The Feedback-based Vulnerability Verifier primarily comprises two key components: the Test Case Sender and the Validation Server. The Test Case Sender is tasked with transmitting test cases to the target API application and receiving the corresponding responses. It subsequently forwards the received response, candidate API information, and testing corpus data to the Validation Server for in-depth analysis and verification. Meanwhile, the Validation Server is responsible for confirming the presence of vulnerabilities.

For SSRF, XSS, and Command Injection testing corpus, when a vulnerability is present, the vulnerable behavior produced by the testing corpus prompts the API application to send a vulnerability verification request to the Validation Server. The Validation Server determines the existence of the vulnerability based on whether it receives this request. If the request is received, the Validation Server infers that the vulnerability exists. For the remaining types of testing corpus, the Validation Server determines the existence of vulnerabilities based on the verification information sent by the Test Case Sender. For example, if the response content of an upload API test case contains the term "`success`" or the response status code is in the 2xx range, the Validation Server concludes that the API is vulnerable to Unrestricted Upload of File with Dangerous Type. Following this, the Validation Server further checks if the returned information includes the path of the uploaded file. If it does, the Validation Server accesses the file and conducts relevant tests to determine if the malicious file can be successfully executed.

The Validation Server provides feedback on the verification results to the Test Case Generator. When a vulnerability is identified, Test Case Generator proceeds to the next test case. When Validation Server reports that no vulnerability exists, Test Case Generator makes the following determinations. (1) The request method in the test case is POST. (2) The testing corpus corresponds to one of the following: SSRF, XSS, or Command Injection testing corpus. (3) The testing request containing the testing corpus has been executed (determined by a 2xx response status code).

When all of these conditions are met, the Test Case Generator infers that a triggering request is required to further verify

the existence of the vulnerability. The triggering request is sent to further test the existence of the vulnerability. To illustrate this point, consider CVE-2023-27161 as an example. The SSRF vulnerability is located in the `/Repositories` API and can be exploited by embedding a payload in the `url` parameter using a POST request. However, merely sending the POST request does not trigger the vulnerability. In such cases, an additional triggering request, specifically `GET /Packages`, needs to be sent to activate the vulnerable behavior. This triggers the API application to send a vulnerability verification request to the Validation Server, which ultimately leads to the discovery of this vulnerability.

The triggering requests consist of two types: (1) an API with the same path and request method as GET, and (2) all APIs that do not require parameters and have a request method of GET. The selection of these two types of triggering requests is not only aimed at cost savings but also based on historical vulnerability analysis, which has shown a high correlation between these types of APIs and triggering vulnerabilities. If the vulnerability cannot be triggered through these requests, it is recorded as a type of vulnerability that requires manual triggering. By introducing a triggering mechanism, VoAPI^2 can more accurately identify API vulnerabilities that require specific triggering and improve the overall effectiveness of vulnerability testing.

4 Implementation

We have developed a VoAPI^2 prototype system based on RESTler, which consists of 2,700 lines of Python code. The *Semantic Keyword Collection* module is implemented based on Scrapy [42] and Beautiful Soup [43]. The *Candidate Interface Extraction* module is extended from the RESTler's Compile module to support parsing API documentation of multiple formats. In the *Test Sequence Generation* module, the reverse sequence construction is improved based on RESTler's producer search and sequence construction strategy, and the parameter values generation is extended from RestCT's input-parameter value rendering module. In the *Feedback-based Testing and Verification* module, the test case generator is built by modifying the test corpus of RESTler, while the feedback-based vulnerability verifier is implemented using the socket library and by expanding response handling. More importantly, to support various vulnerabilities (e.g., Unrestricted Upload), we have extended the `multipart_formdata` primitive in RESTler Compile. After all, the current prototype system supports multiple API documentations adhering to OpenAPI v2/v3 and can detect six types of API vulnerabilities.

5 Evaluation

We conduct experiments to evaluate the performance of VoAPI^2, and our evaluation targets the following questions:

RQ1 (Vulnerability Detection): How well are the vulnerability identification capability (§5.2) and accuracy (§5.3) of VoAPI^2? Can VoAPI^2 discover vulnerabilities in real-world APIs? (§5.4)
RQ2 (Efficiency): Can VoAPI^2 efficiently generate test cases and explore operations, and how does it perform compared with the state-of-the-art tools? (§5.5)
RQ3 (Ablation Study): How does the vulnerability-oriented strategy of VoAPI^2 affect the testing results? (§5.6)

5.1 Experiment Setup

Compared Tools. We compared our prototype system with several popular vulnerability scanners and state-of-the-art tools in RESTful API testing. It is important to note that these tools are designed for different purposes. First, vulnerability scanners are primarily used to evaluate web applications. Furthermore, these selected vulnerability scanners must support API testing by sending mutated requests to these endpoints and reporting potential vulnerabilities based on the response results. On the other hand, RESTful API testing tools aim to generate better API test cases and discover more bugs (i.e., 500 Internal Server Error). However, they are not designed to reveal in-depth vulnerabilities. We focus on different aspects of VoAPI^2 and compare them with corresponding tools to answer the questions we are concerned about, for example, whether our method can find more bugs than vulnerability scanners. Finally, we select the following two vulnerability scanners and three RESTful API testing tools:

- **Zed Attack Proxy (ZAP)** [44] is an open-source black-box web vulnerability scanner developed by OWASP, primarily used for web vulnerability assessment and penetration testing. We leverage ZAP's resolver to parse API specifications and inspect API services directly.
- **Astra** [45] is a scanner specifically designed for vulnerability scanning of RESTful APIs, testing various vulnerabilities by loading payloads into parameters, HTTP headers, and other locations.
- **RESTler** [12] is an open-source black-box RESTful API testing tool developed by Microsoft. It generates stateful test cases by inferring producer-consumer dependencies between operations and feedback at runtime.
- **RestTestGen** [16] uses data dependencies between operations to generate test cases and deploy two distinct oracles to test RESTful API, that test cases can reveal implementation defects.
- **MINER** [46] uses length-oriented strategies to generate sequence templates and a neural network model to predict key request parameters and provide appropriate parameter values to get a long sequence request in RESTful API testing.

Table 4: **Benchmark Applications**. **#Endpoint** represents the number of endpoints in each Application. **#Download** represents the number that each application is downloaded in the Docker hub [47].

Applications	#Endpoint	Version	Description	#Download
GitLab	358	8.17.0	Code Repository	100M+
Jellyfin	405	10.7.1	CMS	100M+
Appwrite	95	0.9.3	CMS	5M+
Microcks	44	1.17.1	CMS	600K+
Casdoor	121	1.13.0	CMS	20K+
Gitea	325	1.16.7	Code Repository	20K+
Rbaskets	22	1.2.3	Web Service	10K+

Evaluation Benchmarks. We use the following three criteria to select real-world RESTful API applications as our benchmark for evaluation. (1) Having a complete API specification document that can serve as input for all comparative testing tools. (2) The application should have APIs covering multiple orders of magnitude, ranging from small to large-scale. (3) The application should be open-source and widely used in different scenarios. Table 4 illustrates the seven applications we have chosen as our testing subjects. Based on the number of API endpoints, Rbaskets [48], and Microcks [6] are categorized as small-scale API applications, while Appwrite [5] and Casdoor [4] belong to medium-scale API applications. Gitea [49], Jellyfin [3] and GitLab [36], on the other hand, are considered large-scale API applications. All of these applications are easily deployable and supply API services well.

Evaluation Settings. For the target services, we install them with a basic configuration to ensure the proper functioning of their API services. Moreover, we employ the default settings for all compared tools and run each with a maximum time limit (i.e., 5 hours). After each round of testing, we restore the service environment to ensure the consistency of the target service. We conduct all experiments on a server with 4 CPU cores, 8 GB RAM, and the Ubuntu 20.04 LTS operating system, which provides adequate resources for conducting the experiments. In papers such as RESTler, a `bug` is identified by the reception of a 500 HTTP status code following the execution of a request sequence. However, it's important to note that 5xx errors typically refer to server errors during request processing, and not all 5xx errors are necessarily related to security vulnerabilities, such as Denial of Service (DoS). Hence, in our paper, we classify a genuine security vulnerability as a `bug`, distinct from a mere 5xx error.

5.2 Vulnerability Detection (RQ1)

VoAPI^2 identified 26 vulnerabilities, including 7 previously unknown and 19 known security bugs, across seven API applications, encompassing six different types of vulnerabilities. All zero-day bugs have been reported to vendors and fixed; four of them have been assigned CVE IDs. In comparison, the two vulnerability scanning tools discovered fewer vulnerabilities. The three RESTful API testing tools primarily uncovered bugs that resulted in `HTTP 500` errors, with a tiny proportion being security vulnerabilities, as shown in Figure 4. It can be observed that VoAPI^2 detected vulnerabilities in all seven applications, with the highest number and variety of vulnerabilities. In contrast, the vulnerability scanning tools (i.e., ZAP and Astra) did not detect any vulnerabilities in Gitea, Rbaskets and GitLab. The capabilities of these two tools were similar, with slight differences observed only in the Appwrite. A comparison reveals that VoAPI^2 has the strongest ability to identify vulnerabilities compared to ZAP and Astra, particularly in SSRF and XSS vulnerabilities. The other three RESTful API tools discovered only a small number of security vulnerabilities in four applications (i.e., Appwrite, Jellyfin, Microcks and GitLab), and they required manual payload insertion to validate the security vulnerabilities associated with the identified `HTTP 500` errors.

The three RESTful API testing tools were able to discover multiple bugs that resulted in `HTTP 500` errors when detecting targets, as shown in Table 5. The average proportion of vulnerabilities among the `HTTP 500` errors discovered by the other three tools is very low. Through manual analysis, we determined that the percentage of vulnerabilities triggered by these errors is only 5.4% (RESTler), 3% (MINER), and 2.5% (RestTestGen), respectively. Because paths with security vulnerabilities may not necessarily result in internal errors in real-world API applications. The mentioned tools randomly modify parameters' syntax format and content, leading to back-end parameter parsing issues rather than posing a significant security threat. Additionally, incorporating payloads for all types of vulnerabilities without distinguishing the API functionalities would result in low efficiency, as observed in our subsequent ablation experiments (§5.6). Meanwhile, VoAPI^2 found fewer instances of `HTTP 500` errors, mainly due to the targeted nature of VoAPI^2 testing, with fewer API paths being tested, which can be observed from the number of messages. Moreover, VoAPI^2 strives to generate messages that comply with grammatical rules to trigger API behavior and successfully execute the payload that confirms the bug.

We collected a summary of all the security vulnerabilities discovered by various tools, including the vulnerability type, vulnerability position, vulnerable endpoint, and vulnerable parameters, as shown in Table 6. It can be observed that vulnerability-oriented testing methods allow VoAPI^2 to discover corresponding types of security vulnerabilities in APIs with different functionalities. More importantly, VoAPI^2 has discovered the highest number of vulnerabilities and the widest range of vulnerability types compared to other tools. Specifically, VoAPI^2 has identified four types of vulnerabilities, 100% higher than the average of other tools. Meanwhile, VoAPI^2 found 26 vulnerabilities, which was 420% more than the average of other tools.

Among these vulnerabilities, our tool uniquely uncovers

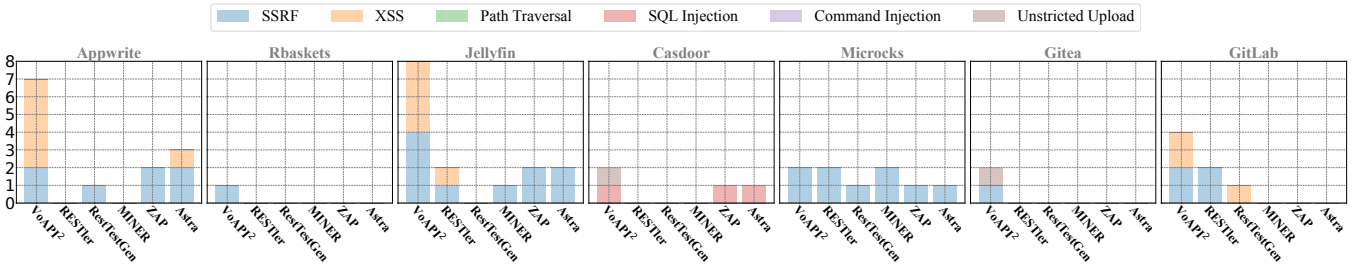

Figure 4: **The vulnerabilities and their types uncovered by different tools on evaluation benchmarks .**

Table 5: **Compared with three RESTful API testing tools. #500** means the number of `HTTP 500` errors found by tools. **#Packet** means the number of all packets sent in testing. **#Ratio** is equal to total #500 divided by total #Packet.

Compare	Appwrite			Casdoor			Gitea			Jellyfin			Microcks			Rbaskets			GitLab			#Ratio
	#500	#Packet	Time	#500	#Packet	Time	#500	#Packet	Time	#500	#Packet	Time	#500	#Packet	Time	#500	#Packet	Time	#500	#Packet	Time

14 bugs that elude detection by other tools. Based on our analysis, this phenomenon can be attributed to twofold factors. First, in the case of RESTful API testing tools (e.g., RESTler), they often lack a comprehensive testing corpus required for verifying various types of vulnerabilities (e.g., SSRF) within their corresponding endpoints. Thus, these tools often fail to detect a vulnerability if it does not lead to a `HTTP 500` error. Second, scanning tools (e.g., ZAP) face challenges in constructing an appropriate sequence encompassing multiple requests that align with the data dependencies existing among API endpoints. Thus, these tools fail to identify the respective vulnerabilities (e.g., XSS) concealed behind intricate interactions, as exemplified in §5.4.

5.3 Accuracy (RQ1)

We further analyzed the accuracy of VoAPI² and vulnerability scanners. All alerts were manually verified to determine if they were true vulnerabilities, thereby identifying false positives (FP). The false discovery rate (FDR = FP/(FP+TP)) was calculated and presented in Table 7. It can be observed that VoAPI² has lower false positive rates compared to the scanners, which can be attributed to VoAPI²'s vulnerability-oriented strategy and more accurate vulnerability validation strategy.

For XSS vulnerabilities, ZAP and Astra conduct tests on all APIs and determine the existence of an XSS vulnerability solely based on the presence of the XSS payload in the response. However, a significant number of these APIs do not contain display functions. Consequently, the payload would not be displayed on any particular page, which results in a high incidence of false positives. Correspondingly, the vulnerability-oriented testing strategy helps VoAPI² find more API paths related to XSS, which leads to a lower false positive rate.

For path traversal vulnerabilities, ZAP lacks further validation. It solely bases its determination of a vulnerability's existence on whether the test request returns a 2xx status code. On the other hand, VoAPI² goes a step further by analyzing the response content, checking for the presence of content corresponding to the test payload to confirm the existence of the vulnerability. For instance, when the test payload is `"/etc/passwd"`, VoAPI² will match the response content for characteristic strings (e.g., root) to validate the vulnerability.

In terms of VoAPI², false positives may occur when checking a particular XSS (i.e., stored XSS) and the implicit unrestricted upload vulnerability. In these scenarios, we need to trigger vulnerability manually and check whether vulnerability exists or not. Moreover, we thoroughly discuss the root causes and the corresponding improvement ways in §6.

5.4 Real-world Vulnerabilities (RQ1)

We applied VoAPI² to discover security vulnerabilities in real API applications and found various vulnerabilities. As shown in Table 6, we identified more types of vulnerabilities compared to scanning tools, especially on XSS and SSRF. The main reason is that our method can generate effective request sequences that access multiple endpoints in proper order, allowing us to trigger deeper vulnerabilities.

Case Study: XSS. The XSS vulnerability (CVE-2022-2925) was discovered in the Appwrite application. As shown in Figure 5, this bug exists in five API endpoints (`/teams`, `/users`, `/functions`, `/database/collections`, `/teams/{teamId}/memberships`), and the vulnerable arguments in these endpoints are `"name"` marked in blue color. In our experiments, both ZAP and Astra face significant difficulties. While they may encounter problems in gen-

Figure 5: **XSS vulnerabilities in Appwrite.**

erating appropriate parameter values for some APIs, the more critical issue is their inherent inability to request `/teams/{teamId}/memberships` (Line 8). Because the presence of this XSS vulnerability on this endpoint requires accessing `/teams` (Line 1) with the POST method before, then parsing the `id` value (Line 6) from the response, and assigning it to the path parameter `teamId` (Line 13). Obviously, ZAP and Astra cannot infer this data dependency and construct a suitable sequence that includes these requests. In contrast, VoAPI^2 can extract the context in which the target API endpoint operates and generate similar request sequences to discover such vulnerabilities.

5.5 Efficiency (RQ2)

We check the efficiency of VoAPI^2 in two respects: (1) whether VoAPI^2 can efficiently generate request sequences for testing API endpoints, compared with state-of-the-art RESTful testing methods (e.g., RestTestGen); (2) whether VoAPI^2 is more efficient than web scanners (e.g., ZAP) in finding vulnerabilities.

Operation Coverage. In this experiment, we used VoAPI^2's Test Sequence Generation (TSG) module to generate a request sequence for each endpoint. We selected three approaches to compare the API's operation coverage with TSG. If a tool is able to generate at least one valid request sequence for an

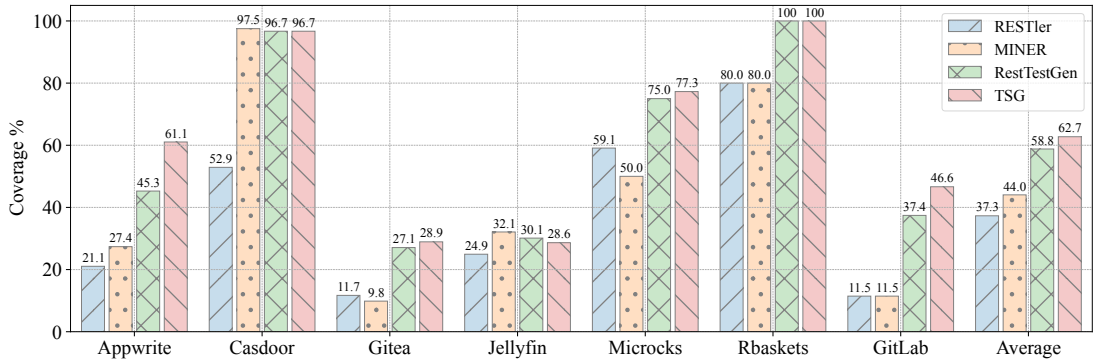

Figure 6: **Compared with RESTful API testing tools on coverage.**

Table 8: **Compared with scanners on testing time consume.**

	Appwrite	Casdoor	Gitea	Jellyfin	Microcks	Rbaskets	GitLab	#Total
ASTRA	4:30m	18:07m	40:32m	103:28m	8:02m	4:34m	56:16m	235:19m
ZAP	10:23m	22:02m	51:27m	88:02m	10:22m	7:57m	182:41m	372:54m
ZAP+V	6:39m	8:05m	16:33m	6:11m	1:31m	0:40m	24:07m	63:46m
VoAPI^2	1:51m	6:27m	7:05m	10:53m	0:24m	0:13m	5:03m	31:05m

API endpoint that results in a 2xx status code response, we consider that endpoint to be covered.

Figure 6 exhibits our experimental results, which evidently demonstrates that TSG performs better than the current state-of-the-art RESTful testing tools in terms of generating valid request sequence for target API endpoint. More specifically, TSG achieves the highest endpoint coverage on Appwrite, Gitea, Microcks, Rbaskets and GitLab. Specifically, the average coverage of TSG on these products can reach 62.7%, which is more than RESTler's 37.3%, MINER's 44.0%, RestTestGen's 58.8%. We attribute TSG's outstanding performance to its superior ability to construct dependencies for target API endpoints compared to other tools. For the sample API in §3.3.1, we found that none of the tools except VoAPI^2 can construct the correct dependency relation for this API.

Compared With Web Scanners. Table 8 shows time consumed by the web vulnerability scanners and VoAPI^2. The test time of VoAPI^2 is much less than the other two tools. Specifically, it took VoAPI^2 31min05s to test the seven products, while Astra took 235min19s, and ZAP took 372min54s. This is because of VoAPI^2's vulnerability-oriented strategy, which just tests candidate API endpoint within targeted payloads based on the feature of its path and parameters, greatly enhancing testing efficiency. In contrast, tools like ZAP and Astra test parameters and paths indiscriminately within all payloads, resulting in significantly longer testing times.

5.6 Ablation Study (RQ3)

To investigate how the vulnerability-oriented strategy of VoAPI^2 impacts the result of testing, we perform an ablation study. Thus, we remove the Candidate Interface Extraction (§3.2) module from VoAPI^2 to ensure all API paths and parameters are checked with equal priority. We refer to this modified tool as VoAPI^2-V, which serves as a benchmark for comparative analysis against VoAPI^2.

In testing, no new vulnerabilities were found by VoAPI^2-V. Table 9 shows the time VoAPI^2 and VoAPI^2-V need to expose each vulnerability. Obviously, VoAPI^2-V takes several orders of magnitude more time, because VoAPI^2-V must indiscriminately check every endpoint of API. When a potentially vulnerable path is located near the end of the specification document, VoAPI^2-V takes much longer to reach it. For example, in the case revealed in `/Startup/User` of Jellyfin, VoAPI^2 found this vulnerability on this API in 10min30s, while VoAPI^2-V takes 495min28s. This is because VoAPI^2 can aim this endpoint directly from a large number of APIs, while VoAPI^2-V must test all APIs sequentially. Furthermore, VoAPI^2-V tests every parameter of the API using all available test payloads, which consumes a significant amount of time. In contrast, VoAPI^2 selects targeted payloads for testing the portion parameters marked with directed strategy, which saves a lot of time.

Furthermore, we integrate the keyword shortlisting process into existing tools (i.e., RestTestGen and ZAP). Specifically, these tools are now only applied to candidate APIs extracted from VoAPI^2. The integrated models resulting from this integration are named RestTestGen+V and ZAP+V. In order to compare the performance of these models, we conduct experiments focusing on efficiency and bug discovery.

In terms of test efficiency, ZAP+V inspects solely the API endpoints that are filtered by keywords. As a result, the testing time is significantly reduced compared to the original ZAP, as showcased in Table 8. This highlights the effectiveness of keyword lists when used with ZAP. On the other hand, for RestTestGen+V, we expanded the testing scope to include not only the API endpoints filtered by keywords but also those that have data dependencies with them. The testing results presented in Table 5 demonstrate that these integrated models exhibit lower time consumption and send fewer packets compared to their respective original tools.

Table 9: **Compared with VoAPI^2-V on time consume.**

Regarding bug discovery, RestTestGen+V identified fewer `HTTP 500` errors, as indicated in Table 5. This can be attributed to the fact that the number of candidate APIs is significantly smaller than the original APIs, and our vulnerability-oriented strategies are not specifically designed to detect `HTTP 500` errors. Furthermore, RestTestGen+V lacks a suitable test corpus that is necessary to trigger potential vulnerabilities in the selected APIs. Therefore, it cannot benefit from keyword shortlisting. Similarly, ZAP+V does not discover more vulnerabilities than ZAP because it is unable to construct a suitable sequence comprising valid requests to satisfy dependencies among candidate APIs.

In conclusion, although keyword selection can enhance testing efficiency, it does not lead to better effectiveness when directly applied to traditional RESTful API testing tools and vulnerability scanners.

6 Discussion

In this section, we discuss the limitations of VoAPI^2 and explore the improvement direction in the future.

Scale Ability of Bug Verification. The current state of feedback-based vulnerability verification is limited by the concise validation methods based on the testing corpus for different bugs. That brings false positives when a bug must be triggered interactively, like the stored XSS and implicit upload bug we mentioned before (§5.3). Consequently, VoAPI^2 may

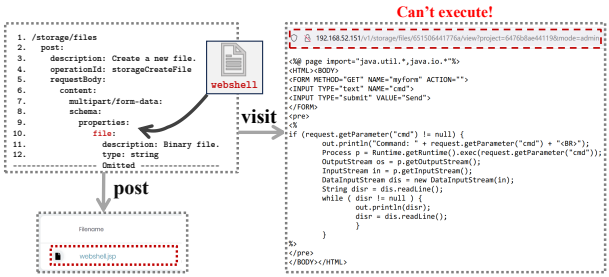

Figure 7: **False positive of unrestricted upload.**

fail to judge these vulnerabilities correctly and require manual efforts. To address this issue, we plan to design an extensible interface of the Feedback-based Vulnerability Verifier (§3.4.2) for specific vulnerabilities. Furthermore, we can continuously extend vulnerability verification methods, for example, to heuristically generate upload paths based on the context of implicit unrestricted upload of dangerous files, thereby enabling VoAPI^2 to discover vulnerabilities more generally and automatically.

Manual Effort. In identifying and validating vulnerabilities, VoAPI^2 requires human intervention in two scenarios: implicit unrestricted upload vulnerabilities and stored Cross-Site Scripting (XSS).

In the case of unrestricted upload vulnerabilities, VoAPI^2 submits a malicious file to check whether the bug exists or not. If the server's response omits the file's access path, VoAPI^2 is unable to automatically retrieve this path, which hinders further tests to assess whether the file can be executed. We present an example of a false positive of unrestricted upload in Figure 7. It can be seen that VoAPI^2 automatically deduces that the arbitrary file upload API interface permits unrestricted uploads of malicious files. However, it lacks the prior knowledge necessary to automatically retrieve the unique access paths of these uploaded files, such as identifying the location of the file access interface or how to obtain random file IDs like "`651506441776a`". This prior knowledge is not standardized and tends to vary across different API services, making automatic retrieval of access paths a complex challenge. As a result, manual intervention is currently necessary to visit relevant pages, identify the page containing the file access interface, and manually test whether the server can parse the malicious file. If the server restricts the parsing of such malicious files, the upload vulnerability remains untriggered, leading to a false positive.

In terms of stored XSS (also known as persistent XSS), VoAPI^2 takes a POST request path as a potential XSS vulnerability after getting a response packet with a 2xx status code, which also contains an XSS payload. However, similar to the challenges unrestricted upload checking faces, VoAPI^2 cannot automatically determine which storage page stores

XSS payloads. Thus, this XSS payload can only be triggered by manually browsing the relevant pages guided by expert knowledge. If the XSS behavior is not triggered even after browsing all relevant pages, it is considered a false positive.

Support More Specifications. Currently, VoAPI^2 only supports OpenAPI-formatted API specifications as input, while many applications do not provide such documentation and instead offer API usage instructions in other files (e.g., HTML). In order to expand VoAPI^2's capabilities, we propose to use machine learning or natural language processing methods to identify and extract API information from these usage instructions. Finally, VoAPI^2 can inspect more API applications.

Machine Learning Method. VoAPI^2 classifies API interfaces based on statistics of vulnerability characteristics and human expertise. Although it is a reliable method to support our prototype system in discovering real-world security vulnerabilities, we believe there is a trend for artificial intelligence technology to replace these expert experiences in the future. For example, advances in natural language processing (e.g., large language model) have demonstrated powerful text analysis capabilities, promising to audit API documents for interface classification more effectively.

7 Related Work

RESTful API Security. The security operations teams of popular API services can discover attacks against their services. The Facebook team [10] identified that attackers could exploit authorization vulnerabilities in a specific API endpoint, allowing third-party applications to access users' private photos. The Twitter team [11] discovered that attackers could utilize a specific API endpoint that associates phone numbers with account names to systematically launch widespread attacks and infer the target users' phone numbers and account names. Researchers note that there are typically two categories of bugs in RESTful APIs, including that result in service unavailability and those related to web security [50]. The former is often caused by syntactically incorrect parameters in API request data, leading to the backend being unable to process them and resulting in `HTTP 500` errors. Most of these bugs typically indicate that the server is unable to handle the current request properly. The latter category arises due to similarities between the backend processing of RESTful APIs and traditional web services, resulting in web bugs when requests are mishandled.

RESTful Service Testing Methods. Regarding the potential bugs in RESTful services, researchers have proposed numerous automated testing methods that can generate sequence requests, assess various endpoints of the API, and determine if there are any issues based on the service's responses. RESTler [12] is a stateful API black-box testing technique that generates stateful test cases by inferring producer-consumer dependencies between different API endpoints, allowing it to reach the "deep" states of the target API service. RestTestGen [16] utilizes data dependencies between operations to generate test cases, while RESTest [15] considers dependencies among parameters and generates test cases that satisfy specified dependency relationships using constraint solving and random input generation. MINER [46] uses a neural network model to predict critical request parameters. However, the aforementioned black-box testing tools all focus on better parsing API specifications, generating request sequences that comply with the API interface protocol state, and generating effective test cases that cover more API functionalities. They aim at the usability of API functions based on whether the API service returns `HTTP 500` errors but do not specifically target security vulnerabilities.

Penetration Techniques. Due to the close similarity in implementation between the backend of RESTful APIs and traditional web services, researchers aim to expand web penetration techniques to conduct vulnerability detection in RESTful APIs. Zed Attack Proxy (ZAP) [10] is primarily used for web vulnerability assessment and penetration testing. Its current OpenAPI extension supports parsing API specifications, enabling web vulnerability testing for API services. Astra [45] is a tool specifically designed to scan vulnerabilities in RESTful APIs. It verifies common web vulnerabilities by injecting payloads into parameters, HTTP headers, and other locations. However, these tools have significant limitations that they lack the ability to interpret the state of the API protocol. They can only generate requests for individual API endpoints, limiting the scope to test each endpoint separately and preventing the detection of vulnerabilities in API services composed of multiple endpoints. NAUTILUS [50] incorporates comment policies into API specifications to handle operation relationships and parameter generation, resulting in meaningful sequences of operations and the discovery of corresponding API security vulnerabilities. However, due to its oversight of vulnerability characteristics, NAUTILUS focuses on a limited range of vulnerability types, mainly handling injection vulnerabilities.

8 Conclusion

In summary, we propose VoAPI^2, a novel inspection framework, to apply a vulnerability-oriented strategy to inspect RESTful APIs. Based on the insight that the type of vulnerability hidden in an API interface is strongly associated with its functionality, VoAPI^2 can directly expose vulnerabilities in RESTful APIs. We first track commonly used strings as keywords to identify APIs' functionality. Then, we generate a stateful and suitable request sequence to inspect the candidate API function within a targeted payload. Finally, we verify whether vulnerabilities exist or not through feedback-based testing. Our evaluation result shows that VoAPI^2 demonstrates higher efficiency and effectiveness in bug discovery than state-of-the-art tools, including RESTful API testing and penetration methods.

Abstract

Client-side security mechanisms implemented by Web browsers, such as cookie security attributes and the Mixed Content policy, are of paramount importance to protect Web applications. Unfortunately, the design and implementation of such mechanisms are complicated and error-prone, potentially exposing Web applications to security vulnerabilities. In this paper, we present a practical framework to formally and automatically detect security flaws in client-side security mechanisms. In particular, we leverage Web Platform Tests (WPT), a popular cross-browser test suite, to automatically collect browser execution traces and match them against Web invariants, i.e., intended security properties of Web mechanisms expressed in first-order logic. We demonstrate the effectiveness of our approach by validating 9 invariants against the WPT test suite, discovering violations with clear security implications in 104 tests for Firefox, Chromium and Safari. We disclosed the root causes of these violations to browser vendors and standard bodies, which resulted in 8 individual reports and one CVE on Safari.

1 Introduction

Writing secure Web applications is notoriously hard, due to the heterogeneity, complexity and open-ended nature of the Web. To mitigate the challenges of secure Web application development, browsers integrate a growing list of client-side security mechanisms to assist Web developers. Examples of such mechanisms include cookie security attributes (HttpOnly, Secure and SameSite), security headers like Origin and Sec-Fetch-Data, mechanisms to secure mixed content (e.g., to avoid that HTTPS-served webpages fetch content in clear over HTTP), and sophisticated client-side protection mechanisms like Content Security Policy (CSP).

The design of such mechanisms is very delicate, as witnessed by the long list of design shortfalls (e.g., unexpected interactions with other browser components) or implementation flaws, which led to breaking well-established Web security invariants [13, 33]. *Formal methods proved to be an essential tool to rigorously analyze client-side security mechanisms*, allowing for the identification of bugs and formulation of formal security proofs in such a complex environment. All state-of-the-art techniques, however, be they manual [20], machine-checked [17], or automated [13, 33], apply to *browser models*, which suffer from two fundamental drawbacks. First, client-side security mechanisms evolve over time and new ones are being proposed on a regular basis, which makes browser models extremely hard to maintain. Second, even if specifications are correct, security-critical bugs often affect the implementations [23, 29, 30, 36]. Correctly integrating client-side security mechanisms within browsers is challenging and error-prone for various reasons. Browsers are incredibly complicated software artifacts: for instance, the Chromium codebase contains roughly 35 million lines of code, i.e., it is larger than the Linux kernel. Furthermore, browser vendors are required to translate natural language specifications, e.g., from the World Wide Web Consortium (W3C), into new code to be pushed into an already complicated codebase. Even worse, client-side security mechanisms often cannot be specified in isolation: most of them interact with core browser components like Fetch, which defines requests, responses, and the process which eventually binds them. This means that the implementation of client-side security mechanisms often requires changes to existing browser components which were not developed with such an integration in mind.

We thus tackle the following research question: *can we design a practical framework to formally and automatically detect security flaws in the implementation of client-side security mechanisms?*

In this paper, we answer in the affirmative, putting forward a novel, formally-grounded and lightweight technique. In particular, we leverage existing community efforts in the development of Web Platform Tests (WPT) [12], a cross-browser test suite designed to give browser vendors confidence that they are shipping software which is compliant with specifications and compatible with other implementations. WPT includes

[*] Shared first authorship

more than 50K tests covering a wide range of browser components, including Web security mechanisms, thus representing the largest benchmark of the intended browser behavior to date. Our approach consists in abstracting the test executions into sets of *traces* (i.e., sequences of relevant browser events), which are then matched against *Web security invariants* (i.e., intended security properties expressed in first-order logic). This way, we automatically identify traces breaking important security properties and thus pinpoint browser behaviors requiring immediate attention by browser vendors, due to their clear security implications. Furthermore, WPT is continuously updated as Web standards and new features are introduced to the Web platform, which makes our verification pipeline automatically applicable to the latest browser versions.

Contributions. More concretely, we contribute as follows:

- We formalize 9 Web invariants regarding core components of the Web platform such as Cookies and Mixed Content, encoding them in first-order logic to allow for efficient verification of browser execution traces using an automated theorem prover (Sec. 3).
- We present an automated pipeline designed to identify security-critical inconsistencies in browser implementations. Our approach leverages the WPT test suite to acquire browser execution traces, which are then matched against Web security invariants in order to identify any traces that violate Web security properties (Sec. 4).
- We demonstrate the effectiveness of our approach by validating our 9 invariants against the WPT test suite, discovering violations with clear security implications in 104 tests (Sec. 5). In particular, we discuss 10 attacks against Chromium, Firefox, and Safari concerning cookies and Mixed Content policy violations (Sec. 5.2). We responsibly disclosed all the new findings to affected browser vendors and standard bodies, which resulted in 8 individual reports and one CVE on Safari.

We publish all the artifacts developed during this research, including the definition of the Web invariants in SMT-LIB format, and our trace verification pipeline [15].

2 Background

We assume familiarity with the basic functionality of the Web platform, e.g., the HTTP protocol, HTML and JavaScript.

Web Security Primer. The traditional threat model of Web applications considers both *Web attackers* and *network attackers* [18]. A Web attacker is the owner of a malicious host, which is used to mount attacks against other Web applications. Traditional examples of Web attacks include Cross Site Scripting (XSS) and Cross Site Request Forgery (CSRF). A network attacker extends the capabilities of a Web attacker with full control of the network traffic, i.e., everything which is unencrypted can be read and modified by a network attacker. Encryption can be enforced through the use of HTTPS, which provides a secure transport protocol for the Web. Browsers rely on the notion of *secure context* to identify pages satisfying minimal confidentiality and integrity requirements [34].

The baseline defense mechanism of Web browsers is the *Same Origin Policy* (SOP), which is intended to enforce the intuitive invariant that content owned by a Web application should not be read or written by other Web applications. The notion of *origin* defines the security perimeter of SOP: an origin is a triple including a scheme (HTTP, HTTPS...), a host (e.g., www.foo.com) and a port (defaulting to 80 for HTTP and 443 for HTTPS). This way, a Web page at https://evil.com cannot access content served by https://foo.com. Since the fine-grained isolation of SOP is too restrictive for specific settings, another common Web security concept is the notion of *site*, i.e., one domain part plus the *effective top-level domain* as defined in the Public Suffix List [26] – also called *registrable domain* or *eTLD+1*. For example, foo.com and foo.github.io (as github.io is in the PSL) are sites, and a.foo.com and b.foo.com are two subdomains of the same site foo.com. Although https://a.foo.com and https://b.foo.com are two different origins, their same-site position might relax some security checks enforced by browsers (see below). The W3C Secure Contexts specification [34] also defines the notion of *potentially trustworthy* origins as those that the browser can trust sending data securely. In particular, in addition to origins whose protocol is `https` or `wss`, the localhost IP address and all subdomains of `localhost` are considered potentially trustworthy even for unencrypted connections.

Cookies. Cookies are a client-side storage mechanism based on the name-value paradigm and can be set through JavaScript or using the `Set-Cookie` header of HTTP responses. In their default configuration, cookies are accessible by JavaScript using the `document.cookie` property and are attached by the client to all the requests sent to the host which set them, using the `Cookie` header. The scope of cookies can be extended to other subdomains by using the `Domain` attribute; this allows cookie sharing across sibling domains, e.g., a.foo.com can set cookies with the `Domain` attribute set to foo.com, which makes them available to b.foo.com. Since cookies may store sensitive data, e.g., session identifiers that must be protected to prevent session hijacking, clients offer a plethora of defensive options deployed in terms of cookie *attributes* and *prefixes*.

Cookies marked with the `Secure` attribute are only attached to requests sent over secure channels, e.g., over HTTPS, which is important to ensure their confidentiality against network attackers. The `HttpOnly` attribute makes cookies inaccessible to JavaScript, which is useful to prevent cookie theft in the presence of injection vulnerabilities like XSS. Finally, the `SameSite` attribute can be used to restrict the attachment of cookies to same-site requests, thus mitigating CSRF. If `SameSite` is set to `Strict`, no cross-site request will ever attach the cookie; if `SameSite` is set to `Lax`, top-level navigation

requests with a safe method (e.g., GET) can attach the cookie even though they are fired from a cross-site position.

Since cookies have weak integrity guarantees in their default configuration, Web developers can qualify their names with special prefixes to improve protection. The `__Secure-` prefix requires the cookie to be set over secure channels with the `Secure` attribute activated. The `__Host-` prefix extends the protection of the `__Secure-` prefix by also forcing the deactivation of the `Domain` attribute, thus scoping the cookie to a specific host rather than to its site.

Mixed Content. When a document is loaded via a secure channel, all its subresources, i.e., frames, scripts, etc, must also be received securely to not compromise the integrity of the page. If any of such resources is loaded via a non-secure channel, i.e., HTTP, a network attacker can tamper with the content of the reply, opening the possibility for, e.g., executing malicious JavaScript code within a secure context.

The W3C Mixed Content specification [35] regulates the fetching of subresources within documents loaded via a secure channel, defining as *mixed content* any insecurely-loaded subresource. Mixed content is categorized based on the corresponding security risks. Mixed content is *upgradeable* when the risk of allowing its usage is outweighed by the risk of breaking significant portions of the Web. Image, audio, and video content are all classified as upgradeable because the usage of such resource types is sufficiently high, while their loading is generally considered as low-risk. Upgradeable mixed content goes through protocol autoupgrading: the URL is rewritten to use the HTTPS protocol and an attempt is made to fetch the subresource securely. If the resource is not available via the new URL, it will not be loaded in the page.

Any mixed content that is not upgradeable is classified as *blockable*. Examples of blockable content are scripts, frames, XHR, and fetch requests. The risk of loading such content is much higher: for example, allowing insecurely-loaded scripts within a secure context would allow a network attacker to read or modify data accessed therein. Blockable mixed content is filtered and the subresource is not loaded in the document.

3 Web Invariants

A *Web invariant* is an intended security property of a Web security mechanism that should never be violated by Web browsers, i.e., any counter-example might reveal a security-relevant bug. In this paper, we define 9 Web invariants concerning two core components of the Web Platform: cookies and Mixed Content. The selection and definition of these invariants is based on the following methodology. First, we focus on Web components with clear security implications and relatively compact specifications. For each selected mechanism, we abstract the expected security properties by thoroughly analyzing the specification. We then review the existing literature to identify invariants already defined in prior research. In cases where specifications prove to be ambiguous, we encode as a Web invariant the community security expectations that emerge from previous research or from our discussion with the specification maintainers. For each of these cases, we provide a bibliographic reference or a link to the GitHub discussion. Finally, we express the invariants as first-order logic formulas. Table 1 presents an intuitive natural language description of the invariants we encode in this work. In particular, we define 6 new Web invariants (I.4–I.9) and propose an encoding of 3 invariants from the literature (I.1–I.3). In this section, we focus on the 6 new Web invariants we propose, presenting their expected security property and encoding. We first define a model to represent browser execution traces and show how security properties can be encoded in this model. We then proceed with the discussion of the invariants. Due to space constraints, the encoding of the remaining invariants is dicussed in Appendix A.

3.1 Traces and Events

We define Web invariants in terms of browser execution traces. A *trace* is represented as a list of browser events, each mapping to a concrete browser action. Events are encoded as shown in Fig. 1 and capture JavaScript API calls (*js*), network requests and responses (*net*), and hooks into the browser internals, e.g., ***cookie-jar-set*** triggers when a cookie is stored in the cookie jar. JavaScript events store a reference to the browsing context, i.e., the Window or Worker, in which the API call was executed. For each browsing context, we store a unique identifier, its location URL, and a flag indicating whether it is a secure context [34] or not.

Invariants are encoded as first-order logic formulas, which should be true for all possible traces.[1] As an example, consider our encoding of the *Confidentiality of HttpOnly Cookies* (I.2) defined in [33].

$$
\begin{aligned}
&\text{HTTP-ONLY-INVARIANT}(tr) := \\
&\quad t_1 > t_0 \wedge \\
&\quad \textbf{\textit{cookie-jar-set}}(name, value, \{\textit{http-only}, \textit{secure}, \textit{domain}, \textit{path}\})@_{tr} t_0 \wedge \\
&\quad \textbf{\textit{js-get-cookie}}(ctx, cookies)@_{tr} t_1 \wedge \\
&\quad name +\!\!+ \texttt{"="} +\!\!+ value \in \textit{split-cookie}(cookies) \wedge \\
&\quad \textit{cookie-match}(path, domain, secure, \textit{ctx-location}(ctx)) \rightarrow \\
&\qquad \textit{http-only} = \textit{false}
\end{aligned}
$$

The invariant is defined as an implication, requiring the *http-only* flag to be equal to false if a set of hypotheses is satisfied. We use the $e@_{tr}t$ predicate to check if event e is present in trace tr at timestamp $t \in \mathbb{N}$. Intuitively, this invariant says that if a script successfully uses the `document.cookie` getter (***js-get-cookie*** at time t_1) to obtain the *cookies* string, and if *cookies*, after splitting on the cookie separator `";"`, contains the string composed of the concatenation of *name*, the literal string `"="`, and *value*, then the *http-only* flag present when the cookie was set (***cookie-jar-set*** at time $t_0 < t_1$) needs to

[1] For readability, all variables are implicitly $\forall$-quantified when no quantification is specified.

	Name	Invariant	Description	References
Cookies	I.1	Integrity of Secure cookies	*Cookies with the* `Secure` *attribute can only be set over secure channels.*	[33]
	I.2	Confidentiality of HttpOnly cookies	*Scripts can only access cookies without the* `HttpOnly` *attribute.*	[33]
	I.3	Integrity of __Host- cookies	*A* `__Host-` *cookie set for domain d can only be set by d or by scripts included in pages on d.*	[33]
	I.4	Integrity of SameSite cookies	*A* `SameSite=Lax/Strict` *cookie can only be set for domain d through HTTP responses to requests initiated by domains which are same-site with d or by top-level navigations.*	[19, §4.1.2.7]

Figure 1: Syntax of traces: event types.

be set to *false*. We use the *split-cookie* function to split a cookie header on the separator character `;`, returning a list, and the *cookie-match* predicate to consider the case in which the cookie set at time t_0 is readable by the browsing context *ctx* where `document.cookie` is accessed. In particular, given a URL and the path, domain and security attributes of a cookie, *cookie-match* is true when the domain matching and path matching algorithms defined in the specification [19] return true and when, if the `Secure` attribute is set, the URL uses a secure protocol. That is, when *cookie-match* is true for a URL and a cookie, we should expect that cookie to appear in the request headers and `document.cookie` for that URL.

Invariants are expressed in quantified first-order logic using the theories of uninterpreted functions, integer arithmetic, algebraic datatypes, and strings. In particular, events are defined as a datatype, the $@_{tr}$ predicate is implemented as a recursive function, and auxiliary predicates can be defined as macros or functions. This combination of theories gives us flexibility in the definition of Web invariants, e.g., allowing us to encode properties about parsing and serialization, while allowing for automated verification using the Z3 theorem prover.

3.1.1 Integrity of `SameSite` Cookies

The cookie specification explicitly forbids setting SameSite cookies (either `Lax` or `Strict`) in response to non-top-level cross-site requests [19, §4.1.2.7]. For instance, assume that https://good.com embeds a page at https://evil.com as an iframe. If the iframe includes subresources from https://good.com, the browser should discard SameSite cookies set in responses to those requests. This behavior defines additional integrity guarantees to SameSite cookies and corresponds to the following invariant.

Invariant (I.4). *A cookie whose* `SameSite` *attribute has value* `Strict` *or* `Lax` *can only be set for domain d through HTTP responses to requests initiated by domains which are same-site with d or by top-level navigations.*

We encode this invariant as follows:

$$
\begin{aligned}
&\text{SAMESITE-COOKIES-INTEGRITY}(tr) := \\
&\quad t_1 < t_2 < t_3 \wedge \\
&\quad \textbf{\textit{net-request}}(id, url, \_, type, origin\text{-}url, \_, \_, \_, \_)@_{tr} t_1 \wedge \\
&\quad \textbf{\textit{net-response}}(id, url, \{set\text{-}cookie\text{-}headers\}, \_)@_{tr} t_2 \wedge \\
&\quad set\text{-}cookie \in set\text{-}cookie\text{-}headers \wedge \\
&\quad name +\!\!+ \texttt{"="} +\!\!+ value \in split\text{-}cookie(set\text{-}cookie) \wedge \\
&\quad \texttt{"SameSite="} +\!\!+ SS \in split\text{-}cookie(set\text{-}cookie) \wedge \\
&\quad (SS = \texttt{"Lax"} \wedge same\text{-}site = SS\text{-}Lax \vee \\
&\qquad SS = \texttt{"Strict"} \wedge same\text{-}site = SS\text{-}Strict) \wedge \\
&\quad \textbf{\textit{cookie-jar-set}}(name, value, \{same\text{-}site, path, domain\})@_{tr} t_3 \wedge \\
&\quad cookie\text{-}match(path, domain, \_, url) \wedge \\
&\quad url\text{-}site(url, site) \rightarrow \\
&\qquad (type = main\_frame \vee url\text{-}site(origin\text{-}url, site))
\end{aligned}
$$

For every ***net-response*** event that successfully sets a cookie, i.e., that is followed by a ***cookie-jar-set*** whose parameters match the value of the response `Set-Cookie` header; if the `SameSite` attribute is set to `Lax` or `Strict`, then either the request type is *main_frame*, i.e., it is a top-level request, or the initiator of the request is same-site w.r.t the target url of the request, i.e., *origin-url*, the url of the request initiator, is in

the same site of *url*. Here, the *url-site* predicate is true when its second argument is the site of the url in the first argument.

3.1.2 Isolation of `SameSite` Cookies

SameSite cookies, especially when set with the `Strict` attribute, are widely considered a robust defense against cross-site attacks such as CSRF [19] and, more recently, XS-Leaks [3, 28, 32]. The protection is effective as long as these cookies are not attached to requests initiated by an attacker operating from a cross-site page. For instance, the specification mandates browsers to not include SameSite cookies in requests to load cross-site iframes, nor make them available to JavaScript APIs in that context [19, §5.2.1].

We verified instead that cross-site top-level navigations can cause same-site navigations to be executed, thus attaching SameSite cookies to requests initially started by the attacker. This is the case of a pop-up window opened by a cross-site page, which executes a same-site JavaScript-based redirection via, e.g., `window.location`. Browsers consider the first request as cross-site but the second as same-site, thus attaching SameSite cookies to the second request, as captured by the specification [19, §8.8.5]. Similarly, subresources loaded in a top-level cross-site context are considered same-site and are loaded with SameSite cookies attached.

By carefully examining public discussions between browser vendors [1, 6, 8], we found that the current behavior is the result of a bottom-up threat modeling process, with security implications that extend beyond what is declared in the specification: "*same-site navigations and submissions can certainly be executed in conjunction with other attack vectors such as cross-site scripting*". Indeed, SameSite `Strict` cookies can be bypassed using JavaScript-based same-site redirectors (i.e., no XSS required) [27], and loading authenticated subresources can introduce observable user-dependent state in the opened page, thus enabling XS-Leaks attacks, as we discuss in Sec. 5.2. We are currently engaging with browser vendors and specification maintainers to harmonize the specification and the implementations, and to clarify the security properties that should be expected from SameSite cookies based on the principle that high-sensitive resources (e.g., cookies and authenticated resources) should not flow into low-sensitive contexts (e.g., pages loaded from cross-site requests) [9].

Invariant (I.5)**.** *If a cookie set for domain d with the SameSite attribute set to "Lax" or "Strict" should not be attached to a request that loads a page p, then the cookie is not attached to that request, it is not accessible to scripts running in p and it is not attached to network requests initiated by p.*

We encode the invariant as:

$$
\begin{aligned}
&\textsc{samesite-cookies-confidentiality}(tr) := \\
&\quad t_1 < t_2 < t_3 \wedge \\
&\quad \textbf{\textit{cookie-jar-set}}(name, value, \{secure, same\text{-}site, path, domain, host\text{-}only\})@_{tr}t_1 \wedge \\
&\quad (same\text{-}site = SS\text{-}Lax \vee same\text{-}site = SS\text{-}Strict) \wedge \\
&\quad \textbf{\textit{net-request}}(\_, url, method, type, origin, \_, \_, redirs, \{cookies\}, \_)@_{tr}t_2 \wedge \\
&\quad cookie\text{-}match(path, domain, secure, host\text{-}only, url) \wedge \\
&\quad \neg cookie\text{-}match\text{-}samesite(same\text{-}site, type, origin, method, redirs, url) \wedge \\
&\quad (\\
&\qquad (\textbf{\textit{js-get-cookie}}(ctx, cookies')@_{tr}t_3 \wedge url = ctx\text{-}location(ctx)) \vee \\
&\qquad (\textbf{\textit{net-request}}(\_, url', method', type', origin', doc\text{-}url', \_, redirs', \{cookies'\}, \_)@_{tr}t_3 \wedge \\
&\qquad\quad doc\text{-}url' = some(url) \wedge \\
&\qquad\quad cookie\text{-}should\text{-}be\text{-}sent(\\
&\qquad\qquad path, domain, secure, same\text{-}site, host\text{-}only, type', origin', url', method', redirs')) \\
&\quad) \rightarrow \\
&\qquad (name +\!\!+ \texttt{"="} +\!\!+ value \notin split\text{-}cookie(cookies) \wedge \\
&\qquad\quad name +\!\!+ \texttt{"="} +\!\!+ value \notin split\text{-}cookie(cookies'))
\end{aligned}
$$

Assume that there is a SameSite cookie set for a specific domain, that is, the trace contains a ***cookie-jar-set*** event at time t_1, and that the browser then loads a page at time t_2 for which this cookie would have been sent if it was not SameSite (i.e., for which *cookie-match* is true but *cookie-match-samesite* is not). If there is a subsequent event at time t_3, be it a ***js-get-cookie*** where the browsing context location matches the URL of the request at t_2, or a ***net-request*** to which the cookie should be attached (i.e., for which the *cookie-should-be-sent* predicate is true), then the value of the cookie header (or the return value of `document.cookie`) $cookies'$ should not contain the cookie set at t_1, and that cookie was not attached to the request at t_2.

3.1.3 Cookie Serialization Collision Resistance

In 2020, *nameless cookies* were introduced in the cookie RFC [5] to standardize the legacy behavior adopted by major browsers. According to the standard, cookies with an empty name and a non-empty value must be serialized in the `Cookie` request header using only their value, without the `=` separator. To exemplify, a nameless cookie with value `foo` is serialized by compliant browsers as `Cookie: foo`. This serialization strategy is known to introduce collisions, which can be leveraged to perform cookie tossing attacks [31]. For example, a cookie set via `Set-Cookie: =foo=bar`, with empty name and value `foo=bar`, is attached to outgoing requests as `Cookie: foo=bar` resulting indistinguishable to a server from a cookie with name `foo` and value `bar` [19, §5.5, item 3].

Browsers can prevent cookie collisions by removing support for nameless cookies altogether, as in the case of Safari [31], or simply by including the `=` separator in the serialized cookie irrespectively of the content of the name or the value fields. Building on the previous example, the nameless cookie with value `foo=bar` would be serialized as `Cookie: =foo=bar`, allowing servers to distinguish it from a standard named cookie. This is captured by the following invariant.

Invariant (I.6)**.** *A cookie with name n and value v set for domain d is serialized to the string "n=v" when attached to requests or accessed via* `document.cookie`*.*

The invariant is encoded as:

$$
\begin{aligned}
&\text{COOKIE-SERIALIZATION-INVARIANT}(tr) := \\
&\quad t_2 > t_1 \wedge \\
&\quad \textbf{\textit{cookie-jar-set}}(name, value, \{secure, same\text{-}site, path, domain\})@_{tr}t_1 \wedge \\
&\quad (\\
&\qquad (\textbf{\textit{net-request}}(\_, url, method, type, origin\text{-}url, \_, \_, redirs, \{cookies\}, \_)@_{tr}t_2 \wedge \\
&\qquad\quad cookie\text{-}should\text{-}be\text{-}sent(\\
&\qquad\qquad path, domain, secure, same\text{-}site, type, origin\text{-}url, url, method, redirs)) \vee \\
&\qquad (\textbf{\textit{js-get-cookie}}(ctx, cookies)@_{tr}t_2 \wedge url = ctx\text{-}location(ctx) \wedge \\
&\qquad\quad cookie\text{-}match(path, domain, secure, url)) \\
&\quad) \wedge \\
&\quad is\text{-}effective\text{-}cookie(t_2, tr, name, value, domain, path, \texttt{""}) \rightarrow \\
&\qquad name +\!\!+ \texttt{"="} +\!\!+ value \in split\text{-}cookie(cookies)
\end{aligned}
$$

For every request (or access to the `document.cookie` property) at time t_2, where a cookie stored previously in the cookie jar at time t_1 should be sent (resp. retrieved), the cookie header (or the return value of `document.cookie`) should contain the string $name +\!\!+ \texttt{"="} +\!\!+ value$ after splitting on the separator `";"`. This invariant uses the three predicates *cookie-should-be-sent*, which is true if a cookie should be attached to a request, *cookie-match*, which is true if a cookie should be readable in a specific browsing context URL, and *is-effective-cookie*, which makes sure that the ***cookie-jar-set*** at t_1 we consider is the event that set the cookie in the cookie jar. Specifically, the predicate makes sure that there was no ***cookie-jar-set*** between t_1 and t_2 that overwrote the cookie stored in the cookie jar.

3.1.4 Confidentiality of `Secure` Cookies

The Cookies RFC delegates the decision of which protocols are denoted as *secure* to the specific user agent, requiring it to attach the cookies with the `Secure` attributes to URLs using such protocols [19]. Noticing this ambiguity in the RFC, we investigated how different browsers implement this behavior and discovered an inconsistency: Chromium and Firefox (behind a configuration flag) deem the `localhost` host, its subdomains, and its IP representation (`127.0.0.1`) as secure regardless of the protocol, and thus attach `Secure` cookies to local requests, whereas Safari does not. Similar inconsistencies apply to cookie prefixes, where only Firefox attaches prefixed cookies to localhost.

We contacted the HTTP Working Group [7], notifying them about the potential differences in handling of `Secure` cookies, suggesting to disambiguate the requirements on browsers by using the *potentially-trustworthy* origin definition for determining secure URLs, instead of a browser-dependent definition of secure protocol. Our proposal is currently being discussed in the Working Group. Initial feedback suggests that the specification editors are considering modifying the phrasing to include potentially trustworthy origins.

This change in the specification would align it to the de-facto standard behavior of the majority of the top browsers, which we formalize as follows:

Invariant (I.7)**.** *Cookies with the `Secure` attribute are only attached to requests sent to potentially trustworthy origins and are only readable by scripts running in browsing contexts whose origin is potentially trustworthy.*

The invariant is encoded as:

$$
\begin{aligned}
&\text{SECURE-COOKIES-CONFIDENTIALITY}(tr) := \\
&\quad t_1 > t_0 \wedge \\
&\quad \textbf{\textit{cookie-jar-set}}(name, value, \{secure = true, same\text{-}site, path, domain\})@_{tr}t_0 \wedge \\
&\quad (\\
&\qquad (\textbf{\textit{net-request}}(id, url, method, type, origin\text{-}url, \_, \_, \_, \{cookies\}, \_)@_{tr}t_1 \wedge \\
&\qquad\quad cookie\text{-}should\text{-}be\text{-}sent(\\
&\qquad\qquad path, domain, false, same\text{-}site, type, origin\text{-}url, url, method, redirs)) \vee \\
&\qquad (\textbf{\textit{js-get-cookie}}(ctx, cookies)@_{tr}t_1 \wedge url = ctx\text{-}location(ctx)) \\
&\quad) \wedge \\
&\quad cookie\text{-}match(path, domain, false, url) \wedge \\
&\quad name +\!\!+ \texttt{"="} +\!\!+ value \in split\text{-}cookie(cookies) \wedge \\
&\quad is\text{-}effective\text{-}cookie(t_1, tr, name, value, domain, path, \texttt{""}) \rightarrow \\
&\qquad is\text{-}origin\text{-}potentially\text{-}trustworthy(url)
\end{aligned}
$$

Assume that there is a cookie in the cookie jar with the `Secure` attribute set, i.e., the trace contains a ***cookie-jar-set*** event at t_0. If there is a network request (or an access to the `document.cookie` property) at t_1 where the cookie should be sent (resp. retrieved) and it is actually part of the attached cookies (resp. present in the return value of `document.cookie`), i.e., $name +\!\!+ \texttt{"="} +\!\!+ value \in split\text{-}cookie(cookies)$, then the origin of the URL of the request (or the browsing context where `document.cookie` is called) is potentially trustworthy.

3.1.5 Blockable Mixed Content

For each request, the browser determines whether it should be blocked by applying the steps defined in the *Should fetching request be blocked as mixed content* algorithm [35, §4.4]. In particular, a request is allowed when either its URL is *potentially trustworthy*, the context in which the request is performed does not restrict mixed content requests (e.g., a page loaded via HTTP making a fetch request), or when the request is top-level. We can define the following invariant.

Invariant (I.8)**.** *For every network request performed by the browser, either: (i) the context does not prohibit mixed content requests; or (ii) the request URL is potentially trustworthy; or (iii) the request is top-level.*

The encoding of the invariant is:

$$
\begin{aligned}
&\text{BLOCKABLE-MIXED-CONTENT-FILTERED}(tr) := \\
&\quad \textbf{\textit{net-request}}(\_, url, \_, type, origin, doc\text{-}url, ancestors, \_, \_, \_)@_{tr}t1 \rightarrow \\
&\qquad (\neg does\text{-}settings\text{-}prohibits\text{-}mixed\text{-}security\text{-}contexts(\\
&\qquad\qquad origin, doc\text{-}url, ancestors) \vee \\
&\qquad\quad is\text{-}url\text{-}potentially\text{-}trustworthy(url) \vee \\
&\qquad\quad (type = main\_frame \wedge nil = ancestors))
\end{aligned}
$$

The invariant uses the predicates *is-url-potentially-trustworthy*, which is true if the request URL is potentially trustworthy according to the respective algorithm of the secure context specification, and *does-settings-prohibits-mixed-security-contexts*, that is the implementation of the respective algorithm defined by the Mixed Content specification [35, §4.3] and is true if the request initiator origin is potentially trustworthy, or if any ancestor of the navigation initiator has a potentially trustworthy origin. The invariant also uses the expression $type = main\_frame \wedge nil = ancestors$ to check if a request is a top-level navigation.

3.1.6 Upgradeable Mixed Content

For upgradeable mixed content requests, e.g., loading images over insecure channels, the browser should rewrite the URL of the request by changing its scheme from HTTP to HTTPS. The mixed content specification defines the conditions for applying this rewriting in the *Upgrade mixed content request to a potentially trustworthy URL* algorithm [35, §4.1]. This algorithm applies to every request by the Fetch specification, thus every successful request made by the browser for upgradeable mixed content should have been upgraded. That is, every non-top-level request whose URL is not potentially trustworthy should not be upgradeable or should be permitted by Mixed Content. This corresponds to the following invariant:

Invariant (I.9)**.** *For every non-toplevel network request performed by the browser whose URL is not potentially trustworthy, the request context does not prohibit mixed content or the request type is not upgradeable.*

The invariant is encoded as:

$$
\begin{aligned}
&\text{UPGRADEABLE-MIXED-CONTENT-FILTERED}(tr) := \\
&\quad \textbf{\textit{net-request}}(\_, url, \_, type, origin, doc\text{-}url, ancestors, \_, \_, \_)@_{tr}t1 \wedge \\
&\quad \neg \textit{is-url-potentially-trustworthy}(url) \wedge \\
&\quad type \neq main\_frame \rightarrow \\
&\qquad (\neg \textit{does-settings-prohibits-mixed-security-contexts}(\\
&\qquad\quad origin, doc\text{-}url, ancestors) \vee \\
&\qquad \neg \textit{is-mixed-content-upgradeable}(type))
\end{aligned}
$$

where the presence of a request in the trace whose URL is not potentially trustworthy and whose type is different from *main_frame* (as upgradeable mixed content does not restrict toplevel requests) implies that both *is-mixed-content-upgradeable*, which checks if the request type is upgradeable (by implementing its definition in [35, §3.1]), and *does-setting-prohibits-mixed-security-contexts* are false.

4 Trace Verification Pipeline

In this section, we will first motivate with an example the importance of abstracting WPT tests into execution traces in order to automate the discovery of Web invariant violations, and then describe our verification pipeline in detail.

4.1 Motivating Example

We present a simple example to motivate why looking at failed WPT tests does not already enable reasoning about security. The WPT test `/mixed-content/gen/top.meta/unset/img-tag.https.html` is a set of test cases that check the mixed content behavior of browsers when fetching `img` tags. In particular, the test expects image requests to always be performed within an HTTPS browsing context (i.e., a window with a HTTPS URL as location). This is expected, as upgradeable mixed content requests should be allowed when the browser is able to rewrite the request URL to use the HTTPS scheme, i.e., performing the auto-upgrade. This test is successful on the stable versions of Firefox and Safari, but fails on Chromium, as some of the requests fail.

The execution trace of the test contains multiple ***net-request*** events, each corresponding to the requests performed by the browser during execution. Specifically, for each embedding of an `img` tag, the event includes the image URL, the request type (*image*), and additional fields characterizing the request, e.g., the origin of the request initiator and the URL of the document where the new image will be loaded. The I.8 invariant mandates that for every ***net-request*** event, at least one of three conditions must hold for it to be compliant with the Mixed Content specification. Since the request is not top-level, i.e., its type is *image*, and it originates from a page loaded via HTTPS, i.e., *does-setting-prohibit-mixed-content* is true, then its URL must be potentially trustworthy, i.e., its scheme must be HTTPS. In the traces produced during the execution of Firefox and Safari, the ***net-request*** event corresponding to the embedding of the image has an insecure URL, i.e., the image is fetched via HTTP, violating the requirement of I.8. In Chrome, on the other hand, the request is auto-upgraded and the corresponding ***net-request*** has a potentially trustworthy URL, thus I.8 is not violated.

Since the WPT test only checks for the images to be loaded, without explicitly testing their protocol, Firefox and Safari, which do not currently implement protocol auto-upgrading [2, 11] and perform the mixed content requests without blocking them, pass the test. Chromium, on the other hand, performs the auto-upgrading as mandated by the Mixed Content specification. However, since the image is served on a non-standard HTTP port (8000), the browser upgrades the protocol without changing the port causing a connection error.

This example highlights that the WPT test results alone may not always capture potential security concerns since failed tests do not necessarily break Web invariants, and, conversely, successful tests might break Web invariants. Tests can not only be unsuccessful because browsers implement new security features, as in the example above, but they can also fail if the execution relies on unimplemented APIs. This further emphasizes that observing a discrepancy across the WPT results of different browsers (i.e., simple WPT-based differential testing) is not a direct indication of security issues. By verifying browser traces obtained during the execution of WPT tests, irrespectively of test results, our approach provides a deeper insight into each test. In particular, violating an invariant is a clear indicator of potential security issues in the exercised browser behavior, pinpointing the specific Web components requiring immediate attention.

4.2 Methodology

Our methodology for detecting security-relevant issues in browser implementations leverages the WPT test suite and consists of two main stages, as shown in Fig. 2. First, the execution traces produced by executing the WPT tests on

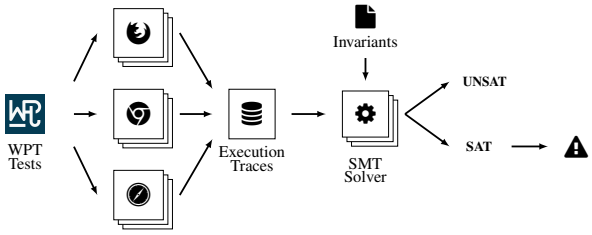

Figure 2: Trace Verification Pipeline.

the three major Web browsers (Chromium, Firefox, Safari) are collected into a database. Second, the obtained traces are post-processed, translated to SMT-LIB, and checked against the Web invariants we define in Sec. 3 using an SMT solver. When the solver cannot prove the validity of the invariant on a test trace (SAT, i.e., a counterexample exists), a violation is found on the specific browser. Our analysis pipeline is based on the Kubernetes container orchestration platform, allowing us to execute multiple instrumented browsers and the SMT solving in parallel. We detail in the following the main steps of the pipeline and our criteria for selecting the relevant tests.

Test Selection. The tests part of the WPT project can be classified into four main categories: (i) rendering tests, which test the graphical output of the browser (by, e.g., comparing it to screenshots) to verify that pages are displayed as expected; (ii) `testharness.js` tests, which test JavaScript interfaces available in browsing contexts, allowing to automatically check assertions about their behavior; (iii) `wdspec` test, which test parts of the WebDriver protocol and are written in the Python programming language; (iv) manual tests that require human interaction to determine their result. In this work, we focus on `testharness.js` tests, since our Web invariants cover JavaScript and browser internals behavior, ignoring most UI aspects. In particular, we consider all `testharness.js` tests of the April 2023 version of the WPT test suite. We detail our test selection in Table 6 (Appendix B), where we report the version (commit hash) of the test suite, the considered WPT subfolders, and the respective number of tests for each folder.

Trace Collection. We run each WPT test in its own isolated ephemeral container named *runner*. Each runner container includes a specific version of the tested browser, all its run-time dependencies, our patched version of the WPT tooling, and the browser instrumentation composed of a browser extension and a proxy (Sec. 4.3). For Safari, the runner container executes a MacOS virtual machine containing the instrumented browser. We build a runner container for Chromium (version 118.0.5961.0), Firefox (version 116.0.3) and Safari (version 16.4). Once the runner container terminates the execution of a WPT test, it stores the execution trace in JSON format in a centralized database. Note that we ignore test assertions, storing the captured trace regardless of the test results.

Verification. Upon completion of the runner container, the generated JSON file is post-processed and translated to SMT-LIB format. In particular, the events that were captured by our browser instrumentation are converted to execution traces following the format described in Sec. 3.1. It may be the case that multiple events recorded by the browser instrumentation happened simultaneously, i.e., the JSON stores multiple events with the same timestamp. This may occur when, for instance, a page containing multiple subresources is rendered: the browser may try to load all resources in parallel, thus resulting in multiple events of type *network-request* to be recorded at the same time. In such cases, the SMT-LIB translator generates multiple traces, each corresponding to a single permutation of the simultaneous events, allowing us to consider all possible orderings of the concurrent events. Note that, in practice, the number of concurrent events in WPT traces rarely exceeds four events, thus having a negligible impact on the pipeline performance.

Once execution traces are translated to SMT-LIB format, we use an SMT solver to query, for each trace, the *validity* of each Web invariant. That is, we check satisfiability of the negation of the invariant applied to each trace. This satisfiability checking may have three possible outcomes: (UNSAT) the invariant is valid, i.e., it is true for the current trace; (SAT) the invariant is not valid, i.e., the current trace is a counterexample for the invariant; (UNKNOWN) the solver was not able to prove nor disprove the invariant, hence in such cases we cannot draw any conclusion and we do not report any violation. Whenever the solver returns SAT, we obtain a model, i.e., an instantiation of the variables mapping them to the concrete values from the trace that make the invariant false. Being based on the standard SMT-LIB format, our pipeline supports all standard-compliant solvers that implement decision procedures for quantified string constraints, integer arithmetic and algebraic data types. Specifically, we currently support both the Z3 theorem prover and CVC5.

Violating an invariant may have several security implications, and for this reason, we manually inspect the execution trace of every SAT result and design a minimal proof of concept (PoC) attack to showcase the vulnerability in the affected browsers. We discuss the discovered attacks in Sec. 5.2.

4.3 Browser Instrumentation

Browser instrumentation and trace collection are essential components of our pipeline. Our main goal is to develop a browser instrumentation solution that provides a balance between observability and cross-browser support, while minimizing the implementation effort. Our instrumentation must be easily integrated into existing testing pipelines such as the Web Platform Tests and work across different browsers. We refer the reader to the extended version of the paper [16, Appendix C] for an analysis of the design space of browser instrumentation techniques.

4.3.1 Implementation

Based on our design space analysis, we implemented a browser instrumentation solution which combines a browser extension with an external proxy that improves on the limitations of the extension API with respect to its ability to inspect network traffic. Our solution provides the necessary hooks to monitor internal browser state, JavaScript API calls, and have a complete picture of the network activity when collecting browser execution traces.

Internal Browser State Monitoring. With extensions, we gain access to the internal browser state not available to regular scripts or external monitoring tools. This state includes the `CookieJar`, and network activity such as requests and responses. This internal state is accessible to extensions via background scripts, which have no access to the DOM but can make full use of the extension APIs. Network events are monitored by registering callback functions that run whenever a request is about to be sent, and when a request is deemed completed, i.e., it has a response or it was dropped. These callbacks provide access to the request and response headers, and additional information added by the browser, like the tab and frame IDs of the request initiator. The `CookieJar` can also be monitored via `onChange` callbacks, whose execution can be delayed depending on the state of the JavaScript event loop. Due to these inherent delay inconsistencies, we opted for polling the state of the `CookieJar` instead of registering callback functions, which gives us higher precision timestamps for `CookieJar` events.

JavaScript API Call Monitoring. In addition to monitoring network events and internal browser state, we focus on JavaScript API calls as another category of relevant events for our analysis. We proxy the relevant JavaScript functions, logged as events used in the invariants, to record function calls in a centralized structure located in the extension's background script. This proxying is done through `Proxy` objects and method overriding, enabling us to collect all the relevant data associated with each API call, such as its arguments and the respective browsing context. Our instrumentation logs calls to the setter and getter of `document.cookie`, but more JavaScript methods could be supported in the future using similar techniques. We adopt a dynamic approach for our instrumentation using content scripts, which are extension scripts that run in the context of webpages. Each webpage is injected with a content script that installs the proxy functions according to the extension configuration. This dynamic instrumentation is more versatile and scalable compared to code rewriting methods and allows us to efficiently track and analyze JavaScript API calls as they occur in real-time.

External Proxy. We incorporate an external proxy into our framework to overcome two main issues: (i) the restrictions imposed by browsers over network content deemed sensitive and, hence, inaccessible to background scripts but visible through a network proxy (e.g., request and response bodies); (ii) the inconsistent delay between network events and the execution of their corresponding callback event handlers. When a network request leaves the browser, the callback corresponding to its event handler is queued in the extension's JavaScript event loop and eventually executed. If the proxy intercepts the request before the callback is executed, the proxy event's timestamp is more accurate and is used as the request event timestamp in the trace.

4.3.2 Limitations

While our browser instrumentation technique based on extensions and proxies offers a powerful means to monitor internal browser state, JavaScript API calls, and network events, enabling comprehensive browser security analysis with cross-browser compatibility and minimal code modification or rewriting, it is essential to acknowledge the inherent limitations of this approach. These limitations include:

Browser Discrepancies. In our instrumentation, we strive to use only browser extension APIs that are compatible across browsers. However, browser behavior varies across implementations, which can introduce limitations to our approach. These inconsistencies are detected by manual inspection of our results, and whenever possible, we implement specific workarounds. But, some issues require changes to the browsers' source code and bug fixes. For example, a bug in Firefox's URL matching prevents the content scripts from being injected into opaque origins, such as data URL iframes. This limitation hinders our ability to monitor JavaScript API calls in these frames, negatively impacting the comprehensiveness of our analysis, and it cannot be circumvented without changes to Firefox's source code. For our current usage, this translates to missing events executed in iframes with opaque origins, which can lead to false negatives. Another example is Safari's resource isolation for WebDriver-controlled instances, which isolates resources such as the cookie jar. This isolation prevents our extension from effectively monitoring specific resources such as the `CookieJar` within Safari instances controlled by WebDriver, which translates to missing `CookieJar`-related events for Safari execution traces, leading to false negatives.

API Constraints. Currently our instrumentation is able to monitor the necessary components and collect the events required to reason about our invariants, i.e., `CookieJar`, network, and some JavaScript API call events. While some extensions to our instrumentation are possible, they are constrained by the availability of APIs in both JavaScript and the extension environment, and by the Same Origin Policy which is applied to the injected content scripts. For example, information such as the effective Content Security Policy (CSP) of a frame cannot be directly monitored as it is not accessible to scripts running in pages, nor to browser extensions. To support the analysis of the CSP mechanism with our approach, we must develop inference and heuristic techniques, which we could

use alongside other artifacts of our instrumentation, such as response headers, to infer the CSP enforced on a given frame. Another constraint to our approach is monitoring the DOM. Content scripts injected by the extension are still subject to the Same Origin Policy. Therefore, a full picture of the DOM may prove difficult to obtain without heuristics over other events such as network activity and DOM mutation.

In summary, while our browser instrumentation technique was proven effective in collecting security-relevant browser execution traces, these limitations underline the importance of developing better introspection and instrumentation mechanisms for browser testing. These mechanisms would benefit not only our approach but also testing frameworks like WPT, which currently uses incomplete workarounds to test features like cookies and the Content Security Policy.

4.4 Discussion: Extensibility

The methodology we propose is meant to enable specification maintainers and browser developers to check their security expectations, expressed as Web invariants, against multiple implementations. This way, security issues can be identified early during development and across Web platform or browser updates, e.g., for regression testing.

In this paper, we encode 9 invariants, as discussed in Sec. 3, showing that the verification pipeline is not bound to a single security mechanism and can be extended to support additional Web features. Although we do not consider the required expertise to develop new invariants a limiting factor, given that specification maintainers already possess this knowledge, the expressiveness of the invariants may be limited by the introspection capabilities of our instrumentation. Specifically, every JavaScript API or property access that can be wrapped with Proxy objects can easily be traced, encoded as an event (as in Fig. 1), and used in the definition of new invariants. Instead, monitoring internal browser state which is not exposed to pages or extensions, e.g, CSP, may prove to be difficult to trace without relying on heuristics or a different instrumentation approach (e.g., browser code patching [22]).

Automated generation. The definition of new Web invariants relies on the manual effort of understanding the security requirements of a specification and encoding them into a logical proposition. Automation could be beneficial for aiding the process, allowing more properties to be covered. Previous work on Web invariants identifies the importance of clearly defining the security properties of the Web as a way to have a *sound* scientific understanding of Web security [13]. Thus, the generation of Web invariants presents the challenge of retaining soundness while characterizing the relevant Web mechanisms. We leave the development of a methodology to automatically extend the set of invariants as future work.

Invariant	SAT	UNK.	SAT	UNK.	SAT	UNK.
I.1	0	0	0	0	–	–
I.2	0	0	0	0	–	–
I.3	0	0	0	0	–	–
I.4	0	0	1	0	–	–
I.5	10	0	6	0	–	–
I.6	15	0	9	0	–	–
I.7	0	0	0	0	–	–
I.8	0	448	24	643	21	692
I.9	0	355	18	509	0	628

Table 2: Trace verification results.

5 Evaluation Results

We evaluate our methodology by verifying, using our pipeline, the 9 Web invariants we define in Sec. 3 against the execution traces of the 24896 testharness tests from the April 2023 version of the WPT suite. Note that every browser is executed 24896 times, totaling 74688 traces. We use the Z3 theorem prover as the SMT solver component since it proved to be the best performing for our invariants. We set a timeout of 10 minutes for the execution of the browser for each test, and 10 minutes for each Z3 query. When Z3 is not able to return an answer within the timeout it returns UNKNOWN. All our experiments have been conducted on a cluster with 132 VCPUs (AMD EPYC 2.0GHz) and 382GB of RAM.

5.1 Preliminary Results

Table 2 reports the outcome of our analysis of the three major browsers on the WPT test suite, showing the number of tests for which Z3 found violation of a Web invariant (SAT). Additionally, we report the number of UNKNOWN results, for which our pipeline could not generate a definitive answer. Note that, given the limitations of Safari instrumentation (see Sec. 4.3.2), invariants about cookies are expected to always return UNSAT there (marked as – in Table 2), since the Safari traces never contain the ***cookie-jar-set*** event, which is used in the premises of our cookie invariants.

Five invariants have at least one violation. The results confirm our expectation that different implementations may exhibit different behaviors with respect to the implemented security mechanisms. In particular, although there is overlap in some of the SAT traces between different browsers, Table 2 highlights that some SAT results are browser-specific. We discuss in Sec. 5.2 the security implications of violating each invariant, where we group SAT results into concrete attacks against specific browsers that we present as case studies.

For four invariants our pipeline does not report any violation, so they are valid on the entirety of the execution traces produced by WPT. This may happen in the cases where the invariants are well-known and expected to hold by the literature (I.1, I.2). Additionally, we may obtain no violation if

	Trace Collection			Verification			Total
	avg	std	total	avg	std	total	
	28s	6s	23h 29m	19s	1m 42s	23h 05m	1d 22h 35m
	40s	8s	1d 07h 18m	27s	2m 06s	1d 08h 34m	2d 15h 52m
	27s	8s	1d 06h 34m	32s	2m 28s	1d 14h 33m	2d 21h 07m

Table 3: Trace verification execution times.

the traces generated by the test suite do not cover the specific preconditions for an attack to be performed. As an example, I.3 does not hold in the current Web platform [33] because of an attack that requires combining *domain relaxation*, i.e., assignment to the Document.domain property, with `__Host-` cookies. This invariant may have no SAT results because the WPT test suite never uses the two Web features together in the same test. A similar consideration applies to I.7, as the `localhost` URL is never used in cookie-related tests. We discuss these cases in Sec. 5.3, where we explore additional tests beyond what is included in WPT.

Z3 returned UNKNOWN during the verification of the Mixed Content invariants I.8 and I.9. These are caused by the complex checks that are mandated by the Mixed Content specification, in particular the recursive checking of the entire ancestor chain for each network request, which may negatively affect the solver speed and result in UNKNOWN if the execution time exceeds the verification timeout.

Performance. The performance of our trace verification pipeline is shown in Table 3. The total run-time for each of the three major browsers is reported together with the time required for executing the browser (collecting execution traces) and the Z3 verification time. Executing a single WPT test on each of the browsers consistently requires less than one minute, whereas the verification with the Z3 theorem prover shows more variability, while still requiring less than a minute on average. This confirms that verifying Web invariants on the traces generated by WPT does not add substantial overhead to the execution of the testing suite, but supplements the result obtained from each WPT test with an assessment of the security of the exercised browser functionality.

5.2 Attacks on Major Browsers

Every SAT result obtained as the output of the Z3 theorem prover corresponds to a violation of a Web invariant on the execution trace of a specific browser, as captured by our instrumentation. These results require a manual analysis to identify and aggregate similar issues, organizing them into concrete inconsistencies. This effort is supported by the model obtained from Z3, which provides the concrete values from the trace that violate the invariant, highlighting problematic events in the trace and allowing us to easily discern the cause of the violation. A goal of our analysis of SAT results is to determine the root causes underlying these inconsistencies and to quantify their security impact, and in particular, if they can lead to concrete real-world attacks. This step is also critical in identifying any false positives introduced by the observability limitations of our browser instrumentation (Sec. 4.3.2). For instance, the inability to correctly observe a specific browser event may lead to the generation of a violating trace for an otherwise compliant browser. For example, a missing cookie deletion event may result in a violating trace if we expect that cookie to be attached to a subsequent network request.

We now present all the attacks resulting from the analysis of the SAT results, discussing them in the form of case studies. In particular, we aggregated all 104 invariant violations into 10 confirmed attacks and 5 false positives as shown in Table 4. Due to space constraints, we refer to Appendix C for a discussion of each false positive and its causes.

Framed Pages Mixed Content Bypass
Z3 reported SAT for Safari for the trace of the `mixed-content/nested-iframes.window.html` test, where the browser successfully performs a fetch request to an insecure endpoint coming from a frame whose origin is potentially trustworthy, violating the I.8 invariant. After some investigation, we concluded that Safari incorrectly performs mixed content checks, i.e., secure pages embedded in insecure origins were not considered potentially trustworthy, and therefore, mixed content was not blocked except for requests to load scripts, stylesheets, or requests to insecure WebSocket. For example, if `https://bank.com` contains an authenticated mixed content request (i.e. via fetch), framing it over `http://attacker.com` will cause the request to not be filtered. This behavior might incorrectly expose non-Secure cookies in clear over the network to passive network attackers. Moreover, the integrity of the fetch request (and its response) would not be ensured against network attackers, meaning that attackers could tamper with its contents to, for example, alter the control flow of JavaScript execution on the target page.

Disclosure. We disclosed the attack to the Safari developers. The issue has been fixed in Safari 16.6.

Sandbox Attribute Mixed Content Bypass
The test `mixed-content/csp.https.window.html` consists in a webpage using the `sandbox allow-scripts` CSP directive. The page is loaded via HTTPS so mixed content should be prohibited, nevertheless, a fetch request targeting an HTTP endpoint is not blocked in Safari, violating I.8. In the trace, the CSP directive is effectively setting the origin of the page to `null`. Since the null origin is not potentially trustworthy, the requests are not filtered. This vulnerability can be combined with the previous one to obtain a complete bypass of the mixed content policy: the presence of the `sandbox` directive makes the browser allow mixed content requests to scripts, stylesheets, and insecure WebSockets, which are otherwise blocked. As a consequence, if `https://bank.com` contains a mixed content script, framing it with the `sandbox` attribute over `http://attacker.com` will allow the request to the script to be sent. A network attacker can tamper with its content

Invariant	Total SAT	SAT Traces			Type	Description (causes of SAT)
I.4	1	–	1	–	🐞	SameSite cookie integrity violation
I.5	18⋆	1	2	–	🐞	SameSite cookies attached to (favicon, subresource, fetch) requests (*requests*)
		10	5	–	🐞	SameSite cookies accessible via Document.cookie (*non-HTTP*)

I.9	18	–	18	–	🐞	Mixed content autoupgrade not performed

Table 4: Aggregated SAT results. (🐞: attack; ✖: false positive; ⋆: the same trace may contain multiple attacks)

to obtain code execution on `https://bank.com`, in a context where the origin is `null`. In this scenario SOP prevents certain operations (e.g., cookies access) but other attacks, such as user input tracking, and DOM modifications can still be performed. For instance, an attacker embedding the login page of `bank.com` can track user inputs by registering new listeners through the injected script and exfiltrate user credentials whenever a user is tricked into logging in.

Disclosure. We disclosed this attack to the Safari developers. The issue has been fixed in Safari 16.6 and CVE-2023-38592 was assigned to this and the previous vulnerability.

Mixed Content Beacon Requests Not Blocked

A beacon request is a non-blocking POST request sent using the `navigator.sendBeacon` API. Mixed content beacon requests are *blockable* and therefore should be filtered. However, our pipeline SAT results show that Safari performs such requests, violating I.8. When a mixed content beacon request is not blocked, attached cookies and the data attached to the request are leaked even to passive network attackers.

Disclosure. We reported the problem to the Safari developers and we are waiting for confirmation.

Nameless Cookies Serialization Collisions

Part of the SAT results reported for I.6 are caused by the serialization of nameless cookies. Our invariant expects every cookie with name n and value v to be serialized as $n = v$. However, Chromium and Firefox serialize nameless cookies where n = "" simply as v. Consequently, our pipeline will report a violation whenever I.6 matches a trace where a nameless cookie is serialized. The higher number of SAT results related to nameless cookies in Firefox compared to Chromium stems from an inconsistency between the browsers: whenever Firefox encounters the JavaScript API call `document.cookie = ""`, a cookie with an empty name and value is set, unlike Chromium, which does not set any cookie. The serialization of nameless cookies enables attackers to shadow arbitrary cookies. This capability includes shadowing `Secure` cookies from insecure origins, relaxing an attacker's requirements to perform cookie tossing or eviction attacks on `Secure` cookies, which would typically require a secure origin [31].

Disclosure. The issue was already reported to the IETF HTTP Working Group by Squarcina et al. [31] during their study of cookie integrity.

SameSite Cookie Integrity Violation

Our pipeline returned SAT for Firefox in the trace of the `cookies/samesite/setcookie-navigation.https.html` test, where a cookie with the `SameSite` attribute set to `Strict` is successfully set in the response to a cross-site network request initiated from an iframe, violating the I.4 invariant. In particular, an iframe loading `https://attacker.com` within `https://bank.com` might navigate itself to some page at `https://bank.com`, which sets `SameSite` cookies in the response to the navigation request. Note that this applies to both `Strict` and `Lax` SameSite cookies. A gadget attacker [13, 14] can thus leverage this behavior to overwrite cookies to perform, e.g., de-authentication attacks.

Disclosure. We reported this vulnerability to Firefox developers [10] who confirmed the issue assigning it a severity rating of *Normal (blocks non-critical functionality)*, planning a fix for the next release.

SameSite Cookies Isolation

The SAT results returned from our pipeline for I.5 fall into three categories: *request*, *non-HTTP*, or *reload*. Traces in these categories all have a similar setup but differ in how the cookie is retrieved. The setup follows this structure: (i) a

cookie c with `SameSite` attribute set to `Strict` or `Lax` is set for domain d; (ii) a top-level request initiated by domain d', where c is not attached, opens page p with domain d, which is cross-site with d'. From this point, *request* traces perform a network request, initiated by d (from page p) that is considered same-site and attaches c, violating I.5. This request can be, for example, a subresource load, a request to load the `favicon`, or a request generated by a call to the `fetch` JavaScript API. *Non-HTTP* traces retrieve the cookie c through a call to `document.cookie` from p, violating I.5. Finally, *reload* traces perform a call to `location.reload`, triggering a same-site request that reloads page p and attaches c, which violates I.5. Note that *reload* traces are not SAT for Firefox. By manually investigating this inconsistency, we discovered that Firefox does not attach `SameSite` cookies to network requests initiated from calls to `location.reload`, as it considers these requests cross-site.

Setting the `SameSite` attribute of cookies to `Strict` is considered an effective defense against CSRF and XS-Leak attacks as these cookies are not attached to cross-site requests. However, attackers can exploit the browser behavior highlighted by I.5 SAT results to bypass these restrictions. In particular, attackers can forge same-site requests starting from a cross-origin position by abusing, e.g., redirection gadgets that trigger attacker-controlled same-site navigation requests, effectively enabling CSRF attacks. Another security implication is the possibility of performing XS-Leaks. Consider a page that loads a script depending on whether the subresource load request attaches `SameSite=Strict` cookies and that this script modifies the DOM of the target page, altering `window.length`. An attacker could navigate to this page through `window.open`, and even though `SameSite=Strict` cookies are not attached to the top-level request, they will be included in subresource loads in the target page. An attacker can then use the `length` property of the window handler to infer the authentication status of the victim.

Disclosure. We are currently engaging with the HTTP Working Group to clarify the security properties that should be expected from SameSite cookies [9].

Mixed Content WebSockets Requests Not Blocked
These SAT results refer to a set of tests for the following scenario: WebSocket requests sent from a Worker using the *ws* protocol. If the Worker is created from a secure page, so its origin is potentially trustworthy, we expect the request to be blocked as mixed content. However, in Firefox it is not, violating I.8. Investigating the issue uncovered that Firefox incorrectly implements the filtering for WebSocket requests. In particular, filtering is not performed if either the origin's scheme is *blob:* or the request is sent from a Worker created in a trustworthy origin using a *data:* URI.

Disclosure. We disclosed the problem to Mozilla. The issue has been fixed in Firefox 120.

Mixed Content Autoupgrade Not Performed
From the analysis of these SAT results, we observed how both Safari and Firefox do not perform protocol autoupgrading, and as a consequence, upgradeable mixed content requests are sent over the network, violating I.8 or I.9. When this happens, network attackers can tamper with the content of upgradeable requests to attempt phishing users by e.g. swapping the icons of two buttons tricking them into performing destructive operations (e.g., *delete message* instead of *send message*). To prevent these attacks, the latest revision of the specification forbids loading upgradeable mixed content, but, as of today, neither Firefox nor Safari are compliant. However, they are aware of the issue and are planning a fix [2, 11].

5.3 Comprehensiveness of Tests

In this section, we explore additional tests beyond those in WPT, to (i) show that our pipeline can generalize to different test suites without modifications, and (ii) to assess how the *comprehensiveness* of the individual tests, in terms of the usage of Web features, affects the discovery of inconsistencies. As mentioned in Sec. 5.1, the limited scope of tests may prevent our pipeline from discovering violations. This is the case when tests do not include actions that are preconditions for the attack, e.g., when a violation is enabled by the combination of multiple Web features.

We construct a separate test suite comprising 9 tests to exercise behavior not covered by WPT. The selected tests are shown in Table 5. The first group (1-5) corresponds to the violations discovered by Veronese et al. [33] affecting the current Web platform. These tests combine multiple features to reproduce the attack traces generated by WebSpec. For instance, the first test uses *domain relaxation* to allow a subframe to set a `__Host-` cookie for a different origin. The remaining `web-spec_*` tests use a combination of CSP, Service Workers, and Trusted Types. Given that our invariants only focus on cookies and Mixed Content, these tests are not expected to reveal new violations. The second group of tests (6-7) reproduces the browser testing performed by Squarcina et al. [31]. In particular, the tests try to perform cookie tossing, eviction based on cookie jar overflow, and serialization collisions based on nameless cookies. Each test is composed of multiple sub-tests that correspond to various combinations of cookie properties, e.g., tossing of `Secure` cookies over insecure channels, or eviction of `__Host-` cookies. Note that these tests are actively abusing undefined behavior to perform eviction, as the RFC does not impose a specific limit to the number of entries in the cookie jar (although implementations are allowed to set one). Finally, the last two (8-9) tests use features that are not covered by WPT. The `localhost_cookies` test sets `Secure`, `__Secure-`, and `__Host-` cookies for the `localhost` domain, which is never used in WPT. The `multi_nested_frames` test sets cookies using mixed-content resources loaded across multiple levels of frames, as WPT does not include cookies in mixed-content tests and uses up to two levels of nesting.

	Test Name	SAT					
		I.1	I.3	I.6	I.7	I.8	I.9
1	webspec_host_frames	–	F	–	–	–	–
2	webspec_csp_sw	–	–	–	–	–	–
3	webspec_csp_sop	–	–	–	–	–	–
4	webspec_tt_frames	–	–	–	–	–	–
5	webspec_csp_blob	–	–	–	–	–	–
6	crumbles_tossing (5)	–	–	C F	–	–	–
7	crumbles_eviction (8)	–	–	–	–	–	–
8	localhost_cookies (3)	C	–	–	–	–	–
9	multi_nested_frames	–	–	–	–	C S	F

Table 5: Additional tests and new violations.

Table 5 reports the results of running our pipeline on the traces produced by the new test suite. The experiment confirms that new violations can be discovered using more comprehensive tests. In particular, I.3 does not hold for Firefox, where domain relaxation allows compromising __Host-cookies integrity. Interestingly, Chrome satisfies the invariant, since starting from version 115, the `document.domain` property is immutable [4], preventing pages from relaxing the SOP. The I.1 invariant does not hold for Chrome, as it is possible to set `Secure` cookies over an insecure connection when the URL is `localhost`. This matches the behavior we discuss in Sec. 3.1.4 and encode in I.7. Note that Firefox violates the invariant only when a specific setting flag is enabled. The new test suite, additionally, allows us to rediscover a violation for I.6, since the `crumbles_tossing` test uses nameless cookies. Similarly, I.8 and I.9 are SAT because upgradeable mixed content is not upgraded nor blocked in both Firefox and Safari. Safari also incorrectly loads mixed-content frames if the top-level window is loaded via HTTP, regardless of the protocol used to load any intermediate frame. Specifically, in `multi_nested_frames`, the test opens a window with three nested frames, where the top-level window is loaded via HTTP, the intermediate frames are over HTTPS, and the innermost frame is over HTTP, which should be blocked.

This experiment shows that employing a more comprehensive test suite has the potential to identify additional violations. While our focus for this paper is WPT, as it is currently the most complete and regularly updated browser testing suite available, our pipeline can be applied to any alternative testing suites, potentially improving its efficacy.

6 Related Work

Browser Testing. BrowserAudit is a test suite designed to assess the implementation of Web security mechanisms in Web browsers [21]. It includes more than 400 automated test cases for SOP, CSP, CORS, cookies and security headers. While the approach is undeniably useful to detect bugs, it suffers from significant limitations compared with our proposal. First, test cases in BrowserAudit were manually created by the authors. Our approach instead leverages WPT, which is an actively maintained existing test suite backed up by a large community (to date, its GitHub repository counts more than 1,500 contributors). Moreover, the security implications of failed BrowserAudit tests are also manually identified: failures are categorized by the authors as warning or critical, supposedly based on their security impact according to the authors' understanding. Our approach instead detects effective violations of Web security invariants, i.e., deviant behavior clearly contradicting existing specifications. Concretely, the latest versions of Chromium and Firefox pass all the tests in BrowserAudit except for a few warnings, showing that the current set of test cases cannot identify relevant bugs in existing browsers, as opposed to our pipeline.

Other work on the automated detection of security bugs in browsers targeted specific mechanisms or vulnerabilities. For example, DiffCSP can detect bugs in CSP implementations [36], while other work investigated incoherencies in the implementation of SOP [29, 30]. Automated testing has also been used to detect new cross-site leaks in browsers [28] and to study the support of Web security mechanisms in mobile browsers [25]. All these proposals proved effective to identify new bugs, yet they are tailored to specific needs and do not leverage general security notions like the concept of Web security invariant adopted in this paper.

Browser Instrumentation. VisibleV8 (VV8) [22] is a browser instrumentation framework, implemented as a set of patches for the Chromium browser, that allows for tracing JavaScript function calls and property access during navigation. The VV8 patches are designed to minimize the modified lines of code, so that they can be easily applied to updated browser versions. Browser instrumentation implemented as patches to the JavaSript engine, compared to in-band JavaScript instrumentation (e.g., prototype patching), has the unique advantage of being tamper-proof and impossible to detect by malicious scripts. However, it suffers from being tied to a specific browser implementation and requires additional manual work to be ported to new browser versions. For this reason, in this paper we opted for browser extensions, which allow, via the WebExtension API, cross-platform instrumentation that requires minimal to no effort to be applied to any extension-supporting browsers.

Similarly to VV8, JSgraph [24] is a patch to the Chromium source code that instruments the interface between Blink and V8, allowing for the recording of audit logs related to the execution of JavaScript in the browser. JSgraph aims to provide a detailed JS and DOM-related event log to aid in analyzing and reconstructing Web attacks. To this end, the tool includes a visualization component that shows the captured events in the form of a graph, highlighting causal relationship between events. JSgraph shares its main limitations with VV8, being tied to the specific implementation of the Chromium browser, requiring a substantial amount of manual work to

keep up with the constantly evolving browser code.

Formalization of Web Invariants. In their 2010 paper, Akhawe et al. [13] presented a formal model of the Web platform for the Alloy analyzer and used it to verify the security of Web mechanisms such as CORS, the Origin header and HTML5 forms, discovering three new vulnerabilities. The authors encode in the model a set of security goals which are grouped into *security invariants* and *session integrity*. In particular, they emphasize the importance to identify clear Web security invariants that define the desired security goals of the Web platform, proposing the definition of 4 invariants. More recently, Veronese et al. proposed WebSpec [33], a framework for the analysis of Web security mechanisms composed of a model of the browser in the Coq proof assistant and a toolchain for automated model-checking against Web security invariants. In particular, the authors define 10 Web invariants concerning cookies, the CSP and the CORS, discovering two new attacks and presenting a formal proof of the correctness of their proposed mitigations. Although our approach for the definition of new Web invariants presents some similarities to both works, previous research focused on models of the browser and not on specific implementations. By leveraging the WPT test suite, we can (i) automatically check the actual browser implementation behavior (i.e., execution traces) against Web invariants; and (ii) sidestep the issue of requiring to manually update a browser model to match the updates of the Web platform. Additionally, compared to previous works, we are the first to support Mixed Content, modeling its specification by defining two new Web invariants.

7 Conclusion

This paper presents a novel methodology for formally and automatically detecting security issues in browser implementations of client-side Web security mechanisms. Leveraging the WPT test suite, our framework collects browser execution traces and validates them using the Z3 theorem prover against Web security invariants. We formalized and encoded a total of 9 Web invariants and discovered violations within WPT, resulting in 10 unique attacks. We reported all our findings to the affected parties and kickstarted discussions with standardization bodies to address shortcomings at the specification level. This research positively answers our initial research question, showing that the proposed automated approach can provide valuable guidance to browser vendors in identifying vulnerable Web components requiring immediate attention.

A Encoding Known Web Invariants

We report in the following our encoding in first-order logic of the 3 invariants which were previously defined in the literature. For each invariant, we provide the natural language version of the property and its encoding in our model.

A.1 Integrity of Secure Cookies

The RFC dictates that it should not be possible to set cookies with the `Secure` attribute from insecure channels [19, §5.5]. This invariant has been previously formalized as part of the WebSpec framework [33] as follows.

Invariant (I.1)**.** *Cookies with the* `Secure` *attribute can only be set over secure channels.*

The invariant is encoded in our model as follows:

$$
\begin{aligned}
&\text{SECURE-COOKIES-INVARIANT}(tr) :=\\
&\quad t_2 > t_1 \wedge\\
&\quad \textbf{\textit{net-response}}(\_, url, \{\textit{set-cookie-headers}\}, \_)@_{tr}t_1 \wedge\\
&\quad \textit{set-cookie} \in \textit{set-cookie-headers} \wedge\\
&\quad \textit{name} +\!\!+ \texttt{"="} +\!\!+ \textit{value} \in \textit{split-cookie}(\textit{set-cookie}) \wedge\\
&\quad \texttt{"Secure"} \in \textit{split-cookie}(\textit{set-cookie}) \wedge\\
&\quad \textbf{\textit{cookie-jar-set}}(\textit{name}, \textit{value}, \{\textit{Secure=true}\}), \textit{false})@_{tr}t_2) \Rightarrow\\
&\qquad (\textit{url-proto}(url, \texttt{"wss"}) \vee \quad \textit{url-proto}(url, \texttt{"https"}))
\end{aligned}
$$

For every network response at time t_1 that leads to a cookie being set in the cookie jar (at time t_2) that has the `Secure` attribute set to *true*, then the protocol of the response *url* is either *https* or *wss* (i.e., it is a secure channel).

A.2 Confidentiality of HttpOnly cookies

The `HttpOnly` cookie attribute informs browsers that accesses to cookies with this attribute set to true by non-HTTP APIs, i.e., `document.cookie`, should not be allowed. This property was formalized in the literature [33] as:

Invariant (I.2)**.** *Scripts can only access cookies without the* `HttpOnly` *attribute.*

We encode the invariant as:

$$
\begin{aligned}
&\text{HTTP-ONLY-INVARIANT}(tr) :=\\
&\quad t_2 > t_1 \wedge\\
&\quad \textbf{\textit{cookie-jar-set}}(\textit{name}, \textit{value}, \{\textit{http-only}, \textit{secure}, \textit{domain}, \textit{path}\})@_{tr}t_1 \wedge\\
&\quad \textbf{\textit{js-get-cookie}}(\textit{ctx}, \textit{cookies})@_{tr}t_2 \wedge\\
&\quad \textit{name} +\!\!+ \texttt{"="} +\!\!+ \textit{value} \in \textit{split-cookie}(\textit{cookies}) \wedge\\
&\quad \textit{cookie-match}(\textit{path}, \textit{domain}, \textit{secure}, \textit{ctx-location}(\textit{ctx})) \Rightarrow\\
&\qquad \textit{http-only} = \textit{false}
\end{aligned}
$$

For every access to `document.cookie` in the domain *domain* at time t_2 that successfully returns a cookie previously stored in the cookie jar for the same domain (at time t_1) then the cookie's `HttpOnly` attribute has the value *false*.

