sending, while RDMA supports zero-copy data transmission.
- TCP constantly consumes CPU when sending data, while RDMA implements network protocols in hardware and does not consume CPU during sending/receiving.

Despite performance benefits, RDMA presents a distinct interface compared to Linux socket and requires applications to change the way of sending/receiving data. RDMA defines *verbs* as basic primitives to access RNICs, including *read*, *write*, *send*, and *recv*. The hosts first register a memory region and allow direct access from remote hosts. When sending data, the sender needs to specify both the address of source data on local host and the destination address on remote host, and then sends messages by posting a *write* verb to the RNIC. The sender can also rely on the receiver to decide the destination address. In that case, the receiver first specifies receiving address by posting a *recv* verb to the RNIC, and then the sender posts a *send* verb with the address of source data.

2.3 Challenges and Opportunities

It is still a challenging task to use RDMA efficiently in SCML. We elaborate on the challenges and opportunities as follows:

Demultiplexing Cost A straightforward way of using RDMA is to write all messages sequentially into the remote memory, which is common in existing applications [22, 24, 25, 32, 40]. However, using a unified remote buffer is inefficient in SCML due to heterogeneous configurations of parties and hybrid protocols. SCML combines multiple secure protocols with their messages mixed in the same buffer, which requires demultiplexing to different protocols' buffers, as shown in Figure 2. With hybrid protocols, RDMA is unaware of the correspondence between protocols and the received messages. The demultiplexing cost cannot be ignored, considering the large amount of data traffic between parties in SCML.

Heterogeneous Communication Patterns The parties in SCML are different entities and may have different runtime configurations (e.g. batch size) resulting in undefined orders of messages arrival. As shown in Figure 2, the orange messages represent two messages of OT. The receiver needs to concatenate them into its buffer. Moreover, the address of messages is unknown to the receiver, so they needs extra interactions to locate the fractioned messages.

Generality in SCML frameworks Although we can set up multiple dedicated buffers for different protocols used in SCML, it is not scalable to new SCML protocols. Developers will have to manually configure the remote memory to send the messages of corresponding protocols.

Opportunities State-of-the-art SCML frameworks develop Domain Specific Languages (DSL) and programming APIs that have high-level description of machine learning tasks to ease the development of SCML programs. They define basic building blocks such as matrix multiplication, convolution, ReLU activation, max pooling, etc. Every building block is determined by several parameters. For example, the convolution layer is determined by the length (or shape) of the input matrix, kernel size, strides, etc. These parameters are determined before execution and will not change throughout the

task.

With these highly structured task descriptions and the secure protocols used to execute the task, we gain the knowledge of the messages that will be sent during task execution at compile time. For example, if the matrix multiplication is implemented using additive secret sharing, and the parties decompose into vector products, we know that the parties will exchange messages that have the same lengths with the decomposed vectors, according to the multiplication in secret sharing protocol [10].

The prior knowledge enables CORA to assign addresses for messages at compile time, so that applications can write messages directly to the corresponding protocol's buffer, saving the cost of demultiplexing.

3 Design

3.1 Overview

A naive incorporation of RDMA into SCML with a unified buffer leads to suboptimal performance due to its extra overhead of copying and reordering messages. The root cause exists in its inability to recognize upper-layer protocols when sending/receiving data. CORA distinguishes itself with a protocol-aware design of RDMA library that has a static demultiplexing scheme generated at compile time, which improves the efficiency of message exchanging. At its core, CORA identifies the message's protocol and writes it to a *preset* memory address on the receiver side using RDMA. The receiver passes the received message's address to upper-layer protocols without an extra copy.

There are mainly two technical challenges encountered when communicating via RDMA. First, it lacks mechanisms to notify receivers when messages arrive because RDMA bypasses receivers' OS. Although receivers can be notified by posting RDMA *recv* verbs, it requires the same communication patterns between the sender and receiver, which is not always satisfied in SCML. Second, heterogeneous communication patterns lead to unpredictable messages' addresses on receivers' memories, leaving receivers unable to locate received messages. It is impractical to preset remote addresses manually, given various protocols' implementations.

CORA solves the technical challenges by leveraging both characteristics of SCML tasks and RDMA operations. First, SCML tasks are naturally data-parallel and input-irrelevant. Each element in an input array is processed with the same function, such as matrix multiplication and activation, and yields the same communication pattern. Second, RDMA allows verbs to carry a customizable immediate number, which serves as a notification to receivers.

CORA assigns ids encoded in immediate numbers to the messages, which notify the receiver when messages arrive. The receiver locates messages from remote parties by interpreting message ids associated with their addresses in the

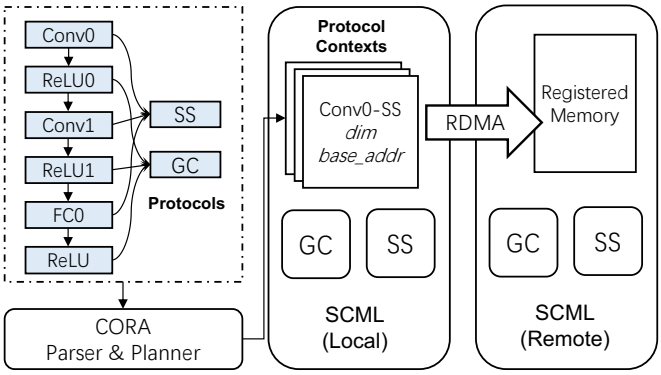

Figure 3: Example of training a model collaboratively with CORA. RDMA is used to send messages to protocols' receiving buffers.

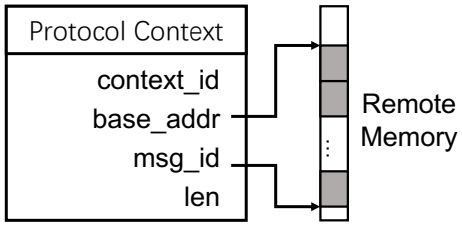

Figure 4: How the protocol context points to a message memory.

Specifically, the input array is applied to the same function, producing message arrays with identical message sizes. We group the messages produced by the input array and access them using a base address and an index. SCML tasks typically require multiple rounds of interactions between parties, leading to multiple message arrays. CORA manages base addresses and indexes with a data structure named *protocol context*. When sending a message, CORA loads the protocol context and writes to the remote address using RDMA. The receiver converts the message id as an index to locate the received message.

We design a *Parser* and a *Planner* to manage protocol contexts. We illustrate their functions with a SCML training task shown in Figure 3. The user defines SCML tasks and provides the backend protocols for secure computation for each layer: Convolution (Conv) layers and Fully Connected (FC) layers are performed with SS protocol, and ReLU activations are performed with GC.

The Parser first processes the model structure, protocol, and input data's length. This information helps to get the memory space needed for each message array. When starting the task, the parties initialize RDMA connections. Each connection registers a memory region on the party's server so that remote parties can write messages directly.

The parties then collaboratively train the model using secure protocols. For each layer, CORA writes messages to the addresses indicated by the protocol context. As shown in

Figure 4, the protocol context assigns a remote address for the message by providing a base address (base_addr) and a message index (msg_id). The remote buffer is filled with a list of messages with the same sizes indicated by grey blocks, as they are produced by the same protocol on different elements in the input array.

The receiver has the same protocol context when receiving messages. When a message arrives, the receiver checks its protocol context for the base address and accesses the message using the index. Upper-layer protocols get the message by reference. Details are shown in §4.

When calculating the next layer, the Planner initializes a new protocol context and allocates a buffer as the base address. The Planner recycles the buffers of existing protocol contexts whose messages have been processed and are no longer needed in the future. Details are shown in §3.3.

3.2 Parser

The Parser is the frontend of CORA, which extracts model structures, backend secure protocols, and input lengths from users' descriptions. It indicates the memory space needed to store messages for each protocol context. The output of Parser reduces the complexity of planning remote addresses when facing all kinds of implementations of secure protocols.

The Parser works without running SCML tasks. With input irrelevance, we know the protocol will yield the same amount of messages on each element in the input array. The Parser extracts the length of input array, which is interpreted as the number of messages. Then CORA gets the memory needed for the layer. For example, in an array with length l where each element corresponds to m messages in the protocol, we have $l \times m$ messages to send to the remote buffer.

Note that some layers, such as convolution, are not performed in a per-element way. For example, convolutions decompose input as subarrays. We classify the layers into arithmetic and boolean layers and apply different parsing methods.

Besides machine learning layers, SCML involves protocols that are not included in model structures. The Parser supports including these protocols in model structures by adding extra layers to models.

- Protocol conversion: SCML may need to convert protocols for encrypting secret data, as no current protocols can support all operations efficiently. Protocol conversions may also involve communication, and CORA builds protocol conversion contexts to accelerate protocol conversion with RDMA (§3.2.3).

- Offline protocols: SCML tasks require generating correlated random data such as Beaver Triples [10] and edaBits [23], which also brings lots of communication (§3.2.4).

3.2.1 Arithmetic Layers

The Parser decomposes arithmetic layers into basic operations and extracts the lengths of messages. Arithmetic layers typically perform matrix multiplications such as convolution layers and fully connected layers. CORA parses the layers' parameters to get the lengths and the adopted secure protocols at compile time as part of the context.

Matrix multiplications are decomposed into inner products of row vectors and column vectors. Assuming the input matrix with lengths $M \times N$ and $N \times P$, the total number of basic operations is $M \times N \times P$. For the messages generated in matrix multiplication, the message ids are $0 \ldots MNP-1$, and the message gets its index with the input elements' positions.

Matrix multiplication has optimized protocol with lower communication overhead [44]. The optimized secure matrix multiplication regards input matrices as a whole. When performing secure matrix multiplications, the optimized implementation yields messages with the same lengths as the input matrices, namely $M \times N$ and $N \times P$. In this case, the message ids are $0 \ldots MN+NP-1$.

Note that the sizes of input matrices are usually specified in the SCML program, which provide us with the sizes of messages at compile time. In rare cases where the SCML program does not specify the lengths of vectors, the parties would have to agree on the input length before execution so that Parser could still get the length and assign indexes for the messages.

3.2.2 Boolean Layers

Boolean layers such as ReLU activation, Softmax activation, and Max Pooling are mostly implemented with protocols such as boolean secret sharing and garbled circuits. Although it is feasible to implement all layers with boolean protocols, current SCML frameworks avoid doing so because boolean protocols are generally less efficient in arithmetic tasks [20].

The Parser assigns message lists with the indexes of data elements. Boolean layers are mainly implemented by feeding the input array's elements iteratively into the boolean protocol. For single-input activations such as ReLU and Softmax, each element yields the same communication pattern; for multi-input protocols such as Max Pooling implemented by comparison protocol, the Parser assigns message lists with the element with minimal index in the input matrix.

Note that boolean layers may have multiple rounds of interaction. For example, Max Pooling layers may be implemented by boolean secret sharing with multiple AND gates, which requires multiple rounds of communication. In this case, the Parser aggregates the total number of gates as the message indexes list.

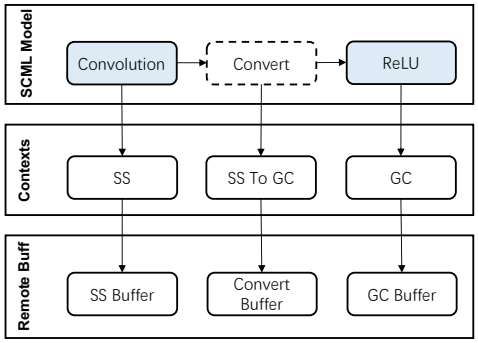

Figure 5: CORA detects protocol conversion and sets up protocol contexts to handle communication during converting.

3.2.3 Protocol Conversion

Existing SCML frameworks usually use hybrid protocols for different operations [43, 45]. For example, arithmetic secret sharing is used for matrix multiplication, while GC is used for Softmax. Hybrid protocols require converting the form of secret sharing to other protocols when needed.

Protocol conversions change the representations of secret data using different conversion functions, which may involve communication [20]. For example, when converting secret data from arithmetic secret sharing to boolean secret sharing, the parties jointly compute a bit extraction circuit; when converting from boolean sharing to arithmetic sharing, the parties evaluate a bit-adder circuit. We regard protocol conversions as extra layers in SCML tasks, as shown in Figure 5.

3.2.4 Offline Protocols

SCML needs protocols that generate Beaver triples and other correlated random data consumed in the online task. Since the generation of triples is not related to the input of online tasks, existing works often schedule these protocols offline, which is done before the execution of online task [43, 44, 58].

Considering that offline protocols may bring large amounts of communication in SCML, especially when the model is large, CORA builds extra protocol context to accelerate communication in offline protocols. Compared to SCML layers, offline protocols do not have associations with the input data. CORA creates a protocol context for offline protocols specifically.

There are mainly two methods for generating Beaver triples: OT-based protocols and HE-based protocols [20]. CORA sends the messages during triple generation to a specific buffer on the remote party. The messages are passed to upper-layer protocols without extra copies.

3.3 Planner

The Planner manages the protocol contexts by assigning their base addresses and message ids before sending/receiving. It realizes memory space needed with the input lengths extracted by the Parser and the message sizes.

When sending a message, the Planner checks if the protocol context exists. If so, it assigns the message id with the data index in the array. Otherwise, it first allocates memory and initializes a new protocol context. The Planner frees the remote memory when the remote party has processed the messages.

Specifically, the remote address is decided by the following equation:

$$\text{dest\_addr} = \text{base\_addr} + \text{msg\_size} \times \text{index} \quad (1)$$

In the equation, dest_addr represents the destination address on remote memory; base_addr represents the base address in the protocol context; msg_size represents the size of message; index is the position of element in the array.

On the sender side, the Planner first gets the message's size, the index in the input array, and the layer's input length. It allocates the memory space for the current layer and initializes the base address. The Planner allocates memory with a simple searching algorithm: it finds the first memory region that satisfies the need. Note that the allocation algorithms are the same for all parties. So, the protocol contexts on different parties have the same base address, guaranteeing that senders write to the same location from which receivers read.

Algorithm 1 How Planner allocates memory space and prepare protocol context for a message

Input: *msg_size*, *input_len*, *p_context*, *index*
G: dependency graph of the model, l: current layer
Output: Modified *p_context*

1: $M \leftarrow msg\_size \times input\_len$ ▷ The total memory needed
2: **if** *p_context* is not initialized **then**
3: Search Remote Buffer to place M
4: **if** Success with *addr* **then**
5: $p\_context.base\_addr \leftarrow addr$
6: **else**
7: Report Failure
8: **end if**
9: **end if**
10: $p\_context.msg\_id \leftarrow index$
11: $p\_context.len \leftarrow msg\_size$
12: **if** l finished **then** ▷ free memory
13: $L \leftarrow l.prev$ ▷ The layers that l_i depends on.
14: $G.L.next -= 1$ ▷ All layers have one less child layer.
15: **if** any layer l_i in $G.L$ has no child layer **then**
16: Free the memory used by l_i
17: **end if**
18: **end if**

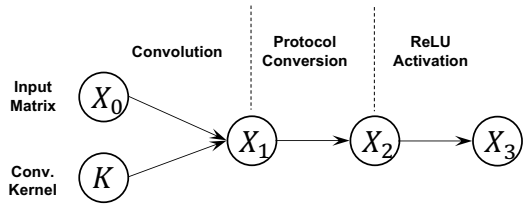

Figure 6: Dependency graph generated from a convolution followed by ReLU activation.

On the receiver side, the Planner modifies the protocol context in a symmetric way to the sender's so that the protocol contexts at both sizes point to the same message on the receiver's buffer. We summarize the algorithm of Planner, as shown in 1.

The Planner releases the memory region of a protocol context when its messages are no longer needed by the remote party. It manages the remote memory usage with a dependency graph generated from the model structure. As shown in Figure 6, each node represents data that correspond to messages in the protocols. The convolution is followed by the activation. For every layer, the Planner associates the protocol context with the layer's data. When the layer's data is no longer used, the Planner releases the memory occupied by this layer. For example, in Figure 6, if X_2 has finished, CORA knows the messages produced during the convolution will no longer be used and releases the memory region used by the protocol context. We list the algorithm of releasing memory in List 1 line 12-17.

Besides machine learning operations, it also brings communication to generate offline data and convert protocols as mentioned in §3.2.4 and §3.2.3. Messages for offline data generation do not depend on messages in machine learning layers. Therefore, the Planner allocates a fixed memory region for offline protocol's context. For protocol conversion, the Planner regards it as an extra layer in the model.

4 Implementation

The core component of CORA is the protocol context. The Parser creates protocol contexts based on the model structure. The Planner initializes the protocol context with the current layer and message sizes. When sending a message, the message address indicated by the protocol context is encoded as a notification to the receiver.

Send Sending messages is implemented using *write* verb with immediate data, which writes data directly to the specified address on the remote host with an additional 32-bit immediate number carried by the verb. The immediate number not only notifies task completion but also carries 32-bit extra data besides the payload. CORA configures the four most significant bits to indicate the protocol, and other bits to indicate the offset. For example, CORA sets 0000 as the most significant bits of the immediate data to indicate OT protocol.

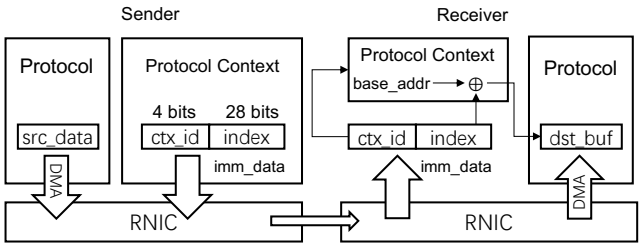

Figure 7: Implementation of sending a message with protocol context.

The remaining bits indicate the offset, which is interpreted as the address on receiving buffer.

Receive On the receiver side, the RNIC will generate a new element in the completion queue when a message arrives. CORA sets a dedicated thread to handle completion elements. It interprets the 32-bit immediate data as the protocol and offset. Next, a completion flag is set to inform upper-layer protocols of a new message arrival.

Note that the immediate number has four bits to encode the protocol contexts, allowing 16 protocol contexts, which are often less than the total number of layers needed. However, the four-bit encoding is enough in runtime because the number of concurrent protocols is usually less than 16. For instance, the parties may only need four protocol contexts for the current layer, the last layer, the next layer, and the offline protocol that generates Beaver triples.

CORA hides the details of sending/receiving from secure protocols by providing socket-like APIs. When CORA executes a layer in a machine learning task, it loads the corresponding protocol context, which contains a base address that points to the remote buffer. The messages are written to the remote address with the offsets associated with the indexes in the array. When a protocol needs to receive a message, it polls for the arrival of that message by checking the finish state with the message id.

Multi-Threading Some frameworks use multiple threads to accelerate computation. There are mainly two cases when using CORA in multithreaded frameworks: The case where worker threads synchronize with only one thread handles communication, and the case where multiple worker threads handle communication.

For the first case, CORA is set up in the communicating thread. The usage of CORA stays the same as the single-thread case; for the second case, we initialize multiple CORA objects in each thread. Each thread binds a unique port, resulting in multiple RDMA connections. Unlike single-threading, multi-threading CORA needs the index of the corresponding element in the global input array when sending or receiving a message because the indexes of the threads' input may overlap. The global index can be converted from the local index and the thread index.

CORA provides a high-level interface for integrating into

Framework	#Existing Lines	#Lines Modified
EMP-OT [3]	1873	54
ABY [20]	20209	141
Piranha [58]	17976	47

Table 1: Number of lines in frameworks and number of lines need to modify in order to utilize CORA

existing SCML frameworks easily. We revised the implementations of Piranha, ABY, and EMP-OT. The numbers of codes changed are shown in Table 1. Although ABY and EMP-OT are not designed for machine learning tasks, they can also use CORA to accelerate communication when using multiple protocols.

```
1
2  void SCML_Layer(Matrix *inputs, Matrix *outputs,
       protocol *p) {
3    // high-level description of the SCML layer
4    // first execute some codes to perform local
       computation
5    Matrix *tmp = local_preprocessing(inputs);
6    // then prepare the messages
7    Matrix *source_data = prepare_message(tmp);
8    // get the protocol context
9    CORA.select_protocol_context(p);
10   // perform interaction
11   CORA.send(source_data);
12   Matrix *recv_data = CORA.recv_msg();
13   // there may be other rounds of interaction
14   // ...
15   // post processing, write output
16   outputs = post_processing(inputs, recv_data);
17 }
```

Listing 1: A general description of how CORA is used in existing frameworks.

Code 1 shows the general procedure of using CORA in existing frameworks. Note that the Matrix data structure and APIs are for demonstration and may differ with frameworks. Existing SCML frameworks typically use Linux sockets to send/receive messages. To send a message, they use send API or write to the socket's file descriptor. CORA replaces this routine with protocol-aware RDMA write. It first loads the protocol context to get the protocol id and remote address for the next write operation. Then we call send API of CORA, which posts a work request to the RNIC and returns. The message should not be modified until the transmission finishes.

For message receiving, CORA replaces this routine with its receive API. The protocol context stores the address of the next message and a flag variable indicating the message's arrival. CORA returns the message's address to the caller when the flag is set. The address is configured at compile time by Planner so that other incoming RDMA operations will not overwrite the message (§3.3).

5 Security of CORA

CORA relies on existing security mechanisms of RDMA to provide isolation of parties. First, a party needs the remote server's key generated specifically for the registered memory region before accessing. Second, a party cannot access other parties' remote memory regions because it lacks other regions' keys. The isolation guarantees that the parties cannot steal other parties' messages.

It is possible to have security issues when using RDMA. For example, the parties may mistakenly store sensitive data in the memory regions accessible by other parties so that other parties can read the sensitive data without notifying the owners. The unintended vulnerabilities may require extra examination in runtime.

Compared to existing SCML frameworks, CORA exposes the memory access pattern to other parties for efficiency. The memory access pattern will not cause security issues because MPC protocols are input-irrelevant. The memory access pattern does not expose information about the secret input.

Moreover, the security of RDMA hardware has been improving. ReDMArk [49] gave mitigation mechanisms to fix RDMA vulnerabilities. Later, Bedrock [59] proposed a hardware-based defense system to secure RDMA without performance penalty. It is expected that the security of RDMA system will continue to be enhanced in the future.

Besides hardware security, the parties may need secure channels to prevent overhearing by adversaries. Recent works have proposed secure channels over RDMA. For example, sRDMA [53] provided efficient authentication and encryption for RDMA to prevent information leakage and message tampering; PANIC [38] implemented multi-tenant isolation in a public cloud. Moreover, the latest commercial RNICs have supported autonomous TLS offload [46], which achieves better performance than TLS on CPU. The TLS offloading has shown the RNIC's efficiency in packet encryption and decryption. Thus, RDMA can bring both performance improvement and security guarantee to applications.

6 Evaluation

Evaluation Overview We summarize the test cases and the results as follows:

- Performance on SCML building blocks, including offline protocols, machine learning layers including matrix multiplication, convolution, and ReLU. The result shows that CORA brings $1.8\times - 7.2\times$ speedup over TCP and $1.6\times - 6.6\times$ speedup over rsocket on basic building blocks (§6.3).
- Performance on model training and inference, including SecureML, LeNet, VGG16, and AlexNet. The result shows that CORA brings $1.2\times - 4.2\times$ speedup over TCP and $1.1\times - 3.9\times$ speedup over rsocket (§6.4).

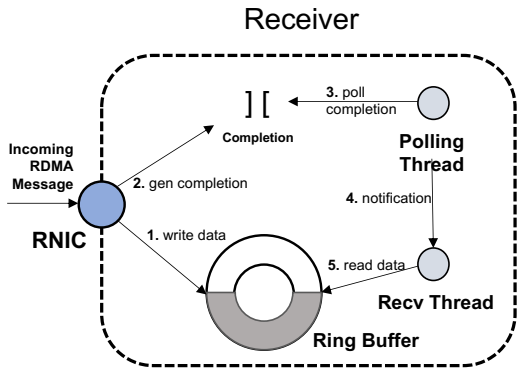

Figure 8: Illustration of rsocket that uses unified ring buffer to send/receive data

- We compare CORA's communication cost to existing transport optimization, including Transputation [12] and MOTION [13] (§6.5).
- Performance Decomposition. We recorded the communication and computation costs during training. We show that CORA reduces communication cost by $2.9\times - 11.0\times$. Communication is no longer the bottleneck of SCML (§6.6).

CORA focuses on deploying SCML in a single datacenter, where servers are interconnected with RDMA network (§2.1). Some SCML frameworks deploy SCML in multiple datacenters. We show that the performance of CORA in inter-datacenter networks is bounded by the propagation delay between datacenters (§6.6).