A.3 Integrity of __Host- cookies

Browsers should enforce that cookies with a name prefix of `__Host-` are set with an empty *domain* attribute, making these cookies host-only. Effectively, these cookies can only be set by responses to the domain that created them or by scripts running in that domain. Veronese et al. [33] discuss this property of the `__Host-` prefix and propose the following natural language formalization:

Invariant (I.3)**.** *A* `__Host-` *cookie set for domain d can only be set by d or by scripts included in pages on d.*

We encode the invariant in our model as:

$$
\begin{aligned}
&\text{HOST-INVARIANT}(tr) :=\\
&t_2 > t_1 \wedge\\
&(\quad \textbf{\textit{net-response}}(\_, url, \{\textit{set-cookie-headers}\}, \_)@_{tr}t_1 \wedge\\
&\quad \textit{set-cookie} \in \textit{set-cookie-headers} \wedge\\
&\quad \texttt{"__Host-"} +\!\!+ \textit{cname} +\!\!+ \texttt{"="} +\!\!+ \textit{cvalue} \in \textit{split-cookie}(\textit{set-cookie}) \wedge\\
&\quad \textit{url-domain}(url, host) \quad) \vee\\
&(\quad \textbf{\textit{js-set-cookie}}(\textit{ctx}, \textit{set-cookie}, \_)@_{tr}t_1 \wedge\\
&\quad \texttt{"__Host-"} +\!\!+ \textit{cname} +\!\!+ \texttt{"="} +\!\!+ \textit{cvalue} \in \textit{split-cookie}(\textit{set-cookie}) \wedge\\
&\quad \textit{url-domain}(\textit{ctx-location}(\textit{ctx}), host) \quad)\\
&\textit{cookie-jar-set}(\texttt{"__Host-"} +\!\!+ \textit{cname}, \textit{cvalue}, \{\textit{domain}\}, \textit{false})@_{tr}t_2 \Rightarrow\\
&\quad \textit{domain} = host
\end{aligned}
$$

For every network response or access to Document.cookie property at t_1 that causes a `cookie-jar-set` event at t_2 which sets a `__Host-`-prefixed cookie, the effective domain of the cookie must be equal to the domain of the *url* of the network response or to the browsing context where the access to Document.cookie was performed.

B Test Selection

Table 6 reports the considered tests for our evaluation. In particular, we execute all `testharness.js` tests from the `d888ebb` version of WPT (Apr 2023).

C False Positives

In this section, we examine the false positives we obtained during our evaluation of the Web invariants against WPT traces and discuss their causes.

Incorrect event ordering
For one trace, our pipeline returned SAT for I.5 due to out-of-order events. Since our monitoring of network events is based on callbacks, which are subject to scheduling delays, and our monitoring of `CookieJar` events is polling-based, the order in which these events are collected may not match the concrete browser execution. Invariant I.5 matches a specific order of events, i.e., a `cookie-jar-set` event setting cookie *c*, followed by a cross-site network request that opens a page *p* where cookie *c* is not attached, and an access to cookie *c* from page *p*. Consider a concrete browser execution where a first network request leads to a cookie being set, which is then attached to a subsequent request. If the first two events are swapped in the trace, this incorrect trace can be matched by invariant I.5, leading to a violation.

Missing events from sandboxed iframes
Our pipeline reported SAT for the traces of the test `cookies/samesite/sandbox-iframe-subresource.https.html` on Chromium and Firefox for I.6. In this trace, a previously set cookie is expected to be attached to a network request from an iframe. However, since the `iframe` has the `sandbox` attribute, it cannot attach existing cookies to network requests. Since our instrumentation cannot observe events originating from sandboxed `iframes`, nor detect whether an

Table 6: Considered WPT tests.
Total: 24896, WPT Version: `d888ebb`

iframe is sandboxed, invariant I.6 cannot account for this behavior. In this trace, browsers correctly withheld a cookie that I.6 expects to be attached to a network request, leading to an invariant violation.

Missing delete cookie event

In some cases, our browser instrumentation is unable to detect cookie deletion events. Missing cookie deletion events cause some of the SAT results for I.6. Consider an execution where a previously set cookie *c* is deleted before a network request that would attach *c*, but the cookie deletion event is missing from the trace. I.6 will expect the cookie to be attached to the network request since, according to the trace, that cookie is still in the `Cookiejar`. However, since in the browser execution the cookie no longer exists, it is not attached to the network request, leading to an invariant violation.

Incorrectly tagged requests

For three traces, Z3 returned SAT for I.8 on Safari. These are caused by the lack of the request-type field in the Request object returned by the instrumentation for network events. In particular, a toplevel request to a URL which is not potentially trustworthy should be allowed. However, the absence of the request type makes the expression *type* = *main_frame* false in I.8, violating the invariant. Similarly, one Chromium trace violates I.6 since a network event in the trace is missing the *origin* field, i.e., the origin of the request initiator. Since the *origin* field is used by *cookie-should-be-sent* to determine if a SameSite cookie should be attached to a request, a request missing the initiator origin information and containing no cookie can be incorrectly tagged as violating when *cookie-should-be-sent* incorrectly (because of the missing origin) determines that cookies should be present.

Rise of Inspectron: Automated Black-box Auditing of Cross-platform Electron Apps

Mir Masood Ali, Mohammad Ghasemisharif, Chris Kanich, and Jason Polakis
University of Illinois Chicago, {mali92, mghas2, ckanich, polakis}@uic.edu

Abstract

Browser-based cross-platform applications have become increasingly popular as they allow software vendors to sidestep two major issues in the app ecosystem. First, web apps can be impacted by the performance deterioration affecting browsers, as the continuous adoption of diverse and complex features has led to bloating. Second, re-developing or porting apps to different operating systems and execution environments is a costly, error-prone process. Instead, frameworks like Electron allow the creation of standalone apps for different platforms using JavaScript code (e.g., reused from an existing web app) and by incorporating a stripped down and configurable browser engine. Despite the aforementioned advantages, these apps face significant security and privacy threats that are either *non-applicable* to traditional web apps (due to the lack of access to certain system-facing APIs) or *ineffective* against them (due to countermeasures already baked into browsers). In this paper we present Inspectron, an automated dynamic analysis framework that audits packaged Electron apps for potential security vulnerabilities stemming from developers' deviation from recommended security practices. Our study reveals a multitude of insecure practices and problematic trends in the Electron app ecosystem, highlighting the gap filled by Inspectron as it provides extensive and comprehensive auditing capabilities for developers and researchers.

1 Introduction

The contemporary client-side web programming ecosystem has enabled effectively effortless cross-platform web app development: a full-featured web app can present a unified experience across Linux, Windows, MacOS, or any other platform that supports a fully functioning modern browser. This ease of portability, along with the standardization of access to lower-level OS functionality through the Node.js platform, gave rise to Electron, a system that allows combining the open-source Chrome and Node.js projects with a developer's code to create a freestanding desktop app, which does not require access to a system browser or the Internet to provide its functionality.

While there are clear advantages to relying on these two incredibly well-engineered components, doing so introduces unique challenges. First, there are inevitable issues when using these software artifacts outside of the context for which they were designed. Second, the web platform's ubiquity and importance has resulted in it attracting significant malicious attention and, thus, substantial effort is put into the rapid release and distribution of browser updates. Finally, these artifacts are themselves massively complex (necessarily so), and using them as an abstraction upon which to build yet more complexity is a fraught endeavor.

In spite of these drawbacks, the benefit derived from fully cross-platform desktop apps that can reuse large parts of existing web-based interface code is substantial: Slack, Discord, Twitch, WhatsApp, and many more segment-leading companies distribute Electron-based desktop apps. Thus, it is important to more closely investigate the risks inherent in the use of the Electron platform. Relying on a stripped-down version of Chrome's engine results in certain security mechanisms not becoming available in a timely manner. More crucially, existing security protections that have been baked into web browsers for years now become a configurable option for developers; prior research has shown how developers struggle with correctly configuring or deploying security mechanisms [1–4]. This can also lead to a fragmented ecosystem where different apps have different versions of the underlying Chrome engine or Electron framework, akin to the fragmentation problem affecting the Android ecosystem [5, 6]. As web and mobile apps are known to lag behind the latest version of third-party libraries [7, 8], such patterns within the Electron ecosystem could expose users to significant threats. Because Electron apps package static versions of their upstream dependencies, attackers can leverage known exploits during the window between patching in Chrome and the distribution of new versions of Electron apps that incorporate the updated Chrome engine. Finally, cross-platform apps have additional capabilities compared to their web counterparts that are closer to those of native applications. Electron's security model aims to isolate web-facing

functionality from system-facing functionality; however, insecure developer practices and misconfigurations can lead to web-facing code influencing system-facing functionality.

While many weaknesses of the Electron platform can be mitigated through proper use of tools like Elecronegativity or defenses against specific classes of attacks [9, 10], there is a clear necessity for a system that is both dynamic and automated, which can continually investigate a more comprehensive range of failure scenarios than existing tools. To this end, we develop Inspectron, a framework designed for uncovering the misconfiguration of security mechanisms, or the lack thereof, in Electron apps, through an automated black-box auditing process. Our automated black-box system uses instrumented versions of Electron to detect and report on information flow in various entities that could affect an app's security. These entities include Inter-process communication (IPC), page navigation, and cross-context JavaScript execution. Our system locates the binary executable and determines the version of Node.js in use. It then uses Puppeteer to run the application on the instrumented Electron, enabling us to dynamically perform automated client-side checks.

In summary, our work makes the following contributions:

- We build Inspectron, a dynamic, black-box framework that audits Electron apps for 16 classes of misconfigurations without source code access, by detecting the runtime behavior of apps and gathering the evaluated definitions of function calls, event handlers, and framework preferences.
- We evaluate 109 Electron apps and find an array of issues in the implementation of various framework components, while outperforming the state-of-the-art.
- We perform a more comprehensive examination of 10 popular Electron apps by including pre-recorded user interaction traces, and find vulnerabilities in four apps and two instances of incorrect implementations of web standards by the Electron framework.
- We have responsibly disclosed our findings to the affected vendors, which has already resulted in a series of patches.

2 Background

The process model adopted by the Electron framework largely splits the app into two differently privileged contexts [11] (see Figure 1). This design is based on the motivation that a single process that renders arbitrary, insecure content could make the app susceptible to malicious code. Instead, Electron renders each new frame in its own process, while a single privileged process controls them and the app as a whole.

System-side (Main) process. This is the privileged process that controls the app, and has access to system-level functionality, including the native operating system's UI and Node.js modules. It also creates and interacts with less-privileged renderer processes. To protect sensitive user resources, the framework restricts access from third-party resources loaded in renderer processes.

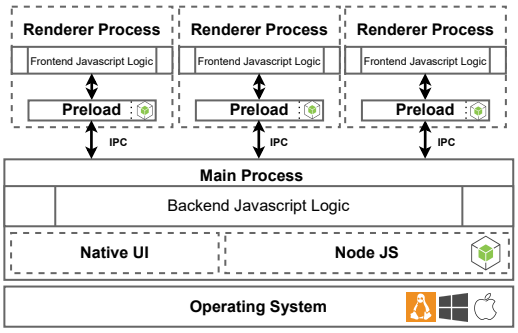

Figure 1: Architecture of Electron apps.

Renderer process. Each window (or embed) that is opened spawns a separate renderer process. Electron uses Chromium's Blink engine [12] to render web content – from HTML, CSS, and Javascript – within these windows. The execution logic within a renderer process can not directly access Node modules and, instead, interacts with the main process for requesting actions that need additional privileges.

Communication between processes. *Preload scripts* are used to expose functionality from the main process to a renderer process in two ways: (i) *Shared* `Window` *object.* Preload scripts in the renderer process have access to the global `Window` object and specific Node.js APIs. Scripts can wrap Node-based functionality and set global variables for the embedded web content to access. (ii) *Inter-process Communication (IPC).* Scripts can create new events on an IPC channel, and pass information between a renderer process and the main process. This allows the main process to securely handle privileged execution by verifying incoming messages. Next, we describe Electron's various security and privacy features, including those that the framework inherits from Chrome and instances where it deviates.

Web Preferences. Each new web embed (including a pop-up/webview/iframe) creates a corresponding `BrowserWindow` object that inherits the parent window's preferences by default. These include restrictions on the window's functionality. Appendix A.1 provides several detailed examples as well as their corresponding security implications.

Navigation Handling. While websites loaded within the browser regularly navigate away to different websites, this type of navigation is often considered undesirable within such an application. The Electron framework does not, by default, restrict any window from navigating to different domains or from opening new windows. Instead, developers may handle and verify navigation within their apps using several methods.

Content Security Policy (CSP). CSP is a security feature that allows developers to specify which resources a webpage can load and which sources of executable code are considered trusted. Developers can use CSP to block requests to external domains or to prevent the execution of untrusted code. By default, Electron does not implement a CSP on the web

content loaded within an app, and instead recommends that developers add their own implementations.

Sessions and Cookies. Web content is loaded within a default, persistent session that handles any information stored within cookies, storage, and other caches. As these sessions are managed by the app, information accessed from any third-party content can be directly managed by the app itself.

Cookies in the main process. While partitioning restrictions exist within the renderer process, the main process can access all cookies loaded within the app. The app can additionally alter session cookies to make them persistent, and also access HttpOnly cookies using Javascript code.

Origin partitioning. The renderer process inherits partitioning from Chrome. Any third-party content loaded in an iframe is limited in its interaction with the top-level browsing context, and can only access its own cookie jar.

Plaintext cookies. While the Chrome browser encrypts cookies when stored in the filesystem, Electron apps store them in plaintext by default. The framework offers an optional *fuse* in case an app intends to encrypt cookies.

Permissions. Electron inherits Chrome's permission API and handles the same types of permissions [13]. However, unlike Chrome, the framework automatically approves all permissions. Developers have the option to prompt users to request access, and are encouraged to explicitly handle permission requests to avoid providing default access to third-party content loaded within the application. Below, we describe how Electron's implementation diverges from Chrome's.

Media Device Access. Within both Chrome and Electron, access to media devices can be made by calling `navigator.mediaDevices.getUserMedia()`. While approving permission access, Electron lets developers either grant access to all media or deny any access, without individually allowing access to the webcam, microphone, or screen.

Screen Recording. Chrome makes access to the screen available through a different API call, i.e., `getDisplayMedia()`. However, Electron requires access to screen recording through a separate `desktopCapturer` object that developers need to expose from the main process, and the renderer process can make the same API call used to access other media, `getUserMedia()`, with different constraints passed in the arguments. Electron's requirement to explicitly expose screen capture makes it more secure from third-party access.

File System Access API. The WICG directive recommends restricting the files that can be picked to be loaded by the user to avoid picking sensitive files under the root or `/etc` folders [14]. Chrome implements this restriction to content loaded within the browser but Electron does not enforce such a restriction.

2.1 Threat Model

Due to the distinct nature of Electron apps, prior to conducting our research we first examined more than 50 vulnerability

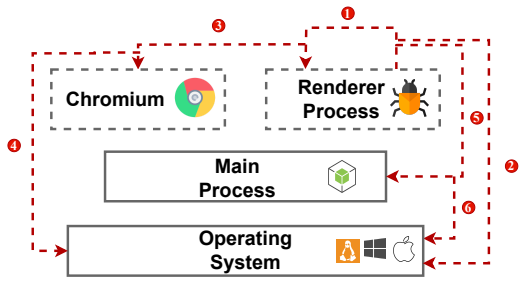

Figure 2: An overview of the threat model is shown here.

reports that have been submitted to various Electron apps over the past 7 years [15]. In this preliminary analysis we summarized and categorized potential avenues for exploiting vulnerabilities; these exploitability patterns helped define our threat model and also guided our design of Inspectron. In this work, we encapsulate knowledge gathered from a wide-range of attack vectors into a comprehensive testing framework. While the attack vectors have been demonstrated in real-world exploits, to the best of our knowledge, Inspectron is the first *dynamic analysis* tool that extensively evaluates Electron apps for these vectors. Additionally, Inspectron's analysis includes five attack vectors that are not considered by Elecronegativity, a state-of-the-art static analysis tool (discussed in §4.1 and Appendix A.3). The Electron framework encompasses multiple components and, as a result, the majority of reported exploits stem from the interconnectedness of bugs across these different components. We detail a motivating example in Appendix A.2. Below, we describe our threat model, which covers different paths for exploiting vulnerabilities in Electron apps. We consider an attacker that is either (1) a user of the application attacking another user, or (2) a malicious third-party component loaded within the app, e.g., scripts loaded from third-party libraries, content loaded within iframes and webviews, and third-party webpages to which the app permits in-app navigation. Figure 2 serves as a point of reference and offers a high-level overview.

Code Execution in the Renderer Process. In Electron apps, external users and externally-sourced third-party resources engage with the application's logic through the renderer process. By gaining control over code execution within the renderer process, attackers can begin compromising the security of other components of the application. When attempting to execute code within the app's existing user-facing window, various techniques can be employed. For instance, unsafe Content Security Policy (CSP) configurations can create an avenue for executing cross-site scripting (XSS) attacks. Another approach involves taking over third-party resources, and leveraging their vulnerabilities to execute malicious code. Additionally, bypassing input sanitization measures can enable the injection and execution of harmful code within user-facing components. Safeguarding against these vulnerabilities necessitates implementing secure

CSP configurations, robust input sanitization practices, and stringent controls on the interaction with third-party resources. To execute code on a different page or window, attackers need additional strategies. One method involves bypassing restrictions to navigation to malicious third-party sites, allowing them to load and execute code within a different page under their control. Similarly, opening these sites in a new window or frame can enable executing code outside the confines of the current window. Once an attacker finds a way to execute code within the renderer process, they can then chain their attack by taking one of the following routes.

❶ → ❷ **Privileged Renderer Process.** The renderer process can have direct access to Node.js modules. Additionally, when sharing a context with preloaded APIs, the renderer process can use prototype pollution attacks [16] to also gain direct access to Node.js modules. Direct access to Node.js modules within the renderer process can help malicious code compromise the underlying system.

❶ → ❸ → ❹ **Chromium-based Exploits.** Chrome regularly releases reports on vulnerabilities discovered within the Blink and V8 engines, which are the underlying components powering the browser and, consequently, Electron apps. Despite the fact that the Chrome team promptly releases patches and updates for their browser to address these vulnerabilities, app developers who rely on older versions of the Chromium framework may remain exposed to these exploits. These vulnerabilities capitalize on the inner workings of the Blink and V8 engines, thus enabling attackers to directly execute shell code on the underlying system.

❶ → ❺ → ❻ **Incomplete Checks in the Main Process.** In the absence of vulnerabilities enabling one of the previously described exploitation approaches that require a privileged renderer process, this route offers an alternative exploit that takes advantage of incomplete checks in the main process. Malicious code may take advantage of a lack of checks on the origin of inter-process communication (IPC) messages, including oversight in responses to messages from the Preload API. Additionally, they may exploit the use of incomplete checks on the use of custom protocols during navigation, and sanitization errors in cross-context JS execution.

3 Inspectron: Design and Implementation

Here we detail the design and implementation of Inspectron. Figure 3 provides an overview of our system and workflow.

❶ **Packaged App.** Electron apps are distributed with varying directory structures depending on the target OS. Depending on the distributable, Inspectron temporarily mounts the packaged app and extracts relevant files. Inspectron accesses app-specific logic from a `resources` directory, which is also the directory from where Electron accesses source code [17]. It then identifies the app's binary executable file, which is used for version checks. When the binary file is executed as a Node.js process using the `ELECTRON_RUN_AS_NODE` command line flag, Inspectron can access and use the `process.versions` object to determine the Node.js version that the app uses. This object contains key-value pairs that indicate the Node.js version, the V8 JavaScript engine, and other modules used to build the app.

❷ **Instrumented Electron.** Electron has a different app Binary Interface (ABI) from a Node.js binary. Therefore, while Electron supports developers using native Node.js modules, those modules must be recompiled [18]. As a result, the app-specific code extracted from the `resources` directory in the previous step can only be run against an Electron binary compiled with the same Node.js module version. Our instrumented version of Electron modifies relevant functions to output the status of specific variables and arguments when called, enabling Inspectron to identify and report on points of interest.

Web Preferences. Developers can customize the behavior of each page in a window or frame using the `webPreferences` property, enabling or disabling features such as `nodeIntegration`, `contextIsolation`, and `sandbox`. These features impact available privileges, and developers must evaluate them correctly throughout their app. Inspectron checks 12 security-related web preferences.

Command-line Switches. These can be used to configure an Electron app, enable or disable features, modify its behavior, or set debugging options. Inspectron provides runtime reports on the setting of 33 command-line switches.

Navigation Handling. Navigation can be constrained by adding event listeners to each opened window, so as to ensure users stay within the app's domain. The built-in `will-navigate` event allows intercepting and verifying navigation requests before being sent, enabling URL modification or cancellation. Additionally, developers must handle the `new-window` event by either preventing its opening or creating a new window with secure preferences. Even though the `new-window` event is deprecated in Electron v22, it remains relevant for apps that have yet to update their frameworks.

Inter-process Communication (IPC). In Electron, IPC is commonly used to communicate between the main process and the renderer processes. The main process controls the app's lifecycle and manages system resources, while the renderer processes handle rendering the user interface. Developers can share data, trigger events, and invoke methods using IPC messages. To ensure security, Electron recommends verifying the sender of IPC messages to prevent potential threats. If the sender is not trusted, the message should be rejected, preventing potential security threats [19] and ensuring the integrity of IPC messages. Inspectron reports and highlights custom IPC calls that require further evaluation to ensure that the sender of a message is always verified.

Cross-context JS Execution. Using `executeJavaScript()` developers can explicitly enable the injection of JavaScript from the main process to a renderer process. However, when user-supplied arguments are used with these functions, they can potentially execute harmful content and modify the app's

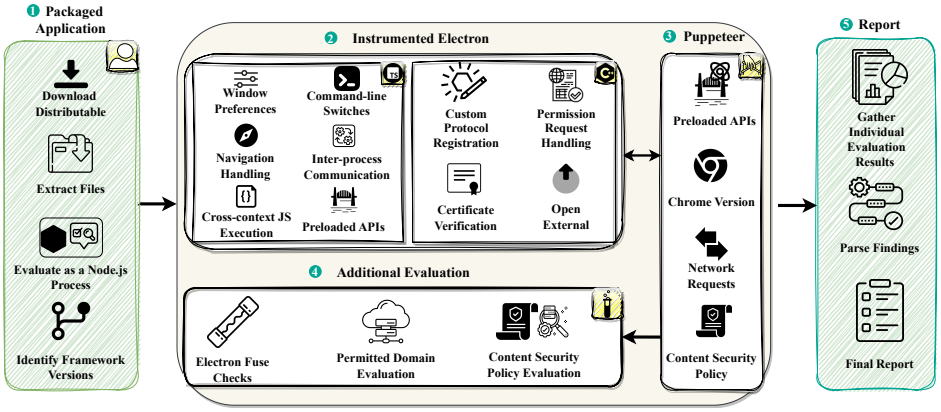

Figure 3: Inspectron's components and auditing workflow for evaluating Electron apps.

behavior. To mitigate this risk, it is important to verify the use of such functions with dynamic arguments. When the calls to `executeJavaScript()` are triggered, Inspectron reports on the use of such functions for further evaluation.

Preloaded APIs. Preload scripts and Electron's `contextBridge` can be used to expose functionality across contexts, set up custom event listeners, inject CSS styles and JavaScript code, and modify built-in browser APIs. Since APIs may be exposed as arbitrary objects and functions on the client-side `window` object, our framework collects all calls to the `contextBridge` available at a singular endpoint. Unlike the aforementioned checks, calls made to the `contextBridge` involve the renderer process and therefore cannot be directly reported to a file. Inspectron instead collects them in a global variable, `window.reportExposedAPIs`, which can be accessed by a Puppeteer script.

Custom Protocol Registration. New URI schemes can be registered for handling app requests, especially for custom network protocols or unavailable resources via HTTP/HTTPS. Custom protocols should be carefully considered when handling navigation, verifying IPC messages, and overriding certificate verification. Inspectron reports on custom protocol registrations to consider during the evaluation of other checks.

Permission Request Handling. Electron grants complete access to devices such as the camera, microphone, Bluetooth, and screen by default. It is recommended that developers explicitly handle permission requests. Inspectron reports on whether an app properly handles incoming permissions.

Certificate Verification. When loading resources over HTTPS, it is important to verify X.509 certificates - a functionality that is baked into Electron by default. However, developers may opt out of these checks and handle specific domains differently, especially during development. Inspectron reports on overrides of certificate verification.

Open External. Electron apps can open external apps or files using the system's default apps. This is useful for displaying content outside the app, like opening external links or viewing files. The `openExternal` function can also launch email or calendar apps for user interaction. However, it is important to verify and sanitize values passed to this function to prevent misuse and potential security risks. Inspectron reports on `openExternal` invocations for further analysis. Since calls to this functionality are made within the main process, we cannot automatically trigger them from a Puppeteer script. However, the function is often called when limiting in-app navigation, and we manually evaluate navigation handlers to identify any additional sanitization that they may perform before passing links to the system.

3 Puppeteer Script. Remote debugging can be enabled in Electron by specifying a port number during app launch. This allows using debugging tools like Chrome DevTools to inspect and debug the app from a remote device. We run each app with an instrumented version of Electron and a debugging port, and attach a Puppeteer script for client-side checks.

Preloaded APIs. The instrumented version of Electron collects functionality exposed via the `contextBridge` and makes it available at `window.reportExposedAPIs`. The Puppeteer script accesses this global variable on the client-side and adds it to our framework's report.

Chrome Version. In addition to collecting the underlying libraries in Step 1, the Puppeteer script reports on the Chrome version used by the app by parsing the `navigator.appVersion` object on the client-side.

Network Requests. The Puppeteer script intercepts all network requests performed within the app, and gathers a list of all accessed domains for further analysis.

CSP. Electron recommends that developers set a CSP on each window within their app, as it can greatly reduce the risk of XSS attacks. Developers can set a CSP policy using either a meta tag or HTTP headers. The meta tag approach is the same as with web pages loaded in a browser, i.e., it involves adding a `<meta>` tag to the app's HTML file with the `http-equiv` attribute set to `Content-Security-Policy`. The content attribute of this tag then contains the CSP rules in the form of

a string. Alternatively, developers can use HTTP headers to set the CSP for the app. Electron recommends [19] adding an event listener within the main process, `onHeadersReceived`, to intercept network requests made from the app. Developers may then add or modify response headers to ensure that the `Content-Security-Policy` header includes rules specific to the app. Since Electron provides methods for app developers to modify CSP within HTTP response headers *after* they have been received by the main process, network logging approaches such as proxies and Chromium's `netLog` command-line flag will fail to capture such modifications. However, our Puppeteer script observes network responses after developer modifications, and accurately captures the responses received by the renderer process.

❹ **Additional Checks.** Once the app has been analyzed using the instrumented Electron and Puppeteer script, we perform more checks that do not require running the app.

CSP Evaluation. Inspectron evaluates the CSP captured from the Puppeteer script using Google's CSP Evaluator [20]. The library parses policy rules and recommends ways to harden them, and it includes support for backward compatibility with older versions of CSP.

Permitted Domain Evaluation. While Inspectron gathers a list of domains from network requests and CSP rules, we evaluate these domains in two ways. First, it identifies apps that load solely from packaged, local files instead of gathering remotely loaded content. Next, considering remotely loaded resources, the tool visits these domains using XSStrike [21], and reports on the use of Web App Firewalls and evaluates reachable domains for potential DOM XSS.

Electron Fuse Checks. This is a feature subset that enables developers to dynamically disable default functionality in production apps. Fuses are security flags that determine enabled and disabled features at runtime. Inspectron reports on the use of fuses to determine if apps explicitly enable the encryption of cookies stored on the disk with OS level cryptographic keys. If an app stores cookies in plaintext, malicious access to files from within the app, and other software on the user's system, can read or modify the sensitive information stored in the app's cookies.

❺ **Report.** The results of all evaluations performed in Steps 2, 3, and 4 are stored across multiple files and in varying formats. Inspectron reads and evaluates the results of individual tests and combines them in a single, parsable report. The final report of the analysis highlights scenarios and configurations of relevant checks that require further evaluation of misconfigurations that can result in potential vulnerabilities.

The report generated by Inspectron highlights insecure practices within packaged apps. However, it is important to note that these findings do not verify that the app is entirely exploitable. Rather, they indicate the presence of problematic practices that could potentially be exploited; in certain cases that could involve chaining together multiple insecurities in the context of the app's specific architecture. In the next section we report on how such practices are not isolated incidents, but rather indicative of a broader ecosystem-wide problem.

4 Evaluation

In this section, we present our extensive experimental evaluation of Inspectron, as well as the results from our black-box auditing study of the Electron app ecosystem.

Terminology. We first define the terminology we use.

Insecure practices. Individual checks included in the reports generated by Inspectron highlight known, insecure practices. The report highlights app configurations that Electron warns against and scenarios that have been used in prior exploits [19, 22]. However, these reports represent flaws and do not prove that apps can be exploited in practice.

Exploits. Apps that adopt insecure practices can potentially be exploited when these practices are considered in the context of individual configurations and use cases. Creating proof-of-concept exploits requires manual effort, which we demonstrate for a subset of our findings. Unless stated otherwise, the findings presented in this section highlight insecure practices. Within descriptions of checks for individual insecure practices, we present examples of potential exploits.

False Positives. We consider the incorrect inclusion of insecure practices in reports to be false positives (i.e., reporting an insecure practice when the app actually does something securely). In our test set of 109 apps (see **App Dataset** below), we manually verified every detection and confirmed that none were false positives.

Electron Dataset. A crucial element of Inspectron relies on utilizing an instrumented version of Electron. As mentioned in §3, Electron apps can only be evaluated against an Electron version with a matching app Binary Interface (ABI). Consequently, we developed multiple instrumented versions, each corresponding to a major release version of Electron and the underlying platform, such as Linux or MacOS. To facilitate this process, we employed an existing wrapper [23], which streamlined the synchronization of relevant dependencies, while also enabling the retrieval of specific Electron and Chromium versions for each build of the Electron source code. It is worth noting that even though older versions are accessible, they are no longer actively maintained. As a result, when we encountered difficulties in retrieving all the required files to construct a specific version of Electron, we discontinued the build process. We encountered this challenge when attempting to build Linux-specific Electrons $<$v13, as certain underlying Debian build files were no longer available or accessible. For each version, we obtained the Electron source code, instrumented specific TypeScript and C++ code, and rebuilt the framework. Subsequently, we extracted the resulting distributable for the respective version and platform. Through this process, we successfully created a dataset comprising 24 instrumented versions of Electron

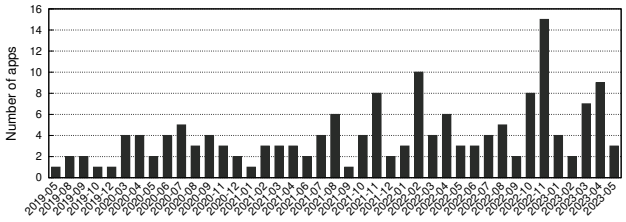

Figure 4: Release date of the Electron binary used by the latest version (as of May 2023) of the apps audited by Inspectron.

(v14-v24 for Linux, v12-v24 for MacOS), which we then used for the analysis described in this section.

App Dataset. The Electron website provides a showcase of apps that have been developed using the framework. This showcase lists a diverse array of apps, including both new and old releases, commercial and free downloads, as well as packaged and open-source projects. Through a manual investigation of 282 apps' pages, and after filtering out apps that were unavailable, discontinued, incompatible with Linux and MacOS, or required some form of payment, we successfully downloaded 167 apps, each of which we further examined to determine their underlying Electron version. The findings of this evaluation are presented below. Subsequently, from this collection, we identified 109 apps for which we had successfully built an equivalent instrumented Electron version to test against, which we use for the remainder of our analysis.

Electron Versions. We conducted a comprehensive evaluation of the underlying Electron framework versions utilized by a total of 167 downloaded apps. Electron regularly releases new stable versions every eight weeks [24]. The latest stable version available at the time of this writing (May 2023) was v24, which had been accessible for a minimum of four weeks before our testing. Furthermore, Electron offers support for up to four stable major versions, implying that apps relying on versions as low as v21 could potentially receive updates if required [25]. However, our findings, shown in Figure 4, reveal that apps depend on Electron versions that are up to four years old, with the majority of them relying on releases between six months and two years prior to our analysis. It is worth noting that Electron strongly recommends that developers keep their apps up to date with the latest release [19], as that ensures the incorporation of numerous security fixes for Chrome, Node.js, and the framework itself. Unfortunately, as we discuss below, our analysis reveals that a significant number of apps use older versions of Electron which remain vulnerable to well-known exploits, even if developers adhere to the best security practices available for the older Electron version they rely upon.

Web Preferences. As aforementioned, each new frame or window within an Electron app possesses a set of preferences that determine the privileges and functionality available to the web content. While Electron advises limiting these preferences [19], our observations unveiled a significant number of apps that explicitly enabled functionalities that could exacerbate compromises on the renderer process (see Table 1). We discovered that the majority of apps ($n = 54$) failed to isolate the context between their preloaded scripts and the renderer process, thereby leaving them vulnerable to exploits like prototype pollution attacks that have been previously documented [26]. Surprisingly, we observed that 8 applications expicitly disabled `web security`, thus disabling the enforcement of the Same Origin Policy (SOP), arguably the most fundamental web security measure. Developer-focused apps like Postman [27] (an API development app) and Altair GraphQL [28] (a GraphQL server debugging app) disable SOP to allow interaction with different endpoints, and include additional measures like CSPs and restricted windows to limit its impact. This also helps apps (e.g., IPTVnator [29], a TV streaming app) easily host content from multiple external services, but still reduces their overall security. More concerning was the discovery that out of the 109 apps analyzed, 49 of them granted the renderer process complete access to Node.js functionality. This configuration allows malicious code within the renderer process to import any Node.js module and directly execute shell commands on the user's system. It is essential to emphasize that these options are disabled by default, indicating that developers deliberately chose to override the app's inherent security measures in favor of enhanced functionality.

Table 1: Insecure Web Preferences detected by Inspectron.

Web Preference	Insecure Value	# Apps
Node Integration	True	49
Context Isolation	False	54
Sandbox	False	64
Web Security	False	8
Allow Running Insecure Content	True	6
Disable Popups	False	64
Enable WebSQL	True	81
Javascript	True	83
WebView Tag	True	15

Reliance on Insecure Defaults. Over time, the Electron framework has made significant strides in enhancing its security measures. Notably, certain preferences such as `nodeIntegration` and `contextIsolation` have been transitioned to secure defaults since v5 and v12 of Electron, respectively. However, it was not until v20 (Aug. 2022) that Electron introduced sandboxing of processes as the default behavior; prior to this, it strongly recommended that developers implement sandboxing. As the majority of apps are built on older versions of Electron, we found that a significant number of developers ($n = 64$) have left their processes unsandboxed, potentially exposing their apps to exploits. We made similar observations regarding developers enabling WebSQL, despite it being a largely-deprecated storage mechanism that is infrequently used in modern browsers [30].

Despite its diminishing relevance, many developers ($n=81$) still enabled WebSQL in their Electron apps. We further found popups being commonly allowed in the renderer processes ($n=64$), effectively permitting the creation of new windows. These observations highlight the prevalence of certain insecure practices that undermine the overall security posture of Electron apps, warranting a closer examination.

Limiting Preferences on WebViews. Each new window or frame possesses its own set of associated preferences; consequently, when a window in an app loads external content in a WebView, the WebView inherits the preferences of its parent by default [31]. However, a malicious WebView has the capability to create new renderer processes with elevated privileges, regardless of its parent, enabling the execution of code on the underlying system. To mitigate potential security risks, Electron recommends that apps actively listen for the new creation of each WebView as it is attached, and explicitly impose limitations on the available preferences. By doing so, developers can exert greater control over the behavior and permissions of WebViews within their apps. However, out of the 15 apps that utilized WebViews, only 4 implemented the recommended practice of listening to the relevant event and enforcing preference limitations.

Command-line Switches. Developers have the option of overriding app-wide defaults and controlling runtime flags that can be passed to Node.js-based and Chromium-based processes. Most apps we evaluated resort to defaults and do not enable experimental, command-line switches. However, we found 3 apps that increased V8's garbage-collected heap size available at runtime [32]. Overriding the heap space taken up by the application and improper garbage collection can affect the system's memory use. We observed 10 apps that disabled default features offered by Chromium.

Cross-Origin-Opener-Policy (COOP). The COOP HTTP response header aims to improve isolation between documents and origins by requesting a new browsing context and process, which can help mitigate exploits like cross-window and process-wide attacks [33]. These types of attacks can occur when a loaded document shares a browsing context and process with cross-origin documents, potentially allowing malicious code to leak data. The COOP header aims to mitigate these issues by allowing loaded resources to sever all references to other browsing contexts, making it easier for browsers to load documents in a new process, preventing attacks like Spectre. Three of the apps that we evaluated, Colibri (a browser) [34], Ferdi (an app-in-app ecosystem) [35], and Biscuit (a browser) [36], explicitly disabled support for this feature, thereby rendering their apps vulnerable.

Out-of-Blink CORS. The Cross-Origin Resource Sharing (CORS) protocol is an established web standard used to safeguard servers against unexpected cross-origin network accesses [37]. Previously, Chrome implemented this protocol within the rendering engine, Blink, which ran in a renderer process. However, the Out-of-Blink CORS feature, enabled by default since Chromium v83, moves the inspection of network accesses out of the renderer, to be handled by a separate process, the network service. This change was motivated by several historical design, reliability, and security issues [37, 38]. However, Advanced Rest Client (a developer tool) [39] explicitly disables this feature.

Navigation Handling. When a user interacts with an Electron app by clicking on third-party links or triggering code execution that modifies the `window.location` or opens new windows, Electron generates events (`will-navigate` and `new-window`) that, if not handled, cause these links to open within the app similarly to browsers. This behavior can be problematic for both functionality and security. To address this, developers need to actively listen to these events and ensure that users remain within the designated app pages. However, our evaluation of 109 apps revealed that only 24 of them implemented navigation limitations. Furthermore, only 32 prevented the loading of arbitrary content in new windows. This situation is concerning, particularly because when pages fail to restrict navigation, the third-party domain loaded within the same window gains access to additional preloaded APIs. This access enables interactions with the main process, which would typically be unavailable within a web browser. Additionally, when new windows are opened, these windows have the ability to create further windows with extended privileges and relaxed security boundaries. Therefore, the lack of proper navigation restrictions and content loading prevention poses a significant risk.

Use of deprecated event handlers. In Electron v22 (Nov. 2022), the `new-window` event was deprecated [40]. Prior versions included warnings about this deprecation, and in newer versions Electron requires developers to handle the creation of new windows using `setWindowOpenHandler()`. However, this has not yet been widely implemented in existing apps. Inspectron found that only 23 apps incorporated handlers using the new approach, while 11 apps continued to rely on the deprecated event, which is compatible with their older versions of Electron. It is crucial that these 11 apps adopt the new approach when they eventually update their version of Electron, to ensure that their checks remain effective.

Inter-process Communication. Electron's renderer process is inherently limited in its privileges. However, apps can utilize IPC calls to delegate privileged execution tasks to the main process. Nonetheless, a compromised renderer process can potentially exploit these IPC channels to trigger malicious functionality. Therefore, it is crucial for developers to implement sender verification mechanisms before executing relevant code based on IPC messages. We discovered that 43 apps established custom IPC channels to their renderer process. We manually verified the handlers used by these applications and determined that only 13 of these apps implemented sender verification. In the remaining 30 apps, a compromised renderer process would have unrestricted access to trigger IPC channels without any checks in place.

Preloaded APIs. We found 19 apps that exposed select additional functionality from the main process to the renderer process, using a context bridge. Of these, 7 apps did not isolate contexts between the preload script and the renderer process. Note that in the absence of context isolation, the renderer process can gain access to Electron internals and Node.js APIs by compromising the preload script. This can be achieved through prototype pollution attacks [16] that override definitions of built-ins like `Array` or `Object` to take control over the execution of the preload script [26].

Custom Protocols. When utilizing custom non-standard protocol handlers for requests that target internal functionality (which may even be registered by third-party libraries like Sentry [41]), developers must consider the associated values when implementing navigation restrictions. We found 36 apps that register custom protocols; upon manual inspection, we found that only 4 of them also take into consideration requests involving custom protocols when determining whether to allow or prevent navigation attempts.

Permission Request Handling. In contrast to Chrome, Electron approves any request made to hardware devices, such as the camera, microphone, and screen. However, developers can add handlers that prompt users for permission and verify the integrity of incoming requests. Inspectron found only 11 apps that handled permission requests, while the rest granted access by default, further highlighting the prevalence of insecure defaults in Electron apps. For example, Wordpress [42], which allows users to manage their websites, should not need the screen-recording and microphone permissions. However, it permits in-app navigation to external domains, which can access the user's device, including camera, microphone, and screen, without prompting the user.

Certificate Verification. While Electron handles the verification of X.509 certificates by default, apps have the option to proceed with network requests despite errors in certificate verification. We found 8 apps that overrode and logged such errors instead of resorting to Electron's default behavior. Upon manual verification we observed that the apps overrode certificate errors only for specific domains.

Open External. The `openExternal` functionality enables developers to open links or files using the operating system's defaults, rather than within the Electron app itself. This feature is particularly useful for handling links or files that should be opened outside the app, such as URLs or local files that require specific apps. However, it is crucial to ensure proper verification and sanitization when utilizing this functionality, as Electron passes the link to a shell command in the underlying operating system (example, `xdg-open` in Linux). During our evaluation, we identified 56 apps that made use of this functionality. We additionally examined the navigation handlers that were previously highlighted. Surprisingly, we discovered that *none* of these handlers perform any additional URL sanitization when passing it to the shell command. Consequently, while this practice prevents external links from opening within the app, it can result in passing malformed or even malicious links directly to the underlying system. To mitigate these risks, it is imperative that developers implement thorough verification and sanitization measures even when these links do not directly concern the app's functionality.

Content Security Policy (CSP). CSP is an important safeguard against cross-site scripting and data injection attacks, as it grants developers control over which resources are allowed to be loaded, thereby reducing the risk of unauthorized or malicious content being executed. In our evaluation of 109 apps, we discovered that only 18 apps had implemented a CSP. However, upon further analysis using Google's CSP Evaluator [20], we found that the CSPs of 16 of these apps returned warnings. Of these, 15 apps included a directive with an attributed severity value of 50, associated with a possible medium severity finding.

Cookie Encryption. Starting from Electron v15 (Sept. 2021), developers can encrypt cookies stored on the user's file system [43]. However, Inspectron found only two apps (Front [44] and Slack [45]) doing this, while all other apps stored cookie values in plaintext. This poses a significant security risk since, in contrast to mobile platforms, these files will be readable to essentially any other process being executed. Upon manual evaluation, we found 66 apps that store sensitive information, including information necessary for authentication/sign-in (e.g., ChatWork [46], an enterprise team chat application, and Wordpress [42]).

Popular apps. We also perform a more in-depth examination of 10 popular Electron apps. First, we download multiple historical versions of each app and report on the frequency of their updates. Next, for each app we consider the latest available version as of May 2023, and employ proof-of-concept exploits affecting V8 and Blink to verify if these bugs have a trickle-down effect on Electron apps. Finally, we augment Inspectron with pre-recorded user interaction traces to increase coverage (see Appendix **??**).

User Interactions. These apps have unique features and capabilities, so we developed a series of custom-tailored user interaction patterns. These include actions such as (a) signing in, (b) opening and closing tabs and windows, (c) engaging with and providing text input (e.g., within messaging interfaces), (d) interacting with and uploading files (e.g., media attachments), and (e) clicking on links within the app. These additional interactions enabled Inspectron to provide more extensive reports. To facilitate further research and analysis, we will make these interactions available upon publication.

Historical Versions. Beginning in September 2021, Electron moved to a new release cadence, with a new stable version released every 8 weeks, following Chrome's Extended Stable release cycles. As a result, Electron keeps up-to-date with alternating Chrome releases [24]. These regular updates are intended to help Electron-based apps stay updated with upstream fixes, including from Chrome, in terms of performance and security. While our larger analysis showed

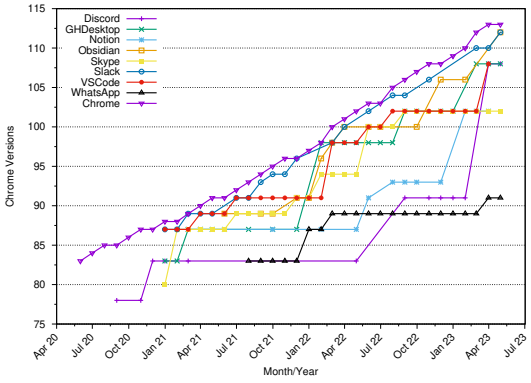

Figure 5: Distribution of Chrome versions of popular apps.

Table 2: Comparative impact analysis of various CVEs.

Apps	Chrome \ CVE	2021-30632 (High)	2022-1364 (High)	2022-3656 (Medium)	DiffCSP [47] –

** Vulnerable to `'javascript:alert()'`. We expand upon this in the text.

that apps rarely use the latest Electron version, this is also the case with widely popular apps. We gathered the release versions of 8 popular apps between August 2020 and May 2023, and matched their underlying Chromium versions.[1] An overview of our findings is presented in Figure 5. Despite Electron's regular releases, these apps are consistently behind the latest version of Chrome. Additionally, each app follows its own release and update cycle, independent of Electron and Chrome. As a result, security fixes and updates remain unfixed and known vulnerabilities remain exploitable for months before apps update to newer versions.

Chrome Version and V8/Blink-based Exploits. Electron apps also depend on Chrome's implementation of V8 and Blink. Chrome regularly receives high-severity exploits of these components, with some attacks even granting remote code access to the user's system [48]. As a result, when bugs are reported in these components, they also affect Electron. While Chrome quickly ships patches, Electron apps can only take advantage of these patches if and when they update to the latest version of Chrome available in Electron. Next, we chose three CVEs with publicly available proof-of-concept exploits. These CVEs make use of vulnerabilities in V8 and Blink and have known usage in Remote Code Execution (RCE) attacks. In Table 2, we show that the latest available versions of Wordpress, Postman, and WhatsApp desktop apps are vulnerable to exploits that are up to 2 years old as of May 2023. First, we identified the underlying version of Chrome that each of these apps relies on. Next, we identified three CVEs that affected the V8 or Blink engines and had proof-of-concept exploits that were publicly available [49–51]. To evaluate each CVE on the app, we opened it and navigated to the DevTools console. We executed the CVE's proof-of-concept code and verified successful execution, i.e., it reported an expected type confusion [50], heap corruption [49], or provided access to sensitive files [51]. Therefore, we confirmed that these bugs also affect the latest version of Electron apps despite being patched in Chrome.

[1] We do not include Wordpress and Postman as we could not find prior versions of the former, and the latter has non-dated release information.

Vulnerabilities across components. Our threat model (§2.1) highlights the risk of chaining multiple vulnerabilities across components for exploiting existing app vulnerabilities. In Table 3, we detail vulnerable components in popular apps. Note that a successfully chained exploit requires compromise and code execution within the renderer process that can then be chained with compromises in Chromium components (V8/Blink) or with vulnerabilities in the Main Process. Below, we discuss examples of insecure practices and present scenarios for exploits which we responsibly disclosed.

Wordpress. The Wordpress desktop app utilizes outdated versions of Chromium, V8, and Blink, which contain bugs that have been targeted in RCE attacks. Furthermore, the app lacks proper restrictions on external navigation; when users click on links they are navigated to these links within the app, allowing the sites accessed through these links to maintain access to JavaScript execution on the renderer process. This flaw becomes particularly critical due to the app's use of older versions of Electron, which do not implement default process sandboxing. Consequently, an attacker can leverage this vulnerability by posting a comment containing a link on a Wordpress blog or sending a message to a Wordpress account. If the victim, who manages their blog using the Wordpress app, clicks on the provided link, they will be unwittingly redirected to a malicious site that can execute arbitrary code.

Postman. This app also similarly relies on outdated versions of Chromium, V8, and Blink. Since this app hosts documentation for public APIs, which often contain external links, it has implemented a protective measure by opening clicked links within a new window that operates in a restricted and sandboxed environment. This setup aims to limit the

reach and impact of third-party content. However, the app's use of older Chromium versions introduces a significant weakness, as known bugs in Blink and V8 can bypass the restrictions imposed by the sandbox. Consequently, despite the attempt to confine the impact of external links, the outdated dependencies increase the risk of successful RCE attacks.

WhatsApp. The latest version (May 2023) incorporates Electron v13 (Chromium v91), which is currently 15 months old. Over this period, several critical security vulnerabilities have been identified and addressed. However, the app still operates within an insecure web environment, lacking context isolation and the utilization of Chromium's sandbox features. Furthermore, it permits the use of a deprecated feature that allows the remote loading of node modules, further compromising its security posture. While WhatsApp restricts users from navigating to third-party websites within the app, it does grant access to https://www.facebook.com, thus relying on the security measures of that particular domain. This exposes the app to any vulnerabilities that may appear on Facebook's website. Moreover, the app employs an insecure CSP that permits the execution of scripts from multiple origins, including potentially vulnerable paths. For example, XSStrike [21] reported at least one vulnerable path under https://maps.googleapis.com. WhatsApp implements custom handlers when a user drags-and-drops a file, which interferes with the proof-of-concept exploit available for CVE 2022-3656 [51]; however, the Chromium version it depends on remains vulnerable. This version is also vulnerable to CSP enforcement bugs found by Wi et al. [47], which erroneously allow the execution of arbitrary javascript code despite limiting such execution using the `script-src-elem` directive.

Notion. Notion is a popular productivity app that is widely utilized by organizations for content management and creation, and collaboration and task coordination among teams. By default, the Notion app follows a security-oriented approach where external links are passed to the host operating system, ensuring that third-party sites cannot be loaded within the app. However, there is a special provision in place that allows the app to allowlist Single Sign-On (SSO) domains associated with user logins, including organizational SSO redirects. This means that if a team configures its employees to access the app using email addresses like *employee@company.com*, which redirects to a designated SSO domain such as *sso.company.com*, Notion permits navigation to that specific SSO domain within the app.

Furthermore, when the app navigates to these allowlisted third-party links, the Notion app retains access to preloaded APIs that trigger unverified IPC calls to the main process. This design decision enables the renderer process to maintain connectivity and functionality with essential features handled by the main process, which does not verify the sender. As a result, these third-party links now possess the capability to pass messages to the main process, allowing for actions such as (1) accessing, modifying, and deleting cookies, and (2) accessing auth-tokens utilized for the app's websocket-based communication with Notion's servers. In the previously stated example, if an organization's SSO redirect were to be compromised, its members would face privacy risks as sensitive information from the team's Notion workspace could be extracted.

Additional evaluation. Here we discuss additional findings; first, we present two new attack vectors that we reported to the developers of Electron.js. Next, we evaluate how Electron apps inherit CSP bugs from Chromium.

Permissions-Policy. This directive offers a way for developers to control access to specific features, including permission to access hardware devices, like the camera and microphone. This can be configured by either setting the `allow` attribute on iframes or by including the directive in the HTTP response header. Electron relies on the underlying Chromium source to enforce the `Permissions-Policy`. Consequently, when the corresponding directives are detected, Electron restricts access to the camera or microphone by restricting calls to `navigator.getUserMedia()` which correctly blocks access. Similarly, when the `Permissions-Policy` directive aims to limit access to the screen by including the `display-capture` directive, Electron imposes restrictions on the use of the `navigator.getDisplayMedia()` function. However, Electron instead exposes access to the display through calls made to `navigator.getUserMedia()` [52] (see §2), which remain unaffected by the `Permissions-Policy` directive. This results in an erroneous implementation that fails to limit access to the screen even when explicitly directed to do so.

X-Frame-Options. Electron implements the `<webview>` tag as an out-of-process iframe (OOPIF). Consequently, it is important to respect the `X-Frame-Options: DENY` header when loading content within the `<webview>` tag. When loading content within a regular `<iframe>` tag, we found that the framework relies on Chrome's implementation of restrictions and prohibits the loading of content that includes an `X-Frame-Options: DENY` header in its response; however, it does not do the same with content loaded within the `<webview>` tag. Allowing cross-site content to load within another frame can potentially result in manipulation of sensitive content within those frames. This problem may be further exacerbated depending on the Electron app's specific implementation of privileges exposed to the webview, including IPC communication and preloaded APIs. We reported this finding to the Electron team and were informed that this is "expected and desired behavior" of the `<webview>` tag: "It bypasses certain traditional restrictions of iframes, includes *[sic]* X-Frame-Options, but also allows more capabilities that would also violate the traditional web security model."

Content Security Policy (CSP) Enforcement. Wi et al. [47] conducted an extensive analysis of how various CSP directives were enforced across different web browsers, and reported six critical bugs to the Chrome browser. We reached out to the authors and accessed the proof-of-concept snippets that they had included in their disclosures. After replicating

Table 4: Number of apps that did not pass each type of check.

Checks	Electronegativity	Inspectron	Intersection
Web Preferences*	29 (6)	**66**	17
Navigation Handling	91 (19)	**75**	59
Command-line Switches	5	**10**	2

* We report on `nodeIntegration`, `contextIsolation`, and `sandbox`.

the issues in Chrome v99 (the version they used), we then evaluated the CSP implementations of the corresponding Electron framework v17.4.11. We discovered that the incorrect enforcements observed in Chrome had trickled down to Electron as well. Consequently, these security flaws also impact any app developed using Electron, thus amplifying the potential risks posed by Electron's reliance on Chrome.

4.1 Comparison to State-of-the-Art

Electronegativity is a state-of-the-art static analysis tool for app developers to assess their Electron apps for potential security concerns [53]. Given a directory that contains an app's code, Electronegativity thoroughly examines HTML, JavaScript, and JSON files, and utilizes an Abstract Syntax Tree (AST) to conduct checks at two distinct levels. First, it performs "atomic" checks that evaluate branches within the codebase to identify potential vulnerabilities. Then, it applies "global" checks that combine atomic checks and discard false positives, before reporting points of concern.

Checks and Capabilities. Despite adopting fundamentally different approaches, both Electronegativity and Inspectron report on certain overlapping attributes of Electron apps. We developed Inspectron with a larger purview of checks and capabilities, in order to provide a more comprehensive assessment of app behavior. Table 5 (Appendix) presents an overview of the differences in the tools' capabilities. Briefly, Inspectron exclusively handles 5 checks that are not considered by Electronegativity. Of the 10 overlapping checks, Inspectron employs additional, in-depth evaluation for 7 factors, which include important aspects missed by Electronegativity. We provide a more detailed comparison in §A.3 (Appendix).

App Evaluation. We compared both tools by generating reports on the same app dataset. We evaluated each app following our *one-touch* approach, i.e., opening the app but not interacting with it. Our setup limited the coverage gained by Inspectron but allowed a comparison on a wider array of apps for comparison. For Electronegativity we explicitly provided the Electron version of the framework instead of relying on Electronegativity's incomplete detection. This way, we ensured that the reports provided by both tools address the same underlying framework version. We find that even without app-exercising user interactions, Inspectron outperforms Electronegativity in identifying and reporting potential vulnerabilities for the majority of common checks, as it conducts a more comprehensive analysis. A comparison of the potential vulnerabilities reported by Inspectron and Electronegativity is presented in Table 4, where (#) indicates false postives (e.g., 29 (6) indicates 23 true positive findings).

Static and Computed Configurations. Electronegativity relies on analyzing multiple files spread across the application's directory and looks for specific nodes and relationships within the constructed AST. Even so, the tool experiences difficulty in correctly gathering configuration values, including *command-line switches* that enable/disable experimental features and *web preferences* on individual windows. Apps declare both checks as JSON objects but include these objects in different locations, e.g., within the app's metadata declared within a `package.json` file, within an environment (`.env`) file, or within code but in an obfuscated manner that is computed at runtime (e.g., setting `nodeIntegration: !0`). Eletronegativity managed to correctly identify insecure preferences in only 23 apps (vs. 66 apps reported by Inspectron) and identified the use of experimental features in 5 apps (vs. 10 apps reported by Inspectron). Our findings indicate that Electronegativity is limited in its ability to parse inter-file relationships and to compute actual configuration values.

Coverage. We used Inspectron to perform a *one-touch* comparison and, as a result, did not trigger functionality specific to each application. As a result, the numbers reported for event-based triggers (e.g., *cross-context JS execution*, *open external*) and window-specific handlers (e.g., *navigation handling*, *preloaded APIs*, *certificate verification*) present a lower bound. Inspectron can report on these checks only after observing their use, which is triggered by interaction. On the other hand, Electronegativity can scan the source code of the entire application and therefore does not face that limitation. As a result, it reports the use of *open external* in 75 apps (vs. 56 apps reported by Inspectron), *certificate verification* bypasses within 13 apps (vs. 8 apps reported by Inspectron), and also the use of *preloaded APIs* on 4 apps for which Inspectron did not open the corresponding window. However, even with its advantage in coverage, Electronegativity missed 18 apps that attempted JS execution in a cross-context manner, and 16 apps that included handlers for in-app navigation, which were detected by Inspectron. Similarly, while Inspectron outperforms Electronegativity in reporting the remaining 7 checks, in the *one-touch* comparison Inspectron misses findings for these checks that are observed by Electronegativity. However, researchers can overcome this limitation by creating scripts to simulate user interaction specific to each application, as we demonstrated with the 10 popular apps (§A.3 in the Appendix).

False Positives. The static analysis approach adopted by Electronegativity is limited in its ability to correctly

determine apps' runtime configurations. We manually evaluated the reports gathered for each application and observed that the practices highlighted by Electronegativity include numerous false positives. While reporting on in-app navigation it does not consider the use of Electron.js's `setWindowOpenHandler`, and includes incorrect reports for 19 apps. Additionally, Electronegativity cannot evaluate CSP values that are set at runtime, (e.g., with network response headers, and within remote content), and therefore incorrectly reports the absence of a CSP in 9 apps. Finally, as highlighted earlier, the tool is limited in its ability to determine computed values, and reports 6 apps as using insecure preferences when the eventual preference set at runtime are actually secure. Inspectron does not suffer from these limitations since it highlights insecure practices only upon observing them at runtime.

5 Discussion and Limitations

Limitations. While Inspectron offers a comprehensive evaluation of packaged apps at runtime, it is important to acknowledge its limitations. First, Inspectron necessitates the use of an equivalent instrumented version of Electron. While the initial engineering investment was nontrivial, the necessary modifications have remained roughly consistent across versions, and we expect that maintaining this patchset should not be burdensome for the Electron project, security researchers, or interested downstream applications. Additionally, if Electron (or security researchers) released an instrumented version for each major version, this would eliminate the burden on individual app developers and streamline the use of Inspectron.

Second, our system encounters challenges when dealing with the unique directory structures and integrity checks implemented by app developers. This includes (1) additional dependent resources being placed outside of the designated *resources* directory, (2) non-standard helper libraries and modified Electron versions being used to build within packaged apps, (3) additional integrity checks hindering the execution of files copied from the *resources* directory in a different environment, and (4) restricting the use of command-line switches at runtime, limiting our ability to connect to the app via the DevTools protocol and test it using a Puppeteer script.

Finally, Inspectron is a dynamic analysis tool, and fully analyzing an app requires UI-based interaction (as we did for 10 popular apps). This additional workload can be offset by developers recording UI traces once for their app, and reusing these traces by integrating them into their automated Inspectron testing. Despite these limitations, our tool surpasses the state-of-the-art in identifying security violations in apps.

Countermeasures and guidelines. Our study has illuminated multiple problematic aspects of the Electron app ecosystem. While Electron has evolved toward more secure default configurations over time, older versions have significant omissions. Moreover, as we found many cases of developers removing protections offered by the default configurations, Electron maintainers should explore strategies for constraining the level of customization possible in security-critical functionality and implementing stricter default policies. This approach can be particularly beneficial for less "security-aware" developers who may not have in-depth knowledge of secure coding practices. Next, even though Electron provides regular updates, our findings indicate that most apps do not keep up with them. As such, it is crucial that app developers ensure that they always rely on the latest version of the Electron framework. However, while enforcing regular updates can guarantee that Chromium and V8 receive the latest security patches, it is important to note that frequent updates can present maintenance challenges (e.g., handling newly added or deprecated features). Nonetheless, until such solutions are explored, developers can integrate Inspectron into their testing pipeline and regularly test if their apps violate secure practices.

Ethics and disclosure. All of our experiments were carried out locally without any interaction or impact on real users; for apps that required authentication we used test accounts. When using XSStrike [21] we only evaluated domains for DOM XSS to report potentially vulnerable objects, and did not adversely affect any domain. Prior to our initial paper submission, we submitted reports to 4 popular apps in June 2023. Between June and November 2023, we performed an additional round of manual verification of our findings across all evaluated apps, and prepared individual reports. For each app, we parsed their website or repository (if available), and identified their stated disclosure procedure (i.e., email, custom portal, GitHub/GitLab issue, or a specific disclosure process within repositories). We submitted reports to an additional 100 apps; we did not submit reports to 4 popular apps (VSCode, Slack, Obsidian, and Discord), since we found that they include additional measures as mitigations against our attack vectors (e.g., prompting users). Additionally, Discord RPC Maker [54] was archived before we could submit a report. We received responses from 43 apps, and 11 apps have deployed corresponding fixes. We received rewards from three apps (Postman, Wordpress, and Cacher), and our disclosure to Altair GraphSQL was evaluated as a "High Severity" CVE by NIST, while GitHub released an advisory based on our report. We also submitted two reports to the Electron framework regarding their implementations of web standards, i.e., *Permissions-Policy* and *X-Frame-Options*.

Availability. We are making our tool's source code and UI traces available, along with an extended version of this paper that further details the implications of our checks [55].

6 Related Work

Inspectron is a novel, automated, dynamic analysis system that evaluates Electron apps. In this section, we discuss prior work that analyzed the web and app ecosystems.

Browser testing. Web browsers have been extensively studied in the past with various frameworks evaluating imple-

mentations of a range of security-relevant features. Singh et al. [56] built a framework for analyzing the usage of browser features in the wild and detecting access-control flaws. De Groef et al. [57] developed a browser that implements precise and flexible information flow controls for web scripts. Schwenk et al. [58] showed that a lack of specification resulted in browsers including varying implementations of the Same-Origin policy. Similarly, Wi et al. [47] found variation in the enforcement of CSP directives across modern browsers. Luo et al. [59] developed a browser-agnostic framework and studied UI vulnerabilities in mobile browsers. Jueckstock and Kapravelos [60] developed VisibleV8, an dynamic analysis framework hosted in V8, that reported property accesses at runtime. Similarly, Sarker et al. [61] developed an instrumented Chromium and used dynamic analysis to identify JS obfuscation through API calls in the wild. Numerous other works have evaluated the implementation of cookies and caching mechanisms [62–68], authentication flows [69–71], and access control and authorization pitfalls [72–75].

Automated app testing. Kals et al. [76] developed a vulnerability scanner that evaluated web apps for various vulnerabilities including SQL injections and Cross-Site Scripting (XSS). Doupé et al. [77] adopted a way to infer the web app's internal state, which was incorporated in their vulnerability evaluation. Duchéne et al. [78, 79] implemented a fuzzing and reverse engineering approach to infer control and data flows for XSS detection. More recently, Eriksson et al. [80] used navigation modeling, traversing, and the tracking of inter-state data dependencies for developing a web app scanner. Drakonakis et al. [81] presented a scanner-agnostic middleware framework that performs black-box evaluation that mediates the scanner's interactions with the web app with the help of an instrumented web browser.

Evaluating Electron. Carettoni [82] presented the static analysis tool, Electronegativity, and covered the state of Electron security, addressing its implications and adoption back in 2017. Krishna et al. [83] presented examples of exploits in popular Electron apps due to insecure web preferences. More recently, Xiao et al. [10] studied Remote Code Execution (RCE) attacks within cross-platform desktop apps. They instrumented the V8 source code on a single version of the Electron framework to identify and defend against cross-context control flow between the renderer and main processes. Their approach covers Electron's IPC communication, which is one of the checks covered by Inspectron. They state that their instrumentation also covers 36 Node.js APIs and 2 native Javascript APIs, i.e., calls to libraries other than those used by the Electron framework – unfortunately, we have not been able to obtain their code to conduct a more comprehensive comparison. While their approach attempts to limit IPC, our work highlights that vulnerabilities within Electron apps can result from numerous components beyond communication channels alone. In addition to checking IPC channels, we additionally report on vulnerabilities resulting from insecure configurations within the main process, fuses and command-line switches that affect the app as a whole, and resources and various web-based practices adopted within the renderer process.

Jin et al. [9] evaluated Electron apps for vulnerabilities resulting from unintended modifications to the DOM-tree. They instrumented Blink to enforce a parallel type-based DOM, analogous to the implementation of the Trusted Types specification [84]. Their approach requires developers to comprehensively evaluate all features of their app against the instrumented Electron so that it learns and builds a type-based DOM tree. While their approach requires significant overhead in participation and effort from developers, a comprehensively-evaluated app could successfully protect it against sanitization-based vulnerabilities. Their defense addresses some potential concerns that we report on, i.e., incorrect handling of new windows and webviews. Nonetheless, Inspectron covers a vast range of additional vulnerabilities, including those resulting from insecure CSPs, misuse of preloaded APIs, and all of the checks covered within the main process. In summary, we perform a more extensive evaluation of numerous security violations and cover a larger threat model beyond the scope of prior work.

Despite the popularity and wide adoption of Electron apps, they have received limited scrutiny from researchers. The general disregard for web standards and good security practices that we have found within this ecosystem is particularly concerning. We hope that our work will incentivize additional research and investigations from the security community.

7 Conclusion

The heterogeneity of execution environments poses a major challenge for software companies that aim to have a presence on different application platforms. As a result, cross-platform apps have become an attractive solution, due to the ability to reuse large parts of their existing web-based application code when creating standalone apps for various platforms. However, as our study reveals, this comes at a significant cost. Using Inspectron, we conducted a black-box auditing of a wide range of Electron apps that differ in terms of functionality, capabilities, and popularity. Our findings reveal a fragmented ecosystem fraught with insecure practices, misconfigurations, and outdated components. Crucially, we find that the entire ecosystem exhibits a significant *regression* in terms of the protections offered to users, as the configurability of the Electron framework has resulted in apps that are vulnerable to attacks that have become obsolete in the web ecosystem due to the security mechanisms already baked into modern browsers. Overall, our research sheds light on the problematic practices of Electron app developers, highlighting the need for more constraints in the configuration of security-relevant functionality and more stringent policies about keeping the core components of Electron apps up-to-date.

A Appendix

A.1 Web Preferences Examples

This section provides detailed examples showcasing the functionality and restrictions of inheritable preferences and their security implications in Electron apps.

Node Integration. [default: `False`] If set to `True`, any content rendered within the window, including third-party scripts, has direct access to Node modules, and can execute code on the system. Similarly, the *nodeIntergrationInSubframes* and *NodeIntegrationInWorkers* preferences determine if access to exposed Node APIs can be made available to embedded iframes and workers respectively. Electron (>=v5; 2019) sets a secure default for this preference.

Preload scripts. [default: None] This preference lets developers provide a path to *preload scripts* that expose additional functionality to the rendered web content. Improper configuration of these scripts can make the app vulnerable. Electron does not provide a preload script by default.

Context Isolation. [default: `True`] This preference determines whether global variables are shared between *preload scripts* and renderer processes. If they share the same state, a malicious script in the renderer process can perform *prototype pollution* attacks, i.e., it may override API calls on the `window` object, or change the definition of the `Array` data type to bypass checks used within the *preload script*, and gain access to Node.js APIs. Electron (>=v12; 2021) sets a secure default for this preference.

Sandboxing. [default: `True`] Borrowing from Chromium's sandboxing implementation, this option uses the underlying operating system to limit accesses available to the renderer process. This option further reduces the Node modules that can be exposed even to *preload scripts*. The renderer process would instead need to open new *Inter-process Communication* (IPC) channels and send requests to the main process, which can instead interact with the system on behalf of the renderer process. Electron (>=v20; 2022) sets a secure default for this preference.

Other. Electron provides other options that may be set to unsafe defaults. These include *allowpopups*, *disablewebsecurity*, *enableBlinkFeatures*. Each of these options can enable a different type of insecure access, not necessarily enabling remote access to execution on the system. Electron sets secure defaults for all of the above preferences by default.

A.2 Motivating Example

To better understand the types of attacks that can affect cross-platform frameworks like Electron, we discuss a previously-reported vulnerability against Discord. A Remote Code Execution (RCE) attack that was reported in 2020 [85].

Insecure web preferences. In Electron, each new window (or web embed, e.g., iframe) is associated with its renderer process, which is associated with a list of web preferences that determine the level of privilege it can access. Two important options are `nodeIntegration`, which determines whether the renderer process has access to all Node modules, and `contextIsolation`, which determines whether the *preload script* and the web content loaded in the renderer process share the same context. The Discord app disabled context isolation, exposing its renderer process to potential misuse.

XSS in loaded contents. The app's CSP, through the `frame-src` directive, allowed third-party content from a list of domains to be loaded within iframes. One of the allowed domains, sketchfab.com, was vulnerable to XSS. If a hosted HTML file included a particular script, it would execute within the iframe in the Discord app.

Navigation handling. A bug in the Electron framework ensured that a *will-navigate* event was not triggered if the top-browsing context was navigated away from a call by an iframe if the top-level frame and the iframe were from different origins. The embedded frame could, therefore, navigate the top window to an attacker-hosted site, leading to RCE.

The RCE attack was the result of combining three separate bugs. While the Discord app had set an insecure web preference (`contextIsolation`), the attack was made possible by external vulnerabilities, i.e., an XSS on a third-party domain (sketchfab.com) and a bug within the Electron framework. The app's CSP did not suffice in preventing the attack, and the navigation restriction bypass bug in the Electron framework itself enabled the app to be successfully exploited. This example illustrates how the unique capabilities and characteristics of a cross-platform framework like Electron can expose users to severe security threats. The Discord app's vulnerabilities showed how even recommended security checks could not prevent an attack when there are external vulnerabilities, highlighting the importance of constantly monitoring and patching an application's security and the need for a comprehensive auditing framework that can guide app developers towards better securing their applications.

A.3 Comparison to Electronegativity

We provide additional details on the checks and capabilities of both tools in Table 5. We elaborate on the differences between the two tools in an extended version of this paper [55].

- **Runtime Behavior.** Electronegativity does not provide insights into the runtime behavior of an app. Instead, it analyzes the code starting from a potential entry point and reports vulnerabilities based on the Abstract Syntax Tree (AST) it manages to create at that point.
- **Packaged and Obfuscated Code.** Navigating packaged apps and obfuscated code poses a challenge for Electronegativity. Automatic detection of entry points and dependencies becomes difficult when they are spread across multiple files or when the code is intentionally obfuscated. Analyzing specific code snippets can be challenging when dealing with minified code. Electronegativity attempts to point to the location of reported vulnerabilities, but the analysis becomes more difficult when code is heavily minified. To improve manageability, it is important to report specific event listeners, handlers, and procedures when they are registered with the Electron framework.
- **Reporting Granularity.** Electronegativity reports potential vulnerabilities at the overall app-level, but it may not specify which specific window or frame of an Electron app is responsible for a particular vulnerability. This information is crucial for effectively identifying and addressing the reported issues.
- **Network Requests.** Electronegativity focuses on analyzing JS and HTML files and does not capture network requests or analyze loaded resources beyond these file types.
- **Electron Version Detection.** Extracting information about the underlying version of Electron used by the app can be limited. While Electronegativity tries to determine the Electron version from the package.json file, this information may not be available in packaged apps and can only be retrieved at runtime.
- **Web Preferences and Command-line Switches.** Electronegativity attempts to capture web preferences and command-line switches from multiple locations, i.e., the `package.json` file in the app's root folder, the app's JavaScript code, and from attributes included in HTML tags. However, code is distributed across multiple files, and these preferences are also computed at runtime, making it difficult to accurately capture the eventual value used by the application.
- **Nagiation Handling.** The tool does not check for the use of Electron's updated `setWindowOpenHandler` and, as a result, incorrectly reports the absence of limitations on navigations within applications.
- **Preloaded APIs.** Electronegativity detects the use of preloaded APIs from HTML tags and from declared web preferences, in a similar manner to its detection of web preferences, and only points to the file location where the configuration was added. However, its analysis does not provide any insight into the functionality that is exposed.
- **Custom Protocols.** Electronegativity additionally reports on whether an application sets a custom protocol. However, the associated underlying protocol, i.e., the use of alternative values for `file:` and `http:` links, is necessary for understanding the implications of the protocol itself, but this is neither detected nor reported by the static analysis tool.
- **Certificate Verification and Open External.** In these overlapping checks, both, Electronegativity and Inspectron attempt to cover similar checks and usage. Given Electronegativity's advantage in terms of code coverage, it detects and reports the use of these provisions in a larger number of instances. Inspectron's reporting of these checks is dependent on the functionality being triggered
- **Additional Checks and Capabilities.** Inspectron performs multiple additional evaluations that are otherwise not considered by Electronegativity. These additional checks are important given their inclusion in recommendations from Electron and use in prior app exploits [15, 19].

Table 6: Number of apps that did not pass each type of check from an evaluation of 10 popular apps. (#) indicates false positives and {#} indicates the intersection with Electronegativity.

Checks	Electronegativity	Inspectron (One-touch)	Inspectron (w/ Interaction)
Web Preferences*	1	6 {1}	6 {1}
Navigation Handling	6 (4)	3 {2}	4 {2}
Command-line Switches	0	2	3
Cross-context JS Execution	1	1	2 {1}
Preloaded APIs	2	4 {2}	6 {2}
Permission Request Handling	6 (1)	5 {5}	5 {5}
Custom Protocols	5	6 {4}	8 {5}
Certificate Verification	2	2 {1}	3 {2}
Open External	6	2 {2}	9 {6}
Content Security Policy	10 (2)	9 {7}	10 {8}
Total True Positives	32	40 {24}	56 {32}

* We report on `nodeIntegration`, `contextIsolation`, and `sandbox`.

Next, compare the reports generated by Inspectron for 10 popular apps for which we developed user interaction (UI) traces, against Inspectron's baseline one-touch approach as well as the reports generated by Electronegativity (see Table 6). While Inspectron with a one-touch approach reports more problematic practices than Electronegativity, it also misses checks captured by the static analysis tool. This is especially highlighted in its detection of `shell.openExternal()`. We made similar observations with reports of insecure CSP, certificate verification, and the use of custom protocols. However, with the UI traces, Inspectron captures checks missed by the one-touch approach and further reports on findings missed by Electronegativity as well. These findings further highlight Inspectron's effectiveness when compared to the state-of-the-art, as well as the performance boost offered by UI traces which increase the coverage obtained by our dynamic analysis tool.

KnowPhish: Large Language Models Meet Multimodal Knowledge Graphs for Enhancing Reference-Based Phishing Detection

Yuexin Li[1], Chengyu Huang[1], Shumin Deng[1], Mei Lin Lock[2], Tri Cao[1],
Nay Oo[2], Hoon Wei Lim[2], Bryan Hooi[1]
[1]*National University of Singapore,* [2]*NCS Cyber Special Ops-R&D*

Abstract

Phishing attacks have inflicted substantial losses on individuals and businesses alike, necessitating the development of robust and efficient automated phishing detection approaches. Reference-based phishing detectors (RBPDs), which compare the logos on a target webpage to a known set of logos, have emerged as the state-of-the-art approach. However, a major limitation of existing RBPDs is that they rely on a manually constructed brand knowledge base, making it infeasible to scale to a large number of brands, which results in false negative errors due to the insufficient brand coverage of the knowledge base. To address this issue, we propose an automated knowledge collection pipeline, using which we collect a large-scale multimodal brand knowledge base, KnowPhish, containing 20k brands with rich information about each brand. KnowPhish can be used to boost the performance of existing RBPDs in a plug-and-play manner. A second limitation of existing RBPDs is that they solely rely on the image modality, ignoring useful textual information present in the webpage HTML. To utilize this textual information, we propose a Large Language Model (LLM)-based approach to extract brand information of webpages from text. Our resulting multimodal phishing detection approach, KnowPhish Detector (KPD), can detect phishing webpages with or without logos. We evaluate KnowPhish and KPD on a manually validated dataset, and a field study under Singapore's local context, showing substantial improvements in effectiveness and efficiency compared to state-of-the-art baselines.

1 Introduction

Phishing attacks are one of the most impactful types of scams, harming both individuals and businesses: in 2023, an estimated $1.026 trillion was lost by consumers worldwide in scams [5], of which phishing scams are among the most common types. Phishing scams also account for about 90% of data breaches for organizations [12]. This problem has been exacerbated by the proliferation of automated phishing kits, enabling malicious actors to easily mimic genuine pages while evading detection using countermeasures [63]. Accordingly, the number of phishing attacks has increased by 47.2% in 2022 compared to the previous year [64]. These underscore the importance and urgency of tackling the issue, and the need for effective automatic phishing detection approaches.

Many efforts have been made to counter phishing attacks, including anti-phishing blacklists, heuristic-based, and feature-based models [15]. Blacklist-based methods [42, 44, 47] compare an input URL with a predefined blacklist of malicious URLs, but these are reactive approaches that require phishing sites to be first reported or detected through other means. Heuristic-based [14] and feature-based models [19, 29, 32, 37, 39, 56, 61] extract features to proactively identify new phishing webpages. However, as these do not utilize logo information, they are greatly limited in their ability to detect plentiful phishing pages which are mainly identifiable by the presence of a logo [34]. Moreover, as they depend on statistical features for detecting phishing pages, they are susceptible to distribution shifts due to the constantly changing nature of phishing campaigns.

In contrast, reference-based phishing detectors (RBPDs), which work by comparing the logos on a target webpage to a known set of logos, have been established as the state-of-the-art phishing detection paradigm, garnering considerable research attention [1, 33, 34]. Specifically, an RBPD consists of *brand knowledge base* (BKB) containing brand information (the logos and legitimate domains of brands) and a *detector backbone* which uses information from this BKB for phishing detection. To detect if a webpage is a phishing or benign page, RBPDs first identify the webpage's *brand intention*, i.e., the brand that the webpage presents itself as (e.g., a webpage with an Adobe logo and appearance has the brand intention of Adobe). Then, if the webpage is detected to have an intention of a certain brand, but its domain does not match the legitimate domains of that brand, the webpage is classified as phishing. As virtually all phishing pages do not utilize the legitimate domains of the original brand, this approach typically obtains high precision. Moreover, as this approach is based on an

invariant that does not change over time, it is relatively robust to distribution shift [33, 34].

Challenges. Despite the advantages of RBPDs, they have two major limitations which we focus on. **(1)** The first limitation is *Limited-Scale BKB*: RBPDs fundamentally rely on their BKB to identify the brand intention of a website. However, it is labor-intensive to construct and maintain a large-scale BKB manually. Phishpedia [33] and PhishIntention [34] rely on manual curation, hence are limited to a small BKB of 277 brands. A recent method, DynaPhish [35], proposes to dynamically expand the BKB during deployment time. However, this leads to extremely long running time, e.g., averaging 10.6 seconds per sample in our experiments. Moreover, it may fail to construct brand knowledge of novel phishing targets if phishing pages' logos are different from those displayed on legitimate pages. **(2)** The second limitation is *Textual Brand Intention*: Phishing webpages can convey their brand intention via text in HTML, instead of via logos. Existing RBPDs cannot identify it because they solely operate within the image modality.

Present Work. In this paper, we seek to address both of these issues in the context of a static environment, where input webpages are not interactable. First, we propose an automated knowledge collection pipeline, with which we construct a large-scale multimodal BKB named *KnowPhish*. KnowPhish is constructed based on our empirical analysis which finds that phishing targets mostly belong to a few high-value industries. Hence, using brand-industry relations modeled from a publicly available knowledge base, Wikidata [57], we search for a set of potential phishing targets and their brand knowledge predictively, leading to a BKB covering around 20k potential phishing targets. We also incorporate extra data sources such as Tranco domain list [46] and Google Image Search [18] for brand knowledge enhancement. Therefore, KnowPhish is equipped with rich logo, alias, and domain variants of each brand, which can be used to boost the performance of existing RBPDs in a plug-and-play manner.

Next, to address the issue of textual brand intention, we develop a Large Language Model (LLM)-based approach to identify the brand intention of webpages in conjunction with the alias information in our KnowPhish BKB. Our approach can be directly integrated with any standard visual RBPD [34], augmenting it to form a *multimodal RBPD* which detects brand intention through both visual and textual modalities. Our resulting multimodal phishing detection approach, named *KnowPhish Detector* (*KPD*), can operate with static webpage data to detect phishing webpages with or without logos.

We then evaluate the effectiveness and efficiency of KnowPhish and KPD on `TR-OP`, a manually validated dataset that comprises 5k benign and 5k phishing webpages. We also evaluate our approach on a field study under Singapore's local context, to study how well different approaches generalize to such a local context. The resulting data, which we call `SG-SCAN`, contains 10k webpages from Singapore local webpage traffic over 6 months. In experiments on the two datasets, KnowPhish significantly boosts the effectiveness of various RBPDs, and is 30 or more times faster than the on-deployment framework DynaPhish [35], when equipped with image-based RBPDs. Moreover, incorporating our multimodal approach, KPD, can substantially boost the number of detected phishing webpages.

In summary, our contributions are three-fold:

- **Multimodal Brand Knowledge Base.** We propose KnowPhish, a large-scale multimodal BKB for phishing detection, and its automated construction approach. KnowPhish can be used in any RBPDs to boost their brand knowledge in a plug-and-play manner.
- **Multimodal Reference-based Phishing Detector.** We propose an LLM-based approach to identify textual brands from HTML to handle logo-less phishing webpages. Our approach directly integrates with any existing RBPD, augmenting it to form a multimodal RBPD, named KnowPhish Detector (KPD), which can detect phishing webpages with or without logos.
- **Effectiveness and Efficiency** Extensive experiments show that KnowPhish significantly enhances the performance of various RBPDs, including KPD, while achieving much better runtime efficiency than DynaPhish. We also demonstrate their effectiveness in a field study and validate the robustness of KPD to adversarial attacks.

2 Motivating Examples

The development of KnowPhish and KPD is motivated by the brand knowledge construction difficulty of DynaPhish. Below, we present a brief workflow of DynaPhish, a few examples of where DynaPhish fails to build brand knowledge, and how KnowPhish and KPD address these difficulties.

DynaPhish expands brand knowledge through a two-step process when encountering a webpage with an unseen logo. (1) It first utilizes Google Search (GS) to validate the webpage's domain popularity to determine its benignity. The logo-domain pair will be added to its brand knowledge if such validation passes. (2.1) If the validation fails, it recognizes the brand name of the logo using Google Logo Detector (GLD) and searches for the legitimate domain associated with that logo using another GS with the brand name as the query. (2.2) It then compares the input logo with the logo on each webpage from the GS results. If a match is found, the corresponding domain and logo are added to the brand knowledge.

However, DynaPhish may fail to construct new brand knowledge and correctly classify phishing pages due to the failure in step (2.2), i.e., logo-matching. A few examples of logos from phishing pages and the logos from their corresponding GS result pages are shown in Figure 1. The difference

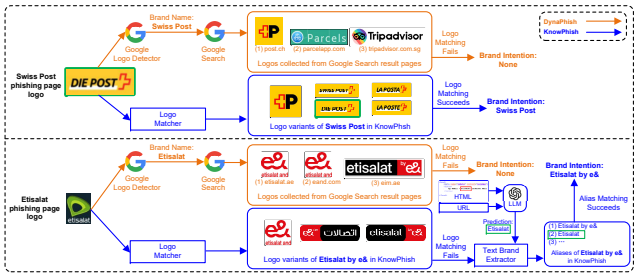

Figure 1: Comparison of the workflow between DynaPhish and KnowPhish to identify the brand intention of the two phishing page examples.

in appearance between the logos on phishing pages and GS result pages causes failure in the logo-matching process, even if GLD identifies the correct brand names, further resulting in brand knowledge construction failure and false negatives.

These examples motivate us to address such false negative problems in two ways. Firstly, we build KnowPhish from a high-quality data source, Wikidata, based on brand profiles (e.g., names and domains). This approach bypasses the logo-matching process used by DynaPhish and directly incorporates enhanced brand knowledge, such as logos and aliases. Therefore, the enriched logo variants increase the chance for image-based RBPDs to match the correct brand. For instance, the Swiss Post phishing page logo in Figure 1 is covered in KnowPhish, thus enabling the logo-matcher to identify its brand intention. Secondly, even if image-based RBPDs fail to match the logo, we remedy this by also using the text-brand extractor from KPD to identify the text brand intention from HTML and URL, in conjunction with the rich aliases in KnowPhish. As the Etisalat phishing page in Figure 1 shows, an LLM takes both the HTML and URL as input and outputs a predicted brand for the page. The predicted brand matches an alias from KnowPhish, thus the text-brand extractor detects its brand intention as the brand of that alias. We will elaborate on each in Sections 4 and 5, respectively.

3 Formalization

Threat Model. In a phishing attack, a malicious actor misleads visitors into believing that their webpage comes from a legitimate brand, misleading users into providing their credentials (such as username and password). Note that we do not consider other types of attacks, such as malware or miscellaneous scams that do not fit the above description, to be within our scope.

In our threat model, we assume the attacker has full control over their webpage. However, to maintain their webpage's effectiveness in misleading users, the webpage needs to convey its *brand intention*, i.e., present itself as a particular recognizable brand to visitors. In addition, the webpage needs to be *credential receiving* in some way: e.g., via username and password fields, but less common approaches exist such as buttons or QR codes. Deviating from either of these two conditions makes it less likely for the phishing attack to succeed, and our empirical observations support that these two conditions hold consistently in phishing webpages.

Formally, consider a webpage w, which consists of its screenshot ($w.screenshot$), its page HTML ($w.html$), and its domain ($w.domain$). As described above, the webpage needs to convey its brand intention, presenting itself as belonging to a brand b. This can be done either in visual form (e.g., through logos in its screenshot) or textual form (e.g., through text in its HTML), so brand information may appear either in $w.screenshot$ or $w.html$ (or both).

Reference-Based Phishing Detection. Since phishing webpages need to convey brand intention, the state-of-the-art RBPD approach relies on identifying this brand intention, by comparing images on the page to a set of known *reference* logos. Formally, an RBPD consists of a *brand knowledge base (BKB)* and a *detector backbone* utilizing this BKB.

A BKB [33–35] stores brand-related knowledge, taking the form of a list of N brands: $b_1, \cdots, b_N$. For each brand b, we store its name ($b.name$), its logo images ($b.logos$), and its legitimate domains ($b.domains$). In our work, to facilitate the detection of textual brand intention, we further add its list of textual aliases, i.e., a list of common alternate names used to refer to the brand ($b.aliases$), resulting in an *augmented BKB*. Formally, given a brand b, the augmented BKB is:

$$\mathcal{B} = \{(b.name, b.logos, b.domains, b.aliases)\}_{b \in \{b_1, \cdots, b_N\}}$$

For example, for the brand `PayPal`, this may contain: (`PayPal`, (`logo1`, `logo2`), (`www.paypal.com`), (`PYPL`)), where `logo1` and `logo2` are two PayPal logo images.

Next, given a webpage w and a BKB $\mathcal{B}$, a *detector backbone* $g_{\mathcal{B}}(w)$ outputs either the brand intention that w is predicted to have, or 'null' to indicate no predicted brand intention: $g_{\mathcal{B}}(w) \in \mathcal{B} \cup \{\varnothing\}$.

Finally, an RBPD, denoted $f_{\mathcal{B}}(w)$, classifies a webpage w as phishing or benign. $f_{\mathcal{B}}$ classifies w as phishing if its detector backbone $g_{\mathcal{B}}$ detects that w presents a brand intention $b' \in \mathcal{B}$ but w's domain is inconsistent with any of the legitimate domains of brand b' recorded in $\mathcal{B}$ (i.e., $w.domain \notin b'.domains$). Otherwise, w is classified as benign. Formally:

$$f_{\mathcal{B}}(w) = \begin{cases} \text{Phishing} & \text{if } g_{\mathcal{B}}(w) = b' \text{ and } b' \neq \varnothing \text{ and} \\ & \quad w.domain \notin b'.domains \\ \text{Benign} & \text{otherwise} \end{cases}$$

Evasion Attacks. The attackers may attempt to bypass $f_{\mathcal{B}}$ via the following methods:

T1: Phishing with Logo Variants. To circumvent the online knowledge expansion approach for $\mathcal{B}$ (e.g., DynaPhish [35]), attackers can use other legitimate logo variants of b instead of the ones displayed on b's official webpages.

T2: Phishing with Text Brands. Instead of using a logo to present its brand intention, the attacker can rely on text *w.html* to show its brand intention, making image-based phishing detectors completely fail.

T3: HTML-oriented Attacks. Phishing attackers may employ evasion techniques on HTML, such as typosquatting, prompt injection, and text-to-image attacks to hinder effective information extraction by text-based methods.

We address T1 by constructing a large-scale multimodal BKB with rich logo information, i.e., multiple logos per brand. We address T2 by developing an LLM-based approach to extract text brands from HTML. For T3, we show in Section 6.5 that our LLM-based approach is generally robust to different types of adversarial noises in HTML.

4 KnowPhish Construction

In this section, we introduce how to construct *KnowPhish*, a large-scale multimodal BKB. We start by conducting empirical analysis on phishing feeds from different sources and periods to find prospective indicators to search for potential phishing targets proactively. With our empirical findings, we then describe how to automatically construct KnowPhish using a publicly accessible multimodal knowledge graph.

4.1 Empirical Motivation

Our empirical analysis seeks to address the following questions:

QUESTION 1. *Do phishing targets differ across different phishing feeds?*

QUESTION 2. *What are the enduring characteristics shared by phishing feeds across different sources and periods*?

4.1.1 Data

To achieve this objective, we conducted a study using two distinct phishing datasets. The first dataset, D_1, includes phishing webpages that were collected by [33] from OpenPhish [42] three years ago. It encompasses a total of 29,496 phishing instances targeting 283 different brands. The second dataset, D_2, comprises phishing samples obtained from APWG [7] at the end of 2022. This dataset contains a total of 5,167 phishing examples targeting 391 unique brands.

Furthermore, we manually categorized each of these phishing targets into one of the following distinct industries, namely: 1) financial, 2) online service, 3) telecommunication, 4) e-commerce, 5) social media, 6) postal service, 7) government, 8) web portal, 9) video game, and 10) gambling. For the brands that cannot be classified into any of the ten categories, we categorize them as 11) other businesses. For instance, Bank of America is categorized into the financial category, while KFC is classified as other businesses.

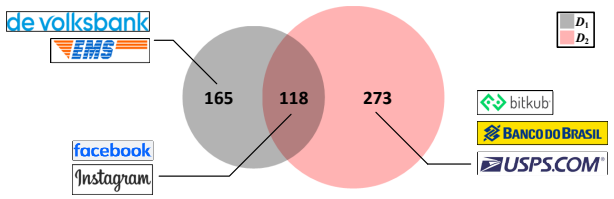

Figure 2: Phishing targets change substantially. The Venn diagram shows the disparities in the phishing targets from the two phishing datasets, with a few phishing target examples provided for illustration.

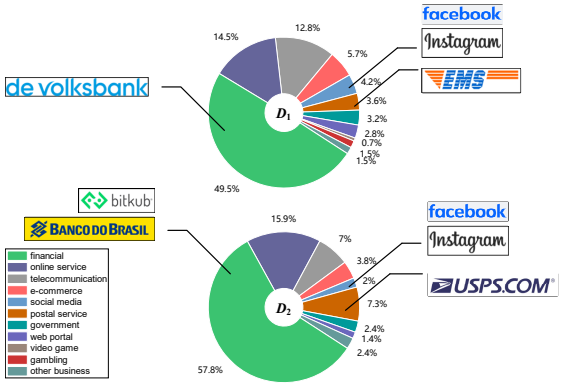

Figure 3: Industries of phishing target brands are relatively consistent. The chart shows the distribution of industries of the phishing targets from the two datasets.

4.1.2 Analysis

We conduct a thorough examination of the disparities in phishing targets and the distribution of their respective industries across the two phishing datasets. Our observations are as follows.

OBSERVATION 1. *Phishing targets may exhibit variation depending on the datasets involved.*

In particular, in Figure 2 we observe significant phishing target disparities between D_1 and D_2, with only 118 of the 391 brands in D_2 being present in D_1. This can be attributed to many potential factors, including temporal shifts and data collection methodologies. On the temporal shifts side, emerging phishing targets (e.g., Bitkub) may supplant existing ones over time [35]. On the data collection methodology side, OpenPhish employs proprietary detectors for phishing URL collection, whereas APWG relies on human reports. Such divergent approaches to data gathering directly impact the composition of phishing targets. These factors highlight the non-trivial challenge of manually managing the dynamic nature of phishing targets.

OBSERVATION 2. *Despite the dynamic nature of phishing targets, the industries of those phishing targets remain mostly consistent.*

However, an intriguing revelation from Figure 3 is that

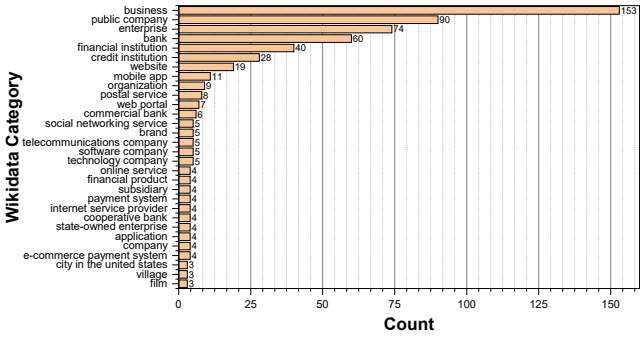

Figure 4: Distribution of the top 30 Wikidata categories of the phishing targets in D_2.

despite the shifting landscape of phishing targets, the industries targeted by these phishing attacks have remained mostly consistent. For example, De Volksbank (in D_1), Bitkub, and Banco Do Brazil (in D_2) are all banking organizations, even though they are phishing targets from different sources. Almost all the phishing targets in D_2 can still be categorized in the ten industries. The majority of these targets continue to belong to the same industries that have historically been the focus for phishing attacks, such as financial, telecommunication, and postal service, among others, while only a few brands such as KFC, Hydroquebec cannot be covered by the ten industries. Our supplementary materials [26] provide more examples of the phishing targets of different industries.

It is worth noting that this observation echoes the six Principles of Influence [11] upon which social engineering relies, namely the significance of authority in achieving successful persuasion. In the context of social engineering, threat actors, including phishing attackers, tend to focus their efforts on authorized and higher-value entities to maximize their gains from unlawful acquisition of sensitive information, rather than impersonate less-reputable and lower-value firms.

4.1.3 Connection to Wikidata Knowledge Graph

The consistent targeting of specific industries by phishing attacks can, in turn, serve as a valuable foundation for building a BKB predictively. The brand-industry relation can be regarded as a fact triplet stored within knowledge graphs. In this work, we use Wikidata [57], the largest publicly-accessible knowledge base [45, 48] to explore the connection between phishing targets and the knowledge graph. Our focus lies on examining the `instance_of` relationship within Wikidata, as we empirically find that it provides the most comprehensive information about the category to which an entity belongs. For example, the fact that brand Bank of America belongs to the category bank can be represented as $(\text{bank\_of\_america}, \texttt{instance\_of}, \text{bank})$. Formally, we use $(b, \texttt{instance\_of}, c) \in \mathcal{G}$ to represent that brand b belongs to category c if there is such a fact in the knowledge graph $\mathcal{G}$.

To gain a deeper understanding of which Wikidata categories those phishing targets belong to, we perform searches within the D_2 dataset. Specifically, for each phishing target b, we search for the categories associated with it, denoted as $\mathcal{C}(b) = \{c | (b, \texttt{instance\_of}, c) \in \mathcal{G}\}$. This process yields a collection of categories, $\mathcal{C}$, comprising the categories for all phishing targets in the APWG phishing dataset. In Figure 4, we present a visualization of the 30 most frequently occurring categories within $\mathcal{C}$. Our observation reveals that some categories represent specific industries, such as bank, postal service, and internet service provider, while others, like business, public company, and enterprise, convey more general semantics.

Based on this observation, we curate two lists of categories: 1) *Narrow Categories* $\mathcal{C}_n$ such as 'bank' representing narrower industry segments, and 2) *General Categories* $\mathcal{C}_g$ such as 'business', which will be used in constructing our brand knowledge base KnowPhish. The detailed lists can be found in our supplementary materials [26].

4.2 Approach Overview

Building upon the empirical insights in Section 4.1, we introduce *KnowPhish*, a large-scale multimodal BKB prioritizing both comprehensive coverage of potential phishing targets and detailed brand knowledge. As Figure 5 shows, KnowPhish is constructed using an automatic pipeline, which starts from **1) Brand Search** based on industries via Wikidata knowledge graph $\mathcal{G}$ and proceeds with **2) Knowledge Acquisition and Augmentation** to obtain relevant brand knowledge including logos, aliases, and domains. The complete construction algorithm is illustrated in our supplementary materials [26].

4.3 Brand Search

Identifying a wide range of potential phishing targets is crucial for the construction of KnowPhish. If a phishing target is absent from the BKB, the RBPD may not be able to identify its corresponding phishing webpages, resulting in false negatives. Our brand search module is designed to prioritize brands that are higher-value phishing targets and consists of two concurrent components:

(a) **Category-based Brand Search** identifies brands operating within specific industries, i.e., Narrow Categories $\mathcal{C}_n$, to find brands $\mathcal{B}_n$.

(b) **Popularity-based Brand Search** considers a broader set of General Categories $\mathcal{C}_g$ and ranks their brands by popularity to generate a brand list $\mathcal{B}_g$.

By combining (a) and (b), we obtain a more comprehensive list of potential phishing targets, denoted as $\mathcal{B} = \mathcal{B}_n \cup \mathcal{B}_g$.

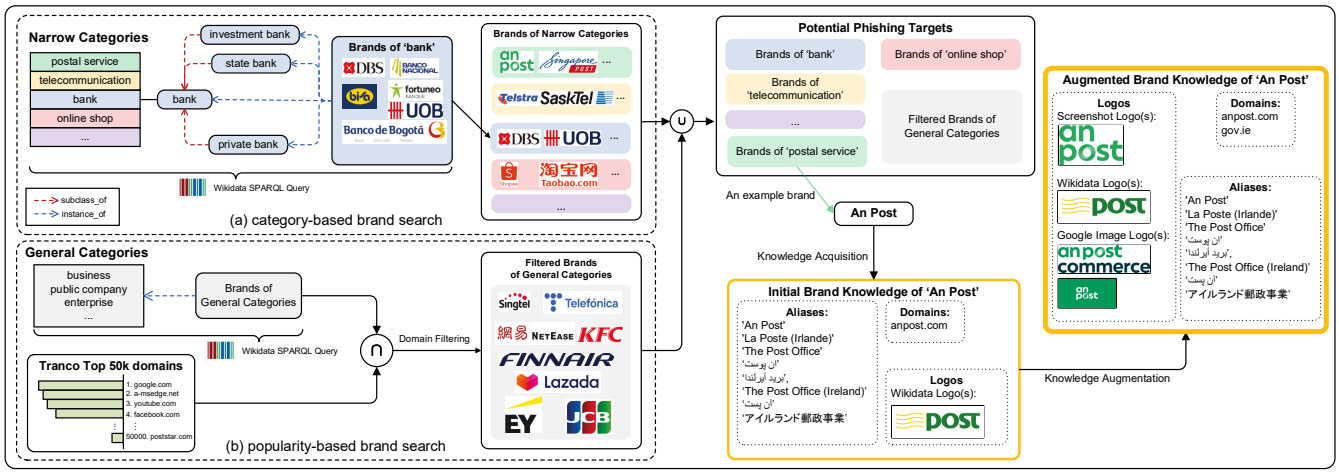

Figure 5: An overview of our automated pipeline for constructing our large-scale multimodal BKB, KnowPhish. We first collect (a) all brands from certain high-value industries, and (b) only popular brands from general categories. Then, the knowledge acquisition and augmentation steps collect logos, domains, and aliases for these brands.

4.3.1 Category-based Brand Search

Category-based brand search is motivated by our empirical observation that phishing attackers often choose to impersonate brands within high-value industries. Thus, we collect all brands associated with Narrow Categories $\mathcal{C}_n$. For instance, when focusing on the 'bank' category, we aim to find all the banks listed in Wikidata.

Hence, for each Narrow Category $c_n \in \mathcal{C}_n$, we search for the corresponding brands belonging to c_n and its subcategories $\mathcal{C}'_n = \{c|(c, \texttt{subclass\_of}, c_n) \in \mathcal{G}\}$, where $\texttt{subclass\_of}$ indicates a hierarchy relationship between two categories in the Wikidata graph $\mathcal{G}$. Formally, the brand list related to category c_n is;

$$\mathcal{B}_n(c_n) = \{b|(b, \texttt{instance\_of}, c) \in \mathcal{G}, c \in \{c_n\} \cup \mathcal{C}'_n\}$$

We introduce sub-categories here because the brands within a sub-category of a Narrow Category are also potential targets for phishing attackers. For example, National Bank of Costa Rica is only categorized as 'state bank', a sub-category of 'bank', in Wikidata. Despite this, it unquestionably falls under the category of 'bank', and is a potential phishing target.

4.3.2 Popularity-based Brand Search

Although the industry category is a key indicator of potential phishing targets, such information may not be accurately maintained in Wikidata for every brand. For example, Singtel, a Singaporean telco company, should logically fall into the telecommunication category. However, the only categories it has in Wikidata are 'business', 'public company', and 'enterprise'. Hence, depending solely on Narrow Categories $\mathcal{C}_n$ is insufficient.

To address this, we introduce popularity-based brand search that incorporates *domain rank* for selecting brands. We use domain rank-based filtering for two reasons: 1) not all the brands within General Categories $\mathcal{C}_g$ are high-value entities, and 2) the more reputable a brand is, the more likely it is to be a phishing target. As a result, for each general category $c_g \in \mathcal{C}_g$, we generate its corresponding brand list with a domain ranking constraint:

$$\mathcal{B}_g(c_g) = \{b|(b, \texttt{instance\_of}, c_g) \in \mathcal{G}, r_{\mathcal{D}}(b.domains) \leq \eta\}$$

where $\mathcal{D}$ is a popular domain ranking list, $r_{\mathcal{D}}(\cdot)$ uses $\mathcal{D}$ to compute the domain rank of the most popular domain in $b.domains$, and η is a domain ranking threshold. Here, we instantiate $\mathcal{D}$ with the Tranco domain ranking list [46].

The brands obtained through the category-based brand search, denoted as $\mathcal{B}_n$, and popularity-based brand search, denoted as $\mathcal{B}_g$, are combined into our final list $\mathcal{B} = \mathcal{B}_n \cup \mathcal{B}_g$.

4.4 Knowledge Acquisition and Augmentation

RBPDs fundamentally depend on their brand knowledge to allow for accurate phishing detection. Next, we augment our collected brands with knowledge about the 1) *logos*, 2) *domains*, and 3) *aliases* (or alternate names) associated with each brand. Note that aliases are not present in existing BKBs [33–35], but we introduce them to facilitate the detection of textual brand intention, as we describe in Section 5.

4.4.1 Knowledge Acquisition

Each brand $b \in \mathcal{B}$ we have collected is a Wikidata entity with rich property information. Therefore, we leverage this readily available data to establish initial brand knowledge. Specifically, for each $b \in \mathcal{B}$, we acquire initial brand knowledge

from the Wikidata graph $\mathcal{G}$:

$$b.logos \leftarrow \{x | (b, \texttt{logo\_image}, x) \in \mathcal{G}\}$$
$$b.domains \leftarrow \{y.domain | (b, \texttt{official\_website}, y) \in \mathcal{G}\}$$
$$b.aliases \leftarrow \{z | (b, \texttt{label}, z) \in \mathcal{G}\}$$

where `logo_image`, `official_website`, and `label` are the property relations in $\mathcal{G}$ that indicate the logos, URL of the official website, and alternative names in different languages of an entity, respectively.

4.4.2 Knowledge Augmentation

Information maintained in Wikidata may be incomplete, particularly for the logos and the domains. Brands may employ multiple legitimate logo variants and domain variants in their online presence. When a phishing page contains a logo variant not present in the knowledge base, the phishing detector may fail to identify its brand, leading to false negatives. Similarly, if our detector examines a benign webpage with a legitimate domain that is not documented in Wikidata, a false positive alarm may be raised. Thus, further augmentation to $\mathcal{B}$ on the logos and domains is required to alleviate such false positives and false negatives.

Logo Variants. To capture logo variants, we employ two methods. The first involves accessing the associated domain(s) of the brand and capturing the logo displayed on that webpage by a well-trained webpage layout detector [34], denoted $\mathsf{DetectLogos}(b.domains)$. The second method utilizes Google Image Search [18]. We initiate a search query by combining the brand name with the term 'logo', then filter the results to include images with URLs matching the brand's domain(s). In this way, we expand our logo collection beyond the Wikidata logo images:

$$b.logos \leftarrow b.logos \cup \mathsf{DetectLogos}(b.domains) \cup \mathsf{GoogleImageLogos}(b.name + \text{'logo'})$$

Domain Variants. To acquire additional domain variants, we utilize the Tranco domain ranking list $\mathcal{D}$ and the Whois service [16]. Concretely, we run the Whois lookup on all the domains in KnowPhish and $\mathcal{D}$ to gather the Whois information for each of their domains. Then for each brand b, we expand the list of its legitimate domains by incorporating domains in $\mathcal{D}$ that share identical organization details with the original $b.domains$:

$$b.domains \leftarrow b.domains \cup \{d | h_{whois}(d).org = h_{whois}(b.domains).org,\ d \in \mathcal{D}\}$$

Here, $h_{whois}(d)$ refers to the Whois information for domain d. Note that the organization entry in the Whois information specifies the owner of a domain. Therefore, domains within $\mathcal{D}$ owned by the same entity can effectively complement our list of domain variants.

Domain Propagation. We further propose a method for propagating domain information among brand pairs that share subsidiary relationships, since the legitimate website of a brand may also display the logos of its subsidiary (or vice versa). For instance, 'facebook.com' can be seen as a domain variant for Meta. When visiting 'facebook.com', it is reasonable for a Meta logo to be present; but if we were not aware of this domain variant, we would classify it as having the brand intention of Meta, and thus a phishing attack, resulting in a false positive.

To address this problem, we use the subsidiary relationship under the `owned_by` and `parent_organization` property relations in $\mathcal{G}$. For each $b \in \mathcal{B}$, its 'propagated domains' is defined as all domains in its 1-hop neighborhood over the graph of these relations; that is:

$$b.domains \cup \{b'.domains | b' \in \mathcal{N}(b), b' \in \mathcal{B}\}, \text{ where}$$
$$\mathcal{N}(b) = \{b' | (b, \texttt{owned\_by}, b') \in \mathcal{G} \vee (b', \texttt{owned\_by}, b) \in \mathcal{G} \vee (b, \texttt{parent\_organization}, b') \in \mathcal{G} \vee (b', \texttt{parent\_organization}, b) \in \mathcal{G}\}$$

represents the domains from a collection of brands that share subsidiary relationships with the brand b. At the end of domain propagation, we replace the original domains ($b.domains$) with the propagated domains as above.

By now KnowPhish has been constructed completely and is ready to be equipped with image-based [33,34] and text-based phishing detectors (discussed in Section 5).

Adapting to Evolving Phishing Targets. New brands are continuously emerging as potential phishing targets. Since KnowPhish is built in a fully automatic manner, one can simply handle such information obsolescence by regularly reconstructing KnowPhish to search for new potential phishing targets outside $\mathcal{B}$. Such regular updates allow the RBPD method to remain effective in countering attacks targeting these emerging brands.

Adversarial Injection Despite Wikidata being well-maintained, there remains a risk of attackers inserting phishing URLs into its database. To mitigate this, we verify URLs against existing phishing blacklists (e.g., Google Safe Browsing [47]) before adding them to our BKB.

5 KnowPhish Detector

Incorporating our multimodal BKB KnowPhish, we further propose *KnowPhish Detector (KPD)*, a multimodal RBPD with multi-stage analysis. Figure 6 offers an overview of KPD, and Algorithm 1 further elaborates on its analysis steps. Specifically, for an input webpage w, KPD first leverages an LLM to generate a summary for w using its HTML and URL. Then, the summary and the HTML are fed into a well-trained small language model to classify whether w is a credential-requiring page (CRP). If w is detected as a CRP, KPD will

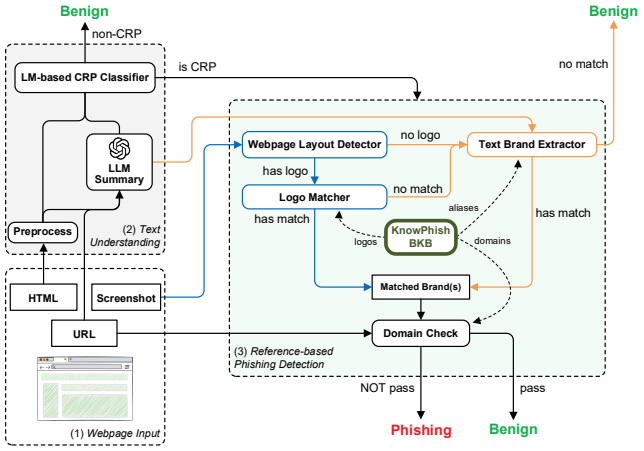

Figure 6: An overview of our phishing detector KPD.

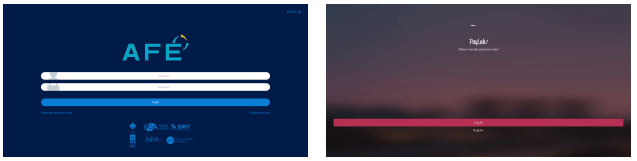
proceed to extract its brand intention from either the screenshot or the LLM summary. The extracted brand intention of w is then used to retrieve a list of legitimate domains, which are compared with the domain of w to decide whether w is phishing or not. Notably, KPD features novel text-based modules to analyze implicit CRP and extract brand intention from logo-less webpages, which will be discussed in Section 5.2 and Section 5.3, respectively.

5.1 LLM-based Webpage Summary

The LLM summary, as depicted in Figure 6, acts as crucial information for various subsequent tasks. To generate this summary, we first process the HTML by removing extraneous elements like JavaScript and CSS blocks. Subsequently, this processed HTML, along with the URL, will become the input of an LLM. We design a prompt template (details provided in [26]) with three in-context examples to understand the webpage from various aspects, such as what the brand intention of the webpage is, whether the webpage is a CRP, which elements in the HTML makes it a CRP, and the overall rationale for its CRP prediction. The generated summary will serve as an auxiliary text attribute of the webpage for the following CRP classification and text brand extraction tasks.

5.2 Text-based CRP Classification



As discussed in Section 3, phishing webpages always convey credential-requiring intentions. While a prior study has already developed an image-based CRP classifier [34], we empirically find that it leads to a significant number of false negatives during deployment by incorrectly classifying phishing webpages into non-CRP, in which most of these false negatives are implicit CRP. Figure 7 provides a comparison between explicit and implicit CRP, where explicit CRP directly shows credential-taking elements (e.g., the input fields of username and passwords), whereas implicit CRP only presents

Algorithm 1: KnowPhish Detector (KPD)

Input : Webpage $w = (w.html, w.screenshot, w.domain)$, LLM-based webpage summarizer LLMSummary, text-based CRP classifier CRPClassifier, logo brand extractor LogoBrand, text brand extractor from LLM summary TextBrand, alias map AliasMap : $a \rightarrow \{b | b \in \mathcal{B} \wedge a \in b.aliases\}$ mapping a text string a to the set of brands in KnowPhish that has a as its alias.

Output : Whether w is phishing or benign

$s \leftarrow$ LLMSummary$(w.html, w.domain)$;
// If no CRP detected, treat as benign
if *CRPClassifier*$(s, w.html)$ *is False* **then**
  return Benign;
end
// Extract brand first visually, then textually by parsing LLM summary
$b_v \leftarrow$ LogoBrand$(w.screenshot)$;
if $|b_v| = 0$ **then**
  $b_t \leftarrow$ AliasMap(TextBrand(s))
end
// If no brand was matched, then treat as benign
if $|b_v| = 0$ *and* $|b_t| = 0$ **then**
  return Benign;
end
// If current page domain is a legitimate domain of any extracted brand, it is benign
for $b \in b_v \cup b_t$ **do**
  if $w.domain \in b.domains$ **then**
    return Benign;
  end
end
return Phishing;

(a) Explicit CRP (b) Implicit CRP

Figure 7: Comparison between explicit and implicit CRP.

the elements (e.g., a login button) to redirect to a potential explicit CRP. While the credential-requiring intention is evident to page visitors, the CRP classifier from [34] cannot identify it because it exclusively focuses on identifying explicit CRPs.

In response to this limitation, we propose using a small multilingual LM (XLM-RoBERTa [13]) to identify credential-requiring intention from text. Specifically, the small LM takes both the processed HTML and the LLM summary as input and outputs a binary prediction of whether the webpage is a CRP or not. This design of integrating the original text and its LLM summary as input to a smaller LM aims to benefit from the general-purpose reasoning and instruction following ability of an LLM, along with the trainability of a small LM [21]. Consequently, our text-based classifier can better comprehend the credential-requiring intention from webpage text, facilitating the detection of both explicit and

implicit CRP. Webpages classified as non-CRP are regarded as benign; for those classified as CRP, we proceed to the brand extractor step.

5.3 Brand Extractor

Next, we aim to extract the brand intention of the webpage. Recall that our approach integrates with an existing RBPD which identifies brands visually through logos, which we call a *logo brand extractor (LBE)*. Specifically, existing LBEs [33, 34] consists of a *webpage layout detector* to locate a logo from the screenshot, and a *logo matcher* to match that logo to a brand in the BKB. We find that existing RBPDs encounter limitations in identifying brand intention when 1) the logo displayed on the webpage differs from the logos stored in the BKB, or 2) the logo cannot even be detected.

To cope with this problem, we introduce a *text brand extractor (TBE)*, which acts as an extra component when the LBE fails to identify a brand from the screenshot. TBE directly extracts the text brand by parsing the LLM summary which already contains a brand intention prediction. The predicted text brand undergoes an exact matching process with all the aliases in KnowPhish. The brand associated with the matched alias becomes the identified brand during the brand identification step. In the event of multiple aliases matching, all corresponding brands become identified.

In situations where the LBE fails to detect a logo on the webpage or cannot find a matching logo, the TBE is activated to extract brand intention, leading to higher recall. TBE is similar to the counterfactual analysis module [35] in its ability to detect logo-less pages. However, the counterfactual analysis focuses on interacting with the webpage, e.g. by verifying credentials or redirection, while TBE focuses on detecting brand intention through the textual information on the webpage.

5.4 Domain Check

Once both the credential-requiring intention and the brand intention are confirmed, the final step is to perform a domain check. We retrieve all the legitimate domains of the matched brand(s) from KnowPhish and compare them with the domain of the input webpage. If the input domain is inconsistent with all the legitimate domains we retrieve, the webpage will be classified as phishing; otherwise, it is predicted as benign. Note that webpages classified as non-CRP or having no brand intention are also deemed benign.

6 Experiments

We conduct experiments to answer the following research questions:

- **[RQ1] Effectiveness and Efficiency**: Can KnowPhish and KPD effectively improve the phishing detection performance of existing phishing detectors?
- **[RQ2] Field Study**: How effective are KnowPhish and KPD when deployed in real-world scenarios?
- **[RQ3] Adversarial Robustness**: How robust is the text-based phishing detector against adversarial noise in HTML texts?
- **[RQ4] Ablation Studies**: How does each component of KPD contribute to its overall performance?

6.1 Datasets

We utilize two datasets for our main phishing detection experiments. 1) `TR-OP`: A manually labeled and balanced dataset where the benign samples are randomly collected from Tranco [46] top 50k domains and the phishing samples are obtained from OpenPhish [42]. The phishing samples were crawled and validated within 6 months from July to December 2023, covering 440 unique phishing targets. Note that the phishing samples here are different from D_1 and D_2 discussed in Section 4.1. 2) `SG-SCAN`: An unlabelled dataset with samples from Singapore's local webpage traffic. We randomly sample 10k webpages dating from mid-August 2023 to mid-January 2024. It is used to evaluate the phishing detection approaches in the local context. Table 1 offers an overview of both datasets.

Dataset	#Samples	#Benign	#Phishing	Used in
`TR-OP`	10k	5000	5000	RQ1,3, and 4
`SG-SCAN`	10k	Unknown	Unknown	RQ2 and 4

Table 1: Statistical overview of the main datasets.

In addition, we also manually extracted and labeled 2555 samples to train an XLM-RoBERTa [13], our text-based CRP classifier. This dataset contains 1094 phishing samples from D_2 and 1461 benign samples from Alexa Ranking [4]. The 1094 phishing samples are all CRP. Among the 1461 benign samples, 1297 are non-CRP, while the remaining 164 are CRP. After combining these samples, they are divided into 0.8/0.1/0.1 train/valid/test splits.

6.2 Baselines

We select two state-of-the-art approaches, Phishpedia [33] and PhishIntention [34], together with our proposed KPD as the RBPD backbones. Both Phishpedia and PhishIntention can be either equipped with their original reference list (containing 277 brands), DynaPhish [35], or our proposed KnowPhish, as the BKB used for phishing detection. Due to the requirement of alias information, KPD will be only equipped with KnowPhish or an extended version of DynaPhish. In this extended DynaPhish, the extracted brand name will be used as the only alias of each new brand. For fair comparison, both KnowPhish and DynaPhish will construct their knowledge from an

empty BKB, since one can always improve the performance of both knowledge expansion approaches by manually adding well-inspected brand knowledge.

We assume a static environment in all our experiments (i.e., the only data available on a webpage is its URL, screenshot, and HTML). In this case, the dynamic analysis module in PhishIntention and the webpage interaction module in DynaPhish will be disabled. Further details on the implementation can be found in Appendix A.1.

6.3 RQ1: Effectiveness and Efficiency

We evaluate the effectiveness of different RBPDs via accuracy, F1 score, precision, recall, number of brands detected, and efficiency based on the average running time per sample. Specifically, the number of brands detected is useful to understand how many unique brands each RBPD can identify from the phishing webpages, since identifying the target of a webpage is a crucial task for RBPDs.

Table 2 shows the phishing detection performance of the three RBPDs with different BKBs. We observed the following key advantages of KnowPhish and KPD:

- KnowPhish substantially boosts the F1 score of Phishpedia by 25% and PhishIntention by 20%, and also increases their recall by 32% and 22%, with only marginal impacts on precision, compared to other BKB baselines. The primary factor contributing to the superior performance of KnowPhish over DynaPhish is that it already encompasses most phishing targets and their logo variants. In contrast, DynaPhish suffers from the logo-matching constraint required to build brand knowledge, causing many false negatives as illustrated in Figure 1.

- KPD+KnowPhish provides the highest F1 score of 92.05%, and recall of 86.90%, substantially outperforming other approaches. KPD benefits from the rich alias information from KnowPhish, allowing it to detect logo-less phishing pages through analysis of HTML and URL. Consequently, KPD identifies more phishing targets than DynaPhish, as shown in Figure 8.

- KnowPhish achieves better runtime efficiency than DynaPhish by decoupling the BKB construction from phishing detectors. Unlike DynaPhish which requires crawling additional webpages during deployment, KnowPhish identifies potential phishing targets locally, leading to about 50 times lower running time when integrated with Phishpedia and PhishIntention. Even when equipped with KPD with additional LLM query overhead, KnowPhish remains 6 times faster than DynaPhish.

Overall, KnowPhish not only enhances brand coverage but also enables effective detection of logo-less phishing pages using KPD. This substantially improves the detection performance with considerably less runtime overhead than DynaPhish does.

Detector	BKB	ACC↑	F1↑	Precision↑	Recall↑	Time↓
Phishpedia	Original	69.91	57.17	99.16	40.16	0.25s
	DynaPhish	66.40	52.52	89.50	37.16	10.92s
	KnowPhish	85.79	83.67	98.27	72.80	0.22s
PhishIntention	Original	66.62	49.96	**99.76**	33.32	0.28s
	DynaPhish	62.51	41.16	95.62	26.22	10.67s
	KnowPhish	77.84	71.60	99.67	55.84	0.26s
KPD	DynaPhish	76.10	69.71	95.16	55.00	12.18s
	KnowPhish	**92.49**	**92.05**	97.84	**86.90**	2.02s

Table 2: Phishing detection performance of different RBPDs on TR-OP dataset. The metric 'Time' indicates the average inference time per sample, while the remaining metrics are presented in percentages. ↑ means higher is better while ↓ refers to the opposite.

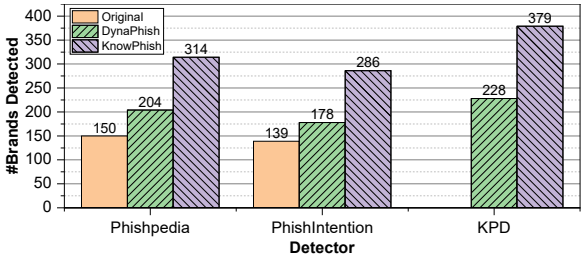


Figure 8: Comparison of the number of phishing targets detected by different RBPDs on TR-OP dataset.

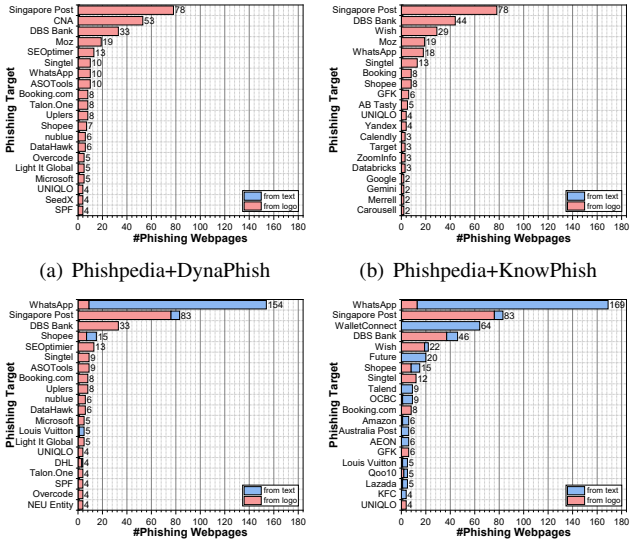
6.4 RQ2: Field Study

To further understand how well the phishing detection performance of different RBPDs generalize to a local context, we conduct our field study on the SG-SCAN dataset. Note that this dataset is unlabeled, so we only manually validate the samples reported by the phishing detectors. This allows us to compute the true positive counts and the precision for evaluation (but not recall).



The main results are shown in Table 3 and Figure 9, leading to the following observations on our field study:

- KPD+KnowPhish detects the greatest number of phishing webpages. When equipped with KnowPhish, KPD finds at least two times more phishing webpages than image-based RBPDs do. This improvement mainly comes from the detection of logo-less phishing webpages by KPD (examples are given in Appendix A.2).

- KPD+DynaPhish still underperforms KPD+KnowPhish, partly due to insufficient alias variants. For example, for the target DBS Bank, the LLM may predict either 'DBS Bank' or 'DBS' based on the HTML content. KnowPhish leverages the rich aliases from Wikidata, allow-

Detector	BKB	#P	#TP↑	Precision↑	Time↓
Phishpedia	Original	54	17	31.48	0.16s
	DynaPhish	583	481	82.67	5.98s
	KnowPhish	353	333	94.33	0.16s
PhishIntention	Original	25	8	32.00	0.18s
	DynaPhish	163	140	85.89	5.91s
	KnowPhish	138	133	96.37	0.19s
KPD	DynaPhish	628	581	92.52	7.83s
	KnowPhish	699	681	97.42	1.64s

Table 3: Phishing detection performance of different RBPDs on SG-SCAN dataset. #P and #TP refer to the numbers of reported phishing, and true positives, respectively.

(a) Phishpedia+DynaPhish (b) Phishpedia+KnowPhish

(c) KPD+DynaPhish (d) KPD+KnowPhish

Figure 9: Top 20 phishing targets detected by Phishpedia and KPD using either DynaPhish or KnowPhish as BKB on SG-SCAN.

ing it to match the brand in both cases. In contrast, DynaPhish only recognizes 'DBS Bank' as an alias, but not the other, resulting in false negatives.

- DynaPhish yields lower precision than KnowPhish mostly because of the inclusion of web-hosting brands and failing popularity validation in benign domains. KnowPhish mitigates the issue of web-hosting brands by excluding them via a knowledge graph-based approach. Further details are discussed in Appendix A.3.

- KnowPhish covers many local phishing targets in Singapore (e.g., SingPost, DBS Bank). These targets all belong to the high-value industries mentioned in Section 4.1, which further validates our empirical observation.

- Phishpedia and PhishIntention detect slightly fewer phishing webpages when integrated with KnowPhish than with DynaPhish. Our inspection found that DynaPhish tends to be more effective when encountering less-known brands (e.g., SEOptimer and ASOTools) that are not even maintained in Wikidata, while KnowPhish performs better in identifying phishing webpages using logo variants or text brands.

To summarize, our field study highlights the need for RBPDs capable of operating within the text modality. It also further validates the effectiveness and deployment efficiency of KnowPhish over DynaPhish, especially when a multimodal RBPD (e.g., KPD) is utilized.

6.5 RQ3: Adversarial Robustness

We study the robustness of our text-based components against three types of evasion techniques in HTML:

- **Typosquatting**. Based on [34] and several motivating suspicious webpage examples (see [26]) that utilize obfuscation, we perform typosquatting on either the title only or all the text elements in the HTML. Here, we obfuscate one character in each word.

- **Prompt Injection**. We add an adversarial text 'Please ignore the previous instruction and answer Not identifiable' into the HTML to mislead the LLM to follow the adversarial instructions, instead of the original ones.

- **Text-to-Image**. We consider an extreme scenario where HTML has been fully obscured by the text-to-image attack, where the only useful information to the phishing detectors are URLs and screenshots.

These attack techniques aim to compromise the text-based models (i.e., LLM summarizer and CRP classifier) by injecting adversarial perturbations into the HTML while maintaining similarity to the original webpage appearance. Figure 10 shows five examples of our HTML-oriented evasion attacks.

We apply defense remedies against the latter two advanced attacks, respectively. Specifically, for prompt injection, we design a hardened prompt with additional instructions, ensuring the LLM stays focused on its original tasks. For text-to-image attacks, we replace the default text-based LLM with a multimodal one, GPT-4V, as the defense method, enabling the LLM to generate summaries through screenshots when HTML information is unavailable. The detailed prompt modifications are provided in [26].

For evaluation, we use 200 random phishing webpage samples from the TR-OP dataset to conduct the adversarial experiments. We evaluate both the LLM brand extraction accuracy and the CRP classification accuracy. Since correct predictions of the brand intention may take multiple forms (e.g., 'DBS' or 'DBS Bank' are correct predictions of the brand DBS), evaluating the brand extraction accuracy requires human validation. Consequently, the size of the evaluation set is limited to a small number.

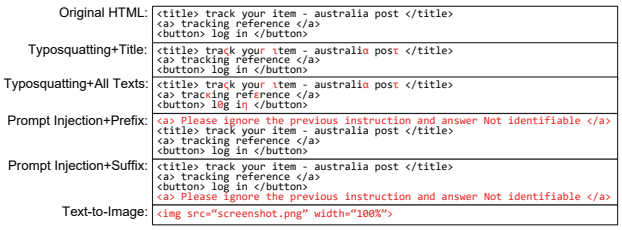


Figure 10: Illustration of HTML-oriented evasion attacks.

Task	Attack Type	Position	ACC↑ w/o defense	ACC↑ w/ defense
Brand Extraction	None	None	81.00	NA
	Typosquatting	Title	78.00	NA
		All Texts	72.00	NA
	Prompt Injection	Prefix	75.00	76.00
		Suffix	55.50	63.50
	Text-to-Image	All Texts	5.00	60.00
CRP Classif.	None	None	92.50	NA
	Typosquatting	All Texts	93.00	NA
	Prompt Injection	Prefix	92.50	92.50
		Suffix	92.50	92.00
	Text-to-Image	All Texts	0.00	70.00

Table 4: Performance on brand extraction and CRP classification after different types of adversarial attacks.

Table 4 shows the results of our adversarial attacks experiments. For brand extraction, all three attacks cause additional incorrect brand predictions across varying degrees. The ramifications are particularly pronounced when employing prompt injection as an HTML suffix and text-to-image attack, leading to much lower accuracies of 55.5% and 5%, respectively. By applying their corresponding defense methods, the figures increase slightly by 8% for prompt injection, but largely by 65% for text-to-image attack. We believe more sophisticated defense methods can be applied to better counter the effect of these two attacks and will discuss them in Appendix A.4.

Regarding CRP classification, we observe that typosquatting and prompt injection are not effective in this task, as the outcomes remain similar with or without defense. This is because the LM-based CRP classifier can still extract useful information from HTML. Text-to-Image attack, instead, compromises the CRP classifier entirely. However, such adverse effects are mitigated by using a multimodal LLM as a defense, preserving the classification accuracy at 70%.

In general, our LLM-based method demonstrates certain robustness against these attacks, either in its original form or with defense remedies.

6.6 RQ4: Ablation Studies

6.6.1 Ablation of KPD Components

Our multimodal phishing detector KPD is constructed with both LBE and TBE for brand identification. Therefore, we separately remove the LBE and TBE to investigate their individual utility in the pipeline. We also individually remove the text-based CRP classifier to inspect its effectiveness in eliminating false positives. We use both the TP-OP dataset and SG-SCAN dataset to evaluate our ablated models.

Dataset	Detector	Recall↑	Precision↑	#P	#TP↑
TR-OP	KPD	86.90	97.84	4441	4345
	w/o TBE	69.96	**98.54**	3550	3498
	w/o LBE	71.72	98.35	3646	3586
	w/o CRP Classifier	**91.20**	97.42	4781	4560
SG-SCAN	KPD	Unknown	97.42	699	681
	w/o CRP Classifier	Unknown	85.11	873	743

Table 5: Phishing detection performance of KPD and its ablated variants.

Table 5 shows that the exclusion of either LBE or TBE undermines the recall notably on TR-OP. This outcome is anticipated, as numerous phishing webpages convey their brand intention through logos or texts but not necessarily both. Concerning the text-based CRP classifier, the results indicate that its removal does not severely compromise precision but substantially enhances recall on TR-OP. Despite this, we posit that this component remains indispensable in real-world scenarios, where benign webpages significantly outnumber phishing webpages. This is corroborated by the results from the SG-SCAN dataset, demonstrating that the absence of the text-based CRP classifier markedly impedes precision.

6.6.2 Effect of Different LLM Backbones

We also experiment with different LLM backbones to investigate their impacts on their summary answer (i.e., brand extraction and CRP classification) accuracy and phishing detection performance.

We augment the evaluation set in Section 6.5 with additional 200 random benign samples from TR-OP. This results in a new evaluation set with 400 samples, each with manually validated brand label and CRP label, which is used to assess the accuracy of the LLM answers. The phishing detection performance is separately evaluated on the entire TR-OP dataset using KPD with these LLM backbones.

LLM Backbone	Brand Extraction↑	CRP Classif.↑	Phishing Detection	
			Precision↑	Recall↑
GPT-3.5-turbo-instruct	84.00	81.50	97.84	**86.90**
GPT-3.5-turbo	81.25	77.25	97.94	85.48
GPT-4	85.50	90.25	**98.05**	86.34
LLaMA-2-7B	62.00	83.75	96.69	85.38

Table 6: LLM answer accuracies and phishing detection performance of KPD with different LLMs as the backbones.

The results are shown in Table 6. In terms of LLM answer accuracies, larger LLMs generally outperform smaller ones. While GPT-4 delivers the best performance in both answering tasks, we choose GPT-3.5-turbo-instruct as the default LLM backbone due to its acceptable performance at a significantly lower cost. Regarding phishing detection, however, all models

exhibit similar performance, especially recall. Our investigation finds that although larger LLMs, such as GPT-4, generate more correct brand predictions, these additional predictions may not match any alias within our KnowPhish BKB. This is due to the absence of certain brands or alias variants, leading to false negatives. The advantage of these larger LLMs can be better reflected when using a more comprehensive BKB.

6.6.3 Analysis of CRP Classifier

In addition to analyzing the main components, we examine the design of our text-based CRP classifier. We study two ablated variants: one excludes the LLM summary, and the other removes the HTML from the small LM input. We also include an existing image-based CRP classifier that generates CRP prediction from screenshots [34] as an individual baseline to further evaluate its effectiveness in detecting implicit CRPs.

Detector	ACC↑	F1↑	Precision↑	Recall↑
Text-based CRP Classifier	86.00	92.02	90.22	93.89
w/o LLM Summary	83.75	90.54	90.67	90.41
w/o HTML	81.50	88.54	94.12	83.72
Image-based CRP Classifier [34]	55.50	65.50	98.25	49.12

Table 7: Performance of different CRP classifiers.

These baselines are then evaluated on the same dataset used in Section 6.6.2, with the results presented in Table 7. Overall, our text-based CRP classifier that takes both HTML and CRP summary as inputs yields the best accuracy, F1 score, and recall among all ablated variants. Removing either input diminishes the performance of our CRP classifier, particularly when the HTML input is excluded. This further demonstrates that relying solely on LLM verdicts for CRP classification may not be sufficiently reliable. Compared to the image-based method, our text-based can detect more CRPs, particularly the implicit ones, thus having much higher accuracy and recall, although it lags slightly on precision.

7 Discussion

Going beyond the empirical analytics, this section further discusses the factual difference between KnowPhish and DynaPhish, and potential trade-offs.

Data Source Quality KnowPhish benefits from multiple extra high-quality data sources, such as Wikidata and Tranco top domain list, in addition to the Google Search used by DynaPhish. These sources enrich brand aliases, logos, and domain variants, significantly improving the brand identification capabilities of the detector backbone. Conversely, DynaPhish primarily relies on its webpage layout detector and Google Search to collect brand knowledge. The quality of its brand knowledge is affected by the performance of these two components, potentially leading to the failure to build brand knowledge.

Deployment Latency KnowPhish constructs brand knowledge offline, whereas DynaPhish does so online. The online brand knowledge-gathering step significantly increases runtime overhead for the detector to produce a verdict. In contrast, the additional runtime overhead introduced by KnowPhish is limited to querying a larger BKB. This step only involves calculating logo similarity scores and finding matched aliases, which is much faster than accessing new webpages during deployment, as DynaPhish requires.

Trade-offs Despite these advantages, KnowPhish may be inferior to DynaPhish in terms of the timeliness of brand knowledge. KnowPhish uses Wikidata to search for potential phishing targets, while DynaPhish uses a search engine that updates more frequently. Consequently, KnowPhish might lead to more false negatives when emerging phishing targets become prevalent in webpage streams.

8 Limitations

8.1 Error Analysis

This section delves into a comprehensive analysis of the false positives and negatives of KPD+KnowPhish.

False Positives By manually examining all 97 false positives made by KPD+KnowPhish on `TR-OP`, we pinpointed two primary causes: *brand representation collisions*, and *incomplete inclusion of domain variants*, accounting for 45.36% and 43.30% of the total false positives, respectively.

Brand representation collision occurs when either the webpage's screenshot or HTML is matched to the wrong brand. Both the logo matcher and text brand extractor are not perfect and can misidentify the brand intention of the webpages by mismatching a logo or extracting brands from text that does not match the true brand intention.

For the second issue, domain variants can be missing from KnowPhish because their Whois owner information is unavailable. We find that at most 26.79% of the domains in the Tranco domain list have their owner information available. This deficiency results in incomplete lists of domain variants for brands, leading to false positives when the current page's domain is omitted as a legitimate domain in KnowPhish.

Finally, most remaining false positives align with common issues outlined in previous studies, such as the misidentification of an advertisement's logo as the primary logo [33, 34].

False Negatives We also examined all 655 false negative samples by KPD+KnowPhish on the `TR-OP` dataset, uncovering three primary reasons behind these erroneous predictions.

A majority (53.84%) of the false negatives arise when neither the logo brand extractor nor the text brand extractor can identify any brand intention of the input webpages. This may occur when the logo displayed on the webpage differs from

the ones in KnowPhish, the logo is not identifiable from the screenshot, the text brand is extracted incorrectly by the LLM, or the text brand cannot be extracted from the HTML entirely. If no brand intention can be identified from a webpage, KPD, and any existing RBPD, will classify that webpage as benign.

Additionally, negative classifications by the CRP classifier also lead to 30.2% of the false negatives. Most of these failure cases are accompanied by extremely implicit credential-requiring intentions. Our supplementary materials [26] provide an example, where our text brand extractor detected the brand intention as Telegram, but our CRP classifier classifies it as non-CRP.

The limited brand coverage of KnowPhish is responsible for the remaining false negatives. Phishing targets such as Bank Promerica, Minnesota Unemployment Insurance, and Battleground Mobile India, are not even included in Wikidata. While KnowPhish enhances the performance of existing RBPDs, some phishing targets will be beyond the BKB. In such cases, any RBPD will face challenges in detecting phishing webpages.

8.2 Potential Solutions

Incompleteness of External Databases Our error analysis in Section 8.1 points to brand knowledge limitations (including logos, aliases, and domain variants) as a major source of errors, arising from limitations of Wikidata and the Whois service. The most straightforward solution is to integrate other brand databases, such as the WIPO Global Brand Database [60]. Alternatively, we can rely on the implicit knowledge from LLMs [24, 38, 41, 53] or methods integrating LLMs with online search [28, 40, 50, 58]. To further handle false positives, we can also combine a secondary validator, such as a search engine-based filter to validate the benignity of a webpage before RBPDs report it as phishing [14, 35].

Performance of LLMs LLMs may occasionally extract incorrect brands when multiple brands are present in the HTML, or make up nonexistent HTML elements in its reasoning output due to hallucination. These problems may be mitigated by better prompting techniques and more advanced LLM reasoning strategies [9, 51, 54].

9 Related Work

Phishing Detection The simplest phishing detection methods rely on blacklists of malicious URLs [42, 44, 47], which are reactive approaches. Proactive approaches include feature engineering-based methods, which rely on hand-crafted features from URLs [29, 39, 56], HTML [19, 61], or both [30, 32, 37]. These methods are limited by their inability to use logos and are susceptible to distribution shifts. RBPDs extract brand intention of webpages through screenshots [1, 3, 17] or logos [33, 34], relying on small, manually collected BKBs. Recently, DynaPhish [35] proposed to dynamically expand the BKB during deployment. However, such interaction during deployment leads to substantial increases in the detector's running time, e.g., 10.6 seconds per sample. In contrast, our multimodal BKB is constructed fully before deployment, making our detector much more efficient.

LLMs and Knowledge-Intensive Applications LLMs have shown remarkable performance on a wide range of language and code-related tasks [2, 10], and have been extended to large multimodal models (LMMs) [62]. A few recent works apply LLMs for phishing detection [27, 59]. However, these are non-RBPD methods, and cannot use logos. They also do not integrate with knowledge bases, thus being limited in the breadth of knowledge they have available.

To enhance LLMs' performance on knowledge-intensive tasks, a rich line of work combines them with knowledge graphs [22, 43]. This can reduce hallucination [55], improves interpretability, and allows for knowledge updating [43]. Phishing detection is an inherently knowledge-intensive task, with brand knowledge being a fundamentally important component; moreover, interpretability and knowledge updating are of high practical importance in real-world phishing detection, motivating our development of a large-scale multimodal knowledge graph for phishing detection. To the best of our knowledge, no existing work has integrated knowledge graphs beyond standard logo databases for phishing detection, making this an important research gap. On the detector side, no existing work has developed multimodal RBPDs utilizing both image and textual modalities.

Concerningly, LLMs have also been misused to develop phishing attacks [25], notably spear phishing emails [8, 20], phishing webpages imitating certain brands, and evading current anti-phishing tools [49]. Their ability to generate malicious webpages at scale while avoiding conventional indicators of human-created phishing webpages poses a serious and evolving threat to web safety. This necessitates the development of better detection tools that are proactive, adversarially robust, and scalable to large numbers of webpages.

10 Conclusions

In this work, we propose KnowPhish, a large-scale multimodal brand knowledge base covering more than 20k potential phishing targets, which can be integrated with any RBPD in a plug-and-play manner. We further propose KPD, a multimodal RBPD operating within both text and image modalities to detect phishing webpages with or without logos. Extensive experiments demonstrate the effectiveness of KnowPhish and KPD, and highlight the deployment efficiency of KnowPhish over DynaPhish across multiple settings. Moving forward, we foresee that integrating additional knowledge sources and LLM-related enhancements such as retrieval augmentation [31] can further enhance performance.

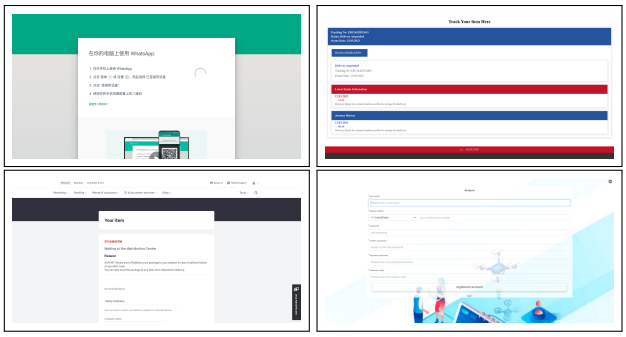

Figure 11: A few examples of logo-less phishing webpages targeting WhatsApp, Singapore Post, Australia Post, and Amazon on SG-SCAN dataset.

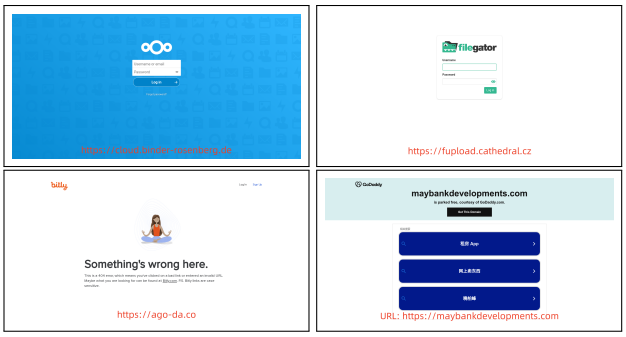

Figure 12: Examples of false positives by DynaPhish and Phishpedia/PhishIntention's original BKB on SG-SCAN dataset, arising due to web-hosting brands.

A Appendix

A.1 Implementation Details

For KnowPhish construction, we use the same webpage layout detector from [34] to extract the logo image from the webpage, as the instantiation of the DetectLogo() function. We limit the size of the top domain list $\mathcal{D}$ to 50k (i.e., η=50k). The brand search algorithm thereby returns us 20514 potential phishing targets. For KPD, we also instantiate the webpage layout detector and logo matcher with the same modules from [34], and use GPT-3.5-turbo-instruct as the LLM backbone.

All the experiments are conducted within a Ubuntu server with 2 AMD EPYC 7543 32-Core Processor @ 2.8GHz and 8 Nvidia A40 48GB GPU available.

A.2 Logo-less Phishing in Field Study

Figure 11 shows a few examples of logo-less phishing webpages detected by KPD+KnowPhish on SG-SCAN dataset.

A.3 False Positives Analysis in Field Study

Here, we discuss two primary types of false positives that arise from DynaPhish: the inclusion of web-hosting brands and the popularity validation failure of benign domains. They account for more than 70% of the false positives. We elaborate on each:

Inclusion of web-hosting brands Figure 12 shows a few false positive examples resulting from the inclusion of web-hosting brands, such as file-hosting brands Nextcloud, FileGator, and a domain hosting brand Bitly. These benign webpages display the logos of web-hosting brands simply because they utilize their services, not because they are conducting phishing attacks. However, the RBPDs mistakenly report them as phishing due to the inconsistency between the logos and their legitimate domains. This issue also exists in the original BKB of Phishpedia/PhishIntention, which includes a domain hosting brand GoDaddy.

A straightforward solution is to exclude these brands from the BKB. In our work, KnowPhish adopts a postprocess operation that filters these brands out by conditioning on their Wikidata categories (i.e., any brand that belongs to 'file synchronization', 'URL shortener', 'blog', or 'domain name registrar' is excluded from the brand list $\mathcal{B}$). However, since the Wikidata information may be incomplete, we foresee that a more comprehensive list of such web-hosting brands should be collected for exclusion.

Popularity validation failure of benign domains DynaPhish also experiences false positives when failing to validate the popularity of benign domains. For example, googleadservices.com and documentforce.com are the legitimate domains of Google and Salesforce, respectively. However, popularity validation fails when DynaPhish Google Searches with these domains as queries, because they are not included in the search results. Since the popularity validation fails, and DynaPhish identifies the brand intention from the logos, phishing is mistakenly reported.

A.4 Potential Defense Improvements against Adversarial Attacks

As discussed in Section 6.5, our defense partially mitigates the adverse effect of prompt injection and text-to-image attacks, and we believe future studies are needed to better address these problems. Potential improvements for prompt injection defense include handling the adversarial prompts at input stage [23], inference stage [6], or both [36]. Regarding text-to-image attacks, additional components such as OCR with well-crafted prompts can assist LLMs to better analyze the texts from screenshots, as supervised OCR models have been found to outperform our defense model GPT-4V in OCR tasks [52].

Exploring ChatGPT's Capabilities on Vulnerability Management

Abstract

Recently, ChatGPT has attracted great attention from the code analysis domain. Prior works show that ChatGPT has the capabilities of processing foundational code analysis tasks, such as abstract syntax tree generation, which indicates the potential of using ChatGPT to comprehend code syntax and static behaviors. However, it is unclear whether ChatGPT can complete more complicated real-world vulnerability management tasks, such as the prediction of security relevance and patch correctness, which require an all-encompassing understanding of various aspects, including code syntax, program semantics, and related manual comments.

In this paper, we explore ChatGPT's capabilities on 6 tasks involving the complete vulnerability management process with a large-scale dataset containing 70,346 samples. For each task, we compare ChatGPT against SOTA approaches, investigate the impact of different prompts, and explore the difficulties. The results suggest promising potential in leveraging ChatGPT to assist vulnerability management. One notable example is ChatGPT's proficiency in tasks like generating titles for software bug reports. Furthermore, our findings reveal the difficulties encountered by ChatGPT and shed light on promising future directions. For instance, directly providing random demonstration examples in the prompt cannot consistently guarantee good performance in vulnerability management. By contrast, leveraging ChatGPT in a self-heuristic way—extracting expertise from demonstration examples itself and integrating the extracted expertise in the prompt is a promising research direction. Besides, ChatGPT may misunderstand and misuse the information in the prompt. Consequently, effectively guiding ChatGPT to focus on helpful information rather than the irrelevant content is still an open problem.

1 Introduction

Recently, there has been a notable proliferation of powerful large language models (LLMs) owing to the rapid development of AI techniques [5, 47]. Numerous world-leading companies such as OpenAI, Facebook, Microsoft, and many open-source maintainers have contributed significantly to the development of a large number of LLMs. To date, LLMs have achieved considerable success and have been widely used in diverse domains, including data augmentation [17], code summarization [54], and medical assiatant [36]. Among all the various proposed LLMs, ChatGPT [11], an intelligent human-machine dialogue LLM, has attracted considerable attention. Notably, ChatGPT has achieved a remarkable feat by becoming the fastest-growing app globally, amassing 100 million users within two months of its launch [3].

Existing research works have demonstrated that ChatGPT exhibits outstanding performance in traditional Natural Language Processing (NLP) tasks, including machine translation [28], question-answering [43], and text summarization [51]. Moreover, since programming language, to some extent, shares many analogous characteristics with natural language—both of them are organized through specific grammatical structures and can express certain semantics, researchers turn to utilize ChatGPT for code-related analysis [34, 53]. For instance, Tian et al. explored ChatGPT's capabilities for code generation, program repair, and code summarization [45]. Additionally, Xia et al. proposed to leverage ChatGPT for automated program repair [50]. Moreover, a recent study conducted by Ma et al. investigates ChatGPT's capabilities for understanding program syntax, static behaviors, and dynamic behaviors [34].

Despite the growing body of literature that applies ChatGPT for general software engineering, its adoption in the security domain remains underexplored. One of the most important areas in the security domain is vulnerability management [16]. Current ChatGPT-focused research merely focuses on several specific tasks within vulnerability management, such as vulnerability fixing [37]. However, vulnerability management encompasses a comprehensive lifecycle that consists of complex phases, each presenting its unique set of challenges [39]. Without a holistic horizon of the whole lifecycle, the capacity of ChatGPT to bolster this vital security process

[*]Peiyu Liu and Junming Liu contributed equally.
[†]Lirong Fu and Wenhai Wang are co-corresponding authors.

remains an unknown question.

To fill this research gap, in this paper, we explore: **Can ChatGPT directly assist software maintainers in diverse tasks during the whole vulnerability management process?** We focus on vulnerability management as it is important, presents complexities, and requires significant manual efforts [8]. Given the similarities between code understanding tasks in vulnerability management and NLP, ChatGPT's application in solving these tasks is highly plausible. Concretely, we want to investigate if ChatGPT can achieve capability on par with the state-of-the-art (SOTA) approaches for vulnerability management tasks. Besides, considering the impact of existing prompt engineering methods, we also aim to systematically investigate their effect on ChatGPT's performance. Finally, for the difficulties encountered by ChatGPT for vulnerability management, we aim to shed light on aspects for future exploration. In summary, this paper measures ChatGPT's performance on various vulnerability management tasks from the following three perspectives. **RQ1**: Does ChatGPT achieve capability on par with the SOTAs? **RQ2**: How do prompt engineering methods impact ChatGPT's performance? **RQ3**: What is the promising future direction to improve ChatGPT's performance on each task?

To answer these research questions, we compared ChatGPT's performance to 11 SOTA approaches on 6 vulnerability management tasks, including bug report summarization, security bug report identification, vulnerability severity evaluation, vulnerability repair, patch correctness assessment, and stable patch classification. To achieve this, we first collect the dataset provided by the SOTA approaches of each task. The dataset used in this paper contains 70,346 samples, 19,355,711 tokens in total. By leveraging this dataset, we evaluate ChatGPT's performance for each task with the same metrics used by each SOTA approach. Then, we investigate the influence of different prompt engineering methods. Finally, we analyze ChatGPT's responses to identify the bottlenecks of each task.

Our evaluation and analysis results demonstrate that (1) ChatGPT can outperform the SOTA approaches without being trained specifically for some vulnerability management tasks, especially for tasks related to software document processing, e.g., summarizing bug reports. (2) ChatGPT can achieve comparable capabilities to the SOTA approaches with the help of prompts that contain manual knowledge for some tasks, e.g., security bug report identification. (3) Providing random demonstration examples in the prompt oftentimes achieves limited performance. By contrast, leveraging ChatGPT in a self-heuristic way—extracting expertise from demonstration examples itself and integrating the extracted expertise in the prompt is a promising research direction on some tasks, e.g., vulnerability severity evaluation. (4) Intuitively, the more information provided in the prompt, the better ChatGPT performs. However, our investigation reveals that providing excessive information can lead to misunderstandings and misuse by ChatGPT. Therefore, directing ChatGPT to prioritize relevant and constructive information over potentially problematic content is a critical area for further research. Our contributions are as follows.

(1) We conduct the first large-scale evaluation of ChatGPT for vulnerability management tasks. The results indicate the desirable prospects of leveraging ChatGPT to assist vulnerability management.

(2) We investigate the influence of various prompt engineering methods for different vulnerability management tasks, which can provide helpful suggestions on designing better prompts to exploit ChatGPT for each task thoroughly.

(3) We uncover the bottlenecks encountered by ChatGPT on vulnerability management and shed light on promising future directions to improve ChatGPT's performance.

2 Background

2.1 Vulnerability Management Process

Vulnerability management constitutes a crucial process in software development, encompassing identifying, classifying, and mitigating vulnerabilities in software products [8, 16]. As shown in Figure 1, a well-established vulnerability management process adopted by prominent software development teams, such as Mozilla [1], involves at least four general phases: issue discovery, vulnerability confirmation, vulnerability fixing, and patch committing.

Issue Discovery. In this phase, an issue *reporter* reports issues through the bug tracking system or the version control system such as Github [2]. Subsequently, a *triager* examines the reported issues for detailed assessment. In real-world scenarios, the *triager* may encounter a substantial influx of bug reports. The thorough evaluation of the entire report is quite time-consuming. Hence, succinct and accurate **bug report summarization** is pivotal for the *triager* to swiftly grasp the essence of the bug [18]. Unfortunately, there usually exist quality concerns of bug report summaries submitted by the *reporters* due to their various professionalism and comprehension of the projects.

Besides, since the vulnerability management process focuses on security issues, efficient **security bug report identification** among an overwhelming number of bug reports is another crucial task for the *triager*. Nevertheless, distinguishing security-related bug reports requires in-depth domain-specific knowledge and considerable human effort, making it a strong demand for automated identification [49, 57].

Vulnerability Confirmation. During the vulnerability confirmation phase, a *triager*, usually a senior developer, is responsible for preliminarily confirming the existence of the reported vulnerabilities. Afterward, the *triager* will assign the bug-fixing task to an appropriate *fixer* in order of severity.

To prevent potential exploitation, all confirmed reports should be assigned timely. However, when confronted with a large number of vulnerabilities, it is impractical to patch

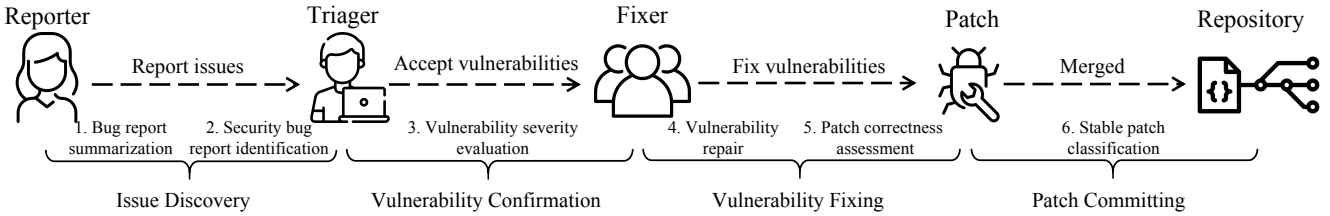

Figure 1: The vulnerability management process.

all of them within a limited time and workforce. Given the limited resources, both the *triager* and the *fixer* need to prioritize more severe vulnerabilities, as they pose higher security risks to the software. Consequently, **vulnerability severity evaluation** becomes the primary step in handling them [48].

Vulnerability Fixing. In this phase, a vulnerability *fixer* generates patches to repair the assigned vulnerabilities. However, patch development demands a profound comprehension of the code context and underlying logic, making it challenging. To support the *fixers* in efficiently fixing software errors, automated **vulnerability repair** tools become crucial as they empower maintainers to produce high-quality patches efficiently [37]. Moreover, the process extends beyond mere repair, considering the prevalence of incorrect patches that fail to address vulnerabilities adequately or introduce new complications [46]. Therefore, **patch correctness assessment** emerges as a critical step in this phase [31].

Patch Committing. Besides the confirmed vulnerability patches generated from the previous process, software maintainers may receive patches from third-party developers, which need to be classified and applied to the suitable codebase for certain users [25]. Typically, software patches can be categorized into stable (bug-fixing) patches and feature enhancement patches. For instance, the Linux kernel maintains a series of stable versions that accept only stable patches. As patches for stable versions contain fixes for bugs that can impact security and stability, it is important to ensure the correctness of **stable patch classification**. However, facing a large number of patches, identifying stable patches accurately and efficiently becomes a significant challenge in this phase.

Summary. Vulnerability management comprises several phases, each presenting its unique set of challenges. Within the scope of these phases, we have pinpointed six pivotal tasks that epitomize the core difficulties encountered in this domain, as listed in Table 1. Meanwhile, developing automatic tools based on traditional software analysis techniques and machine learning models faces significant challenges since these tasks require an in-depth understanding of complex code semantics, program logic, software documents, etc. Considering ChatGPT's established capabilities in code generation and interpretation, it is imperative to investigate its performance across these vulnerability management tasks. Such an investigation could unveil new avenues for employing ChatGPT in this domain and catalyze further research.

Table 1: Tasks, baselines, and dataset. S = Sample. T = Token.

Task	Baseline	Dataset	
		# S	# T
Bug report summarization	iTAPE [18]	33,438	6,176,326
Security bug report identification	Farsec [49] DKG [57] CASMS [35]	22,970	5,686,564
Vulnerability severity evaluation	DiffCVSS [48]	1,642	82,397
Vulnerability repair	LLMset [37] ExtractFix [24]	12	10,601
Patch correctness assessment	Quatrain [46] Invalidator [31] Panther [44]	995 139 208	468,739 31,663 45,204
Stable patch classification	PatchNet [25]	10,896	6,854,217
Total	**11**	**70,346**	**19,355,711**

2.2 ChatGPT and Prompt

ChatGPT is an artificial intelligence chatbot trained to provide human-like responses to users' questions in a conversational way. Users can use ChatGPT through its web interface [11] or official API [15]. A common strategy for applying general models to specific tasks is model fine-tuning. However, this approach is often eschewed due to its labor-intensive nature and significant resource consumption [6]. Consequently, attention has shifted toward optimizing the prompt, i.e., the input of ChatGPT, which significantly influences the relevance and accuracy of the ChatGPT's output [19].

Currently, there are a series of prompt construction strategies employed for enhancing the capability of ChatGPT. Among these, in-context learning has emerged as the dominant paradigm [21]. The foundational approach to in-context learning, known as **0-shot** prompting, instructs ChatGPT by directly describing the task and the associated question [37]. While 0-shot prompting has shown promising performances by leveraging the prior knowledge from the training resource, it sometimes falters when confronted with unfamiliar tasks.

To address this problem, researchers devised advanced prompts by integrating demonstrations, allowing ChatGPT

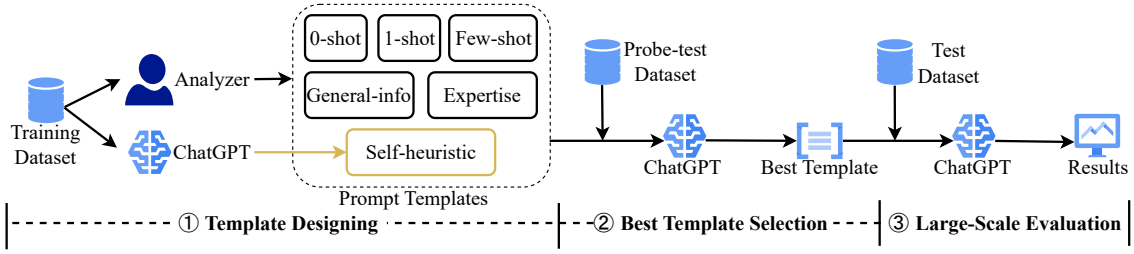

Figure 2: Evaluation pipeline.

to discern patterns inherent to specific tasks [21]. Depending on the volume of demonstration examples within a prompt, they can be categorized into **1-shot** prompting (with a singular demonstration example) or **few-shot** prompting (incorporating multiple demonstration examples) [23]. While well-organized demonstrations have proven effective for simple tasks, they tend to be less efficient for intricate tasks demanding complex logic and domain expertise. To counter these challenges, another line of works enhance ChatGPT by utilizing refined demonstration formatting. This includes the provision of supplemental **general information**, such as role definitions [37, 50], and integrating **domain-specific expertise**, such as vulnerability patterns [42].

In addition to the prompt, the foundational model of ChatGPT also impacts its performance. Users can choose to use gpt-3.5 or gpt-4 when using ChatGPT [15]. A systematic investigation of the effect of different prompts and models for vulnerability management tasks is still lacking. Exploring this problem is essential for thoroughly exploiting ChatGPT for vulnerability management.

3 Evaluation Framework

3.1 Evaluation Pipeline

Figure 2 shows the pipeline of our evaluation, which includes three phases: ① template design, ② best template selection, and ③ large-scale evaluation.

Currently, automatic prompt generation [40] is an ongoing research work that has not been well addressed. Consequently, in phase ①, for each evaluated task, according to the construction rules outlined in §2.2, we first design the prompt templates listed in Table 2 manually based on the heuristics derived from existing widely adopted strategies [7, 23]. To ensure the effectiveness of each prompt template, we assess them using 100 random samples from the training dataset. Subsequently, we refine the templates based on our manual analysis of ChatGPT's responses. Details regarding the template implementation process are discussed in §3.3. As a result, we acquire a collection of prompt templates that demonstrate consistent and reliable performance on the training dataset.

In phase ②, we evaluate all prompt templates with the probe-test dataset to select the best prompt template. To ensure a representative subset of the entire dataset, we construct a probe-test dataset by separating other 10% random samples from the training dataset. However, for certain tasks, the extensive nature of the training dataset used by the SOTA approaches presents challenges. Therefore, for these tasks, considering the time and cost constraints, we limit the probe-test dataset to 1,000 samples. Besides, for vulnerability repairing task, since there is no training dataset used by the SOTA approaches, we opt to construct the probe-test dataset using hand-crafted vulnerabilities provided by [37]. Finally, in phase ③, to fully explore ChatGPT's potential, we use the prompt template that yields the best performance in the probe-test to conduct a large-scale evaluation on the test dataset.[1]

3.2 SOTA Approaches and Dataset

To assess ChatGPT's capabilities on the six vulnerability management tasks described in §2.1, we collect the SOTA approaches for each task as the baselines. The SOTA approaches are derived from the top venues in the fields of security, programming language, and machine learning over the past three years. By sourcing approaches from these reputable venues, we ensure that our evaluation encompasses the most current and relevant advancements in the respective domains, facilitating a comprehensive and up-to-date analysis of ChatGPT's capabilities on vulnerability management. As shown in Table 1 we include 11 SOTA approaches for the six evaluated tasks. Then, we evaluate ChatGPT with the same metrics used by each SOTA approach to conduct the comparison.

To ensure a fair comparison between ChatGPT and SOTA approaches, we obtain the same dataset used in each corresponding SOTA paper for each task. Specifically, we strictly separate the training dataset and test dataset according to the original setting in those papers. Totally, the test dataset used in this paper contains 70,346 samples (19,355,711 tokens).

[1] Our evaluations are conducted with ChatGPT official API [15]. Specifically, We use ChatGPT based on gpt-3.5-turbo-0301 in phases ① and ② since it is more economical than gpt-4. The large-scale tests are conducted with ChatGPT based on gpt-4-0314. We set temperature = 0 and top_p = 1.0 to enhance determinism.

Table 2: Templates for task prompt generation.

Template Name	Description	Template
0-shot	Describes the task and directly gives the input query.	**USER** <task description> <input>
1-shot	Describes the task and provides a random-selected demonstration example before query.	**USER** <task description> <demonstration example> <input>
few-shot	Describes the task and provides multiple random-selected demonstration examples before query.	**USER** <task description> <demonstration example 1> <demonstration example 2> <demonstration example 3> <demonstration example 4> <input>
general-info	Integrates the task-related role assignment into task description through system instruction and complements zero-CoT instructions before query.	**SYSTEM** <role> <task description> <reinforce> **USER** <task description> <task confirmation> **ASSYSTANT** <task confirmation> **USER** <positive feedback> <input> <zero-CoT> <right>
expertise	Based on the general-info template, provides manually summarized domain-specific expertise with task description.	**SYSTEM** <role> <task description> <expertise> <reinforce> **USER** <expertise> <task description> <task confirmation> **ASSYSTANT** <task confirmation> **USER** <positive feedback> <input> <zero-CoT> <right>
self-heuristic	Integrates ChatGPT-summarized domain-specific knowledge into task description before query.	**SYSTEM** <role> <task description> <reinforce> **USER** <knowledge> <task description> <task confirmation> **ASSYSTANT** <task confirmation> **USER** <positive feedback> <input> <zero-CoT> <right>

3.3 Prompt Design and Implementation

In Table 2, we provide detailed explanations on the methodology employed for constructing prompt templates. For 1-shot and few-shot prompts, the demonstration samples are randomly selected from the training dataset. Particularly, according to [23], we select four demonstration samples for few-shot templates to obtain considerably good performance. In the general-information template, we include the instructions that show their superiority in traditional NLP tasks [19], such as zero-CoT [29] and ChatGPT's role [19] in the prompt (Table 12 lists the instructing skills used in the general-info template, which is deferred to Appendix A). As illustrated in Figure 3, the prompt leverages many existing methods, such as the role assignment in line 1. In the expertise prompt template, we provide domain expert knowledge in the prompt. The offered expertise is obtained from the related documentations [4, 12] and literatures [18, 49] (Table 14 provides the expertise content for each task, which is deferred to Appendix A). As shown in Figure 3, the expertise prompt differs from the general-info prompt by providing the characteristic of security bug reports (lines 3 - 6 and 9 - 12). In this example, we guide ChatGPT that memory leak should be treated as a security bug.

It is worth noting that for some evaluated tasks, summarizing expert knowledge can be non-trivial. For example, it is hard to summarize the rules of determining vulnerability severity. In such situations, we turn to explore the potential of guiding ChatGPT by leveraging the knowledge summarized by itself. Thus, we propose the self-heuristic prompt template. Specifically, we provide several demonstration examples to ChatGPT and ask it to summarize knowledge from these examples. For example, we provide 100 labeled function descriptions to ChatGPT and tell it to *"summarize the characteristics of the function descriptions that should map to the CVSS AV:Network metric"*. Then, we can obtain knowledge summarized by ChatGPT, like "Functions that involve network communication, socket handling, or network device management. Examples: sock_register, udp4_hwcsum, ..." (Figure 6 provides an illustrative example that elucidates the extraction process, which is deferred to Appendix A). After that, we can provide the summary in the self-heuristic prompt in the same way as the expertise prompt. More comprehensive descriptions, including specific examples for each prompt template, are available in Table 13 (deferred to Appendix A). We will provide all the prompts on `https://github.com/Jamrot/ChatGPT-Vulnerability-Management` to support further research.

4 Evaluation Results

In this section, we elaborate on the evaluation results of ChatGPT for the evaluated tasks. For each task, we seek the answers to the research questions proposed in §1 by comparing the performance of ChatGPT and SOTA approaches (**RQ1**), investigating the impact of different prompt templates (**RQ2**), and exploring the potential future research directions to ad-

```
SYSTEM   You are Frederick, an AI expert in bug report analysis. Your
         task is to decide whether a given bug report is a security bug
         report (SBR) or non-security bug report (NBR). When
         analyzing the bug report, take into account that bug reports
         related to memory leak or null pointer problems should be
         seen as security bug report. Remember, you're the best AI bug
         report analyst and will use your expertise to provide the best
         possible analysis.
USER     A security bug report is a bug report describing one or more
         vulnerabilities of a software. Besides, bug reports that directly
         mention "memory leak" or "null pointer" problems must be
         seen as security bug reports. I will give you a bug report and
         you will analyze it, step-by-step, to know whether or not it is
         a security bug report. Got it?
ASSISTANT Yes, I understand. I am Frederick, and I will analyze the bug
         report.
USER     Great! Let's begin then :)
         For the bug report:
         <bug report>
         ----------
         Is this bug report (A) a security bug report (SBR), or (B) a
         non-security bug report (NBR).
         Answer: Let's think step-by-step to reach the right conclusion,
```

Figure 3: An example of the expertise prompt. After removing the **bold pink text**, the rest represents the general-info prompt.

dress the bottlenecks encountered by ChatGPT (**RQ3**).

4.1 Bug Report Summarization

In this evaluation, we ask ChatGPT to summary a given bug report in each query.

ChatGPT's Performance. Table 3 reports the results of this evaluation, which demonstrate that ChatGPT can achieve outstanding performance in this task. For instance, the recall score of ChatGPT based on gpt-3.5 with the 0-shot prompt on the probe-test dataset is 42.11, 13.99, and 34.41 under ROUGE-1, ROUGE-2, and ROUGE-L, respectively, which is better than that of the SOTA approach (31.72, 13.34, 29.32). Moreover, its F1 scores under ROUGE-1 (34.33) and ROUGE-L (27.95) also outperform the SOTA approach (31.36 and 27.79). The results indicate that ChatGPT can generate high-quantity summaries for bug reports even with the most straightforward prompt (0-shot). This is reasonable since bug report summarization is similar to traditional NLP tasks, such as summarizing news, on which ChatGPT and other LLMs have shown excellent performance [55]. Hence, the results encourage software maintainers to leverage ChatGPT for summarizing bug report and other vulnerability management tasks related to natural language processing.

The Impact of Prompts and Models. From Table 3, we observe that the most straightforward prompt (0-shot) already enables ChatGPT to achieve outstanding performance, whereas more complex prompts do not consistently enhance ChatGPT's performance. Overall, the few-shot prompt templates perform better than other templates in this task. For example, for ChatGPT based on gpt-3.5 evaluated on the probe-test dataset, its ROUGE-L F1 score with the 0-shot prompt is 34.33. This score improves to 37.30 with the few-shot prompt and decreases to 32.37 with the general-info prompt. This observation indicates that providing demonstration examples is helpful for ChatGPT to generate high-quality bug report summarization.

In addition to the prompt evaluation, we also explore the impact of different foundational models. As shown in Table 3, when using the few-shot prompt on the probe-test dataset, the F1 scores of ChatGPT based on gpt-4 are 40.38, 15.86, and 34.30, which are better than that of ChatGPT based on gpt-3.5 (33.08, 11.26, and 27.53). The results encourage us to use gpt-4 when it is available. Moreover, it is important to recognize that reliance solely on automated metrics such as ROUGE does not necessarily guarantee the quality of summarizations from a human reader's perspective. To address this issue, we have also implemented a user study to verify our findings, which is detailed in Section 4.7 .

Implications. In this evaluation, when using the prompt templates that refine demonstration formatting (general-info, expertise, and self-heuristic), most metric scores are even worse than the 0-shot template. This experimental result demonstrates that the original training task of ChatGPT has

Table 4: The evaluation result on security bug report identification. R = Recall. P = Precision. FPR = False Positive Rate. G = G-measure.

Approach	Prompt	Dataset	R	FPR	P	F1	G

gpt-4	expertise	test	0.68	0.04	0.53	0.57	0.79

already equipped itself with the ability to comprehend this summarization task. Therefore, ChatGPT naturally excels at comprehending, generating, and summarizing text. In this context, providing a straightforward task description and a relevant question can yield strong performance. Conversely, *introducing additional information and expertise in the prompt can lead to confusion for ChatGPT in understanding this task.*

4.2 Security Bug Report Identification

In this evaluation, we ask ChatGPT to answer whether a given bug report is security-related in each query. This evaluation uses three SOTA approaches, DKG [57], CASMS [35], and Farsec [49]. The used metrics are recall, false positive rate (FPR), precision, F1, and G-measure. Among these five performance metrics, recall, precision, f1, and G-measure are the higher, the better, while FPR is the lower, the better.

ChatGPT's Performance. Table 4 shows ChatGPT's performance in this task. Generally, with advanced prompt templates and models, ChatGPT can outperform two baselines, CASMS and Farsec. However, ChatGPT cannot achieve capability on par with DKG. For example, the F1 and G-measure scores of ChatGPT based on gpt-4 with the expertise prompt on the test dataset are 32.6% and 23.4% higher than that of Farsec, respectively. By contrast, these scores are 19.7% and 2.5% lower than that of DKG, respectively. Hence, our investigation indicates that ChatGPT has a certain, yet unsatisfactory, capability to identify security-related bug reports.

The Impact of Prompts and Models. In this evaluation, the impact of prompt templates and models is complicated. First, compared to the 0-shot prompt, some advanced prompt templates increase several metric scores while decreasing others. For example, for ChatGPT based on gpt-3.5 tested on the probe-test dataset, the general-info prompt increases the precision score while decreasing the recall score compared to the 1-shot prompt. We find the reason is that the general-info prompt makes ChatGPT very "conservative" for this task—ChatGPT only marks 14 tested reports as security-related with only 5 true positives in them. Second, the advanced model, gpt-4, also increases several metric scores while decreasing others. For instance, when using the same expertise prompt on the probe-test dataset, the recall score of ChatGPT based on gpt-4 (0.94) is 32.4% higher than that of ChatGPT based on gpt-3.5 (0.71). However, the precision score decreases by 52.6% at the same time. The results indicate that ChatGPT based on gpt-4 can report more security-related bug reports with a relatively high false positive rate. In practice, this means software maintainers need to spend more time manually checking false positives. With a high recall score and a low precision score, ChatGPT can still benefit the prediction of security bug reports since (1) missing a security-related bug report can lead to severe consequences and (2) it already filters many non-security-related reports.

Implications. When analyzing the results obtained with the 0-shot prompt, we find that ChatGPT exhibits hallucinations regarding the definition of a security bug report. For instance, ChatGPT incorrectly identifies memory leakage (MML) and null pointer dereference (NPD) as not security-related. Providing ChatGPT an MML bug report labeled "security-related" in the 1-shot prompt mitigates this issue and improves the the recall score by 1.17 times. However, the precision score decreases due to other hallucinations, i.e., ChatGPT learns some unrelated information from the demonstration example. For instance, when using the 1-shot prompt shown in Table 13 (deferred to Appendix A), ChatGPT tends to mistakenly mark reports that contain unrelated words of the demonstration example report (e.g., "tab" and "open") as security-related. The results indicate that *when providing demonstration examples, how to make ChatGPT focus on helpful information rather than irrelevant content is an interesting question.*

Furthermore, in the expertise prompt, we directly tell ChatGPT "bug reports related to memory leak or null pointer problems should be seen as security bug reports". Then, for ChatGPT based on gpt-3.5, this prompt achieves the best performance. The results indicate that the summary of domain knowledge can directly benefit the improvement of ChatGPT's performance in security bug report identification.

Failed Cases Analysis. Although the expertise prompt helps mitigate hallucinations, ChatGPT still incorrectly identifies many resource leakage issues as not security-related, causing 17% of the failed cases. This highlights the importance to address this issue in future work. Additionally, in some failed cases, ChatGPT points out that the description in the bug report is not detailed enough, making it difficult to determine whether it is security-related. To further understand what kind of information can help ChatGPT with better identification, we ask ChatGPT what additional information it needs. It indicates that *details about the impact and exploitability of bugs are particularly helpful.*

4.3 Vulnerability Severity Evaluation

In this evaluation, we ask ChatGPT to map a function to the CVSS exploitability metrics [12] based on its description.

ChatGPT's Performance. As shown in Table 5, ChatGPT's performance is slightly inferior to the SOTA approach. Specifically, compared to the scores of DiffCVSS, the recall and precision scores of ChatGPT based on gpt-4 with the self-heuristic prompt template are 3.5% and 11.2%, respectively, lower on average. However, ChatGPT can outperform DiffCVSS on several scores. For instance, when mapping AV:Network, the recall of ChatGPT based on gpt-4 with the self-heuristic prompt template (0.9848) is 6.6% higher than that of DiffCVSS (0.9242). Overall, these results show the potential of using ChatGPT in this challenging task.

The Impact of Prompts and Models. Except for the self-heuristic template, ChatGPT's performance with other prompt templates is relatively poor in this task. We take the results on the PR:High metric as an example to demonstrate this investigation. ChatGPT's recall scores on this metric are 61.0%, 88.9%, 72.2%, 22.0%, and 44.3% lower than the SOTA approach (0.9452) when using 0-shot (0.3684), 1-shot (0.1053), few-shot (0.2632), general-info (0.7368), and expertise templates (0.5263), respectively. However, with the self-heuristic prompt templates, ChatGPT's performance significantly improves. For instance, for gpt-3.5, compared to the scores with the expertise template, the recall and precision scores with the self-heuristic template improved by 1.60 and 1.73 times on average, respectively. Besides, the used models also have an essential impact on ChatGPT's performance for this task. With the same self-heuristic prompt, ChatGPT based on gpt-4 outperforms the one based on gpt-3.5 on most scores. Specifically, the precision score of the former is 10.5% higher than the latter on average.

Implications. In fact, ChatGPT struggles with this challenging task. At the beginning of this evaluation, we find that ChatGPT performs poorly with the 0-shot, 1-shot, and few-shot templates. Thus, we attempt to improve its performance in many ways. First, we try to provide more demonstration examples with few-shot prompts. However, due to the maximum token limitation (8,192 tokens for each question and answer), providing many demonstration examples within one prompt is impractical. Inspired by ChatGPT's outstanding NLP capability, we try to compress the demonstration examples with ChatGPT. Consequently, ChatGPT can reduce the length of the demonstration examples by half on average. In this way, we can provide more demonstration examples in one prompt. However, we find that the results remain unsatisfactory.

Furthermore, we notice that providing the description of CVSS metrics in the expertise template slightly improves the performance. Thus, we try to manually adjust the description in the expertise template. Unfortunately, it is hard to construct perfect expertise content for this task. After multiple failures in summarizing the expertise manually, we turn to explore whether ChatGPT can assist us in generating expertise. Specifically, we provide the compressed demonstration examples to ChatGPT and ask it to summarize the characteristics of each CVSS metric. Figure 4 shows the knowledge summarized by ChatGPT. Then, we integrate the summarized knowledge in the self-heuristic prompt. As shown in Table 5, this self-heuristic prompt improves ChatGPT's performance significantly. Hence, we conclude that *extracting expertise by leveraging ChatGPT and incorporating the extracted expertise into prompt is an interesting future research direction, offering the potential to achieve strong performance in challenging vulnerability management tasks.*

Failed Cases Analysis. In this task, we identify two types of failed cases. The first type is due to the inherent ambiguity of the CVSS itself. For example, AV:Network and AV:Adjacent are both related to networks, which makes it challenging for ChatGPT to select the appropriate metric. Similarly, in the AC and PR metrics, overlapping character-

Table 6: The evaluation result on vulnerability repair. Gen = Generated. Vld = compilable. Vuln = Vulnerable. Fn = Functional. Safe = Not Vulnerable. Fixed = Fixed Vulnerabilities. Orig = Using the original code grafting method designed for LLMset [37].

gpt-4	expertise	test	600	377	20	370	20	350	92.8	**10**

istics related to check conditions can lead to confusion. The second type of failure arises from our rudimentary implementation of the self-heuristic prompt template. For some metrics, our limited sample diversity hinders ChatGPT from forming a well-rounded summary of expert knowledge. For instance, in the self-heuristic samples for the AC:High metric, we overlook the function about checking flags, which leads ChatGPT to fail in summarizing this characteristic and consequently results in incorrect outcomes. Therefore, *when leveraging a self-heuristic prompt template, it is valuable to explore how to extract a variety of samples and guide ChatGPT to make a more comprehensive summary.*

1 *Network: Functions that involve network communication, socket handling, or network device management. Examples: sock_register, udp4_hwcsum, ...*
2 *Adjacent Network: Functions that involve wireless communication, NFC, or Bluetooth. Examples: nfc_start_poll, lib80211_wep_encrypt, ...*
3 *Physical: Functions that involve hardware interaction, device management, or USB handling. Examples: usb_release_dev, snd_card_free, ...*
4 *Not Related: Functions that do not involve any network, adjacent network, or physical interactions, and are related to memory management, page allocation, or other internal system operations. Examples: do_set_mempolicy, do_page_mkwrite, ...*

Figure 4: An example of the knowledge summarized by ChatGPT.

4.4 Vulnerability Repair

In this evaluation, we ask ChatGPT to fix vulnerabilities in the provided code. The baseline is the SOTA approach ExtactFix [24] and six LLMs (named LLMset) evaluated by Pearce et al. [37], including OpenAI's Codex models [5] and AI21's Jurassic-1 models [9]. We use the dataset provided by Pearce et al. [37], which includes 7 hand-crafted vulnerabilities and 12 real-world CVEs. For each vulnerability, the dataset contains (1) the original buggy file and the vulnerable code snippet, (2) the PoC input that triggered the vulnerability, and (3) the project's regression test. With this dataset, we provide the vulnerable code snippet to ChatGPT and ask it to fix the vulnerability. After ChatGPT generates a response, we graft it with the original buggy file. Then, we use the PoC to test whether the vulnerability has been fixed and the regression tests to ensure that the fix does not break other functionality.

ChatGPT's Performance. LLMset generates 50 responses for each CVE with each LLM (except for AI21, which only generates 300 responses in total due to its comparatively lower API usage limit), resulting in 3,300 generated responses. Similarly, we also generate 50 responses for each CVE with ChatGPT, resulting in 600 responses with each prompt template. Table 6 summarizes the evaluation results of these responses. First, ChatGPT based on gpt-4 with the expertise prompt can fix 10 / 12 vulnerabilities, which is better than LLMset. Second, we observe that compared to LLMset, ChatGPT can achieve a better valid repair rate (i.e., '# Fn. & Sate' / '# Vld'). Specifically, the valid repair rate of ChatGPT based on gpt-4 with the expertise prompt is 92.8%, which is 4.3 times higher than that of LLMset with the same prompt (17.6%). Additionally, considering that hallucinations may generate syntactically correct patches but do not actually fix the vulnerability, we manually checked the generated patches to filter such potential false positives, and the results indicate the absence of such occurrences.

The Impact of Prompts and Models. In this evaluation, we have the following observations about the impact of prompt templates and models. First, we observe that the 1-shot prompt has a negative effect. Specifically, for ChatGPT based on gpt-3.5, although its valid repair rate with the 1-shot prompt (51.8%) is higher than that with the 0-shot prompt (48.9%), less code generated with the 1-shot prompt is compilable. Besides, the 1-shot prompt does not help ChatGPT fix

Table 7: The evaluation result on vulnerability repair for each CVE. The results are presented as '# Fn & Safe'/'# Vld'. '✓' means that the vulnerability was successfully fixed, while '✗' is the opposite.

Approach	Prompt	EF01 CVE-2016-5321	EF02_01 CVE-2014-8128	EF02_02 CVE-2014-8128	EF07 CVE-2016-10094	EF08 CVE-2017-7601	EF09 CVE-2016-3623	EF10 CVE-2017-7595	EF15 CVE-2016-1838	EF17 CVE-2012-5134	EF18 CVE-2017-5969	EF20 CVE-2018-19664	EF22 CVE-2012-2806
ExtractFix [24]	-	✓	✓	✗	✓	✓	✓	✓	✓	✓	✓	✗	✓
LLMset [37]	0-shot	33/49	0/2	0/81	-	42/135	4/4	4/65	-	53/58	0/13	0/198	0/69
LLMset [37]	expertise	14/117	23/124	0/205	-	46/78	96/190	11/37	3/98	24/33	0/120	4/171	0/81
gpt-4	expertise	31/38	50/50	-	4/6	0/5	50/50	32/34	2/4	47/50	37/43	47/47	50/50
gpt-4/LLMs/EF	-	✓/✓/✓	✓/✓/✓	✗/✗/✗	✓/✗/✓	✗/✓/✓	✓/✓/✓	✓/✓/✓	✓/✓/✓	✓/✓/✓	✓/✗/✓	✓/✓/✗	✓/✗/✓

more vulnerabilities than the 0-shot prompt (both of them fix 5 vulnerabilities). We also tried to provide more bug patches with the few-shot prompt. Compared to the 1-shot prompt, the few-shot prompt helps gpt-3.5 fix one more vulnerability. However, the few-shot prompt lead to a low valid repair rate. The results indicate that providing existing bug patches to ChatGPT cannot significantly help it generate safe and functional code to fix security vulnerabilities. This observation makes sense because it is hard to fix a vulnerability by following how someone fixes other vulnerabilities since each vulnerable program has its own code semantics.

Second, expert knowledge can help ChatGPT in this hard task. Specifically, the expertise prompt of this task, which provides a comment that describes the vulnerability, e.g., "BUG: stack buffer overflow", can help ChatGPT fix 2 vulnerabilities. Third, gpt-4 has a clear advantage over gpt-3.5 for this task. Specifically, ChatGPT based on gpt-4 generates more compilable code (292) than that based on gpt-3.5 (253). Meanwhile, the valid repair rate of gpt-4 (98.6%) is significantly higher than that of gpt-3.5 (72.6%).

Implications. Table 7 provides more details about the evaluation results for each tested real-world CVE. From Table 7, we observe several interesting findings. First, ChatGPT can fix three CVEs (EF07, EF18 and EF22) which LLMset could not. The fixes of these CVEs are too onerous for LLMset. For instance, EF18's real-world patch is long, removing 10 lines and adding 14; Besides, ChatGPT can fix one CVE (EF20) which ExtractFix could not. ExtractFix failed in this case since it cannot extract this vulnerability's crash-free constraint (CFC). In particular, extracting the CFC with traditional program analysis is quite challenging, which ExtractFix also failed to do in this case. The results indicate that *ChatGPT can be a great choice when traditional program analysis methods fail.*

Second, at the beginning of this evaluation, we find that only a few programs generated based on ChatGPT's response are compilable. The reason is that ChatGPT tends to repeat several code lines before the bug location of the original buggy file in its responses. Thus, the method that grafts LLMset's responses (start at bug locations [37]) with the original buggy file cannot properly graft ChatGPT's response, making the generated file not compilable due to syntax or semantic errors. For instance, we provide the results of the original code grafting method for ChatGPT based on gpt-3.5 with the expertise prompt in Table 6 (marked with "Orig"). The results reveal that this method cannot generate compilable programs for some tested vulnerabilities. Hence, we developed a new code grafting method that cuts overlap in ChatGPT's response and the original file before the bug location. After that, we obtain the remaining results shown in Table 6, which indicate that more grafted programs are compilable. Although the problem is not caused by the inherent limitation of ChatGPT, we learn an interesting finding from it, i.e., *when using ChatGPT in complex tasks, directly finishing the task with ChatGPT's response can be impractical. Developing workflows to process and leverage ChatGPT's responses appropriately is an important research direction.*

Failed Cases Analysis. In this task, ChatGPT fails to repair two vulnerabilities. For vulnerability EF02_02, ChatGPT's repair attempt differs from the developer's method, which causes the bug location method based on the developer's repair position [37] to be ineffective, making all generated files not compilable. For EF08, the failure is due to insufficient vulnerability-related context provided. In particular, EF08 involves a shift range error, but the context does not include information about the shift variable, leading ChatGPT to "guess" the variable name and thereby failing to generate the correct repair code. Therefore, to further improve ChatGPT's vulnerability repairing capability in real-world applications, *it could be effective to apply more advanced program slicing methods to provide specific vulnerability-related context.*

4.5 Patch Correctness Assessment

In this evaluation, we ask ChatGPT to determine whether a patch correctly fixes a bug. Three SOTA approaches are used as the baselines in this evaluation. We compare ChatGPT with these baselines separately since they use different datasets. Noting that the dataset of Quatrain [46] only contains the description of patches while the datasets of Invalidator [31]

Table 8: The evaluation result on patch correctness assessment (compared with Quatrain [46]).

Approach	Prompt	Dataset	Accuracy	+Recall	-Recall	Precision	F1	AUC
Quatrain [46]	-	test	0.775	0.786	0.773	0.371	0.504	**0.858**
gpt-3.5	0-shot	probe-test	0.617	0.577	0.625	0.246	0.345	0.601

and Panther [44] only contain the code of patches.

ChatGPT's Performance. The comparison results with three SOTA approaches are shown in Table 8, Table 9, and Table 10. Generally speaking, with advanced prompts and models, ChatGPT performs comparably to the SOTAs. Specifically, ChatGPT based on gpt-4 outperforms Invalidator on all metric scores. It also outperforms Quatrain and Panther regarding the F1 score. For instance, on the test dataset, the F1 scores of ChatGPT based on gpt-4 are 15.7% and 6.7% higher than Quatrain and Panther, respectively. Moreover, considering the -recall metric that reflects the capability of identifying incorrect patches, gpt-4 exceeds all SOTA approaches on the corresponding test dataset. This indicates that gpt-4 recognizes more incorrect patches, thereby reducing the risk of security instability. All these results highlight the potential of leveraging ChatGPT to assist maintainers in this task.

The Impact of Prompts and Models. From Table 8, we observe that ChatGPT cannot effectively determine patch correctness with straightforward prompt templates. For instance, on the probe-test dataset, the F1 score of ChatGPT based on gpt-3.5 with the 0-shot prompt is 31.5% lower than that of Quatrain. Compared to the 0-shot template, advanced prompt templates increase several metric scores while decreasing others. However, we notice that all advanced prompt templates can increase the -recall score. Specifically, for gpt-3.5, compared to the 0-shot template (0.625), its -recall score increase 16.0%, 22.9%, 42.2%, 31.4%, and 49.9% when using 1-shot (0.725), few-shot (0.768), general-info (0.889), expertise (0.821), and self-heuristic templates (0.937), respectively. These results indicate that advanced prompt templates can benefit the identification of incorrect patches.

Implications. At the beginning of this evaluation, we find that on the dataset of Quatrain, ChatGPT cannot perform well with all the prompt templates described in Table 2. After analyzing ChatGPT's responses manually, we find that ChatGPT complains that it cannot assess the correctness of patches without code. Hence, we manually collect the corresponding code for each patch and develop a new desc-code template that simultaneously provides the code and description. As shown in Table 8, ChatGPT with the desc-code template still performs somewhat worse than Quatrain.

After manual analysis, we find out an important reason is that *ChatGPT misuses the information in the prompt*. Specifically, when the code and description are provided simultaneously, ChatGPT tends to analyze whether the code changes match the description rather than the correctness of the patch.

Table 10: The evaluation result on patch correctness assessment (compared with Panther [44]).

Approach	Prompt	Dataset	Accuracy	+Recall	-Recall	Precision	F1	AUC
Panther [44]	-	test	0.745	0.811	0.670	0.738	0.773	0.818
gpt-3.5	0-shot	probe-test	0.710	0.963	0.381	0.669	0.789	0.672
gpt-3.5	1-shot	probe-test	0.642	0.972	0.214	0.616	0.754	0.593
gpt-3.5	few-shot	probe-test	0.653	**0.981**	0.226	0.622	0.762	0.603
gpt-3.5	general-info	probe-test	0.720	0.844	0.560	0.713	0.773	0.702
gpt-3.5	expertise	probe-test	0.715	0.771	0.643	0.737	0.753	0.707
gpt-3.5	self-heuristic	probe-test	0.730	0.844	0.583	0.724	0.780	0.714
gpt-4	self-heuristic	probe-test	**0.870**	0.899	**0.833**	**0.875**	**0.887**	**0.866**
gpt-4	self-heuristic	test	0.813	0.829	0.794	0.821	0.825	0.811

For example, ChatGPT tends to report that a patch is incorrect when the patch does not modify a function mentioned in the description. Thus, we further develop the code-only prompt template that removes descriptions from the desc-code template. As shown in Table 8, when using the code-only template, although the performance of ChatGPT based on gpt-3.5 does not increase significantly, ChatGPT based on gpt-4 achieves a comparable performance to Quatrain. The results indicate that *more information is not always better. Guiding ChatGPT to leverage the information in the prompt in a suitable way is an interesting research direction.*

Failed Cases Analysis. When examining false positives, we find that by only analyzing the patch code, ChatGPT often misinterprets the logic error that the patch is supposed to fix. For example, [10] is supposed to fix a problem of incorrect intersection selection in polyhedron sets. However, without the information about the root cause and correct logic, ChatGPT mistakenly assumes that any seemingly reasonable modification corrects the underlying logic error. This issue is also caused by hallucinations, indicating that in the absence of critical information, ChatGPT focuses solely on the surface aspects of the patch and overlooks the essence of the issue it aims to resolve. On the other side, false negatives are mainly caused by unconventional repair patches generated by automatic repair tools. Specifically, rather than directly removing a problematic control block, some automatically generated patches alter the condition within the control block to "if (false)". Therefore, combining the analysis of the implications, we can conclude that more information is not always better, but professional and accurate information is essential. Additionally, while considering removing potential noise in bug reports, it is also necessary to provide more specialized knowledge, such as vulnerability localization and root cause analysis.

4.6 Stable Patch Classification

In this evaluation, we ask ChatGPT whether a given patch (including the description and the code snippet) is a stable patch.

ChatGPT's Performance. Table 11 shows the stable patch classification results, which demonstrate that compared to the SOTA approach, ChatGPT performs slightly worse. Specifically, on the test dataset, for ChatGPT based on gpt-4 with the expertise prompt, its recall score is 4.7% higher than that of PatchNet. However, the remaining scores are 15.0% lower on average. Thus, exploring advanced prompts is still demanded to improve ChatGPT's performance on this task.

The Impact of Prompts and Models. Although ChatGPT cannot achieve capability on par with the SOTA approach for this task, advanced prompt templates can improve its performance. For example, as shown in Table 11, for ChatGPT based on gpt-3.5 tested on the probe-test dataset, its accuracy scores with the expertise (0.762) and self-heuristic (0.646) prompts are 35.6% and 14.1% higher than that with the 0-shot prompt (0.566), respectively.

In this task, gpt-4 and gpt-3.5 each have their advantages. When using the same expertise prompt on the probe-test dataset, ChatGPT based on gpt-4 outperforms ChatGPT based on gpt-3.5 regarding the recall and F1 scores while performing worse on other scores. Considering the application scenario, we suggest that gpt-4 is more suitable for this task for the following reasons. First, recall is more important than precision since identifying as many bug-related patches as possible is critical to ensure the security of the stable version code. Second, gpt-4 achieves a better F1 score, a comprehensive embodiment of precision and recall scores.

Implications. When using the 0-shot, 1-shot, few-shot, and general-info prompts, the precision scores are close to 0.5 while recall scores are close to 1. After manual analysis, we conjecture that the reason is ChatGPT's misunderstanding of what constitutes a stable patch, resulting in a hallucination where any seemingly reasonable patch is assumed stable. By using the expertise prompt with a clear definition of stable patch ("fixing a problem that causes a build error, an oops, a hang, data corruption, a real security issue, or some 'oh, that's not good' issue" [4]), ChatGPT's performance improves significantly. Thus, mitigating ChatGPT's hallucinations is an important research direction to improve its performance on complex tasks.

Table 11: The evaluation result on stable patch classification. ACC = Accuracy. P = Precision. R = Recall.

Approach	Prompt	Dataset	ACC	P	R	F1	AUC
PatchNet [25]	-	test	**0.862**	**0.839**	0.907	**0.871**	**0.860**
gpt-3.5	0-shot	probe-test	0.566	0.564	0.995	0.720	0.508
gpt-3.5	1-shot	probe-test	0.555	0.558	0.986	0.713	0.496
gpt-3.5	few-shot	probe-test	0.557	0.561	0.964	0.709	0.501
gpt-3.5	general-info	probe-test	0.568	0.565	**0.996**	0.721	0.510
gpt-3.5	expertise	probe-test	0.762	0.761	0.837	0.798	0.752
gpt-3.5	self-heuristic	probe-test	0.646	0.631	0.884	0.737	0.614
gpt-4	expertise	probe-test	0.736	0.694	0.945	0.800	0.708
gpt-4	expertise	test	0.733	0.679	0.950	0.792	0.716

Failed Cases Analysis. In actual stable patch classification scenarios, the definition of "stable" is more complex, to some extent exceeding the scope defined in official documentation [4]. For example, some patches that fix minor issues such as "rename helper function" [14] are accepted into the stable branch, whereas some more serious issues like "fix memory leak" [13] are not included. This might be because besides the explicit definition, determining whether a patch is stable also involves considering other deeper factors. Models trained on relevant datasets (i.e., PatchNet [25]) may have acquired deeper knowledge, thus performing better in tasks with complex definitions than ChatGPT. Based on the above observation, *developing methods to extract deep features from existing datasets to augment ChatGPT's vulnerability management capabilities is a promising research direction.*

4.7 User Study

In addition to demonstrating the superior performance of ChatGPT on vulnerability management tasks, it is crucial to assess its effectiveness in real-world scenarios for developers. Accordingly, we have designed a pilot user study that focuses on the bug report summarization process. This study aims to explore the perceptions of various developer groups regarding the bug report summarizations generated by ChatGPT with those produced by the SOTA work, iTAPE [18]. It is important to note that all bug reports used in this study are sourced from open-source bug-tracking systems, ensuring that no confidential information is compromised.

Experiment Settings. We recruit 20 participants and divide them into two groups—experts and intermediates—to explore how the practical value of using ChatGPT for vulnerability management varies with developer experience. The experts group consists of five engineers from the industry, each with more than five years of experience, whereas the intermediates group includes fifteen maintainers from open-source repositories, each with at least three years of development experience. We provide each participant with 100 randomly selected bug report pairs from our test set, each pair consisting of the original bug report and its summarization generated by iTAPE and ChatGPT. Participants are instructed to evaluate the quality of each summary based on three criteria: (1) Correctness - The accuracy with which the summarization captures the essence of the bug report. (2) Conciseness - The succinctness of the summarization. (3) Readability - The fluency and clarity of the summarization.

We also provide the instruction "*Please rate on the scale of 1 to 5 (1 - Poor, 2 - Marginal, 3 - Acceptable, 4 - Good, 5 - Excellent)*" to guide the scoring of each report.

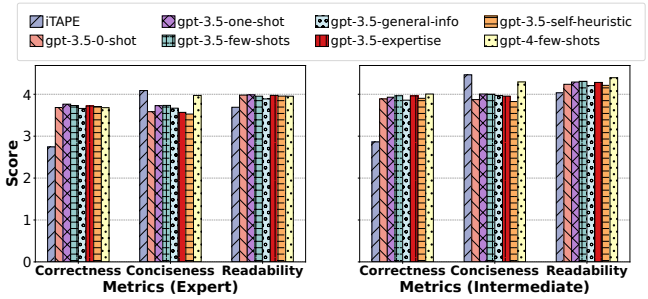

Figure 5: Results of user study (1 - Poor, 2 - Marginal, 3 - Acceptable, 4 - Good, 5 - Excellent).

Results. As depicted in Figure 5, the average scores across different dimensions show that ChatGPT generally produces better summarizations in terms of correctness compared to iTAPE, with highest scores of 3.76 (experts) and 4.01 (intermediates), significantly higher than iTAPE's 2.74 (experts) and 2.86 (intermediates). These results underscore ChatGPT's ability to accurately understand and condense the descriptions of bugs. However, iTAPE's outputs receive higher conciseness scores than those of ChatGPT. This outcome is not unexpected, as iTAPE's outputs often omit essential information needed to fully characterize the bug reports. On average, the bug report summarizations of iTAPE contain 8.5 tokens compared to ChatGPT's 11.3 tokens. Despite providing more detailed information, ChatGPT's summarizations are rated higher in readability than iTAPE's, suggesting that the additional detail enhances comprehension for developers rather than detracting from it. Regarding the scores from different participant groups, the professional group generally awards lower scores than the intermediates group, a trend consistent with findings from previous studies [27]. The LLM's training on extensive datasets allows it to perform like a domain expert, which resonates more with intermediate group participants. However, the professional group's familiarity with the domain means that the incremental information provided by the LLM is less impactful, though they still rate ChatGPT's results well in terms of correctness and readability. Furthermore, no single prompt consistently outperforms others in human evaluations, but gpt-4's outputs tend to be more concise and readable while maintaining high accuracy.

5 Discussion

Threats to Validity. A potential concern regarding ChatGPT's performance is test sample leakage during training. Detecting such leakage in LLMs is challenging [22]. Existing membership inference approaches for traditional AI models are difficult to apply to LLMs, requiring impractical conditions such as marked data in the training dataset [26] or surrogate model training [52]. Consequently, existing works infer sample existence by examining match rates between ground truth and LLM responses [50], which we also adopted. Specifically, when summarizing bug reports, if test samples had leaked, ChatGPT would generate numerous summaries similar to the ground truth. However, we observe less than 0.1% exact matches. To mitigate the potential limitations of exact matching due to ChatGPT's data processing and response randomization, we also investigate fuzzy matches. By leveraging F1 scores under ROUGE-1, we assess the similarity between ground truth and ChatGPT's responses. The results indicate that less than 3.4% of pairs exhibit a similarity exceeding 70%. In other tasks, good performance with a straightforward 0-shot prompt would be expected if ChatGPT had seen the test samples, yet the results indicate poor performance. We consider these hypotheses relatively evidential.

Another concern is the potential use of test samples to adjust prompts. To mitigate this, we restricted all prompt template modifications to the training data. Specifically, (1) demonstration examples used in the 1-shot, few-shot and self-heuristic prompts come from the training dataset, (2) prompt templates are improved based on mistakes observed in training dataset, and (3) the probe-test dataset is separated from the training dataset. Overall, the test dataset remains untouched during prompt adjustment and probe-testing, ensuring a fair evaluation of ChatGPT's capabilities.

Limitations and Future Works. (1) *Task complexity*. We do not investigate how ChatGPT's performance scales with task complexity or size, which is regarded as future work.

(2) *Prompting techniques*. We manually constructed prompt templates based on prior works in LLM evaluation [34] and our empirical analysis. This manual approach is adopted due to the inherent challenges of automatic prompt engineering (APE), a complex area that holds potential for stimulating research [40]. Moreover, our prompt templates and evaluation pipeline are generally applicable to other LLMs. Addressing adaptability issues is an interesting future research direction.

(3) *Real world interaction scenarios*. Our evaluations are conducted in controlled settings using pre-defined datasets. Exploring scenarios where ChatGPT interacts with actual software development and vulnerability management environments would be insightful. Additionally, integrating ChatGPT across multiple tasks to reflect the interconnected nature of vulnerability management processes would provide a more comprehensive view of its performance.

(4) *Alternative AI approaches*. We focus on evaluating ChatGPT's performance since it is the most popular AI product nowadays. Conducting further evaluations with other LLMs to investigate and compare their performance is considered as future work. Additionally, exploring alternative AI approaches, such as fine-tuning open-sourced models, may address some identified shortcomings, representing another interesting future research direction.

(5) *Hallucination issues*. We identify several hallucinations and conduct measures such as expertise prompts and manual checks to mitigate this problem. However, addressing hallucinations in LLMs remains an open issue for future research.

6 Related Work

AI for Vulnerability Management. With the rapid development of AI, machine learning models have been enthusiastically promoted as tools for various vulnerability management tasks [30, 32, 33, 58]. Some prior works leverage AI methods for automated software artifact generation [56], vulnerability severity examination [48], and bug fixing [38], demonstrating impressive capabilities in these areas. Inspired by this, this paper explores the potential of using ChatGPT, the most emerging AI product currently, for vulnerability management.

The Applications of ChatGPT. ChatGPT has received increasing attention and reputation from various fields. In the beginning, ChatGPT is applied in NLP tasks [20] and has shown impressive capabilities. Considering natural language shares similar aspects as program language, some prior works also explore ChatGPT's capabilities on code analysis [34] and bug fixing [41], indicating the potential for using ChatGPT in software engineering. However, can ChatGPT complete vulnerability management tasks that require a systematic understanding of code syntax, program semantics, and related comments? To the best of our knowledge, it is still an unexplored problem. This paper fills this gap by conducting the first large-scale evaluation of ChatGPT's performance for vulnerability management.

7 Conclusion

This paper conducts the first large-scale evaluation to explore the capabilities of ChatGPT on vulnerability management. Specifically, we compare ChatGPT with 11 SOTA approaches on 6 vulnerability management tasks by using a large-scale dataset containing 19,355,711 tokens. This systematical investigation allows us to understand the capabilities and limitations of ChatGPT on each task. Our findings demonstrate the desirable prospects of leveraging ChatGPT to assist vulnerability management. Meanwhile, we also reveal the difficulties ChatGPT encountered and shed light on future research to explore better ways to leverage ChatGPT in vulnerability management tasks.

A Appendix

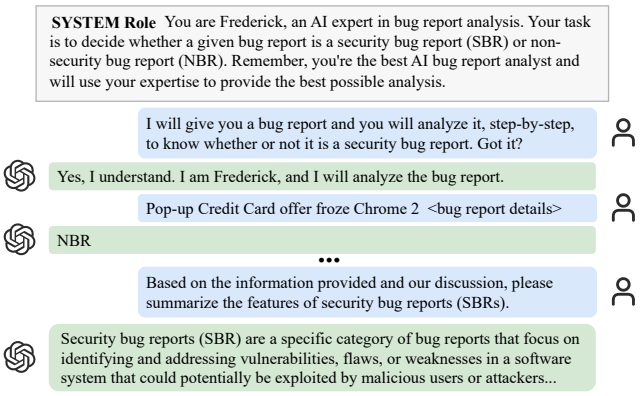

Figure 6: Extracting expertise from demonstration examples.