6.1 Experiment Settings

We run our experiments in a computing cluster with 100 Gbps Mellanox ConnectX-5 RDMA NICs. Each server has an Intel Xeon 5218R CPU (40 cores), 128 GB memory, and a Nvidia Tesla V100 GPU. The ping between servers is about 0.1 ms.

We assume that each party in SCML has one server. Both TCP-based and RDMA-based experiments use the RNIC. RNIC supports both TCP and RDMA traffic by automatically switching between TCP and RDMA modes according to the way of accessing the network interface.

Baseline We compare CORA against the default TCP network in SCML tasks. In addition, to show the benefits of protocol-aware RDMA, we show the performance of CORA over rsocket [7], a general-purpose RDMA library that uses a unified ring buffer to send/receive data, as shown in Figure 8. rsocket sets a unified buffer on the receiver side. When a new RDMA message arrives, RNIC writes the message to the buffer's tail and generates completion. The receiver has a polling thread that notifies the receiving thread when getting a new completion. Then, the receiving thread reads new messages from the buffer's head.

Note that Piranha utilizes GPU and stores data in GPU memory. However, RDMA only supports accessing host memory by default. We use GPUDirect RDMA [2], a built-in feature from CUDA 11.4, so that RDMA can access the GPU's memory just like accessing the host memory.

Test Cases We evaluate the speedup on the following tasks:

Offline Protocols Piranha ignores the cost of the offline phase, which involves generating multiplication triples, and only implements the online phase. However, the offline phase takes a large portion of the total cost when taken into account. Existing SCML frameworks generate multiplication triples based on OT (§3.2.4). We integrate CORA in EMP-OT to test the performance of OT and triple generation.

Basic Building Blocks For basic building blocks, we tested matrix multiplication, convolution, and ReLU activation. We tested the speedup under different sizes of input and different numbers of parties. The matrix multiplications and convolutions are implemented with arithmetic secret sharing. The ReLU activation is based on GC.

Model Training For the whole training process, we tested models in SecureML, LeNet, VGG16, and AlexNet. SecureML and LeNet are trained on MNIST [5] dataset; VGG16 and AlexNet are trained on CIFAR-10 [1] dataset. Each case is implemented with two-party semi-honest (2PC) [44], three-party replicated-ring (3PC) [43], and four-party replicated-ring (4PC) [19] protocols, respectively. These protocols are most widely studied in existing SCML frameworks. All protocols had their field set as 32 bits. The computation on float-point arithmetic is the same as the implementation of SCML frameworks.

Inference When performing an inference task, we pay more attention to the time spent to infer a single data sample because it represents the end-to-end latency of performing an inference task. We tested inference performance with the same model as in the training experiment. We set the input batch size as one to test the inference performance.

6.2 Offline Protocols

One of the most significant costs in the offline phase is to generate Beaver triples [10], which are used when multiplying two secret sharings. Existing works have implemented triple generation based on OT. We test the triple generation based on IKNP OT [9] implemented by EMP-OT [3] library.

For the performance of CORA in OT, we integrate CORA in EMP-OT to test the speedup on different OT protocols, including IKNP and Ferret [61]. The implementations of OT protocols assume semi-honest security settings. We tested TCP, rsocket, and CORA in OT, respectively, and the result is shown in Figure 9. CORA achieves $1.3\times - 4.5\times$ speedup over TCP and $1.1\times - 4.2\times$ speedup over rsocket. The performance of rsocket is bounded by the message copy on both

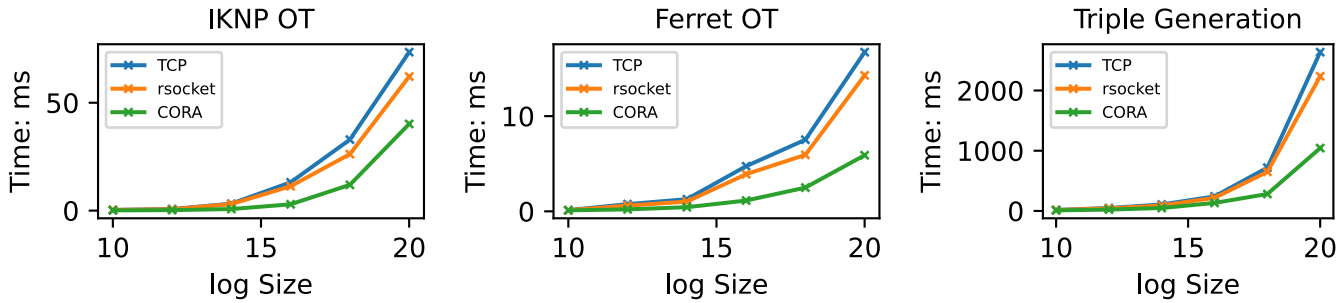

Figure 9: Time elapsed for conducting OT and triple generation.

sides. In the OT task, the sender generates and sends an array of ciphertext to the receiver. On the sender side, rsocket implements the sending task by copying the message to a unified buffer on the local host and posts RDMA *write*. On the receiver side, rsocket copies the received data to the OT buffer. Compared to rsocket, CORA reads source data from the sender's buffer and writes to the receiver's buffer directly without an extra copy.

OT-based Beaver triple generation is performed with a batch of OT tasks [20]. We integrate CORA into ABY, a two-party computation framework that implements the triple generation based on semi-honest IKNP OT with two parties. The width of the triple element is set as 32 bits. For each triple, the parties need 32 OTs. Figure 9 shows the performance improvement. In the figure, N stands for the number of triples to generate. CORA achieves $1.8\times-2.6\times$ speedup over TCP and $1.6\times-2.3\times$ speedup over rsocket.

6.3 Basic Building Blocks

We compare CORA with the default TCP network and rsocket by integrating into Piranha, a GPU-based SCML framework. We run the basic building blocks, including matrix multiplications, convolutions, and activations. In general, CORA achieves $1.8\times-7.2\times$ speedup over TCP and $1.6\times-6.6\times$ speedup over rsocket. Figure 10 summarizes the result for each basic building block.

Matrix multiplication is tested by multiplying two $N\times N$ matrices using arithmetic secret sharing under a semi-honest security setting. The offline phase generates triples with IKNP OT. The matrix multiplication is decomposed as a series of vector dot products. CORA achieves $2.1\times-4.9\times$ speedup over TCP and $1.8\times-4.3\times$ speedup over rsocket.

Essentially, convolution is also decomposed as matrix multiplications. We chose the size of convolution layers that are commonly used in model training and calculated the number of total basic multiplications. In model training on the MNIST dataset and the CIFAR-10 dataset, the convolution cost is from 1.6×10^6 to 5.7×10^8. CORA achieves $1.8\times-4.7\times$ speedup over TCP and $1.6\times-3.5\times$ speedup over rsocket.

For ReLU activation, the operation is implemented by multiplying with a flag, which is generated by comparing with zero. The test is conducted on the implementation of Piranha based on edaBits. The communication task involves one round of reconstruction between parties. CORA achieves $3.6\times-7.2\times$ speedup over TCP and $2.6\times-6.6\times$ speedup over rsocket.

The implementation of basic building blocks usually involves only one round of interaction: matrix multiplication protocol reconstructs the secrets with offset among parties, and ReLU with edaBits reconstructs the masked input with one round of interaction. CORA mainly benefits from the high bandwidth and the zero-copy characteristic compared to TCP and rsocket.

6.4 Model Training and Inference

The training process relies on forward propagations and backward propagations to update model parameters. We set other task parameters the same as the Piranha's, such as the bits reserved for float arithmetic and sizes of ciphertexts. We trained for ten epochs on each model and calculated the average cost for training each batch of data.

The performance of CORA on the whole training process is shown in Table 2. CORA achieves $1.2\times-4.2\times$ speedup over TCP and $1.1\times-3.9\times$ speedup over rsocket. Besides the basic building blocks, the speedup of CORA also comes from the protocol conversion when performing activation on linearly secret sharings (§3.2.3) and the backward propagation process.

6.5 Comparison to TCP Optimizations

To show how CORA improves communication performance compared to other transport optimizations, we tested machine learning tasks using Transputation [12] and MOTION [13]. Transputation, as an independent communication module, is integrated into Piranha for testing. MOTION, however, is a full-stack framework. We only compare their time spent in communication, as shown in Table 3.

Compared to the other two frameworks, CORA has far less communication cost. The speedup over the other frameworks can be explained from two aspects: First, Transputation and MOTION configures the TCP sockets for high-latency

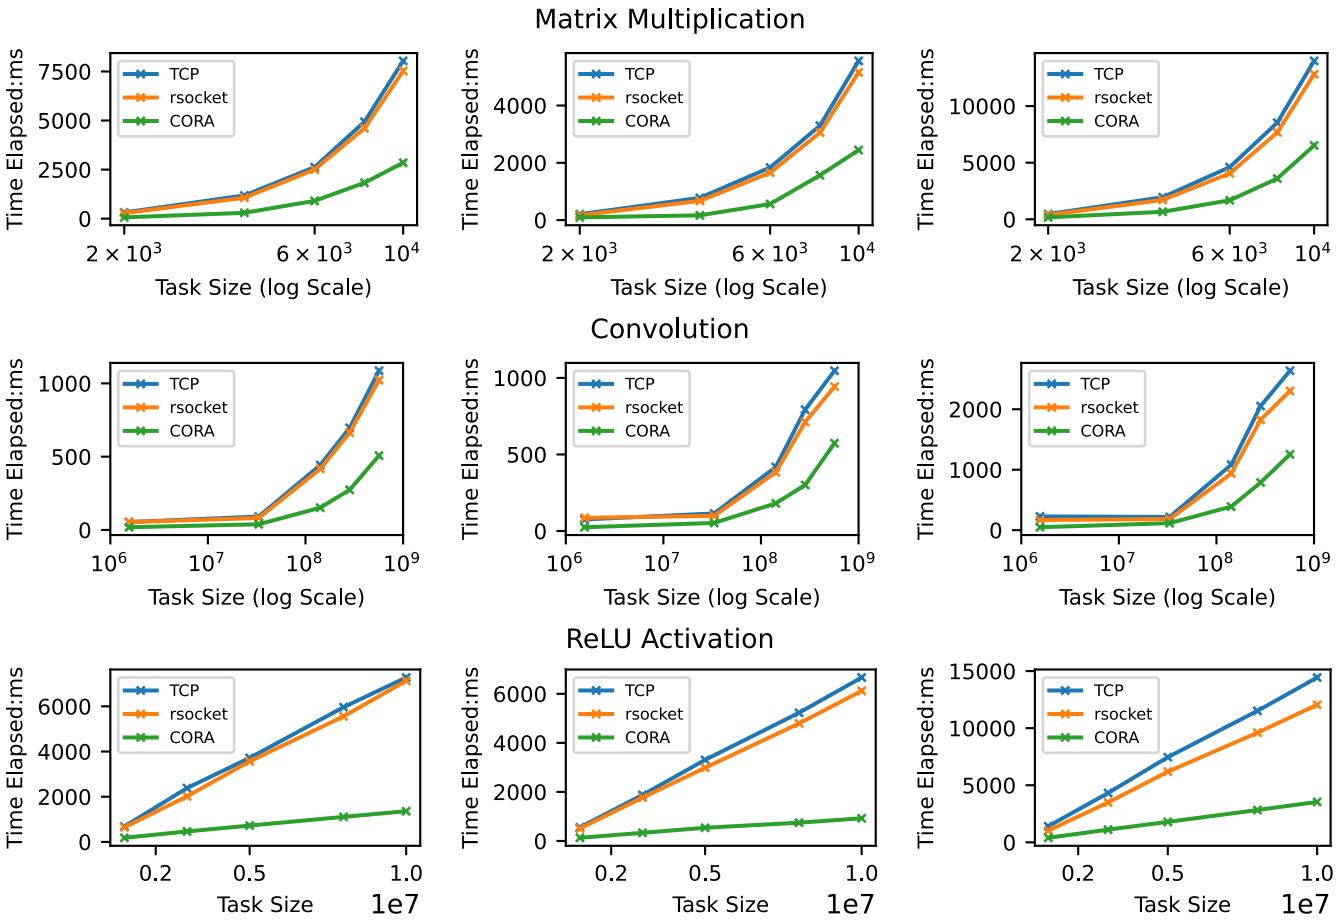

Figure 10: Performance of basic building blocks after applying CORA.

network environments, such as non-blocking operations. However, datacenter provides a low-latency interconnect, and it is more important to optimize data transmission at the end host. Second, TCP-based optimization requires CPU cycles for packet processing. When CPU cores are busy with computing, the communication is delayed.

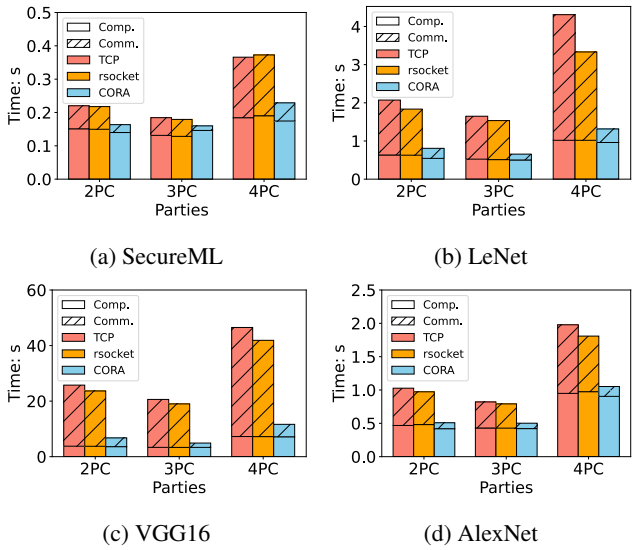
6.6 Performance Decomposition

To inspect how CORA achieves better performance over rsocket and TCP, we profile the communication and computation costs of the training task. We show that CORA has a much smaller communication cost compared to rsocket and TCP.

Figure 11 illustrates the decomposed cost for model training. Compared to CORA, rsocket and TCP have much higher communication cost, which dominates the total cost. In contrast, CORA has much lower communication cost, and the main cost shifts to computation overhead.

When sending a message, rsocket first copies the message into the buffer on the local host and sends the message using RDMA *write*. On the receiver side, rsocket monitors the arrival of new messages by checking the head pointer of the buffer, which can only detect the arrival of messages adjacent to the head pointer. CORA is more efficient because it does not involve copies during sending, and the receiver can get the addresses of arrived messages by checking the immediate data.

Training in Inter-Datacenter Network CORA relies on the high bandwidth and low latency of RDMA network in the same datacenter. For the case where SCML parties reside in multiple datacenters, the network performance is bounded by the bandwidth and propagation delay between datacenters [65]. For example, the Round Trip Time (RTT) between two datacenters across continents could be over 60 ms, and the bandwidth is less than 10 Gbps, compared to an intra-datacenter network that has 100 Gbps bandwidth and $< 1ms$ latency.



We show that the performance of SCML in the inter-datacenter is bounded by the propagation delay after using CORA. We simulate the inter-datacenter network by limiting the bandwidth to 10 Gbps and adding 10 ms RTT between servers. We decompose the communication cost into transmission cost at the end host, including data copy and transmission by RNIC, and the propagation cost. The result is shown in

	Model	SecureML			LeNet			VGG16			AlexNet

Figure 11: Cost decomposition of training different models on different numbers of parties.

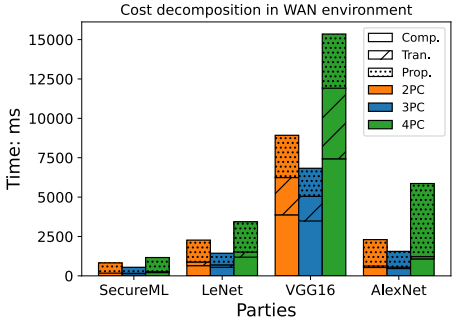

Figure 12: Decomposition of cost in the inter-datacenter environment, where the bandwidth is limited to 10Gbps and RTT=10ms.

Figure 12. It shows that in a network condition where the RTT is 10ms, the propagation cost takes at least nearly half of the total communication cost.

7 Discussion

Performance in Inter-Datacenter Network CORA focuses on accelerating SCML in a intra-datacenter network, where communication bottleneck exists at end hosts. If the parties of SCML reside in multiple datacenters, the network latency between parties could be hundreds of milliseconds and the bandwidth is usually less than 10 Gbps. In this case, the performance of SCML is bounded by the inter-datacenter network, which is out of the scope of this work.

Even with the marginal improvement in the inter-datacenter setting, RDMA is better than TCP in SCML. First, intra-datacenter environment is preferred for machine learning tasks, considering that companies and individuals have already stored their data in datacenters. Recent works such as ABY3 [43], Sharemind [6, 11], PrivPy [37] have deployed SCML among multiple servers in intra-datacenter environment. Second, SCML applications have higher utilization of CPU resources with RDMA, because RDMA implements the data transmission in hardware and does not need consume extra CPU cycles for packet processing.

Applying to General Secure Computation CORA can be extended to general MPC frameworks that use graph-based description of tasks, so that CORA parser can identify the protocol contexts. For example, ABY describes the MPC tasks with a graph, in which the nodes represent gates and the edges represent wires. CORA can be applied to ABY with a new frontend that parses circuit files and produces protocol contexts that match the execution of circuits. Moreover, ABY circuit files can be analyzed by CORA Planner to find the dependency of secret sharings, so that the memory can be reused efficiently. We have applied CORA to ABY, as listed

in Table table 1.

For secure computation frameworks that do not have a high-level description, CORA can be used by managing the receiving buffer as a ring. The developer defines the protocols used in the secure computation program, and CORA creates the buffers that are used specifically for the protocols. When sending a message, CORA writes to the end of the corresponding buffer of the protocol. On the receiving side, CORA passes the addresses of messages to upper-layer protocols. When the receiver consumes messages, it notifies the sender so that the buffer can be reused by other messages.

That said, it might be challenging to apply CORA to general secure computation frameworks. First, some frameworks have optimizations that may change the execution order. For example, MP-SPDZ sorts the computation graph in topology order which results in a different execution order as the task file's, which requires more efforts in order to embed CORA to MP-SPDZ runtime. Second, some frameworks, such as Opaque [68], relies on hardware enclaves that encrypt the memory which can be decrypted only inside the processor. A co-design of RDMA and hardware enclave is needed in order to perform RDMA operation to encrypted remote memory.

Limitations CORA requires that all parties in SCML have RDMA hardwares. If some parties lack RDMA support, they can use soft-ROCE [8], a software implementation of RDMA that does not require dedicated hardware to run RDMA programs. However, soft-ROCE is slower than hardware RDMA, as the packet processing in the software is less efficient than RDMA hardware. Moreover, RDMA performance suffers from bursty and lossy network environments, as there might be head-of-line blocking [71] or deadlock [28], and the packet retransmission in current hardwares is not efficient either. Researchers have been working on new RDMA solutions to address these issues. For example, Tagger [29] proposed efficient deadlock handling, and SRNIC [57] implemented efficient retransmission for RDMA.

8 Related Work

There have been many efforts that could accelerate SCML. We classify existing works with their methods and compare them against CORA.

Protocol Optimizations focus on designing more efficient protocols for secure computation tasks. For example, GAZELLE [31] and MiniONN [41] focused on efficient secure inference on trained models using OT protocols; ABY3 [43] proposed an efficient honest-majority protocol for machine learning among three parties; Falcon [56] proposed an honest-majority and maliciously secure protocol to train neural networks among three parties; Cerebro [69] built a framework for general SCML applications and automatically optimize the circuit layout; Sphinx [54] proposed new protocols for efficient secure online learning; FedSVD [17] accelerated secure singular vector decomposition protocol on large datasets. SOLAR [47] proposed new secret sharing protocol that automatically balance between computation and communication. CORA could bring extra benefit to these works by accelerating communication between parties.

Computation Optimizations accelerate SCML by leveraging hardware such as multi-core CPU, GPU, and FPGA [67]. CPU-based accelerations, such as [14], implemented protocols in parallel to fully utilize CPU cores; GPU-based accelerations, such as HAFLO [18], CryptGPU [52], and Piranha [58], accelerated SCML computation with massive parallel GPU threads. FPGA-based accelerations such as [62] and FLASH [66] accelerated computation with efficient and dedicated FPGA circuits. Computation optimizations are orthogonal to CORA, which could be combined together.

Network Optimizations use other transport protocols to accelerate communication. For example, Shrishak et al. [50] used UDP protocol in lossless network environments, and they chose UDT protocol in Wide Area Network (WAN) environments. Brandt et al. [12] proposed an optimal transport protocol that can adjust to different network environments for secure computation. MOTION [13] adopted full communication serialization that enabled MPC over arbitrary messaging interfaces and removed the need to own network sockets. These works identified TCP sockets as the bottleneck of communication and tried to replace the TCP socket with a more efficient socket system. CORA distinguishes itself with an offloaded transport on hardware, which is more efficient than software transport in network applications. Moreover, CORA combines the SCML communication pattern and RDMA interface to process messages efficiently.

9 Summary

This paper presented CORA to implement SCML over the RDMA network. CORA improves the efficiency of using RDMA in SCML workload by using a protocol-aware design. It maintains socket-like APIs that can be easily integrated into existing SCML frameworks. We compare CORA with TCP and rsocket, a common practice of RDMA without a protocol-aware mechanism, under the SCML building blocks, model training, and inference. Our results show that CORA achieves $1.2\times - 4.2\times$ speedup over TCP and rsocket. CORA's source code is publicly available (https://github.com/renzh1998/CORA).

Abstract

Efforts from emerging technology companies aim to democratize the ad delivery ecosystem and build systems that are privacy-centric and even share ad revenue benefits with their users. Other providers offer remuneration for users on their platform for interacting with and making use of services. But these efforts may suffer from coordinated abuse efforts aiming to defraud them. Attackers can use VPNs and proxies to fabricate their geolocation and earn disproportionate rewards. Balancing proxy-enabled abuse-prevention techniques with a privacy-focused business model is a hard challenge. *Can service providers use minimal connection features to infer proxy use without jeopardizing user privacy?*

In this paper, we build and evaluate a solution, CalcuLatency, that incorporates various network latency measurement techniques and leverage the application-layer and network-layer differences in roundtrip-times when a user connects to the service using a proxy. We evaluate our four measurement techniques individually, and as an integrated system using a two-pronged evaluation. CalcuLatency is an easy-to-deploy, open-source solution that can serve as an inexpensive first-step to label proxies.

1 Introduction

Online advertising revenue in the U.S. reached over $209.7 billion in 2022, almost three times as much as the revenue from U.S. TV advertisements [1, 2]. Companies and service providers increasingly thrive on collecting, processing, and sharing large amounts of data on users, and monetize this data by enabling targeted ads and tracking. Reports have criticised leading companies such as Google and Facebook, calling them surveillance giants, and asserting that their business models are a threat to privacy and even to human rights [3].

With the growing awareness and demand for privacy among the general public, emerging tech companies are aiming to democratize the ad delivery ecosystem by building services that are privacy-focused and even share ad revenue with users. A plethora of companies offer ad and tracker-blocking for users regular browsing experience and provide alternative search engines geared toward privacy. Some also create solutions that promote user agency by allowing users to opt-in to viewing and earning rewards from privacy-preserving ads. On a technical level, such "ad reward networks" make use of browsing activity to generate ads but all the computational process occur locally on the user's device, without any data being exfiltrated to the companies. They then use privacy-preserving protocols to confirm ad event activity and reward users in cryptocurrency based on ad-providers and region-specific pricing. There are several companies that have similar rewards and provide remuneration to users on their platform for making use of their services [4, 5, 6, 7].

One critical threat to these novel types of reward networks is attackers who actively game the reward system by leveraging VPNs or proxies. These attackers fabricate their geolocation to gain access to more high-reward ads and falsify interaction activity to earn disproportionate rewards. Ensuring the long-term viability of these privacy-focused business models necessitates cost-effective and easily deployable techniques to differentiate regular users from those who use VPNs or proxies, for further monitoring for suspicious activity.

Balancing abuse-prevention techniques with rigorous privacy-requirements is a hard challenge, especially if the service provider seeks to uphold user privacy. The state of the art in generic VPN and proxy detection uses a series of heuristics developed by surveilling client traffic at large. Deployed by large platforms, these services use user data to build IP reputation metrics, generate user-specific metrics, and even use black box services that claim to detect "suspicious" users and IP addresses. But to get these metrics, the service provider will need to compromise on protecting the privacy of their users. In short, we seek to answer: *Can service providers build a system using minimum connection features, such as latency, to infer VPN or proxy use, without the need for data collection or jeopardizing user privacy?*

In this paper, we build and evaluate our solution to this question, CalcuLatency, that leverages cross-layer network latency

measurement techniques to differentiate users that are using a remote, long-distance VPN or proxy from those who are not. We leverage the fact that the application-layer latency when a user connects through a proxy is end-to-end (browser to server), whereas, any measurement on the network-layer only reaches the proxy, and the round-trip time (RTT) difference between the two can be a reliable indicator. To this end, we combine existing techniques such as WebSocket RTT, TCP handshake RTT, and ICMP ping, as well as implementing and evaluating a modified traceroute method (0trace), which has not been done before. 0trace conducts hop enumeration from within an *existing, established TCP connection* such as a web-socket session. Using CalcuLatency, we can even differentiate between network-layer and application-layer proxies.