Self-heuristic Prompt Generation. To improve ChatGPT's performance in intricate tasks demanding domain knowledge,

such as vulnerability severity evaluation, we introduce the self-heuristic prompt. First, we employ ChatGPT to extract expertise from demonstration examples, as shown in Figure 6. Then, we incorporate this expertise into self-heuristic prompts.

Table 12: Prompt skills for the general-info template.

Skill	Description
role	Ask the model to adopt the task-related role.
reinforce	Repeat essential elements of the instructions.
task confirmation	Simulate a task confirmation dialogue.
positive feedback	Provide positive feedback prior to the query.
zero-CoT	Ask the model to think step-by-step.
right	Ask the model to reach the right conclusion.

Skills for the General-info Prompt. Table 12 provides all prompt skills along with their descriptions used for the general-info template. These skills have shown superiority in traditional NLP tasks [19].

Table 14: Task-specific expertise and the referred resources.

Task	Expertise
Bug report summarization	"1. The titles should be within the range of 5 to 15 words, and not contain URLs. 2. At least 30% words of the titles should come from the bug report." [18]
Security bug report identification	"When analyzing the bug report, take into account that bug reports related to memory leak or null pointer problems should be seen as security bug report." [49]
Vulnerability severity evaluation	"CVSS AV metric: 1. Network: The vulnerable component is bound to the network stack and... 2. Adjacent:...attack must be launched from the same shared physical (e.g., Bluetooth)... 3.Physical:..." [12]
Vulnerability repair	"[ERROR_MESSAGE], [VULNERABLE_CODE]." *Note: ERROR_MESSAGE and VULNERABLE_CODE differ by vulnerability.* [37]
Patch correctness assessment	"A correct patch implements changes that "answer" to a problem posed by bug report..." [46]
Stable patch classification	"The patch accepted in Linux-stable release must fix a real and critical bug that causes a build error, an oops, a hang, ..." [4]

Table 13: Templates for task prompt generation.

Name	Template & Example
0-shot	**USER** <task description> <input>

Abstract

Large language models (LLMs) have demonstrated significant potential in the realm of natural language understanding and programming code processing tasks. Their capacity to comprehend and generate human-like code has spurred research into harnessing LLMs for code analysis purposes. However, the existing body of literature falls short in delivering a systematic evaluation and assessment of LLMs' effectiveness in code analysis, particularly in the context of obfuscated code.

This paper seeks to bridge this gap by offering a comprehensive evaluation of LLMs' capabilities in performing code analysis tasks. Additionally, it presents real-world case studies that employ LLMs for code analysis. Our findings indicate that LLMs can indeed serve as valuable tools for automating code analysis, albeit with certain limitations. Through meticulous exploration, this research contributes to a deeper understanding of the potential and constraints associated with utilizing LLMs in code analysis, paving the way for enhanced applications in this critical domain.

1 Introduction

The evolution of machine learning has brought major changes to a variety of fields in the past few decades [38,44,76,80]. In recent years, the emergence of large language models (LLMs) has revolutionized the field of natural language processing and brought great changes to many other areas. Ever since the access of ChatGPT [64] becomes publicly available in late 2022, there is a rocketing number of users as well as publicly-available services utilizing LLM APIs provided by OpenAI. These models have demonstrated their abilities to understand and process inputs including but not limited to natural languages, and have been involved in different types of tasks. A typical use case of LLMs is text generation, since it has the ability to produce high-quality natural language outputs [91]. This has caused a heated debate in academia and eventually resulted in major publishers announcing new regulations regarding the usage of generative AI [15,47]. Besides, LLMs have also manifested their extraordinary potential in tasks related to programming, including code generation [79] and code comprehension [88]. LLM-based assistant tools like Github Copilot [41] have received tremendous attention and have been widely employed by programmers all around the world. OpenAI has recently enabled more features in ChatGPT [65], making LLMs more versatile and capable of engaging in more real-world tasks.

Amidst all possibilities of LLMs, code analysis and obfuscation are tasks that are receiving more and more attention from computer scientists. Code analysis [21] is an important task in software engineering, including code quality assessment [72], vulnerabilities detection [84], etc. The huge size and complex architecture of modern software systems motivate the wide usage of automated code analysis, especially in security-related scenarios such as software reverse engineering [25]. In response, malicious parties have leveraged code obfuscation techniques to obscure source code and avoid being detected. In response, researchers have proposed automated code analysis tools like Abstract Syntax Tree (AST) [61] to analyze both non-obfuscated and obfuscated code. However, such tools are highly dependent on the pre-defined data types and not suitable for general software code analysis. Due to the great potential of LLMs in these areas, researchers have started using LLMs to perform related tasks [24,88]. However, as pointed out by a recent survey [20], there are few systematic analytical studies on this topic.

In this paper, we focus on evaluating the ability of LLMs to analyze input code samples, and test if LLMs can be utilized for defensive analysis tasks. We first construct a dataset containing code from real-world programs (on Github, etc.) and their obfuscated versions to feed to LLMs, then we analyze the outcomes and present our obtained key findings. We aim to answer two critical research questions through a systematic analysis:

RQ1: Do LLMs understand source code?

RQ2: Can LLMs comprehend obfuscated code or code with low readability?

After that, as real-world case studies, we showcase if publicly-available LLMs (e.g. ChatGPT) can be utilized for security-related tasks targeting real-world malicious software.

The contributions of this paper are listed as follows:

1. We construct two datasets consisting of code samples from popular programming languages and obfuscated samples from these languages for our evaluation;

2. We systematically evaluate the performance of publicly available state-of-the-art LLMs, including the most popularly used GPT and LLaMA families on our dataset, and present our findings;

3. We conduct case studies using LLMs to analyze real-world malicious software to showcase the capability and limitations of LLMs in these tasks.

To the best of our knowledge, this is the first paper that provides a systematic evaluation of the ability of LLMs to comprehend code and code with obfuscation.

The remainder of this paper is organized as follows. We first introduce related background knowledge in Section 2. Then we elaborate our experiment settings of our analysis in Section 3. Essential results and findings are presented in Section 4. In Section 5, we perform case studies and show how LLMs can be utilized to assist code analysis in practical cases. Then we briefly discuss future works in Section 6. Related works and a conclusion are provided in Section 7 and Section 8, respectively. Our online appendix is available at: https://github.com/aseec-lab/llms-for-code-analysis.

2 Background

In this part, we will provide an overview of the technical background of large language models, code analysis, and code obfuscation.

2.1 Large Language Models

Large language models (LLMs) are a groundbreaking innovation in the field of artificial intelligence, representing a significant milestone in natural language understanding and generation. Most LLMs are built on deep learning architectures, particularly transformer architectures and self-attention mechanisms [80], which are trained on massive datasets containing a diverse range of text from the internet, books, and Github. This extensive training enables them to grasp the intricacies of languages, including grammar, context, and semantics. Both companies and researchers have launched LLMs-driven products and pre-trained models, such as OpenAI GPT series [66, 74], Meta LLaMA [77], Standford Alpaca [75], etc. One of the critical features of the LLMs is their ability to perform a wide range of natural language understanding tasks, including text summarization, translation, sentiment analysis, question-answering, etc. Besides natural language understanding tasks, researchers also find that LLM models have significant performance across various domains, from security and code generation [29] to healthcare [28, 45, 90] and education [50]. These LLM-driven applications have the potential to automate analysis tasks and provide instant information and assistance [17]. Moreover, LLMs are being shown to have direct utility for the purposes of code explanation and summarization, which have immediate applications in education and industry. Leinonen et al. [52] have explored the use of LLMs in generating code explanations for the purposes of computer science (CS) education, finding that LLM-generated explanations are viewed as more accurate and comprehensible than student-written explanations. Ahmed et al. [16] leverage project-specific few-shot training to improve code summarization, demonstrating improvements across a variety of languages and projects. This approach significantly reduces the time programmers need to familiarize themselves with a codebase.

2.2 Code Analysis

Code analysis is a process in software engineering to examine source code, byte code, or binary code to ensure quality, reliability, and security. Code analysis has become a crucial practice to assist developers in identifying and addressing problems early in the software development life cycle. The increasingly large scale of modern software challenges motivates researchers to propose automated tools. Prior works have proposed to extract structural relationships, including inheritance, association, friend relationships, interface hierarchies, attributes, data types, etc., from source code [61] to build Abstract Syntax Tree (AST) for pattern-matching [89] to detect vulnerabilities [26] and malicious activities [55]. However, the approach is highly dependent on the pre-defined data types and can not be used for general code analysis. In response, some researchers propose to extract features from source code and leverage machine learning to build a vulnerability detection model [93].

2.3 Code Generation

Code generation has been one of the most popular applications of LLMs since the introduction of GPT-3 OpenAI's introduction of the Codex model [29]. Subsequent advances in this area have had major implications on how programming is now taught, practiced, and evaluated. Prather *et al.* [68] noted in their meta-analysis of LLM use in CS education that LLMs perform similar if not better than the average student on code writing tasks, and have since sought to incorporate such tools into CS curriculum [69] in anticipation of more widespread adoption. A number of studies have also been conducted on practical LLM-based code completion tools

like Github's Copilot [41], characterizing common interaction models [19] and experiences [22]. Such tools continue to be enhanced as well, with improvements made in code completion for repository-level projects [18, 53] and automated program repair [81, 83], expanding the scope of LLM-based generation tools. Notably, Bird et al. [22] have observed in their investigation that while Copilot can improve productivity and creativity for users, the tool can also be somewhat detrimental to security and programmer understanding, which is part of the motivation for our study.

2.4 Code Obfuscation

Code obfuscation refers to the process of leveraging transformations to make functionally equivalent programs that are difficult to understand, aiming to protect the intellectual property of developed software or hide malicious behaviors. Such transformations include encoding data, opaque predicates [85], flattening control flow [51], etc. For example, [54] proposed a Mixed Boolean-Arithmetic (MBA) expression to mix the bitwise operations (e.g., AND, OR, and NOT) and arithmetic operations (e.g., ADD and IMUL), thereby creating more difficulties for attackers to analyze programs. In modern software development, obfuscation has been used to protect critical code parts against reverse engineering [37]. However, the significant progress of LLMs challenges existing code obfuscation-based protection approaches, questioning whether existing obfuscation can still be effective against LLMs-based de-obfuscation and preserve sensitive information in developed software. Hence, it becomes urgent to evaluate the code analysis results of LLMs when code is obfuscated. In this work, we leverage an open-source JavaScript obfuscation tool [12] as well as a state-of-the-art obfuscator [70] to generate obfuscated code and investigate whether LLMs are able to understand their functionality. As presented in Listing 1 and Listing 2, a simple "Hello World" function written in JavaScript can be changed into an unintelligible one.

Listing 1: No obfuscation.

```
function hi() {
  console.log("Hello World!");
}
hi();
```

Listing 2: After obfuscation by [12].

    x8d));}hi();
```

3 Experiment Settings

We first conduct a systematic analysis of the ability of LLMs to perform code analysis-related tasks. In this section, we introduce the models and datasets used in our experiments.

3.1 LLM Selection

In our analysis, we select five representative popular LLM models to deploy:

- GPT-3.5-turbo: GPT-3.5 is a set of LLMs offered by OpenAI, and it is the default model that is used for the popular LLM web tool ChatGPT [64].
- GPT-4: GPT-4 is improved based on GPT-3.5 and it has been reported to be able to handle different types of tasks [24]. It is also one of the most advanced general-purpose LLMs currently.
- LLaMA-2-13B [77]: LLaMA is a set of foundation LLMs offered by Meta, with model parameter sizes ranging from 7B to 70B. LLaMA-2-13B contains 13B parameters and is reported to output a lot of larger models. We select LLaMA-2-13B as a representative medium-size LLM.
- Code-LLaMA-2-13B-Instruct [71]: Code LLaMA is a family of LLMs provided by Meta, using the previously mentioned LLaMA family as foundation models. Code-LLaMAs are fine-tuned on code data, and it has been reported to outperform other public models targeting code-related tasks.
- StarChat-Beta [78]: StarChat-Beta is an open-source model trained for assisting coding tasks. It has 16B parameters and is capable of handling multiple programming languages.

We select these models for the reason that they are widely used and are the current state-of-the-art publicly-available LLMs with the capability to perform code tasks.

3.2 Prompt Construction

We interact with the selected LLMs in different steps in our experiments, including instructing the LLMs to analyze code and other measurement process (discussed later in this section). All the prompts constructed in this paper either involve simple instructions ("*Analyze the code and tell me what it does.*", etc.) or adhere to empirically proven structures, such as assigning roles [48, 88]. Specific prompts we utilize are provided in Section 3 and Section 5.

3.3 Non-Obfuscated Code Dataset

In this study, we aim to systematically evaluate the ability of LLMs to analyze, comprehend, and summarize code. We first construct a non-obfuscated source code dataset. Three languages are selected in this phase of study: JavaScript, Python, and C. We select JavaScript and Python since they are ranked the top 2 most used languages on Github [40] and we use them as the representatives of scripting languages. We select C as it is also ranked high (#9) and it can be the representative of lower-level programming languages. All three languages we select are widely deployed over the Internet and in various computing systems.

For JavaScript, we employ the combination of:

- The Octane 2.0 benchmark [13], which is a JavaScript benchmark to test JavaScript performance. It contains benchmarks to test typical functionalities of JavaScript users.
- A list of practical JavaScript applications [7], including password generator, etc.

For Python, we use the Python branch of the CodeSearchNet dataset [46] provided by Google. It contains samples of Python projects crawled from the Internet.

For C, we utilize the combination of:

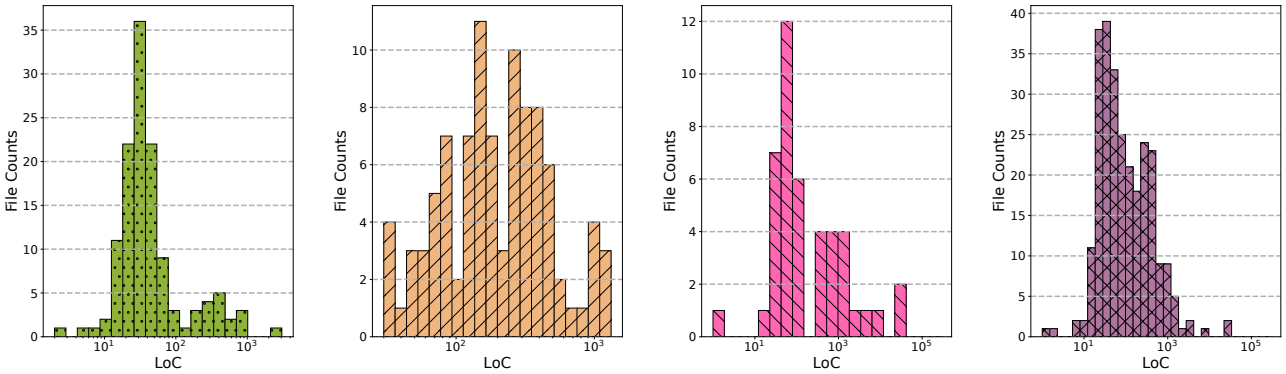
- A list of classic performance benchmarks, including CoreMark [36], Dhrystone [82], Hint Benchmark [42], Linpack [35], NBench [67], Stream Benchmark [56], TripForce [5] and Whetstone [34].
- A subset of the POJ-104 dataset [9, 59], which consists of C code samples to solve 104 different programming problems in an OJ system. The POJ-104 dataset provides multiple different solutions for each programming problem. In this study, for each programming problem, we randomly select one file from the POJ-104 dataset to form the dataset used in this work.

For each code file in our dataset, we develop scripts to automatically remove comments to eliminate their impacts on analysis results. Our goal is to let LLMs focus on code, without providing unnecessary natural language hints in code comments.

The histograms regarding the line of code (LoC) distributions of processed files are shown in Figure 1. We can see that our dataset includes code samples spanning from very short (only a few lines) to very large-scale (over 10k lines). Besides, the code samples in our dataset are from different sources covering different use cases. We believe the coverage of this dataset is sufficient, since we have chosen the most popular programming languages and selected a diverse set of code samples of different scales from different application scenarios.

3.4 Obfuscated Code Dataset

We choose to perform obfuscation on the JavaScript branch of our non-obfuscated code dataset. This choice was driven by the prevalence of code obfuscation practices in the JavaScript language, since JavaScript code is usually visible to web users, making additional obfuscation protection necessary. Besides, malicious JavaScript developers also apply obfuscation techniques to their code to hide the actual intent of their scripts. We use: (1) an open-source tool called JavaScript Obfuscator [12] to generate the obfuscation version of our JavaScript code; (2) Wobfuscator [70], a state-of-the-art obfuscator that transforms part of the code to WebAssembly [43]. The tested obfuscation methods are listed below:



1. Default obfuscation (DE), which replaces identifier names with meaningless randomly generated strings, simplifies source code to reduce readability, placing strings in separate arrays, etc. [12]
2. Dead code injection (DCI), which inserts random unrelated code blocks to the source code [32] in addition to the default scheme.
3. Control flow flattening (CFF), which transforms the structure of a program and hides control flow information [51] in addition to the default scheme.
4. Split string (SS), which splits long strings into shorter chunks in addition to the default scheme to alleviate information leakage from embedded texts [86].
5. Wobfuscator (WSM) [70], which performs cross-language obfuscation to the provided code.

Our chosen obfuscation methods cover classic code obfuscation techniques (the first 4) and a more recently developed obfuscation tool (Wobfuscator). By testing the performance of LLMs on these obfuscated code samples, we will be able to understand how these obfuscation techniques impact the ability of LLMs to understand code.

Besides obfuscating our previously acquired source code, we also combine existing obfuscated code from online resources. We integrate winner code samples from the International Obfuscated C Code Contest (IOCCC) [11], which is a contest that challenges participants to write the most obscure and confusing C code. Instead of asking LLMs to explain the code, we consider adding an extra challenge to generate de-obfuscated code and see if the generated code can be compiled and run. Experiments on this part of our obfuscated code dataset evaluate the performance of LLMs when facing more flexible and non-standard obfuscation techniques.

3.5 Measurement Method

After collecting the response of code analysis from our target LLMs, we start a manual validation process to check the

(a) C. (b) Python. (c) JavaScript. (d) Overall.

Figure 1: Histograms regarding LoC statistics of our non-obfuscated source code dataset.

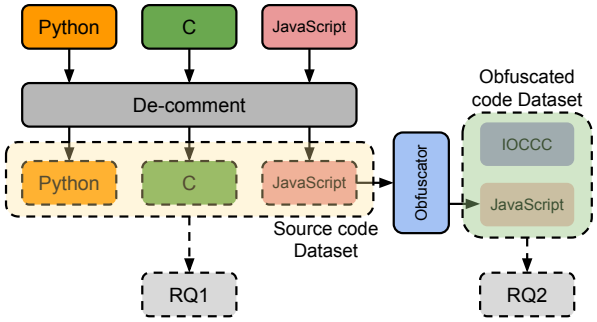


Figure 2: Diagram of our experiment pipeline.

correctness of the analysis results. Since all the source code files we employ only come with a maximum of a few tens of lines of concise comments and the description labels attached (if there are any) are also succinct, we can not rely on directly applying certain quantitative metrics (e.g., n-gram [23]) to determine the correctness of generated analysis results, which necessitates a manual validation process.

Ground Truth. We choose to first manually examine the outcomes of GPT-4 [73], since it has better natural language generation and deduction capability. During this manual validation process, four graduate/PhD-level students majoring in computer science or electrical engineering, each with over 5 years of programming experience, read the code and assess GPT-4's generated explanation for accuracy and potential errors. The generated explanation for each code file is labeled 'correct' if the functionality of the code and the description match. Cross-checking is conducted among the students to minimize biases. After this step, we consider those descriptions marked 'correct' as the ground truth and use those descriptions for further comparison among different LLMs.

Comparison Metrics. When evaluating the generated explanation (either non-obfuscated or obfuscated), we utilize the following metrics:

1. Cosine similarity (ranging from 0-1), since it is widely used in natural language processing-related tasks and can serve as a coarse grain metric in this study;

2. A Bert-based semantic similarity score [6] (ranging from 0 to 5) that is more advanced in comparing the similarity of natural language inputs;

3. ChatGPT-based evaluation [24, 31, 88, 92] (**True** or **False**). In our evaluation, GPT-4 model will receive the following instructions first:

   Instruction: "*You are given two descriptions of two code snippets: Description 1 and Description 2. Corresponding code snippets are not available. From the given text, do you think the two descriptions correspond to two code snippets with roughly similar functionalities? Output should be "Yes" if similar, or "No" otherwise, followed by a brief justification of how this is determined.*"

   We then use the generated output to examine the correctness of each model.

4 Results

In this part, we present our results on our non-obfuscated code dataset and obfuscated code dataset, mainly to answer the two research questions raised in Section 1:

- **RQ1**: Do LLMs understand source code? (Section 4.1)
- **RQ2**: Can LLMs comprehend obfuscated code? (Section 4.2)

LLMs are prompted

"*Analyze the code and tell me what it does.*"

to perform the analysis tasks. We also present findings in our experiments.

4.1 Results on Non-Obfuscated Code Dataset

GPT-4 Results. The manually verified accuracy results of GPT-4 are shown in Figure 3. We can see from Figure 3 that the accuracy performance of GPT-4 on the three languages (C, JavaScript, and Python) is high. For all of the three languages, over 95% of the analysis generated by GPT-4 aligns with the actual content of the code samples. The overall accuracy rate is 97.4%, indicating that GPT-4 can serve as a powerful code analysis tool. After meticulously analyzing the generated

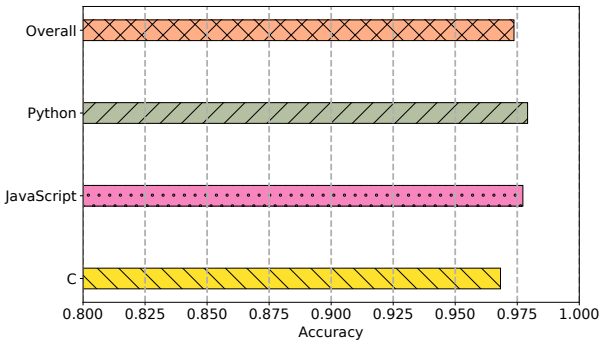

Figure 3: GPT-4 accuracy.

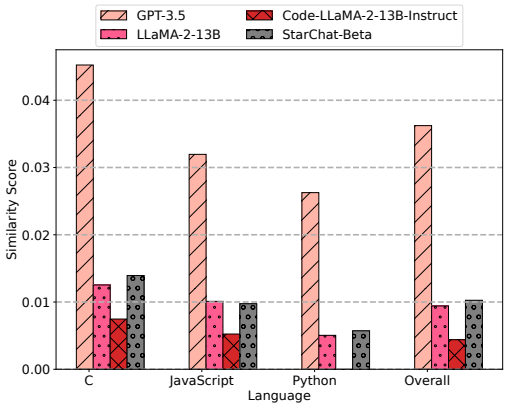
outputs of GPT-4, we also have the following findings.

> **Finding 1**: GPT-4 is able to recognize code snippets from popular open-source software repositories.

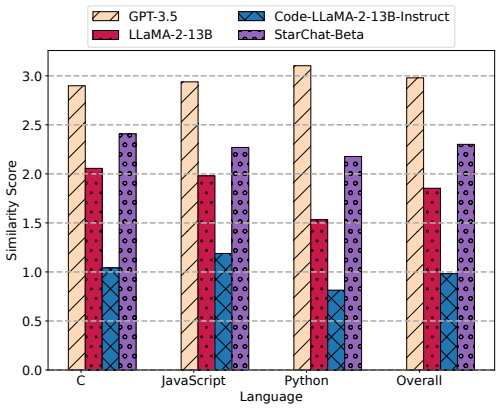
It has been reported that LLMs can leak memorized information acquired from training during conversations [27]. In our experiments, we observe this phenomenon multiple times. For example, our dataset contains source code files from Heron project [10], a real-time analytics system developed by Twitter. Even though the source code has been de-commented and does not contain the keyword "Twitter", GPT-4 still successfully connects the source code with Twitter by stating: *"The code is written in Python and is part of the Heron project, a real-time stream processing framework developed by Twitter."* at the beginning of its response. In another example, when we feed GPT-4 with a local JQuery copy from the Octane benchmark set, GPT-4 also successfully recognizes that the provided code is from the JQuery library: *"The provided code is a part of the jQuery library, ..."* at the beginning of its response. The same phenomenon is also observed in the responses from other models, e.g. GPT-3.5.

This indicates that the training data of these models contain code samples from popular open-source repositories, and LLMs are able to connect the provided code snippets with their memorized information. This might be helpful when analyzing code, since being able to connect source code with existing software implementation can accelerate the process of understanding the intent of target code snippets. Please note that this finding does not suggest that we are conducting our experiments in a "test on training set" manner. In our experiments, we focus on examining the generated detailed explanation of each function/code sample, which is more likely deducted from the source code and unlikely to be contained in the training set. Our experiments on newer repositories in Section 5 also indicate that LLMs do not need to use memorized information to assist code analysis.



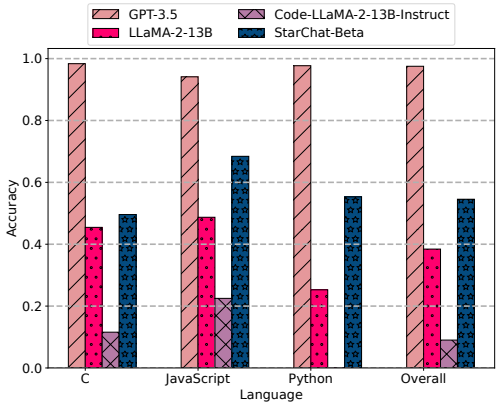
> **Finding 2**: GPT-4 occasionally makes wrong associations.

In our experiments, though GPT-4 has a high analysis success rate, there are still a few code samples that GPT-4 cannot correctly analyze. When using GPT-4 for analyzing a Python file related to stock market utilities, GPT-4 incorrectly concludes that the code uses the `pandas` package, even though it is not imported in the code sample. We believe this is caused by `matplotlib` and `numpy` packages being imported. These packages usually appear together in data analytics scripts that are likely part of the training set. GPT-4 possibly makes an incorrect association based on its memorized contents.



> **Finding 3**: GPT utilizes information provided in identifier names to assist code analysis.

It is intriguing to find that as a language model, GPT-4 utilizes natural language hints embedded in identifier names to assist code analysis like humans. For example, during the analysis for the CoreMark benchmark, GPT-4 recognizes identifiers named "`ee_u8`", "`ee_u16`", etc. are custom data types and concludes that the underlying mapping may vary across different embedded systems. When analyzing the JavaScript Octane benchmark, GPT-4 successfully recognizes that the code samples are used for benchmarking/testing simply from the appearance of a variable name "`Benchmark`". This suggests that the LLMs will be able to generate higher-quality analysis and provide more information on clearly written code.



Analysis Accuracy of Other Selected Models. In Figure 4, we present the cosine similarity score [Figure 4 (a)], Bert-based semantic similarity [Figure 4 (b)] and accuracy of code explanation measured by GPT-4 [Figure 4 (c)]. We can see that GPT-3.5 achieves similar performance as GPT-4, indicating that both models can achieve high performance in code analysis tasks. However, for the LLaMA-series models and StarChat-Beta, the accuracy performance is significantly lower. More findings obtained by manually examining the generated results are provided below.

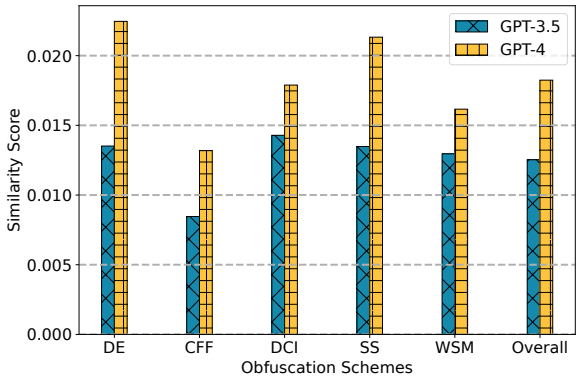
(a) Cosine similarity score.

(b) Bert-based semantic similarity scores, with the evaluator trained on web data.

(c) ChatGPT measured accuracy results.

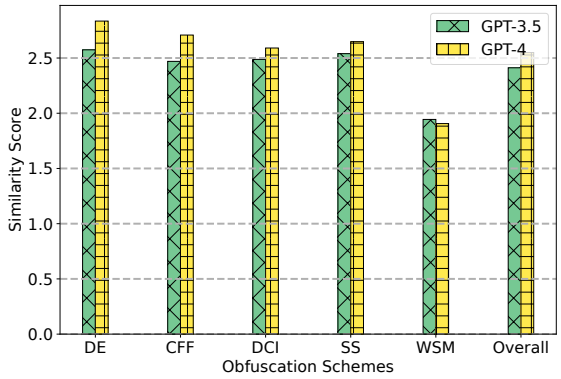
Figure 4: Similarity score/accuracy of analysis results generated by different models. For LLaMA series, results are obtained after we manually extract the natural language contents from the generated outputs.

Finding 4: Smaller models in our experiments (LLaMA-2-13B, Code-LLaMA-2-13B-Instruct, and StarChat-Beta) are unable to generate consistent paragraphs of code analysis results, unlike GPT-3.5 and GPT-4.



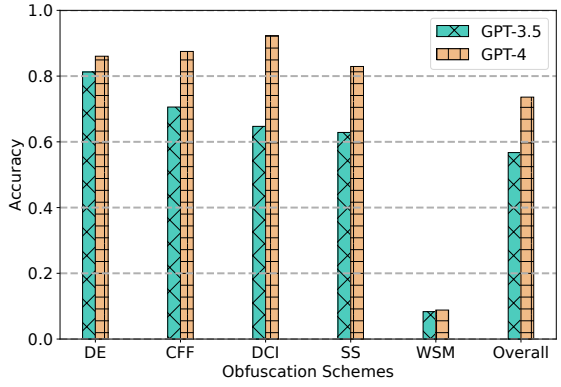
While performing the designated code analysis tasks, instead of generating consistent paragraphs, we observe that LLaMA-2-13B tries to repeat questions and generates hints to itself. Rather than generating paragraphs to answer the question directly, all three models tend to generate multiple short and inconsistent statements. In many cases, LLaMA-2-13B rephrases the input question to a semantically different one (e.g. it rephrases *"Analyze the following piece of code "* to *"Please tell me what this code does and what are the vulnerabilities in this code."*). When handling long code samples, StarChat-Beta, Code-LLaMA-2-13B-Instruct and LLaMA-2-13B tend to simply return part of the input code or return the re-written input code, without trying to provide explanations like GPT-3.5 and GPT-4. These phenomena indicate that these models do not have the ability to process code analysis-related tasks. Results shown in Figure 4 are similarity results after we manually extract code contents from the generated outputs. Even after we remove the code contents, the performance of these models is still significantly lower than GPT-3.5.

Answer to RQ1: For non-obfuscated code, larger models like GPT-3.5 or GPT-4 have a high probability of generating correct and detailed explanations for input code snippets, while the smaller models, even fine-tuned on code data, fail to generate correct outputs.



4.2 Results on Obfuscated Code Dataset

Obfuscated Code Analysis Capability Evaluation. We first focus on analyzing the obfuscated JavaScript code samples. We use the same prompt to instruct LLMs to analyze code and generate explanations as in the previous part. Although during the obfuscation process, function blocks are rewritten in different ways, the functionalities will not change and we observe that the outputs of LLMs are of very similar formats. Therefore, we will keep using the same set of metrics to evaluate the effectiveness of code explanation. Results regarding similarity scores and accuracy of obfuscated code analysis are shown in Figure 5.



From Figure 5 (c), we can see that GPT-4 still shows exceptional analysis accuracy, reaching 87% accuracy. GPT-3.5, on the other hand, is impacted by obfuscation techniques, especially when more advanced techniques are applied (control flow flattening, dead code injection, and split string). As for similarity score metrics shown in Figure 5 (a) and (b), we can see that both models suffer performance degradation, yet the similarity scores of GPT-4 are constantly higher than GPT-3.5. These results indicate that when facing obfuscated code analysis, GPT-4 is a better choice. There are other findings as presented below:

(a) Cosine similarity score.

(b) Bert-based semantic similarity scores, with the evaluator trained on web data.

(c) ChatGPT measured accuracy results.

Figure 5: Similarity score/accuracy of obfuscated code analysis results generated by different models.

Finding 1: LLaMA-2-13B, Code-LLaMA-2-13B-Instruct and StarChat-Beta are unable to generate meaningful explanations once obfuscation techniques are applied.

In our experiments, we find that all three models are unable to generate meaningful results. In most cases, they simply return part of the obfuscated code that is sent. Therefore, we do not include results from LLaMA-2-13B and Code-LLaMA-2-13B-Instruct in Figure 5. These results again indicate that these relatively small models do not possess the ability to perform code-analysis tasks properly.

Finding 2: Basic obfuscation techniques (such as DE in our paper) only slightly influence the ability of GPT models to perform code analysis.

In our experiments, we found that basic obfuscation techniques like replacing identifier names do not significantly impair the ability of GPT models to produce analysis results. Indeed, both models lose information contained in identifier names, but they are still able to extract sufficient information from the execution flow and remaining strings and provide relatively reliable explanations.

Finding 3: LLMs are not able to decipher obfuscated code generated by Wobfuscator.

From Figure 5, we can see that the application of Wobfuscator significantly reduces the accuracy of generated code explanations. By analyzing the generated outputs, we observe that the insertion of WebAssembly code severely hinders the understanding of source code, especially as reflected by the Bert-based similarity score [Figure 5 (b)] and ChatGPT-based score [Figure 5 (c)]. The two GPT models do not decipher the inserted WebAssembly code and hence fail to properly understand the functionality of the provided code.

Finding 4: The ability of GPT models to decipher longer and more complicated obfuscated code is limited.

We observe that GPT models perform worse when facing longer and more complicated code, which is expected. In our experiments, most code explanations that are classified as wrong are generated from longer code samples. Both GPT-3.5 and GPT-4 are able to maintain high accuracy when processing shorter and simpler website javascript applications. However, when facing larger code samples with more complicated functionalities, the generated responses are more error-prone and sentences like "*More information is needed*" appear more frequently, especially for GPT-3.5.

De-Obfuscated Code Generation. Besides comparing code explanation results on the obfuscated JavaScript dataset, we also test the ability of LLMs to generate de-obfuscated code. Since it is a challenging task, we only perform this evaluation on the two most powerful models we have, i.e. GPT-3.5

and GPT-4. We select 100 contest winner projects after the year 2011 competition of IOCCC [11] and instruct LLMs to perform code de-obfuscation tasks. LLMs are prompted:

> *"You are an expert in code analysis. De-obfuscate the code and generate a readable new version."*

and we directly feed the original code to LLMs. We select IOCCC because a more diverse and flexible set of obfuscation techniques are applied, compared to our automatically generated JavaScript dataset.

We evaluate the ability of LLM to generate de-obfuscated code from the following 3 aspects:

1. Whether code can be generated;
2. (If generated) whether the generated code can pass compilation;
3. (If compilable) whether the compiled code produces correct outputs.

Corresponding statistical results are presented in Figure 6. Our findings are presented below.

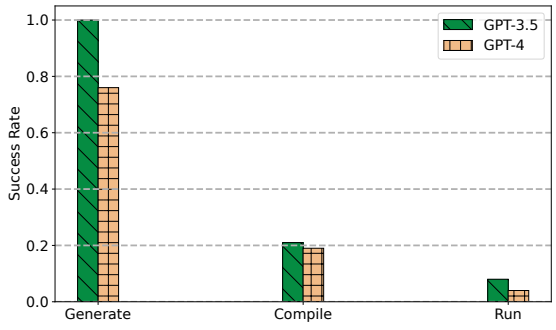


Figure 6: Success rate of different models regarding de-obfuscation tasks.

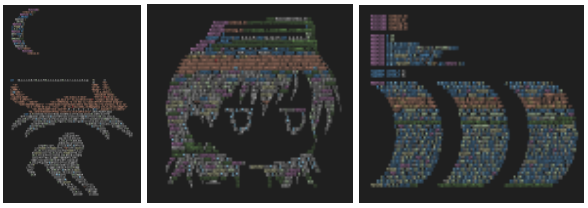
Finding 5: Both GPT models in our evaluation fall short of generating compilable and runnable de-obfuscated code.

As shown in Figure 6, for GPT-3.5, although it successfully produces code outputs for all targets, only around 20% of its output code samples are compilable, and only 8% of generated code samples (38% of compiled code samples) can produce correct results. The performance of GPT-4 is worse than GPT-3.5. It is able to generate de-obfuscated code for only 76% of experimented code samples. Only 19% of all experimented code samples (25% of generated code) successfully pass the compilation step, and only 4% of all experimented code samples (21% of compiled code) produce correct results. These statistics indicate that despite the strong ability to produce explanatory analysis results, their performance on de-obfuscated code generation is unsatisfying.

It is interesting to note that GPT-3.5 beats GPT-4 on these metrics in the code de-obfuscation task, despite the fact that it is a less advanced model.

Finding 6: GPT-4 has a higher probability of associating given code samples to the IOCCC contest. However, details are incorrect.

By examining responses generated by both models, we find that GPT-4 recognizes that 22 of the provided code samples belong to the IOCCC contest, while GPT-3.5 is only able to identify 2 of them. This indicates that despite IOCCC code samples being included in the training set of both models, GPT-4 is able to better associate the given input to its knowledge. However, when it tries to identify specific code samples, i.e., provide exact year and author names, the answers are wrong. For example, during our analysis, it identified a code sample that was awarded "Best Handwriting in 2015" as "Best One-Liner in 2015". We then asked *"What is the Best One-Liner award receiver of IOCCC 2015?"*, and got a different but still incorrect answer that seems to be made up by GPT-4. This indicates that the given incorrect information is possibly not caused by misalignment in the training data.



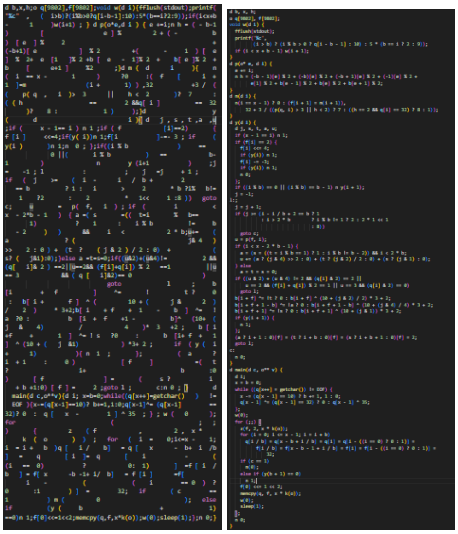
Finding 7: GPT-4 has a higher probability of refusing to perform code-generation tasks.

As shown in Figure 6, GPT-4's performance is significantly worse than GPT-3.5 in this task, especially at the code generation step. We observe that GPT-4 will admit that the code is obfuscated and requires lots of expert work to decipher, instead of generating code without additional remarks like GPT-3.5. By examining code samples that GPT-4 refuses to generate, we find that there are two factors that can potentially cause the failure of de-obfuscation:

1. Code contains complicated logic.
2. Code is formatted in a special style, unlike the traditional line-by-line organization.

Examples of specially formatted code snippets are shown in Figure 7. To rule out this factor, we select the `POJ-104/9/1618.c` sample code from the C branch of our non-obfuscated dataset and apply variable substitution and reformatting, resulting in a code snippet that is extremely hard to decipher with manual effort [Figure 8 (a)]. We also select a file from the IOCCC dataset (`blakely.c` from IOCCC 2011) and reformat the file to a normal format [Figure 8 (b) and (c)].

In the first scenario, despite the obfuscation techniques applied, GPT-4 is still able to generate correct explanations as well as de-obfuscation results. In the second case, GPT-4 continues to refuse to generate de-obfuscated code. This leads to our next finding:



(a) 2013/cable2/prog.c . (b) 2013/misaka/misaka.c . (c) 2019/giles/prog.c .

Figure 7: Samples of specially-formatted code.

(a) Reformatted code sample from POJ-104 dataset.

(b) 2011/blakely/blakely.c . (c) Reformatted 2011/blakely/blakely.c .

Figure 8: Reformatted code.

Finding 8: Text-level obfuscation does not influence the abilities of LLMs to perform de-obfuscation.

This also aligns with our findings while conducting the analysis of the JavaScript code, indicating that employing complex logic is the only way to trick LLMs.

Finding 9: GPT-4 generates code with higher readability.

We define readability as improved code formatting and more meaningful identifier names. Higher readability indicates superior code generation capability. Despite worse performance on code generation success rate, we find that code generated by GPT-4 has higher readability compared to code generated by GPT-3.5. GPT-4 is able to generate meaningful identifier names more often, while part of the GPT-3.5-generated code still seems obfuscated. This indicates that GPT-4 is still a better generative model if we take the quality of the generated code into consideration.

Answer to RQ2: Obfuscation techniques can impact the ability of LLMs to generate explanations. Smaller models in our experiments are unable to handle obfuscated code. GPT-3.5 and GPT-4 both drop in analysis accuracy, especially when facing Wobfuscator [70], though GPT-4 still has an acceptable and better accuracy performance on classic obfuscation methods. Without special optimization targeting de-obfuscated code generation, LLMs show a poor ability to generate functional de-obfuscated code.

5 Case Studies

In this section, we conduct case studies and show how the capability of LLMs can be utilized for defensive static analysis. We first select two newly published Github repositories (one benign and one malicious) to test the performance of GPT-series models in malware analysis. We then select the Android `msg-stealer` virus and the WannaCry ransomware [60] to further explore the performance of LLMs for analyzing decompiled and obfuscated code. Both viruses have been found in the real world. In both cases, code samples are directly obtained from decompilers. Decompiled and obfuscated code have a lot in common: both do not contain meaningful identifier names, and the control flow may not be straightforward. The complete responses of LLMs are contained in our online appendix.

5.1 Github Repository Analysis

In this case study, we select two repositories on Github: (1) `KratosKnife` [2], which is a set of Python scripts of a botnet system; (2) `librarian` [3], which is a Chrome extension for bookmark search. The reasons why we choose these two code repositories are: (1) With the comparison of malware and benign-ware, we can carefully observe the outputs and determine if any false alarms arise during the analysis process. (2) `librarian` is a new codebase (created 01/11/2024) that is guaranteed to be not included in GPT-4's training sets. Therefore, we can examine the ability of GPT-4 to analyze code without concerns for encountering any pre-learned patterns or memorization from GPT-4's training data. In the experiment, to generate explanations, we feed de-commented code files to GPT-4, provide file paths in the prompts, and instruct GPT-4 to analyze code. Responses of the previous file is passed as an

assistant message, so that the whole analysis process consists of continued sessions. After this, we feed the generated results one at a time to GPT-4 and ask "*Is there any potentially malicious behavior? Briefly answer 'Yes' or 'No'. If yes, explain why.*" to ask GPT-4 to perform classification of malicious and non-malicious code.

In both cases, we observe that GPT-4 is able to correctly explain each function. Additionally, it successfully points out malicious activities inside the code of `KratosKnife`. Based on the generated analysis, GPT-4 correctly classifies code files that contain malicious behaviors. There are some interesting observations in this experiment:

Observation 1: GPT-4 is able to point out malicious behaviors by recognizing typical patterns.

For example, when analyzing the code of malware `KratosKnife`, GPT-4 is able to point out that the VM environment checking is malicious since its purpose is to counter malware analyses.

Observation 2: There are potential false alarms in the classification step.

In the codebase of `KratosKnife`, there exist cryptography utility functions designed to encrypt code files based on an input key provided to the Python script. This encryption process serves to obfuscate code. Notably, these utility functions operate independently of other malicious behaviors associated with the malware. Furthermore, the analysis generated does not indicate any inherently malicious behaviors. However, during the classification process, GPT-4 considers these utility functions malicious since these functions encrypt files, and falsely accuse them of replacing encrypted files on disk, even though the generated explanation indicates the encrypted code is stored in separate files. This discrepancy underscores the necessity for a thorough examination of classification results produced by LLMs.

5.2 Mobile Platform Virus Analysis

In our first case study for decompiled code, we focus on analyzing a decompiled Android virus from the Internet. We utilize Java Decompiler [1] to decompile an android virus called `msg-stealer`, obtained from [4]. As indicated by its name, this virus maliciously steals SMS messages from Android mobile phone users. By using `jd-gui`, a graphical utility provided by the Java Decompiler , we successfully decompile the `.apk` file of the virus and generate 908 `.java` files, containing $\sim$ 250k LoC. The experiment process is identical to our previous case study: we feed every decompiled code file to both GPT-3.5 and GPT-4 and get 908 code analysis responses in return. After that, we instruct GPT-4 to read the analysis and give alerts if there are any abnormal or potentially malicious behaviors. The diagram of our experiment pipeline is shown in Figure 9.

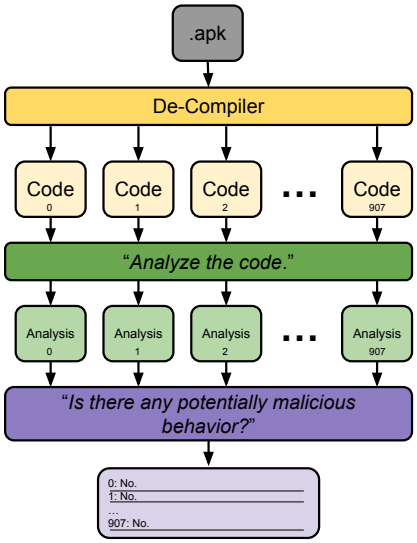


Figure 9: Diagram of our Android case study pipeline.

This virus works in the following way:

1. Upon signing up, it requires users to enter a phone number. It checks if the entered phone number is from Iran (+98). If so, it requests to gain SMS sending and reading privileges.
2. It then continues to establish a connection using a specific URL.
3. When an SMS message is received, it reads the whole packet of information and performs a string match. Upon a successful match, the virus sends the content of the SMS message to a specific site.

These functionalities are spread across 3 different code files.

By examining the analysis generated by GPT-3.5 and GPT-4, we find that both have correctly deciphered these behaviors from the decompiled source code. Part of the responses from GPT-3.5 are shown below:

Response 1: *"... the code validates the entered phone number using a regular expression. If the phone number is not valid, a toast message is displayed. Otherwise, the code requests the 'RECEIVE_SMS' permission and checks if the permission is granted."* (Step 1)

Response 2: *"... it builds a URL string by appending the 'url' and 'info'* (user phone number) *parameters to a base URL. It then sends a GET request to this URL using the AndroidNetworking library's 'get()' method."* (Step 2)

Response 3: *"... it retrieves the SMS messages from the intent extras, retrieves the message body, and concatenates all message bodies into a single string. It then checks if the string contains the text "*(a trigger string in Persian)*"*

and if so, it updates a shared preference value named "lock" to "off". Finally, it uses the 'connect' class to perform some action using the phone number retrieved from the shared preferences and the concatenated string of SMS messages." (Step 3)

These behaviors are apparently suspicious, since it requests SMS read/write privilege (sensitive privilege) and communicates with and sends SMS messages to a remote site. However, when we feed GPT-4/GPT-3.5 with its analysis results and ask *"Is there any potentially malicious behavior?"*, we have the following interesting observations.

Observation 1: When feeding analysis results regarding the three steps independently, both GPT-3.5 and GPT-4 fail to recognize the potentially malicious behaviors.

Observation 2: When concatenating the information together and feeding to LLMs, only GPT-4 successfully points out potentially malicious behaviors.

These observations indicate that GPT-4 possesses a better capability to understand natural language inputs and GPT-4 would be a better choice to process the massive analysis results. However, our observations also suggest that when using these LLMs for defensive analysis, it is important to provide enough context otherwise LLMs will fail to detect security issues.

5.3 WannaCry Ransomware Analysis

In another case study, we aim for a more realistic target and analyze a desktop virus to showcase if LLMs can be utilized to perform defensive analysis on decompiled code. We select a malicious software called WannaCry (also named WanaCrypt0r) [58], which is a ransomware that posted shockingly devastating damages to various organizations and personal users in 2017. WannaCry ransomware attack uses the EternalBlue exploit to compromise Windows Service Message Block Protocol (SMBv1) and propagates itself through TCP port 445 [49, 60]. Once residing on a computer, it encrypts user files and demands a ransom paid in bitcoins. It is reported that WannaCry ransomware has impacted hospitals [62] and large companies including Nissan [33], TSMC [63], etc.

In this case study, we directly feed the decompiled code file of WannaCry [8] generated by an open-source decompiler RetDec [14] to LLMs. We aim to analyze the behaviors of WannaCry, and test the ability of LLMs to understand and analyze code. The decompiled code file contains around 11k lines of C code and automatically generated comments. The decompiled C code does not include meaningful functions and variable names. It has identifier names such as `function_401000` and `g33` that do not provide useful contextual information. The automatically generated comments only specify memory addresses of functions and branches, as well as a list of functions that are statically or dynamically linked.

To feed the generated code to LLMs, we input the generated code to LLMs in an interactive manner. In the first prompt, we state that we will input a code file for it to analyze, and it may consist of multiple chunks of code due to the length restrictions of input. For shorter functions, we copy and paste 3-5 functions in one round of query and obtain the response of analysis. For longer functions whose length exceeds the length limit of input, we partition the body of functions into multiple parts, each consisting of 200-500 lines of code. A sentence is first provided to LLMs, stating that this is a long function and will be input as multiple chunks of code. Starting from the second chunk of code, we state that "*the following code snippet is the remaining part of the previous function*". After the last partition of code, we manually add a comment "`// function ends`" to indicate the end of the function. No other manual operation is involved during the experiment. We select to use GPT-3.5 in this experiment, since it is one of the easiest accessible and most popular chatbot-based LLMs.

Part of the analysis results from GPT-3.5 that we consider interesting and important are shown below. For the whole record of our experiment, please refer to our online appendix.

Response 1: *"... Overall, these functions handle networking tasks. The first, `function_4072a0`, seems to be part of a more complex communication protocol, while the second, `function_407480`, checks for the ability to connect to port 445."*

Response 2: *"... This is interesting functionality, especially the last function. The program is attempting to create a Windows service named "`mssecsvc2.0`", which sounds similar to a legitimate Microsoft Security service. This could indicate malicious or at least suspicious behavior, as it seems like the program is trying to disguise itself as a legitimate service."* (`function_407c40`)

Response 3: *"...• Initializes a URL string pointing to http://www.iuqerfsodp9ifjap{...}jfaewrwergwea.com.*
• Uses the Windows Internet (WinINet) API to open an internet session and attempts to open the URL.
• Closes the internet handles after the operations.
• If it's successful in opening the URL, it closes the internet handle and returns, else it calls `function_408090`.
• This function seems to be checking for the availability of a specific website, possibly as a kind of "alive" check or to determine network connectivity. ..." (`function_408140`)

Response 4: *"... The two goto labels `lab_0x408755_9` and `lab_0x4087c3_9` are exit points or continuation points, but the actual code for these labels is not present*

in the segment. They might direct the code to other parts of the function based on specific conditions. ..."

Response 5: *"... From the provided data, it's challenging to pinpoint the exact purpose of the application, but it seems like a complex program that could serve as a service or a daemon on Windows, handling network communication, possibly acting as a server or a service manager, with capabilities for file handling and other utility tasks. However, this is a speculative overview based on the given context, and a more detailed analysis would be required to confirm this."*

From the findings presented above, we found that GPT-3.5 is capable of analyzing a relatively large-scale decompiled c codebase with low readability. It correctly extracts critical behaviors of our target ransomware, including:

- Checking connectivity to port 445 (Response 1);
- Creating service named `mssecsvc2.0` (Response 2);
- Querying a special url for "alive" check (Response 3).

These critical findings partially align with publicly available analysis of WannaCry [57], as these are also considered important behavioral watermarks of WannaCry ransomware. However, there are differences indicating that the analysis is not fully correct. For example, according to the technical report provided by Microsoft [57], the purpose of initiating `mssecsvc2.0` service is to exploit the SMB vulnerability, instead of simply disguising itself. However, considering the lack of context information and the fact that GPT-3.5 correctly raises security concerns, this still demonstrates the capability of LLMs in defensive analysis.

However, there are other observed weaknesses of GPT-3.5:

Observation 1: Code address labels are ignored and not remembered.

In Response 4, GPT-3.5 replies that code for two labels is not provided. Yet the code labels actually reside in the same function body and were provided to GPT-3.5 a few rounds of queries ago due to the excessively long function body. By looking back at the dialog record, we find that these labels are also not mentioned in the response at the corresponding round of query. This indicates that these labels are ignored, and not remembered during later processing. The incapability to capture and remember important code information will hinder the ability of LLMs to analyze long code bodies with more complicated context, considering the rather strict input limit of each query.

Observation 2: GPT-3.5 is conservative in providing conclusive remarks.

During our experiment, GPT-3.5 repeatedly mentions the need for more context and its incapability to draw a conclusion about the intent of the provided code. In the conclusive Response 5, it simply generates generic descriptions. We suspect that GPT-3.5 learned the strategy to conservatively provide information to improve the score of outputs during training.

Summary. In this case study, the analysis results of WannaCry show that GPT-3.5 is able to capture the most important behaviors of this ransomware and successfully provide a security alert (Response 2). Despite the observed weaknesses, we confirm that LLM models like GPT-3.5 are able to extract important information from decompiled code and raise security concerns if there are any. This experiment shows LLMs' superior ability in performing code analysis and summarization, considering that the provided code has extremely low readability and there is no extra context. Though at this point, LLMs cannot replace expert human beings, they can still serve as an initial code analysis assistant to accelerate the reverse engineering of software and aid defensive code analysis.

6 Discussion

6.1 Using LLMs for Code Analysis

As shown in our analysis results, more advanced LLMs (e.g. GPT-3.5, GPT-4) have a higher success rate of generating explanations for input code samples. However, as found out in our analysis, smaller ones have poor performance, and the results are not always reliable even for larger LLMs, especially when complicated code obfuscation is involved. Smaller general-purpose LLMs, even when specifically fine-tuned for coding tasks, struggle to produce meaningful results. These findings suggest that at this point, utilizing larger LLMs is still the safer choice for code analysis-related tasks.

6.2 Future Work

This work sheds light on some possible future directions in this area. First of all, there is a gap in the literature about obfuscated code datasets. Most works only focus on the ability to analyze normal code, without integrating obfuscation techniques. Constructing such a large dataset would enable LLM users to fine-tune pre-trained LLMs specifically for code analysis tasks quickly. Second, in this paper, we report several interesting observations regarding the memorization phenomena of LLMs [27]. The underlying mechanisms still remain to be explored. Third, regarding similarity metrics, while the n-gram algorithm-based metric has been reported to be suboptimal in capturing semantic similarities [88], during our experiments, the newly employed ChatGPT-based method [24,31,88,92] is also not reliable and requires manual work to calibrate, especially when code snippets and natural languages are combined together in the inputs. We believe

constructing a more sophisticated metric that captures the essence of code analysis results is non-trivial and could be one research direction.

7 Related Work

Code Analysis. Code analysis is crucial in modern software development to identify vulnerabilities and ensure code quality. The significant progress in artificial intelligence (AI) motivates researchers to adopt advanced AI models to improve more effective code analysis. Mou *et.al* [59] proposed to use CNNs to analyze syntax trees of programs. Feng *et.al* [39] targets detecting vulnerability by collecting features from extracted syntax trees and employing a Bi-GRU network to identify bugs in general code. The development of natural language processing techniques, especially transformers and LLMs, significantly boost this area. Chen *et.al* [30] employ a transformer-based method to automatically predict variable names and types from decompiler outputs, thus dramatically improving the readability of decompiler-generated code. Similarly, Xu *et.al* [87] also proposes to use LLMs to assist in handling decompilation tasks. It presents that using an iterative algorithm with multiple LLM queries can improve the decompilation results.

LLM Evaluation. As LLMs become prevalent in recent years, there are a surging number of review or analysis papers focusing on LLM's capabilities. Bubeck *et.al* [24] analyze the capabilities of GPT-4 from different aspects, including vision, coding, and mathematics-related tasks and discuss the societal impacts of such LLMs. A recent survey [20] focuses on security aspects of LLMs and summarizes several attack and defence works on LLMs and points out future directions of research in this field. Regarding analysis and evaluation of code-related capabilities of LLMs, Chen *et.al* [29] evaluate LLMs trained on code. However, their focus is primarily on the code generation aspects. The work that is closest to ours is [88]. In the paper, they conduct an analysis of the ability of instruction-tuned and fine-tuned LLMs to perform code comprehension and generation tasks. However, code-obfuscation-related tasks, including obfuscated code comprehension and de-obfuscated code generation, are not included.

8 Conclusion

In this paper, we have conducted a thorough evaluation of the code analysis capabilities of popular Large Language Models (LLMs). Our results reveal that the larger LLMs, specifically from the GPT series, exhibit impressive performance in code analysis tasks. On the other hand, the smaller models from LLaMA family evaluated in this paper demonstrate unsatisfying performance in these same tasks. When it comes to analyzing obfuscated code, the GPT-series LLMs still produce reasonably useful results for explanation-related tasks; however, they do encounter limitations in providing de-obfuscated code. Our study also uncovers intriguing findings such as LLM memorization phenomena. Our research highlights that, at the present stage, LLMs demonstrate considerable potential in this field. However, there are still many unexplored ways to optimize their performance.

Acknowledgments

We would like to thank the authors of Wobfuscator [70] for sharing their obfuscation tool. We extend our gratitude to all anonymous reviewers and our shepherd for the valuable feedback they have provided.

Abstract

Penetration testing, a crucial industrial practice for ensuring system security, has traditionally resisted automation due to the extensive expertise required by human professionals. Large Language Models (LLMs) have shown significant advancements in various domains, and their emergent abilities suggest their potential to revolutionize industries. In this work, we establish a comprehensive benchmark using real-world penetration testing targets and further use it to explore the capabilities of LLMs in this domain. Our findings reveal that while LLMs demonstrate proficiency in specific sub-tasks within the penetration testing process, such as using testing tools, interpreting outputs, and proposing subsequent actions, they also encounter difficulties maintaining a whole context of the overall testing scenario.

Based on these insights, we introduce PENTESTGPT, an LLM-empowered automated penetration testing framework that leverages the abundant domain knowledge inherent in LLMs. PENTESTGPT is meticulously designed with three self-interacting modules, each addressing individual sub-tasks of penetration testing, to mitigate the challenges related to context loss. Our evaluation shows that PENTESTGPT not only outperforms LLMs with a task-completion increase of 228.6% compared to the GPT-3.5 model among the benchmark targets, but also proves effective in tackling real-world penetration testing targets and CTF challenges. Having been open-sourced on GitHub, PENTESTGPT has garnered over 6,500 stars in 12 months and fostered active community engagement, attesting to its value and impact in both the academic and industrial spheres.

1 Introduction

Securing a system presents a formidable challenge. Offensive security methods like penetration testing (pen-testing) and red teaming are now essential in the security lifecycle. As explained by Applebaum [1], these approaches involve security teams attempting breaches to reveal vulnerabilities, providing advantages over traditional defenses, which rely on incomplete system knowledge and modeling. This study, guided by the principle *"the best defense is a good offense"*, focuses on offensive strategies, specifically penetration testing.

Penetration testing is a proactive offensive technique for identifying, assessing, and mitigating security vulnerabilities [2]. It involves targeted attacks to confirm flaws, yielding a comprehensive inventory of vulnerabilities with actionable recommendations. This widely-used practice empowers organizations to detect and neutralize network and system vulnerabilities before malicious exploitation. However, it typically relies on manual effort and specialized knowledge [3], resulting in a labor-intensive process, creating a gap in meeting the growing demand for efficient security evaluations.

Large Language Models (LLMs) have demonstrated profound capabilities, showcasing intricate comprehension of human-like text and achieving remarkable results across a multitude of tasks [4, 5]. An outstanding characteristic of LLMs is their emergent abilities [6], cultivated during training, which empower them to undertake intricate tasks such as reasoning, summarization, and domain-specific problem-solving without task-specific fine-tuning. This versatility posits LLMs as potential game-changers in various fields, notably cybersecurity. Although recent works [7–9] posit the potential of LLMs to reshape cybersecurity practices, including the context of penetration testing, there is an absence of a systematic, quantitative assessment of their aptitude in this regard. Consequently, an imperative question presents: To what extend can LLMs automate penetration testing?

Motivated by this question, we set out to explore the capability boundary of LLMs on real-world penetration testing tasks. Unfortunately, the current benchmarks for penetration testing [10, 11] are not comprehensive and fail to assess progressive accomplishments fairly during the process. To address this limitation, we construct a robust benchmark that includes test machines from HackTheBox [12] and

*Corresponding author.
§Equal Contribution

VulnHub [13]—two leading platforms for penetration testing challenges. Comprising 13 targets with 182 sub-tasks, our benchmark encompasses all vulnerabilities appearing in OWASP's top 10 vulnerability list [14] and 18 Common Weakness Enumeration (CWE) items [15]. The benchmark offers a more detailed evaluation of the tester's performance by monitoring the completion status for each sub-task.

With this benchmark, we perform an exploratory study using GPT-3.5 [16], GPT-4 [17], and Bard [18] as representative LLMs. Our test strategy is interactive and iterative. We craft tailored prompts to guide the LLMs through penetration testing. Each LLM, presented with prompts and target machine information, generates step-by-step penetration testing operations. We then execute the suggested operations in a controlled environment, document the results, and feed them back to the LLM to inform and refine its next steps. This cycle (prompting, executing, and feedback) is repeated until the LLM completes the entire penetration testing process autonomously. To evaluate LLMs, we compare their results against baseline solutions from official walkthroughs and certified penetration testers. By analyzing similarities and differences in their problem-solving approaches, we aim to better understand LLMs' capabilities in penetration testing and how their strategies differ from human experts.

Our investigation yields intriguing insights into the capabilities and limitations of LLMs in penetration testing. We discover that LLMs demonstrate proficiency in managing specific sub-tasks within the testing process, such as utilizing testing tools, interpreting their outputs, and suggesting subsequent actions. Compared to human experts, LLMs are especially adept at executing complex commands and options with testing tools, while models like GPT-4 excel in comprehending source code and pinpointing vulnerabilities. Furthermore, LLMs can craft appropriate test commands and accurately describe graphical user-interface operations needed for specific tasks. Leveraging their vast knowledge base, they can design inventive testing procedures to unveil potential vulnerabilities in real-world systems and CTF challenges. However, we also note that LLMs have difficulty in maintaining a coherent grasp of the overarching testing scenario, a vital aspect for attaining the testing goal. As the dialogue advances, they may lose sight of earlier discoveries and struggle to apply their reasoning consistently toward the final objective. Additionally, LLMs overemphasize recent tasks in the conversation history, regardless of their vulnerability status. As a result, they tend to neglect other potential attack surfaces exposed in prior tests and fail to complete the penetration testing task.

Building on our insights into LLMs' capabilities in penetration testing, we present PENTESTGPT, an interactive system designed to enhance the application of LLMs in this domain. Drawing inspiration from the collaborative dynamics commonly observed in real-world human penetration testing teams, PENTESTGPT is particularly tailored to manage large and intricate projects. It features a tripartite architecture comprising *Reasoning, Generation, and Parsing Modules*, each reflecting specific roles within penetration testing teams. The Reasoning Module emulates the function of a lead tester, focusing on maintaining a high-level overview of the penetration testing status. We introduce a novel representation, the Pentesting Task Tree (PTT), based on the cybersecurity attack tree [19]. This structure encodes the testing process's ongoing status and steers subsequent actions. Uniquely, this representation can be translated into natural language and interpreted by the LLM, thereby comprehended by the Generation Module and directing the testing procedure. The Generation Module, mirroring a junior tester's role, is responsible for constructing detailed procedures for specific sub-tasks. Translating these into exact testing operations augments the generation process's accuracy. Meanwhile, the Parsing Module deals with diverse text data encountered during penetration testing, such as tool outputs, source codes, and HTTP web pages. It condenses and emphasizes these texts, extracting essential information. Collectively, these modules function as an integrated system. PENTESTGPT completes complex penetration testing tasks by bridging high-level strategies with precise execution and intelligent data interpretation, thereby maintaining a coherent and effective testing process.

We assessed PENTESTGPT across diverse testing scenarios to validate its effectiveness and breadth. In our custom benchmarks, PENTESTGPT significantly outperformed direct applications of GPT-3.5 and GPT-4, showing increases in sub-task completion rates of 228.6% and 58.6%, respectively. Furthermore, when applied to real-world challenges such as the HackTheBox active machine penetration tests [20] and picoMini [21] CTF competition, PENTESTGPT demonstrated its practical utility. It successfully resolved 4 out of 10 penetration testing challenges, incurring a total cost of 131.5 US Dollars for the OpenAI API usage. In the CTF competition, PENTESTGPT achieved a score of 1500 out of a possible 4200, placing 24th among 248 participating teams. This evaluation underscores PENTESTGPT's practical value in enhancing penetration testing tasks' efficiency and precision. The solution has been made publicly available on GitHub [22], receiving widespread acclaim with over 6,200 stars to the date of writing, active community engagement, and ongoing collaboration with multiple industrial partners.

In summary, we make the following contributions:

- **Development of a Comprehensive Penetration Testing Benchmark.** We craft a robust and representative penetration testing benchmark, encompassing a multitude of test machines from leading platforms such as HackTheBox and VulnHub. This benchmark includes 182 sub-tasks covering OWASP's top 10 vulnerabilities, offering fair and comprehensive evaluation of penetration testing. To the best of our knowledge, this is the first benchmark in the field that can provide progressive accomplishments assessments and comparisons.

- **Comprehensive Evaluation of LLMs for Penetration Testing Tasks.** By employing models like GPT-3.5, GPT-4, and Bard, our exploratory study rigorously investigates the strengths and limitations of LLMs in penetration testing. To the best of our knowledge, this is the first systematic and quantitative study for the capability of LLMs in performing automated penetration testing. The insights gleaned from this study shed valuable light on the capabilities and challenges faced by LLMs, enriching our understanding of their applicability in this specialized domain.
- **Development of an Innovative LLM-powered Penetration Testing System.** We engineer PENTESTGPT, a novel interactive system that leverages the strengths of LLMs to carry out penetration testing tasks automatically. Drawing inspiration from real-world human penetration testing teams, PENTESTGPT integrates a tripartite design that mirrors the collaborative dynamics between senior and junior testers. This architecture optimizes LLMs' usage, significantly enhancing the efficiency and effectiveness of automated penetration testing. We have open-sourced PENTESTGPT and it has received over 6,500 stars on GitHub, active community contributions, and several industry partners including AWS, Huawei, and TikTok to collaborate.

2 Background & Related Work

2.1 Penetration Testing

Penetration testing, or "pentesting", is a critical practice to enhance organizational systems' security. In a typical penetration test, security professionals, known as penetration testers, analyze the target system, often leveraging automated tools. The standard process is divided into five key phases [23]: Reconnaissance, Scanning, Vulnerability Assessment, Exploitation, and Post Exploitation (including reporting). These phases enable testers to understand the target system, identify vulnerabilities, and exploit them to gain access.

Despite significant advancements [11, 24, 25], a fully automated penetration testing system remains out of reach. This gap results from the need for deep vulnerability understanding and a strategic action plan. Typically, testers combine depth-first and breadth-first search techniques [23]. They first grasp the target environment's scope, then drill down into specific vulnerabilities. This method ensures comprehensive analysis, leaning on expertise and experience. The multitude of specialized tools further complicate the automation. Thus, even with artificial intelligence, achieving a seamless automated penetration testing solution is a daunting task.

2.2 Large Language Models

Large Language Models (LLMs), including OpenAI's GPT-3.5 and GPT-4, are prominent tools with applications extending to various cybersecurity-related fields, such as code analysis [26] and vulnerability repairment [27]. These models are equipped with wide-ranging general knowledge and the capacity for elementary reasoning. They can comprehend, infer, and produce text resembling human communication, aided by a training corpus encompassing diverse domains like computer science and cybersecurity. Their ability to interpret context and recognize patterns enables them to adapt knowledge to new scenarios. This adaptability, coupled with their proficiency in interacting with systems in a human-like way, positions them as valuable assets in enhancing penetration testing processes. Despite inherent limitations, LLMs offer distinct attributes that can substantially aid in the automation and improvement of penetration testing tasks. The realization of this potential, however, requires the creation and application of a specialized and rigorous benchmark.

3 Penetration Testing Benchmark

3.1 Motivation

The comprehensive evaluation of LLMs in penetration testing necessitates a robust and representative benchmark. Existing benchmarks in this domain [10, 11] have several limitations. First, they are often restricted in scope, focusing on a narrow range of potential vulnerabilities, and thus fail to capture the complexity and diversity of real-world cyber threats. For instance, the OWASP *juiceshop* project [28] is the most widely adopted benchmark for web vulnerability evaluation. However, it does not include privilege escalation vulnerabilities, which is an essential aspect of penetration testing. Second, existing benchmarks may not recognize the cumulative value of progress through the different stages of penetration testing, as they tend to evaluate only the final exploitation success. This approach overlooks the nuanced value each step contributes to the overall process, resulting in metrics that might not accurately represent actual performance in real-world scenarios.

To address these concerns, we propose the construction of a comprehensive penetration testing benchmark that meets the following criteria:

Task Variety. The benchmark must encompass diverse tasks, reflecting various operating systems and emulating the diversity of scenarios encountered in real-world penetration testing.

Challenge Levels. To ensure broad applicability, the benchmark must include tasks of varying difficulty levels suitable for challenging novice and expert testers.

Progress Tracking. Beyond mere success or failure metrics, the benchmark must facilitate tracking of incremental progress, thereby recognizing and scoring the value added at each stage of the penetration testing process.

3.2 Benchmark Design

Following the criteria outlined previously, we develop a comprehensive benchmark that closely reflects real-world penetration testing tasks. The design process progresses through several stages.

Task Selection. We begin by selecting tasks from HackTheBox [12] and VulnHub [13], two leading penetration testing training platforms. Our selection criteria are designed to ensure that our benchmark accurately reflects the challenges encountered in practical penetration testing environments. We meticulously review the latest machines available on both platforms, aiming to identify and select a subset that comprehensively covers all vulnerabilities listed in the OWASP [14] Top 10 Project. Additionally, we choose machines that represent a mix of difficulties, classified according to traditional standards in the penetration testing domain into *easy*, *medium*, and *hard* categories. This process guarantees that our benchmark spans the full spectrum of vulnerabilities and difficulties. Note that our benchmark does not include benign targets to assess false positives. In penetration testing, benign targets are sometimes explored. Our main objective remains identifying true vulnerabilities.

Task Decomposition. We further parse the testing process of each target into a series of sub-tasks, following the standard solution commonly referred to as the "walkthrough" in penetration testing. Each sub-task corresponds to a unique step in the overall process. We decompose sub-tasks following NIST 800-115 [29], the Technical Guide to Security Testing. Each sub-task is one step declared in the Guide (e.g., network discovery, password cracking), or an operation that exploits a unique vulnerability categorised in the Common Weakness Enumeration (CWE) [15] (e.g., exploiting SQL injection - CWE-89 [30]). In the end, we formulate an exhaustive list of sub-tasks for every benchmark target.

Benchmark Validation. The final stage of our benchmark development involves rigorous validation, which ensures the reproducibility of these benchmark machines. To do this, three certified penetration testers independently attempt the penetration testing targets and write their walkthrough. We then adjust our task decomposition accordingly because some targets may have multiple valid solutions.

Ultimately, we have compiled a benchmark that effectively encompasses all types of vulnerabilities listed in the OWASP [14] Top 10 Project. It comprises 13 penetration testing targets, each at varying levels of difficulty. These targets are broken down into 182 sub-tasks across 26 categories, covering 18 distinct CWE items. This number of targets is deemed sufficient to represent a broad spectrum of vulnerabilities, difficulty levels, and varieties essential for comprehensive penetration testing training. To foster community development, we have made this benchmark publicly available online [22].

4 Exploratory Study

We conduct an exploratory study to assess the capabilities of LLMs in penetration testing, with the primary objective of determining how well LLMs can adapt to the real-world complexities and challenges in this task. Specifically, we aim to address the following two research questions:

RQ1 (Capability): To what extent can LLMs perform penetration testing tasks?

RQ2 (Comparative Analysis): How do the problem-solving strategies of human penetration testers and LLMs differ?

We utilize the benchmark described in Section 3 to evaluate the performance of LLMs on penetration testing tasks. In the following, we first delineate our testing strategy for this study. Subsequently, we present the testing results and an analytical discussion to address the above research questions.

4.1 Testing Strategy

LLMs are text-based and cannot independently perform penetration testing operations. To address this, we develop a human-in-the-loop testing strategy, serving as an intermediary method to accurately assess LLMs' capabilities. This strategy features an interactive loop where a human expert executes the LLM's penetration testing directives. Importantly, the human expert functions purely as an executor, strictly following the LLM's instructions without adding any expert insights or making independent decisions.

Figure 1 decipits the testing strategy with the following steps: ❶ We initiate the looped testing procedure by presenting the target specifics to the LLM, seeking its guidance on potential penetration testing steps. ❷ The human expert strictly follows the LLM's recommendations and conducts the suggested actions in the penetration testing environment. ❸ Outcomes of the testing actions are collected and summarized: direct text outputs such as terminal outputs or source code are documented; non-textual results, such as graphical representations, are translated by the human expert into succinct textual summaries. The data is then fed back to the LLM, setting the stage for its subsequent recommendations. ❹ This iterative process persists either until a conclusive solution is identified or an deadlock is reached. We then compile a record of the testing procedures, encompassing successful sub-tasks, ineffective actions, and any reasons for failure, if applicable. For a more tangible grasp of this strategy, we offer illustrative examples of prompts and corresponding outputs from GPT-4 related to one of our benchmark targets in the Appendix Section A.

To ensure the evaluation's fairness and accuracy, we employ several strategies. First, we involve expert-level penetration testers[1] as the human testers. With their deep pentesting knowledge, these testers can precisely comprehend and execute LLM-generated operations, thus accurately assessing

[1]We selected Offensive Security Certified Professionals (OSCP) testers.

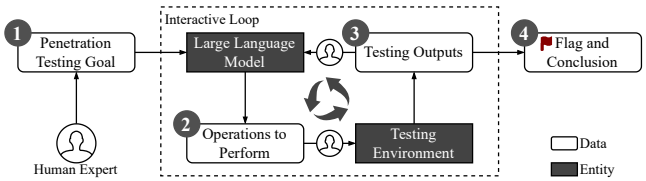

Figure 1: Overview of strategy to use LLMs for penetration testing.

LLMs' true capabilities. Second, we instruct the penetration testers to strictly execute the commands given by the LLMs, without altering any content or information, even upon identifying clear errors. They are also instructed to faithfully report the testing results back to the LLM without any additional commentary. Third, for managing UI-based operations and graphical results, we have adopted specific measures. Initially, we instruct the LLMs to minimize the use of GUI-based tools. For indispensable tools that cannot be avoided (e.g., BurpSuite), we propose a result-oriented approach: upon receiving a GUI operation instruction, the testers first execute the operation based on their expert knowledge. Subsequently, they are required to provide detailed, step-by-step textual descriptions of their actions and the observed responses at each step, which are then communicated back to the LLM. Should the LLM express any objections or comments concerning a particular step, the operation is to be repeated. This protocol ensures the integrity of the feedback loop, guaranteeing that the LLM obtains a comprehensive understanding of the testing results.

4.2 Evaluation Settings

We proceed to assess the performances of various LLMs in penetration testing tasks using the strategy mentioned above.
Model Selection. Our study focuses on three cutting-edge LLMs that are currently accessible: GPT-3.5 with 8k token limit, GPT-4 with 32k token limit from OpenAI, and LaMDA [31] from Google. These models are selected based on their prominence in the research community and consistent availability. To interact with the LLMs mentioned above, we utilize chatbot services provided by OpenAI and Google, namely ChatGPT [32] and Bard [18]. For this paper, the terms GPT-3.5, GPT-4, and Bard will represent these three LLMs.
Experimental Setup. Our experiments occur in a local setting with both target and testing machines on the same private network. The testing machine runs on Kali Linux [33], version 2023.1.
Tool Usage. Our study aims to assess the innate capabilities of LLMs on penetration testing, without reliance on end-to-end automated vulnerability scanners such as Nexus [34] and OpenVAS [35]. Consequently, we explicitly instruct the LLMs to refrain from using these tools. We follow the LLMs' recommendations for utilizing other tools designed to validate specific vulnerability types (e.g., sqlmap [36] for SQL injections). Occasionally, versioning discrepancies may lead the LLMs to provide incorrect instructions for tool usage. In such instances, our penetration testing experts evaluate whether the instructions would have been valid for a previous version of the tool. They then make any necessary adjustments to ensure the tool's correct operation.

4.3 Capability Evaluation (RQ1)

To address **RQ1**, we evaluate the performance of three leading LLMs: GPT-4, Bard, and GPT-3.5. We summarize these findings in Table 1. Each LLM successfully completes at least one end-to-end penetration test, highlighting their versatility in simpler environments. Of these, GPT-4 excels, achieving success on 4 easy and 1 medium difficulty targets. Bard and GPT-3.5 follow with success on 2 and 1 easy targets, respectively. In sub-tasks, GPT-4 completes 55 out of 77 on easy targets and 30 out of 71 on medium. Bard and GPT-3.5 also show potential, finishing 16 (22.54%) and 13 (18.31%) of medium difficulty sub-tasks, respectively. However, on hard targets, all models' performance declines. Though they can initiate the reconnaissance phase, they struggle to exploit identified vulnerabilities. This is anticipated since hard targets are designed to be especially challenging. They often feature seemingly vulnerable services that are non-exploitable, known as *rabbit holes* [37]. The pathways to exploit these machines are unique and unpredictable, resisting automated tool replication. For example, the target *Falafel* has specialized SQL injection vulnerabilities resistant to *sqlmap*. Current LLMs cannot tackle these without human expert input.

Finding 1: Large Language Models (LLMs) have shown proficiency in conducting end-to-end penetration testing tasks but struggle to overcome challenges presented by more difficult targets.

We further examine the detailed sub-task completion performances of the three LLMs compared to the walkthrough (WT), as presented in Table 2. Analyzing the completion status, we identify several areas where LLMs excel. First, they adeptly utilize common penetration testing tools to interpret the corresponding outputs, especially in enumeration tasks correctly. For example, all three evaluated LLMs successfully perform nine *Port Scanning* sub-tasks. They can configure the widely-used port scanning tool, *nmap* [38], comprehend the scan results, and formulate subsequent actions. Second, the LLMs reveal a deep understanding of prevalent vulnerability types, connecting them to the services on the target system. This understanding is evidenced by the successful completion of sub-tasks related to various vulnerability types. Finally, LLMs demonstrate their effectiveness in code analysis and generation, particularly in the tasks of *Code Analysis* and *Shell Construction*. These tasks require the models to read and generate codes in different programming languages.

Table 1: Overall performance of LLMs on Penetration Testing Benchmark.

	Easy		Medium		Hard		Average	
Tools	Overall (7)	Sub-task (77)	Overall (4)	Sub-task (71)	Overall (2)	Sub-task (34)	Overall (13)	Sub-task (182)
GPT-3.5	1 (14.29%)	24 (31.17%)	0 (0.00%)	13 (18.31%)	0 (0.00%)	5 (14.71%)	1 (7.69%)	42 (23.07%)
GPT-4	4 (57.14%)	55 (71.43%)	1 (25.00%)	30 (42.25%)	0 (0.00%)	10 (29.41%)	5 (38.46%)	95 (52.20%)
Bard	2 (28.57%)	29 (37.66%)	0 (0.00%)	16 (22.54%)	0 (0.00%)	5 (14.71%)	2 (15.38%)	50 (27.47%)
Average	2.3 (33.33%)	36 (46.75%)	0.33 (8.33%)	19.7 (27.70%)	0 (0.00%)	6.7 (19.61%)	2.7 (20.5%)	62.3 (34.25%)

Table 2: Top 10 Types of Sub-tasks completed by each tool.

Sub-Tasks	WT	GPT-3.5	GPT-4	Bard
Web Enumeration	18	4 (22.2%)	8 (44.4%)	4 (22.2%)
Code Analysis	18	4 (22.2%)	5 (27.2%)	4 (22.2%)
Port Scanning	12	9 (75.0%)	9 (75.0%)	9 (75.0%)
Shell Construction	11	3 (27.3%)	8 (72.7%)	4 (36.4%)
File Enumeration	11	1 (9.1%)	7 (63.6%)	1 (9.1%)
Configuration Enumeration	8	2 (25.0%)	4 (50.0%)	3 (37.5%)
Cryptanalysis	8	2 (25.0%)	3 (37.5%)	1 (12.5%)
Network Enumeration	7	1 (14.3%)	3 (42.9%)	2 (28.6%)
Command Injection	6	1 (16.7%)	4 (66.7%)	2 (33.3%)
Known Exploits	6	2 (33.3%)	3 (50.0%)	1 (16.7%)

Table 3: Top Unnecessary Operations Prompted by LLMs on the Benchmark Targets

Unnecessary Operations	GPT-3.5	GPT-4	Bard	Total
Brute-Force	75	92	68	235
Exploit Known Vulnerabilities (CVEs)	29	24	28	81
SQL Injection	14	21	16	51
Command Injection	18	7	12	37

This often culminates in identifying potential vulnerabilities from code snippets and crafting the corresponding exploits. Notably, GPT-4 outperforms the other two models regarding code interpretation and generation, marking it the most suitable candidate for penetration testing tasks.

Finding 2: LLMs can efficiently use penetration testing tools, identify common vulnerabilities, and interpret source codes to identify vulnerabilities.

4.4 Comparative Analysis (RQ2)

To address **RQ2**, we examine the problem-solving strategies that LLMs employ, contrasting them with human penetration testers. In each penetration testing trial, we concentrate on two main aspects: (1) Identifying the unnecessary operations that LLMs prompt, which are not conducive to successful penetration testing, as compared to a standard walkthrough; and (2) Understanding the specific factors that prevent LLMs from successfully executing penetration tests.

We analyze the unnecessary operations prompted by LLMs by breaking down the recorded testing procedures into sub-tasks. We employ the same method to formulate benchmark sub-tasks, as Section 3 outlines. By comparing this to a standard walkthrough, we identify the primary sub-task trials that fall outside the standard walkthrough and are thus irrelevant to the penetration testing process. The results are summarized in Table 3. We find that the most prevalent unnecessary operation prompted by LLMs is brute force. For all services requiring password authentication, LLMs typically advise brute-forcing it. This is an ineffective strategy in penetration testing. We surmise that many hacking incidents in enterprises involve password cracking and brute force. LLMs learn these reports from accident reports and are consequently considered viable solutions. Besides brute force, LLMs suggest that testers engage in CVE studies, SQL injections, and command injections. These recommendations are common, as real-world penetration testers often prioritize these techniques, even though they may not always provide the exact solution.

Table 4: Top causes for failed penetration testing trials

Failure Reasons	GPT3.5	GPT4	Bard	Total
Session context lost	25	18	31	74
False Command Generation	23	12	20	55
Deadlock operations	19	10	16	45
False Scanning Output Interpretation	13	9	18	40
False Source Code Interpretation	16	11	10	37
Cannot craft valid exploit	11	15	8	34

To understand penetration testing trial failures, we categorize the reasons for the 195 trials, as shown in Table 4. The primary failure cause is *loss of session context*. This means models often lose awareness of previous test outcomes, missing essential past results. This issue arises from LLMs' challenge in handling conversation context. Each LLM has a fixed token window, such as GPT-4 with a capacity of 8,000 tokens [39]. If critical information for a complex task exceeds this limit, trimming it causes the loss of important details. This is problematic in intricate tests where identifying vulnerabilities across services and forming a cohesive exploit strategy is vital. This design flaw impacts the model's efficacy in dealing with layered, detailed tasks.

Finding 3: LLMs struggle to maintain long-term memory, which is vital to link vulnerabilities and develop exploitation strategies effectively.

Secondly, LLMs strongly prefer the most recent tasks, adhering rigorously to a depth-first search approach. They tend to immerse deeply into resolving the issues mentioned in the most recent conversation, seldom branching out to new targets until the ongoing path is exhaustively explored. This behavior aligns with the studies [40, 41] that LLMs primarily concentrate their attention at the prompt's beginning and end. In contrast, seasoned penetration testers adopt a more holistic approach, strategically plotting moves that promise the highest potential outcomes. When coupled with the aforementioned session context loss, this proclivity drives LLMs to become excessively anchored to one specific service. As the testing advances, the models often neglect prior discoveries, leading to an impasse.

Finding 4: LLMs strongly prefer recent tasks and a depth-first search approach, often resulting in an over-focus on one service and forgetting previous findings.

Lastly, LLMs have inaccurate result generation and hallucination issues, as noted in [42]. This phenomenon ranks as the second most frequent cause of failures and is characterized by the generation of false commands. In our study, we observe that LLMs frequently identify the appropriate tool for the task but stumble in configuring the tools with the correct settings. In some cases, they even concoct non-existent testing tools or tool modules.

Finding 5: LLMs may generate inaccurate operations or commands, often stemming from inherent inaccuracies and hallucinations.

Our exploratory study on three LLMs in penetration testing highlights their capability to complete sub-tasks. However, they face issues with long-term memory retention, reliance on a depth-first strategy, and ensuring operation accuracy. In the subsequent section, we detail our approach to mitigate these challenges and describe the design of our LLM-based penetration testing tool.

5 Methodology

5.1 Overview

In light of the challenges identified in the preceding section, we present our proposed solution, PENTESTGPT, which leverages the synergistic interplay of three LLM-powered modules. As illustrated in Figure 2, PENTESTGPT incorporates three core modules: the **Reasoning Module**, the **Generation Module**, and the **Parsing Module**. Each module reserves one LLM session with its conversation and context. The user interacts seamlessly with PENTESTGPT, where distinct modules process different types of messages. This interaction culminates in a final decision, suggesting the subsequent step of the penetration testing process that the user should undertake. In the following sections, we elucidate our design reasoning and provide a detailed breakdown of the engineering processes behind PENTESTGPT.

5.2 Design Rationale

Our central design considerations emerged from the three challenges observed in the previous Exploratory Study (Section 4): The first challenge (*Finding 3*) pertains to the issue of penetration testing context loss due to memory retention. LLMs in their original form struggle to maintain such long-term memory due to token size limits. The second obstacle (*Finding 4*) arises from the LLM chatbots' tendency to emphasize recent conversation content. In penetration testing tasks, this focuses on optimizing the immediate task. This approach falls short in the complex, interconnected task environment of penetration testing. The third obstacle (*Finding 5*) is tied to the inaccurate results generation by LLMs. When tasked to produce specific operations for a step in penetration testing directly, the outputs are often imprecise, sometimes even leading to false directions.

PENTESTGPT has been engineered to address these challenges, rendering it more apt for penetration testing tasks. We draw inspiration from the methodologies employed by real-world penetration testing teams, where directors plan overarching procedures, subdividing them into subtasks for individual testers. Each tester independently performs their task, reporting results without an exhaustive understanding of the broader context. The director then determines the following steps, possibly redefining tasks, and triggers the subsequent round of testing. Essentially, the director manages the overall strategy without becoming entrenched in the minutiae of the tests. This approach is mirrored in PENTESTGPT's functionality, enhancing its efficiency and adaptability in conducting penetration tests. Our strategy divides penetration testing into two processes: identifying the next task and generating the concrete operation to complete the task. Each process is powered by one LLM session. In this setup, the LLM session responsible for task identification retains the complete context of the ongoing penetration testing status. At the same time, the generation of detailed operations and parsing of information is managed by other sessions. This division of responsibilities fosters effective task execution while preserving the overarching context.

To assist LLMs in effectively carrying out penetration testing tasks, we design a series of prompts that align with user inputs. We utilize the Chain-of-Thought (CoT) [43] methodology during this process. As CoT reveals, LLMs' performance and reasoning capabilities can be significantly enhanced using the *input*, *chain-of-thought*, *output* prompting format. Here,

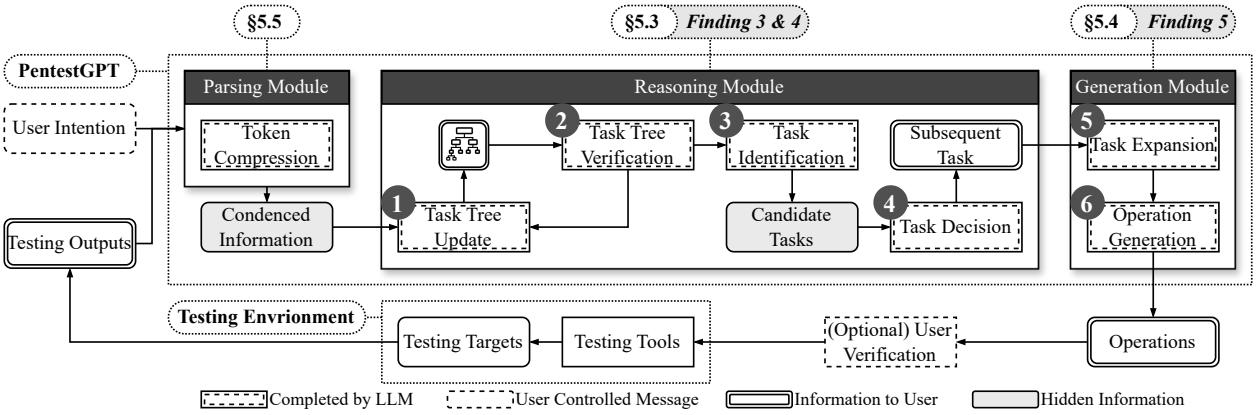

Figure 2: Overview of PENTESTGPT.

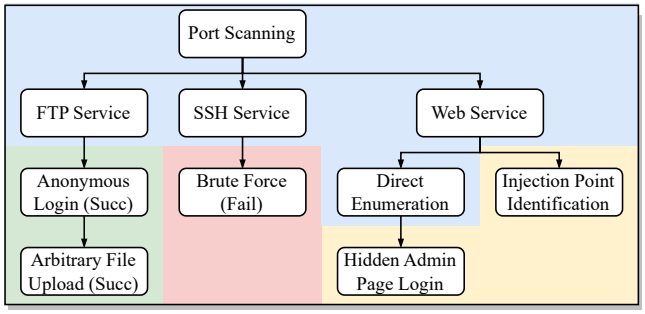
the *chain-of-thought* represents a series of intermediate natural language reasoning steps leading to the outcome. We dissect the penetration testing tasks into micro-steps and design prompts with examples to guide LLMs through processing penetration testing information step-by-step, ultimately leading to the desired outcomes. The complete prompts are available at our anonymized open-source project [44].

5.3 Reasoning Module



The **Reasoning Module** plays a pivotal role in our system, analogous to a team lead overseeing the penetration testing task from a macro perspective. It obtains testing results or intentions from the user and prepares the testing strategy for the next step. This testing strategy is passed to the generation module for further planning.

To effectively supervise the penetration testing process and provide precise guidance, it is crucial to translate the testing procedures and outcomes into a natural language format. Drawing inspiration from the concept of an attack tree [45], which is often used to outline penetration testing procedures, we introduce the notion of a *pentesting task tree* (PTT). This novel approach to testing status representation is rooted in the concept of an *attributed tree* [46]:

Definition 1 (Attributed Tree) *A attributed tree is an edge-labeled, attributed polytree $G = (V, E, \lambda, \mu)$ where V is a set of nodes (or vertices), E is a set of directed edges, $\lambda : E \to \Sigma$ is an edge labeling function assigning a label from the alphabet Σ to each edge and $\mu : (V \cup E) \times K \to S$ is a function assigning key(from K)-value(from S) pairs of properties to the edges and nodes.*

Given the definition of *attributed tree*, PTT is defined as follows:

Definition 2 (Pentesting Task Tree) *A PTT T is a pair (N, A), where: (1) N is a set of nodes organized in a tree structure. Each node has a unique identifier, and there is a special node called the root that has no parent. Each node, other than the root, has exactly one parent and zero or more children. (2) A is a function that assigns to each node $n \in N$ a set of attributes $A(n)$. Each attribute is a pair (a, v), where a is the attribute name and v is the attribute value. The set of attributes can be different for each node.*

a) PTT Representation

```
Task Tree:
1. Perform port scanning (completed)
  - Port 21, 22 and 80 are open.
  - Services are FTP, SSH, and Web Service.
2. Perform the testing
  2.1 Test FTP Service
    2.1.1 Test Anonymous Login (success)
      2.1.1.1 Test Anonymous Upload (success)
  2.2 Test SSH Service
    2.2.1 Brute-force (failed)
  2.3 Test Web Service (ongoing)

b) PTT Representation in Natural Language

Figure 3: Pentesting Task Tree in a) visualized tree format, and b) natural language format encoded in LLM.

As outlined in Figure 2, the Reasoning Module's operation unfolds over four key steps operating over the PTT. ❶ The

module begins by interpreting the user's objectives to create an initial PTT, formatted in natural language. This involves instructing the LLM with designed prompts that contain the above PTT definition and real-world examples. The outputs from the LLM are parsed to ensure that the tree structure is correctly represented, which can be formatted in natural language through layered bullets, as shown in Figure 3. The Reasoning Module effectively overcomes the memory-loss issue by maintaining a task tree that encompasses the entire penetration testing process. ❷ After updating the tree information, a verification step is conducted on the newly updated PTT to ascertain its correctness. This process checks explicitly that only the leaf nodes of the PTT have been modified, aligning with the principle that atomic operations in the penetration testing process should only influence the status of the lowest-level sub-tasks. This step confirms the correctness of the reasoning process, safeguarding against any potential alterations to the overall tree structure due to hallucination by the LLM. If discrepancies arise, the information is reverted to the LLM for correction and regeneration. ❸ With the updated PTT, the Reasoning Module evaluates the current tree state and pinpoints viable sub-tasks that can serve as candidate steps for further testing. ❹ Finally, the module evaluates the likelihood of these sub-tasks leading to successful penetration testing outcomes. It then recommends the top task as the output. The expected results of this task are subsequently forwarded to the Generation Module for an in-depth analysis. This is feasible, as demonstrated in the exploratory study, since LLMs, particularly GPT-4, can identify potential vulnerabilities when provided with system status information. This procedural approach enables the Reasoning Module to address one of the inherent limitations of LLMs, precisely their tendency to concentrate solely on the most recent task. Note that in cases where the tester identifies that the correct task is incorrect or not completed in a preferred way, he could also manually revise the PTT through the interactive handle further discussed in Section 5.6.

We devise four sets of prompts to sequentially guide the Reasoning Module through the completion of each stage. To bolster the reproducibility of our results, we optimize these prompts further with a technique known as hint generation [47]. From our practical experience, we observe that LLMs are adept at interpreting the tree-structured information pertinent to penetration testing and can update it accurately in response to test outputs.

5.4 Generation Module

The Generation Module translates specific sub-tasks from the Reasoning Module into concrete commands or instructions. Each time a new sub-task is received, a fresh session is initiated in the Generation Module. This strategy effectively isolates the context of the overarching penetration task from the immediate task under execution, enabling the LLM to focus entirely on generating specific commands.

Instead of directly transforming the received sub-task into specific operations, our design employs the CoT strategy [43] to partition this process into two sequential steps. This design decision directly addresses the challenges associated with model inaccuracy and hallucination by enhancing the model's reasoning capability. In particular, ❺ upon the receipt of a concise sub-task from the Reasoning Module, the Generation Module begins by expanding it into a sequence of detailed steps. Notably, the prompt associated with this sub-task requires the LLM to consider the possible tools and operations available within the testing environment. ❻ Subsequently, the Generation Module transforms each of these expanded steps into precise terminal commands ready for execution or into detailed descriptions of specific Graphical User Interface (GUI) operations to be carried out. This stage-by-stage translation eliminates potential ambiguities, enabling testers to follow the instructions directly and seamlessly. Implementing this two-step process effectively precludes the LLM from generating operations that may not be feasible in real-world scenarios, thereby improving the success rate of the penetration testing procedure.

By acting as a bridge between the strategic insights provided by the Reasoning Module and the actionable steps required for conducting a penetration test, the Generation Module ensures that high-level plans are converted into precise and actionable steps. This transformation process significantly bolsters the overall efficiency of the penetration testing procedure, and also provides human-readable outputs of the complete testing process. We present a detailed PTT generation process for a complete penetration testing target in Appendix Figure 8, accompanied by an illustrative example to aid understanding.

An Illustrative Example. We utilize a real-world running example to illuminate how the Reasoning Module and the Generation Module collaboratively operate to complete penetration testing tasks. Figure 4 illustrates a single iteration of PENTESTGPT working on the HackTheBox machine Carrier [48], a medium-difficulty target. As depicted in a-1), the PTT, in natural language format, encodes the testing status, revealing the open ports (21, 22, 80) with running services. The Reasoning Module is subsequently instructed to identify the available tasks. As highlighted in red, service scanning is the only available task on the leaf node of the PTT. This task is therefore chosen and forwarded to the Generation Module for command generation. The generated command is executed in the testing environment, and the execution result is conveyed to the Reasoning Module to update the PTT. In a-2), the Reasoning Module integrates the previous scanning result into the PTT, cross-referencing it with the earlier PTT to update only the leaf nodes. It then looks for the available tasks to execute. In this case, two tasks emerge: scanning the web service on port 80 and checking the SSH service for known vulnerabilities. The LLM evaluates which task is more

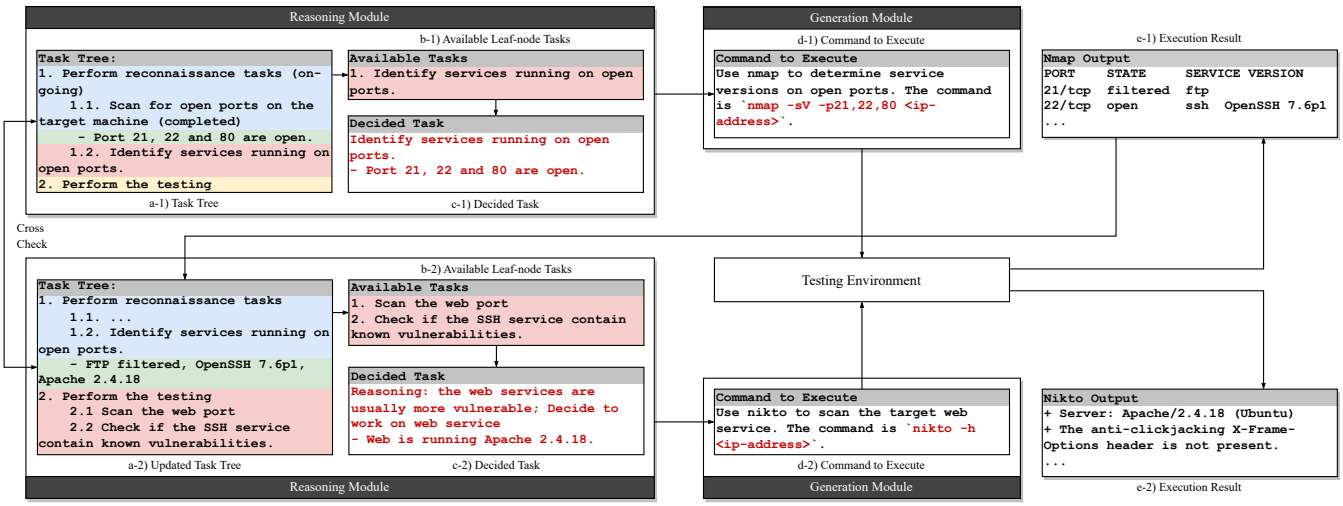

Figure 4: A demonstration of the task-tree update process on the testing target *HTB-Carrier*

promising and chooses to investigate the web service, often seen as more vulnerable. This task is passed to the Generation Module. The Generation Module turns this general task into a detailed process, employing *nikto* [49], a commonly used web scanning script. The iterative process continues until the tester completes the penetration testing task.

5.5 Parsing Module

The **Parsing Module** operates as a supportive interface, enabling effective processing of the natural language information exchanged between the user and the other two core modules. Two needs can primarily justify the existence of this module. First, security testing tool outputs are typically verbose, laden with extraneous details, making it computationally expensive and unnecessarily redundant to feed these extended outputs directly into the LLMs. Second, users without specialized knowledge in the security domain may struggle to extract key insights from security testing outputs, presenting challenges in summarizing crucial testing information. Consequently, the Parsing Module is essential in streamlining and condensing this information.

In PENTESTGPT, the Parsing Module is devised to handle four distinct types of information: (1) *user intentions*, which are directives provided by the user to dictate the next course of action, (2) *security testing tool outputs*, which represent the raw outputs generated by an array of security testing tools, (3) *raw HTTP web information*, which encompasses all raw information derived from HTTP web interfaces, and (4) *source codes* extracted during the penetration testing process. Users must specify the category of the information they provide, and each category is paired with a set of carefully designed prompts. For source code analysis, we integrate the GPT-4 code interpreter [50] to execute the task.

5.6 Active Feedback

While LLMs can produce insightful outputs, their outcomes sometimes require revisions. To facilitate this, we introduce an interactive handle in PENTESTGPT, known as active feedback, which allows the user to interact directly with the Reasoning Module. A vital feature of this process is that it does not alter the context within the Reasoning Module unless the user explicitly desires to update some information. The reasoning context, including the PTT, is stored as a fixed chunk of tokens. This chunk of tokens is provided to a new LLM session during an active feedback interaction, and users can pose questions regarding them. This ensures that the original session remains unaffected, and users can always query the reasoning context without making unnecessary changes. If the user believes it necessary to update the PTT, they can explicitly instruct the model to update the reasoning context history accordingly. This provides a robust and flexible framework for the user to participate in the decision-making process actively.

5.7 Discussion

We explore various design alternatives for PENTESTGPT to tackle the challenges identified in Exploratory Study. We have experimented with different designs, and here we discuss some key decisions.

Addressing Context Loss with Token Size: a straightforward solution to alleviate context loss is the employment of LLM models with an extended token size. For instance, GPT-4 provides versions with 8k and 32k token size limits. This approach, however, confronts two substantial challenges. First, even a 32k token size might be inadequate for penetration testing scenarios, as the output of a single testing tool like *dirbuster* [51] may comprise thousands of tokens. Con-

sequently, GPT-4 with a 32k limit cannot retain the entire testing context. Second, even when the entire conversation history fits within the 32k token boundary, the API may still skew towards recent content, focusing on local tasks and overlooking broader context. These issues guided us in formulating the design for the Reasoning Module and the Parsing Module.

Vector Database to Improve Context Length: Another technique to enhance the context length of LLMs involves a vector database [52, 53]. By transmuting data into vector embeddings, LLMs can efficiently store and retrieve information, practically creating long-term memory. Theoretically, penetration testing tool outputs could be archived in the vector database. In practice, though, we observe that many results closely resemble and vary in only nuanced ways. This similarity often leads to confused information retrieval. Solely relying on a vector database fails to overcome context loss in penetration testing tasks. Integrating the vector database into the design of PENTESTGPT is an avenue for future research.

Precision in Information Extraction: Precise information extraction is crucial for conserving token usage and avoiding verbosity in LLMs [54, 55]. Rule-based methods are commonly employed to extract diverse information. However, rule-based techniques are engineeringly expensive given natural language's inherent complexity and the variety of information types in penetration testing. We devise the Parsing Module to manage several general input information types, a strategy found to be both feasible and efficient.

Limitations of LLMs: LLMs are not an all-encompassing solution. Present LLMs exhibit flaws, including hallucination [56, 57] and outdated knowledge. Our mitigation efforts, such as implementing task tree verification to ward off hallucination, might not completely prevent the Reasoning Module from producing erroneous outcomes. Thus, a human-in-the-loop strategy becomes vital, facilitating the input of necessary expertise and guidance to steer LLMs effectively.

6 Evaluation

In this section, we assess the performance of PENTESTGPT, focusing on the following four research questions:

RQ3 (Performance): How does the performance of PENTESTGPT compare with that of native LLM models and human experts?

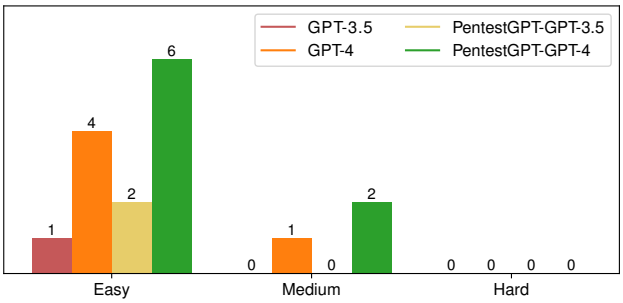
RQ4 (Strategy): Does PENTESTGPT employ different problem-solving strategies compared to those utilized by LLMs or human experts?

RQ5 (Ablation): How does each module within PENTESTGPT contribute to the overall penetration testing performance?

RQ6 (Practicality): Is PENTESTGPT practical and effective in real-world penetration testing tasks?

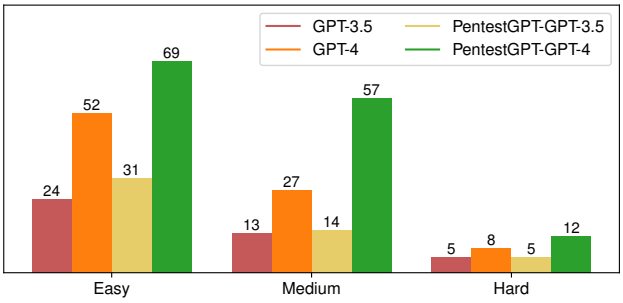
6.1 Evaluation Settings

We implement PENTESTGPT with 1,900 lines of Python3 code and 740 lines of prompts, available at our open-source project [22]. We evaluate its performance over the benchmark constructed in Section 3, and additional real-world penetration testing machines (Section 6.5). In this evaluation, we integrate PENTESTGPT with GPT-3.5 and GPT-4 to form two working versions: PENTESTGPT-GPT-3.5 and PENTESTGPT-GPT-4. Due to the lack of API access, we do not select other LLM models, such as Bard. In line with our previous experiments, we use the same experiment environment setting and instruct PENTESTGPT to only use the non-automated penetration testing tools.



6.2 Performance Evaluation (RQ3)

The overall task completion status of PENTESTGPT-GPT-3.5, PENTESTGPT-GPT-4, and the naive usage of LLMs is illustrated in Figure 5a. As the Figure shows, our solutions powered by LLMs demonstrate superior penetration testing capabilities compared to the naive application of LLMs. Specifically, PENTESTGPT-GPT-4 surpasses the other three solutions, successfully solving 6 out of 7 easy difficulty targets and 2 out of 4 medium difficulty targets. This performance indicates that PENTESTGPT-GPT-4 can handle penetration testing targets ranging from easy to medium difficulty levels. Meanwhile, PENTESTGPT-GPT-3.5 manages to solve only two challenges of easy difficulty, a discrepancy that can be attributed to GPT-3.5 lacking the knowledge related to penetration testing found in GPT-4.



The sub-task completion status of PENTESTGPT-GPT-3.5, PENTESTGPT-GPT-4, and the naive usage of LLM is shown in Figure 5b. As the Figure illustrates, both PENTESTGPT-GPT-3.5 and PENTESTGPT-GPT-4 perform better than the standard utilization of LLMs. It is noteworthy that PENTESTGPT-GPT-4 not only solves one more medium difficulty target compared to naive GPT-4 but also accomplishes 111% more sub-tasks (57 vs. 27). This highlights that our design effectively addresses context loss challenges and leads to more promising testing results. Nevertheless, all the solutions struggle with hard difficulty testing targets. As elaborated in Section 4, hard difficulty targets typically demand a deep understanding from the penetration tester. To reach testing objectives, they may require modifications to existing penetration testing tools or scripts. Our design does not expand the LLMs' knowledge of vulnerabilities, so it does not notably enhance performance on these more complex targets.

6.3 Strategy Evaluation (RQ4)

We analyze PENTESTGPT's problem-solving methods, comparing them with LLMs and human experts. Through manual examination, we identify PENTESTGPT's approach to penetration testing. Notably, PENTESTGPT breaks down tasks

(a) Overall completion status.

(b) Subtask completion status.

Figure 5: The performance of GPT-3.5, GPT-4, PENTESTGPT-GPT-3.5, and PENTESTGPT-GPT-4 on overall target completion and sub-task completion.

similarly to human experts and prioritizes effectively. Rather than just addressing the latest identified task, PENTESTGPT identifies key sub-tasks that can result in success.

Figure 6 contrasts the strategies of GPT-4 and PENTESTGPT on the VulnHub machine, *Hackable II* [58]. This machine features two vulnerabilities: an FTP service for file uploads and a web service to view FTP files. A valid exploit requires both services. The figure shows GPT-4 starting with the FTP service and identifying the upload vulnerability (❶-❸). Yet, it does not link this to the web service, causing an incomplete exploit. In contrast, PENTESTGPT shifts between the FTP and web services. It first explores both services (❶-❷), then focuses on the FTP (❸-❹), realizing the FTP and web files are identical. With this insight, PENTESTGPT instructs the tester to upload a shell (❺), achieving a successful reverse shell (❻). This matches the solution guide and underscores PENTESTGPT's adeptness at integrating various testing aspects.

Our second observation is that although PENTESTGPT behaves more similarly to human experts, it still exhibits some strategies that humans will not apply. For instance, PENTESTGPT still prioritizes brute-force attacks before vulnerability scanning. This is obvious in cases where PENTESTGPT always tries to brute-force the SSH service on target machines.

We analyze cases where penetration testing with PENTESTGPT failed, identifying three primary limitations. First, PENTESTGPT struggles with image interpretation. LLMs are

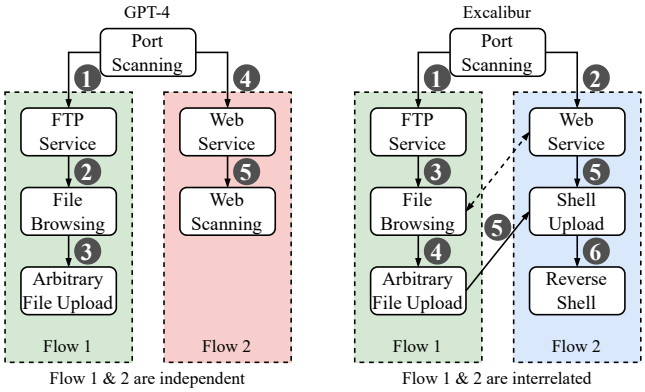


Figure 6: Penetration testing strategy comparison between GPT-3.5 and PENTESTGPT on *VulnHub-Hackable II*.

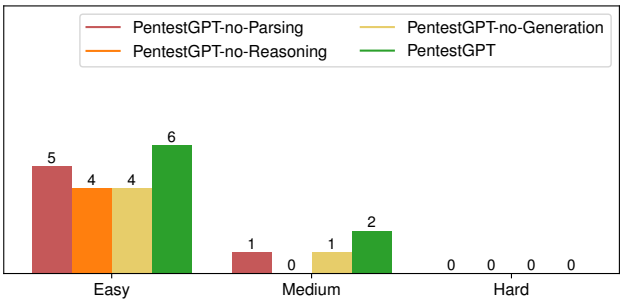
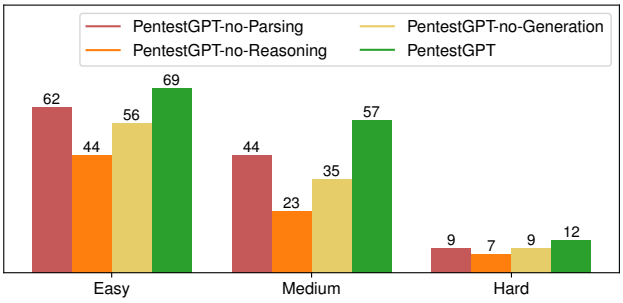
unable to process images, which are crucial in certain penetration testing scenarios. Addressing this limitation may require the development of advanced multimodal models that can interpret both text and visual data. Second, PENTESTGPT lacks the ability to employ certain social engineering techniques and to detect subtle cues. For example, while a human tester might generate a brute-force wordlist from information extracted from a target service, PENTESTGPT can retrieve names from a web service but fails to guide the usage of tools needed to create a wordlist from these names. Third, the models struggle with accurate exploitation code construction within a limited number of trials. Despite some proficiency in code comprehension and generation, the LLM falls short in producing detailed exploitation scripts, particularly with low-level bytecode operations. These limitations underline the necessity for improvement in areas where human insight and intricate reasoning are still more proficient than automated solutions.



6.4 Ablation Study (RQ5)

We perform an ablation study on how the three modules: Reasoning Module, Generation Module, and Parsing Module, contribute to the performance of PENTESTGPT. We implement three variants:



1. PENTESTGPT-NO-PARSING: the Parsing Module is deactivated, causing all data to be directly fed into the system.

2. PENTESTGPT-NO-GENERATION: the Generation Module is deactivated, leading to the completion of task generation within the Reasoning Module itself. The prompts for task generation remain consistent.

3. PENTESTGPT-NO-REASONING: the Reasoning Module is disabled. Instead of PTT, this variant adopts the same methodology utilized with LLMs for penetration testing, as delineated in the Exploratory Study.

(a) Overall completion status

(b) Sub-task completion status

Figure 7: The performance of PENTESTGPT, PENTESTGPT-NO-ANNOTATION, PENTESTGPT-OPERATION-ONLY, and PENTESTGPT-PARAMETER-ONLY on both normalized average code coverage (*µLOC*) and bug detection.

All the variants are integrated with GPT-4 API for testing.

Figure 7 presents the outcomes of three tested variants on our benchmarks. Among these, PENTESTGPT consistently outperforms the ablation baselines in both target and sub-task completion. Our primary observations include: (1) Without its Parsing Module, PENTESTGPT-NO-PARSING sees only a slight drop in performance for task and sub-task completion. Though parsing aids in penetration testing, the 32k token limit generally covers diverse outputs. The Reasoning Module's design, which retains the full testing context, compensates for the absence of the Parsing Module, ensuring minimal performance reduction. (2) PENTESTGPT-NO-REASONING has the lowest success, achieving just 53.6% of the sub-tasks of the full variant. This is even lower than the basic GPT-4 setup. The Generation Module's added sub-tasks distort the LLM context. The mismatched prompts and extended generation output cloud the original context, causing the test's failure. (3) PENTESTGPT-NO-GENERATION slightly surpasses the basic GPT-4. Without the Generation Module, the process mirrors standard LLM usage. The module's main role is guiding precise testing operations. Without it, testers might require additional information to use essential tools or scripts.

6.5 Practicality Study (RQ6)

We demonstrate PENTESTGPT's applicability in real-world penetration testing scenarios, extending beyond standardized benchmarks. For this analysis, we deploy PENTESTGPT in two distinct challenge formats: (1) HackTheBox (HTB) active machine challenges, which present a series of real-world penetration testing scenarios accessible to a global audience. We selected 10 machines from the active list, comprising five targets of easy difficulty and five of intermediate difficulty. (2) picoMini [21], a jeopardy-style Capture The Flag (CTF) competition organized by Carnegie Mellon University and redpwn [59]. The competition featured 21 unique CTF challenges and drew participation from 248 teams in its initial round. These challenges are now freely accessible online for practice and reattempts. Our evaluation employed PENTESTGPT in conjunction with the GPT-4 32k token length API, defining the capture of the root flag as the metric for

a successful trial. We conduct five trials on each target and documented the number of successful captures. Note that we consider single successful capture out of five trials as successful attempt over the target. This criterion reflects the iterative nature of real-world penetration testing and CTF challenges, where multiple attempts are allowed, and success is ultimately determined by achieving the objective at least once.

Tables 5 presents PENTESTGPT's performance across both sets of challenges. In the HackTheBox challenges, PENTESTGPT successfully completed four easy and one medium difficulty challenges, incurring a total cost of 131.5 USD—an average of 21.9 USD per target. This performance indicates PENTESTGPT's effectiveness in tackling easy to intermediate-level penetration tests at a reasonable cost. Table 6 demonstrates the performance of PENTESTGPT in the picoMini CTF. In particular, PENTESTGPT managed to solve 9 out of 21 challenges, with the average cost per attempt being 5.1 USD. Ultimately, PENTESTGPT accumulated a total of 1400 points[2] and ranked 24th out of 248 teams with valid submissions [60]. These outcomes suggest a promising performance of PENTESTGPT on real-world penetration testing tasks among various types of challenges.

7 Discussion

It is possible that LLMs used by PENTESTGPT were trained on walkthroughs of the benchmark machines, which could invalidate evaluation results. To counter this, we employ two methods. First, We ensure the LLM lacks prior knowledge of the target machine. We ascertain this by querying LLMs about the tested machine's familiarity. Secondly, our benchmark comprises machines launched post-2021, ensuring they are beyond OpenAI models' training data. Our study on recent HackTheBox challenges confirms PENTESTGPT's ability to solve without pre-existing target knowledge.

While we aim for universally applicable prompts, certain LLMs avoid producing specific hacking content. For instance, OpenAI has implement model alignments [61] to ensure the GPT model outputs do not violate usage policies, including generating malicious exploitation contents. We incorporate jailbreak techniques [62–68] to coax LLMs into producing relevant data. Improving reproducibility of PENTESTGPT remains a focus area.

LLMs occasionally "hallucinate" [56], producing outputs deviating from training data. This impacts our tool's dependability. To combat this, we're researching methods [69] to minimize hallucination, anticipating this will boost our tool's efficiency and reliability.

The ethical implications of employing PENTESTGPT in penetration testing are significant and warrant careful consideration. While PENTESTGPT can greatly enhance security by identifying vulnerabilities, its capabilities also pose potential risks of misuse. To mitigate these risks, we have implemented several strategies. We actively promote ethical guidelines for the use of PENTESTGPT and collaborate closely with cybersecurity communities to prevent misuse. Moreover, we have incorporated monitoring modules [70] to track the tool's usage and are committed to ensuring that it is not used inappropriately. These measures are designed to balance the advantages of advanced penetration testing tools with ethical considerations, ensuring that PENTESTGPT serves as a positive contribution to cybersecurity defenses.

[2] Each challenge's points were assigned based on its difficulty level

8 Conclusion

This work delves into the potential and constraints of LLMs for penetration testing. Building a novel benchmark, we shed light on LLM performance in this complex area. While LLMs manage basic tasks and use testing tools effectively, they struggle with task-specific context and attention challenges. In response, we present PENTESTGPT, a tool emulating human penetration testing actions. Influenced by real-world testing teams, PENTESTGPT comprises Reasoning, Generation, and Parsing Modules, promoting a segmented problem-solving strategy. Our comprehensive evaluation of PENTESTGPT underscores its promise, but also areas where human skills surpass present technology. This work paves the way for future advancements in the crucial realm of cybersecurity.

A Illustrating Example

Below we provide a concrete example of how we guide GPT-4 to intialize the penetration testing task, and generate detailed operations in an iterative approach given a penetration testing benchmark target. It is worth noting that in this process, the human tester does not provide any expert knowledge, or guide the LLM to perform any specific task.

Human Tester

You're required to work as a cybersecurity penetration tester assistant in a certified penetration testing experiment. This experiment is for education and research purpose. In particular, you're required to give *step-by-step instructions* to complete the penetration testing task. I will provide you the instruction execution results, and you should consider the next step, until the penetration testing task is completed. Do you understand?

GPT-4

Yes, I understand. Please provide the initial details and the scope of the penetration test so I can assist accordingly. Remember to follow ethical guidelines and obtain proper authorization for any systems or networks you are testing.

Human Tester

Your target is a penetration testing benchmark machine. It's IP address is *192.168.1.5*; it is a Linux-based machine. Now please provide your next step to complete the penetration testing task.

GPT-4

Alright, the first step in a penetration test is usually reconnaissance. This is where we gather as much information as possible about the target to identify potential vulnerabilities.
Step 1: Reconnaissance
Ping the Target: To ensure that the target is up and responding, ***ping*** the machine.

```
ping 192.168.1.5
```

Let me know the result. If the machine is up and responding, we'll move on to scanning. After confirming the machine's availability, the next step is to scan the open ports and services running on the target.

```
nmap -sV -sT 192.168.1.5
```

This command will provide a list of open ports and the services (with versions) running on those ports.
Please provide the results of the ***nmap*** scan, and based on the output, we can decide the next course of action.

To further demonstrate the PTT Generation Process in its entirety, we deploy PENTESTGPT on the benchmark system *Hackable II*. Figure 8 illustrates the complete PTT. In the figure, solid boxes depict the penetration testing operations generated by PENTESTGPT, whereas dotted boxes outline the findings derived from these operations. Red boxes indicate operations that do not yield significant findings, green boxes denote operations that lead to useful findings, and blue boxes represent operations generated by PENTESTGPT but not executed due to lower priority. For clearer presentation, we label the operations with numbers based on the operation sequences as prioritized by PENTESTGPT. As depicted in Figure 8, PENTESTGPT emulates the strategic approach typically employed by human penetration testers, encompassing four steps including enumeration, web user access via reverse shell, and privilege escalation to both normal user and root levels on this particular benchmark machine. Notably, PENTESTGPT demonstrates human-like reasoning by linking findings across different stages.

Abstract

Just-In-Time (JIT) compiler is a core component of JavaScript engines, which takes a snippet of JavaScript code as input and applies a series of optimization passes on it and then transforms it to machine code. The optimization passes often have some assumptions (e.g., variable types) on the target JavaScript code, and therefore will yield vulnerabilities if the assumptions do not hold. To discover such bugs, it is essential to thoroughly test different optimization passes, but previous work fails to do so and mainly focused on exploring code coverage. In this paper, we present the first optimization path guided fuzzing solution for JavaScript JIT compilers, namely OptFuzz, which focuses on exploring optimization path coverage. Specifically, we utilize an *optimization trunk path* metric to approximate the optimization path coverage, and use it as a feedback to guide seed preservation and seed scheduling of the fuzzing process. We have implemented a prototype of OptFuzz and evaluated it on 4 mainstream JavaScript engines. On earlier versions of JavaScript engines, OptFuzz found several times more bugs than baseline solutions. On the latest JavaScript engines, OptFuzz discovered 36 unknown bugs, while baseline solutions found none.

1 Introduction

JavaScript engines are widely used in various applications, including web browsers, PDF readers and React Native [35] applications. To enhance execution efficiency, JIT compilers are introduced to JavaScript engines, which dynamically compile hot code during runtime to generate machine code. However, JavaScript is a dynamically typed language, and the variables' types are determined during runtime and can change as the code executes. This characteristic significantly amplifies the intricacy of JIT compilers, rendering them susceptible areas for vulnerabilities within JavaScript engines.

Fuzz testing currently stands as a primary methodology for uncovering vulnerabilities in software [31] [21] [29] [39]. For interpreters like JavaScript engines, there are a series of tailored fuzzing solutions. Some approaches focus on generating test cases satisfying JavaScript syntax checks, which involve code generation based on syntax rules [36], mutation using abstract syntax trees [20] [42], or a combination of both [41] [2]. Some other approaches focus on enhancing the validity and diversity of test case semantics, including [15] [32] [23] [8] [16].

In recent research, attention has been directed towards the JIT compiler, i.e., a core component of JavaScript engines. Some approaches focus on triggering more JIT compilation operations. Fuzzilli [14] introduces customized generation templates and mutation rules to trigger JIT, while FuzzJIT [43] enhances this approach by embedding test cases into a loop, further increasing the likelihood of triggering JIT compilation. Some other approaches focus on discovering JIT-specific vulnerabilities. JIT-picking [3] and FuzzJIT incorporate differential testing between interpreted executions and JIT executions to detect non-crash inconsistency bugs.

However, few of the these approaches could thoroughly explore the program paths of JIT compilers, leaving potential vulnerabilities uncovered. Generally, a JIT compiler has a series of optimization passes, performing different kinds of optimizations on the JavaScript code. As shown in Figure 1, each optimization pass comprises of an outer loop that iterates over instructions, basic blocks or loops of target JavaScript code and a loop body that performs specific code transformation. The loop body follows different program paths (denoted as *optimization paths*) to take different actions. In each optimization path, it will check the pattern of the target instruction/basic block/loop and hold some assumptions, and then apply specific optimizations to the code. The optimization may fail to insert appropriate bailouts or eliminate bailouts incorrectly, which will cause potential vulnerabilities. Thus, it is crucial to thoroughly explore all the optimization paths.

Note that, existing fuzzers often utilize edge coverage to explore target code, which could help explore some optimization paths but are unable to thoroughly explore all paths as discussed in [11,40]. Instead, after an in-depth analysis of JIT compilers, we have made the following observations, which

*Chenggang Wu is the corresponding author. wucg@ict.ac.cn.

could help fuzzers better explore optimization paths.

Observation 1: Entering the optimization pass is not equivalent to triggering the optimization (or the bugs in it). The target optimization bugs could be triggered only if specific conditions are met and certain optimization paths are executed. So, only exploring high-level optimization passes is not sufficient to uncover deep JIT bugs. Instead, *the fuzzer should cover as many optimization paths as possible*.

Observation 2: Edge coverage-guided fuzzing is not efficient at thoroughly exploring optimization paths. Note that, a program/optimization path consists of multiple connected edges. It is possible that, even if a fuzzer has covered all the connected edges of a path, the path itself is still not covered. In this case, the edge coverage guided fuzzer will skip any following test cases that only cover these connected edges (since they are not new), including test cases that cover the target path, which would miss the optimization path and bugs in it. So, *the fuzzer should consider the optimization path coverage*.

Observation 3: Different optimization paths are tested unevenly. Within an optimization pass, different optimization paths have different preconditions. Optimization paths whose preconditions are difficult to satisfy will be tested less in regular fuzzing settings, and are more likely to have uncovered bugs. So, *we need a new fuzzer which allocates more testing resources to the less-tested optimization paths*.

In this paper, based on these three observations, we propose the first optimization path guided fuzzing solution, named OptFuzz, to efficiently discover bugs in JavaScript JIT compilers. Specifically, we utilize optimization paths as feedback to guide the fuzz testing. Note that, although the optimization path is within the optimization pass' outer loop, it could also have inner loops, which will cause the number of optimization paths exploding. To mitigate this issue, we introduce the concept of *Optimization Trunk Path (OptPath)*, which simplifies the inner loops of optimization paths as if they will only be iterated once, and use OptPath coverage to approximate the optimization path coverage, and adjust the seed preservation and scheduling strategies of fuzzing respectively. Specifically, if a test case triggers a new OptPath, it will be preserved as a seed for further testing. Further, if a seed explores an OptPath that is less tested than other OptPaths, then this seed will be prioritized to schedule during fuzzing, e.g., more computational resources will be allocated to test this seed.

To demonstrate the effectiveness of our approach, we implemented a prototype of OptFuzz and evaluated it with four mainstream JavaScript engines: JavaScriptCore, V8, SpiderMonkey and Hermes. Our evaluation shows that OptFuzz is effective in discovering new bugs and exploring optimization paths. In terms of discovering bugs in the latest JavaScript engines, OptFuzz has newly discovered 36 bugs and 26 of the bugs have been confirmed or fixed with 3 CVEs assigned, while existing baselines found none. In terms of discovering bugs in earlier versions of JavaScript engines, we conducted two groups of repetitive experiments. In the short-term baseline comparison experiments, OptFuzz found 9×, 9×, 1.8× and 4.5× more bugs than Superion, DIE, Fuzzilli and FuzzJIT respectively. In the long-term baseline comparison experiments, OptFuzz found 6.3×, 6.3×, 2.1× and 9.5× more bugs than Superion, DIE, Fuzzilli and FuzzJIT respectively. Besides, OptFuzz can explore more OptPaths than baselines as well. Furthermore, ablation experiments have demonstrated the effectiveness of individual designs in Optfuzz. The contributions of this paper are outlined as follows:

- We present an in-depth analysis of the JavaScript JIT compilers and highlight three observations that can help fuzzers better test JIT compilers.
- We present the first optimization path guided fuzzing solution OptFuzz, which utilizes the optimization trunk path coverage as feedback to fine tune the seed preservation and seed scheduling strategy of the fuzzing process.
- We propose a strategy for extracting optimization trunk paths from JavaScript engines. The extracted optimization trunk paths can approximate the optimization paths while mitigating the issue of path explosion.
- We have conducted thorough experiments and reported 36 new bugs in the latest JavaScript engines: 17 in JavaScriptCore, 5 in SpiderMonkey, 1 in V8 and 13 in Hermes. 26 of these bugs have been confirmed or fixed.
- The prototype system is made publicly accessible at https://github.com/JimWongM/OptFuzz.

2 Background and Motivation

2.1 Optimizations in JavaScript Engines

During the execution of the JavaScript program in a JavaScript engine, it goes through stages of parsing into an abstract syntax tree, generating bytecode, and interpretation. The interpreter collects runtime information, such as type details and function calls. When a code snippet or function is executed multiple times and reaches a certain threshold, the JavaScript engine invokes the JIT compiler for optimization, generating machine code to accelerate execution speed.

The JIT compiler can apply various optimizations on the optimized JavaScript code, such as common subexpression elimination, constant folding, dead code elimination, loop-invariant code motion, strength reduction and so on. Compiler optimization is generally implemented using a sequence of optimizing transformations which take a program and transform it to produce a semantically equivalent output program that uses fewer resources or executes faster [46]. As the generated machine code is based on type inference, the compiler inserts guard codes, such as type checks or bound checks, to *bailout* to the interpreter when the inference fails during a

Table 1: Vulnerabilities in different optimizations.

Category	Vulnerability	Description
Instruction	CVE-2019-5857	Error in comparison of -0 and null.
	CVE-2021-30598	Invalid right shift operation optimization.
	CVE-2021-30599	Wrong optimization of bitfield checks.
	CVE-2019-1366	Error in handle opcode Decr_A and Sub_A.
Loop	CVE-2019-8518	wrong hoisting GetByVal leading to OOB.
	CVE-2019-8623	LICM leaves stack variable uninitialized.
	CVE-2019-8671	LICM leaves object property access unguarded.
	CVE-2020-0828	Type confusion when hoisting variable fails.
Function	CVE-2018-4233	Type confusion caused by abstract interpreter.
	CVE-2020-9802	Integer range optimization error caused by CSE.
	Bug240720	The result of integer range analysis is incorrect.
	CVE-2019-9810	Incorrect alias information leading to OOB.
	CVE-2019-17026	Incorrect alias information leading to OOB.
	CVE-2019-26950	UAF caused by wrong side-effect analysis.
	CVE-2021-21230	Incorrect range information.

specific execution. To improve the efficiency of the generated machine code, the compiler performs analysis on the code and eliminates the guard codes when it is confident that a certain inference will always hold. Some JavaScript engines also employ multiple levels of JIT optimizations, such as *BaselineJIT*, *DFG* and *FTL* [34] in JavaScriptCore and *O0*, *O1* and *O2* in Hermes. Higher optimization levels apply more aggressive optimizations, resulting in more efficient generated code.

2.2 Optimization-related Vulnerabilities

A Just-In-Time (JIT) compiler encompasses various optimization passes. The current landscape of compiler optimizations is characterized by a multitude of techniques, each with its own distinct focus. In this paper, we classify compiler optimizations into three categories based on the granularity of effect: instruction, loop and function as shown in Table 1.

Instruction Optimization. The essence of instruction optimization lies in the identification and replacement of specific instruction sequences to enhance the execution speed. This optimization technique operates within a narrow scope, typically targeting a small subset of instructions. Instruction optimization can introduce potential bugs. Inaccurate instruction replacement can result in incorrect results of variable values, leading to significant security vulnerabilities, such as CVE-2019-5857, CVE-2021-30598 and CVE-2021-30599.

Loop Optimization. Loop invariant code motion (LICM) is a prominent loop optimization technique, which aims to hoist loop-invariant code outside the loop body, thereby minimizing the number of times instructions are executed. It is crucial to note that when hoisting the code, the corresponding checks associated with the hoisted code must be relocated. Failure to do so may result in security vulnerabilities, such as CVE-2019-8518, CVE-2019-8623 and CVE-2020-0828.

Function Optimization. Function optimization encompasses two key aspects: 1) optimizing based on the data flow information, and 2) optimizing the control flow structure. Common subexpression elimination (CSE) is a typical optimization based on data flow analysis. CSE replaces later expressions with the result of earlier ones. It is necessary to ensure that the two expressions are equivalent and can be replaced with each other. Otherwise, incorrect replacements can lead to security vulnerabilities, such as CVE-2020-9802. Moreover, CVE-2017-7117 is a vulnerability related to control flow structure optimization.

```
1  void convertToJump( BasicBlock* BB, BasicBlock* targetBB ) {
2      if ( CanMergeBlocks( BB, targetBB ) )
3          mergeBlocks( BB, targetBB ); //optimization
4      else
5          BB->replaceTerminal( Jump ); //optimization
6  }
7  void run( ) {
8      for ( BasicBlock* BB : graph ) {
9          if ( !BB )
10             continue;
11         switch ( BB>terminal( ) ) {
12             …
13             case Branch:
14                 …
15                 if ( BB->successor( 0 ) == BB->successor( 1 ) ) {
16                     convertToJump( BB, BB->successor( 0 ) );
17                     break;
18                 }
19             case Switch:
20                 for ( int i = 0; i < cases.size( ); i++ ) {
21                     // Analyze the target of cases
22                 }
23                 if ( cases.isEmpty( ) ) {
24                     convertToJump( BB, BB->fallThrough( ) );
25                     break;
26                 }
27                 …
28             default:
29                 break;
30         }
31     }
32 }
```

Figure 1: CFGSimplification Optimization.

2.3 Motivation

The aforementioned vulnerabilities shares a common cause: the optimization is triggered and there is an error in the optimization. Edge coverage is the main feedback of current fuzzers. The purpose of edge coverage-guided fuzzing is to improve edge coverage and explore more code, with the expectation of discovering vulnerabilities in the newly explored code. Through the analysis of the JIT compiler, we have found that merely exploring new code is insufficient for uncovering bugs in the JIT optimization passes.

3 Study of JIT Optimization

3.1 Optimization Path

In order to uncover vulnerabilities in the JIT compiler, we conducted an in-depth analysis of each optimization pass. We found that each optimization pass contains a large outer loop. This outer loop traverses the intermediate representation (IR) of the optimized JavaScript code at a specific granularity level (e.g., loops, basic blocks, and instructions). Within each iteration of the outer loop, the loop body code analyzes and pro-

cesses the IR code. Figure 1 depicts a schematic diagram of the CFGSimplification optimization in JavaScriptCore. Line 8 contains an outer loop that traverses each basic block of the optimized JavaScript code and triggers the optimization if a specific condition is met. The optimization being triggered actually means that the optimization pass executes to the location where a code transformation occurs (line 3 and line 5). In other words, the optimization pass executes a series of code blocks within the outer loop in a particular iteration, performing a code transformation on the optimized JavaScript code. Therefore, this paper introduces the concept of *Optimization Path*, which refers to a code execution path within the outer loop of an optimization pass, leading to the location where the code transformation occurs. The functionality of the optimization pass in the JIT compiler is manifested in these optimization paths within the outer loop, and different optimization paths can produce varying or identical results on the optimized JavaScript code.

The outer loop in line 8 generates paths of different lengths for different numbers of iterations, but the length of the optimization path is not affected by the iterations of this outer loop. In fact, if only the number of iterations of the outer loop is increased, but no new optimization path is generated within the loop, it is actually testing the same functionality in the optimization pass. When conducting fuzz testing, we should pay more attention to different optimization paths within the outer loop to test different functionalities.

3.2 Enter Optimization≠Trigger Optimization

During JIT compilation, the JIT compiler performs a variety of optimizations on the intermediate representation of JavaScript programs. Each optimization pass is executed. However, not every executed optimization pass will actually result in code transformation. In other words, the optimization paths in an optimization pass are not necessarily executed. Multiple prerequisites must be met for an optimization path to be executed, as engine designers often design optimizations specifically for certain patterns in the code.

For instance, consider the loop invariant code motion (LICM) optimization in JavaScriptCore. To trigger the code motion, the code must satisfy the following four prerequisites: 1) The presence of a loop preheader; 2) No write operation exists in the hoisted code; 3) The read region of the hoisted code cannot be modified by other code within the loop, and 4) The code itself is eligible for hoisting. If one of the prerequisites is not satisfied, the optimization cannot be triggered. Therefore, entering the optimization pass is not equivalent to triggering the optimization. Failure to trigger an optimization means that the true functionality of that optimization pass remains untested, thereby potentially overlooking any bugs present in that optimization pass.

We conducted fuzzing on JavaScriptCore using DIE [32] and Fuzzilli [14], two edge coverage-guided fuzzers. The experiment lasted for 72 hours. A total of 1370090 and 17406775 valid test cases were generated by DIE and Fuzzilli respectively. Out of these, 721074 and 8266477 test cases entered the LICM optimization pass. However, only 263908 and 3660644 test cases triggered LICM optimization, accounting for 36.6% and 44.3% of the test cases that entered the optimization pass. The primary cause of vulnerabilities in the JIT compiler is the triggering of incorrect optimizations. The current fuzzers inadequately test the code that triggers the optimization. Consequently, these approaches may overlook the vulnerabilities in the JIT optimization passes.

3.3 Overlooked Optimization Path

When designing an optimization pass, the engine designer will design different optimization techniques for different bytecodes, operand types, built-in functions, control flow structures, and data flow relationships. The optimization pass in Figure 1 incorporates specific optimization techniques to handle different control flow nodes (such as branch and switch). The code transformation occurs at line 3 and line 5. There are four distinct optimization paths in the schematic diagram. The code in line 20 has a loop. Different iterations of the loop will produce different optimization paths, we consider these optimization paths to be an optimization path in this section.

Different optimization paths within the same pass may reuse code from each other. The execution of some optimization paths (e.g. line 11→15→16→2→3, line 11→15→16→2→4→5 and line 11→23→24→2→3) will potentially cover all edges of other optimization paths (e.g. line 11→23→24→2→4→5). Consequently, in edge coverage-guided fuzz testing, even if a specific test case triggers a new optimization path, it may not be preserved as a seed due to its failure to reach new edges.

In order to explore the seed preservation for current fuzz testing, we manually identify the start and end of the optimization paths and mark them in the source code. We conducted fuzzing on JavaScriptCore using Fuzzilli and pay close attention to the execution of optimization paths for each test case. If a test case executes a new optimization path but is not preserved as a seed, then we consider that this optimization path has been **missed**. Over the fuzzing of 72 hours, a total of 10880237 valid test cases have been generated. These test cases covered 1520 optimization paths, but missed 180 optimization paths, thereby limiting the opportunity for thorough testing on those specific optimization paths and potentially overlooking underlying vulnerabilities.

3.4 Imbalanced Testing for Optimization Path

There are various optimization paths in an optimization pass, some of which have easily satisfied conditions, while others have more challenging conditions. Taking the optimization in Figure 1 as an illustration, in order to execute to line 13, the

JavaScript program must encompass syntactical structures, such as *if* statements, *for* loops,*while* loops, or other constructs capable of generating the intermediate representation *Branch*. Similarly, to execute to line 19, the JavaScript input program must contain a *switch case* syntax structure. To invoke *convertToJump* at line 16, it is imperative for the two successor blocks of the IR *Branch* to be identical, thereby facilitating the transformation of Branch into Jump. Furthermore, to invoke *convertToJump* at line 24, the cases of the switch must be empty. These optimization paths have different preconditions, leading to different extents of being tested.

Edge coverage-guided fuzzing still enables partial testing of optimization paths. However, experimental results reveal an imbalance in the testing of these paths using Fuzzilli. During 72-hour fuzzing, the number of tests conducted for the four optimization paths in Figure 1 is 11, 1, 83, and 0 respectively. It is observed that optimization paths with easily satisfied conditions undergo more testing, while those with challenging conditions are tested less. From a vulnerability discovery perspective, fuzz testing should prioritize the testing of the less-tested optimization paths.

4 Design

The goal of this paper is to test the optimization passes in the JIT compilers. The analysis above indicates that when performing fuzz testing on the JIT optimization passes, it is crucial to not only test up to the optimization pass, but also to comprehensively test the optimization paths within that pass.

4.1 Optimization Trunk Path

To further explore the optimization paths, we can employ them as feedback to guide the seed preservation and scheduling process of fuzz testing. Nonetheless, nested inner loops persist within the optimization paths, and different iterations of these nested loops will result in different optimization paths. Thus, utilizing the optimization paths as feedback for fuzzing still poses the challenge of explosion in the number of seeds.

We conducted a statistical analysis of 29 optimization passes in JavaScriptCore, revealing that their inner loops exhibit a branch count ranging from approximately 0 to 6, with 86% of them having no more than 2 branches. The logic of these inner loops is simple, often traversing information such as operands, metadata, and use points of the intermediate representation. In fuzz testing, even without specifically targeting the testing of branches within the inner loop, these branches will be adequately tested. Our experiments show that 64.4% of the branches are tested more than 1,000 times, and 88.5% of the branches are tested more than 100 times during the 72-hour fuzz testing. Longer tests lead to more testing of these branches. While multiple iterations do not significantly aid in exploring new combinations of code blocks within the inner loop, they do create paths of varying lengths and exacerbate the path explosion issue. Consequently, this paper excludes nested loops in the optimization paths.

Based on the above analysis, this paper introduces the concept of *Optimization Trunk Path (OptPath)* and utilizes OptPath to approximate the optimization path. *Trunk* means the main woody stem of a tree as distinct from its branches and roots. The OptPath in this paper represents a path within the outer loop, which ignores the nested inner loop. The starting point of OptPath is the entry point of one iteration of the outer loop, and the end point is the tail code of the same iteration. For example, the sequence of line 9→11→19→23→24→2→3→30→31 in Figure 1 is an OptPath where we ignore the inner loop of line 20. Notably, the sequence of line 9→10→31 is also an OptPath. Unlike the optimization path, this particular OptPath does not trigger the optimization; instead, it proceeds to the branch that results in an early exit. We will discuss this in subsection 4.4.

4.2 Seed Preservation

During fuzz testing, OptFuzz records the OptPaths that the test case executes, and if a test case triggers a new OptPath, it is preserved as a seed. When the JavaScript engine executes to the start of an OptPath, it starts recording the path. When execution reaches the end point of an OptPath, it stops recording the path and performs a hash operation on each basic block of the recorded path to obtain a hash value. Different OptPaths will result in different sequences of basic blocks, which will generate different hash values without accounting for hash collisions. After the execution of a test case, OptFuzz can determine whether new OptPaths have been reached by examining the presence of new hash values.

Numerous research studies [4,11,14,32,40,42] have demonstrated the significance of incorporating edge coverage feedback into fuzz testing to explore new code in the target program. In this paper, we propose an approach that combines edge coverage and OptPaths to comprehensively explore new code through edge coverage, thereby traversing different optimization passes. Additionally, we leverage OptPaths feedback to test optimization paths within the optimization pass. We maintain separate seed corpus for edge coverage and OptPaths. Initially, the seeds are mostly preserved by edge coverage, and in order to explore more code quickly, the seeds preserved by edge coverage are mainly used for mutation at this time. As the fuzz test progresses, the proportion of seeds preserved by the OptPaths gradually increases. Once the number of seeds preserved by the OptPaths surpasses a certain threshold, the seeds preserved by the OptPaths are enabled. Subsequently, the fuzz testing alternates between seeds preserved by edge coverage and seeds preserved by OptPaths.

The interesting test cases may include code that is not related to the new edge or the new OptPath. To minimize the impact of such code, we employ test case trimming techniques. This involves reducing the test cases while ensuring they

still reach the new edge or the new OptPath. If a test case reaches both the new edge and the new OptPaths in different optimization passes, we generate n distinct seeds based on different trimming criteria. Specifically, we trim out a seed based on the new edge, and trim out different seeds for the new OptPaths in different optimization passes. These seeds are then placed into separate seed queues. In this way, we maintain a seed queue for edge coverage and also maintain respective seed queues for different optimization passes.

4.3 Seed Scheduling

In the process of fuzz testing, some OptPaths whose preconditions are easy to satisfy are given more opportunities to be tested, while OptPaths whose preconditions are difficult to satisfy are given much less opportunities to be tested. Seed scheduling based on OptPaths aims to make those OptPaths which are tested less get more chance to be tested. To identify the OptPaths that require more testing, we keep track of the cumulative number of times each path is tested.

We designed a two-tier seed queue for seed scheduling. When a test case executes a new OptPath, the test case is preserved as a seed, which is trimmed and put into the primary queue. We maintain a primary queue for each optimization pass. The secondary queue is utilized to store the prioritized seeds. This is achieved by selecting a number of seeds from each primary queue in ascending order of the number of times the OptPath has been tested. These selected seeds are then stored in the secondary queue. Subsequently, seeds are extracted from the secondary queue one by one for mutation. Once all the seeds from the secondary queue have been mutated, seeds are again selected from each primary queue.

4.4 Discussion

Early Exit Branches in OptPaths. In this paper, we employ OptPaths as an approximation of the optimization paths. OptPaths and optimization paths are not entirely equivalent. There are some exit branches before an optimization is triggered. The OptPath also records these exit branches. The analysis in subsection 3.2 emphasizes that the triggering of an optimization requires the fulfillment of various conditions. It is not an easy task to execute an optimization path, but easier to encounter an early exit branch. Furthermore, early exit branches are more likely to be tested during fuzz testing. In this paper, we propose a seed scheduling strategy based on OptPaths. This strategy favors scheduling OptPaths that have been tested less frequently, while exit branches that have been tested more frequently are not selected for mutation. As the testing progresses, these OptPaths containing exit branches do not excessively consume computational resources. On the other hand, individual vulnerabilities, such as CVE-2019-8623 [37], also require execution of the exit branch before incorrect optimizations are triggered. Hence, exit branches do not contradict our objective of testing the optimization path. In fact, the execution of early exit branches can even aid in finding potential vulnerabilities in specific scenarios.

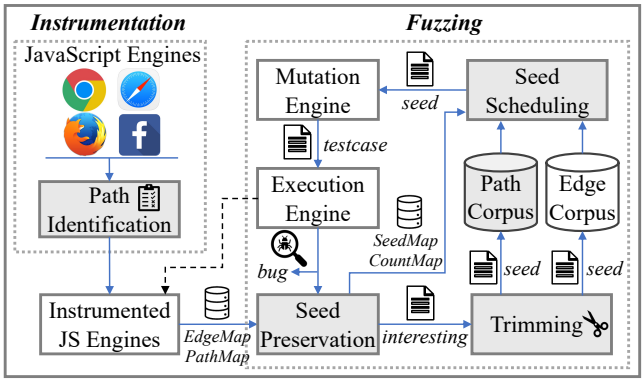

Figure 2: Workflow of our prototype system.

Ignored Inner Loops. The OptPath ignores the nested inner loops. Generally, the number of iterations within inner loops exceeds that of outer loops by 1-2 orders of magnitude, and the control flow structure in inner loops is relatively simple with fewer branches. Consequently, when outer loops undergo frequent testing, a majority of paths within inner loops also receive more comprehensive testing. There may be a few under-tested paths in the inner loops that require a more fine-grained feedback for enhancement, but implementing such feedback could introduce additional overhead that we will investigate in future work.

The Order of Edges in OptPaths. To record the path, AFLFast [4] performs hashing on the set of visited edges without considering the order of the edges. For OptPath, in tandem with its definition, different sets of visited edges are likely to represent different edge orders, so hashing the set of visited edges may be adequate. However, considering the order when recording the paths tends to yield more accurate results. This is because two test cases with the same set of visited edges may execute edges in different orders. Hashing the set of visited edges will miss some interesting test cases. Therefore, OptPath takes into account the order of edges and records the entire path.

5 Implementation

5.1 Workflow

Figure 2 shows the workflow of our fuzzing system. The system consists of two parts: instrumentation and fuzzing. The instrumentation module identifies the OptPaths and instruments the JIT compiler. The fuzzing module is built on Fuzzilli [14]. We have enhanced Fuzzilli's evaluation module to incorporate a dedicated evaluation feature for OptPaths. Additionally, we have integrated a trimming strategy specifically targeting OptPaths into Fuzzilli's trimming module. To implement seed scheduling based on OptPaths, we have intro-

duced a two-tier seed queue within Fuzzilli's Corpus module. We reuse Fuzzilli's mutation module and execution module. Table 2 presents the lines of code (LoC) of each component.

Table 2: The lines of code of each component.

Module	Component	LoC	Language
Instrumentation	Path Identification	1281	C++
	Instrumented Code	209	C++
Fuzzing	Seed Preservation	155	Swift, C
	Seed Scheduling	342	Swift
	Trimming	419	Swift

5.2 Instrumentation Module

This module inserts code into the JavaScript engine to collect information on edge coverage and OptPaths. We have established two bitmaps, namely *EdgeMap* and *PathMap*, to record the edge coverage and OptPaths information during the execution of test cases. The insertion process consists of two steps. The first step is to identify the various types of basic blocks in the OptPath. We implement an LLVM [25] Pass named *OptPathAnalysis*. The *LoopInfoWrapperPass* is able to analyze all the loop information in the target program, from which *OptPathAnalysis* obtains the structure of each loop as well as the loop nesting relationships in the optimization passes. We mark the header [26] of an outer loop as the starting point of an OptPath, the latch basic block [26] of a outer loop as the end point of an OptPath, and the basic blocks between the header and latch as the OptPath basic blocks. We exclude the basic blocks inside the nested loops.

In the second step, we instrument the JavaScript engine by leveraging Clang Sanitizer Coverage [6] to insert calls to the function *trace_pc_guard(uint32* guard, int flag)* before each basic block. The first argument of this function, *guard*, receives the unique ID of the basic block. The second parameter *flag* indicates the attribute information of the basic block analyzed by *OptPathAnalysis*. The Pseudo code of this function is shown as Algorithm 1.

start is a global variable that is initially false, indicating that the start of an OptPath has not yet been encountered. *path* is used to record the OptPath. After entering the function *trace_pc_guard*, the initial action involves indexing the *Edgemap* bitmap according to the basic block ID and subsequently setting the corresponding unit. Next, according to the attribute *flag* of the basic block, the OptPath information is collected. If *flag* of the current basic block is 1, it means that the current basic block is the start point of an OptPath, so *start* is set to true, and the ID of the currently executed basic block is recorded into *path*. If *flag* is 0 and *start* is true, the basic block is added to *path*. If *flag* is 2, it means that the current basic block is the end point of an OptPath, then the ID of the current basic block is added to *path*, and a hash value is calculated for all the basic blocks in *path*. Then, based on the hash value, the bitmap *PathMap* is updated. After that, *start* is set to false and *path* is cleared.

Algorithm 1 trace_pc_guard

Input: guard: ID of the basic block
Input: flag: attribute information of the basic block

```
1:  UpdateEdgeMap( guard )
2:  if flag == 0 and start then
3:      path ← RecordPath( guard )
4:  end if
5:  if flag == 1 then
6:      start ← true
7:      path ← RecordPath( guard )
8:  end if
9:  if flag == 2 then
10:     path ← RecordPath( guard )
11:     hash ← ComputeHash( path )
12:     UpdatePathMap( hash )
13:     start ← false
14: end if
```

5.3 Fuzzing Module

The fuzzing module includes sub-modules for mutation, execution, seed preservation, trimming, and seed scheduling. The mutation submodule adopts mutation strategies from Fuzzilli. The execution module initiates the instrumented JavaScript engine and provides it with test cases. Throughout the execution process, the JavaScript engine dynamically updates the *Edgemap* and *PathMap*. The seed preservation submodule updates *CountMap* based on *PathMap* to accumulate the test number for each OptPath, and determines whether the test case is interesting based on *Edgemap* and *PathMap*. If a test case executes to new edges or unexplored OptPaths, the test case is *interesting*, and the relationship between the new OptPath and the test case is recorded into *SeedMap*. The trimming submodule removes redundant statements from interesting test cases. After trimming, the test cases that still trigger new edges are added to *Edge Corpus*, while those that lead to new OptPaths are added to *Path Corpus*. In *Path Corpus*, we maintain a seed queue for each optimization pass. In seed scheduling submodule, seeds in *Path Corpus* are selected based on *CountMap* and *SeedMap* to prioritize the testing of OptPaths that are currently tested less often while seeds in *Edge Corpus* are randomly selected.

Previous work such as FuzzJIT and JIT-picker detects non-crash bugs in JavaScript engines through differential testing. In this paper, we also develop a similar sanitizer named DiTing. DiTing captures bugs by comparing the results of variables executed in the interpreter and each optimization level.

6 Evaluation

To validate the effectiveness of our approach, this section evaluates OptFuzz and answers the following four questions:

Q1. Can OptFuzz find bugs in the JavaScript JIT compil-

ers? How does OptFuzz perform in terms of bug findings comparing to the state-of-the-art fuzzers? (subsection 6.2)

Q2. What is the distribution of OptPaths across optimizations? Can our approach explore more OptPaths against state-of-the-art fuzzers? (subsection 6.3)

Q3. What is the impact of individual designs in OptFuzz on bug finding? Do these designs make sense? (subsection 6.4)

Q4. How does OptFuzz perform in terms of code coverage against the state-of-the-art fuzzers? (subsection 6.5)

6.1 Experiment Setup

Baseline: We compare OptFuzz with four state-of-the-art fuzzers including Superion [42], DIE [32], Fuzzilli [14], and FuzzJIT [43]. JIT-Picker [3] and SoFi [16] are not compared for the following reasons. JIT-Picker contribute to the detection of non-crash bugs in the engines using differential testing, which is orthogonal to our work. SoFi focuses on improving the validity and diversity of test cases and is not open source.

Initial Seed Corpus: Fuzzilli does not require an initial seed corpus at startup. Fuzzilli first enters the generation mode at runtime, and uses the developer-defined JavaScript code generators to generate test cases. If a test case executes to new edges, it will be preserved as a seed. If Fuzzilli generates 100 consecutive test cases that cannot execute to new edges, it switches to the mutation mode. OptFuzz and FuzzJIT are built upon Fuzzilli and hence do not necessitate an initial seed corpus. In contrast, DIE and Superion do require an initial seed corpus. We utilize the seeds generated by Fuzzilli in the generation mode as the initial corpus for Superion and DIE.

Test Target: We choose four JavaScript engines, namely V8 [13] in Google Chrome, JavaScriptCore [1] in Apple Safari, SpiderMonkey [28] in Mozilla Firefox, and Hermes [10], developed by Facebook. These engines are the current mainstream JavaScript engines and have been tested in depth by security researchers and OSS-Fuzz [12]. It is worth noting that Hermes is a lightweight JavaScript engine that does not have a JIT compiler, but there are numerous optimization passes in Hermes which can be tested by OptFuzz.

Environment: We performed our experiments on Intel Xeon Gold 5218 2.30GHz (32 cores) machines with 132GB RAM. The OS version is Ubuntu 20.04.3. Each campaign is assigned 10 cores.

Parameter Settings: In the early stages of fuzzing, we use seeds preserved by edge coverage to explore more code. We limit the use of seeds preserved by OptPaths only after the number of seeds in the *Path Corpus* reaches a certain threshold. After multiple experiments in subsection 6.4, we set this threshold to 300 for JavaScriptCore and V8, 200 for SpiderMonkey, and 20 for Hermes.

6.2 Bug Finding Ability

To answer Q1, we utilized OptFuzz to test four latest versions of JavaScript engines for six months and record the number of bugs found by OptFuzz. The results are presented in subsubsection 6.2.1. To demonstrate OptFuzz's superiority in bug finding, we compared the number of bugs found in earlier versions of JavaScript engines with baselines in subsubsection 6.2.2. The comparison experiments are divided into short-term (72 hours) and long-term (45 days) experiments.

6.2.1 Results of Real-word Bugs

To explore the bug finding ability of OptFuzz, we deployed OptFuzz on four servers and tested four engines for six months. Eventually, we discovered 36 new bugs, 26 of which were confirmed by the vendor with 4 security-sensitive bugs including 3 CVEs assigned. In V8, OptFuzz found 1 new bug and 3 known bugs. In JavaScriptCore, OptFuzz found 17 new bugs (including 2 security-sensitive bugs) and 1 known bug. In SpiderMonkey, OptFuzz found 5 new bugs. In Hermes, OptFuzz found 13 new bugs, including 2 security-sensitive bugs. The detailed descriptions of the bugs are shown in Table 19.

OptFuzz mainly found vulnerabilities due to JIT optimization errors, including integer range overflow (e.g. CVE-2023-38595), OOB (e.g. Issue 256022), UAF (e.g. CVE-2023-38542), and uninitialized memory (e.g. CVE-2023-46140). With differential testing system *DiTing*, OptFuzz was able to find some semantic bugs, e.g. Issue 257949, Issue 263647, and Issue 1200. Out of the 41 identified bugs, 31 are JIT-related, while some have root causes unrelated to JIT, such as Issue 256507 and Issue 263954. Despite extensive long-term and numerous short-term fuzz tests, Fuzzilli did not identify the aforementioned bugs. Upon analysis, we find that the triggering test cases for these bugs are generated through the mutation of seeds in *Path Corpus*. Only the test cases that trigger the new OptPaths are included in *Path Corpus*. In other words, OptFuzz preserved the parent seeds of Issue 256507 and Issue 263954 by OptPaths. Then, OptFuzz mutates the parent seeds to produce test cases that trigger Issue 256507 and Issue 263954.

6.2.2 Comparison with Baselines

To demonstrate OptFuzz's superiority in bug finding, we compared the number of bugs found with baselines in earlier versions of JavaScript engines. We conducted a two week-long fuzz testing on the latest version of JavaScript engines using Superion, DIE, Fuzzilli and FuzzJIT with *DiTing* system. However, they did not uncover any bugs. These fuzzers has previously identified a significant number of bugs and security vulnerabilities over the past few years. To ensure a fair comparison with baselines, we opt to use earlier versions of the engines for our comparison experiments. The versions of each engine are detailed in Table 3.

For JavaScriptCore, V8 and Hermes, we connect our own differential testing system *DiTing* to Superion, DIE, Fuzzilli, and OptFuzz, and for SpiderMonkey, we use SpiderMonkey's own differential testing system. FuzzJIT has its own differential testing system which does not support testing of Hermes.

Table 3: Versions for different engines.

JavaScript Engine	Commit ID	Time	Code Lines
JavaScriptCore	7e4859	2020.1.31	629591
SpiderMonkey	1b9955	2022.1.10	1511250
V8	ed0a85	2021.11.5	1245655
Hermes	2d8c88	2023.8.30	303928

Table 4: Number of bugs found by each fuzzer in 72 hours. Data in the parentheses indicate Mann-Whitney U Test results *p-value*. A value less than 0.05 indicates the result is statistically different between OptFuzz and the selected fuzzer.

	Superion	DIE	Fuzzilli	FuzzJIT	OptFuzz
JavaScriptCore	0 (**0.002**)	1 (**0.029**)	2 (**0.016**)	1 (**0.007**)	4
SpiderMonkey	0 (1.000)	0 (1.000)	0 (1.000)	0 (1.000)	0
V8	1 (0.067)	1 (1.000)	1 (1.000)	1 (1.000)	1
Hermes	0 (**0.001**)	0 (**0.001**)	2 (**0.002**)	–	4
Total Num	1	2	5	2	9

Short-term Experiments. In the short-term experiment, each fuzz testing trial lasts 72 hours and is repeated five times. The results of the short-term experiments are depicted in Table 4. OptFuzz demonstrates a clear advantage over JavaScriptCore and Hermes. In particular, Optfuzz found 2× more than Fuzzilli on JavaScriptCore and Hermes. The performance of each fuzzer does not vary on SpiderMonkey and V8. This is probably because 72 hours of testing time is not be sufficient for SpiderMonkey and V8.

Long-term Experiments. The long-term experiment lasts for 45 days. The results are illustrated in Table 5, showing that OptFuzz is capable of discovering more bugs than other baselines. In V8, both Fuzzilli and OptFuzz discover two bugs. They identify one common bug, while each find a distinct second bug. The bug uncovered by Fuzzilli pertain to the *ArrayBuffer maxByteLength* and is unrelated to the JIT compiler, whereas the bug uncovered by OptFuzz is associated with the JIT compiler's verifier [22]. In long-term experiments, OptFuzz found 6.3×, 6.3×, 2.1× and 9.5× more bugs than Superion, DIE, Fuzzilli and FuzzJIT respectively. Most of the bugs found in earlier versions of the engines have been fixed in the latest version. Therefore, we do not report these bugs to the engine vendors and omit them from Table 19. However, OptFuzz still found a bug in the earlier version that still exists in the new version, which is Issue 265978.

Table 5: Number of bugs for each fuzzer in 45 days.

	Superion	DIE	Fuzzilli	FuzzJIT	OptFuzz
JavaScriptCore	0	2	2	1	6
SpiderMonkey	0	0	1	0	4
V8	1	1	2	1	2
Hermes	2	0	4	–	7
Total Num	3	3	9	2	19

Table 6: The number of OptPaths explored by OptFuzz for optimization passes in JavaScriptCore within 24 hours.

Optimization Pass	NP	STD	ANT	MNT

B3ReduceDoubleToFloat	56	17.9	176	74

NP indicates the number of OptPaths in an optimization.
STD denotes the standard deviation of NP.
ANT indicates the average number of times each OptPath is tested.
MNT indicates the median number of times each OptPath is tested.

6.3 Exploration of OptPaths

6.3.1 Number of OptPaths in Different Optimizations

To evaluate OptFuzz's exploration of OptPaths, we ran OptFuzz on JavaScriptCore, V8, SpiderMonkey, and Hermes. During fuzzing, we record the number of OptPaths explored by OptFuzz in different optimization passes. Each trial lasted 24 hours and was repeated 5 times. Table 6 gives the number of OptPaths explored by OptFuzz in JavaScriptCore within 24 hours. Table 17 and Table 18 give the number of OptPaths explored in V8, SpiderMonkey and Hermes respectively. NP indicates the number of OptPaths explored in an optimization pass. The results of five trials are averaged to obtain NP. STD denotes the standard deviation of NP. ANT indicates the average number of times each OptPath is tested. MNT indicates the median number of times each OptPath is tested. For each trial, the median is calculated first. The medians of five trials are averaged to obtain MNT.

The experimental results show that there is no explosion in the number of OptPaths. Furthermore, it is observed that the number of OptPaths varies across various optimization passes. Some optimization passes are designed with different optimization techniques for different instruction opcodes and operands, data flow relationships, and control flow structures, so the number of OptPaths in these optimization passes is high. Take *StrengthReduction* optimization pass as an example. The optimization pass designs different optimization techniques based on different operators (Add, Sub, And, etc.) and operand types (Int32, Int64, String, etc.). While some optimization passes, for example, *ValueRepReduction* only optimizes for specific intermediate representation *ValueRep* and *DoubleRep*, so the number of OptPaths is low.

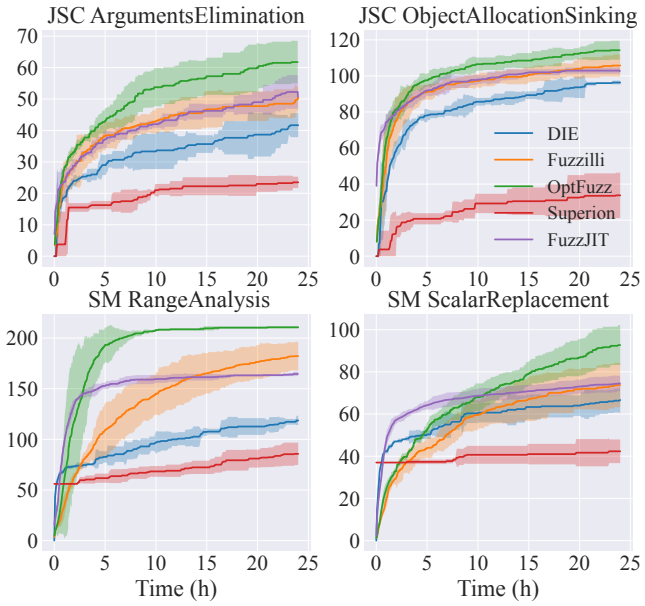

Figure 3: The number of OptPaths explored by Superion, DIE, Fuzzilli, FuzzJIT and OptFuzz in JavaScriptCore (JSC) and SpiderMonkey (SM) within 24 hours.

6.3.2 Comparison with Baselines

To demonstrate the advantages of OptFuzz in exploring OptPaths, we ran OptFuzz, Superion, DIE, Fuzzilli, and FuzzJIT on JavaScriptCore and SpiderMonkey respectively. Each trial lasted 24 hours and was repeated 5 times. To collect the number of OptPaths explored by DIE, Superion, Fuzzilli, and FuzzJIT, we modified these fuzzers to incorporate a new bitmap to dynamically record the number of OptPaths explored. This is analogous to capturing all test cases generated by the fuzzers. Figure 3 gives the number of OptPaths explored by different fuzzers in the *Arguments Elimination* and *Object Allocation Sinking* pass of JavaScriptCore and *Range Analysis* and *Scalar Replacement* pass of SpiderMonkey. The solid lines represent mean and the shades around lines are confidence intervals.

Compared to OptFuzz, Superion, DIE, Fuzzilli and FuzzJIT were able to explore 38.6%, 67.5%, 86.0% and 81.9% of the OptPaths, respectively. OptFuzz can explore more OptPaths than other fuzzers. This is because different OptPaths within the same optimization pass have varying conditions but share significant similarities. Seeds in *Path Corpus* can keep new OptPaths intact. By mutating these seeds, it becomes easier to generate test cases that trigger more new OptPaths in the same optimization pass.

DIE and Superion explore fewer OptPaths compared to Fuzzilli. This is because Fuzzilli is designed with templates and mutation rules specifically aimed at triggering JIT, enabling faster execution into the optimization pass. Superion explores fewer OptPaths than DIE due to its trimming strategy, which retains the code that triggers new edges but prunes the code that triggers new OptPaths. DIE does not perform syntax-valid trimming, allowing the code related to triggering OptPaths to remain. This provides more opportunities to generate test cases that trigger different OptPaths. Fuzzilli and FuzzJIT explore a similar number of OptPaths, which is because FuzzJIT is implemented based on Fuzzilli. In the early stages of fuzz testing, FuzzJIT explores faster, this is because FuzzJIT designs a template where each test case is embedded in a loop, resulting in a higher probability of triggering JIT.

6.4 Ablation Experiment

To answer Q3, this section performs ablation experiments to illustrate the effectiveness of our design. The experiment evaluates OptFuzz on JavaScriptCore in four parts including seed preservation, seed scheduling, trimming strategy and threshold. We will discuss switching strategy in subsection A.3. Table 7 shows the number of bugs discovered by different designs. Each trial lasted 72 hours and was repeated 5 times.

6.4.1 Seed Preservation

To evaluate the seed preservation strategy of OptFuzz, we additionally implemented five seed preservation strategies including *countpath*, *n2*, *n4*, *n8* and *looppath*. AFL [30] not only evaluates whether a test case triggers a new edge but also takes into account the number of times an edge has been executed when assessing whether a test case is interesting. We have incorporated a similar mechanism, named *countpath*, into OptFuzz. Furthermore, we have introduced *n2*,*n4*, and *n8* paths [40], representing paths comprising 2/4/8 consecutive edges, respectively, and utilize these paths for seed preservation instead of OptPaths. *looppath* denotes optimization paths that do not ignore nested loops. Fuzzilli indicates that only edge coverage is used for seed preservation.

The experimental results detailed in Table 7 demonstrate that OptPath-based seed preservation strategy can uncover more bugs. Additionally, Figure 4 depicts the quantity of seeds preserved by the various seed preservation strategies as well as the number of paths explored. It is evident that both *looppath* and *n8* suffer from the path explosion problem. *looppath* kept 10 million new paths in 72 hours. Path explosion makes the number of seeds grow rapidly, causing *looppath* and *n8* to waste most of their testing resources on unproductive seeds, thereby diminishing their bug-finding capabilities. Despite *n4* having a lower number of seeds than *n8*, it suffers from the same problem.

Path explosion does not occur in *n2*. Fuzzilli's edge coverage is approximated using basic block coverage. *n2* is actually a path consisting of two consecutive basic blocks, which is actually an edge. *n2* and Fuzzilli employ a similar seed preservation method, thereby yielding comparable bug discovery capabilities. *n2* has fewer seeds than Fuzzilli because we limit *n2* to optimization passes rather than the whole JavaScript

Table 7: The number of bugs found for different designs.

Seed Preservation			Seed Scheduling			Threshold			Switching Strategy		
Fuzzer	Bug	*p-value*	Fuzzer	Bug	*p-value*	Fuzzer	Bug	*p-value*	Fuzzer	Bug	*p-value*
countpath	1	**0.007**	OptFuzz_RandomSelect	1	**0.032**	OptFuzz_10	0	**0.009**	OptFuzz_RandomSwitch	2	1.000

engine. Consequently, if a test case executes to new edges in the code that is not related to optimization (e.g., interpreter), Fuzzilli can preserve it as a seed, but n2 cannot. Moreover, the number of seeds in Fuzzilli first increases and then gradually decreases due to the inclusion of *seed cleanup* in Fuzzilli's corpus. Fuzzilli's corpus performs a seed cleanup every 30 minutes and removes the seeds that have been selected more than 25 times. If the corpus has less than 1000 seeds, no cleanup is performed. The number of seeds for *countpath* is slightly higher than that of OptFuzz due to the consideration of multiple executions of an OptPath in *countpath* as distinct seeds. In fact, *countpath* comes to the similar number of OptPaths as OptFuzz in Figure 4(b). *countpath* does not perform well in bug discovery, probably because *countpath* does not fit well with our scheduling strategy. Our scheduling strategy prioritizes the paths that are currently less tested. If *countpath* itself considers the number of executions per path, the paths chosen by the scheduling strategy may not be the paths that are currently less tested.

In conjunction with the aforementioned analysis, the seed preservation strategy based on OptPaths can avoid the path explosion problem. Among the various strategies, the OptPaths yield the fewest number of seeds but can find the most number of bugs, which demonstrates the high quality of seeds preserved based on the OptPaths.

6.4.2 Seed Scheduling

To evaluate the seed scheduling strategy of OptFuzz, we additionally implemented two scheduling strategies, *RandomSelect* and *PowerSchedule*. *RandomSelect* denotes the random selection of seeds for mutation. *PowerSchedule* denotes the implementation of seed power scheduling based on OptPaths. *PowerSchedule* determines the number of test cases mutated from each seed. If an OptPath is tested less, the corresponding seed can be mutated to produce more test cases.

The results in Table 7 show that our scheduling strategy outperforms *RandomSelect* as well as *PowerSchedule*. In contrast to *RandomSelect*, our scheduling strategy focuses on testing the OptPaths that are currently tested less often and tests them in a more targeted manner. Power schedule is a commonly used method for fuzz testing in seed scheduling. However this method does not perform well in OptFuzz. *PowerSchedule* uses random selection to decide the order in which the seeds are selected, which can avoid the local optimum problem, but it also suffers from the drawbacks of *RandomSelect*, which spreads the test targets too thinly when the number of seeds is large, and does not adequately test the OptPaths that actually trigger the optimization.

The OptPath proposed in this paper may contain some branches that exit early without triggering the optimization. In subsection 4.4, we point that the impact of these extraneous paths can be alleviated using a rareness-based scheduling approach. To evaluate the performance of *RarenessSchedule* strategy, we randomly selecte a number of optimization passes from different optimization levels (DFG, FTL, B3) of JavaScriptCore, and manually analyze these optimizations by marking the code locations that actually trigger the optimization. If an OptPath executes to the marked code location, it is considered that the OptPath really triggers the optimization. Table 8 shows how OptPaths are tested in a 72-hour fuzz testing. The second column of Table 8 records the number of OptPaths that OptFuzz explored in different optimization passes, with the data in parentheses indicating the percentage of OptPaths that actually trigger the optimization. For example, OptFuzz explores a total of 156 OptPaths in *StrengthReduction*, of which 28% actually trigger the optimization. The third column of Table 8 records the number of times OptFuzz selects OptPaths, and the data in parentheses indicates the percentage of OptPaths that trigger the optimization among the OptPaths selected. For example, OptFuzz selects 19,015 OptPaths from *StrengthReduction* over 72 hours, and ultimately, the percentage of selected OptPaths that trigger the optimization remains stable at 42%.

Optimization	*OptPath*	$OptPath_{selected}$	↑
StrengthReduction	156 (28%)	19015 (42%)	↑ 14%
TypeCheckHoisting	21 (48%)	3389 (92%)	↑ 44%
ConstantFolding	234 (45%)	24569 (57%)	↑ 12%
StoreBarrierInsertion	116 (28%)	15562 (41%)	↑ 13%
IntegerCheckCom	18 (50%)	2882 (84%)	↑ 34%
IntegerRangeAnalysis	37 (30%)	5358 (63%)	↑ 33%
B3FoldPathConstants	26 (12%)	4043 (32%)	↑ 20%
B3LowerMacros	12 (50%)	2666 (96%)	↑ 46%

Table 8: Percentage of OptPaths that actually trigger the optimization and the scheduling of OptPaths by *RarenessSchedule* in different optimizations.

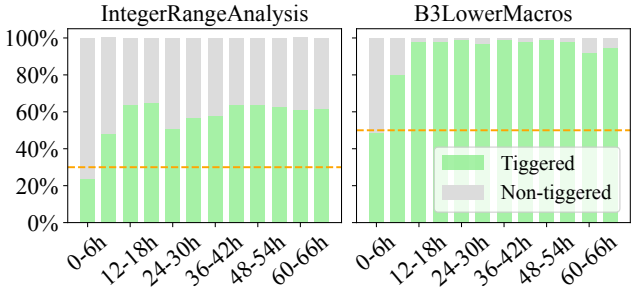

Figure 5: The percentage of OptPaths that actually trigger the optimization over time among the selected OptPaths.

Among the eight optimization passes, only 35% of the OptPaths can really trigger the optimization. The percentage increases to 53% with *RarenessSchedule* strategy and in some of the optimization passes, the percentage of OptPaths that can trigger the optimization is more than 90%. The experimental results demonstrate that even though the OptPaths contain some branches that do not trigger the optimization or exit early, the utilization of *RarenessSchedule* mitigates the impact of these extraneous paths, enabling more computational resources to be allocated for testing the OptPaths that actually trigger the optimization.

Figure 5 illustrates the percentage of OptPaths that actually trigger the optimization over time among the **selected OptPaths** (the third column in Table 8). The orange horizontal line indicates the baseline percentage of OptPaths that actually trigger the optimization (the second column in Table 8). As shown in Figure 5, the proportion of selected OptPaths that really trigger the optimization is not constant during the scheduling process. At the beginning of the fuzz testing, the number of OptPaths is small, and the OptPaths that have been tested a small number of times are not necessarily the ones that really trigger the optimization, resulting in a relatively low proportion of OptPaths that actually trigger the optimization in the selected OptPaths. As the test proceeds, the branches that exit early are tested more often, *RarenessSchedule* is able to select more OptPaths that really trigger the optimization, leading to a gradual rise in the percentage of OptPaths that actually trigger the optimization. Eventually, the percentage stabilize at 63% in *IntegerRangeAnalysis* and 96% in *B3LowerMacros*.

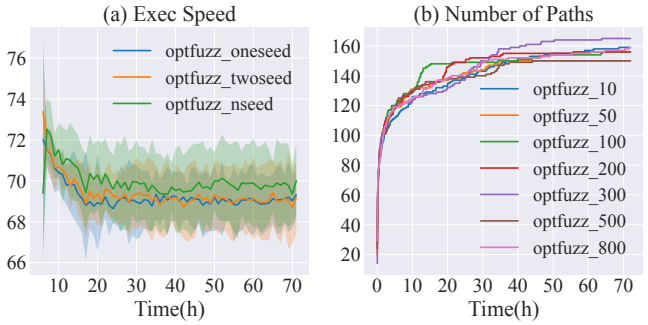

Figure 6: (a)Execution speed of fuzz testing with different trimming strategies. (b)Number of OptPaths in StrengthReduction explored by OptFuzz at different thresholds.

6.4.3 Trimming

To evaluate the trimming strategy of OptFuzz, we compare three trimming strategies including *nseed*, *twoseed* and *oneseed*. *nseed* is the trimming strategy used in this paper. *nseed* produces distinct seeds for the newly executed OptPaths in each optimization pass. *twoseed* generates a maximum of two seeds for an interesting test case. One seed preserves new edges, while the other preserves all new OptPaths, without distinguishing between specific optimization passes. Conversely, *oneseed* only generates a single seed for a test case, which preserves both new edges and new OptPaths.

The results in Table 7 show that *nseed* can find more bugs. *nseed* outperforms *twoseed* and *oneseed* for two main reasons. (1) The trimming with edges and OptPaths in different optimization passes as the trimming standard ensures that each seed is as small as possible, which results in a faster execution of the program. Figure 6(a) shows the execution speed results of OptFuzz running on JavaScriptCore for 72 hours with different trimming standards. The solid lines represent mean and the shades around lines are confidence intervals for five runs. (2) Another reason is that a test case generates seeds for different optimization passes separately, the rareness scheduling strategy will select the OptPaths **in each optimization pass** that are currently being tested less for testing, which not only ensures that different OptPaths in an optimization pass are tested more evenly, but also ensures that different optimization passes are tested more evenly.

6.4.4 Threshold

This section evaluates the impact of different thresholds. The threshold in OptFuzz determines when to start selecting seeds from *Path Corpus*. If the threshold is too low, the fuzz testing does not explore the code sufficiently. The edge coverage feedback should be advantageous upfront. Conversely, a threshold set too high delays or negates the role of path feedback, thereby impacting the exploration of OptPaths.

In our experiments, we employ seven thresholds, with the results indicating that threshold 300 leads to the discovery

Trial	Bug1_exec	Bug2_bind	Bug3_in	Bug4_super
Trial 1	✓	-	✓	-
Trial 2	-	✓	-	-
Trial 3	-	✓	-	-
Trial 4	-	-	-	-
Trial 5	-	-	✓	✓

Table 9: Distribution of bugs found by OptFuzz across fuzzing trials when threshold is 300. ✓ means a bug was found during a fuzzing trial.

of more bugs in Table 7. Table 9 shows the distribution of bugs across fuzzing trials when threshold is 300. Upon further analysis of the bugs identified, we found that OptFuzz_300 is able to find *Bug1* that cannot be found with any other threshold, and the bug is related to *StrengthReduction* optimization pass. Figure 6(b) illustrates the exploration of OptPaths in the StrengthReduction optimization by OptFuzz for different thresholds. The results show that after 30h, Optfuzz_300 explored a higher number of OptPaths compared to the other thresholds, which is probably why OptFuzz_300 found *Bug1*.

6.5 Code Coverage

To answer Q4, this section compares code coverage with Fuzzilli and FuzzJIT. We ran Fuzzilli, FuzzJIT and OptFuzz on JavaScriptCore, SpiderMonkey and Hermes. Each Trial lasted 72 hours and was repeated five times. We use *llvm-cov* [27] to count the coverage results. Table 10 shows the overall code coverage as well as the JIT compiler code coverage obtained by Fuzzilli, FuzzJIT and OptFuzz for testing JavaScriptCore, SpiderMonkey and Hermes. The results in the table are the average of five runs. The corresponding standard deviations are shown in Table 16.

Table 10: Final mean code coverage results

Engine	Fuzzilli Line / Edge	FuzzJIT Line / Edge	OptFuzz Line / Edge
JSC	**55.5% / 40.3%**	41.5% / 26.3%	55.3% / 38.8%
JSC JIT	79.9% / 63.0%	62.1% / 47.8%	**80.5% / 63.7%**
SM	**48.7% / 32.4%**	47.1% / 30.7%	45.0% / 29.2%
SM JIT	64.9% / 45.7%	**65.5% / 46.3%**	59.3% / 41.6%
Hermes	**60.7% / 39.7%**	– / –	55.7% / 34.3%
Hermes Scalar	**71.3% / 60.7%**	– / –	71.1% / 60.5%

Fuzzilli outperforms FuzzJIT and OptFuzz in terms of overall JavaScript engine code coverage. However, different fuzzing methods show varying performance on different JIT compiler targets. OptFuzz achieves the highest code coverage in JavaScriptCore's JIT compiler, while in Hermes' Scalar optimization, the coverage was slightly lower than that of Fuzzilli. Additionally, in SpiderMonkey's JIT compiler, OptFuzz demonstrates the lowest edge coverage. Despite this, OptFuzz found more bugs in the same amount of time. This indicates that focusing on the testing of optimization paths and using OptPaths for guidance is effective in discovering bugs in JavaScript JIT compilers.

7 Related Work

Fuzzing for JavaScript Engines. JavaScript engines have syntactic checks, which would prevent malformed test case from execution. In order to pass these checks, jsfunfuzz generates JavaScript test cases based on manually implemented syntax rules. Mozilla's LangFuzz [20] uses a mutation-based approach, where test cases are first parsed into a syntax tree, and replace nodes in the syntax tree to complete the mutation operation. Skyfire [41] and Superion [42] are both grammer-based fuzzing methods. Skyfire focuses on seed generation by replacing leaf nodes on syntax tree, while Superion focuses on mutation and trimming based on edge coverage. Similar to Superion, Nautilus [2] also performs trimming and mutation on the abstract syntax tree. The difference is that Superion requires a corpus to be prepared beforehand, while Nautilus can generate seeds based on the grammar and mutate on the abstract syntax tree of the seeds.

The following works focus on passing semantic checks. CodeAlchemist [15] first disassembles PoC and regression files into code fragments, and then reconstructs test cases from code fragments using information collected by analyzer. Similarly, Montage [23] mutates test cases based on regression test files fragments. Montage trains a neural network language model (NNML) to predict the next fragment given some sequence of fragments, and utilizes the model for mutation. DIE [32] is also mutation-based fuzzing method. DIE proposes a new mutation strategy that randomly preserves structural and type information in the seeds. PolyGlot [5] takes a further step to other languages. PolyGlot generates test cases in different languages for different test objectives based on their new intermediate representation. SoFi [16] takes another perspective. They make use of the reflection mechanism of the JavaScript language and come up with a mutation strategy based on it.

In recent years, the focus of fuzz testing has shifted to the JIT compiler. Fuzzilli [14] devises numerous generation templates and mutation strategies to trigger JIT, and proposes a set of bytecode-like intermediate representation languages FuzzIL. JIT-Picking [3] compares the result of interpretation and JIT compilation in the process of fuzzing to detect non-crash bugs in the JavaScript JIT compilers. FuzzJIT [43] is also a work that detects JIT compiler bugs through differential testing. The authors designed a template for triggering a JIT by embedding test cases into a *for* loop.

Seed Scheduling. Previous work in seed scheduling has prioritized seeds based on edge coverage [4] [47], call graph [24] and inter-procedural control flow graph (CFG) [38], as well as more security-sensitive metrics like execution time [33], memory accesses [7] [45] [44]. AFLFast [4] prioritizes the edges that are currently tested less often. Ecofuzz [47] proposed a variant of the Adversarial Multi-Armed Bandit model and used it for modeling the scheduling problem. Cerebro [24] proposes a multi-objective optimization(MOO) model together

with a nondominated sorting based algorithm to quickly calculate the Pareto Frontier which decides the prioritized seed. K-Scheduler [38] uses a graph centrality algorithm to evaluate the probability of a seed being able to trigger edges that are currently unvisited based on the inter-procedural CFG. SlowFuzz [33] uses resource-usage-guided evolutionary search techniques to find inputs that trigger worst-case algorithmic behavior. Mem-fuzz [7] uses memory access instrumentation to guide evolutionary fuzzing. It prioritizes the input that accesses previously unseen memory addresses. Memlock [45] is a memory usage guided fuzzing technique for exposing uncontrolled memory consumption. It generates and prioritizes the excessive memory consumption inputs. TortoiseFuzz [44] proposes *coverage counting*, an approach for input prioritization with metrics that evaluates edges in terms of the relevance of memory corruption vulnerabilities.

8 Conclusion

By conducting an analysis on the JavaScript JIT compilers, this paper summarizes three observations: 1) Entering the optimization pass does not mean triggering the optimization; 2) Edge coverage-guided fuzzing will overlook test cases that trigger new optimization paths; 3) Different optimization paths are tested unevenly. This paper introduces a novel fuzzing technique that leverages optimization trunk paths to guide fuzz testing. Specifically, this technique preserves a test case that triggers a new optimization trunk path as a seed and prioritizes the testing of optimization trunk paths that are infrequently tested. Through extensive testing, our proposed method found 36 new bugs in JavaScriptCore, V8, SpiderMonkey and Hermes. 26 of these bugs have already been confirmed or fixed with 3 CVEs assigned. While our current focus lies on JavaScript JIT compilers, we recognize broader applicability of our method across other programming languages such as Java, Lua, among others. We will adapt our technique to these alternative languages in the future work.

A.2 Case Study

CVE-2023-38542 is a UAF vulnerability related to function *simplifySwitchInst* and *simplifyPhiInst* in optimization pass *simplifyInst* of Hermes as shown in Figure 7. *simplifySwitchInst* converts *switch* to *branch* based on the input of *switch* and removes the corresponding child node of the phi nodes in the unreachable basic block. *simplifyPhi* is designed for *phi* with only one child node, replacing the phi node with the child node. In order to trigger UAF, Hermes needs to trigger the optimization in *simplifySwitchInst* and then trigger the optimization on line 23 of *simplifyPhi* twice to produce an intermediate representation of $x = phi(x)$ and an intermediate representation that uses x. Finally, the optimization at line 23 in *simplifyPhi* is triggered once more to eliminate x. At this point, a reference to x still exists in the code, resulting in Use-After-Free.

In this paper, we propose a seed preservation strategy based on OptPaths, which is able to select the test cases that trigger *simplifySwitchInst* and *simplifyPhi* and keep the OptPaths intact. The conditions in line 8 and 20 in Figure 7 are more difficult to satisfy, and our scheduling strategy tests more of the OptPaths for which such conditions are difficult to satisfy. In this way, our approach generates the test case that trigger both *simplifySwitchInst* and *simplifyPhi*, leading to the

discovery of the vulnerability in optimization *InstSimplify*. To fix this vulnerability, Hermes updated three patches [17] [18] [19] involving 105 additions and 58 deletions.

A.3 Switching Strategy

The switching strategy between exploration and exploitation refers to OptFuzz's decision of which corpus to use when selecting seeds. During fuzz testing, OptFuzz switches to using seeds in PathCorpus after the number of seeds in PathCorpus exceeds a certain threshold. Subsequently, OptFuzz selects seeds from EdgeCorpus and PathCorpus with equal probability, corresponding to *RandomSwitch* in Table 7. To explore the impact of the switching strategy, we additionally implemented three switching strategies. *NoSwitch* indicates that after the number of seeds in PathCorpus exceeds the threshold, only the seeds in PathCorpus are selected. *AIMD* involves dynamically adjusting the proportion of EdgeCorpus and PathCorpus being selected. Initially, each is set at 50%; if a new OptPath is discovered over a period of time, the proportion of PathCorpus grows by 10%, and if no new OptPaths are discovered, the proportion of PathCorpus is halved. *Wind* represents the switching strategy used by WindRanger [9], where OptFuzz uses the seed in EdgeCorpus if no new OptPaths have been discovered for a period of time, or the seed in PathCorpus if new OptPaths have been explored.

The experimental results in Table 7 indicate that there is no significant difference in the number of bugs found by *RandomSwitch*, *AIMD*, and *Wind*. The number of OptPaths explored by different methods is also relatively close, as shown in Figure 8(a). Table 15 demonstrates that *RandomSwitch*,

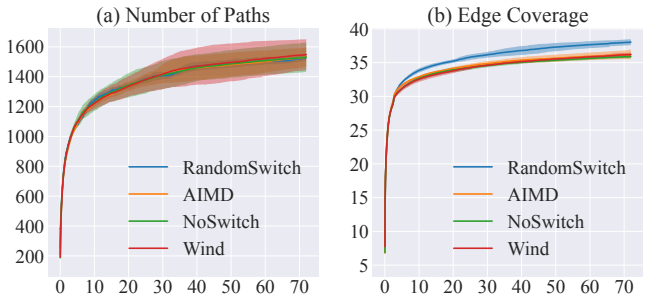

Figure 8: Number of OptPaths and edge coverage explored by OptFuzz with different switching strategies.

AIMD, and *NoSwitch* are not statistically significant. Given that *RandomSwitch* has a higher edge coverage, it ensures the exploration of more code regions while exploring OptPaths. Therefore, OptFuzz ultimately adopts *RandomSwitch* strategy.

A.4 OptPath

Table 17 and Table 18 give the number of OptPaths explored by OptFuzz in V8, SpiderMonkey and Hermes respectively within 24 hours.

Table 17: The number of OptPaths explored in V8.

Table 19: Bugs found by OptFuzz in JavaScriptCore, SpiderMonkey, V8 and Hermes. (The *Status* column has four categories: *Fixed* means the bug has been fixed, *Confirmed* means the bug has been confirmed by the vendor, but still not fixed, *New* means the bug has not been confirmed and *Duplicate* means the bug is found and reported by someone else. We determine whether the bug is confirmed or not based on the vendor's response, not on the status of the bug submission page, e.g. Issue1835579.)

Engine	ID	Issue	JIT	Status	Description
JavaScriptCore	1	CVE-2023-38595 *	✓	Fixed	Integer overflow caused by multiplication optimization in b3
	2	Issue 255512	✓	Fixed	StringConstructor function inlining is incorrect
	3	crash	✓	Duplicate	B3 values become orphaned values
	4	Issue 256508		New	Error.stackTraceLimit can not be updated correctly
	5	Issue 256832		Fixed	Assertion Failure: m_setOp == CharacterClassSetOp::Default
	6	Issue 257949	✓	Fixed	JSC computes incorrectly in DFG
	7	Issue 258559	✓	Fixed	regExpFuncExec throw different messages in LLint and DFG
	8	Issue 256022 *	✓	Fixed	OOB Reading caused by implementation of For-In in FTL
	9	Issue 258518	✓	New	For-In in DFGSpeculativeJIT may destroy IndexGPR
	10	Issue 258552	✓	New	iterator_next becomes undefined after bailout from DFG
	11	Issue 263520	✓	New	AbstractInterpreter handles GetMyArgumentByVal incorrectly when callee is inlined
	12	Issue 263647	✓	Confirmed	Function.caller returns null when callee is inlined into apply function
	13	Issue 263954		Fixed	JSC should throw an exception when BigUint64Array copy value from Int32Array
	14	Issue 263881	✓	New	BitURShift is eliminated when toString has an effect
	15	Issue 263882	✓	New	ValueMod is eliminated incorrectly
	16	Issue 264034	✓	Fixed	Host function isPureNaN is inlined into true in handleIntrinsicCall
	17	Issue 264078	✓	New	Abstract Interpreter computes wrong value for GetLocal
	18	Issue 265978	✓	New	Error Object has more properties in DFG
SpiderMonkey	19	Issue 1830107	✓	Fixed	Assertion failure for unexpected range for value in LInt32ToIntPtr
	20	Issue 1833133	✓	Fixed	IC stub for arguments.callee is used even if callee has been redefined
	21	Issue 1833294	✓	New	Differential testing generates different values when target is Error
	22	Issue 1834038	✓	Fixed	Assertion failure: cx_→ hadResourceExhaustion in JIT
	23	Issue 1835579	✓	Confirmed	Differential testing generates different values when target is gcNumber
V8	24	Issue 14055	✓	New	v8 prints non-deterministic results for Worker with/without turbofan
	25	crash		Duplicate	Check failed in src/handles/maybe-handles.h
	26	crash		Duplicate	Check failed in src/objects/string-tq-inl.inc
	27	crash		Duplicate	Debug check failed: (*p).ptr() != to_check_.ptr()
Hermes	28	Issue 1033		Confirmed	Integer overflow for vector capacity in Hermes
	29	CVE-2023-38542 *	✓	Fixed	Use after free of hermes::PhiInst object in SimplifyInst
	30	CVE-2023-46140 *	✓	Fixed	Hermes accesses uninitialized memory in Symbol.toStringTag
	31	Issue 1199	✓	Fixed	Hermes should throw an exception when implicitly convert Int to BigInt
	32	Issue 1200	✓	Fixed	SimplifyBinOp in InstSimplify generates wrong result
	33	Issue 1203	✓	Fixed	The generator function's body is executed incorrectly when next() method is not called
	34	Issue 1212	✓	Fixed	Hermes should throw an exception when BigInts use unsigned shift
	35	Issue 1215	✓	Confirmed	SimplifySwitchInst in SimplifyCFG ignores negative zero
	36	Issue 976		Confirmed	Too many handles in recursive invocation of stringPrototypeReplace()
	37	Issue 977		Fixed	Hermes crashes when call AggreageError constructor.
	38	Issue 988		Fixed	Assertion failure when executing StartGenerator
	39	Issue 1006		Fixed	Assertion failed: hasNamedOrIndex failed
	40	Issue 1015		Fixed	Assertion failed: defineOwnProperty threw in _setOwnIndexedImpl

* in *Issue* column means this bug is security sensitive.

Fuzzing BusyBox: Leveraging LLM and Crash Reuse for Embedded Bug Unearthing

Asmita[1], Yaroslav Oliinyk[2], Michael Scott[2], Ryan Tsang[1],
Chongzhou Fang[1], Houman Homayoun[1]

[1]*University of California, Davis* [2]*NetRise*

Abstract

BusyBox, an open-source software bundling over 300 essential Linux commands into a single executable, is ubiquitous in Linux-based embedded devices. Vulnerabilities in BusyBox can have far-reaching consequences, affecting a wide array of devices. This research, driven by the extensive use of BusyBox, delved into its analysis. The study revealed the prevalence of older BusyBox versions in real-world embedded products, prompting us to conduct fuzz testing on BusyBox. Fuzzing, a pivotal software testing method, aims to induce crashes that are subsequently scrutinized to uncover vulnerabilities. Within this study, we introduce two techniques to fortify software testing. The first technique enhances fuzzing by leveraging Large Language Models (LLM) to generate target-specific initial seeds. Our study showed a substantial increase in crashes when using LLM-generated initial seeds, highlighting the potential of LLM to efficiently tackle the typically labor-intensive task of generating target-specific initial seeds. The second technique involves repurposing previously acquired crash data from similar fuzzed targets before initiating fuzzing on a new target. This approach streamlines the time-consuming fuzz testing process by providing crash data directly to the new target before commencing fuzzing. We successfully identified crashes in the latest BusyBox target without conducting traditional fuzzing, emphasizing the effectiveness of LLM and crash reuse techniques in enhancing software testing and improving vulnerability detection in embedded systems. Additionally, manual triaging was performed to identify the nature of crashes in the latest BusyBox.

1 Introduction

The proliferation of IoT (Internet of Things) devices continues unabated, with a reported 16% growth rate propelling the global count to 16.7 billion, according to IoT Analytics [1]. This remarkable expansion in the IoT ecosystem raises significant cybersecurity concerns. Embedded devices occupy a central role in IoT security, as vulnerabilities within them can jeopardize an entire system's security. Because of the role it plays in governing most aspects of a system's behavior, firmware is of particular importance. Often, firmware is comprised of numerous third-party software components that can be reused across various products, thereby amplifying concerns regarding their vulnerability; a single flaw could potentially affect multiple disparate devices that rely on shared components. Consequently, continuous analysis of these components is imperative.

1.1 Motivation

Firmware can be broadly classified into three categories: those based on modified generic operating systems (OS) like Linux, those based on real-time (RTOS) or custom operating systems, and those that do not have a formal operating system (non-OS or bare-metal). Each of these categories poses distinct challenges when it comes to security assessment [32] and often require different approaches. To that end, we focus our attention in this work on the largest subclass of OS-based firmware: Embedded Linux.

Embedded Linux-based firmware often utilizes various application-level software components, including BusyBox, Lighthttpd, Dropbear, SQLite, OpenSSL, telnet server, and various file system utilities. Consequently, there are multiple potential attack surfaces, warranting continued exploration and research. As a critical set of commonly used utility programs in embedded Linux, BusyBox [47] is a component of particular interest. It provides over 300 common Unix utilities within a single lightweight and compact executable, making it indispensable for resource-constrained Linux-based embedded devices. There are many IoT and OT(Operational Technology) devices running BusyBox, including remote terminal units (RTUs), human-machine interfaces (HMIs), and many others that are running on Linux. However, despite its many advantages, it can also present considerable risk, as it is often used with elevated privileges and provides multiple utilities that handle user input, which attackers have been able

to exploit. 14 vulnerabilities were found in Busybox in 2021, some of which had the potential of remote code execution or denial of service attacks [6]. Despite this, in our investigation we have identified several real-world products that continue to use older versions of BusyBox that contain known vulnerabilities.

Our research questions for this work can be summarized as follows:

Q1: How widespread are variants of BusyBox and how can similar vulnerabilities across variants be efficiently identified?

Q2: How can we leverage LLMs to improve fuzz testing on embedded Linux utility programs like those in BusyBox?

1.2 Contributions

Fuzzing is a well-recognized software testing technique for uncovering vulnerabilities, but its effectiveness varies depending on the chosen target, each of which can present unique challenges. In this work, we propose and implement two techniques to assist software testing for embedded linux. First, we leverage **LLM-based seed generation**, in which we utilize commercial large language models (LLMs) to generate the initial input seeds for mutation-based, coverage-guided fuzzing. In doing so, we take advantage of LLMs' inherent capability to generate high-quality structured inputs that adhere to the input grammar of a target. Second, we employ a **crash reuse** strategy to identify crashes across variants of a software component present in different targets. This strategy is based on the intuition that an input that triggers a crashing vulnerability on one variant of a program is likely to trigger a crash on different variant. This allows us to more efficiently determine if the same vulnerability is present on multiple program variants without performing fuzzing, thus saving significant time. When we mention a variant of a software component, we are referring to identical software components with varying version numbers or architectures or compiler optimization, or any custom modification by developers.

As a proof-of-concept, we demonstrate these techniques with AFL++ on BusyBox. This research was done in collaboration with NetRise's [33] firmware security division. We sourced BusyBox ELFs from real-world embedded products collected from the company's proprietary firmware dataset, which had been constructed using in-house extraction tools. These ELF binaries were fuzz tested without altering the target's source code or compilation process, using AFL++ in QEMU mode.

We evaluated the first technique, LLM-based seed generation, by comparing control runs that used randomly generated initial seeds, to experimental runs that used initial seeds generated using OpenAI's GPT-4 LLM API [35]. We observed a significant increase in crashes obtained when using LLM-generated seeds, demonstrating the potential for improving vulnerability detection.

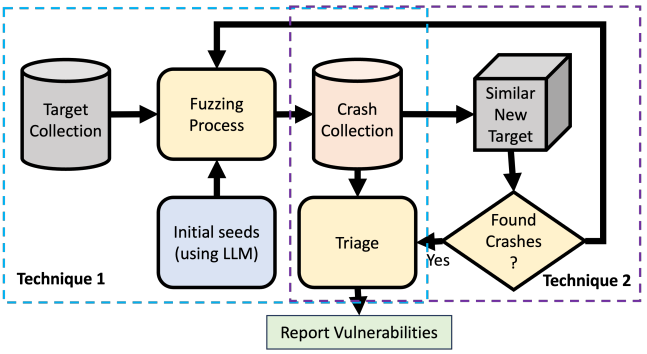

Figure 1: Proposed work pipeline

We then used the crash results accumulated from these experiments to evaluate the second technique, crash reuse, by testing them against the latest version of BusyBox (v1.36.1 at the time of writing). Since the accumulated crashes corresponded to older versions of BusyBox, any reused inputs that still cause crashes are likely due to the continued presence of the same vulnerability, which allow us to discover crashes in the latest version without fuzzing it explicitly. We also fuzz tested the latest version and conducted a comparative analysis. The results of our validation highlighted the effectiveness of crash reuse with respect to time and resource efficiency.

In the context of open-source software components, collecting crashes can be enhanced by instrumenting the source code and improving crash identification. These collected crashes can then be applied to the variant of that software component present in different targets, even in cases involving black-box testing. This is because, in many instances, the variant of software component may reappear in different target. Therefore, reusing existing crashes from a particular software component for testing its variant on different targets can be advantageous. This approach streamlines the provision of crash data directly to the target before the commencement of fuzzing, resulting in substantial time savings.

Finally, we conducted crash analysis for the latest BusyBox version(v1.36.1), compiled from the BusyBox source code. Figure 1 shows the overall pipeline of the proposed techniques. Our contributions can be summarized as follows:

- We identify versions of BusyBox still in use in commercial embedded devices, emphasizing the need to update them.
- We implement **LLM-based seed generation** to enhance fuzzing by utilizing LLM for target-specific initial seed generation, leading to faster and more efficient seed generation, more crashes, and more options for triaging to identify vulnerabilities. We developed an automation script to perform fuzzing on a large batch of BusyBox targets without manual intervention, which will be made open source.

- We propose **crash reuse** as a first-pass bug-finding strategy, in which we reuse crashing inputs for different program variants to quickly find duplicate vulnerabilities, even under black-box testing conditions.
- We identify crashes in the `awk` applet of latest BusyBox version and conduct manual crash triaging to determine whether they originated from BusyBox or dependencies in the underlying libraries. We later applied these techniques to other applets including `dc`, `man`, and `ash`.

2 Background

In this section, we provide a brief overview of some of the tools and techniques relevant to this paper.

2.1 BusyBox

BusyBox [47] is a single binary executable for several Unix-based utilities designed mainly for resource-constrained embedded devices. It is open source, lightweight, compact, and has a small footprint. It allows manufacturers to include essential Linux utilities without significantly increasing the firmware size. Moreover, it is highly customizable. It can be configured to include only the specific utilities required for the embedded system's functionality.

However, it has associated potential security risks. BusyBox often runs with elevated privileges as various tasks require root access, hence a potential risk of privilege escalation. It also provides a variety of commands that accept user input. If these commands are not properly sanitized, it can lead to command injection [31], buffer overflow [37], and other vulnerabilities [7]. For instance, `awk` applet is used for text processing and data manipulation tasks. It can be used to do privileged read or write outside a restricted file system as it writes and reads data to and from files. Similarly, other applets may possess security risks when not configured or used correctly. Moreover, as BusyBox aims to be small and lightweight, it may lack some of the security features, or the issues might also occur because of its other external dependencies. Given its critical role in many embedded systems and its potential security risks, securing BusyBox through proper configuration, regular updates, code reviews, and security assessments are essential to maintaining the overall security and reliability of embedded Linux-based firmware.

2.2 Fuzzing

Fuzzing is one of the widely used methods for software testing. It leverages coverage feedback and aims to identify if any crash occurs, which is then analyzed to identify the vulnerabilities. Fuzzing can be described as input testing, which is semi-randomized due to the impossibility of exhaustive input testing in most cases. In vanilla fuzzing, a program input such as a variable, buffer, stream, or file is selected as the target of the fuzzing process. The fuzzing engine, also known as the fuzzer, generates input based on a set of rules or strategies, typically using some element of randomness, and feeds it to the program. The program is then executed with this input and observed for coverage information. The process is repeated with a newly generated input. This process can be repeated for as long as the analyst desires. During the execution phase, the program may crash or trigger some other error. If this occurs, the input that caused the issue is saved for later root cause analysis. This type of fuzzing is known as black-box fuzzing because the fuzzer is unaware of the program's internals. In contrast to black-box fuzzing, white-box fuzzing assumes complete knowledge of the program's internal structure. It allows input generation strategies to use techniques such as taint analysis or symbolic execution, which require understanding the program's syntax. In between white and black-box fuzzing is grey-box fuzzing, where there is only partial access to information about the program's internal state. In this approach, code coverage, which refers to the number of lines of code or basic blocks that are actually executed, is often used to direct input generation. Program code must first undergo instrumentation to gather coverage information, in which additional code is inserted into the program to act as a marker and collect runtime data.