To evaluate CalcuLatency, we evaluate each of the measurement techniques on their own and also evaluate the system as a whole by using a comprehensive (geo)diverse set of clients. The former is necessary to characterize and quantify, for each technique, the effects of network jitter and reliability of the methods. For the latter, we implement the system as a web service and conduct a two-pronged evaluation of CalcuLatency as a whole: (i) we perform an in-depth testbed evaluation where we maximize the number of VPN products, servers, protocols and browsers tested, from four different user geolocations; (ii) we expand this to include a real-world, crowdsourced evaluation to collect and analyze more diverse user geolocations. To this end, we rally user participation on Twitter and personal contacts, using the authors' accounts. We have participants from 37 different countries located in all (six) continents, 144 autonomous systems, and collect a large crowdsourced dataset.

We find empirically that a viable threshold to consider a particular client as a remote VPN or proxy connection is 50 milliseconds. In 98% of *all direct measurements* from both sets of evaluation, we find that the RTT difference is below this threshold of 50ms. Conversely, 89.1% of *all VPN measurements* in the testbed evaluation and 63.9% of the crowdsourced evaluation have an RTT difference of *above 50ms*. Through location analysis, we were able to attribute a majority of the remaining 10.9% and 36.1% VPN measurements to the fact that the VPN server and the user were located very close to each other.

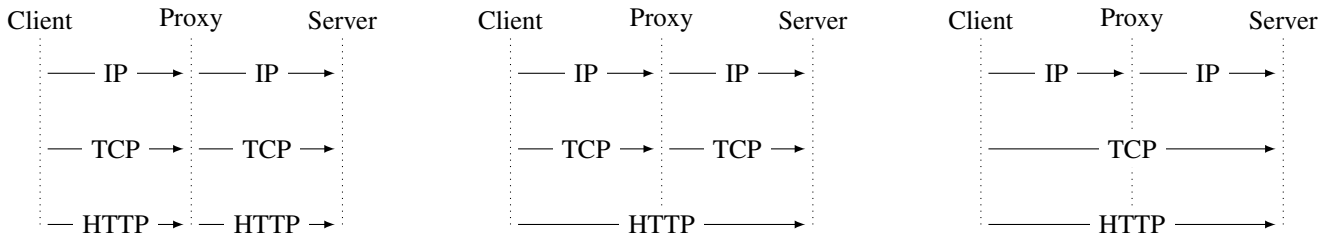
Investigating the VPN measurements whose RTT difference was below 50ms, we find that in a majority of such cases (66.2%) the VPN server is located close to the user (within 650mi). This can be equated to straight line distance between Washington DC and Boston, MA (635mi) or the straight line distance between Mountain View, CA and San Diego, CA (685mi). Surprisingly, this indicates that we can reliably detect proxy use when a user and the VPN or proxy are just 650 miles apart or more.

Overall, we consider 50ms to be the RTT difference threshold for a connection to be labelled as a remote VPN or proxy, our system has a *false negative rate of 2.9%* (28/964) and a low *false positive rate of 0.95%* (2/210).

Adopting a more conservative analysis strategy, if we only consider measurements where ICMP ping is successful and 0trace reaches the client or its network (i.e. 96% of all measurements), we find that the RTT difference is below 50ms for the 210 direct measurements, and none were wrongly flagged using our system. These measurements include 137 unique user IPs from 84 different Autonomous Systems (ASes), from six different continents and over 34 different countries. We also reduce our false negatives to 2.77% (26/937).

While CalcuLatency cannot detect all proxy use especially if the user and VPN are close to each other, CalcuLatency is an easy-to-deploy, open-source solution that can serve as an inexpensive defense against proxy enabled abuse for server-side operators. We incorporate existing methods to calculate network latency and implement a modified traceroute method to overcome the challenges of our probes getting blocked due to stateful firewalls or NATs. Though this traceroute concept was first discussed over two decades ago, we are the first to implement, deploy in a real-world system, and evaluate its performance.

The following are our contributions in this paper: we propose a system, CalcuLatency, that combines existing building blocks and implements measurement techniques to help detect VPNs and proxies. We extensively evaluate our technique and elaborate on its calibration. We perform several controlled and crowdsourced experiments with our system deployed in real-networks and collect data to quantify thresholds and characterize the reliability of our techniques.



Roadmap: In Section 2, we discuss the background of our techniques and the architecture of proxies. In Section 3, we introduce our system architecture, followed by our techniques to measure roundtrip times, the implementation of CalcuLatency (§ 3.5), and our ethics discussion (§ 6). Next, we evaluate each of our building-blocks (§ 4), followed by our two-pronged evaluation of the system (§ 5.1, § 5.2). In § 7, we present our limitation, followed by related work (§ 8) and finally, we discuss CalcuLatency, its implications, and conclude in Section 9.

2 Background

Below, we discuss how network proxies differ in their architecture and we explain each of our measurement methods.

2.1 Architecture of Network Proxies

Figure 1 illustrates how a proxy's type affects the underlying protocol stack. We divide the protocol stack into three layers as per the OSI model: the application layer (HTTP), the transport layer (TCP), and the network layer (IP). Application-layer proxies terminate the application protocol, e.g., to inspect content for malware (Figure 1a). This includes Web

(a) Application-layer proxies, e.g., proxies that work via HTTP `CONNECT`.

(b) Transport- and Sessions-layer proxies, e.g., SOCKS, Tor, and SSH.

(c) Network-layer proxies, e.g., VPNs like OpenVPN and WireGuard.

Figure 1: **Architecture of Network Proxies**—We distinguish between three types of proxies that differ based on the layer at which they terminate client connections. Clients connecting to application-layer (1a) and transport-layer proxies (1b) first establish a TCP connection with the proxy and initiate the proxying using protocol specific messages. The proxies create new TCP connections to the web server, and then establish the tunnel. Whereas, network layer (1c) proxies authenticate the client and establish a tunnel, after which all packets including TCP SYN packets are encapsulated and proxied through the server.

servers that support the HTTP `CONNECT` method. Transport-layer proxies like Tor and SSH (both build on top of the SOCKS protocol) pass through the application protocol but terminate the client's TCP connection (cf. Figure 1b). Clients use SOCKS's signalling mechanism to tell the proxy what destination to connect to. Finally, network-layer proxies like OpenVPN or WireGuard perform NAT but pass through the client's TCP connection (Figure 1c).

2.2 The 0trace Technique

In a traceroute, a client sends multiple packets to a server, with each packet containing an incrementing time-to-live value (TTL) in the IP header. These packets are stateless "stray" packets, meaning that they do not belong to an open network connection. Stateful firewalls may reject such packets, terminating the traceroute.

In 2007, Zalewski invented a traceroute technique that can get past stateful firewalls [8]. This technique—called 0trace—creates trace packets that match the five-tuple of an already-established TCP connection. Unable to tell apart 0trace packets from packets belonging to this TCP connection, stateful firewalls will let 0trace's trace packets pass. 0trace achieves its goal by manipulating network packet headers and does so by crafting its own network packets using Linux's raw socket API. However, this techniques comes at the cost of potentially corrupting the TCP connection at the end: the receiving endpoint may terminate the TCP connection upon receiving an unexpected trace packet.

While 0trace's purpose is hop enumeration in the presence of firewalls, we use it for RTT measurements. The go-to technique for RTT measurements are ICMP echo requests (colloquially called "pings") but we found that many residential ISPs block pings (§ 3.4.1). While 0trace does not always work in such settings, it does allow for more accurate RTTs in the presence of firewalling as we show in Section 4.3.

2.3 The WebSocket API

The WebSocket protocol is an application layer protocol on top of TCP, which offers Web applications a bidirectional socket for communication. While distinct from HTTP, the WebSocket protocol is compatible with HTTP and uses the HTTP `Upgrade` header in its handshake. This allows Web servers to handle both HTTP and WebSocket connections on the same port. Once a WebSocket connection is established, client and server exchange binary data. Web applications can use WebSockets by taking advantage of the JavaScript WebSocket API that's supported by all modern browsers [9]. Later in this work, we use WebSockets to determine the application-layer round trip time between a client and server.

3 Method

Our aim is to measure round-trip times on the application, transport, and network-layers, and use a combination of these different measurements to reason about whether a particular connection is coming through a proxy server. We combine four cross-layer latency measurement techniques into a single software service that we call CalcuLatency. Our system integrates well into existing service provider infrastructure, and we create and publish a pipeline to analyze the collected data.

3.1 System Architecture and Assumptions

A typical client-proxy-service scenario consists of three entities: (i) a service provider that makes available one or more HTTP endpoints to its clients; (ii) clients that use the service provider's services; and (iii) proxy servers that some clients use to disguise their topological (i.e., IP address) and physical (i.e., their home country) location. While most clients are honest, there are some malicious ones that seek to defraud the service provider while using network proxies to disguise their

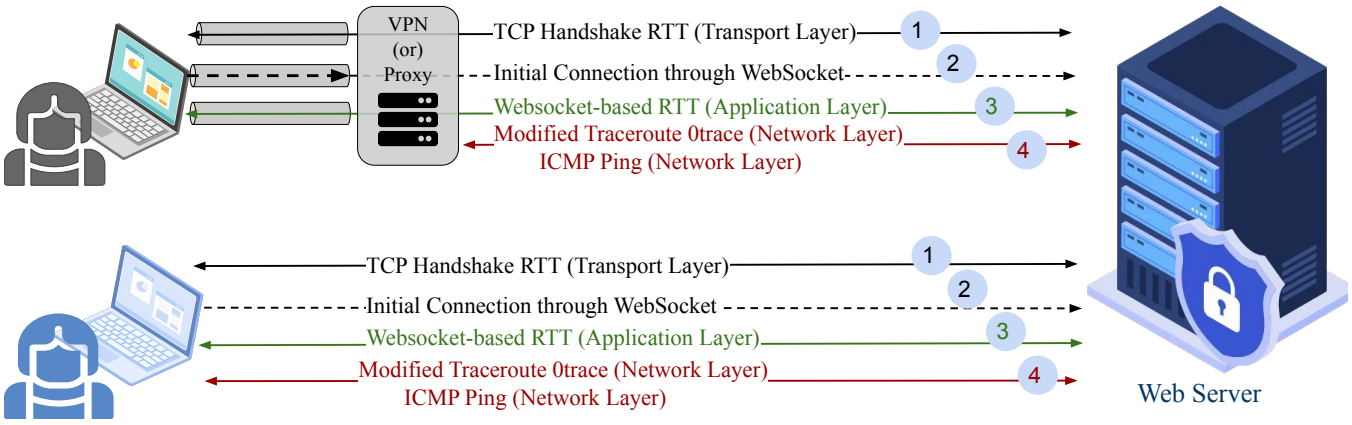


Figure 2: **Measurement Setup**—User connects to the Web server either via a VPN or Proxy (top) or directly (bottom). We illustrate the measurements done in both cases. The network layer measurements only reach the proxy server in case the user is using a proxy, but reaches all the way to the user's public IP if they are connecting directly.

location. For instance, an ad reward network or survey distribution service provides different rewards for geolocations, and users may seek to earn disproportionate rewards using proxies. Service providers need an inexpensive and practical solution that can tell apart clients that use remote proxies to mask their geolocation from those that do not, without user surveillance using blackbox detection techniques. We introduce CalcuLatency to fill this gap.

Broadly, our technique allows for the detection of the three proxy types illustrated in Figure 1. CalcuLatency's key insight is that the use of a proxy affects the layers in the OSI model differently. If we find a non-trivial difference between the application-layer RTT (Δ_{AL}) and the transport-layer RTT (Δ_{TL}) and/or the network-layer RTT (Δ_{NL}), we can conclude that the client is using a proxy server.

Consider a concrete example: A client in India is using a VPN server in Canada to make an HTTP connection to our CalcuLatency server in the U.S. Upon accepting the connection, our server now determines three types of round-trip times to the client, as shown in Figure 2. First, it upgrades the HTTP connection to WebSocket and sends several pings (using JavaScript) to determine the application-layer RTT. Next, our server inspects the (previously-recorded) TCP handshake to infer the transport-layer RTT. Finally, our server determines the network-layer RTT by sending ICMP echo requests and by running a 0trace measurement, which piggybacks onto the already-established HTTP connection.

Having determined all RTTs, our server notes that the WebSocket RTT is 250 ms—time taken for WebSocket pings to travel from the U.S. to Canada, to India, and back. The ICMP echo responses exhibit an RTT of only 35 ms—the time it takes to go from the U.S. to Canada, and back again. This difference manifests because the WebSocket ping was answered by *the client's browser in India* while the network-layer ping was answered by *the proxy in Canada*. Confronted with the RTT difference of $250 - 35 = 215$ ms, the service provider concludes that the client is using a proxy.

Assumptions: First, CalcuLatency requires an HTTP connection between the client and the server. We chose HTTP because of its ubiquity but other application-layer protocols work equally well. Second, the client's proxy must not be geographically close to the user. This assumption is reasonable in the case of service providers that seek to identify users who spoof their country of origin. Third, we assume that clients do not control the network behavior of the proxy and therefore cannot have it delay selected network packets. Instead, we assume that clients either use open proxies or rent them, e.g., as part of a VPN subscription. Even if the client does control the proxy, it is not guaranteed to evade CalcuLatency's detection as our 0trace component can estimate the RTT to the client using adjacent hops on the path that are outside the client's control.

While not universally applicable, we believe that these assumptions are both realistic and commonplace. What's more, CalcuLatency does not suffer from the shortcomings of existing, established proxy detection techniques like IP reputation blocklists that just use IP-to-Geolocation databases [10, 11, 12, 13].

3.2 Determining the Application-layer RTT

How can the service provider determine the application-layer RTT to the client? We chose WebSocket for this task: As of June 2023, WebSocket is supported by all major browsers [14], it is compatible with HTTP, and it is purpose-built for real-time communication, making it a natural choice for determining round-trip times. As mentioned above, CalcuLatency is

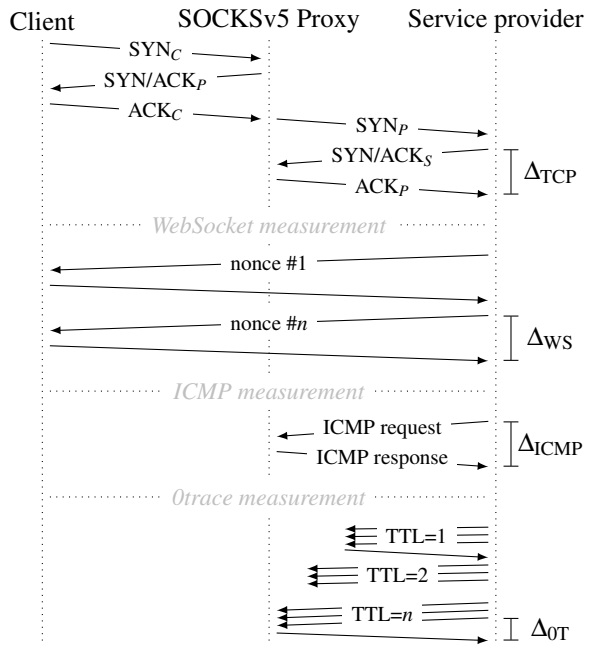

Figure 3: **Measurement Flow**—In this example, the client uses a SOCKSv5 proxy. The service provider determines four round-trip times (on three layers) to infer what kind of proxy the client uses.

not dependent on WebSocket and could employ alternatives, like WebRTC, XMPP, or HTTP page load times [15, § II.B].

Specifically, a client establishes a WebSocket connection with the service provider. The server then sends n WebSocket-based pings to the client as illustrated in Figure 3. Section 4.1 suggests that $n \geq 10$ is useful to make the measurement more robust against transient networking issues or asymmetric routing, both of which interfere with our measurement. In our CalcuLatency system, we send 100 WebSocket-based pings to the client. Upon receiving a WebSocket ping, the client's browser echoes back each ping to the server. Upon receiving the echo response, the server determines the WebSocket RTT on the Application Layer (Δ_{AL}) between itself and the client as follows: $\Delta_{AL} = \min\{\Delta_{AL_1}, ..., \Delta_{AL_n}\}$.

Importantly, our technique must work in an adversarial environment because malicious clients seek to disguise their use of a proxy. These clients control the server-provided JavaScript, and can therefore choose to either delay the echo or send an "anticipatory" echo before having received the corresponding request. The former is against a malicious client's interest because it would increase the odds of CalcuLatency concluding that the client is using a proxy. Malicious clients are therefore incentivized to respond as quickly as possible. To thwart the "anticipatory response" attack, we include a unique nonce in every echo request. The client has to embed the nonce in its echo response, preventing it from sending responses before having received the request.

3.3 Determining the Transport-layer RTT

We take advantage of the fact that in our setting, the client establishes a TCP connection with our server, meaning that we are in control of the TCP three-way handshake. We estimate the RTT between client and server by calculating the time difference between the server responding with a SYN/ACK segment and the client acknowledging receipt with an ACK segment, as discussed by Ding and Rabinovich [16]. We refer to this RTT as Δ_{TL}. Again, clients have no incentive to delay their ACK segment and are unable to send an "anticipatory" segment because of the difficulty of predicting TCP sequence numbers. We find that Δ_{TL} is reliable and straightforward to determine but we have *only a single sample* per connection, which makes this technique susceptible to transient conditions like network congestion. Indeed, Høiland-Jørgensen et al. [17] showed that "20% of the clients experience increased delays of more than about 80 ms, at least 5% of the time."

We considered taking advantage of the TCP timestamp option to measure RTT. We chose not to because TCP timestamps are not universally used [18, § 6] and often exhibit poor granularity—Veal et al. showed in their PAM'05 paper that the majority of 500 popular web servers used a granularity of either 10 ms or 100 ms [19, § 3].

3.4 Determining the Network-layer RTT

Finally, we focus on the lowest layer for which we determine the round-trip time: the network layer. Determining the RTT to an IP address is challenging because it is difficult to reliably get a remote network stack to respond to unsolicited IP packets. Prior work reported that it is increasingly rare for hosts to respond to ICMP echo request, or send a TCP RST segment in response to unsolicited SYN segments [20, § 4]. To maximize success, we draw on two separate techniques to estimate Δ_{NL}, our network-layer RTT: ICMP (see § 3.4.1) and 0trace (see § 3.4.2).

3.4.1 ICMP RTT

CalcuLatency sends five ICMP echo requests to the client. We refer to this measurement as Δ_{ICMP}. Prior work had found that some proxies don't answer to ICMP: 90% of VPN servers tested by Weinberg et al. [10] reportedly ignored ICMP requests. However, they only tested servers belonging to seven undisclosed VPN providers. Due to ICMP's potential usefulness to CalcuLatency, we revisit this topic by asking the following research question:

Do VPN servers respond to ICMP pings? To answer this question, we sent ICMP requests to IP addresses belonging to 80 VPN providers that past work studied [21, 11]. These VPN providers host servers that run various VPN protocols including OpenVPN, WireGuard, and other proprietary protocols. We augment our list of IP addresses with addresses present in the same /24 network as the VPN IP addresses, resulting in a

list of 492 unique IP addresses. We chose to ping adjacent addresses in CalcuLatency because a response from an adjacent address is likely to have a near-identical RTT to that of the actual proxy, which may not respond to ICMP requests. Our ICMP requests to these addresses resulted in 369 addresses (75%) that responded—a higher percentage than what past work found.

VPN servers appear likely to respond to ICMP requests but what about a random sample of the IPv4 population? To answer this question, we ran a ZMap scan [22] targeting a randomly-selected set of 1 million IP addresses. This resulted in 10.52% of IP addresses that responded to our ICMP requests. This is in line with prior work by Bano et al., which found that approximately 10% of IP addresses respond to ICMP pings [20, § 4.1]—making the odds of a response low.

We conclude that VPN servers are significantly more likely to respond to ICMP requests than randomly-selected IP addresses, which includes residential clients that don't use a proxy. We therefore decide to augment our ICMP measurement with 0trace, which we discuss in the next section.

3.4.2 0trace RTT

We use Zalewski's 0trace technique [8] for the purpose of determining the round-trip time between the server (where the 0trace measurement is initiated) and a connecting client. Again, we take advantage of the fact that our setting has the client establish a WebSocket connection to the server, meaning that we have an already-established TCP connection that 0trace can use for its TTL and RTT measurement.

We developed a Go package that implements 0trace. This package uses Linux's raw socket API to send manually-crafted TCP segments with incrementing IP time-to-live (TTL) values. We carefully craft 0trace packets to match the TCP five-tuple of the WebSocket connection,[1] so that firewalls between client and server will not interfere. Our 0trace implementation keeps incrementing the TTL until either (i) the responding IP address is identical to the client's IP address; or (ii) until TTL 32 is reached. For each TTL, we send three redundant probes to account for potential packet loss [23]. If we don't receive a response to any of our three probe packets within five seconds, we mark the given TTL as unresponsive. The RTT of our 0trace measurement (Δ_{0T}) is the round-trip time of the probe packet *that made it the farthest* to the client, i.e., the probe packet with the largest TTL.

We specifically use 0trace because it can get past (CG)NAT and stateful firewalls by operating on existing TCP connections. Furthermore, even if 0trace measurements do terminate at the NAT-box due to network level rules, we argue that the distance between a NAT and the user's machine is less than 1,000 km as most are typically deployed by their ISP [24].

[1]The five-tuple consists of IP source and destination addresses; TCP source and destination ports; and the IP protocol.

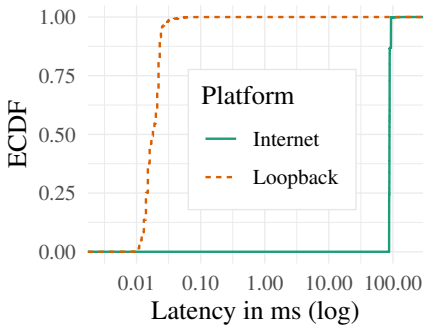

Figure 4: Latency distribution of TCP handshake measurements over two networks.

Being equipped with four techniques that measure the RTT across three OSI layers, we now devise a decision tree that helps us collapse all our measurements into a single verdict: does the client use a proxy?

3.5 Implementation and Deployment

CalcuLatency combines our application, transport, and network-layer measurements into a single service. We implemented CalcuLatency in both Go and JavaScript (WebSocket pings). The Go service consists of (i) a Web server with an endpoint that speaks WebSocket, (ii) a Go package that records TCP handshakes to extract round trip times, and (iii) a package that runs a 0trace measurement to the client.

While developing our 0trace Go package, we take advantage of the ICMP error requirements stated in RFC 1812 and RFC 792, which state that the returned ICMP error message will contain (parts of) the original datagram's data [25, 26]. We find that the ICMP error message reliably contains the IP header of the original datagram in the ICMP datagram. Hence, we design our server to keep track of the IP ID in for each TTL-limited probe it sends out, and it uses the IP ID obtained from the IP header of the original datagram from the received ICMP error packet to correspond the hop IP to the particular TTL value. Using the packet sent time and packet received time, the server calculates the RTT for each hop that responds with the ICMP error. It repeats the process until (if) it reaches the VPN IP, or until the maximum TTL value. All our code is available online under a free software license but we omit the URL to preserve our anonymity.

In real-world systems, CalcuLatency can be deployed as part of a CAPTCHA. The CAPTCHA can be non-interactive and consist of HTML and JavaScript, which initiates a WebSocket connection to the CalcuLatency server. In the first phase, CalcuLatency sends hundred WebSocket pings to the client to estimate the application-layer RTT. After CalcuLatency determines the application-layer latency, we calculate the RTT of the TCP handshake, send ICMP pings, and use 0trace to determine the network-layer RTT, as discussed

above. Clients that CalcuLatency deems to be using a proxy can be flagged for manual inspection.

4 Building Block Evaluation

Before evaluating CalcuLatency in its entirety, we study its building blocks in isolation.

4.1 Reliability of WebSocket Pings

Unlike our network-layer RTT methods, which are typically handled by the kernel's network stack, our application-layer method—WebSocket—traverses not only the kernel's network stack but also the client's browser, and is therefore subject to more jitter. To characterize and approximate this jitter, we built an HTTPS-based Web service that sends 10,000 sequential WebSocket echo requests to the client and measured the round-trip time $\Delta_{WS_1}, \ldots, \Delta_{WS_{10,000}}$ for each request. We made these measurements over the loopback interface to eliminate networking delays and isolate processing delays.

Figure 11 in the Appendix illustrates the results for two consumer laptops (ThinkPad X1, MacBook Pro) running two browsers. The median RTT for all distributions is less than 1.4 ms, and 99% of RTT measurements completed in less than 2.4 ms. All distributions exhibit a long tail, presumably due to transient load spikes. *CalcuLatency must account for this by running multiple measurements, spaced out over time.*

4.2 Reliability of TCP Handshake RTT

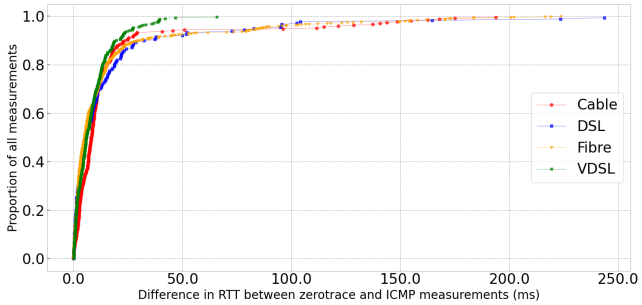
We conduct an experiment to understand the reliability of the TCP handshake in measuring RTT. We used Go to build an HTTP server that served a static index page. In parallel to serving this index page, the server uses libpcap to record the TCP handshake; in particular the time delta between the server responding to the client's SYN with its SYN/ACK segment and the subsequent receipt of the client's ACK. We built a shell script that establishes 86,400 TCP connections: one connection per second for 24 hours. We ran this experiment in two network settings: in the "Loopback" setting, client and server run on the same machine, communicating over the loopback interface. By excluding the Internet, this setting highlights computational latency. In the "Internet" setting, client and server run on separate machines, communicating over the Internet. The client ran on a VPS in Ohio, U.S. while the server ran on a VPS in Paris, France.

Figure 4 illustrates the results of this experiment. In the "Internet" setting, we see a minimum, median, and maximum latency of 87, 88, and 171 ms, respectively. 99% of handshakes exhibit a latency of less than 94 ms—only 7 ms more than the minimum. The "Loopback" setting, we observe a median latency of 18 µs. 99% of handshakes exhibit a latency of less than 34 µs. As expected, we observe a long tail in both and we account for outliers by running repeated measurements.

The TCP RTT is readily available and straightforward to calculate, but we only get a single measurement per TCP connection. One could work around this limitation by having the client establish multiple TCP connections to the server.

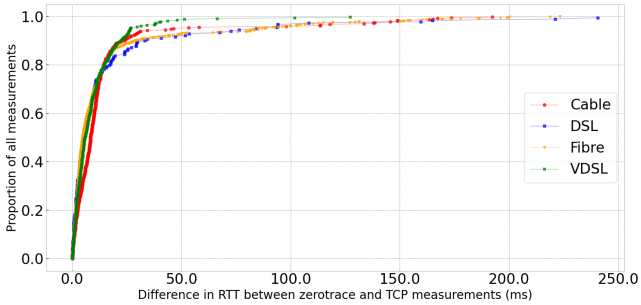
4.3 Reliability of 0trace Pings: Considering the Variance of Latency Across the Internet

To evaluate the reliability of 0trace, we conduct a large scale measurement with endpoints having a variety of configurations to understand potential effects on the results. For this experiment, we take advantage of the RIPE Atlas network.



First, we set up an HTTPS server that runs our 0trace code whenever a client connects to the server. Next, we instruct the RIPE Atlas probe to run an **ICMP** and a **TCP traceroute** using both the IPv4 and v6 addresses towards the server, and an **"SSL" measurement** to fetch our server's TLS certificate, which trigger our 0trace measurement toward the client's IPv4 address. For each RIPE Atlas probe, we measure three different RTT values (0trace and two traceroute RTTs). We repeat each of these measurements three times to account for any transient errors. We then determine the absolute difference between the 0trace RTT and the other traceroute RTTs, which serve as ground truth in each case. Appendix B contains a breakdown of the available RIPE probes and our selection.

Our initial experiments to explore whether running latency measurements at different times of the day influence the measured RTT difference (presented in Appendix C and Figure 13) revealed no significant differences even when the RTTs were measured every 3 hours. *To maximize the utility of our measurements considering concurrency limits and resource constraints, we trade-off the small benefit in reliability of running multiple experiments per day, for the diversity of a larger number of RIPE probes over a long period of time.*



For our measurements, we selected probes that are "connected" (not abandoned or disconnected), with a public IPv4 and IPv6 address, valid country code, with all the desirable tags. Note that while we request all eligible probes to participate in our measurements, not all of them do [27]. **We had 2,350 RIPE Atlas probe IP-probe ID pairs** that fully completed the SSL, ICMP and TCP traceroute measurements, i.e. they either reached our server directly or their last hop IP address was in the same AS as our server. The distribution of these probes over continents, ASNs, and different access technology is described in the Appendix B.

Differences in local and last-mile access technology We evaluate our hypothesis of whether the probe's last-mile access technology (derived from the probe's tags) has large effects on the latency seen from the server side.

We present our results for the RTT difference between the 0trace result and the probes' TCP and ICMP traceroutes separately. We find that VDSL has three outlier RTT differences

(a) Difference between 0trace-determined RTT and RIPE Atlas-determined ICMP RTT in ms.

(b) Difference between 0trace-determined RTT and RIPE Atlas-determined TCP RTT.

Figure 5: **Comparing the RTT differences between probes with different local last-mile access technology—** In 80% of *all measurements* the RTT difference is less than 18ms. However RTT differences in TCP are lower and more stable. Removing three outliers from VDSL, we see that the differences between the access technology become more pronounced for the remaining 20% of the values, with cable performing worse, and Fibre performing marginally better with no outliers.

measuring 388ms, 1970ms, and 2640ms and upon investigation we note that these were due to two German RIPE probes in AS8881 and AS3320 which failed to reach far in the traceroute. To improve readability of our figure, we have removed these three cases and note them separately in Figure 14 in Appendix F. From Figure 5, we see that 95% of all ICMP measurements have an RTT difference lower than 111ms in Cable, 94.93ms in DSL, 86ms in Fibre[2], and 31.3ms in VDSL. Similarly, 95% of all the TCP measurements have an RTT difference lower than 46.3ms in Cable, 93.8ms in DSL, 87.9ms in Fibre, and 30.7ms in VDSL (including outliers).

In summary, we see that the RTT differences in TCP are lower and more stable, that is, 0trace measurements are closest to the TCP ground truth RTTs. We note that in 80% of *all measurements* the RTT difference is less than 18ms. We see that the differences between the access technology become more pronounced for the remaining 20% of the measurements, with cable performing worse, and Fibre performing slightly better than others considering it has no outliers.

Our experiments show that given that 0trace is able to match ground truth for >80% cases, and in 95% of cases has a maximum difference of 111ms in RTT when compared with ground truth. Given the results of our experiment, we can reason about the generalizability of our measurements. We can be confident that when measuring long distance proxies, these differences of 111ms will not hinder CalcuLatency's ability to detect the proxies, and in the remaining 5% of cases, it may inflate the endpoint RTT, which may lead to false negatives that CalcuLatency can tolerate.

5 Evaluating CalcuLatency in Practice

We conduct a thorough evaluation of CalcuLatency using a two-pronged approach. First, we conduct an evaluation with a controlled testbed where we control the webserver, the client, and test our system with a variety of different VPN products and proxy servers, that run multiple different protocols. We test the system with mobile connections, various different user locations, without any proxies connected, and then by connecting to various VPN and tunnelling protocols. Next, we extend on this experiment by conducting a large evaluation with volunteer Internet users. This mimics a real-world deployment test for CalcuLatency because we draw on a geographically diverse population that's representative of the average Internet user. For this experiment, we set up our measurement server at a university network and advertised our crowd-source measurement page via social media channels.

5.1 Control Testbed Evaluation

We conduct a controlled evaluation of our CalcuLatency service by creating a testbed and collecting various measurements ourselves. In our experiment, we controlled the webserver that conducted the measurements. We had teammembers run tests from their devices from fifteen different home and mobile networks using four different popular browsers—Chrome, Mozilla Firefox, Safari, and Brave.

Our network locations include three cities in the U.S. and one city in Canada, UAE, and India each from multiple networks. We conduct both direct measurements from these networks and also run measurements while connecting to various different VPN and proxy servers around the world. We instrumented an automation script using Selenium to trigger measurements from multiple different browsers on a computer at the same time. In both the direct connection case and when we turned on a VPN, we use this automation script to conduct multiple experiments from different browsers towards the same server. We re-ran a direct measurement each time we started experiments, from each browser, and repeated

[2]We are preserving the spelling used in the RIPE Probe Tag

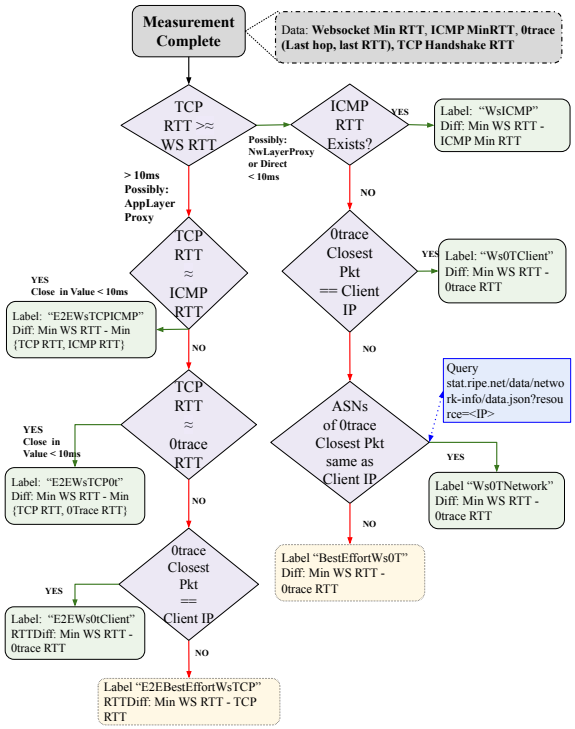


Figure 6: **Decision Tree—**We create a decision tree that uses the round-trip times measured using our four different techniques. Based on their results, we use a combination of these values to decide whether a particular experiment can be labeled as a possible proxy connection. The two yellow nodes refer to cases that lack some of the measurement results and are hence, labeled "best effort" calculations.

it between different experiments. The VPNs and proxies used to conduct these experiments include ten popular, commercial VPN providers including Astrill VPN, CyberGhost VPN, ExpressVPN, IPVanish, IVPN, Mozilla, Mullvad, NordVPN, Private Internet Access, Surfshark. These VPN providers offer multiple different protocols such as Wireguard, OpenVPN, and other proprietary protocols such as OpenWeb and Lightway. We also instrumented our own SOCKS5 proxy servers and tested them as well. We do not measure or reason about security and privacy aspects of the tested commercial VPN providers; our aim is to simply connect to various servers they offer and evaluate our CalcuLatency measurement service.

5.1.1 Data Characterization

In total, we conducted 891 unique experiments with 354 unique client IPs. Our measurements came from 337 unique VPN or proxy server IPs belonging to 82 different autonomous systems (ASes), and 17 unique direct, client IPs belonging to 12 different ASes. Overall, we collected data from four different countries.

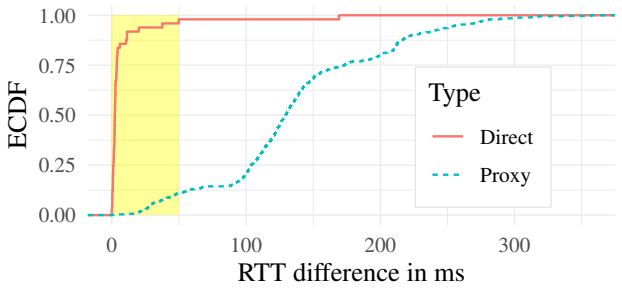

Figure 7: **ECDF of RTT difference for the 891 control, testbed evaluation measurements**—From our measurements, we find that over 98% of direct measurements and less than 11% of VPN measurements have an RTT difference below 50 ms (shaded in yellow).

5.1.2 Results

We calculate the RTT difference for each experiment using a decision tree that we devised (Figure 6).

First, we check if the TCP handshake RTT (Δ_{TL}) $\gtrapprox$ websocket RTT (Δ_{AL}), i.e. if they are within $\pm$ 10 ms. If so then the experiment is a network layer proxy or a direct measurement. In this case, the Δ_{TL} cannot be used for calculating the RTT difference. Hence, we use the ICMP RTT, if it exists, and if not, we will use 0trace RTT as Δ_{NL}. In order to differentiate and identify which value was used as Δ_{NL} and to record the conditions that are met according to the decision tree, we assign labels for each end node of the tree. For instance, in this case, if ICMP RTT does not exist (i.e. ICMP was not supported by the client IP), we will use 0trace RTT and assign different labels based on whether 0trace reached the client IP (*0TClient), 0trace did not reach the client but reached the same ASN as the client (*0TNetwork), and label it a "best effort" if none of these conditions is met. We only use the 0trace RTT from the last successful hop for the calculation.

However, if $\Delta_{TL} \lessapprox \Delta_{AL}$, then the experiment could be an application layer proxy. In this case, we check if $\Delta_{TL} \approx$ to either of the Δ_{NL} (ICMP RTT, 0trace RTT). If not, we follow the same procedure as above and use ICMP RTT if it exists, and if not, fallback to 0trace if it reaches the client IP or its ASN. Finally, if none of those conditions are met, we label it a "best effort" and use TCP RTT to calculate the RTT difference.

In our control testbed evaluation, **we find that in 98.0% of the direct measurements (48 of 49) the calculated RTT difference is less than 50 ms**, as shown in Figure 7. Upon investigating, the anomalous direct measurement belonged to an Indian mobile network provider, where the ICMP failed and 0trace was unable to reach even the same network, hence it was a "best effort" calculation. We will revisit the "best effort" cases in §5.3.

Next, we investigate the VPN measurements, we find that the RTT difference is above 50 ms in 89.1% of all VPN mea-

surements (750 of 842), shown in Figure 7. Among the rest of the 10.9% of VPN experiments, we find that in 60.9% of them (56 of 92), the VPN server is close to the user geographically, i.e. the straight line distance between user and VPN server is less than 650 miles. This is equal to the straight line distance between Washington DC and Boston, MA (635 miles) or the straight line distance between Mountain View, California and San Diego, California (685 miles). This is expected, as specified in our assumptions, our technique primarily seeks to identify longer-distance remote VPN users.

We investigated the 14 unique VPN server IPs belonging to 36 of 92 measurements (39.14%) where the user to VPN distance was above 650 miles. We found that six of those 14 IPs belonged to AS9009 (corresponding to 17 of 36 measurements), and for all these IPs, the VPN provider claims their location to be in a Latin American country (Mexico, Costa Rica, The Bahamas, Venezuela, Chile, Argentina). However, when we investigated their ICMP RTTs as measured from our server in the U.S. Midwest region, we find that all their RTTs ranged between 28 ms–52 ms. We used the speed of the Internet approximation provided by Katz-Bassett et al. [28] which is $\frac{4}{9}$ c, where c is the speed of light traveling in a vacuum, and find that for all of these experiments, **the locations of the VPN server as reported by the VPN provider is an impossibility**. Their true geolocation appears to be much closer than that what is reported.

For the remaining 19 experiments with eight unique VPN server IPs, we were not able to disprove the advertised location of the server with the RTT measurements. However, five VPN servers belonged to the same VPN provider which may have a policy to inflate ICMP values. The other two IPs did not have a reliable ICMP value for us to confirm or disprove their advertised location.

Overall, we find that 50 ms is a viable threshold for the RTT difference to distinguish a direct measurement from one coming through a remote VPN or proxy. We expand on this evaluation by conducting a real-world evaluation to increase the diversity of our "direct" connections and user locations.

5.2 Real-world Crowdsourced Evaluation

Next, we conduct an evaluation of our system in practice, using real-world measurements. We developed the CalcuLatency system, created a web server, and deployed it on a subdomain of our university. To obtain ground truth about the measurements, we create a form that users fill out to give us information regarding their setup. We ask users to optionally provide us with an email with which we can reach them, whether they are connecting to us though a mobile or a desktop, who their internet service provider is, and their current location (to reason about the measured latencies and physical distance). We then ask users if they are connecting to us via a VPN, or directly. If they are using a VPN, we request them to enter their VPN server location if known, and any details about their VPN provider.

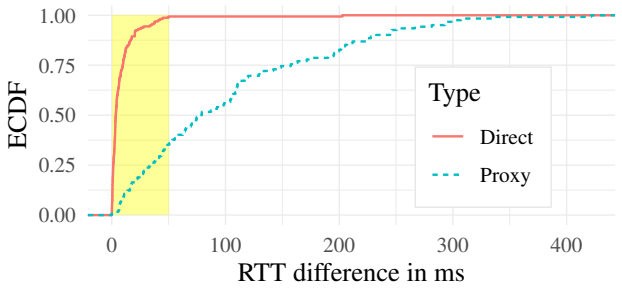

Figure 8: **ECDF of RTT difference for the 283 public crowdsourced evaluation measurements**—From our collected measurements, we find that over 98% of direct measurements and 36.1% of VPN measurements have an RTT difference below 50 ms (shaded in yellow).

We recruited users by publicizing a call for participation on Twitter using the authors' twitter handles and collected data for this experiment over a period of 15 days. We did not target or advertise towards specific Twitter users and chose not use platforms like Prolific or MTurk as they have not been evaluated to be generalizable for network measurement (but rather for qualitative studies).

5.2.1 Data Characterization

We collected 283 unique experiments from 252 unique client IPs, with (self-reported) 161 direct measurements and 122 VPN measurements. Our 161 direct measurements came from 145 unique client IPs from 93 different autonomous systems (ASes). Our 122 VPN measurements came from 109 unique VPN IPs belonging to 51 different ASes. The most number of measurements for the direct measurements came from ASN 7922, followed by ASNs 701, 7018, 21928 and 3320 belonging to Comcast, Verizon, AT&T, T-Mobile, and Deutsche Telekom. We provide a more detailed breakdown of these IPs by ASN in the Appendix E. Overall, we collected data from over 37 different countries from all (six) continents.

5.2.2 Results

Based on the same decision tree explained in §5.1 and Figure 6, we calculate the RTT difference and label each experiment with the appropriate label from the tree. **We find that 98.8% of all direct measurements have an RTT difference below 50 ms** (159 of 161) as shown in Figure 8, following the same trend as our controlled testbed evaluation, despite a large increase in the variety and diversity of our collected direct measurements. Upon investigating the remaining 1.2% (2 of 161) measurements, we find that one measurement was conducted through Safari and indicates that the IP is an iCloud

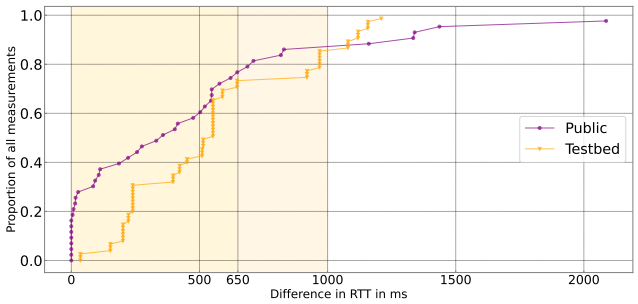

Figure 9: **CDF of the distance between user and VPN when RTT difference < 50ms**—Majority of VPN experiments with a low RTT difference (below 50ms) are located close to the user. 66.2% of these cases, the proxy is only upto 650 miles away from the user (in yellow), and 89% of these cases, the proxy is < 1000 miles from the user (in orange).

Private Relay IP, we conclude that the user may have overlooked the fact that private relay was turned on, and hence this is a "proxy" measurement. The other experiment had an abnormally large 0trace RTT value, labeled a "best effort" calculation (We explore this in §5.3).

Next, we investigate the VPN measurements, the RTT difference in 63.9% of measurements (78 of 122) are above the threshold of 50 ms, also shown in Figure 8. Of the 36.1% VPN measurements whose RTT difference is below 50 ms, we find that in 77.3% of the cases (34 of 44), the user and the VPN server are below 650 miles apart, which we consider as the minimum threshold for it be a "remote proxy", as shown in Figure 9. We use the locations provided by the user in our form and also compare the VPN IP-geolocation. Another 2.2% (1 of 44) was an experiment mislabeled as a VPN measurement, although the client IP indicates it is in the same location as the user. Of the remaining 20.5% of measurements (9 of 44), we did not see any proof to disprove the apparent location of the VPN.

5.3 Results Combining the two Evaluations

Overall, if we consider 50 ms to be the RTT difference threshold for a connection to be labelled as a remote proxy, our method has a low *false positive rate of 0.95%* (2/210 direct measurements). On the other hand, we find that 14.1% (136 of 964) VPN measurements had an RTT difference below this threshold. However, only 2.9% (28/964) of VPN measurements are located over 650 miles away from the user, and are legitimate (i.e. excluding VPNs with fake locations, and mislabeled experiments). Thus, we consider 2.9% our method's *false negative rate*.

What percentage of VPN servers respond to ICMP pings? In our evaluations, we collected a total of 434 unique VPN IPs, and we find that over 94.2% of these IPs (409/434) responded to ICMP pings. A majority of the VPN server IPs that did not respond to ICMP pings belong to Astrill VPN (14/25), which may have a policy for some/all of its servers to not respond to ICMP pings. Of the rest, four VPN servers belonged to personal OpenVPN VPN servers, three other servers others belonged to SOCKS5 proxies, and the remaining four were miscellaneous VPN services including iCloud Private Relay.

Does removing all best-effort calculations improve our method? Yes! Combining both sets of evaluation, we see that exactly 4.0% of all measurements (47/1174) was labeled "best effort calculations", which means that the experiment did not contain successful ICMP measurements, and that TCP RTT measurement (Δ_{NL}) is too close in value to Δ_{AL}, and 0trace did not reach the client or even the same network as the client IP. Since these anomalous measurements only comprise 4% of all measurements, we do an investigation into what our analysis would look like if we removed these measurements. When a service provider deploys CalcuLatency, they can achieve this by simply labeling all "best effort" experiments as requiring a re-run and have the client conduct another round of measurements.

From Figure 10, we see that a 100% of all direct measurements have an RTT difference less than 50 ms, and 86.2% of VPN measurements (808 of 937) have an RTT difference greater than 50 ms. Of the 13.8% (129 of 937) VPN measurements that have an RTT difference below 50 ms, we find that 66.7% of measurements are less than 650 miles away from them user and another 13.2% advertise fake VPN locations as we found in §5.1. The remaining 26 VPN experiments whose RTT difference is less than 50 ms but distance from the user is more than 650mi are false negatives, and the average distance between the VPN server and user in these cases is 1089 miles.

In summary, in a more conservative analysis setting where we only consider the experiments where we obtain all measurement data points (96% of all collected measurements), *we do not find any false positives and false negative rate is 2.77% (26/937).* In production systems, the experiments that we exclude in this analysis, i.e. those that are labelled "best-effort", can be marked by service providers for deeper inspection and for re-running of the experiment to remove transient issues.

6 Ethics

Before running a public, crowd-sourced evaluation of our system detailed in § 5.2, we contacted our institution's IRB and were informed that our project is exempt from regulation. Our crowdsourcing evaluation web service presents a input form and did not trigger any measurements until the user reads, inputs data about the measurement, and consents to the measurements. The index page also outlines the measurements conducted, data collected, and that any latency data collected may possibly be published to help future research, after anonymizing the last octet of each visitor's IP address. From the web service, we measure the user's latency using

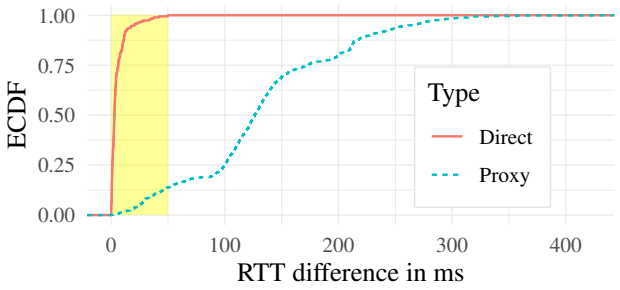

Figure 10: **ECDF of RTT difference of 1127 reliable measurements**—This analysis contains measurements that did not have a "best effort" label from our decision tree. 100% of all direct measurements and 86.2% of all VPN measurements have an RTT difference below 50 ms (in yellow).

four different methods and any data collected is only accessible to the authors of this paper.