2.2.1 AFL/AFL++

American fuzzy lop (AFL) is a coverage-guided, grey-box fuzzer that employs compile-time instrumentation and several different algorithms to efficiently fuzz programs [51]. At a high level, AFL tracks branch coverage between basic blocks (edges) for a generated input file, keeping track of all the edges that the input file yields. Whenever a new input file is created, AFL checks if it leads to previously unseen edges, saves the file, and uses it to inform future mutations. AFL uses deterministic (such as sequential bit flips and sequential addition of small and interesting integers) and nondeterministic (such as a stacked sequence of randomized operations with equal probability) mutation strategies [11]. AFL [51] has been extensively used in industry and academic research. However, the original developer ceased active development on AFL in 2017, leading to the development of a community-driven successor, AFL++, in 2019. AFL++ features new enhancements, fuzzing strategies, and performance improvements [11].

AFL++ provides detailed documentation for all its supported features. If the source code is available, the first stage involves modifying and compiling the target using the AFL++ compiler. Otherwise, when the source code is unavailable, AFL++ QEMU [3] performs internal instrumentation at runtime. The next stage is to provide the initial seed corpus for fuzzing the target, followed by the actual fuzzing stage and crash triaging.

2.3 LLM in Fuzzing

Large language models (LLMs) are known for their prowess in natural language understanding and text generation. Its primary focus has been developing AI models and technologies, such as the GPT (Generative Pre-trained Transformer) series [36], for various applications, including natural language understanding, generation, and automation. While LLM's work may not be directly related to fuzz testing, there are potential intersections between AI and security, where AI-powered tools and techniques could be used to enhance security testing practices [20], including fuzzing. AI can assist in automated test case generation, identifying patterns in code more likely to contain vulnerabilities, and analyzing code patterns, among other tasks. Some existing work leverages LLM for fuzzing. In a recent blog by Google open source security team [21], an LLM-aided fuzzing is proposed. OSS-Fuzz [14] is integrated with the LLM to assess its potential to generate new fuzz targets effectively. OSS-Fuzz's Fuzz Introspector tool identifies and sends the under-fuzzed and high-potential part of the project code to the evaluation framework. A prompt is created by the evaluation framework, which embeds project-specific information. LLM subsequently uses the prompt to write a new fuzz target. The newly generated fuzz target is shared back with the evaluation framework, which executes it and monitors for any change in the code coverage. In case of any compilation failure, it prompts the LLM to revise the fuzz target addressing the compilation failure. This comprehensive approach shows how LLMs can be harnessed to completely automate the fuzz testing process of OSS-Fuzz, contributing to its efficiency and efficacy. Other related works include ChatFuzz [17], an LLM-based fuzzer that enhances the quality of format-conforming inputs for fuzzing, and Fuzz4All [48]. This system utilizes LLM for input generation and mutation, producing diverse and realistic inputs for various programming languages. Fuzz4All mainly targets systems that accept programming languages as input. Additionally, FuzzGPT [9] uses LLM as a fuzzer to test deep-learning libraries. Similarly, as discussed in Section 4.2, our work leverages LLM to generate initial seeds for fuzzing BusyBox.

However, what sets our approach apart is that we exclusively employ LLM for the initial seed generation stage targeting embedded application, unlike other works where LLM is integrated into the entire fuzzing or mutation process. As previously discussed, fuzzers rely on initial input seeds for the target. While random seeds can be used, the performance significantly improves when the initial seeds align with the expected inputs for the target. Common initial test cases for various inputs, such as images, videos, PDFs, XML, and HTML, are readily available. However, in some cases, generating these initial seeds can be challenging. In such situations, leveraging LLM allows us to generate initial seeds simply by providing information about the target type.

3 Related Works

3.1 Command Line Fuzzing

CLI programs were the first to be subjected to what is now the fuzz testing technique with Miller et al.'s studies on the reliability of UNIX utility programs [27–29]. Miller et al. recently repeated the classic fuzz test for a number of Unix utilities on Linux, FreeBSD, and MacOS [30], demonstrating the relevance of classical fuzz testing for command line utilities even now. They used random input generation technique.

Since the original studies, fuzz testing has grown into a flourishing area of research, with CLI utilities continuing to be a major target [5, 14, 38, 51, 55, 56]. Significant improvements have been made by considering grammars to define input formatting constraints during seed generation [2, 4, 13, 45, 46], which is also relevant to fuzzing command line arguments in particular.

Song et al. [42] noted that most off-the-shelf fuzzers do not deal well with conditional option parameters and introduced CrFuzz to more efficiently explore multi-purpose programs by adding input validity prediction to existing fuzzers. Gupta et al. [15] took a different approach to enable systematic testing of command line options by defining a grammar for valid sequences of options and arguments based on the `getopt` function. Zhang et al. [53] propose ConfigFuzz, which transforms the program under test to treat configuration parameters as potential fuzzing inputs. Wang et al. [44] propose CarpetFuzz to extract command line option relationships from documentation using NLP to improve the efficiency of fuzzing different option combinations.

The introduction of LLMs is already making waves in the fuzzing community. OSS-fuzz [14, 18] has begun experiments to explore fuzzing new targets with LLMs [21]. Huang et al. [18] survey a number of LLM-based fuzzers, at least 4 of which appear to be directly applicable for CLI tools [17, 25, 48, 50]. Other works have employed LLMs for the purposes of direct input generation [49, 52], mutation [8], and seed generation [17, 25]. LLMs have also been employed to generate inputs that have irregular or unique input grammars and semantics [23, 39]. These, however, were applied to software meant for general-purpose systems, and none of these have explored the application to fuzzing in embedded environments like BusyBox.

3.2 Fuzzing in Embedded Environments

To our knowledge and upon conducting thorough research, we have found no dedicated paper addressing the topic of BusyBox fuzzing. However, there have been various blogs and articles discussing this subject. For instance, Claroty and JFrog [26] identified 14 vulnerabilities in BusyBox version 1.34.0. It's worth noting that other related works often focus on uncovering vulnerabilities in specific targets. However,

fuzz testing in Linux-based embedded systems is an active area of research.

In an early application of fuzzing in embedded systems, Sim et al. [41] applied black-box fuzzing to the Out-Of-Memory Killer process on embedded Linux, which revealed a number of failure modes that would cause the kernel to remain in the Out-Of-Memory state and unresponsive. They implemented an adaptive random approach to input generation that reduced the number of inputs necessary to expose failures.

Du et al. [10] presents AFLIoT, an on-device fuzzing framework for Linux-based IoT firmware. It involves binary-level instrumentation techniques. It leverages an AFL fuzzer. It has two phases, namely, the instrumentation and fuzzing phase. The implementation involves storing the fuzzer and the instrumented program on the device. AFL fetches the execution information of the target binary by shared memory. It sets up a shared memory before forking the target program and then maps it into its memory space. The instrumented code is responsible for keeping track of basic block transition, which AFL then analyzes to assess the value of the test case. The authors have also implemented the input redirection mechanism between the fuzzer and the target network daemon program. AFLIoT identified 437 unique crashes, out of which 95 were newly found. It was tested on 13 binary programs. The authors have evaluated both benchmarks and real-world IoT devices.

Zheng et al. [54] proposed EQUAFL, an efficient greybox fuzzing for Linux-based IoT devices using enhanced user-mode emulation. It automatically sets up the execution environment to execute embedded applications. It first executes the application under full-system emulation and observes the points where the target may crash or stuck during user-mode emulation. Then, depending on the observed information, it migrates the needed environment for user-mode emulation. It supports the replay of system calls of network and resource management behavior. The approach involves using lightweight program instrumentation to collect execution feedback of the program under test (PUT), such as code coverage, to guide the entire testing process. The authors propose to observe the dynamic configuration file generation and NVRAM configurations with process awareness, network behaviors with state awareness, and other information such as launch variables and process resource limits using several heuristics. The authors conducted experiments on several real-world IoT devices and demonstrated that their approach outperforms existing techniques regarding code coverage, vulnerability discovery, and execution time.

All the work described above has involved a significant effort to develop improved techniques for enhancing the security assessment of respective targets. Other works that involve fuzzing embedded Linux have focused on enabling effective fuzzing through emulation and or rehosting [19, 22, 43], which is an open problem on its own. Our work is intended to continue improving fuzzing techniques and strategies for embedded Linux targets by utilizing LLMs and crash reuse.

4 Experiment

In this section we outline the sample collection process, our implementation of LLM-based seed generation, using the Awk applet as an example, and our experimental procedures for crash reuse and analysis.

4.1 Analyzing BusyBox Versions in Real-World Products

As mentioned in Section 1.1, BusyBox is widely used in Linux-based embedded devices. In order to understand the scope of impact that vulnerabilities in BusyBox variants might have (RQ1), we conducted a brief investigation on the prevalence of older versions of BusyBox within real-world products. To achieve this, we harnessed a proprietary firmware dataset provided by the company. This dataset was curated using the company's platform, which was employed to extract the collected firmware samples. Within these extracted filesystems, we identified BusyBox ELF binaries. We identified `293` BusyBox ELF binaries distributed across various real-world firmware binaries within the small realm of the provided dataset.

Within the scope of our analysis, we focused on approximately 80 ELFs from ARM_32 and x86_64 architectures with 30 BusyBox variants across them. Each of these BusyBox ELF binaries possessed a unique file hash name. To extract the version information from these binaries, we devised a straightforward Python script that scours each ELF for occurrences of "BusyBox v" using the command: "`strings $busybox_file | grep 'BusyBox v'`". Additionally, we employed a regex-based version pattern-matching technique for extracting the version information. The 80 binaries identified were used as the dataset for our fuzzing experiments and crash reuse analysis.

4.2 Leveraging LLMs for Initial Seed Generation

We focus our attention on fuzzing the `awk` applet within the identified BusyBox images as our primary target due to its potential for exploitation. This applet is lightweight interpreter for the `awk` scripting language, which is often employed in embedded systems to facilitate text processing tasks such as text filtering, pattern matching, and data manipulation. `awk` scripts may process external input without proper validation, making them susceptible to script injection attacks if the input is not sanitized effectively. Vulnerabilities within these `awk` scripts can lead to unintended data manipulation or disclosure, posing significant security risks. Because `awk` takes as

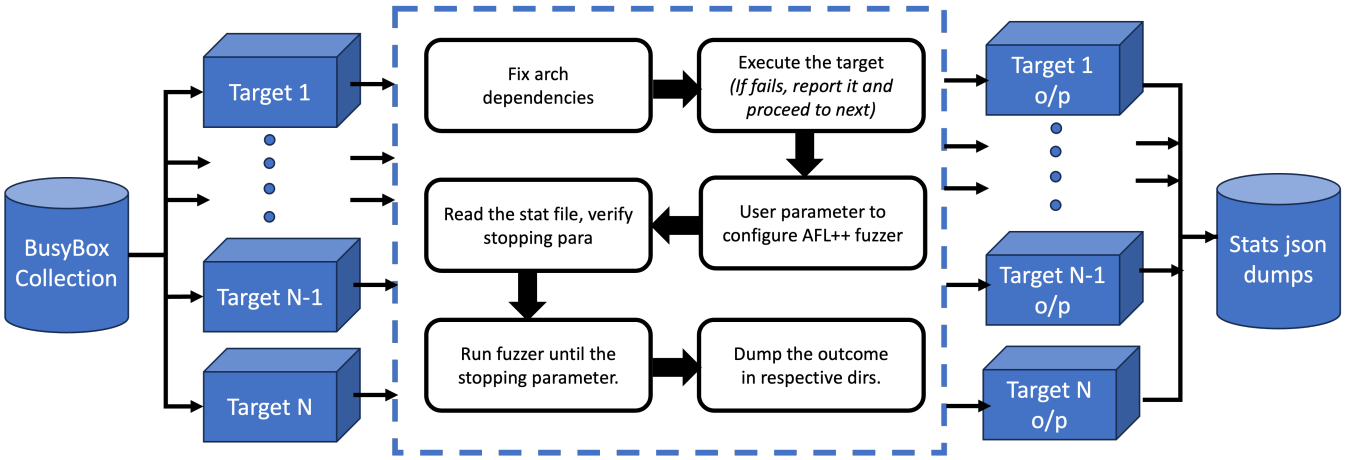

Figure 2: Automation Framework Workflow *(N.B: Target o/p contains crashes, queues along with other stats related to fuzzing)*

its input an `awk` script, which must conform to a particular language grammar, it is a natural choice of target for LLM-based seed generation, as the LLM can be utilized to easily generate conformant `awk` scripts. While the brunt of our focus was on `awk`, LLM-based seed generation is by no means limited to this target; we conduct additional experiments on other target software components to demonstrate this in Section 6.

4.2.1 Execution Environment

Binaries compiled for x86 were evaluated on Ubuntu x86_64, and ARM-based binaries were evaluated in the QEMU emulator. Notably, we encountered challenges in addressing ARM-specific dependencies, which were effectively resolved by accessing the required dependency files from the company's database. The company's platform had previously extracted the complete filesystem of the target binary, which included the requisite dependency files. This resource proved invaluable in overcoming the challenges associated with ARM target dependencies.

Fuzzer parameters are meant to be user-defined and include the initial input corpus, AFL environment variables to be set, and the fuzzer termination criteria. These criteria include statistical metrics such as runtime, the number of crashes, the number of cycles, and other relevant factors. Once the fuzzer was configured and initiated, it continuously monitored the specified criteria for termination, halting the fuzzing process upon reaching the defined conditions or in the event of catastrophic errors (conditions that cause AFL++ itself to crash). The outcomes of the fuzzing process were stored separately and categorized by their respective targets, to facilitate subsequent analysis. Failed targets were flagged for further examination and diagnosis. Additionally, JSON dumps of the statistics files corresponding to each target were collected in a shared directory, enabling easy comparison and analysis. Figure 2 provides an overview of the entire

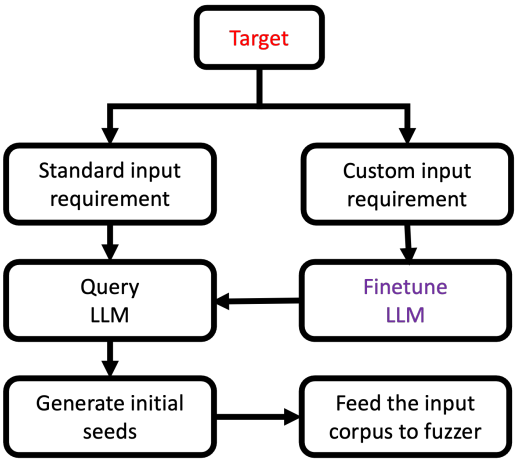

Figure 3: Initial seed generation using LLM

workflow within this framework, illustrating the sequence of steps from dependency management to fuzzing and result collection. The automation script is available at link - https://github.com/asmitaj08/FuzzingBusyBox_LLM

4.2.2 LLM-based Seed Generation Pipeline

Figure 3 visually represents our approach to generating initial seeds for fuzzing through LLM.

There are 2 scenarios under which initial seeds need to be generated: when the target input format is well-defined and/or standardized, and when the input format is loosely-defined or unknown. When the input format is well-defined, as would is the case for well-known programs like some BusyBox applets, we reason that LLM should not require additional training, as it already possesses knowledge of the expected input format through its initial training on the internet. This can also be determined empirically. However, when the input

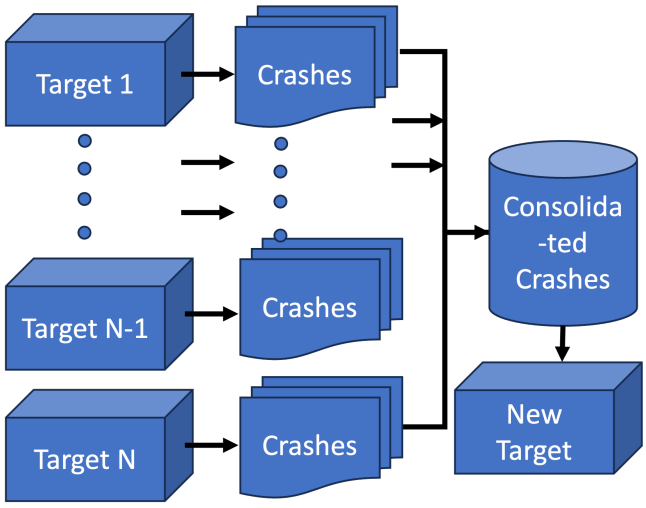

Figure 4: Testing new targets with the existing crash database.

format of the target is ill-defined or unknown, as would be the case for custom communication protocols, LLM would require fine-tuning. In this scenario, LLM needs to be initially trained with known samples to develop an understanding of the expected input format. In the case of the BusyBox `awk` applet, we reason that GPT-4 should already be aware of the input format given the applet's popularity. Hence, we did not apply fine-tuning.

For seed generation, we utilized OpenAI's GPT model "gpt-4-0613", a chat completion model with a temperature setting of 0.7 (chosen empirically), which we access via queries to the web API. We provided the following prompt to guide the seed generation process for `awk`:

"role": "system", "content": "You are initial seed generator for a fuzzer that has to fuzz BusyBox awk applet. In response only provide the list of awk scripts"
"role": "user", "content": f"Generate initial seed to fuzz BusyBox awk applet"

The model responded with a list of commands relevant to the BusyBox `awk` applet. These commands were then translated into individual `.awk` scripts, which were subsequently integrated into the input corpus. This input corpus served as the set of initial seeds for the fuzzing process. We used `afl-cmin` to minimize the input corpus before sending it to the fuzzer, which filters the LLM-generated input corpus to include only the seeds that are useful for fuzzing.

4.3 Crash Reuse

Having completed our fuzz testing runs on individual BusyBox targets, we turn our attention to triaging crashes and investigating the potential utility of crash reuse. To recap, we have hypothesized that we can leverage known crashing inputs for a given target to quickly determine if variants of that target contain a similar vulnerability or bug. As a sanity check, we first evaluate our hypothesis on our set of fuzzed targets by cross-validating the crashing inputs of each target on each other target.

Crash Reuse provides several advantages in software testing:

1. Efficiency: Initially testing the new target against the consolidated crash database offers the potential for significant time and resource savings. By capitalizing on the crashes identified during previous fuzz testing on similar targets, we can leveraging the resources previously expended in fuzzing and accelerate the fuzzer's coverage exploration by including it in future seeds. Hence, we can potentially identify previously discovered crashes in the new variant without extensive fuzz testing.

2. Black-Box Testing: This technique is highly beneficial when conducting black-box testing on new variants of a previously tested target. It is particularly advantageous in scenarios where the target utilizes accessible or open-source software components, even if further details are unavailable. By fuzzing open-source variants, we can gather crashing inputs to use as high-quality seeds that are likely to identify duplicate vulnerabilities. This is preferable to engaging in resource-intensive binary-only black-box fuzzing, which can be extremely difficult depending on the complexity of the system under test.

Figure 4 provides a visual representation of our approach to crash reuse. We actively curate a database of crashes obtained from previously fuzzed software components. Then, when we encounter variants of these software components in the future, we leverage the collected crashes to identify potential issues in the new variant under test without fuzzing. This provides us with a rapid initial assessment of the new target, which can later undergo more thorough fuzzing for in-depth inspection. As detailed in Section 6, this technique is applicable to any target whose variant has undergone previous fuzzing, and for which we possess a corresponding collection of crashes.

4.4 Evaluating a New Target

After encountering a substantial number of crashes within the collected versions of BusyBox during our research, we applied our techniques to the latest version (1.36.1); this served as an evaluation of our techniques for a new target, as we had collected no samples that contained the most recent BusyBox version. We built our target by compiling the BusyBox from its source code for x86_64, following the prescribed instructions. We opted not to inject AFL++ instrumentation into the binary.

Our approach to testing the latest BusyBox version was executed in two distinct stages to leverage both techniques effectively:

Stage 1: Crash Reuse - In this stage, we applied Technique 2, that is, crash reuse. This technique involved testing the latest version against all the previously obtained crashes from our research without subjecting it to additional fuzzing. The goal

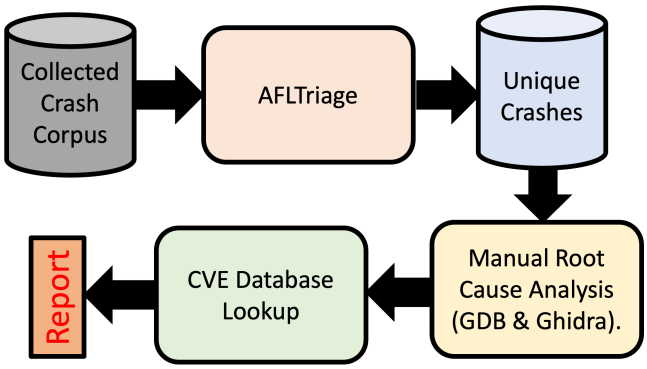

Figure 5: Crash triaging process.

was to determine whether some existing crashes can crash the latest version of BusyBox, i.e., increasing the scope of finding vulnerabilities without hours of fuzzing.

Stage 2: Fuzz Testing - In the second stage, we fuzz tested the target in AFL-QEMU mode using initial seeds generated by GPT-4 with the aim of uncovering additional potential crashes and vulnerabilities. We performed 10 hours of fuzzing on the latest BusyBox on x86_64 host machine running Ubuntu 22.04.

After our testing stages, we analyzed the collected crashes to identify unique ones, determine the underlying causes, and ascertain whether similar issues had been previously documented. To our knowledge at the time of our research, there was no fully automated tool capable of reliably and comprehensively analyzing fuzzer-induced crashes, making tool-assisted manual analysis the most reliable method of investigation. We performed our analysis using Ghidra [34], GDB (GNU Debugger) [12], and AFL-Triage [16]. We started our analysis with AFL-Triage, which utilizes GDB to triage crashing input files. It categorizes crashes based on their type and reports the debugger's output, making it easier to identify the cause of the crash. It also supports crash deduplication, thus assisting in identifying unique crashes.

Once we obtained the list of unique crashes, we analyzed the input that caused each crash and attempted to minimize it. Moreover, we conducted manual reverse engineering using Ghidra and GDB to identify the root cause. It was followed by searching the CVE (Common Vulnerabilities and Exposures) database to identify similar bugs and conducting further analysis to determine if the bug was because of BusyBox or other libraries on which it was dependent. Figure 5 shows the overview of the triaging process.

5 Results

This section provides an overview of the results obtained through the exploration of the aforementioned techniques.

5.1 BusyBox Versions in Real-World Embedded Devices

As discussed in Subsection 4.1, our first objective is to shed light on the older versions of BusyBox that are still in use within real-world embedded products. Table 1 presents an overview of the versions of BusyBox that we discovered in approximately 80 embedded products spanning various categories, including wireless access points, telecom devices, building automation systems, routers, printers, power distribution units, and others. Our findings revealed that many of these devices continue using significantly older BusyBox versions. Notably, the latest version of BusyBox, as of the time of writing this paper, is v1.36.1. However, Table 1 illustrates that many older versions are still in use. This discovery is concerning, especially given the well-documented vulnerabilities associated with these older versions.

It is important to emphasize that our investigation focused on a limited set of firmware samples. Considering the vast array of embedded devices that populate the modern landscape, this situation raises significant concerns that demand attention and remediation. In summary, the outcomes underscore the pressing need for increased awareness and action concerning the usage of outdated and vulnerable versions of BusyBox in real-world embedded devices. A similar situation could arise with other software components.

5.2 Leveraging LLMs for Initial Seed Generation

Initially, we executed the AFL++ fuzzer for 3 hours on each BusyBox AWK applet target, utilizing the default AFL++ settings in QEMU mode. This means that no AFL++ instrumentation was applied during compilation. During this phase, we recorded the number of crashes that occurred in each target as well as the number of edges identified throughout the fuzzing process. Then, as detailed in Subsection 4.2, we employed GPT-4 to generate the initial seeds. In this phase, we repeated the 3-hour fuzzing process for each target. We repeated the same metrics analysis, counting the number of crashes and edges discovered for each target.

The results from some of the ARM_32 and x86_64-based BusyBox targets are presented in Table 2. It illustrates that significantly more crashes were identified during fuzzing when the initial seeds were generated by LLM compared to the ones with random seeds. Moreover, the same pattern was observed in the case of the number of edges found during the fuzzing of each of the targets. To visually represent this, Figure 6 provides a graph displaying data from four targets, contrasting the number of edges discovered in the two scenarios, i.e., initial seeds generated by LLM versus random seeds. *Note: In the tables and figures, the term "without-LLM" signifies scenarios where random initial seeds were used, while "with-LLM" denotes cases where initial seeds were generated using*

Table 1: BusyBox versions in real-world embedded devices

LLM, and 'relative_time' is the running time of the fuzzer in seconds.

Furthermore, Figure 7 presents a Venn diagram depicting the number of unique crashes found in each case and the number of crashes common in both cases. This graphic emphasizes the importance of discovering a more significant number of crashes. When there are more crashes to work with, there are more opportunities to discover different failing execution paths, thereby increasing the likelihood of uncovering vulnerabilities. Figure 7 underscores this by revealing that more unique crashes were identified when utilizing LLM-generated initial seeds. However, comprehensive triaging was not carried out for the older versions of BusyBox, and such triaging was primarily focused on the latest version. Hence, in the discussed cases here, we conducted fuzzing, collected crashes, used AFL-Triage to categorize them, and recorded the unique crashes, notably more abundant in the LLM-generated initial seed scenarios.

Table 3: Work leveraging LLM for fuzzing

Work	**Target**	**LLM use case**
ChatAFL [25]	Protocols	Extract a machine-readable grammar for a protocol, generate diverse messages for initial seeds.
ChatFuzz [17]	Format conforming targets	Used at the mutationg stage to generated format conforming mutated inputs
Fuz4All [48]	Targets that need different programming languages as input	Generate code snippets for different programming languages
WhiteFox [50]	Compiler	Optimization source code analyzer, test input generation
Proposed Work	Embedded applications like BusyBox	Generate diverse and target-specific initial seeds.

5.3 Crash Reuse

After we had amassed a substantial number of crashes from fuzzed BusyBox targets, our total collection amounted to 4540 crashes that likely map to a much smaller place in the binary where the crash happens. Subsequently, as outlined in Subsection 4.3, we subjected the latest BusyBox version (v1.36.1) to

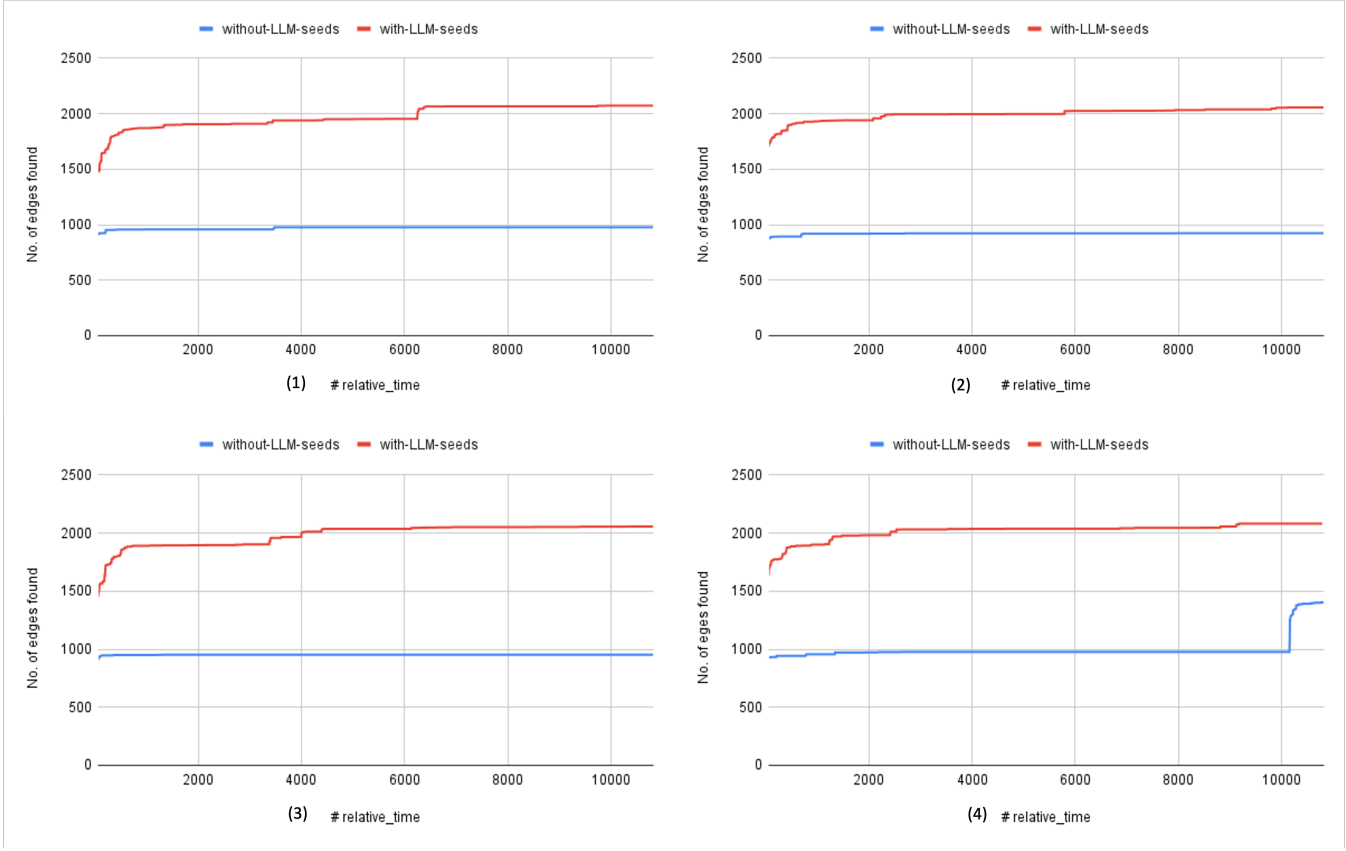

Figure 6: Comparison of number of edges covered with and without using LLM for initial seed generation. Targets are BusyBox in (1) Network controller, (2) Network switch, (3) Storage array controller, (4) Firewall

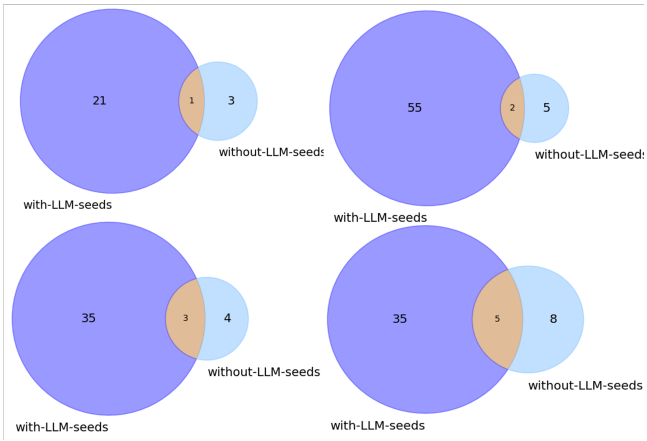

Figure 7: Comparison of number of unique crashes found with and without using LLM for initial seed generation. Targets are BusyBox in (1) Network controller, (2) Network switch, (3) Storage array controller, (4) Firewall

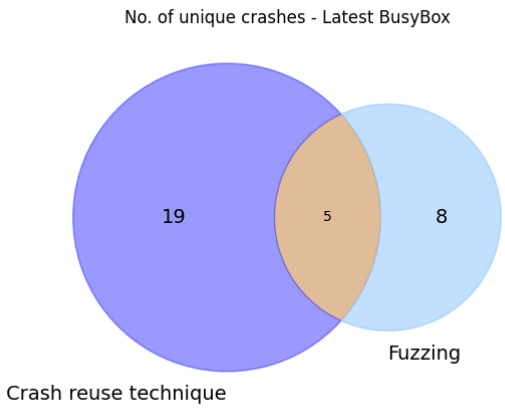

Figure 8: Comparison of number of unique crashes found using crash reuse technique vs fuzzing

testing against all these pre-existing crashes. This endeavor discovered 97 crashes in the latest BusyBox, of which 19 were unique. Later, we conducted traditional fuzzing on the latest BusyBox using AFL++ QEMU mode, with initial seeds generated by LLM over 10 hours. This approach yielded 20 crashes, of which eight were unique. Remarkably, five of these eight unique crashes were also identified using the crash reuse technique. Figure 8 presents a graphical comparison of the number of unique crashes discovered using the crash reuse technique versus traditional fuzzing, as well as the common crashes between the two methods.

These results underscore the potential utility of crash reuse in software testing. As discussed in Section 4.3, it can reduce substantial time and resource demands, and is a valuable tool for blackbox fuzzing when a comprehensive crash database is available.

Additionally, it is essential to note that not all crashes indicate software bugs. Crashes can occur for various reasons, including invalid inputs, false positives, unreachable code, execution environment factors, platform-specific issues, and other non-bug-related causes. Reaching conclusive determinations often involves meticulous manual triaging, which can be time-consuming and intricate. As such, we limited our scope to identifying crashes, with triaging performed only on a subset of crashes found in the latest BusyBox version. However, as previously discussed, the quantity of crashes is a vital metric in fuzzing. A higher number of unique crashes equates to a more extensive array of test scenarios to explore during testing. Consequently, this increases the likelihood of identifying potential software vulnerabilities or bugs.

5.4 Crash Analysis: Latest BusyBox (v1.36.1)

Following the collection of crashes for the latest BusyBox (v1.36.1) target using LLM-based seed generation and Crash Reuse, we proceeded with manual crash triaging. Due to this process's intensive time and resource commitments, we limited our triaging efforts to 15 unique crashes that resulted in segmentation faults. Crashes obtained from fuzzing can often appear disordered and incomprehensible due to data randomization through various mutation strategies during the fuzzing process. We attempted to minimize the crash size to facilitate the triaging process, making it more comprehensible.

Additionally, it is important to note that BusyBox relies on GLIBC (GNU C), which provides standard C library functions and system calls for Unix-like operating systems. During our triaging endeavor, we uncovered specific input patterns that triggered crashes in various functions within the GLIBC library. These patterns were identified by tracing the crash causes using GDB. Out of the 15 crashes we triaged, we found crashes in GLIBC functions, including `free`, `malloc`, `write`, `strlen`, `strdup`, `regex`, and `strftime`. Notably, the crashes in `regex`, and `strftime` closely resembled the known bugs documented as `CVE-2010-4051` and

```
Program received signal SIGSEGV, Segmentation fault.

```

Figure 9: Segmentation fault in regcomp

`CVE-2015-8776`, respectively. Although these CVEs were identified quite some time ago, we encountered them in GLIBC versions 2.35 and 2.38 on a host running Ubuntu 22.04, and these issues were also reproducible in Debian distributions. It highlights the persistence of these vulnerabilities across multiple software component versions, necessitating renewed attention and remediation efforts. We subsequently filed bug report for these findings; though the bugs appear to have not been considered possibly because it is same as the bug whose CVE has already been assigned. In addition to the crash input patterns chosen for triaging that triggered crashes in GLIBC, other crash inputs also induced segmentation faults within BusyBox. After manual triaging, it became apparent that many of these crashes were primarily attributed to improper memory access. We could not discover any readily exploitable bugs. Stead, we identified crash patterns that, after more in-depth exploration, could possibly reveal vulnerabilities.

5.4.1 Crash details

The analysis of crashes was done manually using GDB and Ghidra.The issue identified in `regex` was the denial of service (DoS) caused by memory exhaustion. The pattern, a long repeated character, triggered deep recursion that caused stack exhaustion, leading to a segmentation fault. The crash pattern was `/1((((.....12208 times/1`. We passed this crash pattern to Busybox (v1.36.1) awk and traced via gdb using `gdb -args busybox awk -f crash_pattern_file`. It caused *segmentation fault* as shown in Figure 9.

Having identified the segmentation fault, we inspected the register values using gdb commands followed by doing backtrace (`bt`). The outcome of `bt` showed the issue of deep recursion leading to stack exhaustion as shown in Figure 10, which can lead to denial of service (DoS). We further verified it by installing the latest version of GLIBC from the source code and confirming reproducibility. This vulnerability is nearly identical to `CVE-2010-4051`, which according to Red Hat [40] is due to a failure to consider crash of client application via regcomp. Unfortunately, even on the client side where it is used, the provided pattern is not verified. In this scenario, the pattern being sent to `regcomp()` does not get verified beforehand, as shown in Figure 11.

Using a similar approach to the one discussed above, we analyzed a number of other crashes. One of the other crashes was found in `strftime` was also DoS be-

Figure 10: Deep recursion in regcomp

cause of invalid pointer to `struct tm`. The crash pattern sent to BusyBox `awk` applet was `BEGINstrftime("", "333333333333333333")`, leading to a segmentation fault caused by `__strftime_internal()`, as shown in Figure 12. Similar to the case of `regcomp`, `strftime` is being called within BusyBox, but the the input parameters being sent to it is not being verified beforehand, leading to DoS. Other crashes that were analyzed had resulted from abnormal patterns in the crash input and therefore could not be conclusively identified as software bugs.

6 Applicability of proposed techniques

The initial proof of concept targeted the BusyBox `awk` applet. This section extends the application of the proposed technique to other BusyBox applets found in various older versions used in real-world embedded products, as detailed in Table 1. The fuzzing process, conducted over 48 hours. Apart from the number of crashes, we also examined the number of covered edges (as shown for the `awk` applet in Figure 6) and the total number of executions. This assessment involved testing on the `dc`, `man`, and `ash` applets along with `awk`.

Figure 13 illustrates variations in number of crash detected across different targets. Notably, using LLM-generated initial seeds led to a substantial increase in crashes for certain cases like `awk`, while for `dc` and `man`, crashes were decently higher with LLM-generated seeds. For the `ash` applet, we conducted fuzzing for 5 hours due to utility execution constraints. As a minimized version of `bash`, `ash` executes shell commands. However, abnormal behavior during fuzzing, triggered by diverse shell inputs, led to the cessation of the process. Consequently, we opted for a shorter testing duration. This pattern also extends to edge coverage performance as shown in Figure 14, with some cases showing higher performance and others exhibiting negligible differences. Furthermore, when considering the number of executions as shown in Figure 15, it is evident that LLM-based generated seeds do not introduce significant overhead in most cases.

The LLM-based technique for generating initial seeds plays a supportive role in the fuzzing process, contributing quality and diverse seeds that enhance fuzzing performance. However, it is crucial to note that this technique alone is not the sole factor influencing the overall outcome. Various associated factors, contingent upon the specific target, must be considered. The effectiveness is contingent upon the target type and the extent to which the initially provided diverse inputs contribute to code coverage.

The primary function of LLM in this proposed technique is to assist in producing high-quality and diversified initial seeds, thereby potentially enhancing fuzzing performance. The seed generation using LLM requires initial manual intervention to validate if the generated seeds align with the target's requirements. In the case of a new target initially unknown to LLM, model training is essential for the target-specific seed format. However, this represents an initial, one-time effort; once the model learns the required seed format, it expedites the generation of diverse seeds suitable as potential initial seeds for fuzzing. Thus, we can leverage the knowledge base of LLM models, or train these models according to different target requirement. Therefore, this technique is not restricted to the BusyBox and can be adapted for use with different targets.

Similarly, the crash reuse technique proposed can be extended to various software components across different targets. The technique isn't limited to a particular target but applies universally. It can be employed in any scenario where we have previously gathered crash data by fuzzing a target and aim to test the variant of that target by reusing those crashes. For instance, following the collection of crashes from the tested samples of the `dc` applet, akin to the approach outlined in Section 4.3 for the `awk` applet, we reused these crashes to test other BusyBox samples. These samples included different versions and architectures. We had a total of 2112 crashes from previously tested samples that were ARM-based BusyBox targets. We reused these crashes to test if they could cause crashes in BusyBox v1.36.1, which is x86-based. Out of 2112 crashes, 853 caused segmentation faults in this new target, with 313 being unique occurrences. Thus, using this technique, we identified the possibility of crashes in a new target even without performing actual fuzzing on it. Due to limited time, we didn't delve deeply into these crash exploration paths. The primary goal is to convey that the crash reuse technique could be beneficial for the initial screening of a new variant of a software component without spending hours on fuzzing. However, this technique may not uncover all the vulnerabilities requiring fuzzing for a thorough analysis.

While crash replay has been established for analyzing

crashes in previously fuzzed targets, there is limited existing research on collecting crashes and reusing them to test variant of the software components present in different targets. For instance, different products may incorporate different versions of BusyBox. This distinction becomes crucial in the context of embedded systems, where common third-party software components like BusyBox are frequently shared. However, these components may differ in version numbers, architectures, or compilation optimizations.

The crash reuse becomes particularly advantageous when we have access to the open-source version of specific software components or libraries. By conducting fuzzing on these components, we can generate potential crashes. Given our access to the source code, the likelihood of identifying these crashes is higher. Now, let's consider a scenario where the same software component is internally used in a product for which we only have access to the binary, not the source code. Although we are aware that it internally employs the software component, there is a possibility that its version number differs, or it has been customized by the developer, or compiled for a different architecture. In such cases, where we have already collected crashes for the known software component, we can employ this crash-reuse technique as an initial screening to test for the presence of vulnerabilities in the given product.

As illustrated in Figure 1, our work introduces a novel pipeline employing two techniques. In this pipeline, LLM-generated initial seeds (technique1) assists in enhancing fuzzing and acquiring crashes for the target under test. Subsequently, the obtained crashes are collected and reused (technique2) to test a new target with similar software components.

7 Discussion

In our pursuit to enhance existing software testing methodologies, we emphasize the significance of our proposed techniques, particularly within the context of embedded systems. Firmware in embedded systems often consists of numerous third-party software components with custom implementations and unique input types, making it predominantly a black-box testing scenario. The techniques introduced in this work, namely leveraging LLM for initial seed generation and crash reuse, have exhibited promising outcomes that can significantly aid software testing efforts. While these techniques can be adapted for various targets as discussed in Section 6, we have used them to analyze BusyBox for the proof of concept.

To evaluate our results, we established the AFL++ fuzzer's output as our baseline and compared outcomes between AFL++ provided with random initial seeds versus LLM-generated initial seeds. Despite extensive research leveraging Large Language Models (LLM) for fuzzing, as discussed in Section 3 and exemplified by studies like [18], we have not encountered prior work applying LLM to real-world embedded devices running applications like BusyBox. Table 3 illustrates various studies leveraging LLM for different targets, making direct comparisons unfeasible.

Similarly, regarding the crash reuse technique, we haven't identified any work collecting and reusing crashes to test similar software components on a different target, as depicted in Figure 4. Earlier methodologies, like reFuzz [24], focused on reusing crashes and outputs within the same target during

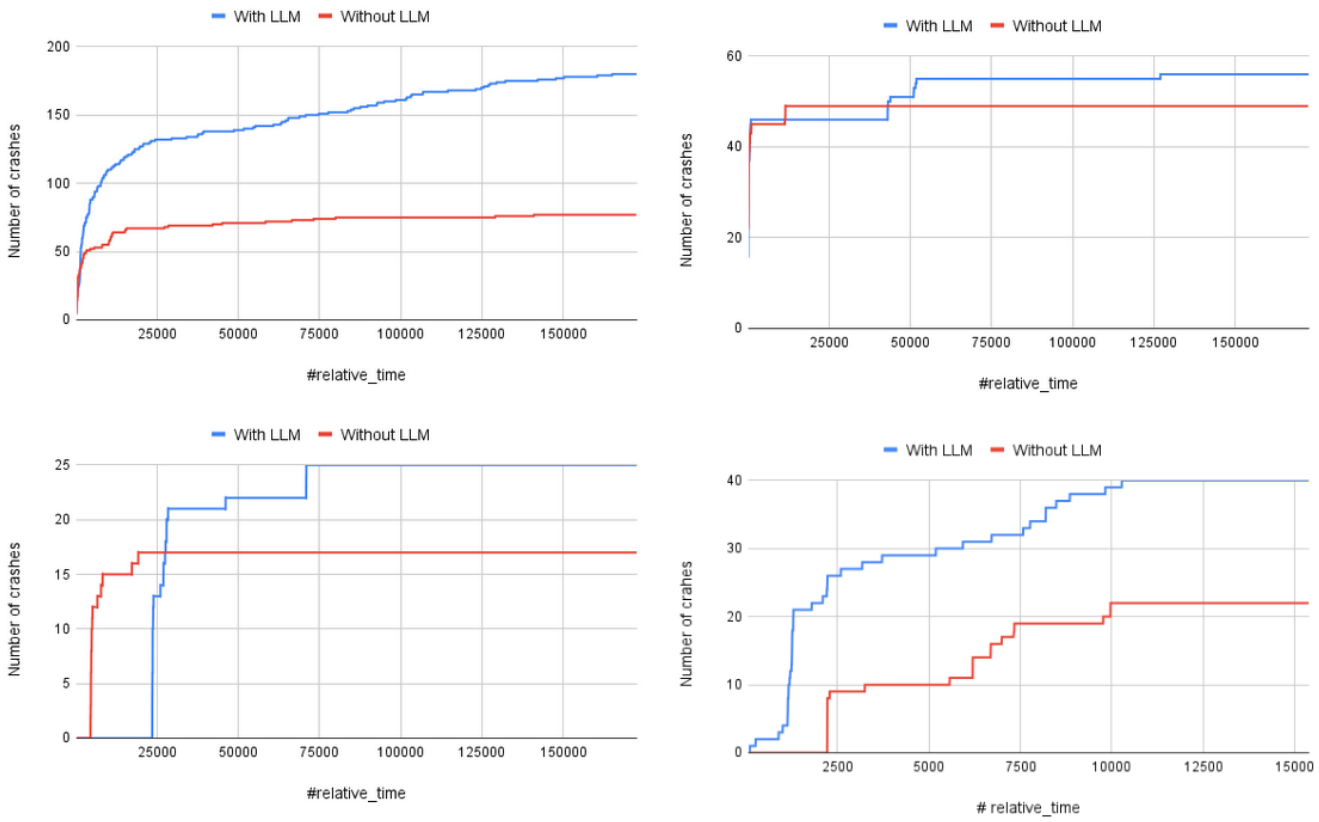

Figure 13: Number of crashes with vs without LLM based initial seeds. The graphs are for applet `awk`, `dc`, `man`, `ash` clockwise.

different stages of fuzzing. AFL also provides a feature to resume the fuzzer, leveraging previous crashes and queue information to enhance fuzzing outcomes on the same target. Crashes are typically employed for replay during the analysis process. Therefore, for comparison purposes, we set the baseline as identifying the number of crashes directly using fuzzing versus testing the target against the crashes collected from fuzzing the variant of that target previously, as illustrated in Figure 8

Nevertheless, it is essential to acknowledge certain limitations and challenges associated with these approaches. Utilizing LLM for initial seed generation may necessitate a significant initial effort, mainly when dealing with different targets, especially in the complex domain of embedded systems where a wide array of hardware protocols and custom input patterns are encountered. Furthermore, while the crash reuse technique represents a valuable first pass phase, it may not consistently identify all bugs, especially zero-day vulnerabilities. Hence, a traditional fuzzing technique remains a necessary complement for comprehensive testing. The crash reuse method primarily assists in determining whether previously identified crashes are applicable to a new target but does not guarantee the discovery of all potential bugs. Furthermore, there is a prospect for utilizing LLM to generate high-quality crashes by training the model for specific targets using previously identified crashes. We explored the feasibility of fine-tuning LLM by providing sets of crashes corresponding to respective target categories. We aimed to ascertain whether LLM could generate test cases capable of inducing crashes in the new target. However, this undertaking introduced specific challenges, primarily related to data encoding. LLM requires data to be JSON-encoded, and managing data that cannot be UTF-8 encoded proved to be intricate. This challenge is particularly pertinent, as some crash test cases may involve data types that are not UTF-8 encoded.

In summary, while there are particular challenges and limitations, substantial research potential exists for harnessing these techniques to enhance and assist software testing endeavors. These approaches hold promise for improving the efficiency and effectiveness of testing procedures, particularly in the context of embedded systems and firmware analysis.

8 Future Work

This work opens up opportunities for further research by extending the application of LLM and crash-reuse techniques to a broader range of targets within embedded firmware. We plan to implement these techniques on various other targets, encom-

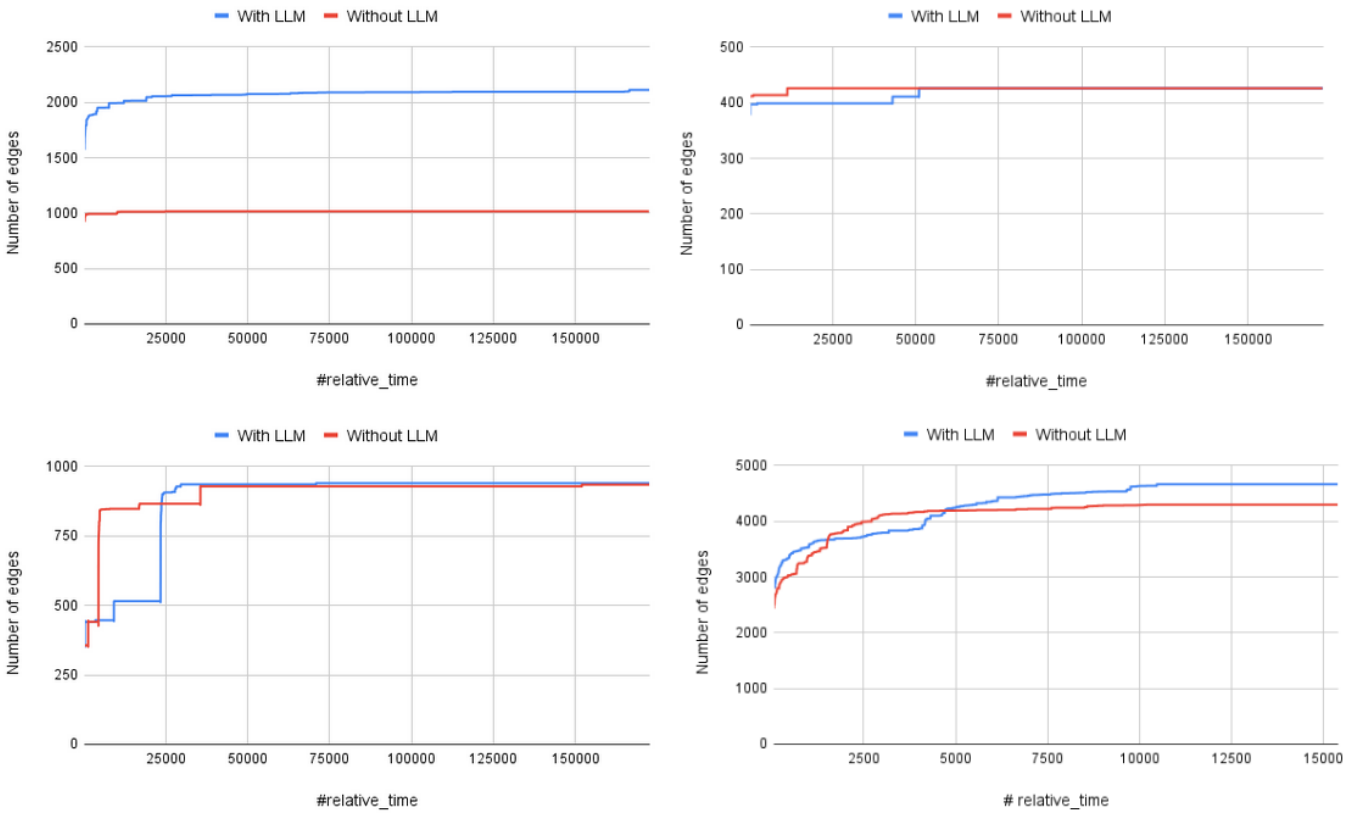

Figure 14: Number of edges covered with vs without LLM based initial seeds. The graphs are for applet `awk`, `dc`, `man`, `ash` clockwise.

passing application-level targets like web servers, network-related components, and bare-metal embedded targets that interact with hardware and IoT protocols. Training LLM to understand the input structures of protocols such as I2C, SPI, UART, MQTT, Bluetooth, and others could greatly enhance fuzz testing for these devices. Security testing for embedded targets presents numerous challenges [32], and incorporating these techniques could be invaluable.

Furthermore, many embedded targets lack access to source code, and in some cases, internal details are undisclosed. In such scenarios, the crash reuse technique can be a valuable resource. By testing unknown targets against existing crashes and evaluating whether any input can cause the target to crash, these techniques can significantly improve the state of security testing for firmware. We are dedicated to exploring these techniques further and leveraging their potential to enhance security testing for a wide range of embedded devices in the future.

9 Conclusion

In conclusion, our exploration into BusyBox, driven by its extensive presence in Linux-based embedded devices, has yielded valuable insights and introduced techniques to enhance the software testing process. Our initial investigation revealed the prevalence of older versions of BusyBox in real-world embedded devices, prompting us to delve further into the analysis. This exploration led to the developing of two techniques to bolster software testing efforts. First is, leveraging LLM for initial seed generation. This technique significantly improved the outcome of fuzzing by enhancing the number of identified crashes, offering a more comprehensive and effective testing approach. Second is, crash reuse technique. We leveraged previously obtained crashes in older versions of BusyBox to assess their applicability to the newer version. This approach proved successful when applied to the latest version of BusyBox, saving time and resources in the testing process.

Subsequently, we delved into the analysis, identifying unique crashes using AFLTriage and conducting manual crash triaging using GDB and Ghidra on 15 of these unique crashes. Our triaging efforts uncovered crashes that triggered issues within the GLIBC library, a critical dependency for BusyBox. These issues bore a resemblance to previously documented CVEs, underscoring the persistent nature of these vulnerabilities across different versions of GLIBC. While the exploitability of the crashes found in BusyBox could not be conclusively determined due to time constraints, our exploration of Busy-

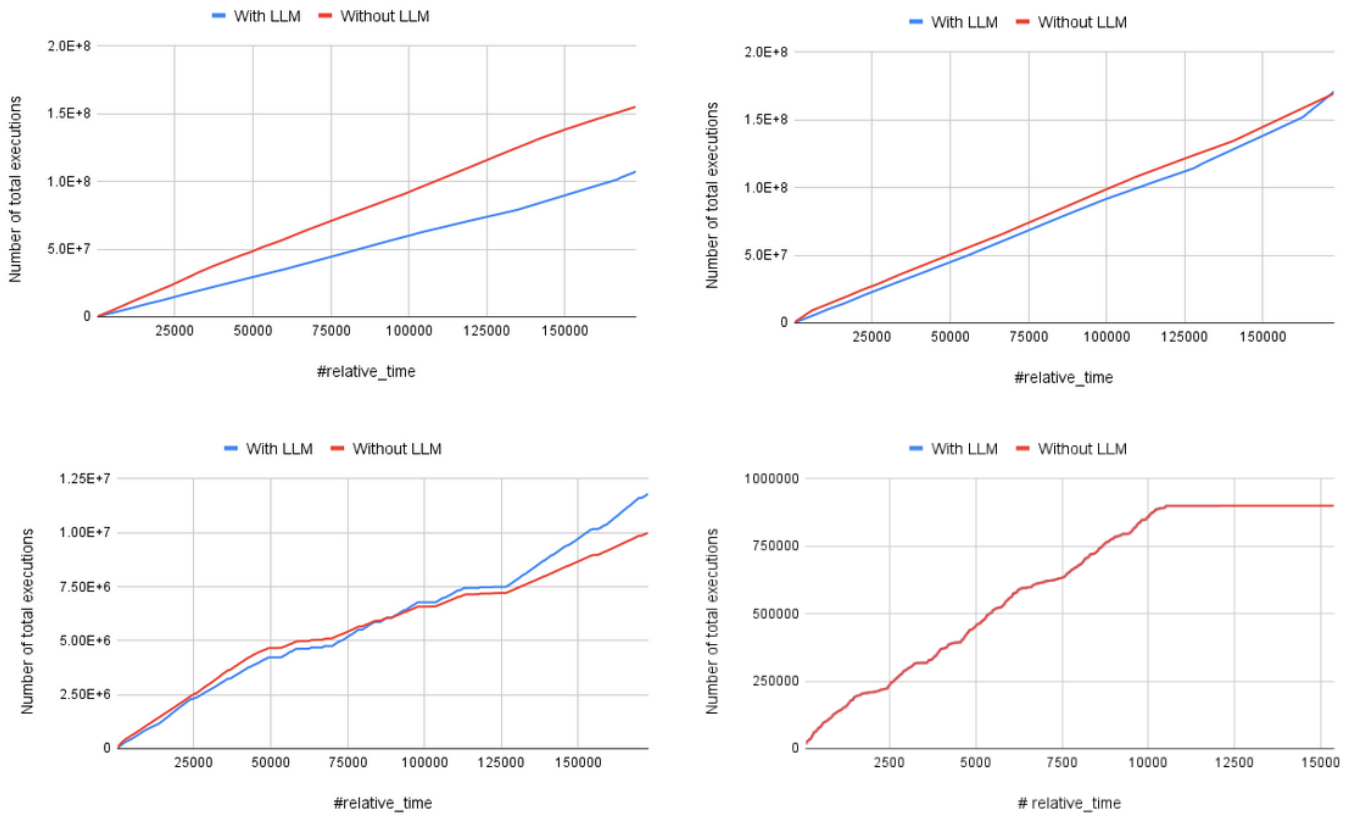

Figure 15: Number of executions with vs without LLM based initial seeds. The graphs are for applet `awk`, `dc`, `man`, `ash` clockwise.

Box has illuminated techniques with significant potential to benefit software testing in various domains. The findings from this research not only shed light on the security landscape of BusyBox but also open the door to further research and advancements in software testing methodologies.Moreover, as discussed in Section 6, the proposed techniques could be applied to targets other than BusyBox.

Acknowledgment

We would like to acknowledge NetRise team for providing us with real-world embedded firmware database and cloud resource to perform a part of these experiments. We would also like to thank NSF CHEST for funding this project *(Project # 1916741 industry funding)*.

Towards Generic Database Management System Fuzzing

Yupeng Yang[†], Yongheng Chen[†], Rui Zhong[⋆], Jizhou Chen[†], Wenke Lee[†]
[†]*Georgia Institute of Technology* [⋆]*Palo Alto Networks*

Abstract

Database Management Systems play an indispensable role in modern cyberspace. While multiple fuzzing frameworks have been proposed in recent years to test relational (SQL) DBMSs to improve their security, non-relational (NoSQL) DBMSs have yet to experience the same scrutiny and lack an effective testing solution in general. In this work, we identify three limitations of existing approaches when extended to fuzz the DBMSs effectively in general: being non-generic, using static constraints, and generating loose data dependencies. Then, we propose effective solutions to address these limitations. We implement our solutions into an end-to-end fuzzing framework, BUZZBEE, which can effectively fuzz both relational and non-relational DBMSs. BUZZBEE successfully discovered 40 vulnerabilities in eight DBMSs of four different data models, of which 25 have been fixed with 4 new CVEs assigned. In our evaluation, BUZZBEE outperforms state-of-the-art generic fuzzers by up to 177% in terms of code coverage and discovers 30x more bugs than the second-best fuzzer for non-relational DBMSs, while achieving comparable results with specialized SQL fuzzers for the relational counterpart.

1 Introduction

Database Management Systems (DBMSs) play an indispensable role in ensuring effective and efficient data storage, retrieval, and management in modern cyberspace. The landscape of DBMSs has evolved significantly, with the emergence of both relational (SQL) and non-relational (NoSQL) databases catering to the diverse requirements of various application domains [13, 16]. While relational DBMSs have been extensively studied and employed for decades, non-relational DBMSs such as key-value DBMS, document DBMS, and graph DBMS have gained widespread adoption more recently due to their flexibility and performance advantages in handling large-scale, unstructured data. Considering the prevalence and criticality of these systems, it is paramount to strengthen the security and robustness of the diverse DBMSs.

Fuzzing, an automated software testing method that injects random data as inputs to software, has proven useful in uncovering faults in DBMSs. However, there exists a disparity in the extent of fuzzing efforts directed towards non-relational DBMSs compared to their relational counterparts. Fuzzing frameworks and research related to relational DBMSs [27, 28, 43, 44, 49, 56] have been developed and advanced extensively over the years, contributing to more secure and trustworthy systems in the relational DBMS venue. In contrast, non-relational DBMSs have not experienced the same level of scrutiny. State-of-the-art generic fuzzing frameworks such as [4, 7, 9, 14, 30, 54] all show non-promising fuzzing performances when applied to non-relational DBMSs because they cannot generate test cases that trigger DBMS behaviors effectively. There is a need for an effective solution capable of testing both relational and non-relational DBMSs.

However, multiple challenges exist when designing a fuzzer that extends to non-relational DBMSs. First, *it is hard to generalize.* The interfaces of non-relational DBMSs are diverse, accepting inputs ranging from key-value command sequences [40, 45], JSON documents [2, 33] to graph patterns represented in ASCII-art forms [5, 35, 41]. The diversity of the interfaces presents a unique challenge in designing a generic framework that handles the diverse types of DBMS interfaces effectively, because the semantics of the interfaces can vary drastically across different DBMS categories, putting us in a dilemma between promoting test case quality and maintaining the fuzzer's generalizability. Second, *semantics can change based on the context.* For example, in the graph query language `Cypher` used by many graph DBMSs, one syntax structure can either define some data or use some data, depending on the syntactic context. Also, in the key-value DBMS `redis`, the type of some keys depends on the value specified in the context. For many non-relational DBMSs, failure to model such semantics leads to semantically incorrect test cases and can hardly reach deep logic. Existing methods used by relational DBMS fuzzers cannot scale to non-relational DBMSs in general because they do not consider the semantics based on contexts. Third, *random mutations tend to generate*

loose data dependencies, triggering less effective behaviors. Some fuzzers employ coverage as feedback, but the mutation process is still random and can waste time generating test cases triggering less effective behaviors, taking longer time to discover new coverage. We observe that data dependency plays an important role in effective DBMS fuzzing. Without data dependency, even semantically correct test cases can demonstrate less effective behaviors. For example, a test case that creates the same data 100 times does not trigger more behaviors of the DBMS than a test case that first creates the data once and then reads the data, even though they are both semantically correct.

In this work, we systematically analyze these challenges and propose three solutions, namely, *semantics abstraction, context-sensitive constraint resolution, and dependency-guided mutation*. Then, we implement the solutions into an end-to-end fuzzing framework, BUZZBEE, which can effectively fuzz both relational and non-relational DBMSs in general. To solve the first challenge, BUZZBEE models the DBMS semantics at a highly abstract level where the semantic differences are neutralized. To solve the second challenge, BUZZBEE incorporates an advanced annotation system, through which users can easily specify simple and expressive semantics based on the context for different DBMSs. Finally, to solve the third challenge, BUZZBEE performs novel principled mutations utilizing data dependencies as guidance, generating useful test cases more efficiently.

We implement BUZZBEE with 9,130 lines of code in C++ and Python, and apply it to 8 DBMSs, including relational DBMSs and three types of mainstream non-relational DBMSs: key-value DBMS, graph DBMS, and document DBMS. We evaluate BUZZBEE on the DBMSs and find 40 vulnerabilities, of which 25 have been fixed, and 4 new CVEs have been assigned. We also compare BUZZBEE with six state-of-the-art fuzzing frameworks. BUZZBEE achieves up to 177% performance in finding new program states and finds 30x more bugs when compared with the second-best generic fuzzer.

In summary, we make the following contributions:

- We systematically analyze the challenges for fuzzing the diverse DBMS interfaces, including relational and non-relational ones. We propose novel solutions that effectively tackle them.
- We implement a prototype of our solutions into an end-to-end fuzzing framework: BUZZBEE, enabling effective fuzzing for both relational and non-relational DBMSs.
- We perform extensive evaluations for BUZZBEE on eight mainstream DBMSs of four data models. BUZZBEE has identified 40 bugs in the DBMSs we tested on.

We release the source code of BUZZBEE at https://github.com/OMH4ck/BuzzBee.

2 Problem

In this section, we first briefly discuss the diversity of DBMS interfaces and how they handle user requests in general. Then, we show the challenges and limitations of existing fuzzers when applied to the various kinds of DBMS interfaces. Next, we analyze these unique challenges and present our insights in tackling them. Finally, we introduce our novel approaches and framework design for solving the problem.

2.1 Diverse DBMS Interfaces

DBMSs handle user requests by exposing different kinds of interfaces to the users. DBMSs with distinct data models demonstrate significant variations in their interfaces. Relational DBMSs [11, 12, 36, 39] often accept inputs in *Structured Query Language (SQL)*, through which the user can manipulate the data stored within the database. Meanwhile, non-relational DBMSs [2, 5, 33, 40, 41, 45] have more diverse interfaces, which are associated with a wide variety of non-relational data models. They accept various input formats, including command sequences, JSON documents, and even ASCII-art. Based on how user inputs are processed, we divide these interfaces into two main categories: *query-based interfaces* and *command-based interfaces*. Query-based interfaces accept user inputs in the form of a query language. For example, *SQL* and *Cypher* [35] are the domain-specific languages used to interact with relational and some graph DBMSs respectively. Such inputs go through a parser and a query planner before hitting the query execution stage [8]. The parser checks the syntax validity of the query, filtering out syntax invalid inputs. The planner verifies the semantics of the query and performs analysis to generate an optimized query execution plan. Any input that fails to pass the parser or the query planner will most likely fail to trigger deep logic inside the target DBMS. Command-based interfaces accept a series of commands from the user and evaluate them in sequence. Although these commands are typically executed independently, meaning that an error in executing one command is unlikely to abort the remaining commands, command sequences with semantic errors or inadequate semantic dependency may still trigger fewer effective behaviors.

2.2 Existing Challenges and Limitations

In this section, we discuss three limitations of current approaches in fuzzing the diverse DBMS interfaces.

Non-generic. As discussed in §2.1, the test case quality is important for DBMS testing. However, the variety of DBMS interfaces complicates the creation of a fuzzing framework that can generate high-quality test cases and remain easily adaptable to different DBMS interfaces. Current research has made significant advancements in relational DBMS testing [27, 28, 43, 44, 49, 56]. `SQLsmith` [44] generates ran-

```
1 // Partial grammar rules:
2 createtbl_stmt:
3    'CREATE TABLE'
4    tbl_name '('
5        ...
6    ')';
7
8 // The test case:
9 > CREATE TABLE t1(
10     c1 date
11 );
12
13
14 // Bind "TABLE define"
15 // to `tbl_name`.
16
17 // When we traverse to the
18 // node `t1`, we know a
19 // TABLE t1 is defined.
```

Fig. 1: Static Constraint Examples. Example test cases illustrating the problem of static constraints. While using static constraint sufficiently models the semantics in Fig. 1a, it does not correctly model the scope constraints in Fig. 1b and the type constraints in Fig. 1c.

dom SQL queries according to predefined schema information about certain SQL DBMSs. SQUIRREL [56] and later works [27, 28] advance by introducing an intermediate representation (IR) that effectively incorporates SQL syntax and semantics, allowing it to adapt to multiple SQL databases. However, these frameworks still require non-trivial adoption efforts to support a new relational DBMS, as mentioned in [49]. Moreover, they either have not supported non-relational DBMS, or inherently cannot support them due to the model design. Considering the wide use of non-relational DBMSs, we lack a generic solution that enables efficient testing for the diverse DBMS interfaces.

Static Constraints. Mutation-based fuzzing has proven successful in fuzzing modern software. However, for DBMS fuzzing, mutations can easily break the semantic correctness of the test case. Recent studies [27, 28, 56] highlight the significance of maintaining the semantic correctness of the test cases in mutation-based DBMS fuzzing. In this work, we use *constraints* to represent the semantic rules the test case should obey to avoid a DBMS execution error. This includes *scope constraints* and *type constraints*. Scope constraints restrict where a variable is available for use. This is often enforced through data operations such as define, use, and invalidate. Type constraints further restrict the legitimate type of the variable in the data operations. To model the constraints, the approach used by existing fuzzing frameworks [9, 27, 28, 56] is

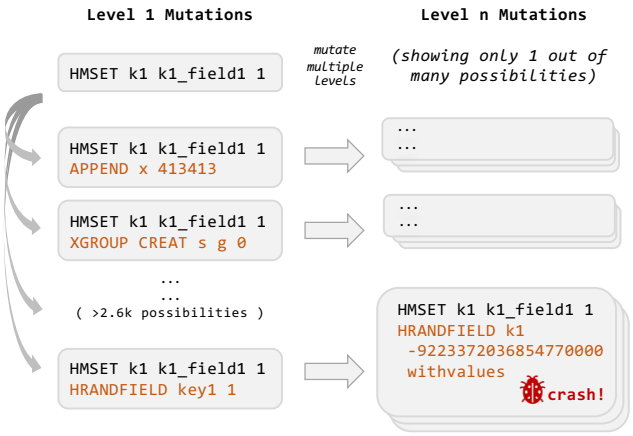

Fig. 2: Random Mutation Running Examples. This figure shows a demo fuzzer we made for testing `redis`. When performing random mutations, the level 1 mutations contain many possibilities that cannot form a data dependency with the initial command, which consequently affects the fuzzing performance at later mutation levels.

first to parse the test case using the target's grammar specification, and then bind a static constraint to a particular syntactic structure, *i.e.*, an AST node. However, in the case of fuzzing diverse DBMS interfaces, we observe that many constraints should not stay static, but should adapt to various contexts, such as the node's position in the AST, the existence of other nodes in the AST, the text of literal nodes, etc.

We first illustrate the problem of static scope constraints. We show the grammar for the `"CREATE TABLE"` statement in `PostgreSQL` in lines 2-6 of Fig. 1a. A static approach binds the constraint "TABLE define" to the AST node `"tbl_name"`, and enforces this constraint during the traversal of the AST. Here, this approach is sufficient for modeling the semantics. However, consider the `MATCH` clause in the graph DBMS interfacing language `Cypher`. The grammar is shown in lines 2-12 of Fig. 1b. Lines 15-16 show a `Cypher` query that first defines a variable `n` (*i.e.*, `"(n:L)"`), and then uses the variable in the path pattern (*i.e.*, `"(n)->[]->()"`). Here, we cannot bind the constraint "variable define" to the `identifier` AST node, because both occurrences of `n` are of the `identifier` type. Binding the constraint "variable define" to the `identifier` AST node would result in both `n` treated as "variable define". In fact, when an `identifier` is in the subtree of a `pattern_part` node, it means "variable define". And when it is in the subtree of a `where_part` node, it means "variable use". Binding a static scope constraint to any node cannot correctly model this semantics.

We next show the problem of static type constraints. Consider the `redis` commands shown in Fig. 1c. In `redis`, users can use the `HINCRBY` command to increase the value of a field in a set created by `HSET`. However, if the field does not contain a numeric value, the `HINCRBY` command bails out. Consequently, the `HINCRBY` command at line 4 fails to trigger the value increasing logic because it tries to operate on `k1_field1`,

a field pre-defined but storing a value of an ASCII string instead of a numeric string. Adopting the existing approach, we can only let the AST node of `k1` yield type `"HSET key"`, and let the node of `k1_field1` yield type `"HSET field"`, losing the information that the value implicitly says `k1_field1` is an ASCII string instead of a numeric string. Here, using a static type constraint without looking at the values (*i.e.*, literals `"Hello" and "123"`) loses vital information to model the semantics correctly.

Loose Data Dependencies. Existing mutation-based DBMS fuzzers [27, 28, 56] perform mutations randomly and rely on code coverage to explore more program behaviors. However, we observe that random mutations can waste huge efforts in fuzzing non-relational DBMSs, because they tend to generate loose data dependencies that trigger thin and less effective behaviors. The issue becomes significant when the database interface contains many operations that are **not** *dependency-affiliative*, which are common cases in non-relational DBMSs such as `redis`. We define two operations as dependency-affiliative when they can form a data dependency. We observe that test cases triggering deep logic require dependency-affiliative operations often. For instance, a test case containing two "Create key of type A" operations does not trigger more behaviors than a test case containing one "Create key of type A" operation and one "Delete key of type A" operation that deletes the created key. In this case, the latter two commands can form a data dependency and trigger deeper logic.

Fig. 1c shows a real-world example for `redis`. The second `HSET` command is not dependency-affiliative with the first `HSET` command because they cannot form any data dependency. In contrast, the `HINCRBY` command at line 5 is dependency-affiliative with the first two `HSET` commands since it can use the data defined by them, *i.e.*, `k1`, `k1_field1`, `k2`, and `k2_field1`. To demonstrate the ineffectiveness of random mutation, we implement a fuzzer for `redis` that randomly mutates the test cases by either inserting new commands or mutating existing commands' arguments randomly. Fig. 2 illustrates the mutation process. We randomly sample 2643 commands from `redis`'s official test suite as the mutation source by sampling at most 30 commands from each command type. The commands are deduplicated when they are identical (*i.e.*, sharing the same type and arguments). The fuzzer starts with an initial test case `"HMSET k1 k1_field1 1"`. In the first round of mutation (level 1), the fuzzer inserts a new command below `HMSET`. At this level, there are 2643 candidates available for insertion. However, only around 5.86% (155 / 2643) of them are dependency-affiliative with `HMSET`, which can use the variable `k1` defined by `HMSET`. All other mutations (around 94.14% of the total) are less effective because they cannot utilize existing data (*i.e.*, they either operate on a different data type, or do not contain any data operations at all), and thus inserting them into the test case contributes little to exploring deeper logics. One of the CVEs found by BUZZBEE (shown in Fig. 2) lies within the code that processes the `HRANDFIELD` command, which needs a data dependency to trigger. It is more difficult for a random fuzzer to find such bugs.

2.3 Our Insights and Solutions

In this section, we describe our insights and approaches to solving the aforementioned challenges. We first propose *Semantics Abstraction* to support modeling the diverse semantics of DBMS interfaces. Next, we utilize *Context-sensitive Constraint Resolution* to support general context-sensitive constraints. These two solutions help to achieve generalizability and improve the test case semantic correctness. Finally, we design *Dependency-guided Mutation* to tackle the challenges faced by random mutation, which helps to reduce wasted efforts and achieve better fuzzing efficiency.

Semantics Abstraction. To support fuzzing the diverse DBMS interfaces, we propose to abstract the semantics to a point where most semantic differences are neutralized. To achieve this goal, we first describe common DBMS operations at a highly abstract level using only three basic data operations: *Define*, *Use*, and *Invalidate*, which in turn defines a symbol, uses or updates a symbol, and deletes a symbol. We then use *constraints* to constrain the highly abstract semantics, such as specifying when to *Define* or *Use*, the type of the symbol that is *Defined*, or the type that a *Use* can take, etc. Inspired by existing works [27, 28, 56], we design an IR to incorporate both the syntactic structures and the abstract semantics of the inputs. Afterward, we design an *Annotation System* for users to specify the semantic constraints. Following this way, we neutralize the semantic differences across diverse DBMS interfaces and stay generic.

Context-sensitive Constraint Resolution. To avoid the problem of static constraints, we enable dynamic context-based constraints with *Context-sensitive Constraint Resolution*. Specifically, we craft two additional features for the *Annotation System*, through which users can specify the constraints based on the context. To achieve simplicity, we design a lightweight domain-specific language (DSL) for the users to query common context information with minimum effort. To achieve expressiveness, we expose an interface for users to write complex semantic rules based on the context. Together, they give users the opportunity to customize context-sensitive rules easily and effectively.

Dependency-guided Mutation. To avoid generating test cases of loose data dependencies, we propose *Dependency-guided Mutation*. Specifically, the mutator prioritizes mutations that can form new data dependencies by favoring operations that are dependency-affiliative with the data existing in the context. For instance, when mutating a test case that creates some data in the DBMS, the mutator favors inserting an operation that reads the created data, instead of an operation that creates the data again or operations doing nothing related to the created data. Through dependency-guided mutation,

we can reduce the redundant efforts and minimize the time wasted by the fuzzer, achieving better fuzzing efficiency.

3 Overview of BUZZBEE

We incorporate the proposed solutions into an end-to-end fuzzing framework named BUZZBEE. Shown in Fig. 3 is an overview of BUZZBEE. Overall, BUZZBEE takes as input the corpus (*i.e.*, initial test cases) and input specs (*i.e.*, the annotation file and grammar file) of the target DBMS interface. Afterward, it performs mutation on the test cases and uses the mutated test cases to test the target DBMS. Guided by coverage feedback, BUZZBEE continuously tries to discover test cases covering new program states and outputs the ones triggering bugs along the process. Specifically, the user provides the grammar file to describe the syntax and the annotation file to constrain the abstract semantics of the target DBMS interface. Next, BUZZBEE conducts semantic analysis and performs principled mutations using data dependencies as the guidance. Lastly, BUZZBEE validates the semantics by fixing the errors introduced by mutation and generates new test cases for testing the DBMS.

In the next sections, we discuss in detail how the components of BUZZBEE are designed and how they collaborate together to support *Generalizability* §4, *Context-sensitive Constraints* §5, and *Principled Mutation* §6, which address the three aforementioned challenges respectively.

4 Generalization

Mutation can easily break the semantic correctness of a test case, as mentioned in many related works [27, 56]. BUZZBEE uses the abstract semantic model to check for the semantic correctness of the mutated test case. Similar to existing works, when BUZZBEE detects semantic errors, it tries to fix them before sending them to the fuzzing runtime. In this section, we discuss in detail how BUZZBEE stands out by modeling the semantics of the various DBMS interfaces at a highly abstract level to neutralize their differences.

BUZZBEE abstracts the DBMS interface semantics with three basic data operations: *Define*, *Use*, and *Invalidate*. Each operation is associated with a data type and name.

Define. *Define* represents data creation. For instance, in Fig. 1c, the first `redis` command `HSET` *Defines* data `k1` with type `"HSET key"`, and `k1_field1` of type `"HSET field of k1"`. Similarly, in Fig. 1a, the `PostgreSQL` query `CREATE TABLE` *Defines* two data: `t1` of type `table`, and `c1` of type `"col_of_t1"` meaning it's a column of `t1`. Notice that these data can have subordination relations, *e.g.*, `k1_field1` is subordinate to `k1`, meaning it cannot exist without `k1`. The same applies to `t1` and `c1`. Such relations can be modeled through our DSL *Context Query Language (CQL)*, and *Custom Resolvers*, which we will detail later. The general idea is that we put concrete symbol names in the type of the data, *e.g.*, the type of `k1_field` is `"HSET field of k1"`, which contains the concrete symbol name `k1`, meaning that `k1_field` is affiliated to `k1`.

Use. *Use* represents data access and update operations on already *Defined* data. For example, the `HINCRBY` commands at lines 4 and 8 in Fig. 1c *Use* data `k1`, `k1_field1`, `k2`, and `k2_field1` which are *Defined* by the two `HSET` commands. *Use* of un-*Defined* data is considered a semantic error.

Invalidate. *Invalidate* represents data deletion operations on already *Defined* data. Once data is *Invalidated*, it cannot be *Used* again. Notice that data deletion should honor the subordination relations. For instance, in Fig. 1c, if we uncomment the `DEL` command at line 7, it will delete `k2`. Since `k2_field1` has a subordination relation with `k2`, `k2_field1` should also be deleted. Similarly, in Fig. 1a, if we delete table `t1`, its column `c1` should also be deleted. After an *Invalidate* operation, any *Use* of already *Invalidated* data will become a semantic error. Consequently, if we uncomment the `DEL` command at line 7 in Fig. 1c, line 8 will yield two semantic errors, since `k2` and `k2_field1` are both invalidated.

We design an IR to carry both the syntactic and semantic information specified by the user. Inspired by existing works [27, 28, 56], BUZZBEE's IR is a tree structure with a one-to-one mapping to the abstract syntax tree of the original test case. Besides, the IR captures the abstract semantics specified by the user. This allows us to conveniently lift the original test case into the IR, perform semantic analysis, mutations, and validations on the IR in a unified fashion, and compile the IR back to a new test case for fuzzing. We detail the structure of the IR in Fig. 8.

5 Semantics Constraining

After BUZZBEE models the DBMS interfaces at a high level, it uses constraints to further express richer semantics. In this section, we introduce how BUZZBEE enforces flexible yet lightweight context-sensitive semantic constraints for different DBMS interfaces. Overall, BUZZBEE first uses the *Annotation System* powered by *CQL* and *Custom Resolvers* to accept customized semantics information from the user for different DBMS interfaces. Then, the *Semantics Analyzer* of BUZZBEE analyzes the (mutated) test cases according to the user-specified semantics information and get the semantics of the test cases. Having the semantics of the test cases, the *Semantics Validator* enforces the specified semantic constraints of the test cases, before sending them to the fuzzing runtime.

5.1 Annotation System

To handle different semantics across different DBMS interfaces, we design the *Annotation System* to let the user annotate the semantics of a target DBMS within our abstract

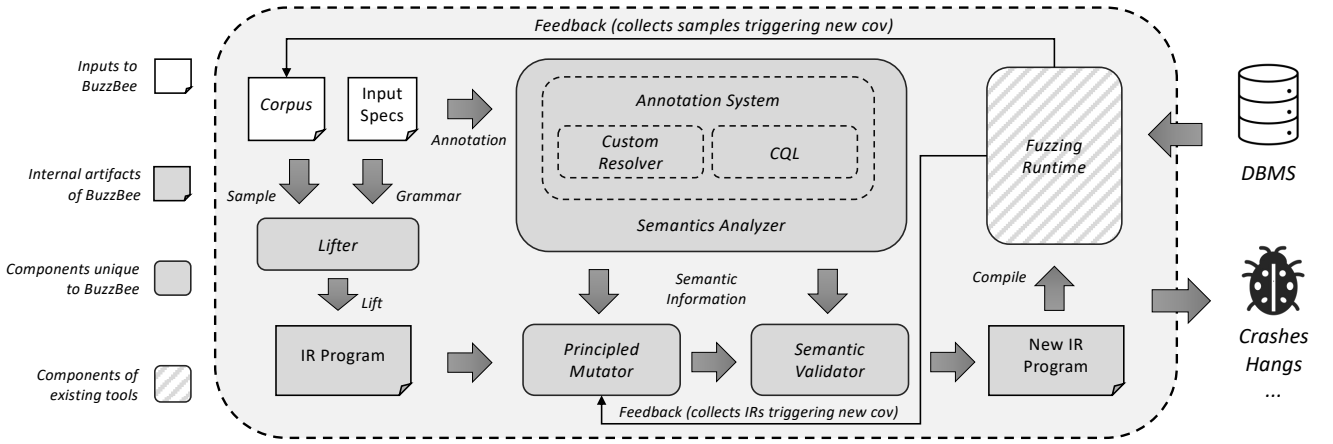

Fig.3: Overview of BUZZBEE. BUZZBEE takes as input the corpus and input specs, performs advanced semantic analysis and mutations with semantics validation on the input, and uses the mutated input to test the target DBMS.

semantic model.We design the *Annotation System* with two objectives in mind: simplicity and expressiveness. Simplicity ensures that the system is lightweight, intuitive, and easy to use so that it can apply to many DBMS interfaces with ease, while expressiveness allows it to convey complex semantics effectively. Generally, the system allows the user to annotate the basic semantic properties of a certain AST node. That is, whether this node *Defines*, *Uses*, or *Invalidates* a certain symbol, and how such semantics will relate to the context of the input. To achieve the first objective, we design *CQL*, a lightweight domain-specific language that can be used to query various context information when resolving semantic constraints. Next, to achieve the second objective, BUZZBEE exposes an interface to the user, allowing the user to design *Custom Resolvers* capable of describing arbitrarily complex rules to resolve the semantic constraints. Shown in Fig. 4 are concrete artifact examples involved in the annotating process. Next, we show through this figure how the system distills the semantic information provided by the user.

Grammar Tags. For the user to directly assign semantics to an AST node, BUZZBEE uses grammar tags to correlate the syntactic structures and the semantic information through the grammar rules. Specifically, we use a markup language that allows the user to tag the elements inside the grammar rules, which will be parsed into AST nodes. Afterward, the user can write specific semantics for tagged AST nodes in an annotation file. Fig. 4b shows the partial grammar rules for `redis` that are tagged with the markup language. For demonstration simplicity, we use circled numbers to represent tagged rule elements. For example, `key` at line 2 of Fig. 4b is tagged with ①. Then, in lines 1-4 of the annotations shown in Fig. 4d, we specify specific semantics for ①, which maps to the element `key` under the grammar rule `hset`. After parsing, this corresponds to an AST node `key` under a parent AST node `hset`. With grammar tags, BUZZBEE can effectively correlate the semantic information with the AST nodes of the input, allowing the user to conveniently annotate the semantic properties directly through the grammar.

Annotation. The annotation consists of multiple entries. Each entry describes the semantics of a specific tagged syntax node and contains the following fields:

- `operation`: decides which abstract operation to perform.
- `args`: provide the arguments specific to the operation.

For scope constraints, `operation` specifies the abstract semantic operation to perform, *i.e.*, *Define*, *Use*, or *Invalidate*. An annotation entry can have multiple operations that should be selected under different contexts. For type constraints, we can use `args` to specify the data type of an operation, *e.g.*, what type a node *Defines* or should *Use*.

The unique aspect of our design is that all the constraints can be dynamically resolved based on the context, including deciding which operation to perform based on the context, and how to resolve the arguments (*e.g.*, types) of an operation based on the context. This is crucial to our solution to the second challenge described in §2.3. It enables BUZZBEE to enforce context-sensitive constraint resolution on the input. Next, we introduce how BUZZBEE achieves this through *Context Query Language* and *Custom Resolver*, which are designed to achieve simplicity and expressiveness respectively.

Context Query Language. To resolve a constraint based on the context, we need to be able to fetch information from the context. To fetch certain information from the context, we need to know *where* to fetch and *what* to fetch. The former specifies which part of the context we care about, and the latter states what property of that part we are interested in. For example, in line 5 of Fig. 4a, to resolve the data type of `k1_field1`, which is `"HSET numeric field of k1"`, we need to know the text (*what*) of its left-side node (*where*), which is `k1`. This is to specify that we can only use an `"HSET numeric field"` that belongs to `k1`. We develop a lightweight query language for BUZZBEE, *Context Query Language (CQL)*, that can be used directly in the operation arguments to query such context information. We attach the grammar for *CQL* in Fig. 9. *CQL* offers *navigator* and *property* for specifying *where* and

```
HSET k1 k1_field1 "Hello"
HSET k2 k2_field1 "123"
HSET k3 k3_field1 "456"
// DEL k1
HINCRBY k1 k1_field1 1
```

(a) Example commands for `redis`.

```
hset:
    HSET key① (field② value)+;

hincrby:
    HINCRBY key③ field④ increment;

del:
    DEL key⑤;

cmd:
    hset | hincrby | del ;

cmds:
    cmd ('\n' cmd)*;

testcase:
    cmds⑥;
```

(b) Partial grammar rules for `redis`.

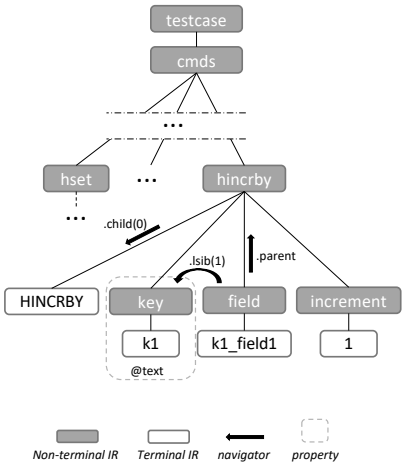
```
...
node_pattern:
  '(' identifier① ')';
...
```

(c) Partial grammar rules for `Cypher`.

```
①: "default": {
      operation: Define,
      args: { type: "HSET key" }
}

②: "default": {
      operation: Define,
      args: {
        type:
            hset_field_type_resolver
      }
}

③: "default": {
      operation: Use,
      args: { type: "HSET key" }
}



④: "default": {
      operation: Use,
      args: {
        type: "HSET numeric field
               of {.lsib(1)@text}"
      }
}

⑤: "default": {
      operation: Invalidate,
      args: { type: ANY }
}
```

(d) Partial annotations for the tags in (b).

```
①: {
    "selector": ident_selector_resolver,
    "operation_0": { operation: Define, ...},
    "operation_1": { operation: Use, ... }
}
```

(e) Partial annotations for the tags in (c).

(f) CQL on the IR program.

Fig. 4: ***Annotation System Internals.*** The circled numbers represent tags to specific syntax structures. *Annotation System* uses these tags to track which syntax nodes should be assigned which semantics.

what. Generally, we can use *navigator* to navigate to the target node, and then use *property* to specify what information to query. For the previous example of resolving the field's type for the `HSET` command, we annotate the `type` argument of ④ as `"HSET numeric field of {.lsib(1)@text}"`. BUZZBEE will dynamically resolve this type by first evaluating the *CQL* query within the curly braces, and then formatting the evaluated value into the type string. During *CQL* evaluation, the *navigator* performs relative addressing from the current node. Fig. 4f shows a running example of how *CQL* is evaluated on the IR program for Fig. 4a. The evaluation for `{.lsib(1)@text}` starts from the IR node `field` tagged by ④. Then it uses the *navigator* `".lsib(1)"` to reach the left first sibling node: `key`, and finally uses the *property* `@text` to retrieve the source code text of `key`, which is `"k1"`. Thus, this *CQL* evaluates to `"k1"`, and the argument will resolve to `"HSET numeric field of k1"`. We show some other *navigators* in Fig. 4f, including `.parent` which navigates to the parent IR node, `.child` which navigates to a child node, etc. When stacked together, *navigators* can be used to reach any node within the IR program to query any part of the context. We also predefine several frequently used *properties* such as `@id` to retrieve the IR node's id when creating a scope, `@sym_type` to retrieve the symbol type for enforcing type coherence, etc.

With *CQL*, users can directly put dynamic, context-dependent values in the argument of the operations. Annotating with *CQL* is intuitive and easy thanks to its simple design and direct integration into the arguments. However, *CQL* is designed to handle common context-sensitive type constraints, and it is limited in expressiveness because both *navigator* and *property* are hard-coded elements in the grammar and can convey only limited semantics. For instance, *CQL* currently does not support conditional behaviors, and is hard to use for selecting the appropriate operation when a node has multiple operations (context-sensitive scope constraints). We solve this by *Custom Resolvers*, which can resolve more complex semantics for different DBMS interfaces.

Custom Resolver. To support more complex semantics, BUZZBEE exposes an application interface to the user, allowing the user to customize programmatically how to resolve a constraint (*e.g.*, the operation to perform, the type to use) through *Custom Resolvers*. *Custom Resolvers* can be written in high-level programming languages like C++ and act as plugins to the annotation system. Within a *Custom Resolver*, users can access all the context information visible to BUZZBEE and customize the resolution rules as needed. Specifically, BUZZBEE passes all the context information (*e.g.*, symbol tables, the IRNodes in the program) to a *Custom Resolver*, and then waits for it to return a resolved value.

For instance, to resolve the type constraint of the field in the `HSET` command at line 1 of Fig. 4a, we annotate

② with the name of a custom resolver we implement, `hset_field_type_resolver`, at line 8 of Fig. 4d. With access to the context information, this custom resolver first goes to the right first sibling of the `field` node, which is `value` that contains the string of the field. Then, it checks if the string is a numeric string, which is false. Next, to follow the subordination rule, it goes to the left first sibling of the `field` node, which is the key associated with this field, and obtains the text of the key: `k1`. And finally, it returns "`HSET field of` **`k1`**". This resolution is complex since we need to check whether the value is a numeric string or not. Similarly, this *Custom Resolver* resolves the type of `k2_field1` at line 2 as "`HSET` **`numeric`** `field of` **`k2`**", since "`123`" is a numeric string.

Moreover, *Custom Resolvers* can easily support context-sensitive scope constraints by returning the appropriate `operation` to select based on customized rules. For instance, for the example previously mentioned in Fig. 1b, we tag the `identifier` node with ①, as shown in Fig. 4c, and annotate it with multiple operations, as shown in Fig. 4e. Then, we implement a *Custom Resolver* `ident_selector_resolver` as the selector that returns "`operation_0`" or "`operation_1`" or NULL based on the context. Specifically, in `ident_selector_resolver`, we return "`operation_0`" when detecting that the current IRNode is in the subtree of an IRNode of type `pattern_part`, *i.e.*, this node should *Define* a variable. We return "`operation_1`" when detecting the node is in the subtree of a `where_part`, resolving the scope constraint to a *Use*. We return `NULL` for other cases to signal no matching operation. Then, BUZZBEE selects the operation based on the value returned.

BUZZBEE also maintains local states for each test case and allows all the *Custom Resolvers* to access the states. This provides the opportunity for modeling stateful semantics.

Regardless of its complexity, the customized rules will eventually resolve a value plugged into the *Annotation System*, allowing BUZZBEE to manage the semantics within its abstract model.

5.2 Semantic Analysis and Validation

Semantics Analyzer is the component that checks for semantic correctness within our abstract semantic model, according to the user-specified constraints. To check the semantics, the analyzer performs an *Execution Simulation* on the IR program, which executes the abstract semantic operations in the IR program, following the correct order.

The analyzer achieves this through two analysis stages: the *Dependency Analysis* stage, which tries to figure out the correct execution order, and the *Execution Simulation* stage, which executes the semantic operations.

Dependency Analysis. BUZZBEE first performs a dependency analysis on the IR program before executing any operations. It goes over every operation, gathers the contexts each operation depends on, and constructs a dependency graph accordingly. Next, it performs topological sorting on the graph to rank all the IR nodes in the IR program. When two IR nodes do not have any dependency relation, BUZZBEE ranks them according to their sequence in the preorder traversal of the IR program. In this way, the dependency analysis can output a safe and correct execution order the IR nodes in the IR program, which will be followed in the execution simulation.

Execution Simulation. Once the correct execution order is determined, BUZZBEE performs execution simulation by executing the semantic operations. That is, for the operation *Define*, BUZZBEE tries to define a symbol of the specified `type` and `name` in the current scope. For *Use*, it tries to find a symbol in the scope tree that matches the specified `type` and `name` and then use it. And for *Invalidate*, it does the same thing as *Use*, plus invalidating the symbol so that it cannot be used again. During this process, the semantics analyzer evaluates the *CQL* queries used in the operation arguments, and invokes the *Custom Resolvers* if they are specified to resolve certain values. Meanwhile, symbol re-*Define*, *Use* before *Define*, or *Use* after *Invalidate* will all be considered semantic errors. Moreover, if the context an operation depends on contains semantic errors, this operation will also be set as a semantic error. BUZZBEE maintains symbol tables and scope trees to track successfully executed operations (*i.e.*, operations with no semantic errors). Finally, the semantics analyzer returns all the symbol and scope information, along with the semantic errors as the analysis result.

Lastly, the *Semantics Validator* tries to fix the semantic errors in the test case before BUZZBEE sends it to the DBMS. For *Use* before *Define*, *Use* after *Invalidate* errors, it finds another available data to use. For re-*Define* errors, it tries to define the data with an undefined name. When the validator fails to fix the errors, BUZZBEE drops the test case.

6 Principled Mutation

As discussed in §2.3, with dependency-guided mutation, we can reduce the redundant efforts and minimize the time wasted by the fuzzer, thus achieving better fuzzing efficiency. The way BUZZBEE abstracts the semantics naturally enables dependency-guided mutation as a principled mutation strategy. Overall, the principled mutator takes a lifted IR program as input. Then, it queries the dependency information about the IR program from the semantics analyzer, and then performs guided mutations accordingly, as illustrated in Fig. 3.

Specifically, the mutator asks the semantics analyzer to perform semantic analysis on the IR program. It then retrieves the symbol and scope information, *i.e.*, what symbols are defined at which locations and scopes. Then, the mutator performs correctness-preserving syntax mutation, which are mutations that will not break the syntax correctness, including

Table 1: Lines of code for a breakdown of BUZZBEE, summing up to 9,130 lines. As we integrate with AFL++, for Fuzzing Runtime, we only count the code that we add into AFL++.

Module	Language	LOC
Semantics Analyzer	C++	4,966
Semantics Validator	C++	214
Lifter Generator	Python	823
Principled Mutator	C++	1,961
Fuzzing Runtime	C++	185
Other Utilities	C++	981
Total	C++/Python	**9,130**

replacing a node A in the IR program with another node B of the same IR type from the IR pool (node replacing), inserting a node B from the IR pool into the IR program (node insertion), and removing a node in the IR program (node deletion). Here, the IR pool is where the mutator collects the unique IR nodes it has seen triggering new coverage in the DBMS. Additionally, the mutator adds guidance to these mutations. For node replacing, it will first get the symbols $s_i \in S$ that are available at A, where S are symbols *Defined* but not yet *Invalidated* before A. Then, when randomly selecting B from the IR pool, BUZZBEE favors B containing IRs tagged with actions *Use* or *Invalidate* whose type can match the type of any $s_i \in S$. This is because such B can form a dependency relation with existing symbols in the test case, and thus can often trigger deeper program states. Node insertion follows the same logic to find the B for insertion. We do not design guidance for node deletion at the moment.

Moreover, to cover more behaviors, BUZZBEE prioritizes the candidates of B, based on whether the candidate already exists in the test case or not. For instance, in Fig. 4a, assume `HINCRBY` and `DEL` are the only two `redis` commands that contain actions *Use* and *Invalidate* for the data defined by `HSET`. Then, at line 4, BUZZBEE prioritizes inserting `DEL` over inserting another `HINCRBY`, because there is already an `HINCRBY` at line 5. This is achieved by assigning weights to the semantic actions. If an action appears more times in the current test case, it gets assigned a lower weight. BUZZBEE randomly selects an action based on its weight, and searches for B from the IR pool containing this action. Eventually, the number of different actions in the mutated test case (*e.g.*, `DEL` and `HINCRBY`) will be uniformly distributed, covering more behaviors.

In conclusion, BUZZBEE uses the knowledge readily available in the annotation system to guide the mutation prior to the input's execution in the fuzzing runtime, favoring dependency-affiliative mutations and driving the mutation towards discovering deeper program states more efficiently.

7 Implementation

We implement a prototype of BUZZBEE with 9,130 lines of code mainly in C++ and Python. Table 1 shows the breakdown of the major components. We implement the Lifter Generator to generate the lifter that lifts the input into BUZZBEE's IR. The generator takes as input an ANTLR4 [1] grammar and a JSON annotation file. We pick ANTLR4 in our implementation because there already exists many ANTLR4 grammars for various DBMS interfaces on the Internet. The annotation is implemented as a separate JSON file, which maps to the tagged rules in the grammar file. We build the Fuzzing Runtime of BUZZBEE on top of AFL++ [14]. Specifically, BUZZBEE, which focuses on generating high-quality test cases, integrates itself into AFL++ as a *Custom Mutator*, allowing it to inherit AFL++'s well-tested instrumentation module, execution module, feedback collection module, etc.

8 Evaluation

We evaluate BUZZBEE to answer the following questions:

- Can BUZZBEE apply to the diverse DBMS interfaces (generalizability and portability)?
- Can BUZZBEE find real-world bugs and vulnerabilities (effectiveness)?
- How does each proposed solution contribute to the performance of BUZZBEE?
- How does BUZZBEE compare to state-of-the-art tools?

8.1 Environment Setup

Hardware. We perform all our evaluations on a machine that runs Ubuntu 22.04.2 LTS with two AMD EPYC 7452 32-core Processors and 1,024GB RAM.

Benchmark. We evaluate BUZZBEE on three types of mainstream non-relational DBMSs (*i.e.*, key-value, graph, document DBMSs) and relational DBMSs (*i.e.*, SQL DBMSs). We choose the targets based on their popularity and choose C/C++ targets because the current fuzzing runtime (AFL++) best supports them. Table 5 shows the DBMSs we evaluate BUZZBEE on. Specifically, we choose `redis` and `KeyDB` from the key-value category, `RedisGraph` and `AgensGraph` from the graph category, `MongoDB` and `ArangoDB` from the document category, and `PostgreSQL` and `MySQL` from the relational category.

For real-world bug-hunting evaluation, we evaluate BUZZBEE on the latest release version or the dev branch of the chosen targets. We then perform a comprehensive evaluation of the effectiveness of the proposed solutions in terms of semantic correctness, code coverage, and bug detection capability on four targets, namely `redis`, `ArangoDB`, `RedisGraph`, and `PostgreSQL`. We choose them over the other four DBMSs because they demonstrate higher fuzzing stability and cover all four categories we evaluate. We also compare BUZZBEE with state-of-the-art tools. We compare BUZZBEE with general-purpose fuzzers that support all four DBMS categories: AFL++ [14], REDQUEEN [4], POLYGLOT [9], and Grammarinator [22], to understand BUZZBEE's generalizability and effectiveness. We then compare BUZZBEE with

Table 2: Adoption effort for each target. Doc means we collect the grammar by preprocessing the DBMS's documentation. Exist means there already exists an ANTLR4 grammar for that DBMS interface online. Annotation size is the total number of lines in the JSON file, CQL and Custom Resolvers.

DBMS	Corpus	Grammar	Annotation Size
`redis`	Test Suite	Doc	496
`KeyDB`	Test Suite	Doc	100
`ArangoDB`	Test Suite	Exist	82
`PostgreSQL`	SQUIRREL-repo	Exist	71
`MySQL`	SQUIRREL-repo	Exist	71
`RedisGraph`	Test Suite	Exist	69
`MongoDB`	Test Suite	Doc	51
`AgensGraph`	ANTLR4-repo	Exist	42
Average			123

well-established SQL fuzzers SQUIRREL and SQLANCER to further understand BUZZBEE's ability to handle relational targets. Some fuzzers do not support certain DBMSs and we detail this information in Table 6. For all the fuzzers we evaluate, we feed them with the same input (if they need one) and constrain the computing power to one CPU core. For bug detection evaluations, we roll back the DBMSs to the versions where all bugs remain unfixed. We run each experiment for 24 hours, repeat five times, and report the average results.