We acknowledge that there are potential misuses of our CalcuLatency system that server-side operators and service providers could use to penalize VPN users. However, services currently employ black-box techniques to do similar blocking that maybe even more discriminatory. Our solution aims to identify users that connect to far-off, remote VPNs specifically to abuse systems, and will serve as one of several anti-fraud identifiers. Previous work has found that a majority of VPN users use it for privacy and security purposes [29]. Such legitimate VPN users can still connect to servers closer to themselves to enjoy the privacy benefits of the VPN and still evade our remote proxy detection.

7 Limitations

CalcuLatency cannot reveal proxy users in all cases. We can only detect proxy users if the proxy is sufficiently far enough from the user, from our measurements this distance appears to be at least 650 miles or more. Otherwise if the user and proxy are closer, the RTT difference may be too small to detect the proxy. This may be a prohibitive limitation for some service providers, and a non-issue for others because users may deliberately choose proxy servers that are geographically far away from them, to disguise their physical location. For example, users defrauding rewards networks want access to higher-reward locations, or users of streaming services often use VPNs to appear to be in another country, to get access to geo-restricted content. Each service operator can decide based on their business needs if they are conservative (treat ambiguous users as direct users) or be more aggressive (treat ambiguous users as proxy users). The service provider can also choose to subject ambiguous users' connections to further tests to confirm observations.

Our technique becomes less accurate in the presence of highly restrictive firewalls that discard all ICMP traffic. For perfect accuracy, we need to receive ICMP error packets from the client itself. The farther away we are from the client, topologically, the less accurate our RTT measurements become. While such restrictive firewalls do exist, our results suggest that they are the exception rather than the rule. We find from our evaluation that 94.2% of all VPN or proxy server IPs respond to ICMP pings, and over 56% of direct connections respond to ICMP pings, which is much higher than reported before. Additionally even if direct ICMP pings are disallowed, 0trace can function as long as the firewall does not discard ICMP error responses.

If a server-client pair uses the Multipath TCP (MTCP) protocol, it could reduce the effectiveness of CalcuLatency, due to the fact that this protocol uses multiple network routes concurrently within the same TCP connection, which could cause skewed results when comparing the 0trace RTT measurement to the application-layer RTT measurement since they could have traveled different paths. However, Shreedhar et al. determine that MTCP usage is extremely low compared to TCP (0.5%), and the vast majority of MTCP traffic is from a single company (Apple), which means that CalcuLatency would still be viable in the vast majority of use-cases [30].

Finally, we also present an analysis of how latency measurements can vary when it comes to dual-stack endpoints, where IPv6 connections to the server side can influence a bloat in the measured latency differences. We present an analysis using RIPE Atlas probes in the Appendix D. However, CalcuLatency only supports IPv4 based 0trace measurements, and we leave the optimization of IPv6 based latency calculation for detecting proxy-enabled abuse for future work.

8 Related Work

We provide an overview of related work on latency measurement techniques and its applications, Internet liveness tests, and proxy detection methods.

Latency Measurements: In a 2021 blog post, Tschacher writes that using in-browser measurements and on the server side by measuring RTT of the incoming TCP/IP handshake, website owners can infer that a visitor is using a proxy using the latency difference [31]. However, the blog post conducts a limited evaluation and relies only on one incoming TCP/IP connections and the handshake to identify RTT which may be affected by packet loss and transient factors.

Weinberg et al. [10] used ping-time measurements to hosts in known locations to estimate the locations of 2,269 proxy servers. They also found that over 90% of VPN servers and their first hop routers tested ignore ICMP pings and do not send time exceeded packets. Hopper et al. [32] estimate that an Internet host in 2007 can be uniquely identified by knowing its RTT to five randomly chosen hosts. Pelsser et al. [33] studied whether ICMP ping provides a good estimation of

delay and find that from an application perspective, ICMP ping actually gives a poor estimate of the delay and jitter as it can vary between flows.

Jiang et al. propose two techniques that a passive in-path monitor can use to measure the TCP round-trip time including the handshake [34]. Unlike this work, CalcuLatency has access to bidirectional flows and can analyze all three segments of the TCP handshake. In 2020, Livadariu et al. found that using RTT measurements from probing an IP from multiple vantage points (including from within its own AS) is a more viable strategy than using geolocation databases [35].

Cloud Providers: Dang and Mohan [36] investigated latency specifically towards cloud service providers in 2021, with a focus on developing regions. They found that geographical distance has a high impact on latency towards cloud systems. Kashaf et al. [37] determine that a majority (95%) of websites that are hosted in or serve traffic primarily to Africa rely on third-party cloud infrastructure. These two conclusions support the efficacy of CalcuLatency in lower traffic regions. Dang and Mohan conclude that the last-mile technology used is the greatest factor for latency when reaching a cloud provider, but the results from our RIPE Atlas measurements show that the last-mile technology does not have a large impact on the measured RTT.

Internet Liveness: In their CCR'18 paper, Bano et al. perform Internet-wide scans to study the population of addresses that respond to probes [20]. They found ICMP probes are the most effective to discover alive hosts but TCP probes can further add to the population of alive hosts. A combination of ICMP, TCP, and (to a lesser extent) UDP results in the most complete picture of liveness. Bano et al.'s results inform how CalcuLatency attempts to determine an address's network-layer or transport-layer latency.

Proxy Detection: Much work has focused on detecting proxies; mostly on detecting Web proxies, VPNs, and Tor. Weaver et al.'s PAM'14 paper studied the prevalence of in-path Web proxies by sending controlled application-layer measurements between clients and a server, controlled by the researchers using Netalyzr [38]. In an S&P'19 paper, Mi et al. studied the emerging ecosystem of end user systems that serve as proxies to others—often without the knowledge of the owners of the proxies [39].

Hoogstraaten [40] explored several server-side VPN detection methods, such as using existing IP information databases (WHOIS, rDNS), fingerprinting TCP options like advertised MSS, and even timing based measurements. But they only propose limited latency based measurements to identify internet-layer proxies, and conducted a short proof of concept. The closest related work is by Webb et al. [15] who also proposed detecting proxies and VPNs based on traffic timing and latency. They measure the RTT for each connecting IP address and flag anomalies in the distribution of these RTTs as proxies. However, their method must be trained for each IP address, and hence is not practical.

9 Discussion and Conclusion

In this paper, we present and evaluate our system CalcuLatency that incorporates several network RTT measurement techniques and leverage the application-layer and network-layer differences in roundtrip-times when a user connects to a service using a proxy (which are absent when the user connects to the service directly). We implement and evaluate each building block of our system individually: WebSocket RTT measurement on the application-layer, TCP handshake RTT recorded on the transport-layer, and ICMP ping and 0trace hop-enumeration RTT on the network-layer. We integrate all these techniques into one system called CalcuLatency and conduct a two-pronged evaluation: a control testbed environment where we test multiple different VPN products, proxy protocols, and server locations with over 337 unique VPN or proxy server IPs tested. To expand the diversity of our evaluation, we rally users and collect a public, crowdsourced, real-world evaluation of our system, which gained us 283 measurements from 37 different countries in all six continents.

Our evaluations reveal that a round-trip time difference of 50 milliseconds between the application and network-layer latencies is a viable, empirical threshold to consider a particular client as a remote VPN or proxy connection. We open-source our code in order to help encourage future research [41, 42].

CalcuLatency provides a preliminary, labelling technique for service-providers, and must not serve as the only signal for detecting "malicious proxy traffic". Not all VPN users are attackers and not all VPN or proxy traffic is abusive. Hence, our method only serves as one of the signals and service providers must leverage business-specific logic and make decisions on flagging connections as possible abuse traffic. For example, reward networks can flag certain connections as malicious and use such signals over time to detect and curb abusive consumers.

We acknowledge that service providers could potentially misuse this method to penalize all proxy use. However, we emphasize that our method's inherent design of detecting long-distance proxies and VPNs still protect legitimate proxy use and its users. Users could evade detection by using proxies close to their location, which gives them better performance and the requisite privacy and security features of the VPN.

Ensuring the adoption, success, and sustainability of privacy-focused business models rely heavily on the availability of computationally cost-effective and easily deployable techniques. Service providers must strike a delicate balance between implementing robust abuse-prevention mechanisms and maintaining a rigorous commitment to privacy. With CalcuLatency, we provide an open-source technique that can be readily deployed as a software service that can support efforts that prioritize user interests and their privacy.

10 Acknowledgment

The authors are grateful to Armin Huremagic, Riya Agarwal, Farzad Siraj for their help with the evaluations. We thank the reviewers for their feedback, and RIPE Atlas for generously granting credits to conduct an evaluation of our techniques. Continent	Top 1% ASes		Top 10% ASes		Top 50% ASes	
	Elig.	**Com.**	Elig.	**Com.**	Elig.	**Com.**
Europe	29.8	**31.3**	65.4	**66.2**	87.2	**87.3**
N. America	36.5	**24.6**	67.3	**61.4**	88.8	**87.8**
Oceania	28.9	**30.1**	53.0	**39.7**	87.2	**82.2**
S. America	7.2	**15.6**	32.5	**28.1**	66.2	**65.6**
Asia	10.9	**9.7**	41.5	**40.0**	77.2	**74.2**
Africa	15.9	**43.8**	39.7	**43.8**	71.4	**75.0**

Table 1: Distribution of probes over the top 1%, 10% and 50% stratified by the continent of the probes. "Elig." refers to the percentage of eligible probes that exist in RIPE Atlas and "Com." refers to the percentage of probes that actually participated in and completed our measurements successfully. This table shows that the distribution of eligible probes closely follow the distribution of the probes that actually participated in our measurements, showing that our selection strategy did not skew our results.

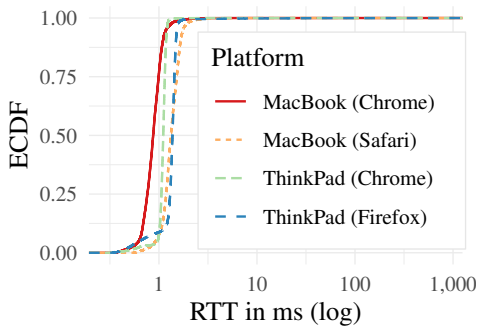

Figure 11: RTT distribution of WebSocket measurements on four platforms.

A Reliability of WebSocket Pings

Figure 11 illustrates the results from our WebSocket ping measurement with 10,000 WebSocket echo requests from two consumer laptops (ThinkPad X1, MacBook Pro) with two browsers: ThinkPad is a X1 Carbon 8th generation equipped with a i5-10210U CPU, and ran Chrome 111 and Firefox 111. The 2023 MacBook Pro is equipped with an M2 Pro CPU, and ran Safari 16.3 and Chrome 111. We find that the median RTT is less than 1.4ms for all measurements and 99% of the RTT measurements completed in less than 2.4ms. Hence, we account for this by running multiple measurements, spaced out over time in CalcuLatency.

B RIPE Atlas Probes Characterization

In our analysis outlined in 4.3, we downloaded the RIPE Atlas probes list latest on January 11, 2024 [43]. The total number of probes by unique probe ID was 38,554. But many probes have the same public IPv4 address, and the number of unique IPv4 addresses is 27,004.

We had to filter probes by eligibility based on multiple criteria. We found that 1,497 (3.9% of 38,554) probes had no public IPv4 OR IPv6 addresses. We found 588 (1.5%) probes had a bad country code where the country code either did not exist or the length of the country code was not two (specified by ISO-3166). We found that there were 1,107 (2.9%) probes that had undesirable tags attached to them, namely "system-geoloc-disputed", "core", "cloud", "vps", "ixp", "ipv6-only", or probe's tags start with "data-center" or "datacenter".

Importantly, we found that that 24,454 (63.4%) probes were either disconnected and/or abandoned, and were hence unusable. We also had to filter out 126 (0.3%) probes that do not have an IPv4 address specifically because 0trace relies on the IPv4 stack on the endpoint contacting us. We identified a set of 97 valid "tags" that determine usable probes. We eliminated 5,382 (14%) of probes that had **none** of the 97 desirable tags.

Of the 38,554 probes in the RIPE Atlas probe file, the total number of ineligible probes as defined by the criteria above was 33,154 (85.99% of 38,554). **Therefore, the number of eligible probes were 5,400 (14%).** Note that while we request all these eligible probes to participate in our measurements, not all of them do [27]. RIPE Atlas documentation mentions that it is possible for probes to not participate if the requested probes were too busy to take on new jobs, or had changed statuses, i.e. become disconnected or offline.

As mentioned in Section 4.3, we have 2,350 RIPE Atlas probe IP-probe ID pairs that fully completed the SSL, ICMP and TCP traceroute measurements. Overall, there are 2,304 unique RIPE Atlas probe IPs belonging to 2,193 unique probe IDs, because some probe IPs have multiple probe IDs associated with them and some probes have multiple IPs. The probes we have in our measurement covered all continents: Europe (1539), North America (378), Australia/Oceania (73), South America (32), Asia (155), and Africa (16).

The distribution of these probes over the top 1%, 10% and 50% of ASes per continent is shown in Table 1. We see that the distribution of eligible probes closely follow the distribution of the probes that participated in our measurements, thereby showing that our selection strategy did not skew our results.

The distribution of eligible and participated probes across different access technology shown in Table 2.

C Measurements done at different times of day and days of the week

We tested the hypothesis that running latency measurements at different times of the day in the local time of the probe

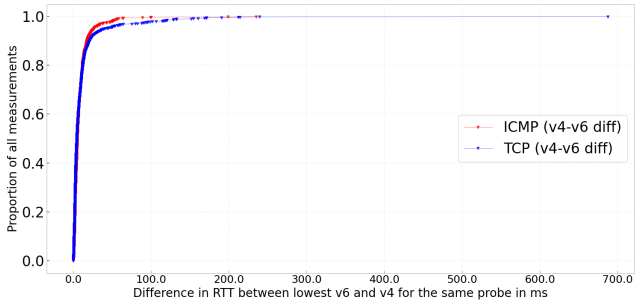

Figure 12: **RIPE Atlas IPv4 and v6 RTT Differences**—From our measurements, we find that in over 85.4% of the probes the difference between the RTTs of the terminal hops done from the traceroutes of IPv4 and IPv6 addresses (ICMP and TCP separately) is less than 50ms, which is exactly our margin threshold. In all cases above 50ms, the IPv6 traceroute RTT was markedly higher.

Tags (Associated RIPE Tags)	Eligible	**Participated**
Fibre (Fibre, FTTH)	2124	**906**
Cable (Cable)	1071	**365**
VDSL (Only VDSL or VDSL2)	475	**268**
DSL (DSL and not VDSL/VDSL2)	356	**160**

Table 2: Distribution of probes over access technology in the set of eligible probes and probes that actually participated in our measurement. This table shows that the distribution of tags follows the participation rate of ≈46%

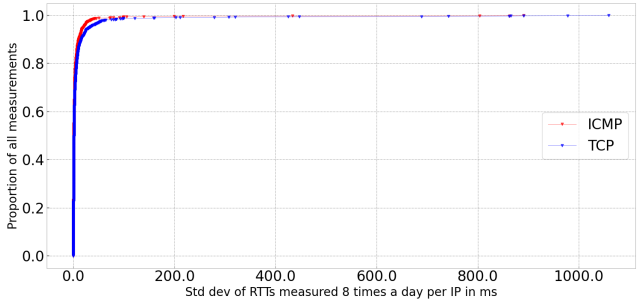

Figure 13: **CDF of Standard Deviation of RTTs per RIPE Probe IP** measured eight times a day—We see that in both ICMP and TCP traceroutes the standard deviations in over 90% of all probes is less than 9.2ms and 10.9ms respectively.

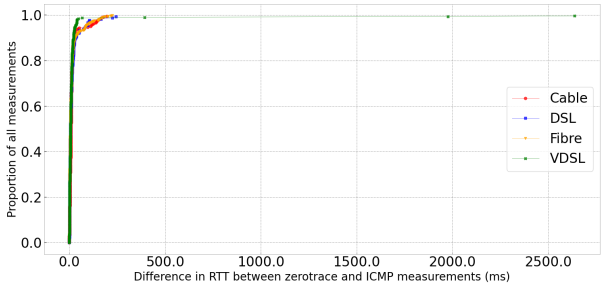
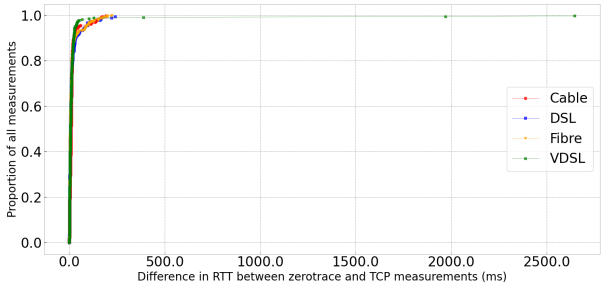
could lead to variance in expected RTT due to different traffic patterns at different times. So, we restricted our measurements to run at eight different times during the day, with respect to the local time of the probe, extrapolated from the latitude and longitude of the probe. We also ran these measurements on weekdays and weekends over two weeks to observe any differences. We had 1,345 probes that completed the TCP traceroute measurements, and 1,196 that completed the ICMP traceroutes over multiple days.

Our measurements show that in both ICMP and TCP traceroutes, the standard deviations of the RTTs throughout the day is low per IP address. Figure 13 shows that in 90% of probes, the standard deviation is lower than 9.2ms and 10.9ms in ICMP and TCP respectively. Moreover, in over 95% of probes, the standard deviation is lower than 15.7ms and 21.1ms in ICMP and TCP respectively. The outlying 5% measurements are not belonging to any specific group of probes and are equally spread out among the tags, locations, and times.



Since RIPE Atlas has a daily quota and a concurrency limit for measurements, our aim is to maximize the usefulness of our measurements. If we run measurements at different times of the day and repeat each measurement thrice to account for errors, we can only measure a maximum of 595 probes a day (Maximum credits per day: 1,000,000, divided by credits need per measurement round per probe (420) times 4 repeats). But since our experiments revealed that there is no significant difference in latency for 95% of the cases when measured at different times of the day, *we make the trade-off of missing out the 5% of probes with some variance in measurements taken at different times of the day, and rather choose to expand our measurements to include a larger variety and diversity of probes from different geolocations and last-mile technology.* In the rest of this section, we present results from our wider, diverse measurement run that was aimed at maximizing the number of probes, and conducted over a three day period (Sunday–Tuesday).

D RIPE Atlas Probes v4 vs v6 Differences



Since RIPE Atlas allows us to run Internet measurements from their probes which have IPv4 and IPv6 dual stack probes, we wanted to identify if our CalcuLatency and its evaluation have any significant effects if the tested endpoints are dual-stack. However, we note that our 0trace system is currently only able to run and measure towards an IPv4 address, since we rely on the IPID field and ICMP(v4) error responses in our system design. If the endpoint makes a TCP handshake via their IPv6 address, 0trace will not be able to run towards that host.

Nevertheless, we conducted measurements from the IPv4 and IPv6 addresses of the same probe. We find that the RTT difference between the terminal hops in the ICMP traceroute and TCP traceroute. We find that in ≈ 90% of the probes, the RTT difference between the IPv4 and IPv6 traceroutes in a given protocol (ICMP/TCP) is below 50ms, as shown in Figure 12. There is a long tail with the RTT differences, and upon manual investigation we notice that in each case, the IPv6 traceroute ended early, and had bloated RTT values and hence the difference turned out to be large.

We note that our CalcuLatency at the moment only supports IPv4 based 0trace measurements and so, we present this

(a) Difference between 0trace-determined RTT and RIPE Atlas-determined ICMP RTT in ms.

(b) Difference between 0trace-determined RTT and RIPE Atlas-determined TCP RTT.

Figure 14: **Comparing the RTT differences between probes with different local last-mile access technology**

analysis in the appendix, and leave the optimization of IPv6 based latency calculation for detecting proxy-enabled abuse for future work.

E Public Real-World Crowdsourced Evaluation ASN distribution

As mentioned in Section 5.2, we had 161 direct measurements that came from 145 unique client IPs belonging to 93 different autonomous systems (ASes), and 122 VPN measurements that came from 109 unique VPN IPs belonging to 51 different ASes. Overall, we collected data from over 37 different countries from all (six) continents.

We provide a more detailed breakdown of the IPs by autonomous system number. Our direct measurements had at least two measurements from the following AS numbers: 7922, 701, 7018, 21928, 3320, 36375, 33915, 3209, 24309, 1257, 22773, 35807, 577, 61832, 27, 20115, 5089, 3215, 6167. The rest of the 74 ASes had one measurement from them. Our VPN measurements had at least two measurements from the following AS numbers: 9009, 212238, 60068, 136787, 39351, 16509, 136557, 132825, 137409, 63949, 20473, 13335, 60781, 197706. The rest of the 34 ASes had one measurement from them.

F Differences in local and last-mile access technology

Figure 14 contains all the data from our evaluation of our hypothesis of whether different last-mile access technologies have large effects on the latency seen from the server side. We divide and present our results for the RIPE Atlas probe's TCP and ICMP traceroutes separately. In Section 4.3, we presented results without outliers for better visibility. Here, we present all our results.

We see that there are only three outliers, all of which were tagged with VDSL as the access technology. As noted in Section 4.3, these outliers had an RTT difference of 388ms, 1970ms, and 2640ms and upon investigation we note that these were due to two German RIPE probes in AS8881 and AS3320 which failed to reach far in the 0trace traceroute. These cases would be characterized as "best effort" in the real world operation of the CalcuLatency system and would be marked for retrying and not used for determination.

6SENSE: Internet-Wide IPv6 Scanning and its Security Applications

Georgia Institute of Technology
6sense-team@cc.gatech.edu

Abstract

Internet-wide scanning is a critical tool for security researchers and practitioners alike. By exhaustively exploring the entire IPv4 address space, Internet scanning has driven the development of new security protocols, found and tracked vulnerabilities, improved DDoS defenses, and illuminated global censorship. Unfortunately, the vast scale of the IPv6 address space—340 trillion trillion trillion addresses—precludes exhaustive scanning, necessitating entirely new IPv6-specific scanning methods. As IPv6 adoption continues to grow, developing IPv6 scanning methods is vital for maintaining our capability to comprehensively investigate Internet security.

We present 6SENSE, an end-to-end Internet-wide IPv6 scanning system. 6SENSE utilizes reinforcement learning coupled with an online scanner to iteratively reduce the space of possible IPv6 addresses into a tractable scannable subspace, thus discovering new IPv6 Internet hosts. 6SENSE is driven by a set of metrics we identify and define as key for evaluating the generality, diversity, and correctness of IPv6 scanning. We evaluate 6SENSE and prior generative IPv6 discovery methods across these metrics, showing that 6SENSE is able to identify tens of millions of IPv6 hosts, which compared to prior approaches, is up to 3.6x more hosts and 4x more end-site assignments, across a more diverse set of networks. From our analysis, we identify limitations in prior generative approaches that preclude their use for Internet-scale security scans. We also conduct the first Internet-wide scanning-driven security analysis of IPv6 hosts, focusing on TLS certificates unique to IPv6, surveying open ports and security-sensitive services, and identifying potential CVEs.

1 Introduction

IPv4 Internet scanning has transformed security research. Beginning with the debut of Durumeric et al.'s ZMap [25] at USENIX Security 2013, researchers used fast IPv4 Internet scans in more than 700 peer-reviewed papers to: uncover new classes of security weaknesses [23], understand attacker behavior [3], guide the development of new protocols like TLS 1.3 and SMTP-STS [1, 24], improve DDoS defenses and censorship circumvention platforms [42, 68], and uncover in-progress network attacks [26]. Data collected from Internet scans also enabled researchers to notify hundreds of thousands of server operators about vulnerable systems [43].

While fast Internet scanning has helped us understand a range of Internet security questions, the scope of understanding is confined to the 32-bit IPv4 address space. This limitation stems from existing end-to-end tooling employing an *exhaustive* scanning methodology by which they send packets to *every single IPv4 address* on the Internet, totaling billions of packets per scan. This brute force method is unable to scale to IPv6's roughly 340 trillion trillion trillion addresses.

As IPv6 adoption grows, currently comprising more than 40% of Google's traffic [34], it becomes critical to develop tools to extend Internet scanning into the IPv6 space. Moreover, prior work has demonstrated differences in security posture between dual-stacked IPv4 and IPv6 systems [21] along with IPv6-specific security challenges, indicating a need for IPv6 security and vulnerability assessments. Worsening the problem, IPv6 utilization is not uniform across the globe. Tools that are unable to explore IPv6 will fundamentally limit our understanding of security threats and potentially bias results to specific regions, populations, and technologies.

The lack of technology to perform Internet-wide IPv6 scanning has not gone unnoticed. Given the intractability of exhaustive enumeration, IPv6 scanning approaches must be, by necessity, driven by *heuristic* and *learning* methods. Such initial approaches to IPv6 address generation have been undertaken and are numerous [5, 17–19, 29–31, 35, 39, 45, 46, 50, 59, 61, 71–73]; these works largely focused on *Target Generation Algorithms* which build an understanding from a set of known addresses and generalize new addresses to scan.

Unfortunately, these methods have fundamental limitations that preclude their use for large-scale Internet security scans: 1) They are frequently offline algorithms [17–19, 29, 46, 50, 71]; meaning they cannot adapt to online scanning results, which we will show is critical to enumerating hosts. 2) They

frequently do not account for IPv6 aliases[1], causing accuracy and hit-rate reporting in prior work to be misleading. We will show that aliasing is a substantial challenge in IPv6 Internet scanning, and surmounting aliasing is key to performing security scans. 3) They are not deployable for security scanning tasks. As we will show in Section 6, existing solutions either generate such large quantities of aliased addresses they are intractable for deployment or produce limited unique active hosts. These challenges make them undeployable by researchers to achieve similar security results as with IPv4.

Orthogonal to prior approach limitations, no concrete metrics have been established for evaluating IPv6 scanning solutions, with multiple papers utilizing similar metrics with different definitions (e.g., "Hits" with and without accounting for aliases). Worse still, commonly used metrics do not account for the unique structure of IPv6 addresses, whereby a single end-site can be assigned a /64 prefix, rather than a full distinct address. Establishing a set of consistent metrics is key to producing effective IPv6 security scans.

We design, deploy, and evaluate 6SENSE, an end-to-end reinforcement learning [67] IPv6 scanning system designed for Internet-wide security scans. 6SENSE leverages IPv6 address and autonomous system (AS) deployment patterns to perform per-AS address generation. 6SENSE finds significantly more hosts than prior IPv6 discovery methods. 6SENSE's design and implementation are driven by six important IPv6 scanning metrics we identify as influencing the efficiency, correctness, diversity, and deployability of IPv6 scanning systems. As a part of our evaluation, we identify and describe these metrics and evaluate available and tractable IPv6 discovery approaches across these metrics, demonstrating that 6SENSE greatly outperforms existing solutions and provides a significantly greater diversity of discovered hosts and networks. We also show 6SENSE is tunable against these metrics, as well as by protocol and port, allowing researchers to focus their scans based on their scanning needs. Lastly, we deploy 6SENSE to perform an initial Internet-wide scanning-driven security analysis of IPv6 hosts to demonstrate the promise of generative IPv6 security scanning.

Specifically, our contributions include:

- Identifying, defining, and evaluating a set of six comprehensive metrics for IPv6 scanning performance that can form the basis of future evaluations of scanning approaches.
- Developing a new generalized approach to IPv6 address generation and scanning, and implementing that approach as 6SENSE. 6SENSE uses reinforcement learning from a set of known addresses to generate a diverse set of candidate IPv6 addresses which it subsequently scans. Of note is 6SENSE's understanding of IPv6 address structure and allocation strategies, techniques lacking from prior approaches. We believe 6SENSE can not only serve as a platform for Internet-scale IPv6 security studies, but 6SENSE's framework and tooling can be iterated on and enhanced to yield continually improving IPv6 Internet scan results.
- Deploying available prior IPv6 generative approaches and evaluating 6SENSE against each approach across our metrics, finding up to 3.6x more hosts and 4x more end-site /64 assignments than prior approaches.
- Performing the first scanning-driven, Internet-wide security analysis of IPv6 hosts. We explore 3 security contexts: TLS Certificates, sensitive exposed internal services, and open ports. We also conduct a qualitative study of insecurity and configuration issues with discovered IPv6 hosts.
- Discovering 81K security-sensitive devices exposed to the Internet, ranging from virtualization tools to enterprise networking hardware to consumer devices.
- Quantifying the potential CVE exposure of discovered devices, finding at least 70 applicable CVEs.

6SENSE has been open-sourced at `https://github.com/IPv6-Security/6Sense` to suppport IPv6 security research.

2 IPv6 Background

IPv6 addresses are 128 bits. Each consecutive 4 bits has a hexadecimal representation called a nybble. Within an address, the 128 bits are (conceptually) split into Upper-64 bits and Lower-64 bits. Typically, the Upper-64 bits describe an allocation or assignment, although prefix sizes vary [40]. The Lower-64 bits describe a specific host.

Upper-64 bits: Allocation + SSID. An allocation specifies a prefix leased from the Regional Internet Registry (RIR) to an organization. Commonly, this allocation is of size /32 or larger [40]. The remaining bits of the Upper-64 bits are a subnet ID (SSID), varying in usage. An SSID may begin a pattern continuing into the Lower-64 bits, it may be incremental, or it may follow a pattern entirely of its own. Further, SSID similarities within the same allocation vary. We observe that some SSIDs within allocations follow patterns. This is partly from observing incremental and other obviously patterned SSIDs. Additionally, Upper-64 bits, in practice, may correspond to end-sites [63], but may vary in size.

Lower-64 bits. The Lower-64 bits, also known as the interface identifier (IID), are commonly assigned to a single end-site [37]. End-sites often utilize specific patterns in the IID range (e.g., addresses with `::1` Lower 64 Bits are frequently observed), some guided by RFCs [11, 37]. However, some hosts utilize fully randomized IIDs [16, 33]. While fully randomized IIDs are intractable to scan, prior work suggests patterns in IIDs do exist and are common [29].

Aliasing. Aliasing (sometimes called pseudo-dense regions) is a significant challenge for IPv6 measurements [27, 30, 50], and occurs when a large contiguous IPv6 range is fully responsive on all addresses. However, it is infeasible that each

[1] Aliases are impossibly large fully responsive IPv6 prefixes, frequently assigned to a single machine [30, 73]. Such regions are extremely common [30].

address represents a distinct active host due to the number of addresses. Scanning methods optimizing for discovered active addresses may over-dedicate resources to exploring aliased regions, resulting in misinterpreted and poor results. Aggressively scanning aliased prefixes may also present ethical issues by overloading in-path networks. While we present a dealiasing approach in Section 5.3, we note studying the effects of aliasing on security measurements and developing different dealiasing methods remains an open problem. We note dealiasing in the IPv6 scanning context does not typically refer to resolving singular devices with addresses in separate networks. Rather, it focuses on contiguous active regions.

3 Related Work

IPv6 Scanning. ZMap [25] introduced fast Internet-wide IPv4 scanning by comprehensively enumerating the entire IPv4 address space. While this tool revolutionized IPv4 network security, the tremendous size of IPv6—340 trillion trillion trillion addresses—prohibited similar approaches for IPv6 scanning. Instead, recent work introduced IPv6 target generation [29, 50, 64]. Target generation approaches (TGAs) use known IPv6 addresses to deduce new active addresses and can be categorized into Initial Explorations, Generative Tree Approaches, and Machine Learning Approaches.

Initial Explorations: The first IPv6 TGA was introduced by Ullrich et al. [64] and leveraged common static addressing patterns in known prefixes. Subsequently, Foremski et al. [29] presented Entropy/IP which, given known "seed" addresses, produces a statistical model of the dependencies between nybbles. This model generates addresses by varying high-entropy nybbles. 6Gen [50] identifies dense address space regions through seed address clustering and generates within these regions. Liu et al. [46] introduced 6Tree, which builds a tree of addresses initialized by the seeds. It scans the address region for leaf nodes, iteratively merging scanned nodes into larger regions up the tree. Relative to modern approaches, these models are not competitive as they are not adaptive.

Generative Tree-Based Approaches: 6Hit [39] introduced the first online reinforcement learning system as an online extension to 6Tree. 6Hit targets generation towards more active 6Tree nodes and recreates the tree when hitrates plateau. However as it does not dealias, it gravitates towards aliased regions, resulting in ineffective practical scanning.

Separately, DET [61] builds upon 6Tree by regenerating the address tree after fixed increments. DET updates 6Tree to use an entropy-based tree branching method. It splits generation into multiple batches, recreating the tree based on active addresses between each batch. DET is an online approach, but it lacks alias detection and gravitates toward aliased regions. Furthermore, DET's repeated tree reconstruction is heavyweight and slow. 6Graph [71] leverages DET's approach for generating address trees based on entropy, however, it extracts the high-density IPv6 region patterns from leaf nodes offline, and later applies them to generate addresses by sampling within those regions. As it is offline, it cannot adapt over time, including to aliases.

Machine Learning Approaches: Cui et al. [17] presented 6GCVAE, the first deep learning approach, using gated convolutional variational autoencoders. Next, 6VecLM [19] used word embeddings and transformers to generate candidate addresses. Unfortunately, these approaches tended to generate invalid IPv6 addresses (e.g., in unallocated ranges) and degenerating into aliased regions. 6GAN [18] updated these methods by using sequential generative adversarial networks to solve these problems but suffers performance issues.

Other Approaches: Li et al. explored non-generative IPv6 router discovery whereby they leveraged the behavior of some routers to respond to packets addressed to non-existent devices within their subnet with ICMP Destination Unreachable [44]. From these ICMP packets, their tool extracts the last-hop in-path router. This approach is fast as it has no generative or learning components. Where applicable this method is apt; however its leveraging of such control packets from routers limits it to only devices that generate such ICMP Destination Unreachable responses, as well as only to on-path last-hop routers (rather than end hosts). It has not been shown applicable for Internet-wide scanning.

IPv6 Security. Previous work studying IPv6 security policies has been limited by the method of identifying active IPv6 addresses. Czyz et al. identified dual-stack hosts with fingerprinting and found that many applications were more open on IPv6 than on IPv4 [21]. Borgolte et al. analyzed the security of collected IPv6 addresses through DNSSEC reverse zones, finding that the openness of applications varied [7]. Li et al. deployed their ICMP Destination Unreachable method across 13 residential ISPs, and performed security analysis by classifying periphery devices by vendor, identifying device vulnerabilities, DDoS amplification, and routing loops [44].

Prior generative IPv6 scanning work has not directly addressed security, leaving it as future work [50, 73]. Early TGAs only evaluate their performance based on responsive addresses per category (such as from router, server, and client seeds) [29, 64]. Moreover, generative tree-based and machine learning approaches focus solely on discovery performance compared to prior work [17–19, 39, 46, 50, 70, 71]. By using an IPv6 hitlist [30], Song et al. explore the hit-rate change based on different services using various protocols and ports [61]. Security is largely an unexplored field in the generative Internet-wide IPv6 scanning space; we share our initial security explorations in Section 7.

4 IPv6 Scanning Metrics

Given the inability to exhaustively search the IPv6 address space, it is critical to establish metrics to understand the effec-

tiveness of proposed IPv6 scanners at discovering hosts and thus performing security studies. Prior work largely used the overall number of found addresses ("hits") to naively express the utility of approaches [5, 17–19, 29–31, 35, 39, 45, 46, 50, 59, 61, 71–73]. "Hit-rate" extends this metric to balance hits against the number of scan probes sent. While hits are important, they fail to capture crucial dimensions of IPv6 host discovery that are important for security studies. They treat all active addresses equally, although as previously discussed, large-scale IPv6 aliasing produces active addresses that are not distinct meaningful hosts to measure. Meanwhile, optimizing for hits also ignores network or host diversity, potentially resulting in skewed views of the IPv6 Internet.

Here, we propose a broader set of metrics—four positive and two negative—that better encompass the performance of IPv6 scanners. Note, our metrics exclude seed inputs (counted as "duplicates") from results to reflect additive performance. We envision that for different studies, different metrics could be optimized for. For example, surveying infrastructure reachability requires AS diversity, while monitoring residential router vulnerabilities may require more active Upper-64s.

[+] Number of Hits. Counting hits is useful as a first approximation of an IPv6 scanner's potential, and prior work primarily relied upon this metric [29, 30, 39, 50, 61, 73]. However, as discussed, hits do not effectively convey host or network diversity and can be skewed by addresses in aliased regions. Thus we define this metric as the number of active IPv6 addresses found in a given scan (excluding seeds) minus those identified as in aliased regions.

[+] Number of New /64 Subnets with Hits. To capture the diversity of end-sites found by an IPv6 scanning approach, we consider the number of non-seed /64 subnets with non-aliased hits. Per RFCs [63], /64s are the most specific prefix for end-site assignment. While /64s may not always delimit end-sites, allocation policies specifically recommend against assigning more specific prefixes [57]. Thus, examining /64 subnets can provide us with additional evaluation of diversity not captured by counting hits. We acknowledge that /64s are not necessarily static, as prior work has characterized the mobility of IPv6 addresses and prefixes [52, 58]. However, we maintain that even with address and prefix churn, counting /64s remains a valuable evaluation metric.

[+] Number of Newly Generated /64 Subnets. To quantify the diversity of IPv6 scanner exploration, even if it fails to find hits in certain subnets, we also consider how many new /64 subnets are generated (beyond seed /64s). While this metric may not directly translate into improved hits, we believe it provides intuition on how a method explores the space.

[+] Number of ASes with Hits. Here, we consider network diversity by quantifying the number of distinct ASes found with a non-seed non-aliased hit. We can map addresses to ASes using the Routeviews Prefix-to-AS mappings Dataset (pfx2as) [8]. By including AS counts alongside /64 counts, we highlight two distinct perspectives on the diversity of discovered addresses. We note that ASes are not a perfect representation of network diversity [32], and there is potential to refine or expand this metric based on routing information.

[-] Number of Duplicate Addresses Generated. Generative approaches to IPv6 scanning have a key problem: repeatedly generating the same address. Such duplicate addresses result in lost generative budget and repeated scans of the same address. Thus, here we quantify the number of IPv6 addresses generated more than once by a system. We treat generating seed addresses as a form of duplicate. Although this metric does not directly correlate to our other discovery metrics, counting duplicates generated is important to evaluate the effectiveness and efficiency of a scanning method.

[-] Aliased Hits. Aliased IPv6 regions are a significant problem for IPv6 scanning (Section 2), and further work is necessary to fully understand their impact, as well as develop sophisticated strategies to identify them and account for them in scanning metrics. In the context of our metrics, we deploy our online dealiasing approach and quantify the number of active IPv6 addresses found within aliased regions. In conjunction with our other metrics, this metric allows us to fully evaluate method diversity and effectiveness.

5 Methodology

The space of approaches to IPv6 scanning is vast; prior work tried numerous heuristic, statistical, and learning regimes. We now present an overview of our design, motivated by past work and the need for a deployable system for security studies.

Starting point: Generalizing from Known Addresses. IPv4 systems simply enumerate addresses; IPv6 needs a different approach. TGAs largely generalize from known addresses, or "seeds." We adopt this approach but expand it to also understand patterns in how addresses are *allocated*.

Utilizing Domain-Specific Knowledge: Address Structure. As previously discussed, an IPv6 address typically has 3 components: allocation, SSID, and Lower-64 bits. Unlike prior approaches, we use this domain-specific knowledge in our method (to optimize address discovery), with different approaches for each section of the address space.

Efficient Exploration: Allocation-Aware, Metric-Driven Online Learning. We take an online reinforcement learning approach to generalize known network allocations into generated addresses. This allows us to update our learned representation in real-time, a key to improving system performance. Moreover, this design allows us to explore regions and optimize our learning toward specific metrics.

Leverage End-Host Behavior: Lower-64 Bits. We leverage domain-specific knowledge of common Lower-64 bit patterns (e.g., routers at ::1, IPv4 embedding, MAC encodings, incrementing addresses) to iteratively explore Lower-64

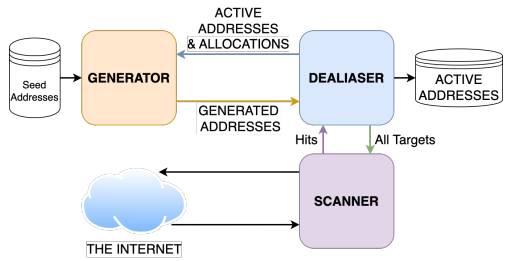

Figure 1: 6SENSE overview. 6SENSE consists of three components: Address Generator (Figure 2), Dealiaser (Figure 3), and Scanner. The Generator passes generated full addresses to the Dealiaser to perform online alias resolution (see Figure 2). The Dealiaser performs both offline and online dealiasing. The Dealiaser then interacts with the scanner to perform Internet scans of IPv6 addresses. Each component is broken down in more detail in subsequent figures. Sub-component figures are color-coordinated with their parent.

bits patterns. We pair this with our learned representation of allocations and SSIDs to produce candidate addresses to scan.

Online Dealiasing. Since aliased regions are likely to "sinkhole" scanners optimizing for hits, discovering hosts within aliased regions provides limited value to researchers. Known lists of aliased regions provide an important resource to preemptively avoid aliases, but cannot account for changes in allocations or new aliases. To effectively scan the IPv6 space, it is critical for scanning systems to include online dealiasing.

5.1 6SENSE Overview

6SENSE, shown in Figure 1, is an end-to-end online IPv6 scanning system. It consists of three core components: Address Generator, Dealiaser, and Scanner. We summarize and subsequently describe the system in this section.

Scanning IPv6 begins with address generation. We leverage IPv6 address assignment and allocations to generate active addresses efficiently. We handle the Upper-64 bits and Lower-64 bits of addresses separately, leveraging domain-specific knowledge of how addresses are allocated and utilized. This distinction is based on RFC guidance that specifies the most specific allocation that should be given to an end-site is a /64, with the end-site deciding how to assign to hosts within the /64 based on various schemes [63].

6SENSE samples known IPv6 allocations using a weighted Reinforcement Learning update technique (Section 5.2.1). It sends these variable-length allocations to an LSTM [38] to generate candidate Upper-64 bits of addresses (Section 5.2.2). Finally, 6SENSE provides these Upper-64 bits to an iterative Lower-64 bits generator that uses domain knowledge to pair Upper-64 bits to likely active Lower-64 bits (Section 5.2.3).

After generation, 6SENSE provides addresses to the Dealiaser (Section 5.3). The Offline Dealiaser performs prefix matching to exclude known aliased addresses before active probing (Section 5.3.1). Addresses then proceed to the Online Dealiaser (Section 5.3.2) and the Scanner (Section 5.4). The Scanner interacts dynamically with the Online Dealiaser to determine if addresses lie in aliased regions by sending additional probes to addresses near active IPs.

Finally, dealiased active addresses are returned to the Generator, which uses them to retarget generation toward active regions. This adaptive system allows 6SENSE to discover active regions sparsely represented in input datasets, far outperforming prior static methods. By adjusting *how* we use active addresses to retrain generation, we can vary the target of generation based on customized metrics. This, coupled with the modular scanning approach, allows our model to adapt to individual use cases (Section 5.2.1).

5.2 Address Generation

Address generation is broken down into three distinct parts. First, 6SENSE generates candidate IPv6 allocations. These are blocks of IPv6 addresses allocated in input datasets. Next, it extends those allocations to a full Upper-64 bits, comprising the subnet prefix of each address. Finally, it generates specific Lower-64 bits based on observed patterns.

5.2.1 Allocation Generation

6SENSE's allocation generation uses the Explore-Exploit Reinforcement Learning paradigm [62]. Exploration maximizes the Breadth of generated results by exploring all allocations present in the seed dataset, and exploitation maximizes results in known successful regions (Depth) by weighting more heavily towards active prefixes. Since exploitation is overloaded in security contexts, we use the terms: Breadth–Depth.

We specifically focus our search on seed allocations since vast quantities of the IPv6 address space are unallocated [20], and many other allocated regions are unused [40].

Breadth. For the first N_s addresses, 6SENSE generates equally from each allocation in the seeds. At the end of this phase, 6SENSE uses scan results to discard allocations without active addresses. It weights the remaining allocations proportional to their hit-rates.

The optimal N_s varies per port/protocol. To further generalize our approach, we introduce an automated threshold discovery mechanism to determine N_s. The goal of exploring is to find as many active regions (allocations) as possible before moving to the Depth phase. Thus, we base our stopping criteria on the rate of new allocations found. We sample a fixed-size ($1M$) block of addresses during exploration, and after each block b, estimate the scaled gradient G_b of new active allocations A_b using the difference: $G_b = \frac{A_b - A_{b-1}}{A_b}$. Breadth completes when G_b drops below a tunable threshold.

To properly balance AS discovery across ports, we set the tunable completion threshold to 0.005 for experiments

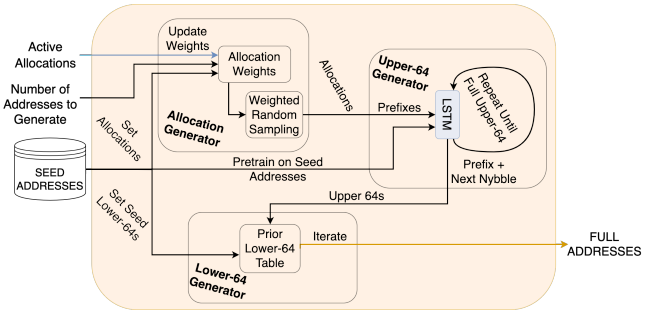

Figure 2: 6SENSE's Address Generator. 6SENSE uses weighted allocation sampling to target specific known IPv6 allocations. Once allocations are selected, it uses an LSTM trained on known subnet utilization patterns to create a candidate Upper-64 bits. From this, known Lower-64 bit patterns are iterated upon to create full candidate 128-bit addresses.

in Section 6. Optimal thresholds vary with the number of addresses sampled, but 0.005 allows proper balancing of AS and Allocation discovery across 100M IPs.

Depth. In subsequent iterations, 6SENSE samples in batches of N_i addresses. It weights sampling based on hit-rates over the past $3N_i$ iterations. We chose a N_i of $1M$ for ICMP. To reflect their expected reduced volume of active addresses, we chose $5M$ for the other ports and protocols tested in Section 6.4. In this way, 6SENSE moves away from allocations where it ceases finding hits or exhausts discoverable addresses. This phase is crucial, as it allows 6SENSE to avoid exhausting its scanning budget in unused or undiscoverable prefixes.

5.2.2 From Allocations to Full Upper-64 bits

As an end-site can be assigned up to a /64, full Upper-64 bits are more likely determined by the allocation and the organization it is leased to [63]. Thus, we cannot rely on fixed patterns for generation. Instead, our Upper-64 generator must discover new statistically significant patterns within the Upper-64 bits. These patterns account for organization-specific and generalizable Upper-64s. Because the Lower-64 bits are not fixed, we may wish to sample an Upper-64 multiple times, so our sampling mechanism must account for the frequency we sample the same Upper-64 bits within an allocation.

Sequential Modeling suites this task well, while also capturing positional dependencies within addresses [14]. Sampling Upper-64 bits sequentially (from allocations) captures the frequency of active seed Upper-64 bits per allocation and Upper-64 bit assignment patterns. 6SENSE uses an LSTM for its relative simplicity and speed. The LSTM takes as input an allocation and sequentially predicts each next nybble, up to 64 bits. The nybble granularity aligns with prior work [17–19, 29, 39, 46, 50, 59, 61, 71, 72]. We sample from our LSTM in batches of 50K to balance time and memory.

By generating using a deep learning model, we characterize the Upper-64 bit patterns in terms of allocation-specific patterns, generalizable patterns across allocations (Upper-64 bit patterns in one allocation may be referenced by the LSTM weights for another allocation with less data), and the frequency of Upper-64 bits within an allocation. This also makes 6SENSE robust to sparsely represented regions in the seed addresses. For these regions, the LSTM generates more seed Upper-64 bits (since only these Upper-64 bits appear in that region in the seed dataset) allowing us to efficiently explore different Lower-64 bits within these known active Upper-64s. This per-allocation structure allows us to parallelize address *generation* across GPUs, which we discuss in Section 6.6.

For training, we ran our LSTM with a batch size of 3200, a learning rate of 0.001, and two LSTM layers of sizes: 512, and 256. This structure balances LSTM predictive power with generative speed. Our training dataset consists of every prefix within our active seed dataset between the allocation length and 15 nybbles (60 bits) with masked variable allocation lengths. The labels for each prefix are the next nybble within the Upper-64 bits. We train for 50 epochs and use a dropout of 0.2 per iteration, to prevent overfitting. While we want 6SENSE to roughly emulate seed patterns, overfitting can decrease diversity in the addresses by only generating seed Upper-64 bits and not exploring new ones.

5.2.3 Lower-64 bits Generation

There are numerous well-defined Lower-64 bit patterns within IPv6 addresses. Many common patterns, however, include a bottom-up counting strategy, with active Lower-64 bits having similar lowest bits. The similarity of the low bits means an exhaustive iterative search around the lowest bits of the Lower-64 bits is both efficient and fruitful.