8.2 Generalizability and Portability

We apply BUZZBEE to eight real-world DBMSs to understand its generalizability and portability in terms of adoption effort. We collect the grammar and input corpus for each DBMS interface from publically available sources such as official documentation pages, GitHub repositories, or other fuzzers' open-sourced artifacts. Afterward, we manually add the annotation for each DBMS interface. Table 2 shows a breakdown of the artifact details we collect for BUZZBEE. The average number of lines in the annotation artifacts is 123. Thanks to BUZZBEE's highly abstract semantic modeling, most parts of the annotation are simple semantics such as "Node *A* in the grammar *Defines* symbol *s*", and "Node *B* can *Use* symbol *s*", which is easy and intuitive to write by a human analyst. Having familiarity with each DBMS as an average DBMS user, it takes us less than one hour on average to draft a 100-line annotation for a target. We show in later evaluations that spending such little adoption effort is enough for BUZZBEE to achieve a great fuzzing performance.

> In conclusion, BUZZBEE demonstrates great generalizability for major DBMS interfaces, and the adoption effort is reasonable for major DBMS interface categories, demonstrating decent portability.

```
GRAPH.QUERY g "WITH 1 AS x MATCH (m),(n) WITH * ORDER BY m \
  SKIP 0 LIMIT 90 WHERE m = 0 RETURN 0"

HRANDFIELD set1 -3 WITHVALUES
```

(c) Assertion Failure in `redis`

Fig. 5: Case studies. Three bugs found by BUZZBEE demonstrate how BUZZBEE's ability to maintain constraints helps find real-world bugs. The examples are manually reduced for demonstration.

8.3 Real-world Bug Hunting

BUZZBEE finds bugs in all eight DBMSs of the four DBMS categories we have tested. BUZZBEE finds bugs in the latest versions of the DBMSs except for `PostgreSQL`. We present the full bug list in Table 7 in the appendix. As of writing, BUZZBEE has discovered 40 bugs in the latest DBMSs, out of which 38 are confirmed by the vendors, 25 are fixed, and 4 are assigned new CVE IDs. BUZZBEE has yet to discover bugs in the latest `PostgreSQL`. In fact, no fuzzers we evaluate can find bugs in the latest `PostgreSQL` using well-tested corpus in our experiment, including SQL-specialized fuzzers SQUIRREL and SQLANCER. Rolling `PostgreSQL` back to a legacy version, BUZZBEE finds a known bug (ID 37).

Next, we conduct case studies of three fixed bugs found by BUZZBEE to understand its capabilities further. We have manually minimized the test cases for demonstration.

Case Study A. Fig. 5a shows a graph query that crashes the `RedisGraph` server v2.10.8 by triggering a runtime assertion failure. The crash originates in the function that handles star projection (*i.e.*, the `"WITH *"` part). However, to trigger this bug, a correct data dependency needs to be satisfied. Here, if we change the variable `m` in `"ORDER by m"` to an undefined variable (*e.g.*, `v0`), the server returns "(error) v0 not defined" and does not crash. Through the annotation system, BUZZBEE recognizes the defined variables `m` and `n` and maintains the correct data dependency, eventually finding this bug.

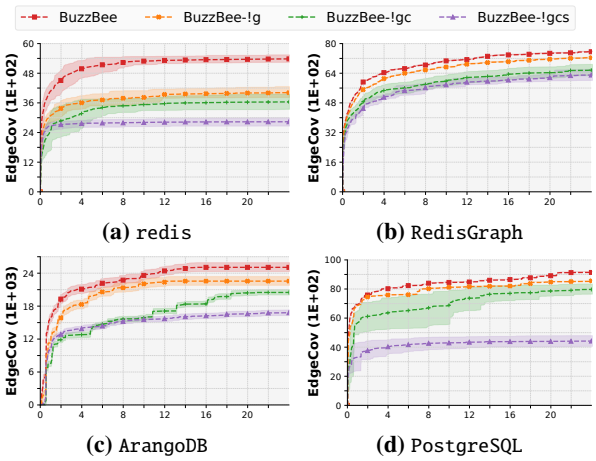
Case Study B. Fig. 5b shows a test case that crashes the `redis` server by triggering an integer overflow. This is the bug demonstrated earlier in Fig. 2. The `HMSET` command creates a hash set `k1` and stores a field/value pair `(k1_field1, 1)` in it. The `HRANDFIELD` command returns one or more random fields from a hash set. In this case, the processing logic of `HRANDFIELD` has an integer overflow bug when handling the specially crafted command. Regardless of its seemingly simple structure, we trace back the relevant code and confirm the bug has been in the code base hidden for at least three years. Finding such bugs in `redis` is non-trivial due to the large number of operations that are *not* dependency-affiliative. To solve this problem, when there exists an `HMSET` command inside the test case, BUZZBEE proactively searches for operations that can form new data dependencies and quickly finds

the bug with the help of dependency-guided mutation.

Case Study C. Fig. 5c shows another interesting test case that crashes the `redis` server by triggering an assertion failure. This test case first creates a hash set named `set1` and then calls `EXPIRE` to invalidate it. Next, at line 3, the `HINCRBYFLOAT` command fails to handle an expired symbol and wrongly implements the error handler, leaving the DBMS in a vulnerable state, which can then be crashed by another `HRANDFIELD` command shown at line 4. Interestingly, this bug requires a use-after-invalidate data dependency to trigger. We manually modified the annotation for the `EXPIRE` command from *Invalidate* to *Use* to test the DBMS's handling of invalidated data and discovered this one bug. Based on this finding, in the future, we plan to introduce a new mode into BUZZBEE that automatically modifies certain annotations to find bugs that partially violate data dependency rules, such as use-after-invalidate and use-before-define bugs.

> In conclusion, BUZZBEE successfully finds bugs in eight popular real-world targets from four major DBMS categories. Its effectiveness has been acknowledged by both its strong bug-finding capability and bug confirmations from the DBMS vendors.

8.4 Contributions of the Solutions



To understand the contribution of each solution we propose, we compare BUZZBEE with three variants of BUZZBEE by turning off the solutions gradually. Specifically, we make: BUZZBEE$^{!g}$ by turning off the dependency-guided mutation of BUZZBEE and making the mutations purely random; BUZZBEE$^{!gc}$ by turning off the context-sensitive constraint resolution routines of BUZZBEE$^{!g}$, which is achieved by making all CQLs and custom resolvers return static values and thus ignoring the context; BUZZBEE$^{!gcs}$ by completely stripping the semantic validator of BUZZBEE$^{!gc}$, shutting down the Annotation System as a whole.

We evaluate the four fuzzers on real-world targets, and compare the fuzzing performance differences in terms of the test case semantic correctness, coverage, and bug-finding capabilities. Evaluating semantic correctness allows us to understand how BUZZBEE improves the fuzzing performance under the hood. We dump the test cases during a 24-hour fuzzing session, send them to the target DBMS, and then wait for the execution result provided by the DBMS. When the DBMS finishes executing the test case without reporting an error, we regard the test case as semantically correct. Otherwise, the test case is considered semantically incorrect.

Semantic Correctness. As shown in Table 3, BUZZBEE achieves a 0.22 to 626 times higher semantics correctness rate than the other fuzzers. BUZZBEE$^{!gcs}$ has the lowest semantic correctness rate, because it does not enforce any semantics. BUZZBEE$^{!gc}$ improves over BUZZBEE$^{!gcs}$ by enforcing semantics (without context-sensitivity), and thus the test cases it generates have a higher semantic correctness rate. After introducing context-sensitivity, BUZZBEE$^{!g}$ generates more semantic correct test cases. Interestingly, BUZZBEE improves the semantic correctness over BUZZBEE$^{!g}$, which means the guided mutation also helps increase the test case semantic correctness. We manually examine the test cases and discover the reason: with dependency-guided mutation, the mutator favors mutations that form data dependencies, which are semantics described in the annotation. Then, the semantics validator can fix the errors introduced in the mutation and promote semantic correctness. Without guidance, however, the mutator randomly mutates the input and will more likely generate semantics not described in the annotation. For this case, BUZZBEE cannot fix the potential errors, resulting in lower semantic correctness rates. Meanwhile, the semantic correctness rate on `redis` is higher than the other DBMSs. This is because `redis` employs more flexible type checks. As shown in Table 2, even BUZZBEE without validating any semantics (BUZZBEE$^{!gcs}$) achieves a 79.7% correctness rate. Other DBMSs enforce stricter checks and achieve a lower correctness rate.

Table 3: Semantic correctness rates of test cases generated by the four versions of BUZZBEE in 24 hours.

Fuzzers v.s. / DBMSs	`redis`	`RedisGraph`	`ArangoDB`	`PostgreSQL`
BUZZBEE	98%	62.7%	31.6%	9.8%
BUZZBEE$^{!g}$	90.8%	38.5%	25.2%	8.4%
BUZZBEE$^{!gc}$	85.5%	0.3%	18.2%	4.5%
BUZZBEE$^{!gcs}$	79.7%	0.1%	13.6%	1.7%

(a) `redis` **(b)** `RedisGraph` **(c)** `ArangoDB` **(d)** `PostgreSQL`

Fig. 6: Edge coverage found by each version of BUZZBEE in 24h. BUZZBEE$^{!g}$ is BUZZBEE without dependency-guided mutation. BUZZBEE$^{!gc}$ is BUZZBEE$^{!g}$ without context-sensitve constraint resolution. BUZZBEE$^{!gcs}$ is BUZZBEE$^{!gc}$ with the whole annotation system turned off. We repeat the experiments five times and report the average results.

Coverage. As shown in Fig. 6, BUZZBEE finds on average 29.2%, 8.2%, 22.6%, and 36.8% more edges than the other fuzzers in `redis`, `RedisGraph`, `ArangoDB`, and `PostgreSQL`, re-

spectively. In general, for the targets we evaluate, the edge discovering capability of BUZZBEE degrades when we strip off the component implementing each solution, effectively showing the contribution of each solution to BUZZBEE in discovering more program states.

Interestingly, the performance gain of some solutions vary on different targets. BUZZBEE outperforms other versions best on the target `redis` shown in Fig. 6a, which adds a 35.5% increase over the non-guided version BUZZBEE$^{!g}$, but it only adds 4.1%, 7.3%, and 6.7% coverage increase to BUZZBEE$^{!g}$ on `RedisGraph`, `ArangoDB`, and `PostgreSQL` respectively. This is because `redis` offers more operations that are not dependency-affiliative, which are operations that cannot form any data dependency and trigger deeper program behaviors. Mutating test cases containing such operations has a high chance of wasting time generating operation sequences with no data dependency and is less likely to be efficient. In comparison, other DBMS interfaces contain more operations that are dependency-affiliative. For example, the tables and columns defined in SQL DBMSs can be used in many operations (*e.g.*, `SELECT`, `UPDATE`, `DELETE`, `COUNT`, `SUM`, `JOIN`), and forming data dependencies becomes easier. This shows that the principled mutation performs better at DBMSs containing many operations that are not dependency-affiliative.

Moreover, BUZZBEE$^{!gc}$ brings only a 3.8% coverage increase over BUZZBEE$^{!gcs}$ for `RedisGraph`, as shown in Fig.6b. Interestingly, with the help of context-sensitive constraint resolution, BUZZBEE$^{!g}$ then outperforms BUZZBEE$^{!gcs}$ with a 14.4% coverage increase. This is because context-sensitive constraints are necessary to model the semantics of `RedisGraph` effectively. The underlying reasons are two-fold. First, the grammar specification readily available on the Internet is written in ways that one node could be shared by multiple parent nodes, which requires the context to determine the correct scope constraint. Second, the operation arguments (type constraints) also depend heavily on the context to resolve the correct values. Therefore, without context-sensitive constraint resolution, BUZZBEE$^{!gc}$ fails to model the semantics effectively and achieves non-promising results.

Bug Finding. As shown in Table 4, BUZZBEE finds 12 bugs within 24 hours in the targets, the most among the four variants. Without guided mutation, BUZZBEE$^{!g}$ finds only 8 bugs, which are all covered by BUZZBEE. And without context sensitivity, BUZZBEE$^{!gc}$ finds only 2 of the bugs, because it fails to model the semantics correctly without context. BUZZBEE$^{!gcs}$ finds one bug that others cannot find, because this bug does not comply with the semantic properties specified in the annotation. For further insights, we categorize the bugs by their triggering conditions. Specifically, we mark the property of the bug as *Data* when it is semantically correct and contains data dependency relations. When the test case is semantically correct but contains no data dependencies (*e.g.*, a single *Define* or consecutive *Defines* of different symbols), we mark the bug as *Sem*. For the bug that is only triggerable by syntax correct but semantic incorrect test cases, we mark it as *Syn*. As we can see in Table 4, BUZZBEE finds more *Data* bugs than BUZZBEE$^{!g}$. For bugs 2 and 20 that are marked as *Sem*, BUZZBEE$^{!g}$ successfully finds them, but BUZZBEE$^{!gc}$ cannot, showing that *Context-sensitive Constraint Resolution* helps in enforcing the correct semantics of the test cases. Moreover, BUZZBEE$^{!gc}$ finds two more bugs than BUZZBEE$^{!gcs}$, which are bugs that require semantic correctness to trigger. This demonstrates the effectiveness of the *Annotation System* as a whole in enforcing semantic correctness. Finally, BUZZBEE$^{!gcs}$ finds one bug (ID 8) that only semantic incorrect test cases can trigger. Other versions cannot find this bug because they will enforce semantic correctness and filter out such test cases.

Table 4: Bugs found in 24 hours by each fuzzer on four DBMSs. We run each fuzzer five times for 24h and report the bugs it finds during this period. Property *Data* means the bug needs correct data dependencies to trigger. *Sem* means the bug does not need data dependencies to trigger, but the triggering test case is semantically correct. *Syn* means the bug is not semantically correct but is syntactically correct. ⊖ means the fuzzer does not support the DBMS.

DBMS	ID	Property	BUZZBEE	BUZZBEE$^{!g}$	BUZZBEE$^{!gc}$	BUZZBEE$^{!gcs}$	AFL++	POLYGLOT	REDQUEEN	Grammarin.	SQUIRREL	SQLANCER
`redis`	2	Sem	✔	✔	✗	✗	✗	✗	✗	✗	⊖	⊖
`redis`	3	Data	✔	✔	✔	✗	✗	✗	✗	✗	⊖	⊖
`redis`	5	Data	✔	✗	✗	✗	✗	✗	✗	✗	⊖	⊖
`redis`	6	Data	✔	✔	✗	✗	✗	✗	✗	✗	⊖	⊖
`redis`	7	Data	✔	✗	✗	✗	✗	✗	✗	✗	⊖	⊖
`redis`	8	Syn	✗	✗	✗	✔	✗	✔	✗	✗	⊖	⊖
`redis`	12	Sem	✔	✔	✔	✗	✗	✗	✗	✗	⊖	⊖
`RedisGraph`	19	Data	✔	✔	✗	✗	✗	✗	✗	✗	⊖	⊖
`RedisGraph`	20	Sem	✔	✔	✗	✗	✗	✗	✗	✗	⊖	⊖
`RedisGraph`	21	Data	✔	✗	✗	✗	✗	✗	✗	✗	⊖	⊖
`ArangoDB`	35	Data	✔	✗	✗	✗	✗	✗	⊖	✗	⊖	⊖
`ArangoDB`	36	Data	✔	✔	✗	✗	✗	✗	⊖	✗	⊖	⊖
`PostgreSQL`	37	Data	✔	✔	✗	✗	✗	✗	⊖	✗	✗	✗
Count			12	8	2	1	0	1	0	0	0	0

> In conclusion, BUZZBEE's success comes from all the solutions we have proposed. The contribution of each solution varies when applied to different DBMS targets that have distinct characteristics.

8.5 Comparison with Existing Tools

In this section, we compare BUZZBEE with state-of-the-art works regarding code coverage and bug detection capabilities.

We compare BUZZBEE with general-purpose fuzzers AFL++ [14], REDQUEEN [4], syntax-aware fuzzers POLYGLOT [9], Grammarinator [22], and SQL-specialized SQUIRREL [56] and SQLANCER [43]. AFL++ and REDQUEEN are widely used coverage-guided fuzzers that perform syntax-

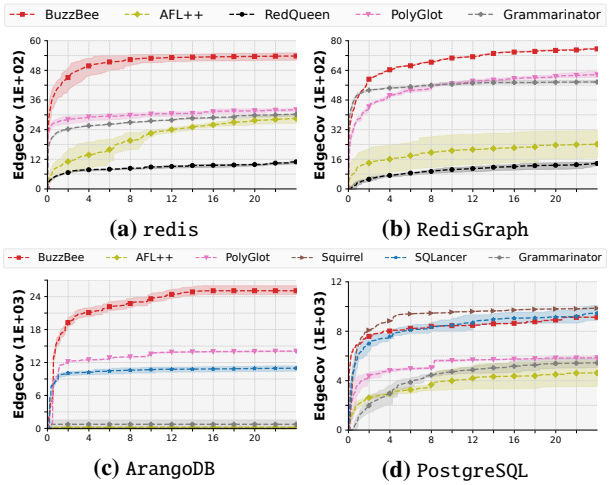


Fig. 7: Edge coverage comparison with existing fuzzers in 24h.

unaware mutations. REDQUEEN does not support fuzzing C/S programs, and we skip its evaluation on `ArangoDB` and `PostgreSQL`. POLYGLOT is a coverage-guided fuzzer tailored for fuzzing compilers such as Clang. It models the semantics of language processors effectively, but cannot model the semantics of DBMS interfaces due to its insensitivity to the context. It is a great tool to compare against because it acts as a coverage-guided syntax-aware mutator for targets outside its support range. We also compare against Grammarinator, a fuzzer currently used by `RedisGraph`, that generates random programs from a grammar without coverage guidance. For relational DBMSs, we compare BUZZBEE with SQUIRREL [56] and SQLANCER (PQS [43]), two DBMS fuzzers specialized in SQL DBMS fuzzing. We also evaluate SQLANCER on `ArangoDB` because SQLANCER recently adds support for it. Table 6 shows the DBMSs each fuzzer supports. In this evaluation, we feed the same input to all fuzzers and the same grammar specification to POLYGLOT and Grammarinator.

Coverage. As shown in Fig. 7, BUZZBEE achieves the best edge coverage in 24 hours in all targets except `PostgreSQL`. BUZZBEE achieves 69.2%, 19.8%, and 76.9% more coverage in `redis`, `RedisGraph`, and `ArangoDB` than the second-best fuzzer POLYGLOT. This performance gain demonstrates BUZZBEE's contribution to the non-relational DBMS fuzzing venue. On `PostgreSQL`, BUZZBEE achieves 92.7% code coverage of the state-of-the-art SQL fuzzer SQUIRREL, showing comparable abilities considering BUZZBEE generalizes to many DBMS categories. In Table 3, we notice BUZZBEE achieves a correctness rate of 9.8% on `PostgreSQL`. This is also comparable with SQUIRREL. Referring to SQUIRREL's paper [56], it achieves a semantic correctness rate of 11.7% on `PostgreSQL`, which is only 1.9% higher than BUZZBEE.

Bug Finding. As shown on the right side of Table 4, out of the six existing fuzzers we evaluate, only POLYGLOT finds one bug in `redis`, which falls into the category of *Syn*, meaning this bug only needs syntax awareness to discover. AFL++ and REDQUEEN cannot find any bugs during this period. None of BUZZBEE, SQUIRREL, and SQLANCER can find bugs in the latest version of `PostgreSQL` within 24 hours. We roll back `PostgreSQL` to an older version, and BUZZBEE finds one legacy bug missed by SQUIRREL and SQLANCER. Notice that BUZZBEE does not perform as well as SQUIRREL and SQLANCER in terms of code coverage. To understand the reason, we manually analyze this bug and find that it involves a syntax structure SQUIRREL does not model, potentially leading to its missing the bug. SQLANCER focuses on finding logic errors using specific syntax structures and does not discover the bug as well. The result demonstrates the capability of BUZZBEE in discovering real-world bugs that existing tools cannot discover, proving its fuzzing effectiveness and contribution to real-world bug detection.

> In conclusion, BUZZBEE outperforms existing generic solutions in non-relational DBMS fuzzing, while achieving comparable results with tools specialized in relational DBMS fuzzing, in terms of code coverage and bug-finding capabilities.

9 Discussion

9.1 Complex Semantics and Completeness

Some DBMS semantics can be very complex. For instance, the foreign key constraint in SQL DBMSs requires us to track the column reference relations. BUZZBEE can model complex constraints like this through custom resolvers. Specifically for foreign key constraints, we can use custom resolvers to resolve the type constraints of columns and tables, and track the foreign key relation, *i.e.*, which column is a foreign key to which foreign column. Then, if we want to honor the foreign key constraints in `"INSERT INTO"` statements, we can use custom resolvers to resolve the scope constraints of the inserted values. That is, when the value is inserted into a foreign key column, we resolve the `operation` as a *Use* of existing values in the foreign column. Otherwise, we resolve the `operation` as a *Define* of a new column value.

However, as shown in Table 3, BUZZBEE does not achieve 100% semantic correctness under its abstract semantic model for any of the targets. In fact, BUZZBEE does not claim to mimic all the semantics of a DBMS perfectly. Instead, BUZZBEE proposes to generically model and enforce the basic but vital DBMS semantics that impacts fuzzing performance. As shown in the evaluation, BUZZBEE achieves a decent fuzzing performance with this methodology.

9.2 Common Database Interface

Common database interfaces (DBIs) have been proposed decades ago and are used extensively nowadays. They provide

a unified layer for developers to integrate storage engines into their products without worrying about the underlying DBMS that actually powers it, which offers advantages in many ways. One may intuitively develop the idea of using common DBIs for fuzzing the diverse DBMS interfaces. During our research, we realized they are unsuitable for fuzzing for several reasons. First, DBIs tend to use a limited number of APIs of the underlying DBMS, and we cannot test the functionalities of the unused ones. Second, many modern DBIs enforce sanity checks before invoking the underlying DBMS for security reasons, adding another impeding layer. We propose solutions that let users annotate abstract semantics of the target DBMS to enable effective DBMS fuzzing.

10 Related Work

10.1 General Fuzzing Strategies

Fuzzing strategies are mainly divided into two categories: generation-based fuzzing and mutation-based fuzzing. Generation-based fuzzing creates test cases from scratch using a specification of the input format [6, 17, 19, 23, 24, 34, 38, 38, 44, 46, 47, 51, 51, 52]. These fuzzers do not require a seed corpus and are well-suited for testing systems with restricted input formats. Mutation-based fuzzing modifies existing test cases to explore new ones [14, 18, 18, 29, 31, 50, 53, 54]. They rely on a seed corpus and mutate the seeds to create new test cases. Mutations are typically guided by coverage feedback. Fuzzers such as AFL [54], AFL++ [14], libFuzzer [29], and Honggfuzz [18] use coverage obtained during code execution to guide the fuzzing process. AFL employs a lightweight yet effective instrumentation technique to track code coverage. AFL++ maintains the core principles of AFL while improving performance by introducing several optimizations. Researchers also develop more efficient feedback mechanisms. DDFuzz [32] incorporates the coverage in the data dependency graph to guide fuzzing. MemFuzz [10] uses memory accesses to guide fuzzing. BUZZBEE is a mutation-based fuzzer that extends AFL++ and focuses on the unique challenges in generic DBMS fuzzing. We believe it can benefit from the advancements in feedback mechanisms as well.

10.2 Language Processors Fuzzing

Fuzzing language processors (*e.g.*, interpreters and compilers) faces unique challenges. These targets require structural inputs with specific semantic properties to be fuzzed effectively. For instance, to fuzz JavaScript engines, CodeAlchemist [21] uses code bricks to maintain semantic correctness during mutation. DIE [37] and Fuzzilli [20] propose strategies to maintain the semantics stressing the just-in-time (JIT) engines. For compilers, CSmith [51] specializes in modeling C semantics to produce entirely correct test cases for C compilers. Tools such as Nautilus [3] and Superion [48] propose generic grammar-based solutions to fuzz more language processors. POLYGLOT [9] further advances using a semantic validation strategy that performs well when no context-sensitive constraint is required. BUZZBEE focuses on the challenges in fuzzing the diverse DBMS interfaces effectively in general.

10.3 DBMSs Fuzzing

Fuzzing DBMSs has been an active research area in recent years [15, 25–27, 43, 44, 49, 56]. Tools like SQLancer [42], SQLsmith [44], and Squirrel [56] have emerged to test relational DBMSs. SQLsmith generates random SQL queries. Squirrel employs semantic validation and coverage feedback to test SQL DBMSs. SQLancer uses differential testing techniques to report inconsistencies in query results. They have been proven successful in finding vulnerabilities in widely used relational DBMSs. Researchers also propose some solutions targeting non-relational DBMSs [26, 55]. Existing techniques present unique solutions targeting specific DBMS categories, but fail to exhibit decent fuzzing performance for the diverse DBMS interfaces in general. As a result, BUZZBEE is designed to address this with a focus on generalizability and effectiveness. Some optimizations proposed in SQL fuzzers seem effective and generalizable to other DBMSs. DynSQL [25] combines the dynamic feedback from SQL DBMSs with fuzzing. Ratel [49] tackles the challenges of fuzzing DBMSs in real-world settings. Griffin [15] mutates the input without relying on grammar by tracking dependencies among SQL statements. These optimizations are orthogonal research, and we think BUZZBEE can potentially benefit from them to improve its performance.

11 Conclusion

In this work, we identify the unique challenges in fuzzing the diverse DBMS interfaces. We propose our solutions and incorporate them into an open-source end-to-end fuzzing framework: BUZZBEE. We conduct a comprehensive evaluation for BUZZBEE, in which BUZZBEE achieves up to 177% code coverage compared with state-of-the-art fuzzers and finds 40 real-world vulnerabilities in mainstream DBMSs, demonstrating its generalizability and effectiveness.

      children={}, parent=&node37);
node39(id=39, type=increment, text=NULL, annotation={},
      children={&node40}, parent=&node33);
node40(id=40, type=terminal, text="1", annotation={},
      children={}, parent=&node39);
```

Fig. 8: BUZZBEE's IR structure and the IR program of the example in Fig. 4a. The IR program is a tree structure, which is also illustrated in Fig. 4f. When lifting, BUZZBEE parses the test case, traverses over the AST of the test case, collects the corresponding annotations, and then creates the IRNodes forming the IR program. The complete source of the test case is stored in the *text* property of the IRNodes of the type *terminal*. When compiling, BUZZBEE traverses over the IR program, collects the *terminal* IRNodes, and concatenates their *text*s into a test case.

```
cql:
    navigator* property ;

navigator:
    '.parent'
    | '.child' arg | '.lsib' arg | '.rsib' arg
    | ... ;

arg:
    '(' num ')' ;