6SENSE first extracts a list of previously seen Lower-64 bits for each allocation, ordered by frequency. While sampling, each time it sees a repeated Upper-64, 6SENSE generates a new Lower-64 in the following order:

1. **Prior Lower-64 bits:** The Lower-64 bits of the Upper-64 bits' allocation in order of frequency in the seed dataset, skipping Upper/Lower pairs already present in the seeds.
2. **`::1`:** Due to the prevalence of `::1` in known configurations and observed IPv6 addresses, 6SENSE tries `::1`, if not already present in the prior Lower-64 bits.
3. **Iterative:** Iteration over the bits of each Lower-64 in the Upper-64's allocation. 6SENSE tries all Lower-64 bits in the allocation, counting to modulo 16, to cover each nybble.

Sampling Lower-64 bits by allocation leverages organization-level patterns, while iterating prevents duplicates and uses domain knowledge of the most common patterns. Finally, by trying `::1` we leverage behaviors common across allocations.

We note this technique is relatively simple, but as shown in Section 6, it is both efficient and powerful. We expect future work can further mine this portion of the address space.

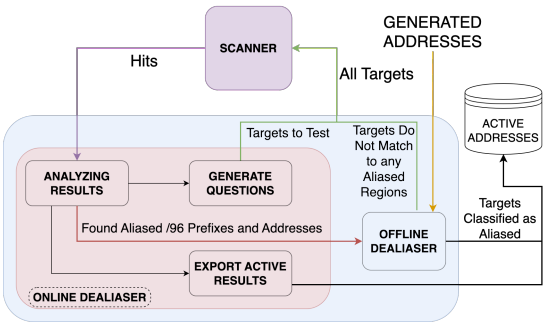

Figure 3: 6SENSE's dealiaser. The system contains both an offline dealiaser that identifies previously discovered regions, and an online dealiaser that deduces if hits are aliased.

5.3 Detecting and Resolving Aliases

The tension between maximizing hits and aliased regions creates a unique challenge. Generators blindly optimizing for hits primarily generate from aliased regions if they are not identified. To prevent this, 6SENSE identifies aliased addresses both before and after scanning to prevent generators from over-allocating later scanning resources to them.

6SENSE's multi-tiered dealiaser, shown in Figure 3, consists of two components. First, we classify aliased addresses using alias lists from prior work [31]. Second, any active address passing prefix-based alias detection is sent to an online dealiaser. This structure leverages known aliases and density-based alias detection, without substantial speed decreases.

5.3.1 Prefix-Based Dealiaser

Offline dealiasing is a useful first step to reducing the overhead of online approaches. 6SENSE's offline dealiaser is implemented in Golang, and it uses the list of aliased prefixes provided by Gasser et al. [31]. However, to ensure we do not filter dealiased addresses or inadvertently discover false positives, we first dealias each prefix using the online dealiasing approach described in Section 5.3.2 at each prefix's granularity. We initialize 6SENSE with a list of mentioned aliases stored in a modified radix tree, where aliased prefixes are represented as leaf nodes divided by bit level. After the initial tree construction, 6SENSE performs alias lookups by sending candidate IPs to the Offline Dealiaser in batches to match the longest prefix. If the target IP does not match an alias, it is sent to the scanner and the Online Dealiaser.

5.3.2 Online Dealiaser

The online dealiaser is designed to work with an IPv6 scanner by determining if a target IP address is in an aliased region at a given prefix. We adapt and modify an offline algorithm proposed by Murdock et al. [50]. We chose a /96 prefix granularity for the online dealiasing. A more specific prefix level may incorrectly label dense regions as aliased, while a less specific prefix level may miss fine-grained aliasing. However, one can change parameters to perform dealiasing under different granularities and thresholds for labeling a region as aliased. To account for loss in our dealiasing, our generator discards allocations where over 50% of active addresses are aliased, providing a lower bound on our findings.

When we encounter a responsive prefix in a batch for the first time after offline dealiasing, the online dealiaser generates 3 more random IP addresses (per [50]) in that prefix and queues them in the scanner. After waiting for scanning to complete, we check how many responses were received for each prefix. If at least 2 out of the 3 addresses for a given prefix responded to our probes, we label that prefix aliased. Otherwise, we label it dealiased. Then, the resulting aliased and dealiased data is returned to the offline deliaser to update the tree, and to the generator for online weight updates.

Unlike prior work, we select a majority threshold (2 out of 3 instead of 3 out of 3) as a conservative lower-bound approach to reduce the probability of exploring aliased regions (false negatives), potentially at the expense of excluding non-aliased regions (false positives). This tradeoff is apt since the probability of finding *any* address in a non-aliased region randomly is low, while the cost of exploring aliased regions is high. We discuss this further in Section 6.2.

5.4 Scanner

Although there are existing IPv6 scanning tools available [5, 30], they lack important functionality, such as blocklisting (ZMapv6, Yarrp6) and packet verification (Yarrp6). Further, ZMapv6 is simply the IPv4 version of ZMap with IPv6 support added on, leading to a sprawling code base containing not applicable features (e.g., packet generation) as well as configuration and usage issues. To address these concerns, we developed a new IPv6-purpose-built scanner, inspired by ZMap [25] but purpose-built for interacting with generative IPv6 systems. We implemented our scanner in Golang, which has been used for other network measurement tools [41, 74].

The system has various packet probing modules (e.g., ICMP Echo Reply scan, TCP SYN scan, and UDP DNS scan), packet validation, input/output parsing, blocklisting (not available in prior IPv6 scanners), monitoring, and feedback facilities. We perform packet validation to confirm received packets are in response to our scan by embedding validation bits in the probe packet [25]. These are generated by hashing the source and destination addresses with a key randomly generated at scan initiation (with the SHA256 algorithm). The scanner then statelessly regenerates and verifies the validation bits.

5.5 Datasets

Seed Dataset. A key facet of 6SENSE is the generalization and learning of IPv6 patterns based on a comprehensive input

Dataset Name	Pop.	Unique	De-Aliased	Active
Censys Certs	Servers	320,328	128,497	75,253
IPv6 Hitlist	All	6,763,519	6,746,480	5,866,234
CAIDA DNS Names	Servers	345,776	268,233	141,019
Cisco Umbrella	Servers	130,742	44,808	35,157
Rapid7 FDNS	Servers	15,015,809	5,154,197	1,651,805
Scamper	Routers	333,811	325,559	25,169
Majestic Million	Servers	135,290	24,134	18,446
Alexa Top 1 Million	Servers	95,375	9,028	7,196
Tranco	Servers	292,090	84,268	64,181
SecRank	Servers	109,686	59,744	35,688
Over All Sources	All	21,278,453	11,104,852	6,349,455

Table 1: Overview of our input seed dataset. We categorize the address types from each dataset and across address status.

set of existing, known active IP addresses. Table 1 presents our dataset. To build this dataset we aggregate potentially active IPv6 addresses from a variety of sources. We begin with the public IPv6 hitlist created by Gasser et al. [30, 73], and augment it with IPv6 addresses collected with Scamper [9]. Furthermore, we collect domain names from CAIDA's DNS [10], Rapid 7 Forward DNS [56], and Censys's dataset of X.509 certificates accessed in December 2022 [12, 22]. For completeness, we additionally use domain top lists: Cisco's Umbrella [65], The Majestic Million [48], Tranco [55], SecRank [69], and an archival version of the Alexa Top 1 Million [2]. For each domain, we use ZDNS [41] to resolve it to IPv6 addresses and add these addresses to our dataset.

To refine the dataset, we dealias and scan all addresses. Active addresses include the total number of active, dealiased addresses on ports TCP80, TCP443, UDP53, or ICMPv6. We perform online and offline dealiasing described in Section 5.3 to identify aliases, including those missed by prior work.

ASes and Allocations. To distill our input seed dataset into ASes and allocations, we need a source of such information. We use the CAIDA Routeviews Prefix to AS mappings [8] to gather prefixes and their corresponding ASes. We use these prefixes as our allocations. In total, we found 49,364 allocations in our seed dataset.

For generation, we revise our prefixes. As our Upper-64 bit generator is designed to generate the next nybble of a prefix, we need starting allocation prefixes in multiples of 4. Thus, for generation, we expand the allocations into all possible allocation values to the closest nybble. We additionally expand any allocation with a prefix less specific than /32 by enumerating all prefixes of size /32 within the less specific prefix. We highlight that adding these additional prefixes allows us to generate a more representative number of Upper-64s per network (Section 5.2) in the case of prefixes that are less specific than a /32. We also emphasize that the nature of our dataset makes the effect of this expansion on performance insignificant. Our dataset [8] is created with routing data. Prior work [40] illustrated that routes with a measurable active IP are most likely to be of size /32 or /48, and rarely less-specific than a /32. In the case of prefixes that are not at nybble boundaries, we expand to a maximum of 8 new prefixes (e.g., when the prefix is 3 bits away from a nybble boundary; i.e., /37 expands to /40), making any over-representation of these networks and performance overhead negligible.

5.6 Ethics

We begin by following the ethics of scanning outlined in the ZMap paper [25]. Namely, we: 1) randomize all scans and packets generated at all phases to ensure network infrastructure is not stressed, 2) operate at a low scanning rate of 10,000 packets per second, total, across all networks (discussed further subsequently), 3) use well-identified (via DNS, whois, and webpages) machines to perform scans, 4) provide parties an opportunity to opt-out of scans, and 5) maintain a blocklist of IP addresses who were opted out of scanning.

Further, we look to recent censorship measurement work [6, 53, 54] which articulate a framework, based on the Belmont [28] and Menlo [4] reports, for reasoning about the risks of Internet measurement. Specifically, the notions of justice, beneficence, and respect for law and public interest. From this framework, we devise methods and procedures that seek to: 1) ensure infrastructure or machines are not stressed or damaged, 2) seek to minimize risk, and 3) ensure that those who bear the risk of measurements are also the beneficiaries of said measurements. The latter point is particularly apt in the context of security studies, as those who bear the risk of these measurements—end hosts—are specifically the individuals who will receive direct benefits from understanding the security risks and associated vulnerabilities, via our disclosure of these discoveries to CERTs and ISPs.

IPv6 Scanning Speed. A unique problem in IPv6 Internet scanning is aliasing (Section 2), whereby vast continuous address ranges map to a single or handful of devices. Thus a generative IPv6 scanner could direct a large portion of its scanning budget towards a single device, believing it to be an entire network. This raises the question of what is an ethical speed at which to scan the IPv6 Internet. Our work seeks to identify and eliminate aliased regions (Section 5.3), potentially at the cost of alias false positives (Section 6.2). However alias classification errors are possible and scanning incurs some inherent risk. Returning to the framework above, our goal is to minimize potential risk; we propose (and adhere to within this work) a scan-rate of 10,000pps. Such a limit ensures that the overall scan-rate of the system does not exceed approximately 5-7Mbps, a value significantly below many modern Internet connections (e.g., the classification of broadband [15]). This value is such that even if aliases are explored and our randomization of IPs is poor, our system does not cause a Denial-of-Service (DoS) event. We note that such efforts do not eliminate risk, rather, our work seeks to minimize risk such that the benefits of large-scale Internet measurement exceed those inherent risks (beneficence), while

ensuring those that bear the risk are also those that benefit from the results (justice).

We believe that scanning at higher speeds can be ethical if specific attention is paid toward the reliable identification of IPv6 aliases—such a problem is not yet well studied, and worthy of exploration. To this end we note that our system has the capability of running significantly faster (Section 6.6), but we strongly discourage such speeds until such time that better dealiasing techniques exist or other safety mechanisms are in place. We note that a bad-actor *could* utilize our system to launch DoS attacks. Such an outcome is possible, but not rational; our system is a strictly worse DoS tool than even random address selection due to the significant performance overhead of machine-learning-based packet generation.

IPv6 Scanning Best Practices. Summarizing our principles above and prior work [25,66], we suggest (and document how we adhere to) the following practices for IPv6 Scanning:

- Clearly identify all scanning activity with DNS records, webpages, and where possible IP WHOIS information that identifies the researchers and provides a means of contact.
  - *All machines used for scanning have forward and PTR DNS records that indicate the machine is used for network scanning and identify our organization. The scanning IPs/domains contain webpages that explain our activity and provide an email address within our organization to contact for more information or to opt-out.*
- Respond to questions openly and promptly, and provide a means to opt-out of future measurements.
  - *The webpage hosted on each scanning IP/domain includes a contact email at our organization. We respond to all emails promptly (within one business day) and immediately exclude requested ranges from scanning. We received three contacts during the course of this project, responded to each, and none requested opt-ing out.*
- Work with local network operators to ensure research activity does not disrupt normal operation, and work with CERTs or similar entities to remediate discovered vulnerabilities.
  - *We worked with our local IT unit to place our scanning machines outside of infrastructure that could be impacted by scanning, and will be continually passing discovered vulnerable IPs to our local CERT.*
- Where possible, consider the use of public datasets rather than performing active measurements from scratch.
  - *We used existing datasets as seeds, but given the nascent nature of this work, no such public dataset exists.*
- Attempt to identify and remediate aliases during scanning.
  - *We develop new methods to identify and remediate aliases, discussed in Section 5.3.2.*
- Rate-limit, distribute, and randomize all scanning activity such that errors in alias detection do not result in DoS.
  - *As discussed above, we rate-limit all scanning activity to 10,000pps, and fully randomize all scanning activity.*

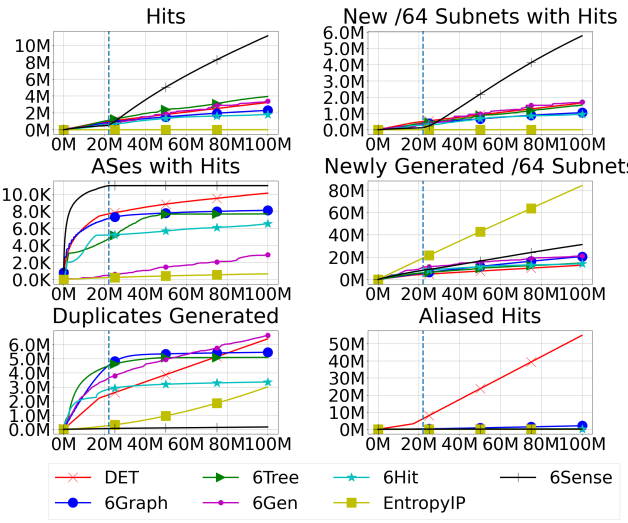

Figure 4: ICMP results across our six metrics, comparing 6SENSE to other approaches. For all figures, the x-axis is the cumulative number of addresses generated/scanned, and the y-axis is the cumulative sum of the given metric. The vertical line represents when 6SENSE transitions from Breadth to Depth based on the diversity gradient. 6SENSE finds 2.8x more hits than any other method, 3.3x more /64s than any other method, and does so with nearly no duplicates or aliases.

6 Evaluation

For our evaluation of 6SENSE, we use the metrics from Section 4 to show how well our system can find hosts in the IPv6 space. Our evaluation focuses on comparing 6SENSE to the six best previously proposed address discovery methods.

6.1 Evaluation Setup

All systems were executed and tested on a 64-core AMD EPYC 7452 processor with 512GB of ram and an NVIDIA A40 GPU with 48GB of GPU Ram. For the evaluation, our scanning system operated 10,000 packets-per-second (pps). All hosts were scanned from a purpose-built academic scanning network in North America.

Limitations of prior methods. While this section focuses on comparing 6SENSE to 6 prior methods, we note that other methods exist. Broadly, we found that prior methods not evaluated here were either closed-source with insufficient description to reproduce [35,60,72], or could not generate or execute in a reasonable amount of time [17–19, 70]. For example, when using 6Forest [70] to generate 100M IPs, it ran for over two weeks before exhausting memory. Additionally, prior work [73] also encountered challenges running 6GAN [18]. Resource limitations for training and generation across models limited us to evaluating 100M IPs. We also filter AS12322 due to prolific aliasing that does not conform to traditional

sizing. We note prior work found significant portions of their hits in this AS [61], likely pointing to substantial aliasing.

6.2 Dealiasing Thresholds

Prior generative scanning that attempted dealiasing generated 3 random packets to a given /96 prefix, and required all 3 sent packets to return hits for the prefix to be classified as aliased [50]. During the development of 6SENSE, we noted that some aliased /96 prefixes displayed inconsistent and lossy behavior resulting in alias detection *false negatives*. These regions could then in turn produce large numbers of aliased hits given the online nature of the system.

To understand the effect of this number-of-hits threshold on alias detection, we conducted a small-scale study of 10M generated addresses (distributed randomly across all seed allocations) where we varied our alias detection threshold between requiring 1 to 3 (out of 3) generated packets to be hits in order to classify a range as aliased. Across 190K total active /96s we find a threshold of 3 gives us 4,255 aliased /96s. Decreasing to 2 results in the classification of 17 additional potentially aliased prefixes. Decreasing to 1 results in 33 additional potentially aliased prefixes.

For each additional prefix evaluated at both thresholds of 1 and 2, we perform manual investigation. We find that the majority of discovered prefixes belong to a single AS, AS28573, with behavior that may denote either aliases at smaller granularity than /96 or dense regions. Excluding this AS, we find that at 2 packets, we identify 6 additional true aliased, but lossy, regions; repeated additional probes could resolve the alias. At thresholds of both 1 and 2 addresses, we find 1 region that we suspect is dense.

For the remainder of our experiments we select a threshold of 2 out of 3 packets, which we believe provides an acceptable trade-off between controlling for lossy-but-aliased regions, and alias detection false-positives excluding a handful of dense regions. We note the problem of alias resolution is complex, and deserves significant further research.

6.3 ICMP Results

Previous IPv6 work [30, 73] indicates that ICMP echo requests are most likely to be responsive if any other protocol (e.g. TCP80, TCP443, or UDP53) is responsive. Thus, we begin our evaluation by comparing 6SENSE to DET, 6Tree, 6Hit, 6Graph, 6Gen, and Entropy/IP on ICMP echo scans. We note that performing a comparison against these frequently incomplete solutions required significant effort, including developing custom toolchains and scanners to deploy them.

Our comparison results are shown in Figure 4. After 100M probes, **6SENSE finds 2.8x more hits than the prior highest-performing discovery method**. It does so while also discovering 3.3x more new /64 subnets—a metric more likely to represent new end-sites on the Internet. It does this efficiently,

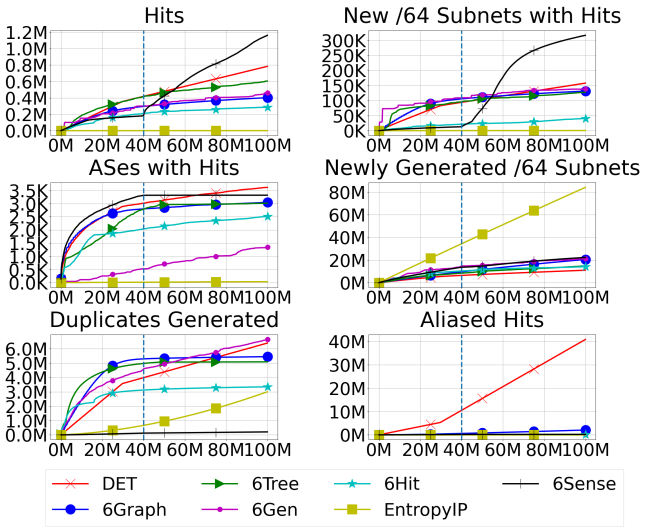

Figure 5: TCP443 results across metrics and approaches. 6SENSE finds 1.4x more hits and 2x more /64s than any other method, with minimal duplicates and aliases.

generating minimal duplicates and aliases. 6SENSE has similar AS coverage to other methods. As our method focuses on address discovery via known ASes, we expect a plateau of discovered ASes matching the input dataset, although even this outperforms most prior work. Note while Entropy/IP generates significantly more Upper 64s, it performs very poorly, as it generates many IPs in unassigned/unallocated networks.

A key observation is the substantial number of duplicates and aliases generated by other methods. Without 6SENSE's online approach to dealiasing as a first-order concern, most hits from these tools are duplicates or aliases, yielding poor or incorrect security results. Another interesting observation is that across each of the positive metrics, a different non-6SENSE tool yielded the best results (behind 6SENSE), indicating that, pre-6SENSE, no single alternative approach was optimal for IPv6 ICMP Internet-wide scanning.

6.4 TCP443, TCP80, and UDP53

Prior generative work focused *exclusively* on finding responsive hosts using ICMP. While ICMP is important, many security applications require identifying hosts responsive to specific ports. Thus we perform a similar evaluation to ICMP except we focus on completing three-way handshakes for TCP443 and TCP80 and finding DNS servers on UDP53.

Figure 5 shows the results for finding responsive hosts on TCP443. After 100M probes, 6SENSE continues to yield better results on both Hits and New Upper-64s, finding **1.4x more hits and 2x more active /64s than other methods**, doing so efficiently with minimal duplicates and aliases. We note that our transition from Breadth to Depth, while optimal for new hosts, produced slightly worse AS coverage. We explore

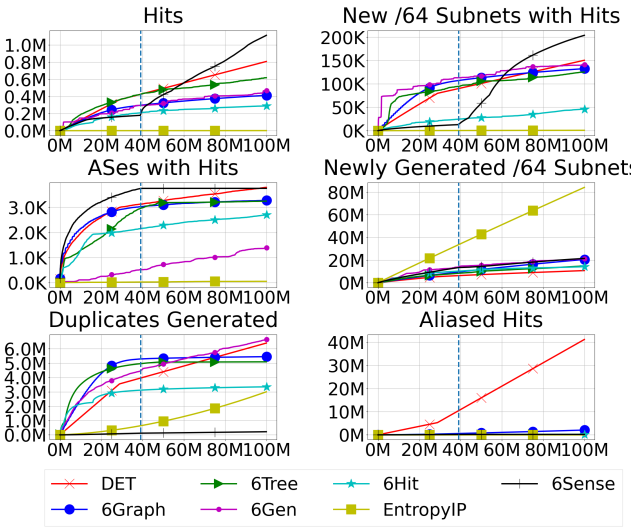

Figure 6: TCP80 results across metrics and approaches. 6SENSE finds 1.3x more hits and 1.3x more active /64s than other methods, and does so more efficiently with minimal duplicates and aliases.

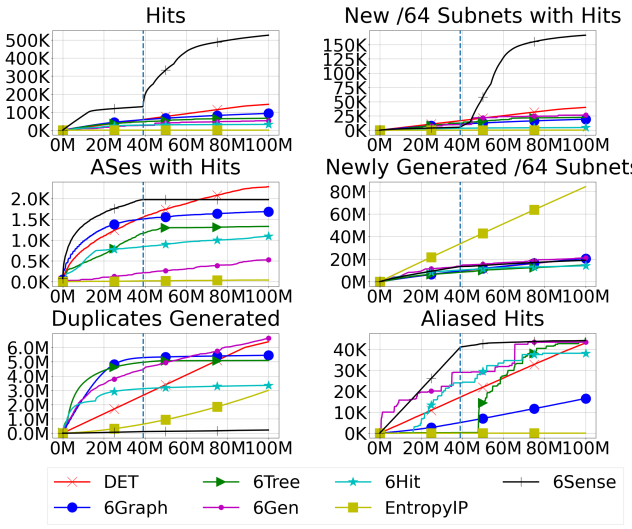

Figure 7: UDP53 results across metrics and approaches. 6SENSE finds 3.6x more hits and 4x more active /64s than other methods, with minimal duplicates and aliases.

this trade-off further in Section 6.8, finding AS coverage can improve at the expense of raw hosts. Section 7.1 explores this scan's TLS certificates.

Figure 6 shows the results of identifying responsive hosts on TCP80. After 100M probes, 6SENSE continues to yield better results for both Hits and New Upper-64s, efficiently finding **1.3x more hits and 1.3x more active /64s than other methods** with minimal duplicates and aliases. We note that our transition from Breadth to Depth, does not yield reduced AS coverage compared to other approaches. These results are broadly similar to those for TLS443.

Figure 7 shows results for 6SENSE and other methods identifying responsive DNS resolvers on UDP53. In this evaluation, we generate a valid DNS request for `akamai.com` (a domain not expecting censorship [54]) and consider a hit to be a host returning any valid DNS response, as our goal is understanding if the host speaks the protocol. We observe 6SENSE performs substantially better in identifying UDP53 hosts than any other method, and its performance gap is larger than for ICMP and TCP443. After 100M probes, **6SENSE finds 3.6x more hits and 4x more active /64s than other methods**. On UDP53, 6SENSE experiences a dramatic improvement when transitioning from Breadth to Depth, signifying the identification of dense resolver regions. Interestingly, aliasing is limited across methods on UDP53, with models only finding tens of thousands of aliased hits. We are uncertain why UDP53 exhibits less aliasing than ICMP and TCP protocols.

Overall Discovery. Combining all 6SENSE's output, we found 11,882,633 Hits and 6,128,152 new active Upper-64s, substantially more than any prior IPv6 generative scanning method on a 100M budget, shown in Table 2.

	ICMP	TCP80	TCP443	UDP53	Total
/128s	11,118,330	1,113,150	1,162,222	526,606	11,882,633
/64s	5,776,637	203,948	316,372	166,573	6,128,152

Table 2: Overall number of new active IPv6 hosts (/128s) and /64s 6SENSE discovers across all experiments.

6.5 Lower-64 Analysis

Beyond hits and new end-sites discovered, it is also important to understand the diversity of Lower-64 bit patterns (IIDs) uncovered and how those were identified during our Lower-64 generative phases. We begin by examining this in 3 phases of 6SENSE's Lower-64 generation as described in Section 5.2.3: Phase 1 (using seed IIDs, split out into ::1 or other IIDs); Phase 2 (trying ::1 if not seen already), and Phase 3 (iterative sampling). Table 3 shows these results across our 4 scan experiments. We notice across ports that iterative sampling provides the greatest number of active IIDs (at over 60% for TCP80, TCP443, and UDP53 and almost 40% for ICMP). Similarly, ::1 takes up a large portion, followed finally by seed IIDs from the same allocation. Phase 2, expectedly, has minimal effect as ::1 is quite common within seed datasets.

We explore discovered IIDs further with Figure 8, a CDF

	Phase 1, ::1	Phase 1, Other	Phase 2	Phase 3
ICMP	35.76%	24.37%	0.06%	39.79%
TCP80	14.91%	9.33%	0.03%	75.71%
TCP443	24.30%	7.91%	0.04%	67.74%
UDP53	29.84%	3.50%	0.03%	66.61%

Table 3: Breakdown of discovered addresses by 6SENSE Lower-64 generation phase, across each experiment.

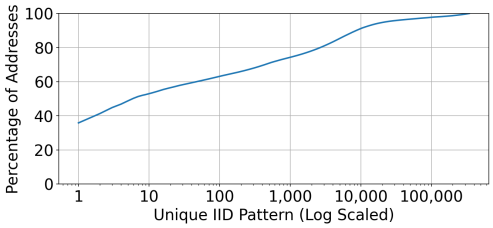

Figure 8: CDF of the discovered Lower-64 (IID) Patterns across hits in our ICMP experiment.

	6SENSE		DET	E/IP	6Gen	6Hit	6Tree	6Graph
	Total	Non-Dealias.						
10k pps	9,503	6,023	2,376	5,799	8,494	8,291	7,982	6,944
Unconst.	118,604	72,098	3,217	26,123	97,087	91,010	91,324	23,062

Table 4: Scan speed (pps) of 6SENSE and prior systems. We show 6SENSE's total scan rate and the rate excluding dealiasing probes (as online dealiasing consumes some scan budget). Constrained to 10k pps, 6SENSE is over 2x faster than DET, the closest competitor in hits, and commensurate with other methods. Unconstrained 6SENSE is 22x faster than DET.

of the discovered IID patterns across hits in our ICMP experiment. The most common pattern was ::1 (per Table 3), appearing for 35% of addresses. While the most common 100 IID patterns account for 65% of addresses, 6SENSE discovers many other patterns, with the remaining 35% comprising 342,594 unique addresses. Thus, 6SENSE discovers a diverse set of addresses both learning observed common patterns while also discovering new ones.

6.6 Runtime Evaluation

Table 4 shows the generation and scanning speed of 6SENSE and prior methods when constrained to 10k pps and when unconstrained (discussed next). When constrained, 6SENSE devotes a sizable portion of its scan budget to online dealiasing, unlike most other systems which do not perform online dealiasing. Still, when compared to DET, the closest competitor to 6SENSE in overall hit-performance, 6SENSE generates and scans over twice as fast, and is commensurate with other prior systems (which yield fewer hits).

As 6SENSE is a learning system, its runtime is divided between training, occurring only once per dataset, and execution (the generative and scanning process per scan). Scans can be run numerous times and for varying lengths on a single trained model. In the constrained 100M experiment, 6SENSE trains once for 4.27hr and then scans 100M generated IPs in 4.61hr. Factoring training into overall execution time, 6SENSE is faster than DET (8.88hr vs 11.69hr), but slower than other approaches; repeated and larger scans amortize this training cost and result in 6SENSE performing better over time. We note that slower execution, especially at slower scan speeds, is expected, given that 6SENSE is a deep learning solution.

	Hits	New Upper-64s	No-Send Speed
6SENSE	11,132,715	6,007,234	72.1K pps
No LSTM	4,881,122	-	84.5K pps
No Online Dealiasing	5,634,095	2,488,028	71.4K pps

Table 5: Ablation study of 6SENSE's LSTM and online dealiaser. We evaluate the yield of each ablation, as well as the system's speed in a No-Send simulated experiment.

	DET	6SENSE: Depth	6SENSE: Breadth
ICMP	10,109	10,998	12,503
TCP80	3,787	3,749	4,536
TCP443	3,707	3,319	3,970
UDP53	2,283	1,973	2,410

Table 6: Diversity of ASes, across each experiment, for DET, 6SENSE's Breadth and 6SENSE's Depth phase. We find optimizing towards an AS-diversity metric increases the overall AS coverage by 14–22%, depending on the protocol.

Unconstrained Speed and Parallelization. While we conducted all our experiments at a rate of 10k pps (per our ethical framework in Section 5.6), here we explore how fast our approach can run without an artificial rate limit. To explore this question while respecting our ethical framework, we modified 6SENSE such that: 1) we remove rate-limit constraints, 2) we do not actually transmit packets, and 3) we simulate a uniformly distributed hit-rate of 11% on generated packets, and 0.1% on detected aliases. Both of these values are based on our ICMP results in Section 6.3. This approach allows us to observe how our system scales without the ethical challenges of scanning the Internet at high speed. We further modify our experimental setup such that we parallelize the *generation* LSTM component of 6SENSE across multiple GPUs. The design of 6SENSE affords straightforward parallelization as the LSTM can be copied across devices, and generation can be performed in parallel, isolated to individual prefixes. We then evaluate both default and parallelized 6SENSE, utilizing 8 NVIDIA A40 GPUs (Section 6.1).

Default 6SENSE can scale to 26,917pps, more than 2.6x of our intentionally limited evaluation. Meanwhile, parallelized 6SENSE can achieve 72,098pps, or more than 7.2x our intentionally limited evaluation. The sub-linear speedup originates from only parallelizing generation, not learning nor updates. Table 4 shows the unconstrained performance of 6SENSE compared to other systems. When unconstrained, 6SENSE generates and scans 22x faster than DET, but slower than some other systems (which yield less hits). While we expect further optimizations are possible, we stress that generative scanning tools should not be operated at such speeds without significantly more exploration in effective and safe dealiasing.

6.7 Ablations

We next investigate how much of 6SENSE's yield is attributable to our Upper-64 generation techniques, Alloca-

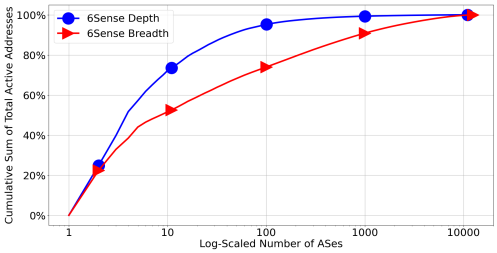

Figure 9: CDF of the distribution of ASes for ICMP experiments, optimizing for hits (Depth) vs diversity (Breadth). X-axis is log scaled. Optimizing for diversity increases the number of ASes by 14%, with a more uniform distribution.

tion sampling+Lower-64 generation techniques, and online dealiasing approach. To understand this, we evaluate three versions of 6SENSE on ICMP with 100M probes: 1) full 6SENSE, 2) a version of 6SENSE where we replace our Upper-64 generating LSTM with random sampling from our seed dataset's /64s within each allocation ("No LSTM"), and 3) 6SENSE without online dealiasing (but with the full LSTM). For our experiment without online dealiasing, we still perform offline dealiasing of the seed dataset, consistent with all other experiments. We additionally evaluate each version's speed through a similar No-Send simulation as in Section 6.6.

Table 5 depicts the performance of each version, evaluating the Hits and New Upper-64s in the ICMP experiments, and the No-Send simulated speed. Removing the LSTM results in only 4.8M active addresses compared to 6SENSE's 11.1M (and inherently does not yield new Upper-64s). Thus, the hits contributed by the LSTM are not from only repeating Upper-64s in the seeds, but also from its discovery of new Upper-64s. Removing online dealiasing results in 5.6M hits across 2.5M Upper-64s, down from 6SENSE's 11.1M and 6M, respectively. Note that our system without online dealiasing still outperforms other models. From our No-Send simulated speed analysis, we find that removing the LSTM component speeds up the system by roughly 17%, and the online dealiaser has negligible impact on No-Send speed.

6.8 Optimizing for Metrics: Breadth vs. Depth

To understand how our diversity gradient approach to Breadth vs. Depth allows us to balance between hits and AS diversity, we performed an alternative evaluation of 6SENSE on ICMP, TCP80, TCP443, and UDP53. In this alternative version, we focused on optimizing solely for AS diversity by staying in the Breadth phase for an entire generative run. Table 6 shows the results compared to DET, which had the best AS diversity behind 6SENSE. This experiment reveals that we can increase AS coverage by 14–22%, depending on the protocol.

This demonstrates the customizability of our weighted allocation search structure. Adjusting the threshold and metric allows us to tune the model for different metrics. The weighting

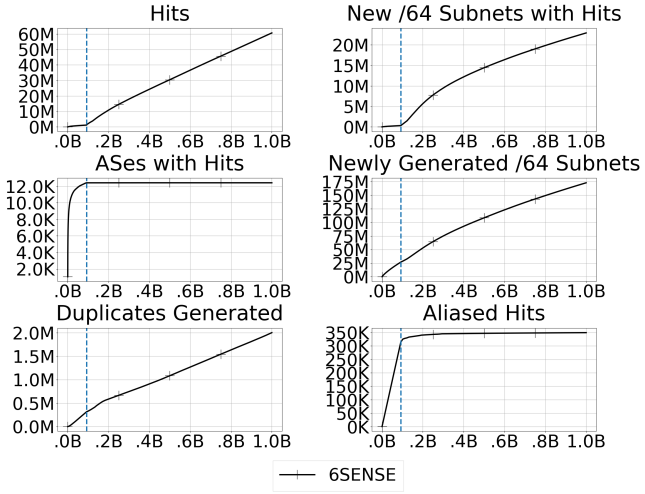

Figure 10: ICMP results across metrics and approaches for 1 Billion Addresses. 6SENSE finds 60.7M active IPs in 22M Upper 64s with minimal duplicates and aliases.

structure lends itself to further customizations, e.g., weighting towards allocations where we have yet to find addresses.

Depth vs Breadth Host Composition. We next look at the composition of each 6SENSE strategy. The overall composition of the hosts 6SENSE discovered in our prior evaluation is shown in Figure 9. We find that 6SENSE discovers hosts across a wide variety of ASes. Cloudflare (AS 13335, a CDN), Sky (AS 5607, a residential broadband provider), and Claro (AS 28573, a mobile provider) are the top network providers, indicating a mix of both servers and client addresses. Returning to the trade-off between Breadth and Depth, we also explore the host composition of 6SENSE in Breadth mode (optimizing for AS diversity), also shown in Figure 9. While the total number of ASes increases by 14%, we see that the composition of hosts is significantly more uniform, with the top ASes comprising fewer total hits. This increase in compositional diversity is compelling, indicating that optimizing toward specific metrics based on the scanning application is both feasible and fruitful.

6.9 Large Scale ICMP Scan

Finally, Figure 10 shows the results of using 6SENSE to identify responsive hosts on ICMP for a large scale scan of 1 Billion addresses. At 1 Billion addresses, 6SENSE continues to find active hosts, with 60.7M active IPs in 22M Upper 64s. For this experiment we set our G_b threshold to 0.0005, 10x lower than for 100M, and similarly our Depth N_i to 10M to account for the 10x increase in scan budget. We notice this leads to similar AS findings, 12.4K, as the Breadth method in Section 6.8, since this threshold leads to a similar exploration cutoff point of 92M (compared to 100M in Section 6.8).

Active Hosts	Total Certs	Unique Certs	New Certs
1,165,518	805,617	157,690	109,128

Table 7: Observed certificates across the new IPv6 addresses discovered by 6SENSE. To calculate new certificates we compare our discovered dataset with Censys, finding 109,128 certificates that have not been previously observed via scans, name-based crawls, or certificate transparency logs.

Category	Example	Count

Unknown	-	28,217

Table 8: Case study of security-specific TCP443 device types.

7 Security Analysis

To demonstrate the utility of 6SENSE, we perform the first Internet-wide scanning-driven IPv6 host security study, analyzing 4 dimensions: 1) TLS certs, 2) Exposed internal services, 3) Applicable CVEs, and 4) Common open ports.

7.1 TLS Certificates

For all IPv6 TCP443 hosts 6SENSE discovered (Section 6.4), we use ZGrab2 [74] to connect and negotiate a TLS connection. We record connection metadata, certificate information, and payload data. Table 7 presents our measurement results. Across 1.2M hosts active on port 443, we collected certificates from 806K hosts, making up 158K unique certificates.

To understand the additive value of IPv6 scans vs. IPv4 scans, we compare all certificates we collected to the certificate dataset in Censys [22], one week after collection. Censys catalogs certificates through Internet-wide IPv4 scans of 3,500 TCP ports (including TCP443) on a rolling basis [13]. It additionally incorporates certificates from domain name scans (e.g., domain top lists) and certificate transparency logs. Thus, observed certificates not found in the Censys dataset are most likely IPv6-specific and from a unique population not found via other methods. From this analysis, we discover 109K never-before-seen certificates in the wild, pointing to a unique population of devices that are observable only in IPv6. Section 7.2 show these are largely end-user devices.

Device Category	Device Name	CVEs
Switches	Cisco WS-C3650	10
	Brocade ICX 7450	7
	Lenovo EN4093R	1
Routers	D-Link DIR-853/ET	12

Printers	HP M479	3
	HP Officejet 3830	5
	HP Officejet 4650	2
	HP Officejet Pro 8600	2
	HP LaserJest M15w	6
	HP Deskjet 5730	1
Total	-	70

Table 9: *Vulnerability Analysis.* Potential CVEs for devices discovered by 6SENSE.

Among the identified new certificates none are browser-trusted, unsurprisingly, as browser-trusted certificates must appear in approved certificate transparency logs [36], and Censys incorporates all such logs. Examining the **purported** issuers: the common issuers are D-Link, a producer of consumer routers (78,533 unique certificates), and Let's Encrypt (10,230 unique certificates). DigiCert (1,407 unique certificates) is the next most common issuer, followed by a diverse set, including Amazon, Microsoft, Cisco, VMWare, and hobbyist projects. We stress that since these are not trusted certificates, the identity of these issuers cannot be trusted. We further explore this population of discovered devices next.

7.2 Population Case Studies

We perform a case study of the IPv6 hosts that 6SENSE newly discovered to better understand what devices and services are exposed. We began by exploring all purported issuers on certificates from TCP443, manually selecting issuers of security interest, such as consumer routers, enterprise switches, and VM services. For hosts with certificates issued by such issuers, we crawled the website landing page hosted on TCP443. We manually created webpage fingerprints for several types of devices and applied them to characterize a subset of the hosts.

Table 8 presents an overview of our findings. We broadly classify our discovered devices into the following categories: (1) Routers, (2) Security Tools, (3) Virtualization Tools, (4) Enterprise Switches, and (5) Printers.

We found publicly exposed login pages for all devices found under the categories of routers, switches, security and visualization tools. Such devices are especially vulnerable if misconfigured (i.e., default credentials are still in use). For many printers, we found publicly exposed configuration landing pages that required no authentication. Such configuration pages give the ability to: (1) perform various actions using the

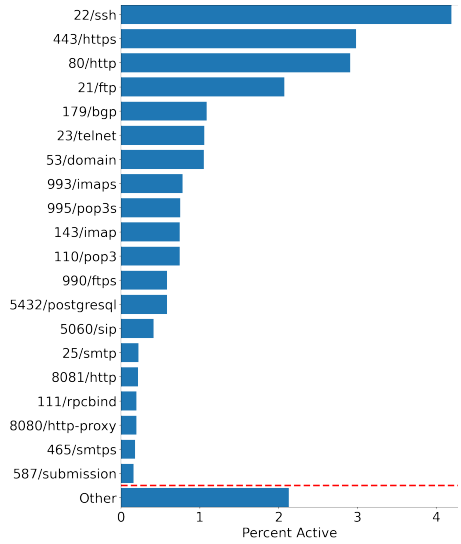

Figure 11: Top 20 most common ports from a random sample of discovered ICMP active hosts. SSH is the most common open service, with numerous sensitive networking (e.g., BGP) and security (e.g., PostgreSQL, rpcbind) services exposed.

printer (print/scan), (2) change the settings of the printer, (3) update device firmware, (4) view printer history, or (5) infer sensitive information such as physical location.

Broadly, we discovered a large number of Internet-exposed configurations and login pages on tens-of-thousands of devices traditionally not observable on the open Internet. These include routers, modems, printers, enterprise switches, virtualization tools, and security products. These services, particularly those of virtual machine services, enterprise network hardware, and security tools, represent significant security threats whereby an attacker can compromise key infrastructure if weak or default credentials are in use. Exposure of such devices has two potential causes: (1) They depend on IPv6 non-discoverability for security, which clearly does not hold, or (2) these devices have IPv6-specific misconfigurations. Section 8 discusses this further.

7.3 CVE Analysis

From the devices discovered from certificates, we sample from each category to perform an in-depth manual analysis to extract device-specific information. This process involved visiting the hosts manually in a browser to understand: (1) the type of content hosted on these hosts and their purpose, (2) any discernible product-specific information such as device name. We explicitly **did not** perform any form of automated vulnerability testing for ethical reasons; we do not own the devices, do not have consent, nor do we have confidence that such testing is safe as it could crash or damage the devices.

We were able to successfully extract device name and model for: (1) routers belonging to D-Link, ZyXEL, and Hitron, (2) commercial switches belonging to Cisco, Brocade, and Lenovo, and (3) printers belonging to HP. For extracted devices, we then used a combination of different vulnerability databases [49,51] to obtain CVEs associated with each device, presented in Table 9. We find a total of 70 CVEs associated with the specific devices, indicating *potential* vulnerability, as we did not explicitly attempt to exploit these vulnerabilities.

IPv4 vs. IPv6 Differences. During our manual analysis, we repeatedly discovered landing pages for printers that appeared to be connected to WiFi access-points via an IPv4 address in the private range (devices behind a NAT) but were publicly accessible through IPv6. This points to a specific configuration challenge where consumers and/or their devices broadly utilize NAT as a security tool, discussed more in Section 8.

7.4 Port Scans

To understand the population and potential security implications of our discovered hosts, we used Nmap [47] to conduct TCP port scans of the top 100 ports (according to Nmap) across 6Sense's ICMP hits. Given Nmap's limited speed, we scan a random 0.1% sample of our discovered addresses.

Figure 11 presents an overview of our results. We find that the most common open TCP service is SSH, on over 4% of discovered hosts, followed by HTTP and HTTPS (∼3% each), and FTP (∼2%). Such a profile may be indicative of consumer network devices. Interestingly, services such as BGP also appear, suggesting non-consumer network equipment. More concerning is the presence of open PostgreSQL, rpcbind, and other security-sensitive services, commonly exploited in the past. These observations reinforce those made in Section 7.2, that misconfigurations and reliance on IPv6 non-discoverability are prevalent.

7.4.1 IPv4 Comparisons

We now compare the distribution of popular open ports between our IPv6 results and IPv4. To do this, we collect the IPv4 port distributions from Censys [22] for the 100 ports we scanned in IPv6. Figure 12 shows the results of this comparison. To properly compare IPv4 and IPv6, we need to normalize the volume of hosts represented in each dataset, as there is no effective way of comparing exhaustive scans to IPv6 generative scans. We do this by examining the total fraction each protocol contributed to the set of ports found.

We show the top 20 ports found for IPv4 vs. the top 20 ports found for IPv6 with this normalization. We notice significant differences in the distribution and top ports between IPv4 and IPv6. While both have high concentrations at 443 and 80, IPv6 weights more heavily towards 22/ssh. This suggests a higher concentration of discoverable devices with SSH open. Notably, IPv6 shows much higher 179/bgp open ports, suggesting more discoverable non-consumer networking devices. Alternatively, IPv4 finds significantly greater distributions of 8443/https and 8008/http and sees 5060/sip more often. Other

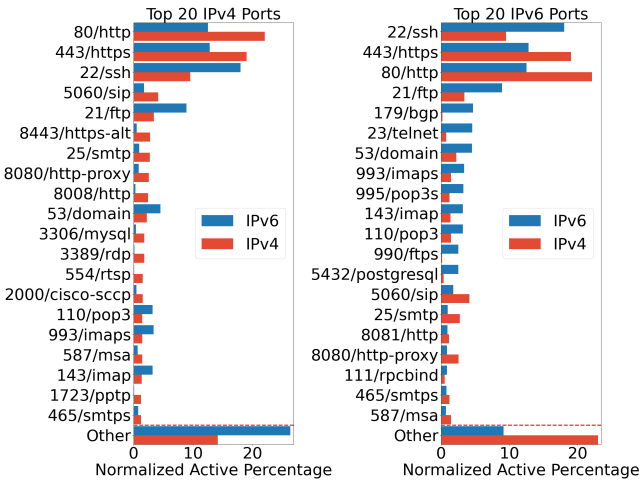

Figure 12: Top 20 most common ports for IPv4 vs. IPv6. Data is normalized by cumulative total number of active ports.

differences seem less intuitive, such as the higher prevalence of 3306/mysql in IPv4 vs. 5432/postgresql in IPv6 and the higher 25/smtp in IPv4 vs. 993/imaps and 995/pop3s in IPv6.

It is unclear whether these fundamental differences stem from a different distribution of discoverable devices in IPv6, difficulties in comparing such differing protocols, or differences in the fundamental distributions of IPv6 and IPv4 devices. Prior work [21] performed IPv4 to IPv6 comparisons on dual-stack hosts and found similar results with higher proportions of SSH and BGP services open on IPv6 compared to IPv4. Our results combined with these prior observations point to the possibility of fundamentally different scanning-accessible populations with different security properties, validating the need for 6SENSE and showing its security potential.

8 Concluding Discussion

We developed 6SENSE, an end-to-end IPv6 scanning system that significantly outperforms existing IPv6 host discovery methods along multiple metrics. 6SENSE's design overcomes limitations of prior approaches, affording practical large-scale IPv6 Internet scans. We demonstrated its utility by conducting a security analysis of IPv6 hosts at scale, uncovering several serious concerns. Here, we distill key lessons learned through developing 6SENSE, as well as directions for future work.

Metrics and Use-Cases Matter. Our work shows that based on the metrics used and the specific protocol, IPv6 scanning solutions can vary significantly in terms of both performance and end-result. While we defined six initial scanning metrics, future work must carefully consider the appropriate metrics for different security studies, based on how those metrics impact dataset biases and end-to-end results.

Further Innovation. While 6SENSE enabled us to conduct the first scanning-based security study of IPv6 hosts, there is still room for algorithmic improvements, particularly in exploring allocations and generating candidate Lower-64 bits. We hope 6SENSE can serve as a framework for the community to adopt and improve IPv6 scanning tools and datasets.

Dealiasing is not solved. While we present an initial aliasing solution, we note that the actual problem of IPv6 aliasing is significant, and requires a more sophisticated dynamic solution that is able to differentiate dense regions from aliased regions, robust to network effects, and adaptive to alias size.

Indications of IPv6 Security Problems. Our results uncover serious security issues across the IPv6 address space. We speculate that these issues arise from three potential causes. First, differences in firewall and service configurations between IPv4 and IPv6 result in device operators inadvertently leaving IPv6 services exposed [21]. Second, the vast nature of the IPv6 space has led to a "security through obscurity" mindset, where device operators assume that their devices are protected by simply being undiscoverable. This clearly does not hold, as 6SENSE demonstrates. Third, the widespread deployment of NAT for IPv4 masked extensive end-host configuration issues, now exposed in IPv6 since hosts are no longer hidden behind NATs. All told, these findings motivate the need for substantial investment in IPv6 network security.