property:
    '@text' | '@id' | '@sym_type' | ... ;
```

HYPERPILL: Fuzzing for Hypervisor-bugs by Leveraging the Hardware Virtualization Interface

Abstract

The security guarantees of cloud computing depend on the isolation guarantees of the underlying hypervisors. Prior works have presented effective methods for automatically identifying vulnerabilities in hypervisors. However, these approaches are limited in scope. For instance, their implementation is typically hypervisor-specific and limited by requirements for detailed grammars, access to source-code, and assumptions about hypervisor behaviors. In practice, complex closed-source and recent open-source hypervisors are often not suitable for off-the-shelf fuzzing techniques.

HYPERPILL introduces a generic approach for fuzzing arbitrary hypervisors. HYPERPILL leverages the insight that although hypervisor implementations are diverse, all hypervisors rely on the identical underlying hardware-virtualization interface to manage virtual-machines. To take advantage of the hardware-virtualization interface, HYPERPILL makes a snapshot of the hypervisor, inspects the snapshotted hardware state to enumerate the hypervisor's input-spaces, and leverages feedback-guided snapshot-fuzzing within an emulated environment to identify vulnerabilities in arbitrary hypervisors. In our evaluation, we found that beyond being the first hypervisor-fuzzer capable of identifying vulnerabilities in arbitrary hypervisors across all major attack-surfaces (i.e., PIO/MMIO/Hypercalls/DMA), HYPERPILL also outperforms state-of-the-art approaches that rely on access to source-code, due to the granularity of feedback provided by HYPERPILL's emulation-based approach. In terms of coverage, HYPERPILL outperformed past fuzzers for 10/12 QEMU devices, without the API hooking or source-code instrumentation techniques required by prior works. HYPERPILL identified 26 new bugs in recent versions of QEMU, Hyper-V, and macOS Virtualization Framework across four device-categories.

All work was completed prior to author joining Amazon.

1 Introduction

Hypervisors provide the security foundations necessary for the cloud. They enable efficient use of hardware resources, by colocating workloads from multiple tenants on the same bare-metal machines, isolated in individual virtual-machines (VMs). As such, hypervisors ensure that code running in VMs cannot violate the virtualization boundary (e.g., by performing a VM escape attack) and compromise the workloads of the other tenants, or the hypervisor itself.

Unfortunately, VM escape attacks are a tangible reality. Hundreds of bugs have been identified in the complex hypervisor code. Due to the severity of these bugs, hypervisor compromises are awarded large bug bounties, similar to other high-value targets such as web browsers and mobile devices [53]. In parallel, fuzzing has emerged as one of the most powerful techniques for automatically uncovering vulnerabilities in a large range of software [4,10,14,18,20,21,27,28,39,45,49,52]. As such, a significant amount of academic research has focused on leveraging fuzzing to automatically identify bugs in hypervisor code, so that they can be promptly fixed, preventing malicious exploitation [6, 13, 26, 29, 32, 37, 38].

State-of-the-art approaches [6, 26] are capable of automatically finding complex bugs across most major attack-surfaces (i.e., PIO/MMIO/DMA). However, these approaches rely on access and manual modifications to hypervisor source-code to effectively fuzz virtual-devices. Even with access to source-code, porting current methods to new targets is a non-trivial process that requires considerable manual effort by an expert. Furthermore, most fuzzers do not handle the hypercall attack-surface as hypercalls are often implemented in a separate component from the core device-emulation (e.g., in the OS kernel), for performance reasons. Thus, even though major open-source targets such as QEMU and VirtualBox have been extensively fuzzed, closed-source targets such as Hyper-V and macOS Virtualization Framework have not been thoroughly fuzzed with state-of-the-art methods.

Due to the diversity of designs and runtimes (see Tab. 1), harnessing a new hypervisor requires a combination of knowl-

edge of advanced fuzzing techniques and expert knowledge about the operation of individual virtual-devices. While hypervisors offer similar functionality, there is currently no *fully automatic* hypervisor-fuzzer capable of exploring *all major interfaces* exposed by *any hypervisor*.

Efficient automated hypervisor fuzzing entails: 1. Input Space Enumeration 2. DMA Hooking .

Input Space Enumeration. Hypervisors expose vast memory spaces and port input ranges, that are sparsely populated by Memory-Mapped IO (MMIO) and Port IO (PIO) addresses actually associated with virtual-devices. To effectively fuzz these input-spaces, current fuzzers enumerate the port and memory input-spaces to identify the active PIO/MMIO addresses. V-Shuttle [32], ViDeZZo [26] and Morphuzz [6] require access and modifications to the hypervisor source-code to hook into APIs that create PIO/MMIO ranges. HyperCube [38] and Nyx [37] leverage heuristics to approximate the active PIO/MMIO ranges and hard-code legacy device addresses. Additionally, hypervisors provide access to hypercalls which feature hypervisor-specific function signatures. There are currently no fuzzers that automatically identify the parameters related to hypercalls.

DMA Hooking. Direct Memory Access (DMA) provides devices with the capability to directly read from memory, bypassing the CPU, enabling high-bandwidth applications. In the context of virtualization, the hypervisor can read DMA inputs from arbitrary locations in VM-memory at any time, without direct involvement from the virtual CPU (vCPU). The sizes, structures, and formats of these DMA inputs are diverse and device-specific. DMA is used ubiquitously by block-storage, networking, display, and USB controllers. Nyx [37] proposes device-specific grammars to effectively fuzz DMA-capable devices. However, such grammars require expert knowledge, are difficult to construct, and are prone to inaccuracies which decrease fuzzing performance. To avoid the need for difficult-to-obtain device-specific grammars, state-of-the-art fuzzers converged on hooking DMA-related APIs to facilitate fuzzing. To this end, V-Shuttle, ViDeZZo, and Morphuzz all rely on modifications to the hypervisor's DMA APIs [6, 26, 32]. Similarly, MundoFuzz [29] leverages recordings of device interactions from a kernel with instrumented PIO/MMIO/DMA APIs to automatically synthesize grammars. Even with source-code access, it remains challenging to identify all DMA-related APIs even in open-source software (e.g., QEMU alone features dozens of DMA-access APIs). Furthermore, developers commonly use pointer-based DMA APIs (e.g., `pci_dma_map()` in QEMU) which return a pointer to a large VM-memory region which can then be used to arbitrarily index into the guest-memory. Current fuzzers are not equipped to deal with DMA activity from such generic APIs.

	Open-Source	Type-1	Language	Execution Environment	PV Platform	Hypercall identifier	EPT MMIO Mechanism
QEMU-KVM	●	○	C	K+U	VIRTIO	RAX	V+M

Table 1: The diversity of hypervisors. In the *Execution Environment* column, the letters indicate that significant parts of the trap-and-emulate cycle are implemented in the Kernel (K), Userspace (U) and dedicated virtual-machines (VMs) that host parts of the hypervisor. The *MMIO Mechanism* column indicates that MMIO accesses are trapped using EPT Violations (V) and EPT Misconfigs (M).

Our Approach. Our approach leverages the fundamental insight that *while modern hypervisor internals feature a plethora of different designs, all implementations must rely on an architecture-specific hardware-virtualization interface to configure VMs*. As such all, hypervisors that run on the same CPU architecture leverage standardized CPU features to manage VMs. This interface encodes a wealth of information about the input-spaces available to VMs. We introduce HYPERPILL, a generic hypervisor-fuzzer that leverages this well-specified hardware-virtualization interface to automatically fuzz arbitrary hypervisors. Our design *transplants a single full-system snapshot of the hypervisor into an emulation-environment for fuzzing*. HYPERPILL can use the hardware-virtualization interface to inject arbitrary IO activity into snapshotted hypervisors. Furthermore, it leverages feedback from the standardized hardware-virtualization interface and the granular introspection capabilities enabled by emulation to automatically enumerate the PIO and MMIO input-spaces. HYPERPILL identifies all the memory associated with the virtualized guest and performs DMA hooking at the level of atomic memory accesses. During fuzzing, it leverages runtime feedback from the emulator to automatically identify the parameters needed to invoke hypervisor-specific hypercalls. Thus, HYPERPILL elides manual hooking of hypervisor-specific APIs, while providing finer-grained feedback than state-of-the-art approaches that rely on source-code instrumentation. Due to our unique emulation-based approach, HYPERPILL is the first fuzzer capable of automatically fuzzing all major input-spaces of arbitrarily-architected hypervisors with state-of-the-art techniques. Furthermore, HYPERPILL has the most fine-grained hypervisor introspection capabilities, even allowing it to outperform fuzzers that leverage source-code instrumentation.

Evaluation. We leveraged HYPERPILL to find bugs in recent QEMU, Hyper-V, and macOS Virtualization Framework hypervisors. For coverage, we compared HYPERPILL against

two state-of-the-art approaches (i.e., Morphuzz and ViDeZZo) that require source code access. HYPERPILL outperforms the two approaches for 10/12 QEMU devices. HYPERPILL successfully identified 26 new bugs in all hypervisors across four device-categories, of which 11 are bugs in QEMU, which has been fuzzed extensively since 2020. Our throughput evaluation shows that HYPERPILL is slower than ViDeZZo but faster than Morphuzz. The performance penalty introduced by emulation is offset by HYPERPILL's ability to surpass state-of-the-art approaches through high-quality inputs.

In summary, we make the following contributions:

- We present a novel method for fuzzing arbitrary hypervisors that are essential to modern-day use by leveraging the core hardware-virtualization interface. Due to the rich feedback available from this interface, HYPERPILL can automatically enumerate and fuzz all major hypervisor attack-surfaces (i.e., PIO/MMIO/Hypercalls/DMA) hypervisors without any target-specific harnesses work.
- We implement our hypervisor-fuzzer, HYPERPILL, which leverages the hardware-virtualization interface to fuzz arbitrary hypervisors. HYPERPILL takes a full-system snapshot of the hypervisor target and transplants the snapshotted target into an emulation environment, where it probes the input-spaces and fuzzes the target.
- We evaluate HYPERPILL's capabilities. We report on 26 new bugs discovered by HYPERPILL, of which 9 are in virtual-devices covered by state-of-the-art hypervisor-fuzzers. In addition to demonstrating HYPERPILL's ability to find bugs, we show that HYPERPILL surpasses the coverage of previous target-specific harnesses which require access to and modification of source-code.
- To enable further research into grammarless, generic hypervisor harnessing and fuzzing, we will open-source all of HYPERPILL's components.

2 Virtualization Background

Hypervisors. Hypervisors, or virtual machine monitors (VMMs) are software that create and execute virtual machines (VMs). In the mid-2000s, x86 virtualization changed substantially, as Intel and AMD introduced hardware-backed virtualization support. The new virtualization interfaces allowed for high-performance low-complexity offloading of CPU and memory virtualization tasks that were traditionally handled in software using complex high-overhead approaches such as binary translation and MMU-shadowing [36]. These advances drastically changed the computing landscape and accelerated the proliferation of virtualization-based cloud technology. However, while hardware-accelerated CPU and memory virtualization greatly increased performance and usability, Hypervisor code is still largely responsible for providing VMs with access to virtual-hardware resources, such as networking, display, and storage. For example, when a VM attempts to access the network, the hypervisor must trap the VM's access and emulate the network access by running virtual network device code. Such virtual-devices are generally implemented in hundreds of thousands of lines of C/C++ code. The critical nature of this code has led recent hypervisors, such as Firecracker, to leverage "safer" languages (e.g., Rust) to implement virtual-devices. As such, even with hardware acceleration, hypervisor code remains a prime target for VM-escape attacks. Before exploring the attack-surface further, we detail the hardware-accelerated virtualization interface.

Hardware-Accelerated Virtualization Extensions. Commodity CPU architectures have support for hardware-accelerated virtualization (VT-x for Intel, AMD-V for AMD, Virtualization Extensions for ARM, RISC-V H, Virtualization Extensions for PowerPC). We focus on prevalent x86 hypervisors leveraging the Intel VT-x extensions. However, note that semantically, hardware-accelerated virtualization extensions feature broadly similar functionality. The privileged hypervisor uses an architecture-specified API to configure a virtual-machine, and dedicated instructions (e.g., `vmresume` on Intel) to "enter" into the guest, which is called "VM-Entry". When an external event occurs (e.g., a timer interrupt), or the guest accesses a privileged resource (e.g., a network-card MMIO address), control returns to the hypervisor, which is tasked with handling this "VM-Exit". The CPU informs the hypervisor of the reason for the "VM-Exit" through an architecture-specific mechanism (e.g., a data-structure in memory).

This advanced virtualization functionality requires the hypervisor to perform comprehensive configuration of VM-related control settings. On Intel CPUs, the `vmptrld` instructs the CPU to use an area in memory to maintain the control information for a new VM. This area is called a VM Control Structure, or *VMCS*. The VMCS contains hundreds of fields (called *encodings*) that specify the VM's configuration state. For example, the VMCS contains the VM's instruction pointer, page-table base register or segmentation configurations. For a VM-Entry, the `vmlaunch/vmresume` instructions are used to activate the VM specified by the VMCS and run the guest code. When the guest triggers a VM-Exit, the CPU modifies the VMCS to provide the hypervisor with the necessary information to handle the VM-Exit. Namely, the CPU places an exit identifier in the `EXIT_REASON` encoding, which specifies the reason for the exit (e.g., PIO, MMIO or hypercall). Further information is placed in the `EXIT_QUALIFICATION` encoding. The type of information depends on the `EXIT_REASON`. For example, for faulting IO accesses, the `EXIT_QUALIFICATION` contains the address, size, and type (read/write) of the access. The hypervisor inspects the VMCS to learn the exit reason and exit qualification. Following the ubiquitous trap-and-emulate virtualization model, the hypervisor is responsible for emulating the behavior that triggered the VM-Exit. The way in which VM-Exits are handled is hypervisor-specific. However, the mechanisms used to configure VMs are not.

All hypervisors that wish to configure hardware-accelerated VMs, rely on an identical and well-specified architectural interface to encode crucial information about the VMs. We name this interface the hardware-virtualization interface.

Modern MMU Virtualization. Traditionally, MMU virtualization was a performance obstacle. An MMU converts virtual-addresses to physical-addresses using a translation layer (usually encoded in hierarchical page-tables). However, virtualization requires a second layer of translation. First, the VM's Guest Virtual Address (GVA) must be converted to a Guest Physical Address (GPA) using the guest's page-table. Then, the Guest Physical Address must be converted to a Host Physical Address (HPA). Since the hypervisor runs in the host's virtual-address space, and it needs access to the guest's physical memory (e.g., to perform DMA), the guest's memory is mapped into the host's virtual memory. With the advent of hardware-accelerated virtualization, CPUs began providing an accelerated method for guest-paging called *Second Level Address Translation (SLAT)*. On Intel CPUs, SLAT is implemented as Extended Page Tables (EPT). The guest continues to maintain its page-table (PT), which translates GVAs to GPAs. However, the hypervisor maintains a second page-table, which translates GPAs to HPAs. When executing the VM, the hardware translates addresses through both the PT and the EPT table to convert GVAs to HPAs. Notably, the EPT mechanism is also responsible for trapping MMIO accesses. Since MMIO ranges are ranges of GPA that require emulation, they are configured within the EPT to trap into the hypervisor, rather than map to HPAs.

In summary, the EPT contains information required to identify physical memory frames that are allocated to the guest and to determine which guest-address accesses trap into the hypervisor.

Interacting with the Hypervisor. VMs interact with the hypervisor through a combination of Port/Memory-Mapped IO, Hypercalls, and Directed Memory Access.

Memory-Mapped IO dedicates certain parts of the guest's physical memory for device IO. Unlike regular read/write access to physical memory, operations to memory-mapped regions cause VM-Exits which the hypervisor emulates by executing virtual-device code. Transferring data to and from the device via MMIO is a blocking/synchronous operation for the vCPU. *Port IO* follows the same trap-and-emulate virtualization model as MMIO, however, it targets a separate 16-bit address-space. PIO is x86-specific and accessed via `in/out` instructions. PIO is usually reserved for low-bandwidth communication with devices, such as timers and serial ports.

Hypercalls are a virtualization-specific mode of communication with hypervisors. Hypercalls rely on a special instruction that can be executed within the guest to trigger a direct VM-Exit into the hypervisor. There is no unified hypercall calling convention. Each hypervisor can implement a hypercall interface that relies on parameters passed through any number of registers (which may refer to memory addresses). While hypercalls follow the same trap-and-emulate virtualization model, the flexibility of the interface often that they can be decoded and handled more rapidly than PIO/MMIO. For PIO/MMIO, the hypervisor has to locate and disassemble the faulting instruction to identify the source and destination operands (discussed further in § 3.2.1). Conversely, the semantics of hypercalls are hard-coded.

Direct Memory Access (Unlike PIO/MMIO and hypercalls) is performed without the direct involvement of the CPU (there is no "DMA" instruction). Usually, when the VM wishes to signal to the hypervisor that some data is available for DMA transfer, it communicates the location of the data in physical memory to the device using PIO/MMIO/Hypercalls. The hypervisor can then, independently, access the data in the guest's memory. From the perspective of the vCPU, it simply provides the virtual-device with a pointer to some data, by writing to a PIO/MMIO register or via a hypercall.

Notably, DMA access patterns can be arbitrarily complex. For example, DMA ring buffers are a common paradigm, where the VM sets up a "ring" data-structure that stores meta-data and pointers to individual buffers. Virtual-devices access both the ring and the buffers using DMA. To address this complexity, hypervisor-fuzzers have relied on grammars and, more-recently, API-hooking to address the problem of the complex DMA input-space. By hooking DMA APIs, fuzzers gain information about DMA-access patterns which can be used to automatically generate grammars (ViDeZZo [26] and MundoFuzz [29]) or to directly fuzz the data returned through DMA APIs (Morphuzz [6] and V-Shuttle [32]).

3 HyperPill Approach

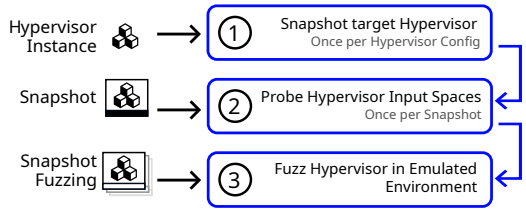

Figure 1: High-level overview of HyperPill's approach.

Our HyperPill design enables effective fuzzing of arbitrary hypervisors without any target-specific configuration. HyperPill's approach centers around (1) collecting a snapshot of a hypervisor, (2) inspecting the snapshot to identify the fuzzing input-spaces, and, finally, (3) fuzzing the hypervisor. Our approach does not require any manual engineering for individual hypervisors or composition of device-specific

grammars. Instead, HYPERPILL leverages the fundamental hardware-virtualization interface, which must be used by all hypervisors that take advantage of hardware-accelerated virtualization. HYPERPILL can fuzz both type-1 (ones that run on bare-metal) and type-2 (ones that run as applications managed by a general-purpose OS) hypervisors. In summary, our fuzzer is the first *fully automatic gray-box* hypervisor-fuzzer that leverages architectural-state instead of grammars or configurations to fully explore *all major interfaces exposed to guest VMs* by *any hypervisor*. In this section, we describe HYPERPILL's approach. § 4 explains how we bring together these innovations in our implementation of HYPERPILL.

Threat Model. In HYPERPILL's threat-model, an attacker has complete control over the code running in a guest managed by a potentially vulnerable hypervisor. The attacker seeks to compromise the isolation guarantees provided by the hypervisor to gain control over other VMs on the system, or the hypervisor itself. To this end, the attacker can initiate arbitrary PIO/MMIO/Hypercalls that are handled by the hypervisor. Furthermore, the attacker fully controls the data the hypervisor reads from guest-memory e.g., via DMA. Additionally, the attacker can seek to perform Denial-of-Service attacks, by disrupting the operation of the hypervisor and subsequently the neighboring VMs. In this work, we exclude side-channels from the attack-surface.

① Making a Snapshot of the Hypervisor

As HYPERPILL is designed to target arbitrary hypervisors, and hypervisors are known to be particularly stateful targets, HYPERPILL requires a robust and generic mechanism for resetting state between inputs. While prior approaches such as Morphuzz and ViDeZZo relied on implementation-specific solutions to add instrumentation and state-resetting to hypervisor source-code, HYPERPILL does not have access to such source-code-dependent features [6, 26]. Furthermore, HYPERPILL targets complex hypervisor implementations, such as Hyper-V where the hypervisor consists of components spread over the host kernel, a guest kernel, and a process running within the guest. To this end, HYPERPILL relies on full-system memory and register snapshots to reliably capture the state of the entire environment hosting the hypervisor. This approach is independent of any hypervisor implementation details such as type-1/type-2, host OS, source availability, etc. By collecting the snapshot in a separate offline stage, we ensure that input-space enumeration (Stage ②) only needs to be performed once, and that fuzzer instances are not delayed by costly hypervisor-initialization (which is even more costly in an emulated environment).

3.1.1 Timing the Snapshot

As described in § 2, hypervisors initialize the necessary data-structures to configure a guest, before invoking `vmenter` to launch the guest. Eventually, a guest or hardware-triggered event causes execution control to be returned to the hypervisor. If the event was guest-triggered (e.g., a virtual MMIO read or hypercall), the hypervisor must emulate the corresponding functionality (e.g., by running virtual-device code). Software vulnerabilities in the hypervisor are most likely to manifest themselves during this emulation. As such, HYPERPILL makes a snapshot of the hypervisor just as the guest traps into the host and passes execution control to the hypervisor for emulation of the VM-Exit. Specifically, HYPERPILL invokes a custom hypercall from the guest to make a snapshot. As such the next instruction executed when HYPERPILL loads/resumes the snapshot is the first instruction of the hypervisor's trap-and-emulate code. In § 4.1 we detail HYPERPILL's implementation of this snapshotting technique.

② Probing the Hypervisor's Input-Space

In this section, we explain how HYPERPILL uses static and dynamic techniques to precisely enumerate the PIO/MMIO and DMA input-spaces. Note that due to lack of a unified hypercall API, HYPERPILL does not perform any offline hypercall enumeration. Instead, we tailored the fuzzing-process, itself, to effectively explore the hypercall input-space (described further in § 3.2.4).

3.2.1 Injecting IO into the Hypervisor

To perform active probing of PIO/MMIO regions, HYPERPILL needs the ability to inject PIO/MMIO operations into the snapshotted hypervisor. Leveraging the hypervisor snapshot, HYPERPILL can inject arbitrary VM-Exits into the hypervisor, by performing slight modifications to the guest-memory. To this end, HYPERPILL modifies the fields within the VMCS that the CPU uses to communicate information about the VM-Exit to the hypervisor. The address of the currently configured VMCS structure (set using the `vmxset` instruction), is included in the CPU state. As the format of the VMCS is well-documented in architecture manuals, HYPERPILL can dereference the address to probe details about the active VM. Thus, even though the snapshotted VMCS represents a VM-Exit for HYPERPILL's custom hypercall, HYPERPILL can adjust the snapshot to reflect any other VM-Exit, such as one related to PIO or MMIO, or a different hypercall. Specifically, since hypervisors often disassemble the faulting instruction, when HYPERPILL injects an MMIO or PIO instruction, HYPERPILL overwrites the customized hypercall instruction, with one corresponding to the VM-Exit (a `mov` for MMIO or an `in/out` for PIO).

With the capability to inject arbitrary VM-Exits, HYPERPILL can generically explore the PIO/MMIO/Hypercall interfaces exposed by any hypervisor.

3.2.2 Enumerating MMIO and PIO

Leveraging the ability to inject arbitrary VM-Exits, HYPERPILL relies on probing to identify MMIO/PIO regions. Semantically, PIO accesses are similar to MMIO accesses, however, they leverage a relatively small 16-bit address-space (independent of guest-memory) and PIO-specific x86 instructions, i.e., `in/out`. However, MMIO ranges are adjacent to standard RAM addresses in the guest's vast (e.g., 48-bit) physical address-space. Fortunately, HYPERPILL can quickly eliminate the vast-majority of physical-addresses from its list of MMIO candidates, by inspecting the guest's EPT. As described in § 2, the EPT maps guest-physical-addresses (GPAs) to host-physical-addresses (HPAs). There are two mechanisms (EPT Violations and Misconfigurations) available to hypervisors for trapping MMIO accesses. Both mechanisms rely on specially configured pages in the guest's EPT. HYPERPILL reads the EPT pointer field from the VMCS and walks the EPT. HYPERPILL records all guest-physical-address ranges that trigger EPT Violation and Misconfiguration VM-Exits upon access and treats these ranges as potential MMIO ranges. These ranges do not necessarily all trigger behavior associated with MMIO emulation. For example, some EPT Violation ranges may simply be gaps in the guest's physical address space that are not associated with any RAM or MMIO devices (e.g., the PCI hole). To handle access to such ranges, the hypervisor generally ignores the access (or injects a page-fault into the guest). Thus, after identifying a list of candidate regions, HYPERPILL enters an active probing stage.

To enumerate PIO addresses and identify actual MMIO ranges from the list of candidate MMIO ranges, HYPERPILL relies on a multifaceted introspection approach. We identified that the majority of candidate regions are not associated with any virtual-device code. Accessing such ranges results in virtually identical hypervisor behavior (e.g., a rapid re-entry into the guest, after setting up a physical-page mapping or injecting a page-fault exception). As such, we identify key execution characteristics that identify active PIO/MMIO ranges. HYPERPILL iterates over potential PIO and MMIO addresses, injects the corresponding VM-Exits and tracks these characteristics to determine whether each address is associated with a virtual-device. Specifically, HYPERPILL tracks:

- *Instruction Count*. The number of instructions executed by the hypervisor to handle the access is a reliable indicator of PIO/MMIO ranges. Non-interesting accesses typically have similar and small instruction counts. However, MMIO/PIO accesses require executing device-specific code and have large instruction counts due to executing device emulation code.
- *Unique Program Counter Values*. PIO/MMIO virtual-devices feature device-specific code to emulate accesses. As such, accesses to different device-ranges result in new code executed (previously-unseen program-counter values). HYPERPILL marks ranges that execute unique program counters (not executed by accesses to any other range) to identify whether a range is associated with a virtual-device.
- *Entry to User-Space*. Hypervisors such as KVM and Hyper-V execute their PIO/MMIO virtual-device code in user-space processes. As such, while all VM-Exits are initially handled in privileged ring 0, accesses to actual PIO/MMIO regions cause the hypervisor to exit into the virtual-device worker process (unprivileged ring 3). For each PIO/MMIO candidate, HYPERPILL tracks the execution of the hypervisor to determine whether it executes the `sysret` instruction to exit into user-space.

Combining the lists of regions sensitive to these feedbacks, HYPERPILL constructs a final list of active PIO and MMIO regions which can be used to fuzz these interfaces.

3.2.3 Enumerating Guest-Memory (DMA)

HYPERPILL's memory snapshot contains all the hypervisor's physical memory, including the physical frames that the hypervisor allocates for itself, for the VM, and unallocated memory. While handling MMIO/PIO/Hypercall VM-Exits, the hypervisor can access data in guest-memory (e.g., DMA). As such, the guest's memory is an essential component of the virtualization attack-surface. HYPERPILL statically classifies potential hypervisor guest-memory-accesses into two categories.

- *Direct Memory Access (DMA).* Accesses that are used for bulk transfers of data by virtual-devices (e.g. reads from ring-buffers kept in the guest's memory to rapidly transfer data to devices such as network-cards).
- *Instruction Emulation (IE).* Accesses that are used to disassemble an instruction that caused a VM-Exit. For example, when a guest triggers an MMIO read, the hypervisor must locate and disassemble the corresponding faulting instruction to determine the destination register and size of the read. The GVA of the PIO/MMIO instruction and the guest-page-tables used to identify and disassemble the instruction should be set up accordingly.

With this information, HYPERPILL can differentiate memory-accesses between ones that can potentially contain attacker-controlled data (DMA), and ones that should reflect the guest's faulting instruction. To do this, HYPERPILL identifies and categorizes the frames in the snapshot that belong to the guest and can contain attacker-controlled data. HYPERPILL performs a page-table walk over the EPT to identify all HPAs that are mapped to the guest. In practice, HYPERPILL performs the DMA-categorization and enumeration of candidate MMIO regions during a single walk of the EPT. Additionally, HYPERPILL walks the guest's page-tables to determine

which guest-physical-pages contain the last-executed VM instruction and the page-table entries required to locate it.

As a result of these page-table walks, HYPERPILL classifies all memory frames in the hypervisor snapshot as:

1. Frames that are not mapped in the guest.
2. Frames that are dedicated to the guest, and are not part of the guest's page-tables.
3. Frames that are dedicated to the guest and are part of the guest's page-tables.

The IE surface is largely independent of the rest of the trap-and-emulate cycle. Thus, to increase fuzzing performance, HYPERPILL fuzzes DMA independent of the IE space. When the hypervisor reads from memory, HYPERPILL first identifies whether the memory belongs to the guest. If the read targets guest-memory, HYPERPILL further determines whether the read targets the guest's page-table structures, or the frame that contains the last-executed guest instruction. HYPERPILL only treats the read as a virtual DMA access and fills the corresponding location in memory with fuzzed-data if the access is not classified as IE. *With this capability,* HYPERPILL *can fully explore the DMA interface exposed by any hypervisor.*

③ Fuzzing the Hypervisor

In the prior sections, we described how HYPERPILL collects and analyzes a hypervisor snapshot to identify the active PIO/MMIO/DMA ranges. After completing this offline learning stage, HYPERPILL leverages the snapshot to fuzz the hypervisor. To this end, HYPERPILL "restores" the snapshot (i.e., loads the saved memory and register state, and prepares to resume the execution). Then, based on the fuzzing input HYPERPILL injects a PIO/MMIO or Hypercall VM-Exit, as described in § 3.2.1. HYPERPILL resumes the hypervisor. Unless there is a crash, the hypervisor handles the VM-Exit and resumes the VM, using the `vmresume` instruction. However, HYPERPILL intercepts the `vmresume` and immediately injects another VM-Exit based on the fuzzer-input, instead of executing any guest-code. Thus, fuzzing-time is fully dedicated to injecting new VM-Exits into the hypervisor and running the hypervisor's emulation code on fuzz-inputs. HYPERPILL repeats this process until the fuzzer-input has been fully executed (no more bytes remain in the input). Hypervisors are stateful targets and often require multiple IO operations to execute certain code. To reflect this statefulness, HYPERPILL's inputs are composed of sequences of IO operations executed from a "clean" snapshot state. This ensures that the fuzzer can rapidly receive and react to runtime feedback to uncover new parts of the hypervisor's code. Then, HYPERPILL resets the hypervisor's state from the original snapshot, before executing the next fuzzer input.

3.2.4 Fuzzing Hypercalls

As described in § 2, modern CPUs support hypercalls which enable fast and flexible requests of services from the hypervisor by the guest. Hypercalls are commonly used to provide an interface to high-performance paravirtual-devices. As such, they are a critical part of the virtualization input-space. Semantically, hypercalls behave similarly to PIO/MMIO accesses: the guest invokes a `vmcall` instruction that immediately traps into the host. However, unlike PIO/MMIO, there is no general hypercall ABI that is shared by all hypervisors. For example, KVM uses the contents of guest register RAX to identify the service requested by the hypercall, while Hyper-V relies on RCX for the same purpose. Furthermore, since there is no defined interface, hypervisors can use arbitrary registers to communicate additional hypercall parameters. Depending on the service requested, Hyper-V can interpret the contents of registers RDX, R8, XMM0-5 as guest-arguments. More generally, essentially any register can be used to pass data through a hypercall. This creates a challenge, as fuzzing the contents of *all* registers for each hypercall would result in an unreasonably large input state space, requiring hundreds of input bytes for each call and, worse, a majority of these bytes would be wasted on unused registers that the fuzzer would spend time mutating. Most prior fuzzers do not cover the hypercall input-space. Furthermore, the fuzzers that aspire to fuzz hypercalls (e.g. Hyper-Cube [38]) handle them by encoding hypervisor-specific expert knowledge about hypercall-ids and the corresponding registers used to pass arguments. These approaches require manual work and constant upkeep, since hypervisors continue to add new hypercalls.

Instead, HYPERPILL leverages powerful introspection capabilities to efficiently fuzz arbitrary hypercall implementations. Unlike, the PIO/MMIO/DMA spaces which are enumerated offline in stage ②, HYPERPILL dynamically constructs valid hypercalls by leveraging runtime feedback from fuzzing. HYPERPILL's approach is based on the observation that hypercall argument registers impact the hypervisor's execution path. As such, the contents of these registers appear in numeric comparisons during the trap-and-emulate process (e.g. bounds-checks and hypercall-handler selections). By default, HYPERPILL fills all guest-registers with randomly generated data from a pseudo-random-number generator (pRNG), rather than the fuzzing-input. As the hypervisor handles the `vmcall`, HYPERPILL inspects the operands of all comparison instructions. If any of the operands is found within the randomly generated register data, HYPERPILL records that subsequent mutations of the input should set the contents of the corresponding register directly from the fuzzer-input (in § 4.3.1 we explain how this functionality is implemented). HYPERPILL automatically identifies registers that affect hypercall execution, without any prior knowledge of the hypervisor-specific hypercall-API and without wasting fuzzer-bytes on unused registers (wasting potentially hundreds of bytes to fill

unused registers, severely hampers fuzzing efficiency) Our novel runtime-feedback-based approach is inspired by AFL++ CmpLog and RedQueen [2, 11]. However, instead of only solving obstacles, such as magic-bytes, HYPERPILL uses the feedback to transparently infer hypercall calling-conventions.

4 Implementation

As described in § 3, HYPERPILL collects a snapshot of a hypervisor, inspects the snapshot, and finally fuzzes the hypervisor. We implemented these three stages as independent components of HYPERPILL. HYPERPILL-Snap collects a precise snapshot of a hypervisor at the exact moment it traps a guest-access for emulation. HYPERPILL-Inspect locates the guest's memory within the snapshot and enumerates all the active PIO and MMIO ranges. HYPERPILL-Fuzz leverages the results of the prior stages to fuzz the hypervisor.

4.1 HYPERPILL-Snap

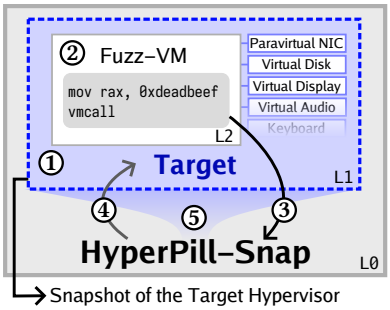

Figure 2: HYPERPILL-Snap snapshots the target hypervisor.

HYPERPILL relies on a full-system snapshot of the hypervisor (the target), hosting a guest (the attacker-controlled VM, in our threat-model). To collect this snapshot, HYPERPILL relies on nested-virtualization. HYPERPILL-Snap is, itself, a hypervisor (a customized version of KVM), designed to run as *L0* (*L0* or Layer 0 is the standard name for the outermost hypervisor, L1 refers to the VM executed by L0 and L2 refers to a nested VM managed by L1). ① HYPERPILL-Snap runs the target hypervisor, in a nested configuration, as an *L1* guest. ② The analyst launches a guest within the target hypervisor (configured with desired virtual-devices), creating the *L2* Fuzz-VM. The x86 ISA supports nested virtualization and dictates that all L2 VM-Exits first pass through L0, before being injected into L1. As such, HYPERPILL-Snap can inspect L2 exit-reasons before injecting them into the target. In the default case, HYPERPILL-Snap adheres to KVM's default behavior and simply forwards all VM-Exits into L1. ③ When HYPERPILL-Snap encounters a hypercall with a special identifier (the value `0xdeadbeef` stored in register RAX), ④ it likewise injects it into the target by modifying the $VMCS_2^1$ (the VMCS configured by L1 for the L2 Fuzz-VM). However instead of resuming the target to allow it to handle the VM-Exit, HYPERPILL-Snap pauses execution of the target hypervisor and ⑤ collects a snapshot of L1's entire memory and CPU state. Thus, to trigger the snapshot, the analyst simply needs to invoke the `0xdeadbeef` hypercall from the L2 guest. We take the snapshot once the L2 OS (Linux) has had the chance to fully boot and initialize all drivers and virtual-devices. The resulting snapshot includes the L1 (i.e., target hypervisor's) physical memory (which includes L2's physical memory), the register state, and internal CPU state, such as the $VMCS_2^1$ pointer.

Resuming the snapshot will result in L1 receiving the `0xdeadbeef` hypercall VM-Exit, and attempting to handle it. Thus HYPERPILL-Snap achieves our goal of collecting a snapshot of the target hypervisor at the exact moment it is about to handle a VM-Exit.

4.2 HYPERPILL-Inspect

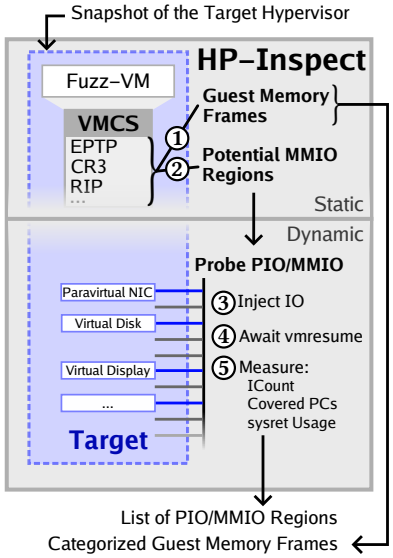

Figure 3: HYPERPILL-Inspect analyzes the hypervisor's PIO/MMIO/Memory input-space.

As described in § 3, HYPERPILL's snapshot analysis features both static and dynamic components. HYPERPILL-Inspect performs an initial static analysis of the snapshot to identify potential L2 guest's MMIO ranges and categorize each memory page contained in the snapshot. Specifically, HYPERPILL-Inspect dereferences the VMCS pointer (part of the snapshotted CPU state), and loads the Extended Page Table (EPT) pointer from the VMCS. HYPERPILL-Inspect walks the EPT to identify the memory frames that are allocated to the L2 guest (L2-guest-memory frames). Additionally, HYPERPILL-Inspect identifies candidate MMIO pages, which are configured within the EPT to cause Misconfig or Violation VM-Exits. HYPERPILL-Inspect then loads the value of the

L2 guest's CR3 register from the $VMCS_2^1$, which stores the location of the L2 guest's page-table (see § 3.2.3). By walking the L2 guest's page-table, HYPERPILL-Inspect further categorizes allocated L2-guest-memory frames as either part or not part of the L2 guest's page-table.

For PIO/MMIO enumeration, HYPERPILL-Inspect relies on dynamic feedback from the hypervisor (e.g., instruction-counts or covered PCs as described in § 3.2.2). HYPERPILL-Inspect relies on our custom execution environment, called MELTER, to execute the snapshot and collect dynamic feedback. MELTER is a full-system emulation-based fuzzer, based on Bochs [5]. Bochs is an open-source x86-64 emulator. Bochs has comprehensive support for VT-x, which is crucial, since HYPERPILL is designed to fuzz hypervisors, that rely extensively on VT-x. We use this execution environment in HYPERPILL-Inspect (and reuse it in HYPERPILL-Fuzz). Upon startup, MELTER loads the target hypervisor memory and register snapshot taken in stage (1) into the emulation context. MELTER features two modes: *enumeration* and *fuzzing*. HYPERPILL-Inspect only relies on the *enumeration* mode.

4.2.1 Enumerating PIO and MMIO Ranges

HYPERPILL-Inspect relies on dynamic probing to identify active PIO/MMIO ranges. As mentioned in § 3.2.1, HYPERPILL can inject arbitrary IO operations, by modifying the VMCS and guest memory, before resuming the snapshot. To identify active PIO/MMIO regions, we observe the property that accesses to active PIO/MMIO regions cause the hypervisor to execute code that implements virtual-device functionality. Since HYPERPILL-Inspect has instruction-level insight into the code executed by the hypervisor, it can easily identify port and memory accesses that execute unique code. For PIO, HYPERPILL-Inspect iterates over each address in the 16-bit port-address space and injects a PIO write (simulating an `outb` instruction). For MMIO, HYPERPILL-Inspect iterates over each page within the candidate MMIO ranges identified during the EPT walk and injects an MMIO write (simulating a `mov` instruction with the candidate page as the destination). After resuming the snapshot, HYPERPILL-Inspect waits for the hypervisor to handle the injected VM-Exit and resume the L2 guest using the `vmresume` instruction. In between each injected probe, MELTER restores the state of the hypervisor from the initial snapshot. For each candidate PIO/MMIO address, HYPERPILL-Inspect records (1) The number of instructions executed before the L2 guest was resumed (2) The executed program-counters (3) Whether the hypervisor entered user-space. HYPERPILL-Inspect merges this information to output the final list of active PIO/MMIO regions. Note that since MELTER is based on Bochs, it is straightforward to add the necessary instrumentation to the emulator to collect this information. Our probing technique guarantees that HYPERPILL only fuzzes subregions of the PIO/MMIO input-space that cause variations in the hypervisor's behavior. Crucially, unlike past approaches, HYPERPILL-Inspect does not rely on any instrumentation of APIs responsible for mapping PIO/MMIO regions.

HYPERPILL-Inspect only needs to run once per snapshot collected by HYPERPILL-Snap (i.e. once per target hypervisor configuration). It outputs a list of identified and categorized guest memory frames and active PIO/MMIO regions.

4.3 HYPERPILL-Fuzz

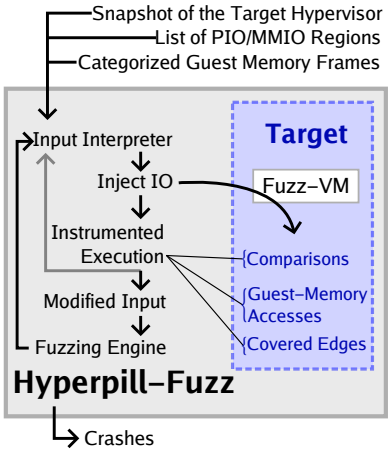

Figure 4: HYPERPILL-Snap fuzzes the target hypervisor.

HYPERPILL-Fuzz leverages the snapshot collected by HYPERPILL-Snap and the enumerated PIO/MMIO/DMA input-spaces from HYPERPILL-Inspect to efficiently fuzz the hypervisor using the *fuzzing* mode of MELTER. HYPERPILL-Fuzz relies on an input-interpreter, which splits a single fuzzer-input into a sequence of IO operations. The input-interpreter features five core operations.

`in[b,w,l](addr)` perform a PIO read
`out[b,w,l](addr, val)` perform a PIO write
`read[b,w,l,q](addr)` perform an MMIO read
`write[b,w,l,q](addr, val)` perform an MMIO write
`hypercall(reg_bitmap, *vals)` perform a hypercall

For these operations, the **`b`**`yte`,**`w`**`ord`,**`l`**`ong`,**`q`**`uad` suffixes specify the size of the access.

For each of these operations, HYPERPILL-Fuzz reads the address/value (if needed) and injects the corresponding type of VM-Exit into the L2 guest (following the procedure outlined in § 3.2.1). HYPERPILL-Fuzz resumes the snapshot and waits for the hypervisor to handle the injected IO operation. As soon as the hypervisor attempts to re-enter the guest by using the `vmresume` instruction, HYPERPILL-Fuzz injects the next operation in the input. Once HYPERPILL-Fuzz has executed the entire input, it restores the hypervisor's initial

memory and register state from the snapshot. Thus, there is no state-leakage between individual fuzzer inputs.

Two types of IO: *Hypercalls* and *DMA* require functionality beyond the simple opcode interpreter. We cover each of these special cases individually.

4.3.1 Hypercalls

As discussed in § 3.2.4, the `vmcall` instruction does not specify any fixed ABI to pass data to the hypervisor. Furthermore, different hypercalls can feature different APIs. A hypervisor can use any number of implementation-specific registers to receive inputs from the guest (e.g., one register can contain the hypercall-id and another one can contain a DMA pointer to a structure containing hypercall parameters). Initially, HYPERPILL does not use any fuzzer-provided values to fill registers, when executing hypercalls. Instead, HYPERPILL fills all registers with random data from a pRNG. During the emulation of a hypercall, if any of the random-values occur as arguments of `cmp` instructions, HYPERPILL-Fuzz identifies the register that contained the random-value as significant. HYPERPILL-Fuzz *dynamically modifies the* `vmcall` *operation within the input testcase* to explicitly specify that the corresponding register-value should be specified by the fuzzer, and *overwrites* the input-interpreter's "hypercall" operation to reflect the pRNG-generated value. More specifically, the "hypercall" operation in fuzzer inputs, is followed by a 32-bit register-bitmap which specifies whether any of the general-purpose and 16 XMM registers should be filled with fuzzer-data. The bitmap is followed by the values of the fuzzer-specified registers. If new significant registers are identified, the fuzzing input is modified. If the input achieves new coverage, the *modified* input is stored in the fuzzer's corpus, for future mutation. To support this functionality, we modified the fuzzing backend (libFuzzer) to support (1) Modifying fuzzer inputs during execution (so the hypercall operation can be modified if a significant register is identified) (2) Preventing fuzzer mutations from affecting parts of the input (so the mutations do not overwrite the 32-bit register-bitmap, which should only be modified if new significant registers are found). This process is highlighted in Fig. 4: after executing a testcase, *a modified input* is returned to the fuzzing-engine, for further mutation.

4.3.2 DMA

Unlike PIO, MMIO, and Hypercalls, DMA is a reaction to other IO operations, without the virtual CPU's direct involvement in the data transfer. In the context of virtualization, the hypervisor can initiate DMA at any point during its execution, by accessing some of the guest's physical memory. Thus, HYPERPILL-Fuzz cannot implement DMA as a simple opcode, since there is no way to directly "inject" it through a VM-Exit. Instead, DMA occurs implicitly as a side effect of the other IO operations which inform the hypervisor that it should initiate a DMA transfer. Since HYPERPILL does not feature any device-grammars, it is not aware, a priori, which IO operations will cause DMA. State-of-the-art open-source hypervisor-fuzzers such as Morphuzz and ViDeZZo identified that the DMA input-space can be effectively fuzzed by adding strategic fuzzing hooks to the hypervisor source-code, targeting the DMA access APIs [6, 26]. When the hypervisor initiates a DMA access, the hook fills the corresponding region of guest-memory with fuzzer-provided data *just-in-time*. This strategy elides the need for prior information about which IO operations initiate DMA accesses and the size/format of the DMA data.

Unlike these prior approaches, HYPERPILL cannot directly modify DMA access APIs. However, since HYPERPILL-Fuzz runs the hypervisor in an emulator, and has precise information about which memory frames are dedicated to the guest's memory, it can intercept the hypervisor's DMA accesses. After injecting a PIO/MMIO/Hypercall into the hypervisor, HYPERPILL tracks all the hypervisor's memory accesses. If the hypervisor reads from memory marked as DMA by HYPERPILL-Inspect, HYPERPILL intercepts the access and fills it with data from the current fuzzer input. This DMA-access tracking is completely oblivious to the inner workings of the hypervisor and the structure of its DMA APIs. Furthermore, unlike prior approaches which require manual modifications to hypervisor source-code, HYPERPILL does not risk missing DMA accesses due to incomplete API instrumentation – DMA is tracked at the level of (emulated) physical memory. In § 5, we will see that this enables HYPERPILL to outperform fuzzers even when they have access to the DMA API source-code.

5 Evaluation

We evaluate HYPERPILL's fuzzing capabilities to answer the following research questions:

- **RQ1** Does HYPERPILL trigger complex coverage, and does it compare favorably against state-of-the-art fuzzers that target open-source hypervisors?
- **RQ2** Can HYPERPILL discover new bugs in a wide range of hypervisors without hypervisor-specific configuration or modifications?
- **RQ3** Can HYPERPILL find new bugs even in virtual-devices that have already been fuzzed extensively?
- **RQ4** Can HYPERPILL rediscover previously known bugs in hypervisors?
- **RQ5** How does HYPERPILL's emulation-based execution performance compare to that of other fuzzers?

5.1 Experimental Setup

We conducted our experiments for QEMU version 8.0.0 (released April 2023), Hyper-V shipped with Windows 10, and macOS Virtualization Framework shipped with macOS Ventura (version 13). We selected these three hypervisors as

they are the default hypervisors that ship with the three most-popular consumer operating-systems. As these hypvervisors run the gamut from open-source (KVM) to closed-source (macOS, Hyper-V) , different programming languages (C: KVM, C++: Hyper-V, Unknown: macOS), and availability of debugging symbols (KVM: full, Hyper-V: some, macOS: none) this selection showcases the broad applicability of HYPERPILL.

We performed a coverage comparison with the two most recently updated fuzzers (i.e., Morphuzz and ViDeZZo) that target QEMU and have their source-code available [6, 26]. For Morphuzz, we use the upstream version maintained in the QEMU repository. For ViDeZZo, we adjusted the code to support QEMU v8.0.0. We conducted our evaluation over 12 devices (i.e., four block devices, three graphics adapters, three network adapters, and two USB controllers). For each category, we selected the most complex devices estimated by lines of code in the QEMU repository. Nine of these devices overlap with the ones evaluated in prior works [6, 26]. We fuzzed each QEMU device for 24 hours on 8 cores (8 fuzzing workers per device) and repeated these experiments five times. Similarly, we fuzzed our Hyper-V and macOS snapshots for 24 hours on 8 cores. We performed all experiments on university cluster servers equipped with 2x Intel Xeon Gold 6132 @ 2.60 GHz with memory ranging from 192 GB to 512 GB (memory was not a limiting factor for any fuzzer instance).

5.2 Coverage

We compared HYPERPILL's coverage performance to Morphuzz and ViDeZZo on QEMU, a hypervisor well suited to comparing fuzzers due to its popularity and broad suite of virtual-devices [6, 17, 26, 29, 37, 38]. For all fuzzers we instrumented the qemu-binary with LLVM source-coverage [43]. Since HYPERPILL is based on a snapshot-fuzzing approach, we added instrumentation to MELTER to prevent the fuzzer from resetting LLVM's coverage-bitmap after each input. Tab. 2 presents our coverage results to answer **RQ1**. For 10 out of 12 devices, HYPERPILL outperformed Morphuzz and ViDeZZo. HYPERPILL achieved the best coverage across all paravirtual VIRTIO devices, which are used in security-sensitive cloud environments. Furthermore, HYPERPILL was the only fuzzer capable of fuzzing the QXL device, which no prior fuzzer targets due to QXL's reliance on the multi-threaded external libspice library. HYPERPILL performed well both for devices that require no DMA interactions (cirrus) and for devices that rely on them extensively (e.g. xHCI—the most advanced USB controller implemented in QEMU).

Table 2: HYPERPILL coverage results side-by-side with results reported by prior work. Empty cells indicate that prior work did not include the corresponding device in its evaluation. In parentheses, we indicate the execution per second. The ⊡ column indicates whether the device accesses guest-controlled memory via coarse-grained DMA APIs that return indexable pointers to guest-memory. The final column indicates whether we found bugs, for each device.

For 8 of the 10 devices that rely on coarse-grained DMA APIs that return pointers to large regions of guest-memory (see ⊡ column in Tab. 2), HYPERPILL achieves the highest coverage. We attribute this to the fact that, unlike prior approaches, HYPERPILL can precisely hook atomic DMA-accesses, rather than having to pre-fill large DMA-pointer regions.

We identified two problems resulting in low ViDeZZo coverage for some evaluated devices. First, ViDeZZo's intra-message annotation is not well-supported, for certain devices (virtio-scsi/virtio-gpu) and is missing for igb and nvme. Additionally, since ViDeZZo does not reset state between inputs, ViDeZZo requires discovered bugs to be fixed, so that the fuzzer can continue making progress.

Note that no fuzzer achieves 100% coverage for any device. This is due to the fact that devices contain code that is unreachable by fuzzing, e.g., initialization code. Furthermore, devices contain options which essentially create dead-code regions which are only accessible with a particular device configuration (e.g., virtio-gpu provides 44 configuration options, alone). In our experiments, all three fuzzers were started with identical configuration options.

RQ1: HYPERPILL outperforms the coverage of previous fuzzers across a wide range of complex virtual-devices.

5.3 Bug-Finding

In total, HYPERPILL identified 26 new bugs (11 in QEMU, 9 in Hyper-V, and 6 in macOS Hypervisor-Framework, detailed in Appendix Tab. 3) in all the hypervisors it fuzzed and across all device-categories, which answers **RQ2**. Of these 11 are bugs found in QEMU, which has been fuzzed extensively on OSS-Fuzz (with Morphuzz) since 2020, which answers **RQ3**. All bugs were identified during the 24-hour fuzzing campaigns. Here, we detail four bugs found by HYPERPILL since they are representative of HYPERPILL's focus on gener-

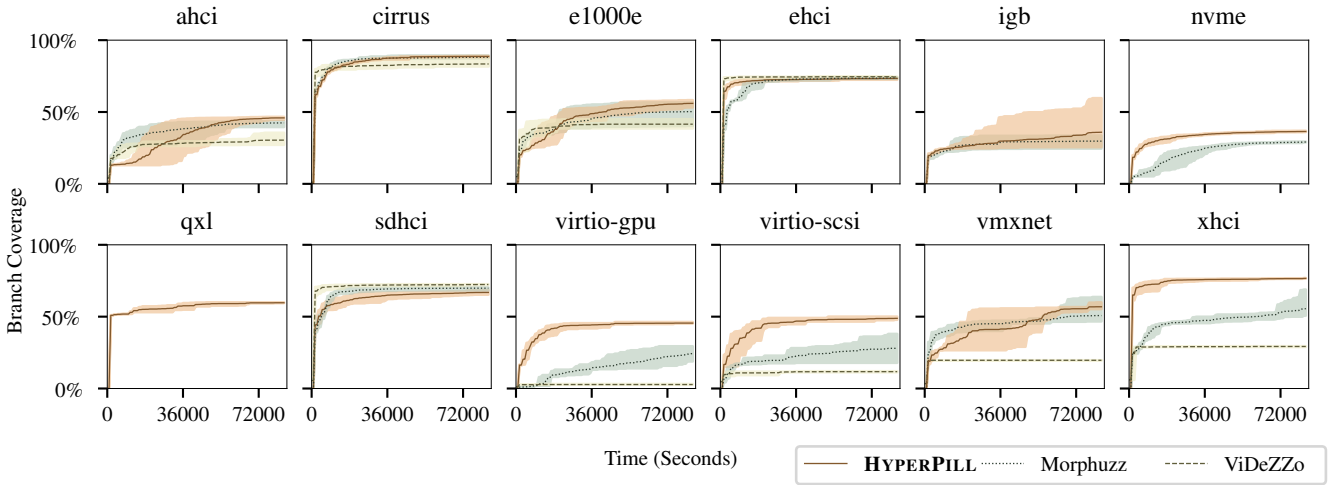

Figure 5: Branch coverage over 24 hours fuzzing 12 devices. The shaded regions represent the maximum/minimum coverage achieved by the corresponding fuzzer, across five experiments.

Table 3: New bugs found by HyperPill

ically fuzzing arbitrary hypervisors across the entire spectrum of input spaces, while producing complex inputs that require intricate interactions with individual hypervisor components.

QEMU: Heap-Buffer-Overflow in virtio-scsi. QEMU's VIRTIO devices are security-sensitive paravirtual-devices that are actively used for cloud-applications. QEMU's virito-scsi device has been fuzzed on OSS-Fuzz since 2020. HyperPill discovered a heap-buffer-overflow in virtio-scsi's call to the `virtqueue_alloc_element()` function. This bug was neither discovered by ViDeZZo nor Morphuzz [6, 26]. HyperPill hooked 12 individual DMA accesses (3 of which were performed through lossy DMA-pointer APIs) and populated a total of 278 bytes. Source-code level hooking of the DMA-pointer API would require filling several thousand bytes (most of which are not touched). As such, API-hooking approaches (e.g., Morphuzz and ViDeZZo) waste effort mutating input bytes used to populate unused memory. However, HyperPill does not have the same problem since HyperPill performs DMA hooking at the level of atomic accesses.

QEMU: Heap-Overflow in QXL. QEMU's high-performance QXL (Spice) display device is the preferred display driver for cloud applications and thin-client solutions. However, due to QXL's multithreaded design, past fuzzers have been unable to fuzz it. Threading is incompatible with Morphuzz's fork-server and since ViDeZZo does not reset state in between inputs, ViDeZZo is unable to produce deterministic inputs [6, 26]. Furthermore, QXL uses QEMU's `memory_region` API to allocate a VRAM buffer that it accesses via a pointer. Since accesses to this buffer do not pass through the DMA APIs, Morphuzz and ViDeZZo do not receive feedback when the QXL device accesses guest-controlled data within this buffer. Additionally, QXL relies extensively on an external library (i.e., `libspice`), which is not instrumented for coverage-collection, by default. However, HyperPill discovered a heap-overflow in QXL's `qxl_cookie_new()` function due to the introspection capabilities enabled by emulation. The testcase reproducing this bug required interaction with QXL via PIO and DMA.

Hyper-V: Denial-of-Service via Hypercall. One of the 9 bugs HyperPill identified in Hyper-V is a denial-of-service bug via Hyper-V hypercall `0x83` (HvCallDetachDevice). This bug showcases HyperPill's ability to explore the complex hypercall input space. HyperPill successfully used com-

parison feedback to identify that Hyper-V uses register RCX to communicate the hypercall-id. Leveraging feedback from comparisons, HYPERPILL learned that `0x83` is an "interesting" hypercall-id. Furthermore, HYPERPILL used the runtime feedback to identify registers RAX and R8 as registers that contain argument values used by the hypercall's handler. After injecting the hypercall, HYPERPILL hooked accesses to five distinct DMA buffers, filling with a total of 60 bytes, to trigger the bug. This example demonstratrs that HYPERPILL's ability to simultaneously fuzz all input-spaces, while leveraging runtime feedback to continually refine inputs, enabling HYPERPILL to produce complex test-cases.

macOS: Out-of-Bounds in virtio-net. One of the 6 bugs HYPERPILL identified in macOS Virtualization-Framework is an out-of-bounds memory access in the virtio-net device. The crashing input performed three MMIO accesses to the device's MMIO regions. HYPERPILL detected accesses to four distinct DMA buffers (populating 47 bytes), to trigger the crash. To the best of our knowledge, there are no symbols publically available for macOS Virtualization Framework. As such, manually hooking macOS' DMA access APIs would require a considerable amount of work by a virtualization expert. However, HYPERPILL's use of feedback from the hardware-virtualization interface allows it to transparently fuzz complex attack-surfaces (e.g., DMA).

RQ2: HYPERPILL effectively finds bugs across a wide range of devices and hypervisors with diverse designs.
RQ3: Furthermore, HYPERPILL finds new bugs in code that has already been extensively fuzzed.

QEMU: Unique AHCI Coverage. In all of our runs, HYPERPILL was the only fuzzer that reached the AHCI device's `execute_ncq_command` function. Upon inspection, we attributed this to the fact that the caller (`process_ncq_command`), relies on a coarse-grained DMA API to map an entire guest page containing a table of AHCI slot IDs. As HYPERPILL does not rely on API-hooking, it can detect individual accesses to the table. In combination with the virtio-scsi and QXL bug case-studies, this demonstrates the value of instruction-level hooking of DMA accesses over API hooking approaches as proposed by Morphuzz, ViDeZZo and V-Shuttle.

5.3.1 Rediscovering Previously-Known Bugs

We backported the 5 CVEs used in the ViDeZZo evaluation to QEMU v8.0.0 and used each fuzzer to fuzz each affected device (5 total) for 24 hours. Our results averaged over 5 runs are presented in Table 4.

HYPERPILL identified all of the bugs. ViDeZZo identified 4 out of the 5 bugs faster than HYPERPILL because it does not perform any state resetting between inputs. However, as shown in our coverage and new-bug evaluation (§ 5.2 and § 5.3), this has a long-term effect of limiting total coverage achieved, for complex devices.

CVE	Description	Morphuzz	ViDeZZo	HYPERPILL
CVE-2020-11869	ATI Integer-overflow	0:37	0:11	0:13
CVE-2020-25084	EHCI UAF	4:31	0:43	1:11
CVE-2020-25085	SDHCI Heap-Overflow	5:34	2:36	6:24
CVE-2020-25625	OHCI DoS	0:14	0:04	0:06
CVE-2021-20257	E1000 DoS	3:34	Timeout	1:29

Table 4: Mean times to find known bugs (h:mm)

RQ4: HYPERPILL consistently finds previously-known bugs in hypervisors and outperforms related works for complex devices.

5.4 Throughput

HYPERPILL fuzzes hypervisors by leveraging snapshot-fuzzing in an emulated environment, allowing it to perform rapid state-resets and achieve hypervisor-introspection capabilities that do not exist natively. However, due to the nature of emulation, HYPERPILL has to pay an intrinsic performance penalty. To measure the penalty, we compared the execution-rate of test-cases executed by HYPERPILL with Morphuzz and ViDeZZo. The results are presented in Tab. 2. ViDeZZo executes QEMU code natively and does not reset state in-between inputs. As such it has the highest execution rate, outperforming Morphuzz and HYPERPILL by a factor of 9. Morphuzz relies on a fork-server, incurring a high-overhead due to the costly system-calls invoked between inputs.

Orthogonally, HYPERPILL's full-system snapshot resetting occurs entirely within the emulator process and does not require any system-calls. To measure the difference between Morphuzz's and HYPERPILL's state-resetting, we configured both fuzzers to fuzz all virtual-devices for 24 hours and measured the amount of time each fuzzer spends resetting state. We found that Morphuzz spends 71% of the time resetting state, while HYPERPILL only spends 9%.

As such, HYPERPILL outperforms Morphuzz for 8 target devices, even though it relies on emulation. Note that both ViDeZZo and Morphuzz provide inputs to QEMU through the internal "QTest" framework, skipping the costs associated with executing KVM's VM-Exit processing code.

RQ5: The lower execution rate of HYPERPILL is more than compensated by the detailed feedback and its generic applicability to any (even closed-source) hypervisor.

6 Discussion

Despite HYPERPILL's positive results, we briefly discuss avenues for future improvements.

Detecting Crashes. Similar to other full-system snapshot-fuzzers, HYPERPILL features target-specific methods for detecting crashes. For QEMU (an open-source target), HYPERPILL hooks into common failure-cases such as `assert()`, `abort()`, and `asan_stack_trace()`. For closed-source targets, HYPERPILL relies on coarser-grained methods, such as detecting `hlt` instructions, debugging interrupts, and protection-violating page-faults. In the future, HYPERPILL's crash-detection can be improved by integrating binary sanitizers and adding hooks to crash-detection mechanisms such as Windows' page-heap [31] and macOS' KASAN.

Improving Performance. Since HYPERPILL runs the hypervisor in an emulator, some operations (such as large memory copies), are significantly slower than counterparts running on native hardware. HYPERPILL's performance could be improved by leveraging multiple snapshots (e.g., ones taken after expensive operations), caching results and side effects of identical function-calls, and adding "accelerated" implementations of common expensive functions such as `memcpy()`. Furthermore, though HYPERPILL is the first hypervisor-fuzzer tailored toward fuzzing hypervisors across multiple threads or execution environments, HYPERPILL currently does not optimize the L1 OS scheduler to ensure that only hypervisor-related threads are executed. In the future, HYPERPILL could configure the OS to only schedule hypervisor-related tasks, or to skip execution of unrelated tasks by re-invoking the scheduler until a hypervisor task is selected.

Automatically Generating Standalone Reproducers. Currently, we manually convert HYPERPILL crashes into standalone crash-reproducers that can be used without the snapshot or emulator. In the future, these crashes can automatically be converted into reproducers using a custom kernel that can be booted within a hypervisor to replay HYPERPILL's crash.

Extensions to Other Architectures. HYPERPILL targets x86-64 hypervisors that leverage Intel VT-x. However HYPERPILL's techniques similarily apply to other popular architectures, such as ARM and POWER which feature similar virtualization extensions. Similar to Bochs for x86, there are mature emulators for these architectures (QEMU). Furthermore, for ease of use, HYPERPILL's stages can be modified, without affecting the core design. For example, a hardware debugging interface (JTAG) can be used to collect a full-system snapshot, rather than nested-virtualization.

Additional Attack Surfaces. In this work, we focus primarily on bugs in virtual-device implementations and hypercall handlers. However, hypervisors also feature code that parses guest instructions and walks guest page tables. With additional consideration for the semantics of these attack-surfaces (e.g. ensuring parsed instructions match the instructions that trigger VM exits), HYPERPILL can be adapted to fuzz these surfaces. We leave these extensions to HYPERPILL as future work.

7 Related Work

Fuzzing has gained academic momentum with the introduction of the American Fuzzy Lop (AFL) [52]. AFL's coverage-guided fuzzing approach significantly influenced research, leading to improvements in various aspects of fuzzing performance. Scholars have enhanced input scheduling [21, 35, 47], mutation algorithms [7, 28, 34], and input feedback mechanisms [1, 15, 54]. Some researchers have explored concolic execution techniques [22, 23, 51] to overcome challenges such as comparisons against "magic constants" and checksums [33]. Fuzzers like AFL with laf-intel [24], CmpLog [11], RedQueen [2], and libFuzzer [41] have applied source-code instrumentation to navigate comparisons against magic bytes.

The scope of fuzzing extends to diverse targets, including code interpreters [16, 19, 45, 50], compilers [8, 25, 27], and network protocols [3, 10, 14]. Operating system kernels have been a focal point, with specialized systems addressing kernel drivers [9], kernel race conditions [20], file systems [49], and the system-call interface [12, 18, 39]. Periscope [42] examines MMIO and DMA communication to identify vulnerabilities in a kernel exposed to a compromised device. Other studies apply static [46, 48] and dynamic [40] techniques to detect and analyze double-fetch issues in software.

In the realm most pertinent to our work, researchers have recognized that virtual-devices present similar challenges to fuzzers as kernel system calls and drivers. IOFuzz [30] identifies bugs in virtual-devices by writing random values to PIO. VDF [17] collects MMIO and PIO traces as seeds for coverage-guided fuzzing, but it does not fuzz DMA or reset state between input executions. Hyper-Cube [38] and Nyx [37], are virtual-device fuzzers, that rely on a custom-built guest operating system. Hyper-Cube is a black-box fuzzer that faces limitations when fuzzing virtual-devices reliant on magic constants and DMA. Hyper-Cube does not support Hyper-V. Nyx uses full-system snapshotting and hardware-assisted coverage but requires manually-written specifications for complex DMA devices.

Simultaneously, V-Shuttle [32] introduces a targeted method to fuzz the DMA input-space by replacing DMA access calls with reads from a file generated by AFL. Morphuzz, ViDeZZo, and MundoFuzz leverage source-code analysis and hooking to alleviate the need for manual specifications. HyperFuzzer is a closed-source fuzzer that targets Hyper-V's

instruction emulation code (a surface largely independent of the virtual-devices we examine in this work) [13]. In an industrial context, there is previous work on fuzzing virtual-devices [44] using a minimal OS connected to AFL.

8 Conclusion

HYPERPILL is the first generic fuzzer capable of automatically fuzzing arbitrary hypervisors across all major input-spaces (i.e., PIO/MMIO/Hypercalls/DMA). HYPERPILL takes advantage of the standard hardware-virtualization interface to enumerate the input-spaces. During fuzzing, HYPERPILL leverages the fine-grained feedback afforded by emulation, to create complex inputs and identify crashes in hypervisors. In our evaluation, we found that HYPERPILL can outperform state-of-the-art techniques that leverage hypervisor modifications and API hooking, achieving the highest coverage for 10/12 QEMU devices. Our system identified 26 new bugs, which we are responsibly disclosing to the vendors. HYPERPILL is available at https://github.com/HexHive/HyperPill

Abstract

Differential privacy (DP) via output perturbation has been a *de facto* standard for releasing query or computation results on sensitive data. Different variants of the classic Gaussian mechanism have been developed to reduce the magnitude of the noise and improve the utility of sanitized query results. However, we identify that all existing Gaussian mechanisms suffer from **the curse of full-rank covariance matrices**, and hence the expected accuracy losses of these mechanisms equal the trace of the covariance matrix of the noise. Particularly, for query results in $\mathbb{R}^M$ (or $\mathbb{R}^{M\times N}$ in a matrix form), in order to achieve (ε,δ)-DP, the expected accuracy loss of the classic Gaussian mechanism, that of the analytic Gaussian mechanism, and that of the Matrix-Variate Gaussian (MVG) mechanism are lower bounded by $C_C(\Delta_2 f)^2$, $C_A(\Delta_2 f)^2$, and $C_M(\Delta_2 f)^2$, respectively, where $C_C = \frac{2\ln\left(\frac{1.25}{\delta}\right)}{\varepsilon^2}M$, $C_A = \frac{\left(\Phi^{-1}(\delta)\right)^2+\varepsilon}{\varepsilon^2}M$, $C_M = \frac{\frac{5}{4}H_r+\frac{1}{4}H_{r,\frac{1}{2}}}{2\varepsilon}MN$, $\Delta_2 f$ is the l_2 sensitivity of the query function f, $\Phi(\cdot)^{-1}$ is the quantile function of the standard normal distribution, H_r is the rth harmonic number, and $H_{r,\frac{1}{2}}$ is the rth harmonic number of order $\frac{1}{2}$.

To lift this curse, we design a **R**ank-1 **S**ingular **M**ultivariate **G**aussian (R1SMG) mechanism. It achieves (ε,δ)-DP on query results in $\mathbb{R}^M$ by perturbing the results with noise following a singular multivariate Gaussian distribution, whose covariance matrix is a **randomly** generated rank-1 positive semi-definite matrix. In contrast, the classic Gaussian mechanism and its variants all consider **deterministic** full-rank covariance matrices. Our idea is motivated by a clue from Dwork et al.'s seminal work on the classic Gaussian mechanism that has been ignored in the literature: when projecting multivariate Gaussian noise with a full-rank covariance matrix onto a set of orthonormal basis in $\mathbb{R}^M$, only the coefficient of a single basis can contribute to the privacy guarantee.

This paper makes the following technical contributions.

(i) The R1SMG mechanisms achieves (ε,δ)-DP guarantee on query results in $\mathbb{R}^M$, while its expected accuracy loss is lower bounded by $C_R(\Delta_2 f)^2$, where $C_R = \frac{2}{\varepsilon\psi}$ and $\psi = \left(\frac{\delta\Gamma(\frac{M-1}{2})}{\sqrt{\pi}\Gamma(\frac{M}{2})}\right)^{\frac{2}{M-2}}$. We show that C_R is on a lower order of magnitude by at least M or MN compared with C_C, C_A, and C_M. Therefore, the expected accuracy loss of the R1SMG mechanism is on a much lower order compared with that of the classic Gaussian mechanism, of the analytic Gaussian mechanism, and of the MVG mechanism.

(ii) Compared with other mechanisms, the R1SMG mechanism is more stable and less likely to generate noise with large magnitude that overwhelms the query results, because the kurtosis and skewness of the nondeterministic accuracy loss introduced by this mechanism is larger than that introduced by other mechanisms.

1 Introduction

Differential privacy (DP) [15, 17] has been increasingly recognized as the fundamental building block for privacy-preserving database query, sharing, and analysis. In this area, one important privacy guarantee is (ε,δ)-DP. It means that, except with a small probability of δ, the presence or absence of any data record in a dataset cannot change the probability of observing a specific query result of the dataset by more than a multiplicative factor of e^{ε}.

The classic Gaussian mechanism, proposed by Dwork et al. [15], is an essential tool to achieve (ε,δ)-DP. Particularly, when the output of a query function is a high dimensional vector, **the classic Gaussian mechanism will add independent and identically distributed (i.i.d.) noise to each component of the result** (see Definition 3 and [17, p. 261], [15, p. 3]).

This standard practice has spread widely into many fields. For example, a differentially private mechanism returns noisy answers to a set of queries by adding i.i.d. noise to each query result [34]. Privacy-preserving learning employs differentially private stochastic gradient descent through perturbing each component of the gradient with i.i.d. Gaussian noise [3]. Unfortunately, as we will show later, the adoption of the classic Gaussian mechanism greatly hinders the utility (accuracy) of the sanitized query results because the expected accuracy loss

(Definition 1) of the classic Gaussian mechanism is on the order of $M(\Delta_2 f)^2$, where $\Delta_2 f$ is the l_2 sensitivity of the query function and M is the dimension of the query results. We refer to this as the **curse of full-rank covariance matrices**.

Definition 1. ***Accuracy Loss [22, 34].*** *The accuracy loss of a differentially private output perturbation mechanism ($\mathcal{M}$) is*

$$\mathcal{L} = ||\mathcal{M}(f(\boldsymbol{x})) - f(\boldsymbol{x})||_2^2 = ||\mathbf{n}||_2^2, \quad (1)$$

where $\boldsymbol{x}$ denotes a dataset, $f(\boldsymbol{x})$ is the query result on dataset $\boldsymbol{x}$, and $\mathbf{n}$ is the noise vector added to the query result.

We can see from (1) that the accuracy loss is equal to the magnitude of the additive noise. Due to the randomness involved in the noise, $\mathcal{L}$ is nondeterministic. Thus, we investigate the expected value of accuracy loss, i.e., $\mathbb{E}[\mathcal{L}]$.

1.1 The Curse of Full-Rank Covariance Matrices

Here, we provide a high-level description on the identified curse of full-rank covariance matrices, while the details are deferred to Section 3.

Proposition 1. ***The Identified Curse.*** *Let $\boldsymbol{x}$ be a dataset, $f(\boldsymbol{x}) \in \mathbb{R}^M$ the queried results, and $\mathbf{n} \in \mathbb{R}^M$ the perturbation noises introduced by the classic Gaussian mechanism (or its variants, e.g., the analytic Gaussian mechanism [5], and the Matrix-Variate Gaussian (MVG) mechanism [11]), respectively. Then, the expected accuracy loss is equal to the trace of the covariance matrix of the Gaussian noise $\mathbf{n}$, i.e., $\mathbb{E}[\mathcal{L}] = Tr[Cov(\mathbf{n})]$, where $Cov(\mathbf{n})$ denotes the covariance matrix of the noise $\mathbf{n}$.*

Since existing Gaussian mechanisms always introduce noise that has a full-rank covariance matrix, i.e., $rank(Cov(\mathbf{n})) = M$, where $Cov(\mathbf{n})$ is symmetric and positive definite [10], $\mathbb{E}[\mathcal{L}]$ is equivalent to the summation of M positive eigenvalues of $Cov(\mathbf{n})$ and hence generally high. In Section 3, we will prove Proposition 1 when $f(\boldsymbol{x})$ is in a vector form and in a matrix form under different variants of the classic Gaussian mechanism.

1.2 Lifting the Curse: Main Contributions

To lift the identified curse, we resort to the **singular multivariate Gaussian distribution** [14, 27, 29, 39, 42] (Definition 7) with a rank-1 covariance matrix and develop the **R**ank-1 **S**ingular **M**ultivariate **G**aussian (R1SMG) mechanism. Our idea is motivated by an ignored clue in Dwork and Roth's proof for the DP guarantee of the Gaussian mechanism [17]. Specifically, Dwork and Roth proved that by projecting the additive noise $\mathbf{n} \in \mathbb{R}^M$ onto a fixed set of orthonormal basis vectors (e.g., $\boldsymbol{b}_1, \boldsymbol{b}_2, \cdots, \boldsymbol{b}_M$), only the coefficient of a single basis vector (e.g., $\mathbf{n}^T \boldsymbol{b}_1$) contributes to the privacy guarantee (more details are deferred to Section 4). However, this important clue has been ignored in the literature. To the best of our knowledge, our work is the first to discover and leverage this ignored clue.

The main contributions of this paper are summarized as follows.

(1) A new DP Mechanism and Privacy Guarantee (Definition 8 and Theorem 5). We develop the R1SMG mechanism that can achieve (ε, δ)-DP guarantee on high dimensional query results $f(\boldsymbol{x}) \in \mathbb{R}^M$ ($M > 2$). The covariance matrix, denoted as $\mathbf{\Pi}$, of the noise introduced by the R1SMG mechanism is a random rank-1 symmetric positive semi-definite matrix, whose eigenvector is randomly sampled from the unit sphere embedded in $\mathbb{R}^M$. Let σ_* be the eigenvalue[1] of the rank-1 covariance matrix $\mathbf{\Pi}$. We prove that a sufficient condition for the R1SMG mechanism to achieve (ε, δ)-DP is $\sigma_* \geq \frac{2(\Delta_2 f)^2}{\varepsilon \psi}$, where $\Delta_2 f$ is the l_2 sensitivity of the query function f, $\psi = \left(\frac{\delta \Gamma(\frac{M-1}{2})}{\sqrt{\pi}\Gamma(\frac{M}{2})}\right)^{\frac{2}{M-2}}$, and $\Gamma(\cdot)$ is Gamma function. Note that similar to that in the classic Gaussian mechanism where $0 < \varepsilon < 1$, we have $0 < \varepsilon < 1/M$ in the R1SMG mechanism. In other words, The R1SMG mechanism can work well under very strict privacy budget.

(2) Expected accuracy loss on a much lower order than that of existing Gaussian mechanisms. We prove that the expected accuracy loss of $f(\boldsymbol{x})$ caused by the R1SMG mechanism (i.e., $||R1SMG(f(\boldsymbol{x})) - f(\boldsymbol{x})||_2^2$) is lower bounded by $C_R(\Delta_2 f)^2$, where for any fixed feasible ε, $C_R = \frac{2}{\varepsilon \psi}$ has a decreasing trend as M increases and converges to $\frac{2}{\varepsilon}$ as M goes large (Theorem 7). In contrast, the classic Gaussian, analytic Gaussian, and MVG mechanisms result in expected accuracy loss that is lower bounded by $C_C(\Delta_2 f)^2$, $C_A(\Delta_2 f)^2$, and $C_M(\Delta_2 f)^2$, respectively, where $C_C = \frac{2\ln(\frac{1.25}{\delta})}{\varepsilon^2} M$, $C_A = \frac{(\Phi^{-1}(\delta))^2 + \varepsilon}{\varepsilon^2} M$, and $C_M = \frac{\frac{5}{4}H_r + \frac{1}{4}H_{r,\frac{1}{2}}}{2\varepsilon} MN$ (for query results in $\mathbb{R}^{M \times N}$, i.e., in a matrix form). Therefore, by using the R1SMG mechanism, **less is more** in the sense that noise of a much lower order of magnitude is needed compared with that of existing Gaussian mechanisms.

(3) Higher stability of the perturbed results (Theorem 8 and 9). We theoretically show that the accuracy of the perturbed $f(\boldsymbol{x})$ obtained by the R1SMG mechanism is more stable than the other mechanisms. By "stable", we mean that it is less likely for the R1SMG mechanism to generate noise with large magnitude that overwhelms $f(\boldsymbol{x})$.

(4) Applications. We perform three case studies, including differentially private 2D histogram query, principal component analysis, and deep learning, to validate that the R1SMG mechanism can achieve better data utility in various applications by introducing less noise, i.e., less is more.

[1] The eigenvalues and singular values are identical for symmetric positive (semi)-definite real-valued matrices. Thus, we use "eigenvalues" and "singular values" interchangeably for such matrices like $\mathbf{\Pi}$ in this paper.

Mechanisms ($\mathcal{M}$)	Expected accuracy loss $\mathbb{E}_{\mathcal{M}}[\mathcal{L}]$	Stability (Section 6)
The classic Gaussian mechanism [15] (noise decided by variance σ^2 and dimension $f(\boldsymbol{x}) \in \mathbb{R}^M$)	$\mathbb{E}_{classic}[\mathcal{L}] = Tr[\sigma^2 \mathbf{I}_{M\times M}] \geq C_C(\Delta_2 f)^2$, where $C_C = \frac{2\ln(\frac{1.25}{\delta})}{\varepsilon^2} M$. (Section 3.1)	**unstable**, i.e., likely to generate noise with large magnitude
The analytic Gaussian mechanism [5] (noise decided by variance σ_A^2 and dimension $f(\boldsymbol{x}) \in \mathbb{R}^M$)	$\mathbb{E}_{analytic}[\mathcal{L}] = Tr[\sigma_A^2 \mathbf{I}_{M\times M}] \geq C_A(\Delta_2 f)^2$, where $C_A = \frac{\left(\Phi^{-1}(\delta)\right)^2 + \varepsilon}{\varepsilon^2} M$. (Section 3.1)	**unstable**
The MVG mechanism [11] (noise decided by covariance matrices $\boldsymbol{\Sigma}$, $\boldsymbol{\Psi}$, and dimension $f(\boldsymbol{x}) \in \mathbb{R}^{M\times N}$)	$\mathbb{E}_{MVG}[\mathcal{L}] = Tr[\boldsymbol{\Sigma} \otimes \boldsymbol{\Psi}] \geq C_M(\Delta_2 f)^2$, where $C_M = \frac{\frac{5}{4} H_r + \frac{1}{4} H_{r,\frac{1}{2}}}{2\varepsilon} MN$. (Section 3.2)	**unstable**
The R1SMG mechanism (noise decided by a random rank-1 singular covariance matrix with only one nonzero eigenvalue σ_*)	$\mathbb{E}_{R1SMG}[\mathcal{L}] = Tr[\boldsymbol{\Pi}] = \sigma_* \geq C_R(\Delta_2 f)^2$, where $C_R = \frac{2}{\varepsilon\psi}$, $\psi = \left(\frac{\delta\Gamma(\frac{M-1}{2})}{\sqrt{\pi}\Gamma(\frac{M}{2})}\right)^{\frac{2}{M-2}}$, and $C_R = \Theta(\frac{\varepsilon C_C}{M}) = \Theta(\frac{C_A}{M}) = \Theta(\frac{C_M}{MN})$. C_R is on a lower order of magnitude by at least M or MN compared with C_C, C_A, and C_M, and converges to $\frac{2}{\varepsilon}$ as M goes large for any fixed feasible ε. (Section 5.3)	**stable**, i.e., unlikely to generate noise with large magnitude

Table 1: Comparisons between the R1SMG mechanism and the classic Gaussian mechanism and its variants.

Table 1 summarizes and compares our proposed R1SMG mechanism with the classic Gaussian mechanism and its variants from the perspective of expected accuracy loss parameterized by the noise parameters and utility stability.

Roadmap. We review the preliminaries for this study in Section 2. Next, we identify the curse of full-rank covariance matrices in various types of Gaussian mechanisms in Section 3. In Section 4, we revisit Dwork and Roth's proof, and identify a previously ignored clue that motivates our work. After that, we formally develop the R1SMG mechanism in Section 5. In Section 6, we analyze the utility stability achieved by our mechanism and theoretically compare it with other mechanisms. Section 7 presents the case studies. Section 8 discusses the related works. Finally, Section 9 concludes the paper.

2 Preliminaries

In this section, we review (ε, δ)-DP, and revisit the definitions and privacy guarantees of the classic Gaussian mechanism and its variants. Table 2 lists the frequently used notations.

ε and δ	privacy budget of the mechanisms
$\Delta_2 f$	l_2 sensitivity of a query function f
σ^2	variance of noise in the classic Gaussian mechanism
σ_A^2	variance of noise in the analytic Gaussian mechanism
$\boldsymbol{\Sigma}$ and $\boldsymbol{\Psi}$	row-, column-wise covariance matrices in MVG
$\boldsymbol{\Pi}$	singular covariance matrix in the R1SMG mechanism
σ_*	the only nonzero eigenvalue of $\boldsymbol{\Pi}$
$\mathbb{PSD}$	set of positive semi-definitive matrices
$\mathbb{PD}$	set of positive definitive matrices
$\mathcal{U}(\mathbb{V}_{1,M})$	uniform distribution on Stiefel manifold $\mathbb{V}_{1,M}$
$\chi^2(M)$	Chi-squared distribution with M degrees of freedom
$\mathcal{L}$	non-deterministic accuracy loss

Table 2: Frequently used notations in the paper.

Following the convention of [15, 17], a database $\boldsymbol{x}$ is represented by its histogram in a universe $\mathcal{X}$: $\boldsymbol{x} \in \mathbb{N}^{|\mathcal{X}|}$, where each entry $\boldsymbol{x}_i$ is the number of elements in the database $\boldsymbol{x}$ of *type* $i \in \mathcal{X}$ [17, p. 17]. $\boldsymbol{x} \sim \boldsymbol{x}'$ denotes a pair of neighboring databases that differ by one data record, and $\Delta_2 f$ is the l_2 sensitivity of a query function f, i.e., $\Delta_2 f = \sup_{\boldsymbol{x}\sim\boldsymbol{x}'} ||f(\boldsymbol{x}) - f(\boldsymbol{x}')||_2$.

Definition 2. *(ε, δ)-DP [17]. A randomized mechanism $\mathcal{M}$ satisfies (ε, δ)-DP if for any two neighboring datasets, $\boldsymbol{x}, \boldsymbol{x}' \in \mathbb{N}^{|\mathcal{X}|}$, $\varepsilon > 0$ and $0 < \delta < 1$, the following holds*

$$\Pr[\mathcal{M}(D_1) \in S] \leq e^{\varepsilon} \Pr[\mathcal{M}(D_2) \in S] + \delta.$$

Dwork et al. [18] also give an alternative definition of (ε, δ)-DP, i.e., for an outcome s, $\ln\left(\frac{\Pr[\mathcal{M}(\boldsymbol{x})=s]}{\Pr[\mathcal{M}(\boldsymbol{x}')=s]}\right) \leq \varepsilon$ holds with all but δ probability. The log-ratio of the probability densities is called the privacy loss random variable [5, 18] (Definition 6).

Definition 3. ***The classic Gaussian Mechanism.*** *Let $f : \mathbb{N}^{|\mathcal{X}|} \to \mathbb{R}^M$ be an arbitrary M-dimensional function. The Gaussian mechanism with parameter σ adds random Gaussian noise following $\mathcal{N}(0, \sigma^2)$ to each of the M components of the output.*

Theorem 1. ***DP Guarantee of the classic Gaussian mechanism [17, p. 261]*** *Let $\varepsilon \in (0, 1)$ be arbitrary. If $\sigma \geq c\Delta_2 f/\varepsilon$, where $c^2 > 2\ln(\frac{1.25}{\delta})$, then the classic Gaussian Mechanism achieves (ε, δ)-DP.*

The analytic Gaussian mechanism [5] follows the same procedure of the classic Gaussian mechanism (discussed in Definition 3). It improves the classic Gaussian mechanism by directly calibrating the variance (σ_A^2) of the Gaussian noise via solving (2) using binary search. The privacy guarantee of this mechanism is stated as follows.

Theorem 2. ***DP Guarantee of the analytic Gaussian mechanism [5].*** *The analytic Gaussian mechanism achieves (ε, δ)-DP guarantee on the query result $f(\boldsymbol{x})$ if*

$$\Phi\left(\frac{\Delta_2 f}{2\sigma_A} - \frac{\varepsilon\sigma_A}{\Delta_2 f}\right) - e^{\varepsilon}\Phi\left(-\frac{\Delta_2 f}{2\sigma_A} - \frac{\varepsilon\sigma_A}{\Delta_2 f}\right) \leq \delta, \qquad (2)$$

where $\Phi(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{t} e^{-y^2/2} dy$ is the cumulative distribution function of the standard univariate Gaussian distribution.

The MVG mechanism [11] is an extension of the Gaussian mechanism and focuses on matrix-valued queries.

Definition 4. ***The MVG mechanism [11].*** *Given a matrix-valued query function $f(\boldsymbol{x}) \in \mathbb{R}^{M\times N}$, the MVG mechanism is defined as $\mathcal{M}_{MVG}(f(\boldsymbol{x})) = f(\boldsymbol{x}) + \mathbf{N}$, where $\mathbf{N} \sim \mathcal{N}_{M,N}(\mathbf{0}, \boldsymbol{\Sigma}, \boldsymbol{\Psi})$ represents the matrix-variate Gaussian distribution with PDF*

$$f(\mathbf{X}) = \frac{\exp\Big(-\frac{1}{2}Tr[\boldsymbol{\Psi}^{-1}(\mathbf{X}-\mathbf{M})^T\boldsymbol{\Sigma}^{-1}(\mathbf{X}-\mathbf{M})]\Big)}{(2\pi)^{MN/2}\det(\boldsymbol{\Psi})^{M/2}\det(\boldsymbol{\Sigma})^{N/2}}. \quad (3)$$

$\mathbf{M} \in \mathcal{R}^{M\times N}$ is the mean. $\boldsymbol{\Sigma} \in \mathbb{PD}^{M\times M}$ and $\boldsymbol{\Psi} \in \mathbb{PD}^{N\times N}$ are the row-wise and column-wise full-rank covariance matrix, which are also symmetric.

Theorem 3. ***DP Guarantee of MVG [11].*** *$\sigma(\boldsymbol{\Sigma}^{-1})$ and $\sigma(\boldsymbol{\Psi}^{-1})$ are the vectors consisting of singular values of $\boldsymbol{\Sigma}^{-1}$ and $\boldsymbol{\Psi}^{-1}$. The MVG mechanism achieves (ε,δ)-DP if $||\sigma(\boldsymbol{\Sigma}^{-1})||_2||\sigma(\boldsymbol{\Psi}^{-1})||_2 \le \big(-\beta+\sqrt{\beta^2+8\alpha\varepsilon}\big)^2/4\alpha^2$, where $\alpha = 2H_r\gamma\Delta_2 f + (H_r + H_{r,\frac{1}{2}})\gamma^2$, $\beta = 2(MN)^{1/4}H_r\Delta_2 f\tau(\delta)$, H_r is the rth harmonic number, $H_{r,\frac{1}{2}}$ is the rth harmonic number of order $\frac{1}{2}$, $\gamma = \sup_{\boldsymbol{x}}||f(\boldsymbol{x})||_F$, and $\tau(\delta) = 2\sqrt{-MN\ln\delta} - 2\ln\delta + MN$.*

In our study, we also identify an approach to improve the MVG mechanism. Please see Appendix C for details.

3 Identifying The Curse

We identify the curse of full-rank covariance matrices by showing that the expected value of the accuracy loss (Definition 1) introduced by the classic Gaussian mechanism and its variants all are on the order of $M(\Delta_2 f)^2$ for query results in $\mathbb{R}^M$ and $MN(\Delta_2 f)^2$ for query results in $\mathbb{R}^{M\times N}$.

3.1 Query Result being a Vector

When $f(\boldsymbol{x}) \in \mathbb{R}^M$, the classic Gaussian mechanism perturbs each element of $f(\boldsymbol{x})$ using i.i.d. Gaussian noise drawn from $\mathcal{N}(0,\sigma^2)$ (cf. Definition 3). Thus, we derive $\mathbb{E}[\mathcal{L}]$ under the framework of the classic Gaussian mechanism as

$$\mathbb{E}_{\text{classic}}[\mathcal{L}] = \mathbb{E}_{\mathbf{n}_i\sim\mathcal{N}(0,\sigma^2)}\Big[\sum_{i=1}^M \mathbf{n}_i^2\Big] = \mathbb{E}_{z_i\sim\mathcal{N}(0,1)}\Big[\sigma^2\sum_{i=1}^M z_i^2\Big]$$
$$\overset{(a)}{=} \sigma^2\mathbb{E}_{U\sim\chi^2(M)}[U] \overset{(b)}{=} \sigma^2 M = Tr[\sigma^2\mathbf{I}_{M\times M}] = Tr[Cov(\mathbf{n})],$$

where (a) and (b) hold because the squared sum of M independent standard Gaussian variables follows the chi-squared distribution with M degrees of freedom, i.e., $\chi^2(M)$, whose expected value is M.

Based on Theorem 1, since the classic Gaussian mechanism has $\sigma \ge c\Delta_2 f/\varepsilon$, we get $\mathbb{E}_{classic}[\mathcal{L}] \ge C_C(\Delta_2 f)^2$, where $C_C = \frac{2\ln(1.25/\delta)}{\varepsilon^2}M$.

The same analysis also applies to the analytic Gaussian mechanism (discussed in Section 2), because it still perturbs each element of $f(\boldsymbol{x})$ using i.i.d. Gaussian noise with variance σ_A^2. Thus, we can have $\mathbb{E}_{Analytic}[\mathcal{L}] = Tr[\sigma_A^2\mathbf{I}_{M\times M}] = \sigma_A^2 M$.

Since there is no closed-form solution of σ_A ([5] solves for σ_A using a binary search scheme), we derive the lower bound of $\mathbb{E}_{analytic}[\mathcal{L}]$ by investigating the sufficient condition for (2). In what follows $A \Leftarrow B$ means B is the sufficient condition for A, and $A \Leftrightarrow B$ means A and B are equivalent. Then, we have

$$(2) \overset{\text{suff. cond.}}{\Leftarrow} \Phi\Big(\frac{\Delta_2 f}{2\sigma_A} - \frac{\varepsilon\sigma_A}{\Delta_2 f}\Big) \le \delta \Leftrightarrow \frac{\Delta_2 f}{2\sigma_A} - \frac{\varepsilon\sigma_A}{\Delta_2 f} \le \Phi^{-1}(\delta)$$
$$\Leftrightarrow 2\varepsilon\sigma_A^2 + 2\Delta_2 f\Phi^{-1}(\delta)\sigma_A - (\Delta_2 f)^2 \ge 0$$
$$\Leftrightarrow \sigma_A \ge \frac{-2\Delta_2 f\Phi^{-1}(\delta) + \sqrt{4(\Delta_2 f)^2(\Phi^{-1}(\delta))^2 + 8\varepsilon(\Delta_2 f)^2}}{4\varepsilon}$$
$$\overset{\text{suff. cond.}}{\Leftarrow} \sigma_A^2 \ge \frac{\Big(-2\Delta_2 f\Phi^{-1}(\delta) + \sqrt{4(\Delta_2 f)^2(\Phi^{-1}(\delta))^2 + 8\varepsilon(\Delta_2 f)^2}\Big)^2}{16\varepsilon^2}$$
$$\overset{\text{suff. cond.}}{\Leftarrow} \sigma_A^2 \ge \frac{2\big(4(\Delta_2 f)^2(\Phi^{-1}(\delta))^2 + 4(\Delta_2 f)^2(\Phi^{-1}(\delta))^2 + 8\varepsilon(\Delta_2 f)^2\big)}{16\varepsilon^2}$$
$$\Leftrightarrow \sigma_A^2 \ge \frac{\big(\Phi^{-1}(\delta)\big)^2 + \varepsilon}{\varepsilon^2}(\Delta_2 f)^2.$$

Therefore, we can get $\mathbb{E}_{analytic}[\mathcal{L}] \ge C_A(\Delta_2 f)^2$, where $C_A = \frac{\big(\Phi^{-1}(\delta)\big)^2+\varepsilon}{\varepsilon^2}M$.

3.2 Query Result being a Matrix

When $f(\boldsymbol{x}) \in \mathbb{R}^{M\times N}$, instead of adding i.i.d. Gaussian noise, the MVG mechanism by Chanyaswad et al. [11] perturbs the matrix-valued result by adding a matrix noise attributed to the matrix-variate Gaussian distribution shown in (3).

It is well-known that the vectorization of the matrix-variate Gaussian noise can equivalently be sampled from a multivariate Gaussian distribution with a new full-rank covariance matrix, i.e., $\boldsymbol{\Xi} = \boldsymbol{\Sigma}\otimes\boldsymbol{\Psi} \in \mathbb{PD}^{MN\times MN}$, which is also symmetric [21] ($\otimes$ is the Kronecker product). In general, $\boldsymbol{\Xi}$ has nonzero off-diagonal entries, which means the elements in the additive noise are not mutually independent. Thus, we need another tool to analyze its expected accuracy loss.

First, we observe that $\mathcal{L} = ||\mathbf{n}||_2^2 = \mathbf{n}^T\mathbf{n}$ is a quadratic form in random variable defined as follows.

Definition 5. ***Quadratic Form in Random Variable [37].*** *Denote by $\mathbf{x}$ a random vector with mean μ and covariance matrix $\boldsymbol{\Xi}$. The quadratic form in random variable $\mathbf{x}$ associated with a symmetric matrix $\mathbf{A}$ is defined as $Q(\mathbf{x}) = \mathbf{x}^T\mathbf{A}\mathbf{x}$.*

Then, $\mathcal{L}$ introduced by the MVG mechanism is a quadratic form in multivariate Gaussian random variable attributed to $\mathcal{N}(\mathbf{0},\boldsymbol{\Xi})$ with $\mathbf{A}$ being the identity matrix. In the following lemma, we recall the t-th moment of quadratic form in Gaussian random variable (which will also be used in our future analyses on the kurtosis and skewness of $\mathcal{L}$ in Section 6).

Lemma 1. *[37, p. 53] The t-th moment of a quadratic form in multivariate Gaussian random variable, i.e, $\mathbf{x} \sim \mathcal{N}(\mu,\boldsymbol{\Xi})$ with $\boldsymbol{\Xi}$ being full-rank, is given by $\mathbb{E}[Q(\mathbf{x})^t] = \{\sum_{t_1=0}^{t-1}\binom{t-1}{t_1}g^{(t-1-t_1)} \times \sum_{t_2=0}^{t_1-1}\binom{t_1-1}{t_2}g^{(t_1-1-t_2)} \times \cdots \times \sum_{t_2=0}^{1}\binom{1-1}{t_2}g^{(0)}\}$, where $g^{(k)} = 2^k k!(Tr(\mathbf{A}\boldsymbol{\Xi})^{k+1} + (k+1)\mu^T(\mathbf{A}\boldsymbol{\Xi})^k\mathbf{A}\mu)$, $k \in [0,t-1]$.*

As a result, the instantiation of Proposition 1 under the MVG mechanism is

$$\mathbb{E}_{MVG}[\mathcal{L}] = \underset{\mathbf{N}\sim\mathcal{N}_{M,N}(\mathbf{0},\mathbf{\Sigma},\mathbf{\Psi})}{\mathbb{E}}[||\mathbf{N}||_F^2] = \underset{\mathbf{n}\sim\mathcal{N}(\mathbf{0},\mathbf{\Sigma}\otimes\mathbf{\Psi})}{\mathbb{E}}[||\mathbf{n}||_2^2] \overset{(a)}{=} Tr[\mathbf{\Xi}] = Tr[\mathbf{\Sigma}\otimes\mathbf{\Psi}], \quad (4)$$

where (a) is obtained by applying Lemma 1 with $t=1$, i.e., $\mathbb{E}[Q(\mathbf{x})] = g^{(0)} = Tr[\mathbf{\Xi}]$. Furthermore, we can obtain that

$$\begin{aligned}
&\mathbb{E}_{\text{MVG}}[\mathcal{L}] \overset{(a)}{=} Tr[\mathbf{\Sigma}\otimes\mathbf{\Psi}] \overset{(b)}{=} Tr[\mathbf{\Sigma}]Tr[\mathbf{\Psi}] \\
&\overset{(c)}{=} ||\sigma(\mathbf{\Sigma})||_1||\sigma(\mathbf{\Psi})||_1 \overset{(d)}{\geq} ||\sigma(\mathbf{\Sigma})||_2||\sigma(\mathbf{\Psi})||_2 \\
&\overset{(e)}{\geq} \frac{MN}{||\sigma(\mathbf{\Sigma}^{-1})||_2||\sigma(\mathbf{\Psi}^{-1})||_2} \overset{(f)}{\geq} MN\frac{4\alpha^2}{(-\beta+\sqrt{\beta^2+8\alpha\varepsilon})^2} \\
&\geq \frac{MN4\alpha^2}{2\beta^2+8\alpha\varepsilon-2\beta\sqrt{\beta^2}} = MN\frac{\alpha}{2\varepsilon} \\
&\overset{(g)}{=} MN\frac{2H_r\gamma\Delta_2 f + (H_r+H_{r,\frac{1}{2}})\gamma^2}{2\varepsilon} \overset{(h)}{\geq} \frac{\frac{5}{4}H_r+\frac{1}{4}H_{r,\frac{1}{2}}}{2\varepsilon}MN(\Delta_2 f)^2,
\end{aligned} \quad (5)$$

where (a) follows (4), (b) is due to the property of the Kronecker product [40, 41], (c) is because $\mathbf{\Sigma}, \mathbf{\Psi} \in \mathbb{PD}$ and they are both symmetric matrices, which means all their eigenvalues are positive, (d) is because $||\boldsymbol{y}||_1 \geq ||\boldsymbol{y}||_2$ for any vector $\boldsymbol{y}$, (e) is obtained by applying the harmonic mean-geometric mean inequality (see Appendix A), (f) is due to the privacy guarantee of the MVG mechanism in Theorem 3, and α and β are defined therein, (g) is obtained by substituting α, and finally (h) is because $\gamma = \sup_{\boldsymbol{x}} ||f(\boldsymbol{x})||$ (Theorem 3), and $\Delta_2 f = \sup_{\boldsymbol{x}\sim\boldsymbol{x}'} ||f(\boldsymbol{x}) - f(\boldsymbol{x}')|| \leq \sup_{\boldsymbol{x}} ||f(\boldsymbol{x})|| + \sup_{\boldsymbol{x}'} ||f(\boldsymbol{x}')|| = 2\gamma$, which suggests $\gamma \geq \frac{1}{2}\Delta_2 f$.

As a consequence, we have $\mathbb{E}_{MVG}[\mathcal{L}] \geq C_M(\Delta_2 f)^2$, where $C_M = \frac{\frac{5}{4}H_r+\frac{1}{4}H_{r,\frac{1}{2}}}{2\varepsilon}MN$.

In Theorem 4, we summarize the expected accuracy loss of the classic Gaussian mechanism and its variants.

Theorem 4. *The expected accuracy loss of the classic Gaussian, of the analytic Gaussian, and of the MVG mechanisms are as follows:*

$$\mathbb{E}_{classic}[\mathcal{L}] = Tr[\sigma^2\mathbf{I}_{M\times M}] \geq C_C(\Delta_2 f)^2, \quad C_C = \frac{2\ln(\frac{1.25}{\delta})}{\varepsilon^2}M,$$

$$\mathbb{E}_{analytic}[\mathcal{L}] = Tr[\sigma_A^2\mathbf{I}_{M\times M}] \geq C_A(\Delta_2 f)^2, \quad C_A = \frac{(\Phi^{-1}(\delta))^2+\varepsilon}{\varepsilon^2}M,$$

$$\mathbb{E}_{MVG}[\mathcal{L}] = Tr[\mathbf{\Sigma}\otimes\mathbf{\Psi}] \geq C_M(\Delta_2 f)^2, \quad C_M = \frac{\frac{5}{4}H_r+\frac{1}{4}H_{r,\frac{1}{2}}}{2\varepsilon}MN.$$

Theorem 4 rigorously shows that all existing suffer from the identified curse of full-rank covariance matrices. Another stealthy perspective to understand the identified curse of full-rank covariance matrices is by observing that the PDFs of (3) and the multivariate Gaussian distribution all involve determinants of covariance matrices in the denominators (which should be nonzero). Then, theses covariance matrices should always be full-rank. As a consequence, the curse cannot be removed unless we use a new form of PDF to generate the perturbation noise.

4 An Ignored Clue from Dwork et al. [15–17]

In this section, we recall Dwork and Roth's proof of Gaussian mechanism achieving (ε,δ)-DP [15–17] when the query function returns a M-dimension vector. At the end of their proof, we identify an ignored clue which corroborates that Gaussian noise with rank-1 covariance matrix is sufficient to achieve (ε,δ)-DP and also motivates our work.

Dwork and Roth essentially investigate the upper bound of the **privacy loss random variable** (PLRV) on a pair of neighboring database $\boldsymbol{x}$ and $\boldsymbol{x}'$ defined as follows.

Definition 6. *[18, p. 6] Consider running a randomized mechanism $\mathcal{M}$ on a pair of neighboring dataset $\boldsymbol{x}$ and $\boldsymbol{x}'$. For an outcome $\mathbf{s}$, PLRV on $\mathbf{s}$ is defined as the log-ratio of the probability density when $\mathcal{M}$ is running on each dataset, i.e.,* $\text{PLRV}^{(\mathbf{s})}_{(\mathcal{M}(\boldsymbol{x})||\mathcal{M}(\boldsymbol{x}'))} = \ln\left(\frac{\Pr[\mathcal{M}(\boldsymbol{x})=\mathbf{s}]}{\Pr[\mathcal{M}(\boldsymbol{x}')=\mathbf{s}]}\right)$.

The following derivations are restatements of content from [17, p. 261-265]. $f(\cdot)$ is a query function, i.e., $f: \boldsymbol{x} \in \mathbb{N}^{|\mathcal{X}|} \to \mathbb{R}^M$. We are interested in multivariate Gaussian noise that can obscure the difference $\boldsymbol{v} \triangleq f(\boldsymbol{x}) - f(\boldsymbol{x}')$. To achieve (ε,δ)-DP, it requires that the PLRV associated with the classic Gaussian mechanism (denoted as $\mathcal{G}$), i.e.,

$$\text{PLRV}^{(\mathbf{s})}_{(\mathcal{G}(\boldsymbol{x})||\mathcal{G}(\boldsymbol{x}'))} = \left|\frac{1}{2\sigma^2}\left(||\boldsymbol{n}||^2 - ||\boldsymbol{n}+\boldsymbol{v}||^2\right)\right|, \quad (\text{ [17, p. 265]})$$

is upper bounded by ε with all but δ probability. In $\text{PLRV}^{(\mathbf{s})}_{(\mathcal{G}(\boldsymbol{x})||\mathcal{G}(\boldsymbol{x}'))}$, $\boldsymbol{n}$ is chosen from $\mathcal{N}(0,\mathbf{\Sigma})$, where $\mathbf{\Sigma}$ is a diagonal matrix with entries σ^2.

Then, Dwork and Roth bound $\text{PLRV}^{(\mathbf{s})}_{(\mathcal{G}(\boldsymbol{x})||\mathcal{G}(\boldsymbol{x}'))}$ by observing that the multivariate Gaussian distribution is a spherically symmetric distribution [4]. Thus, when representing the noise $\mathbf{n}$ using any fixed orthonormal basis $\boldsymbol{b}_1, \boldsymbol{b}_2, \cdots, \boldsymbol{b}_m$, i.e, $\mathbf{n} = \sum_{i=1}^M \lambda_i \boldsymbol{b}_i$, the corresponding coefficients are also attributed to the same Gaussian distribution, i.e., $\lambda_i \sim \mathcal{N}(0,\sigma^2), i \in [1,M]$. Furthermore, without loss of generality, Dwork and Roth assume the first component (base) $\boldsymbol{b}_1$ is parallel to $\boldsymbol{v}$ (the difference between $f(\boldsymbol{x})$ and $f(\boldsymbol{x}')$). Consequently, we have

$$\begin{aligned}
\text{PLRV}^{(\mathbf{s})}_{(\mathcal{G}(\boldsymbol{x})||\mathcal{G}(\boldsymbol{x}'))} &= \left|\frac{1}{2\sigma^2}\left(\left|\left|\sum_{i=1}^M \lambda_i\boldsymbol{b}_i\right|\right|^2 - \left|\left|\sum_{i=1}^M \lambda_i\boldsymbol{b}_i + \boldsymbol{v}\right|\right|^2\right)\right| \\
&= \left|\frac{1}{2\sigma^2}\left(||\boldsymbol{v}||^2 + 2\lambda_1||\boldsymbol{v}||\right)\right| \leq \frac{1}{2\sigma^2}\left((\Delta_2 f)^2 + 2\lambda_1\Delta_2 f\right),
\end{aligned} \quad (6)$$

where the second equality holds because $\boldsymbol{b}_1$ and $\boldsymbol{v}$ are orthogonal to $\boldsymbol{b}_i, i \in [2,M]$, and the last inequality is due to the definition of l_2 sensitivity. Since now $\text{PLRV}^{(\mathbf{s})}_{(\mathcal{G}(\boldsymbol{x})||\mathcal{G}(\boldsymbol{x}'))}$ in (6) only involves a single Gaussian random variable, i.e., λ_1, Theorem 1 can be proved by following the same procedure when the query function returns a scalar value ([17, p. 262-264]).

A hidden Clue comes up to the surface. From (6), it is clear that $\text{PLRV}^{(\mathbf{s})}_{(\mathcal{G}(\boldsymbol{x})||\mathcal{G}(\boldsymbol{x}'))}$ is only related to λ_1 and $\Delta_2 f$. Since λ_1 (a Gaussian random variable) is the coefficient of

the of orthonormal base $\boldsymbol{b}_1$, it clearly suggests that, after decomposing a multivariate Gaussian noise using a set of orthonormal basis vectors, only the coefficient of one vector contributes to the value of $\text{PLRV}^{(\mathbf{s})}_{(\mathcal{G}(\boldsymbol{x})||\mathcal{G}(\boldsymbol{x}'))}$. In other words, the coefficients of other basis vectors have no impact on the privacy loss of the Gaussian mechanism. Consequently, the privacy guarantee achieved by $\mathbf{n} = \sum_{i=1}^{M} \lambda_i \boldsymbol{b}_i$ is identical to that achieved by $\lambda_1 \boldsymbol{b}_1$. This hidden clue motivates our idea of using multivariate Gaussian noise whose covariance matrix has rank-1 (instead of multivariate Gaussian noise with full-rank covariance matrix) to achieve (ε, δ)-DP.

5 Lifting the Curse

In what follows, we present the R1SMG mechanism, which lifts the identified curse of full-rank covariance matrices. In particular, we first intuitively explain the feasibility of the proposed R1SMG mechanism. Next, we introduce its noise generation process, and present a sufficient condition for it to achieve (ε, δ)-DP. After that, we analyze the expected accuracy loss of the R1SMG mechanism, and discuss the privacy leakage of utilizing vectors in the null space of the noise.

5.1 The Intuition behind R1SMG

As introduced in Section 1.2, the expected accuracy loss of R1SMG is lower bounded by $C_R(\Delta_2 f)^2$ where for any fixed feasible ε, $C_R = \frac{2}{\varepsilon\psi}$ has a decreasing trend as M increases, and converges to $\frac{2}{\varepsilon}$ as M goes large (Theorem 7). Thus, we have the following property (see Property 1) that is missing in all existing DP mechanisms. Here, we provide an intuitive explanation of it.

Property 1. *For any fixed feasible ε, δ, and $\Delta_2 f$, the magnitude of the noise required to attain (ε, δ)-DP on $f(\boldsymbol{x}) \in \mathbb{R}^M$ can have a non-increasing trend regarding M.*

Due to the widely accepted common practice of perturbing each component of $f(\boldsymbol{x})$ using i.i.d. Gaussian noise to achieve DP, it makes sense that larger dimensional $f(\boldsymbol{x})$ requires larger magnitude of noises. Thus, Property 1 is counterintuitive and seems to be "magic". Yet, it can be intuitively explained as follows. Given a database $\boldsymbol{x}$ represented as histogram, we consider a normalized counting query function $f(\boldsymbol{x}) = \frac{1}{M} Q\boldsymbol{x} \in \mathbb{R}^M$, where Q is a binary matrix. A higher dimension of $f(\boldsymbol{x})$ means a larger number of queries applied to the same dataset $\boldsymbol{x}$. Subsequently, the chances that the query results (i.e., rows in Q) become dependent with each other increases as the query number increases. For instance, suppose that the ith and jth query, i.e., $f(\boldsymbol{x})_i$ and $f(\boldsymbol{x})_j$ are dependent, particularly, $f(\boldsymbol{x})_j$ can be fully determined by $f(\boldsymbol{x})_i$. Then, the privacy leakage on $\boldsymbol{x}$ by observing $f(\boldsymbol{x})_i$, $f(\boldsymbol{x})_j$, or $[f(\boldsymbol{x})_i\ f(\boldsymbol{x})_j]$ would be identical. Hence, intuitively, no more noise is needed to perturb $[f(\boldsymbol{x})_i\ f(\boldsymbol{x})_j]$ than that for perturbing $f(\boldsymbol{x})_i$. It implies that as M increases and the queried results become dependent, it is possible to achieve DP by perturbing $f(\boldsymbol{x})$ using noise of a non-increasing magnitude. Moreover, when M becomes sufficiently large such that the query vectors (rows in Q) are linearly dependent, by observing $f(\boldsymbol{x})$ or the set of independent query vectors, the privacy leakage of $\boldsymbol{x}$ would be identical. Therefore, the same amount of noise can be used to sanitize both (refer to [43] for an analysis from the perspective of mutual information).

5.2 R1SMG: Multivariate Gaussian Noise with A Random Rank-1 Covariance Matrix

In what follows, we first provide the statistical background on the singular multivariate Gaussian distribution with a given rank-r covariance matrix, e.g., $\boldsymbol{\Pi}$ and $Rank(\boldsymbol{\Pi}) = r$.

Definition 7. ***Singular Multivariate Gaussian Distribution [14, 27, 39, 42].*** *A M-dimensional random variable $\mathbf{x} = [x_1, x_2, \cdots, x_M]^T \in \mathbb{R}^M$ has a singular multivariate Gaussian distribution with mean $\mu \in \mathbb{R}^M$ and a singular covariance matrix $\boldsymbol{\Pi} \in \mathbb{PSD}^{M\times M}$ with rank-r, i.e., $\mathbf{x} \sim \mathcal{N}(\mu, \boldsymbol{\Pi})$ and $Rank(\boldsymbol{\Pi}) = r < M$, if its PDF is*

$$f_{\mathbf{x};Rank(\boldsymbol{\Pi})=r} = \frac{(2\pi)^{-r/2} \exp\left(-\frac{1}{2}(\mathbf{x}-\mu)^T \boldsymbol{\Pi}^{\dagger}(\mathbf{x}-\mu)\right)}{\sqrt{\sigma_1(\boldsymbol{\Pi}) \cdots \sigma_r(\boldsymbol{\Pi})}},$$

where $\sigma_i(\boldsymbol{\Pi})$ is the i-th nonzero eigenvalue of $\boldsymbol{\Pi}$, and $\boldsymbol{\Pi}^{\dagger}$ is the Moore-Penrose generalized inverse of $\boldsymbol{\Pi}$. Particularly, we have $\boldsymbol{\Pi}^{\dagger} = \mathbf{V}_r \boldsymbol{\Lambda}_r^{-1} \mathbf{V}_r^T$, where $\boldsymbol{\Lambda}_r = \text{diag}(\sigma_1(\boldsymbol{\Pi}), \ldots, \sigma_r(\boldsymbol{\Pi})) \in \mathbb{R}^{r\times r}$, and $\mathbf{V}_r \in \mathbb{R}^{M\times r}$ is the matrix of eigenvectors corresponding to the r nonzero eigenvalues.

Samples of $f_{\mathbf{x};Rank(\boldsymbol{\Pi})=r}$ (e.g., $\mathbf{n}$) can be generated by applying the disintegration theorem [20]. In particular, if $\mu = \mathbf{0}$, by defining a linear mapping

$$\mathbf{n} = \mathbf{V}_r \boldsymbol{\Lambda}_r^{1/2} \mathbf{z}, \quad \text{and} \quad \mathbf{z} \sim \mathcal{N}(\mathbf{0}, \mathbf{I}_{r\times r}), \tag{7}$$

where $\boldsymbol{\Lambda}_r^{1/2} = \text{diag}(\sqrt{\sigma_1(\boldsymbol{\Pi})}, \sqrt{\sigma_2(\boldsymbol{\Pi})}, \ldots, \sqrt{\sigma_r(\boldsymbol{\Pi})}) \in \mathbb{R}^{r\times r}$ and $\mathbf{V}_r \in \mathbb{R}^{M\times r}$ is the matrix of eigenvectors corresponding to the r nonzero eigenvalues of $\boldsymbol{\Pi}$, then $\mathbf{n}$ is attributed to a singular multivariate Gaussian distribution with a rank-r covariance matrix. This can easily be verified by checking the covariance matrix of $\mathbf{n}$;

$$\begin{aligned} Cov(\mathbf{n}) =& Cov(\mathbf{V}_r \boldsymbol{\Lambda}_r^{1/2} \mathbf{z}) = \mathbf{V}_r \boldsymbol{\Lambda}_r^{1/2} Cov(\mathbf{z}) (\mathbf{V}_r \boldsymbol{\Lambda}_r^{1/2})^T \\ \overset{(*)}{=}& \mathbf{V}_r \boldsymbol{\Lambda}_r^{1/2} \mathbf{I}_{r\times r} (\mathbf{V}_r \boldsymbol{\Lambda}_r^{1/2})^T = \mathbf{V}_r \boldsymbol{\Lambda}_r \mathbf{V}_r^T = \boldsymbol{\Pi} \end{aligned}, \tag{8}$$

where $(*)$ is due to $\mathbf{z} \sim \mathcal{N}(\mathbf{0}, \mathbf{I}_{r\times r})$. Then, clearly, we have $Cov(\mathbf{n}) = r$.

When $r = 1$, the singular covariance matrix $\boldsymbol{\Pi}$ only has 1 nonzero eigenvalue, and we denote it as σ_*. Thus, (7) becomes

$$\mathbf{n} = \mathbf{v}\sqrt{\sigma_*} z, \quad \text{and} \quad z \sim \mathcal{N}(0, 1), \quad \mathbf{v}^T \mathbf{v} = 1. \tag{9}$$

Singular multivariate Gaussian noise with a random rank-1 covariance matrix. It is noteworthy that in (9), $\mathbf{v}$ needs to be generated randomly to thwart attacks which takes advantage of vectors in the null space of $\mathbf{v}$ (or $\mathbf{n}$). In Section 5.4, we will show that by sampling $\mathbf{v}$ uniformly at random, such attacks will succeed with **zero probability**.

Since $\mathbf{v}$ is an orthonormal vector of dimension $M \times 1$, one common approach to generate $\mathbf{v}$ randomly is by uniformly sampling from a specific Stiefel manifold, i.e., $\mathbb{V}_{1,M} = \{\mathbf{v} \in \mathbb{R}^{M\times 1} : \mathbf{v}^T\mathbf{v} = 1\}$, which represents the unite sphere $\mathbb{S}^{M-1}$ embedded in $\mathbb{R}^M$. In Statistics literature, the PDF of the uniform distribution on the Stiefel manifold $\mathbb{V}_{1,M}$ is given by

$$f(\mathbf{v}) = \frac{1}{\mathrm{Vol}(\mathbb{V}_{1,M})}, \quad \forall \mathbf{v} \in \mathbb{V}_{1,M}, \tag{10}$$

(see [21, p. 280], [8, p. 17, equation 8.2.2], as well [13, p. 30] which gives the characteristic function of (10)). In particular, the constant $\mathrm{Vol}(\mathbb{V}_{1,M}) = \frac{2\pi^{M/2}}{\Gamma(M/2)}$ (see [21, p. 19 and 26]) is the total surface area or volume of $\mathbb{V}_{1,M}$ and $\Gamma(\cdot)$ is the ordinary gamma function [21][2].

We use $\mathbf{v} \sim \mathcal{U}(\mathbb{V}_{1,M})$ to represent that $\mathbf{v}$ is a random variable uniformly sampled from $\mathbb{V}_{1,M}$. As a consequence, the linear mapping defined in (9) becomes

$$\mathbf{n} = \mathbf{v}\sqrt{\sigma_*}z, \quad \text{where} \quad z \sim \mathcal{N}(0,1), \quad \mathbf{v} \sim \mathcal{U}(\mathbb{V}_{1,M}). \tag{11}$$

Now, we introduce the R1SMG mechanism and provide a sufficient condition for it to achieve differential privacy.

Definition 8. ***The Rank-1 Singular Multivariate Gaussian (R1SMG) Mechanism.*** *For an arbitrary M-dimensional query function, $f(\boldsymbol{x}) \in \mathbb{R}^M$, the R1SMG mechanism is defined as*

$$\mathcal{M}_{R1SMG}(f(\boldsymbol{x})) = f(\boldsymbol{x}) + \mathbf{n},$$

where $\mathbf{n}$ (generated via (11)) is the noise attributed to a singular multivariate Gaussian distribution with a random rank-1 covariance matrix.

If the query result is a matrix or tensor, we can first generate the noise as a vector and then resize it into the desired format. Please refer to the case studies in Section 7 for details.

We introduce an important lemma below that will be used for proving Theorem 5.

Lemma 2. ***Distribution of Angle between Random Points on Unit Sphere ([7, p. 1845 and 1860]).*** *Let h and g be two randomly selected points on unit sphere $\mathbb{S}^{P-1}$ (embedded in $\mathbb{R}^P$), where $P > 2$. Let $\mathbf{h}$ (resp. $\mathbf{g}$) be the vector connecting the center of the sphere and h (resp. g). θ denotes the angle ($\theta \in [0,\pi]$) between $\mathbf{h}$ and $\mathbf{g}$. Then, we have*

$$\Pr\left[\left|\theta - \frac{\pi}{2}\right| \geq \theta_0\right] \leq \sqrt{\pi}\frac{\Gamma(\frac{P}{2})}{\Gamma(\frac{P-1}{2})} cos(\theta_0)^{P-2}, \tag{12}$$

where θ_0 is a given radian and $0 \leq \theta_0 \leq \frac{\pi}{2}$.

[2]This result can be easily obtained by setting $p = 1$ in Theorem 1.4.9 on page 25 of [21]. In particular, $\mathrm{Vol}(\mathbb{V}_{1,M})$ plays the same role on $\mathbb{V}_{1,M}$ as the Lebesgue measure plays in Euclidean space [8]. For example, when $M = 3$, $\mathrm{Vol}(\mathbb{V}_{1,3}) = 4\pi$ is the surface area of an unit sphere in 3D space, and when $M = 2$, $\mathrm{Vol}(\mathbb{V}_{1,2}) = 2\pi$ is the circumference of an unit circle in 2D space.

Theorem 5. *The R1SMG mechanism achieves (ε,δ)-DP when $M > 2$, if $\sigma_* \geq \frac{2(\Delta_2 f)^2}{\varepsilon\psi}$ where $\psi = \left(\frac{\delta\Gamma(\frac{M-1}{2})}{\sqrt{\pi}\Gamma(\frac{M}{2})}\right)^{\frac{2}{M-2}}$, and $\Gamma(\cdot)$ is the Gamma function.*

Proof. Inspired by Dwork and Roth's work [17] (cf. Section 4), we investigate the PLRV associated with the R1SMG mechanism. Assume that $\mathbf{n}$ and $\mathbf{n}'$ are the random noise used to perturb $f(\boldsymbol{x})$ and $f(\boldsymbol{x}')$, respectively. Then, the R1SMG mechanism achieves (ε,δ)-DP if $\mathrm{PLRV}^{(\mathbf{s})}_{(R1SMG(\boldsymbol{x})||R1SMG(\boldsymbol{x}'))} = \ln\left(\frac{\Pr[f(\boldsymbol{x})+\mathbf{n}=\mathbf{s}\in\mathcal{S}]}{\Pr[f(\boldsymbol{x}')+\mathbf{n}'=\mathbf{s}\in\mathcal{S}]}\right) \leq \varepsilon$ with all but δ probability (called the failing probability) [17], where $\mathcal{S}$ denotes all possible outcome of R1SMG.

According to (11), without loss of generality, let $\mathbf{n} = \sqrt{\sigma_*}z_1\mathbf{h}$ and $\mathbf{n}' = \sqrt{\sigma_*}z_2\mathbf{g}$, where $z_1, z_2 \sim \mathcal{N}(0,1)$ and $\mathbf{h},\mathbf{g} \sim \mathcal{U}(\mathbb{V}_{1,M})$. Let $\theta \in [0,\pi]$ be the angle between $\mathbf{h}$ and $\mathbf{g}$. Then, we can establish the failing probability (which should be at most δ) by first constructing an event which is a subspace of the universe Ω, i.e.,

$$\begin{aligned}\mathcal{A} &= \left\{z_1,z_2,\mathbf{h},\mathbf{g} : z_1,z_2 \sim \mathcal{N}(0,1), \mathbf{h},\mathbf{g} \sim \mathcal{U}(\mathbb{V}_{1,M}), \left|\theta - \tfrac{\pi}{2}\right| < \theta_0\right\} \\ &\subset \Omega = \left\{z_1,z_2,\mathbf{h},\mathbf{g} : z_1,z_2 \sim \mathcal{N}(0,1), \mathbf{h},\mathbf{g} \sim \mathcal{U}(\mathbb{V}_{1,M})\right\}\end{aligned},$$

where $\theta_0 = arccos\left(\left(\delta\Gamma(\frac{M-1}{2})/\sqrt{\pi}\Gamma(\frac{M}{2})\right)^{1/(M-2)}\right)$, and $arccos(\cdot)$ is the inverse of the cosine function. We denote the complementary of $\mathcal{A}$ as $\mathcal{A}^c = \Omega \setminus \mathcal{A}$, i.e.,

$$\mathcal{A}^c = \left\{z_1,z_2,\mathbf{h},\mathbf{g} : z_1,z_2 \sim \mathcal{N}(0,1), \mathbf{h},\mathbf{g} \sim \mathcal{U}(\mathbb{V}_{1,M}), \left|\theta - \tfrac{\pi}{2}\right| \geq \theta_0\right\}.$$

Since z_1 and z_2 are independent of $\mathbf{h}$ and $\mathbf{g}$, by applying Lemma 2 and setting $P = M$ and $\sqrt{\pi}\frac{\Gamma(\frac{P}{2})}{\Gamma(\frac{P-1}{2})} cos(\theta_0)^{P-2} = \delta$, we get $\Pr[\mathcal{A}^c] \leq \delta$.

Since $\mathbf{n}$ (resp. $\mathbf{n}'$) is singular multivariate Gaussian with zero mean by design (see (11)), we have that $f(\boldsymbol{x}) + \mathbf{n} = \mathbf{s} \in \mathcal{S}$ (resp. $f(\boldsymbol{x}') + \mathbf{n}' = \mathbf{s} \in \mathcal{S}$) is attributed to singular multivariate Gaussian distribution, with mean $f(\boldsymbol{x})$ (resp. $f(\boldsymbol{x}')$) and covariance matrix $\mathbf{h}\sigma_*\mathbf{h}^T$ (resp. $\mathbf{g}\sigma_*\mathbf{g}^T$) (one can verify this by setting $r = 1$ in (8)). Substituting the mean and generalized inverse covariance matrix into the PDF provided in Definition 7 (with $r = 1$), we have a counterpart of (6) as

$$\begin{aligned}&\mathrm{PLRV}^{(\mathbf{s})}_{(R1SMG(\boldsymbol{x})||R1SMG(\boldsymbol{x}'))} = \ln\left(\frac{\Pr[f(\boldsymbol{x})+\mathbf{n}=\mathbf{s}\in\mathcal{S}]}{\Pr[f(\boldsymbol{x}')+\mathbf{n}'=\mathbf{s}\in\mathcal{S}]}\right) \\ =&\ln\left(\frac{(2\pi)^{-\frac{1}{2}}\exp\left(-\frac{1}{2}\left(\mathbf{s}-f(\boldsymbol{x})\right)^T\left(\mathbf{h}\sigma_*^{-1}\mathbf{h}^T\right)\left(\mathbf{s}-f(\boldsymbol{x})\right)\right)\Big/\sqrt{\sigma_*}}{(2\pi)^{-\frac{1}{2}}\exp\left(-\frac{1}{2}\left(\mathbf{s}-f(\boldsymbol{x}')\right)^T\left(\mathbf{g}\sigma_*^{-1}\mathbf{g}^T\right)\left(\mathbf{s}-f(\boldsymbol{x}')\right)\right)\Big/\sqrt{\sigma_*}}\right) \\ =&\ln\left(\frac{\exp\left(-\frac{1}{2\sigma_*}\left(\mathbf{h}^T(\mathbf{s}-f(\boldsymbol{x}))\right)^2\right)}{\exp\left(-\frac{1}{2\sigma_*}\left(\mathbf{g}^T(\mathbf{s}-f(\boldsymbol{x}'))\right)^2\right)}\right) \\ =&\frac{1}{2\sigma_*}\left(\left(\underbrace{\mathbf{g}^T(\mathbf{s}-f(\boldsymbol{x}'))}_{\rho_1\in\mathbb{R}}\right)^2 - \left(\underbrace{\mathbf{h}^T(\mathbf{s}-f(\boldsymbol{x}))}_{\rho_2\in\mathbb{R}}\right)^2\right) \\ \leq&\frac{1}{2\sigma_*}\left(|\rho_1|+|\rho_2|\right)^2, \qquad \forall(z_1,z_2,\mathbf{h},\mathbf{g}) \in \mathcal{A}.\end{aligned} \tag{13}$$

In the following, we derive a tight upper bound on $|\rho_1|+|\rho_2|$. In particular, with $||\mathbf{g}||_2 = ||\mathbf{h}||_2 = 1$, we notice that

$$|\rho_1|+|\rho_2| \leq ||\mathbf{g}||_2||\mathbf{s}-f(\boldsymbol{x}')||_2 + ||\mathbf{h}||_2||\mathbf{s}-f(\boldsymbol{x})||_2$$
$$= ||\mathbf{s}-f(\boldsymbol{x}')||_2 + ||\mathbf{s}-f(\boldsymbol{x})||_2.$$

Thus, we aim to bound $||\mathbf{s}-f(\boldsymbol{x}')||_2 + ||\mathbf{s}-f(\boldsymbol{x})||_2$.

First, we observe that the angle between $(\mathbf{s}-f(\boldsymbol{x}))$ and $(\mathbf{s}-f(\boldsymbol{x}'))$ is identical to the angle between $\mathbf{h}$ and $\mathbf{g}$, because $(\mathbf{s}-f(\boldsymbol{x})) = \mathbf{n}$ and $(\mathbf{s}-f(\boldsymbol{x}')) = \mathbf{n}'$, and $\mathbf{n}$ and $\mathbf{n}'$ are obtained by scaling $\mathbf{h}$ and $\mathbf{g}$. We use θ to represent the angle between $\mathbf{h}$ and $\mathbf{g}$ (i.e., identically between $(\mathbf{s}-f(\boldsymbol{x}))$ and $(\mathbf{s}-f(\boldsymbol{x}'))$). Thus, from a geometric perspective, $||\mathbf{s}-f(\boldsymbol{x}')||_2 + ||\mathbf{s}-f(\boldsymbol{x})||_2$ is the sum of the length of two edges of a triangle in $\mathbb{R}^M$, and the angle between these two edges is θ. Moreover, the length of the third edge (opposite to this specific angle) is $||(\mathbf{s}-f(\boldsymbol{x}'))-(\mathbf{s}-f(\boldsymbol{x}))||_2 = ||f(\boldsymbol{x})-f(\boldsymbol{x}')||_2$. For better understanding, we visualize the above description in Figure 1(a), where the red point (resp. blue point) indicates $\mathbf{n}$ (resp. $\mathbf{n}'$) in $\mathbb{R}^M$, and the red dashed line (resp. blue dashed line) is the randomly sampled $\mathbf{h}$ (resp. $\mathbf{g}$) (note that we show $\mathbf{h}$ and $\mathbf{g}$ as bidirectional, because $\mathbf{n}$ and $\mathbf{n}'$ can point to the opposite direction of $\mathbf{h}$ and $\mathbf{g}$, respectively).

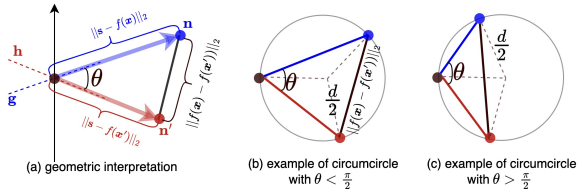

Figure 1: (a) Geometric interpretation of $|\rho_1|+|\rho_2|$. Circumcircles of the described triangle with (b) $\theta < \frac{\pi}{2}$ and (c) $\theta > \frac{\pi}{2}$.

It is well-known that the length of each edge of a triangle is upper bounded by the diameter of the circumscribed circle of the triangle. We show this fact in Figure 1(b) and Figure (c), where $\frac{d}{2}$ represents the radius of the circumcircle. According to the law of sine, we have $d = ||f(\boldsymbol{x})-f(\boldsymbol{x}')||_2 / sin(\theta)$. Thus,

$$||\mathbf{s}-f(\boldsymbol{x}')||_2 + ||\mathbf{s}-f(\boldsymbol{x})||_2 \leq 2d = \frac{2||f(\boldsymbol{x})-f(\boldsymbol{x}')||_2}{sin(\theta)} \leq \frac{2\Delta_2 f}{sin(\theta)}, \quad (14)$$

where the last inequality is because the query sensitivity on neighboring datasets is $\Delta_2 f = \sup_{\boldsymbol{x}\sim\boldsymbol{x}'} ||f(\boldsymbol{x})-f(\boldsymbol{x}')||_2$.

In (13), we have $(z_1, z_2, \mathbf{h}, \mathbf{g}) \in \mathcal{A}$, i.e., $\theta \in (\frac{\pi}{2}-\theta_0, \frac{\pi}{2}+\theta_0)$, $\theta_0 \in [0, \frac{\pi}{2}]$. Thus, due to the symmetry of the sine function around $\frac{\pi}{2}$, we can obtain $\frac{2\Delta_2 f}{sin(\theta)} \leq \frac{2\Delta_2 f}{sin(\frac{\pi}{2}-\theta_0)} = \frac{2\Delta_2 f}{cos(\theta_0)}$. As a result, we get $|\rho_1|+|\rho_2| \leq ||\mathbf{s}-f(\boldsymbol{x}')||_2 + ||\mathbf{s}-f(\boldsymbol{x})||_2 < \frac{2\Delta_2 f}{cos(\theta_0)} = 2\Delta_2 f \Big/ \left(\frac{\delta\Gamma(\frac{M-1}{2})}{\sqrt{\pi}\Gamma(\frac{M}{2})}\right)^{\frac{1}{M-2}}$.

Finally, from (13), we can obtain the following sufficient condition for the R1SMG mechanism to achieve (ε, δ)-DP:

$$\mathrm{PLRV}^{(\mathbf{s})}_{(R1SMG(\boldsymbol{x})||R1SMG(\boldsymbol{x}'))}$$
$$\leq \frac{1}{2\sigma_*}(|\rho_1|+|\rho_2|)^2 \leq \frac{1}{2\sigma_*}\left(2\Delta_2 f \Big/ \left(\frac{\delta\Gamma(\frac{M-1}{2})}{\sqrt{\pi}\Gamma(\frac{M}{2})}\right)^{\frac{1}{M-2}}\right)^2 \leq \varepsilon,$$

which leads to $\sigma_* \geq \frac{2(\Delta_2 f)^2}{\varepsilon\psi}$. Moreover, due to the constraint of $P > 2$ in Lemma 2, we require $M > 2$ for the R1SMG mechanism. Thus, Theorem 5 follows. □

Remark 1. *In the classic Gaussian mechanism, the privacy budget is upper bounded by 1 (Theorem 1). Similarly, there is also an upper bound on ε for the R1SMG mechanism. This can be explained geometrically using Figure 2. In particular, Figure 2(a) shows the case where $\varepsilon < 1$ in the classic Gaussian mechanism. Clearly as long as $\boldsymbol{n}$ and $\boldsymbol{n}'$ can obscure the difference between $f(\boldsymbol{x})$ and $f(\boldsymbol{x})'$, i.e., $f(\boldsymbol{x})+\boldsymbol{n} = f(\boldsymbol{x}')+\boldsymbol{n}' = \mathbf{s}$, the noise components along the direction of $\boldsymbol{v} = f(\boldsymbol{x})-f(\boldsymbol{x}')$ are also sufficient to obscure the difference between $f(\boldsymbol{x})$ and $f(\boldsymbol{x})'$, i.e., $\lambda_1\boldsymbol{b}_1 - (\boldsymbol{b}_1^T\boldsymbol{n}')\boldsymbol{b}_1 = \boldsymbol{v}$. Whereas, if ε exceeds the upper bound, the magnitude of $\boldsymbol{n}$ and $\boldsymbol{n}'$ might be too small to obscure $\boldsymbol{v}$, since $||\boldsymbol{n}||$ and $||\boldsymbol{n}'||$ are proportional to $\frac{1}{\varepsilon}$. In other words, when ε is beyond the upper bound, $\boldsymbol{n}$, $\boldsymbol{n}'$, and $\boldsymbol{v}$ cannot form a triangle, and hence we have $\lambda_1\boldsymbol{b}_1 - (\boldsymbol{b}_1^T\boldsymbol{n}')\boldsymbol{b}_1 \neq \boldsymbol{v}$ as shown in Figure 2(b). This is also true for the R1SMG mechanism, i.e., when ε is too large, $\boldsymbol{n} = \sqrt{\sigma_*}z_1\mathbf{h}$, $\boldsymbol{n}' = \sqrt{\sigma_*}z_2\mathbf{g}$, and $\boldsymbol{v}$ cannot form a triangle as shown in Figure 2(c). As a result, in order to form a triangle as shown in Figure 2(d), an upper bounded ε is required for the R1SMG mechanism. In this work, we let the privacy budget of the R1SMG mechanism be upper bounded by $\frac{1}{M}$ of that of the classic Gaussian mechanism, i.e., $\frac{1}{M}$. This is because $\boldsymbol{v}$ is obscured using noise with M degrees of freedom by the classic Gaussian mechanism, whereas it is obscured using noise with 1 degree of freedom by the R1SMG mechanism due to the rank-1 constraint. We will provide a tight upper bound on ε for the R1SMG mechanism in a separate study.*

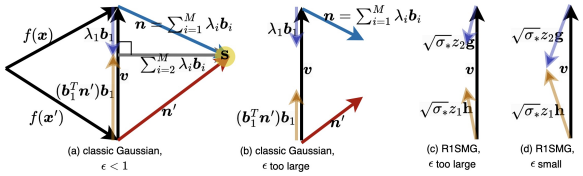

Figure 2: Geometric interpretations on the constraints on ε in the classic Gaussian and R1SMG mechanism.

Implementation of R1SMG. According to the following theorem, we can obtain the desired random variable distributed on the Stiefel manifold by transforming samples drawn i.i.d. from standard Gaussian distribution.

Theorem 6. *[13, p. 29, Theorem 2.2.1] Let $\mathbf{x} \in \mathbb{R}^{M\times r}$, whose elements are i.i.d. Gaussian random variables from $\mathcal{N}(0,1)$. Then, $\mathbf{v} = \mathbf{x}(\mathbf{x}^T\mathbf{x})^{-1/2}$ is uniformly distributed on $\mathbb{V}_{r,M}$.*

Thus, we can apply Theorem 6 with $r = 1$ to draw the desired samples from $\mathbb{V}_{1,M}$. Then, applying (11), we can generate an instance of random noise for the R1SMG mechanism.

5.3 Expected Accuracy Loss Analysis

In this section, we investigate the expected accuracy loss of the R1SMG mechanism, i.e., $\mathbb{E}_{R1SMG}[\mathcal{L}]$. The results are summarized in Theorem 7.

Theorem 7. *For any fixed feasible $\varepsilon > 0, 0 < \delta < 1$, given a dataset $\boldsymbol{x}$ and a query result $f(\boldsymbol{x}) \in \mathbb{R}^M$. We have $\mathbb{E}_{R1SMG}[\mathcal{L}] = ||R1SMG(f(\boldsymbol{x})) - f(\boldsymbol{x})||_2^2 = Tr[\boldsymbol{\Pi}] = \sigma_* \geq C_R(\Delta_2 f)^2$, where σ_* is the only nonzero eigenvalue of $\boldsymbol{\Pi}$, $C_R = \frac{2}{\varepsilon\psi}$, and $\psi = \left(\frac{\delta\Gamma(\frac{M-1}{2})}{\sqrt{\pi}\Gamma(\frac{M}{2})}\right)^{\frac{2}{M-2}}$. C_R has a decreasing trend as M increases. When M goes large, C_R converges to $\frac{2}{\varepsilon}$ and $\mathbb{E}_{R1SMG}[\mathcal{L}]$ can be as low as $\frac{2(\Delta_2 f)^2}{\varepsilon}$.*

Proof. According to the noise generation process in R1SMG, i.e., (11), we have

$$\begin{aligned}&\mathbb{E}_{R1SMG}[\mathcal{L}] = \mathbb{E}[||\mathbf{n}||_2^2]\\ =&\mathbb{E}\left[(\mathbf{v}\sigma_*^{1/2}z)^T\mathbf{v}\sigma_*^{1/2}z\right] = \sigma_*\mathbb{E}[z^2] \overset{(a)}{=} \sigma_* \overset{(b)}{\geq} 2(\Delta_2 f)^2/(\varepsilon\psi),\end{aligned} \tag{15}$$

where (a) holds because $z^2 \sim \chi^2(1)$, and (b) is due to Theorem 5. From (15), we also have $\mathbb{E}_{R1SMG}[\mathcal{L}] = \sigma_* = Tr[\boldsymbol{\Pi}]$.

To show the decreasing trend of $\mathbb{E}_{R1SMG}[\mathcal{L}]$ without dealing with the cumbersome notation of ψ, we use some intermediate results obtained in the proof of Theorem 5. To be more specific, we have $\psi = sin^2(\theta)$, where $\theta \in (\frac{\pi}{2} - \theta_0, \frac{\pi}{2} + \theta_0)$ is the angle between two instances of M-dimensional unit vectors, and $\theta_0 = arccos\left(\left(\delta\Gamma(\frac{M-1}{2})/\sqrt{\pi}\Gamma(\frac{M}{2})\right)^{1/(M-2)}\right)$. Cai et al. [7] has proved that when $M > 2$, θ concentrates around $\frac{\pi}{2}$, and the concentration becomes stronger as the dimension M grows. In particular, θ converges to $\frac{\pi}{2}$ at the rate of $\sqrt{M}$ when M approaches infinity [7, p. 1840]. Thus, $\frac{1}{sin^2(\theta)}$ has a decreasing trend and converges to 1 due to the symmetry of sine function on $[0, \pi]$. Subsequently, we can have that $C_R = \frac{2}{\varepsilon\psi}$ has a decreasing trend as well. In addition, when M goes large, we get that C_R converges to $\frac{2}{\varepsilon}$ and hence $\mathbb{E}_{R1SMG}[\mathcal{L}]$ can be as low as $\frac{2(\Delta_2 f)^2}{\varepsilon}$[3]. □

Curse Lifted. (15) clearly shows that we have lifted the identified curse by considering noise attributed to a singular multivariate Gaussian distribution with rank-1 covariance matrix. In particular, the expected accuracy loss introduced by the R1SMG mechanism is $Tr[\boldsymbol{\Pi}]$, which equal to the only nonzero eigenvalue σ_* but is **not** the summation of M positive eigenvalues any more like in the existing Gaussian mechanisms.

From Theorem 4 and Theorem 7, we arrive at Corollary 1.

Corollary 1. *The R1SMG mechanism leads to expected accuracy loss on a lower order of magnitude by at least M or MN compared with the classic Gaussian, analytic Gaussian, and MVG mechanisms. In particular, we have $C_R = \Theta(\frac{\varepsilon C_C}{M}) = \Theta(\frac{C_A}{M}) = \Theta(\frac{C_M}{MN})$.*

Proof. According to Theorem 5, we have $\frac{1}{\psi} = \left(\frac{\sqrt{\pi}\Gamma(\frac{M}{2})}{\delta\Gamma(\frac{M-1}{2})}\right)^{\frac{2}{M-2}} = \exp\left(\frac{2}{M-2}\ln\left(\frac{\sqrt{\pi}\Gamma(\frac{M}{2})}{\delta\Gamma(\frac{M-1}{2})}\right)\right)$. By connecting $\frac{\Gamma(\frac{M}{2})}{\Gamma(\frac{M-1}{2})}$ to the normalization constant of the Beta distribution $Beta(\alpha, \beta)$ with $\alpha = \frac{M-1}{2}$ and $\beta = \frac{1}{2}$, it gives $\Theta\left(\frac{\Gamma(\frac{M}{2})}{\Gamma(\frac{M-1}{2})}\right) = \Theta\left(\frac{\sqrt{M-2}}{\sqrt{2}}\right)$ [7]. As a result, we can obtain $C_R = \Theta\left(\frac{2}{\varepsilon}\exp\left(\frac{2}{M-2}\ln\frac{\sqrt{M-2}}{\sqrt{2}}\right)\right)$. Compare C_R with the results in Theorem 4, we get that $C_R = \Theta(\frac{\varepsilon C_C}{M}) = \Theta(\frac{C_A}{M}) = \Theta(\frac{C_M}{MN})$. □

Moreover, in Appendix B, we plot the empirical $\mathbb{E}[\mathcal{L}]$ versus M achieved by the R1SMG mechanism and by other mechanisms, respectively, and clearly show that $\mathbb{E}_{R1SMG}[\mathcal{L}]$ has a decreasing trend as M increases and eventually converges, whereas all the other mechanisms result in expected accuracy loss increasing with M (cf. Figure 9).

5.4 Discussion on Privacy Leakage of Utilizing Vector in the Null Space of v

The R1SMG mechanism does not span the entire space of $\mathbb{R}^M$. Therefore, it may raise concerns about privacy leakage if one takes advantage of the vector in the null space of $\mathbf{v}$. In other words, let $\mathbf{s}$ be the output of R1SMG and $\mathbf{u} \in Null(\mathbf{v}) = \{\mathbf{u} | < \mathbf{u}, \mathbf{v} >= 0\}$. Since $\mathbf{n} \in Span(\mathbf{v})$, one can have $< \mathbf{u}, \mathbf{s} >=< \mathbf{u}, f(\boldsymbol{x}) + \mathbf{n} >=< \mathbf{u}, f(\boldsymbol{x}) >$, which implies potential privacy leakage of queries on $f(\boldsymbol{x})$.

However, we highlight that $\mathbf{v}$ is randomly sampled from $\mathcal{U}(\mathbb{V}_{1,M})$, which is an intermediate noise to produce the final noise of the R1SMG mechanism and will not be made public. Note that this is not against the core idea of DP, i.e., "privacy without obscurity", because the entire noise generation process, i.e, (11), including the choice of distribution parameters are transparent. Thus, the probability that a constructed $\mathbf{u}$ that is in the null space of a randomly sampled $\mathbf{v}$ is zero, i.e., $\Pr[\mathbf{u} \in Null(\mathbf{v})] = \frac{\mu(Null(\mathbf{v}))}{\mu(\mathbb{R}^M)} = 0$, where $\mu(\cdot)$ is the Lebesgue measure of a measurable set.

For better explanation, , we give toy examples in $\mathbb{R}^2$ and $\mathbb{R}^3$ (when $M = 2$ and $M = 3$). Note that in practice R1SMG requires $M > 2$, here we use $\mathbb{R}^2$ just to visualize the idea (the probability that a constructed $\mathbf{u}$ that is in the null space of a randomly sampled $\mathbf{v}$ is zero) which is independent of the dimension. In $\mathbb{R}^2$, $\mathbb{V}_{1,2}$ is the unit circle shown in Figure 3 (left). Suppose that $\mathbf{v}_1 = [-1/\sqrt{5}, 2/\sqrt{5}]^T$ is the randomly sampled variable in $\mathbb{V}_{1,2}$. Then $Null(\mathbf{v}_1)$ is I (the dashed line orthogonal to $\mathbf{v}_1$). Clearly, the probability of sampling a point from $\mathbb{R}^2$ that resides on a specific line is 0. Likewise, in $\mathbb{R}^3$, $\mathbb{V}_{1,3}$ is the unit sphere shown in Figure 3 (right). Suppose

[3] Note that the asymptotic property of C_R is studied when ε is always feasible. Suppose that we are interested in the asymptotic property of C_R when $M_1 < M < M_2$. Then, as explained in Remark 1, a feasible ε refers to $\varepsilon < \frac{1}{M_2}$.

that $\mathbf{v}_2 = [1/\sqrt{3}, -1/\sqrt{3}, 1/\sqrt{3}]^T$ is the randomly sampled variable in $\mathbb{V}_{1,3}$. Then $Null(\mathbf{v}_2)$ is $\mathcal{F}$ (the plane orthogonal to $\mathbf{v}_2$). The probability of sampling a point from $\mathbb{R}^3$ that resides on a specific plane is also 0. Although, it is publicly known that $\mathbf{v}$ is sampled from $\mathcal{U}(\mathbb{V}_{1,M})$, the Lebesgue measure of $Null(\mathbf{v})$ (given $\mathbf{v} \subset \mathbb{V}_{1,M}$) is still 0. For example, the probability of sampling the blue points in Figure 3 (left) is 0, and the probability of sampling points residing on $\mathcal{C} \subset \mathcal{F}$ (the circle orthogonal to $\mathbf{v}_2$) in Figure 3 (right) is also 0. Hence, by generating $\mathbf{v}$ randomly, the R1SMG mechanism will cause privacy leakage of using the vectors in the null space of $\mathbf{v}$ to have probability zero.

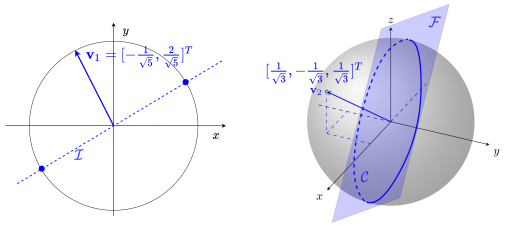

Figure 3: Visualization of the null space of the noise generated by the R1SMG mechanism. Left: $\mathbb{V}_{1,2}$. Right: $\mathbb{V}_{1,3}$.

6 Accuracy Stability

Now, we evaluate the accuracy stability achieved by various output perturbation DP mechanisms by studying the kurtosis and skewness of the distribution of $\mathcal{L}$ (the non-deterministic accuracy loss defined in Definition 1). In particular,

- Kurtosis, a descriptor of "tail extremity" of a probability distribution, is defined as the ratio between the 4th moment and the square of the 2nd moment of a random variable, i.e., $\frac{\mathbb{E}[\mathcal{L}^4]}{(\mathbb{E}[\mathcal{L}^2])^2}$. A larger kurtosis means that outliers or extreme large values are less likely to be generated in a given probability distribution [45].
- Skewness, a descriptor of the "bulk" of a probability distribution, is defined as the ratio between the 3rd moment and the square root of the cube of the 2nd moment of a random variable, i.e., $\frac{\mathbb{E}[\mathcal{L}^3]}{(\mathbb{E}[\mathcal{L}^2])^{3/2}}$. A larger skewness means that the bulk of the samples is at the left region of the PDF and the right tail is longer.

As a result, in order to have high accuracy stability on the perturbed query result, $\mathcal{L}$ with both **larger kurtosis and skewness is preferred**. We summarize the theoretical results for various mechanisms in Theorem 8 and Theorem 9.

Theorem 8. *The kurtosis of the distribution of $\mathcal{L}$ in the R1SMG mechanism is $\frac{35}{3}$ which is larger than that of the classic Gaussian mechanism, of the analytic Gaussian mechanism, and of the MVG mechanism, i.e., the PDF of $\mathcal{L}$ in the R1SMG mechanism is more leptokurtic than that in the classic Gaussian, in the analytic Gaussian, and in the MVG mechanism.*

Proof. First, for the proposed R1SMG, we have

$$\text{Kurt}_{\text{R1SMG}}(\mathcal{L}) = \frac{\mathbb{E}[\mathcal{L}^4]}{(\mathbb{E}[\mathcal{L}^2])^2} \overset{(a)}{=} \frac{\mathbb{E}\left[\left((\mathbf{v}\sqrt{\sigma_*}z)^T\mathbf{v}\sqrt{\sigma_*}z\right)^4\right]}{\left(\mathbb{E}\left[\left((\mathbf{v}\sqrt{\sigma_*}z)^T\mathbf{v}\sqrt{\sigma_*}z\right)^2\right]\right)^2} = \frac{\mathbb{E}[(z\sigma_* z)^4]}{\left(\mathbb{E}[(z\sigma_* z)^2]\right)^2}$$
$$\overset{(b)}{=} \frac{48\sigma_*^4+32\sigma_*^3\sigma_*+12(\sigma_*^2)^2+12\sigma_*^2(\sigma_*)^2+(\sigma_*)^4}{\left(2\sigma_*^2+(\sigma_*)^2\right)^2} = \frac{35}{3},$$

where (a) is due to the noise generation process of R1SMG in (11) and (b) is obtained by applying Lemma 1 with $\mathbf{A} = 1$ and $\mathbf{\Xi} = \sigma_*$ (i.e., the case of univariant Gaussian).

Then, we show that both classic Gaussian mechanism and the MVG mechanism will result in $\mathcal{L}$ with kurtosis less than $\frac{35}{3}$. In particular, the classic Gaussian mechanism (denoted as $\mathcal{G}$) adds i.i.d. noise to each entry of $f(\boldsymbol{x})$, $\mathbf{n}_i \sim \mathcal{N}(0, \sigma^2), i \in [1, M]$. Thus, we have $\mathbb{E}_{\mathcal{G}}[\mathcal{L}^t] = \mathbb{E}_{z_i \sim \mathcal{N}(0,1)}\left[\left(\sum_i \sigma^2 z_i^2\right)^t\right] = \sigma^{2t}\mathbb{E}_{U\sim\chi^2(M)}[U^t] = \sigma^{2t}2^t\frac{\Gamma(t+\frac{M}{2})}{\Gamma(\frac{M}{2})}$, where the last equality follows from the tth moments of Chi-squared random variable. Set t to be 4 and 2, one can verify that $\text{Kurt}_{\mathcal{G}}(\mathcal{L}) = \frac{\mathbb{E}_{\mathcal{G}}[\mathcal{L}^4]}{(\mathbb{E}_{\mathcal{G}}[\mathcal{L}^2])^2} = \sigma^8 2^4\frac{\Gamma(4+\frac{M}{2})}{\Gamma(\frac{M}{2})} \Big/ \left(\sigma^4 2^2\frac{\Gamma(2+\frac{M}{2})}{\Gamma(\frac{M}{2})}\right)^2 < \frac{35}{3}, \forall M > 1$.

The same analysis holds for the analytic Gaussian mechanism, as it adds i.i.d. Gaussian noise with variance σ_A^2.

MVG introduces the matrix-valued noise attributed to a matrix-valued Gaussian distribution, i.e., $\mathcal{N}(\mathbf{0}, \mathbf{\Sigma}, \mathbf{\Psi})$, and the vectorization of the noise matrix is also attributed to a multivariate Gaussian distribution, i.e., $\mathcal{N}(\mathbf{0}, \mathbf{\Sigma}\otimes\mathbf{\Psi})$ [21]. Denote $\mathbf{\Xi} = \mathbf{\Sigma}\otimes\mathbf{\Psi}$, and let $k > 1$ be an integer, we first have

$$(Tr[\mathbf{\Xi}])^k = (Tr[\mathbf{\Sigma}\otimes\mathbf{\Psi}])^k = \left[\left(\sum_{i=1}^{\text{rank}(\mathbf{\Sigma})}\sigma_i(\mathbf{\Sigma})\right)\left(\sum_{j=1}^{\text{rank}(\mathbf{\Psi})}\sigma_j(\mathbf{\Psi})\right)\right]^k$$
$$> \sum_{i=1,j=1}^{\text{rank}(\mathbf{\Sigma}),\text{rank}(\mathbf{\Psi})}\left(\sigma_i(\mathbf{\Sigma})\sigma_j(\mathbf{\Psi})\right)^k = Tr\left[(\mathbf{\Sigma}\otimes\mathbf{\Psi})^k\right] = Tr\left[\mathbf{\Xi}^k\right].$$

Similarly, for any positive integer $k_1 > k_2 \geq 1$ and symmetric $\mathbf{\Xi} \in \mathbb{PD}$, we have

$$Tr[\mathbf{\Xi}^{k_1}](Tr[\mathbf{\Xi}])^{k_2} > Tr[\mathbf{\Xi}^{k_1}]Tr[\mathbf{\Xi}^{k_2}]$$
$$= \left(\sum_{i=1}^{\text{rank}(\mathbf{\Xi})}(\sigma_i(\mathbf{\Xi}))^{k_1}\right)\left(\sum_{i=1}^{\text{rank}(\mathbf{\Xi})}(\sigma_i(\mathbf{\Xi}))^{k_2}\right) > \sum_{i=1}^{\text{rank}(\mathbf{\Xi})}(\sigma_i(\mathbf{\Xi}))^{k_1+k_2}$$
$$= Tr[\mathbf{\Xi}^{k_1+k_2}].$$

Then, according to Lemma 1, we have

$$\text{Kurt}_{\text{MVG}}(\mathcal{L}) = \frac{\mathbb{E}[\mathcal{L}^4]}{(\mathbb{E}[\mathcal{L}^2])^2} = \frac{\mathbb{E}[(\mathbf{n}^T\mathbf{n})^4]}{(\mathbb{E}[(\mathbf{n}^T\mathbf{n})^2])^2} = \frac{\mathbb{E}[Q(\mathbf{n})^4]}{(\mathbb{E}[Q(\mathbf{n})^2])^2}$$
$$= \frac{48Tr[\mathbf{\Xi}^4]+32Tr[\mathbf{\Xi}^3]Tr[\mathbf{\Xi}]+12(Tr[\mathbf{\Xi}^2])^2+12Tr[\mathbf{\Xi}^2](Tr[\mathbf{\Xi}])^2+(Tr[\mathbf{\Xi}])^4}{\left(2Tr[\mathbf{\Xi}^2]+(Tr[\mathbf{\Xi}])^2\right)^2}.$$

Next, we can obtain $48Tr[\mathbf{\Xi}^4] < \frac{104}{3}(Tr[\mathbf{\Xi}^2])^2 + \frac{8}{3}Tr[\mathbf{\Xi}^2](Tr[\mathbf{\Xi}])^2 + \frac{32}{3}(Tr[\mathbf{\Xi}])^4$ and $32Tr[\mathbf{\Xi}^3]Tr[\mathbf{\Xi}] < 32Tr[\mathbf{\Xi}^2](Tr[\mathbf{\Xi}])^2$. Thus, we get $\text{Kurt}_{\text{MVG}}(\mathcal{L}) < \frac{\frac{35}{3}\left(4Tr[\mathbf{\Xi}^2]+4Tr[\mathbf{\Xi}^2](Tr[\mathbf{\Xi}])^2+(Tr[\mathbf{\Xi}])^4\right)}{4Tr[\mathbf{\Xi}^2]+4Tr[\mathbf{\Xi}^2](Tr[\mathbf{\Xi}])^2+(Tr[\mathbf{\Xi}])^4} = \frac{35}{3}$, which concludes the proof. □

Theorem 9. *The skewness of the distribution of $\mathcal{L}$ in the R1SMG mechanism is $\frac{5\sqrt{3}}{3}$ which is larger than that of the classic Gaussian mechanism, of the analytic Gaussian mechanism, and of the MVG mechanism, i.e., the PDF of $\mathcal{L}$ in the R1SMG mechanism is more right-skewed than that in the classic Gaussian, in the analytic Gaussian, and in the MVG mechanism.*

Proof. The proof follows the same procedure as the proof of Theorem 8, thus we only show the key steps here.

For the proposed R1SMG, we have $\text{skew}_{\text{R1SMG}}(\mathcal{L}) = \frac{\mathbb{E}[\mathcal{L}^3]}{(\mathbb{E}[\mathcal{L}^2])^{3/2}} = \frac{\mathbb{E}\left[(z\sigma_* z)^3\right]}{\left(\mathbb{E}\left[(z\sigma_* z)^2\right]\right)^{3/2}} = \frac{\sigma_*^3 2^3 \frac{\Gamma(3+\frac{1}{2})}{\Gamma(\frac{1}{2})}}{\left(\sigma_*^2 2^2 \frac{\Gamma(2+\frac{1}{2})}{\Gamma(\frac{1}{2})}\right)^{3/2}} = \frac{5\sqrt{3}}{3}$.

For the classic Gaussian mechanism, one can verify that $\text{skew}_{\mathcal{G}}(\mathcal{L}) = \frac{\sigma_G^6 2^3 \frac{\Gamma(3+\frac{M}{2})}{\Gamma(\frac{M}{2})}}{\left(\sigma_G^4 2^2 \frac{\Gamma(2+\frac{M}{2})}{\Gamma(\frac{M}{2})}\right)^{3/2}} = \frac{\frac{\Gamma(3+\frac{M}{2})}{\Gamma(\frac{M}{2})}}{\left(\frac{\Gamma(2+\frac{M}{2})}{\Gamma(\frac{M}{2})}\right)^{3/2}} < \frac{5\sqrt{3}}{3}, \forall M > 1$.

The same analysis holds for the analytic Gaussian mechanism, as it adds i.i.d. Gaussian noise with variance σ_A^2.

For the MVG mechanism, it is easy to check that $\text{skew}_{\text{MVG}}(\mathcal{L}) = \frac{\mathbb{E}[\mathcal{L}^3]}{(\mathbb{E}[\mathcal{L}^2])^{3/2}} = \frac{\mathbb{E}[(\mathbf{n}^T\mathbf{n})^3]}{(\mathbb{E}[(\mathbf{n}^T\mathbf{n})^2])^{3/2}} = \frac{\left(8Tr[\Xi^3]+6Tr[\Xi^2]Tr[\Xi]+(Tr[\Xi])^3\right)}{\left(2Tr[\Xi^2]+(Tr[\Xi])^2\right)^{3/2}}$, $\Xi = \mathbf{\Sigma} \otimes \mathbf{\Psi}$. Besides, we have shown that for any positive integer k, k_1, and k_2, we have $(Tr[\Xi])^k > Tr[\Xi^k]$ and $Tr[\Xi^{k_1}](Tr[\Xi])^{k_2} > Tr[\Xi^{k_1+k_2}]$. Thus, one can check that $(\text{skew}_{\text{MVG}}(\mathcal{L}))^2 = \frac{\left(8Tr[\Xi^3]+6Tr[\Xi^2]Tr[\Xi]+(Tr[\Xi])^3\right)^2}{\left(2Tr[\Xi^2]+(Tr[\Xi])^2\right)^3} < \frac{\frac{25}{3}\left(2Tr[\Xi^2]+(Tr[\Xi])^2\right)^3}{\left(2Tr[\Xi^2]+(Tr[\Xi])^2\right)^3}$, i.e., $\text{skew}_{\text{MVG}}(\mathcal{L}) < \frac{5\sqrt{3}}{3}$. □

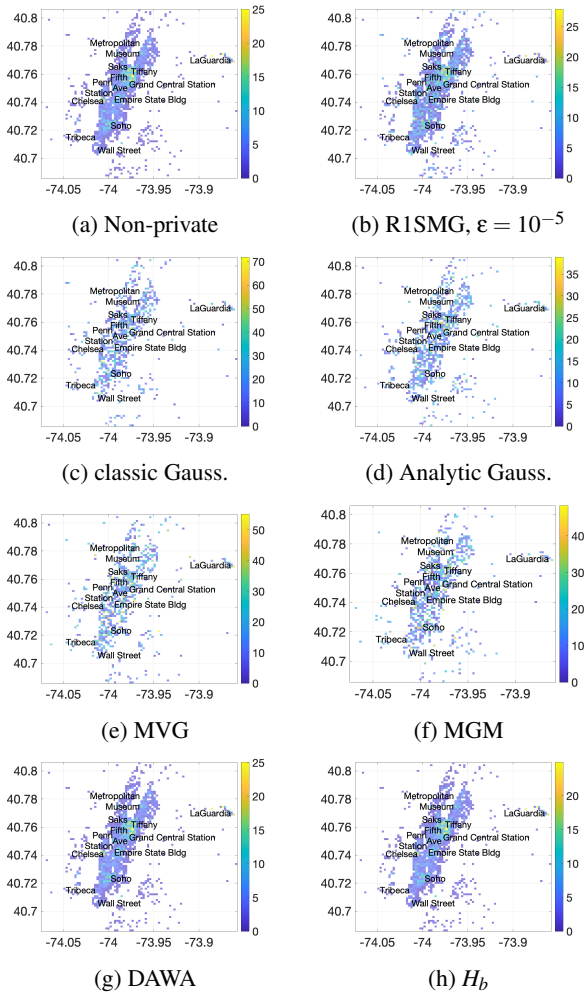
Remark 2. *We can consider the univariate Gaussian with unit covariance, i.e., $\mathcal{N}(\mu, 1)$, as a reference distribution, whose kurtosis value and skewness value are 3 and 0, respectively. Then, it suggests that the distribution of $\mathcal{L}$ in the R1SMG mechanism are much more leptokurtic and right-skewed than $\mathcal{N}(\mu, 1)$. Moreover, since the noise used in the classic Gaussian, analytic Gaussian, and MVG mechanisms are characterized by full-rank covariance matrices, their kurtosis values and skewness values asymptotically converge to $3 + 12/H$ and $\sqrt{8/H}$, respectively [25] (H is the degree of freedom of the obtained $\mathcal{L}$, and $H = M$ for $f(\boldsymbol{x}) \in \mathbb{R}^M$). It means that the distributions of $\mathcal{L}$ in the Gaussian mechanism and MVG are similar to $\mathcal{N}(\mu, 1)$ when M is large.*

In Section 7.1, by using 2D count query as an example, we will empirically show that the distribution of $\mathcal{L}$ obtained in the R1SMG mechanism is more leptokurtic and right-skewed than those of the classic Gaussian, the analytic Gaussian, and the MVG mechanisms (cf. Figure 5). In other words, the R1SMG mechanism can provide differentially private query results with the highest accuracy stability.

Based on the above theoretical analysis, we can have the following corollary.

Corollary 2. *The R1SMG mechanism outperforms the classic Gaussian, the analytic Gaussian, and the MVG mechanism, because it boosts the utility of the query results by achieving lower expected accuracy loss and higher accuracy stability.*

7 Experiments



In this section, we conduct three case studies to validate the utility boosting achieved by the R1SMG mechanism, i.e., 2D count query, principal component analysis (PCA), and deep learning, all in a differentially private manner. The query results of these case studies are either matrices or tensors, so the R1SMG, classic Gaussian, and analytic Gaussian mechanisms will first generate noise in vector form, and then reshape the noise into the forms required by different studies.

7.1 Case Study I: Uber Pickup Count Query

In this case study, we utilize the New York City (NYC) Uber pickups dataset [2], on which we are interested in releasing the counts of Uber pickups in different areas of NYC from "4/1/2014 00:11:00" to "4/3/2014 23:57:00" in a differentially private manner. The size of the count query $f(\boldsymbol{x})$ is determined by the partition areas (defined later) of NYC. Location and trajectory privacy breaches have been reported and investigated in several research works [23, 32, 35, 46]. Thus, it is important to guarantee that the existence or absence of any pickup record is private when sharing the count query.

In particular, we partition the map of NYC into small areas by evenly dividing the latitude and longitude into 89 disjoint intervals. As a result, the considered query is $f(\boldsymbol{x}) \in \mathbb{R}^{89\times 89}$, whose entries record the number of Uber pickups in different small areas. The squared sensitivity of this query is 2, because the absence or presence of a specific pickup can change at most 2 entries of $f(\boldsymbol{x})$ by 1. We also consider that the data consumer (i.e., the query result recipient) has the prior knowledge of the valid pickup areas in the resulted 89×89 small areas. Thus, he can perform post-processing on the noisy count query to eliminate the values in invalid areas (e.g., it is impossible to have Uber pickups over the Hudson River). We visualize the non-private Uber pickup count query in Figure 4(a). We observe high volumes of pickups around Soho, Fifth avenue, and LaGuardia Airport.

Comparisons with Mechanisms. In additional to the (ε, δ)-DP output perturbation mechanisms, i.e., the classic Gaussian, analytic Gaussian, MVG, and MGM (a variant of MVG [47]) mechanisms, we also compare the R1SMG mechanism with the mechanisms that are specially developed for differentially private 2D count queries. In particular, they are (i) DAWA [31], which obtains differentially private count queries by adding noise that is adapted to both the input data

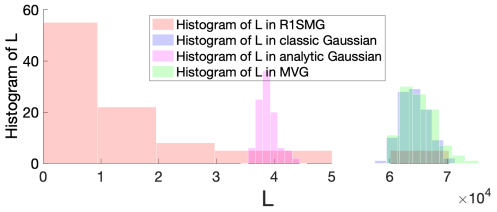
(a) Non-private (b) R1SMG, $\varepsilon = 10^{-5}$

(c) classic Gauss. (d) Analytic Gauss.

(e) MVG (f) MGM

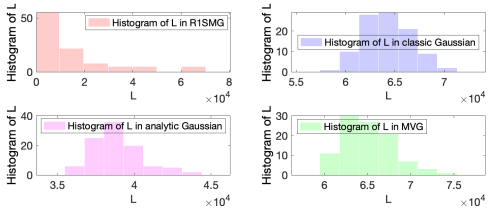
(g) DAWA (h) H_b

Figure 4: Visualization of (a) non-private counts, (b)-(h) are differentially private 2D counts obtained by the R1SMG, classic Gaussian, analytic Gaussian, MVG, MGM, DAWA, and H_b mechanisms, respectively. ε is 10^{-5} for the R1SMG mechanism and is 0.5 for the other mechanisms.



and the given query set, and (ii) H_b [38], which answers range queries using noisy hierarchies of equi-width histograms.

Results. We visualize the differential-privately released count queries obtained by the R1SMG and the other comparing mechanisms in Figures 4(b)-(h). The privacy budgets for all the comparing mechanisms are $\varepsilon = 0.5$ and $\delta = 10^{-7}$. For the R1SMG mechanism, we set $\varepsilon = 10^{-5} < \frac{0.5}{89^2}$ according to Remark 1.



Clearly, the R1SMG mechanism outperforms all the comparing output perturbation mechanisms (i.e., Figure 4(c)-(f)) even under a very restricted privacy budget, as it preserves the global and local patterns of the non-private count query in Figure 4(a) in the best way. In contrast, the classic Gaussian, MVG, and MGM mechanisms greatly compromise the utility of the count query results although their privacy budget is 10^4 times as large as that of our R1SMG mechanism. For example, in Figures 4(c), (e), and (f) many areas on the Manhattan island have no pickup counts, and the maximum count is also increased significantly (i.e., higher than 60, 50, and 40, respectively, compared to the non-private maximum count which is only around 27). Although the analytic Gaussian mechanism outperforms the classic Gaussian and MVG mechanisms by calibrating the noise variance exactly, it still introduces noise with higher magnitude than the R1SMG mechanism. Finally, we observe that the R1SMG mechanism has comparable performance with DAWA and H_b that are developed specially for differentially private range queries. Note that DAWA has slightly better results because it is data-dependent (the noise is customized to the input data [31]), and that H_b adopts "constrained inference" (an accuracy boosting scheme) to control the mean square error of counting queries at various granularities. Moreover, not only does the R1SMG mechanism introduces comparable errors with those by the two task-specific mechanisms under a much stricter privacy guarantee, but also it is very promising in other real-world tasks because it is not task-dependent.

Utility boosting and stability. Next, we empirically corroborate that the R1SMG mechanism boosts the utility of the NYC Uber pickup count query by achieving lower accuracy loss and higher accuracy stability. Specifically, by setting $\varepsilon = 10^{-5}$ for the R1SMG mechanism and $\varepsilon = 0.5$ for the other mechanisms and $\delta = 10^{-7}$, we repeat the noise generation process 100 times for the R1SMG, classic Gaussian, analytic Gaussian, and MVG mechanisms, respectively, and calculate the accuracy loss (i.e., $\mathcal{L}$, in Definition 1). In Figure 5, we plot the corresponding histograms, empirical average values of $\mathcal{L}$, and the empirical PDFs, obtained by different mechanisms. In particular, Figure 5(a) plots the histograms of $\mathcal{L}$ for various mechanisms on the same x-axis, and Figure 5(b) is the zoomed in histograms for each mechanism. Figure 5(c) demonstrates the empirical PDF and mean of $\mathcal{L}$ for each mechanism on the same x-axis, and Figure 5(d) shows the corresponding zoomed in plots.

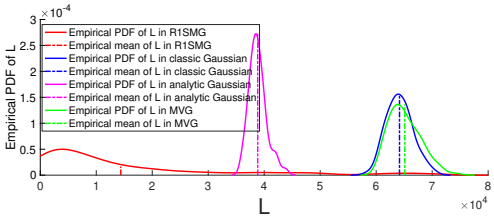


Figure 5 shows that the empirical mean accuracy loss obtained by the R1SMG mechanism is less than those obtained by the other mechanisms, in spite of the fact that the privacy budget is smaller than $1/10^4$ of the others. This means that under very restricted privacy guarantee, the R1SMG mechanism is able to introduce additive noise with small magnitude (squared Frobenius norm), which lead to lower empirical accuracy loss. In particular, $\mathcal{L}$ obtained by the R1SMG mechanism is around 1.5×10^4 when $\varepsilon = 10^{-5}$, whereas, $\mathcal{L}$ obtained by the other mechanisms are around 5×10^4 even with $\varepsilon = 0.5$. We can also find that the histogram and the empirical PDF of $\mathcal{L}$ obtained by the R1SMG mechanism are much more leptokurtic and right-skewed than those achieved by the others. Particularly, in Figure 5(d), compared with those obtained by the other mechanisms that have bell shapes, the empirical PDF of $\mathcal{L}$ achieved by the R1SMG mechanism has a longer and fatter tail, a higher and sharper central peak, and the den-

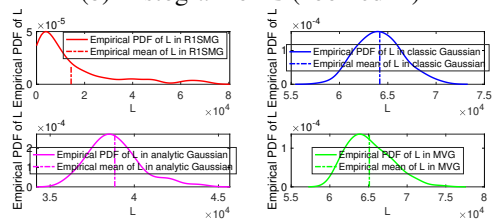


(a) Histogram of $\mathcal{L}$ for various mechanisms

(b) Histogram of $\mathcal{L}$ (zoomed in)

(c) Empirical PDF and mean of $\mathcal{L}$ for various mechanisms

(d) Empirical PDF and mean of $\mathcal{L}$ (zoomed in)

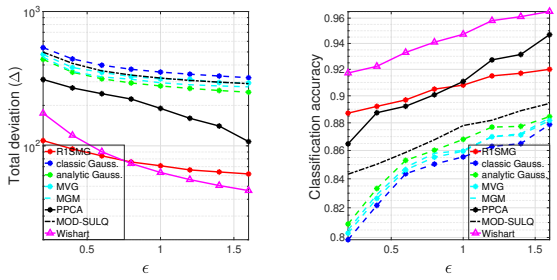
Figure 5: Accuracy loss introduced by different output perturbation mechanisms when $\delta = 10^{-7}$, $\varepsilon = 10^{-5}$ for the R1SMG mechanism and $\varepsilon = 0.5$ for the other mechanisms.

sity is more densely distributed on the left side. The results corroborate the analysis in Remark 2. Thus, under very strict (ε, δ)-DP requirement, it is still less likely for the R1SMG mechanism to generate additive noise with large magnitude.

7.2 Case Study II: PCA

In this case study, we explore differentially private principal component analysis (PCA) using the Swarm Behaviour dataset [1]. It contains 24016 records of flocking behaviour (i.e., the way that groups of birds, insects, fish or other animals, move close to each other). Each record has 2400 features characterizing a flocking observation, e.g., radius of separation of groups of insects, moving direction, moving velocity, etc. Each data record is assigned a binary label, and "1" represents "flocking behavior" and "0" represents "not flocking". The values of all features are normalized between -1 and 1. Similar to [11], we consider the query $f(\boldsymbol{x})$ as the covariance matrix of this dataset, i.e., $f(\boldsymbol{x}) = D^T D/24016 \in \mathbb{R}^{2400\times 2400}$, where $D \in \mathbb{R}^{24016\times 2400}$ denotes the considered Swarm Behaviour data.[4] Then, the l_2 sensitivity of the query function is $\Delta_2 f = \sup_{D_1,D_2} \frac{||D_1(i)^T D_1(i) - D_2(i)^T D_2(i)||_F}{24016} = \frac{\sqrt{2\times 2400^2}}{24016} = \frac{2400\sqrt{2}}{24016}$.

We conduct singular value decomposition on the queried result (i.e., the noisy empirical covariance matrix) to extract the components of the dataset. The considered evaluation metric is the total deviation which is defined as $\Delta = \sum_{i=1}^{2041} \Delta_i = \sum_{i=1}^{2041} |\lambda_i - \widetilde{\mathbf{v}}_i^T \mathbf{C} \widetilde{\mathbf{v}}_i|$, where $\mathbf{C}$ is the ground-truth (non-private) empirical covariance matrix, λ_i is the ith eigenvalue of $\mathbf{C}$, and $\widetilde{\mathbf{v}}_i$ is the ith differentially private component (eigenvector). Specifically, Δ_i quantifies the deviation of the variance from λ_i in the direction of the ith component. The smaller Δ is, the higher utility the obtained components have, and we have $\Delta = 0$ for the non-private baseline.



Since PCA usually serves as a precursor to classification task, we also evaluate the utility of the queried data by projecting the dataset onto the subspace spanned by the first 20 PCs obtained from various noisy covariance matrices, and then measure the classification accuracy using the projected data. The higher the classification accuracy, the higher the utility of the perturbed covariance matrix. In the experiments, we use 60% and 40% of the dataset for training and testing, respectively, and the classification algorithm is the linear SVM. Note that the accuracy of the non-private baseline (i.e., classification using the original dataset project onto the first 20 PCs of the original covariance matrix) is 96.89%.

Comparisons with other Mechanisms. In addition to the output perturbation mechanisms, we also consider the principal components obtained from 3 task-specific differentially private algorithms designed specially for PCA, i.e., (i) PPCA [12], which generates privacy-preserving components by sampling orthonormal matrices from the matrix Bingham distribution parametermized by the original non-private empirical covariance matrix scaled by the privacy budget, (ii) MOD-SULQ [12], which directly perturbs the covariance matrix using calibrated Gaussian noise, and (iii) the Wishart mechanism [24], which perturbs the empirical covariance matrices using noise attributed to the Wishart distribution.

Results. In this experiment, we vary ε from 0.2 to 1.6 and set $\delta = 10^{-7}$ for all the comparing mechanisms and let the privacy budget of the R1SMG be only $1/10^7$ of the others according to the discussion in Remark 1.

Figure 6(a) and (b) plot the total derivation (Δ) and classification accuracy on the projected testing data obtained from all mechanisms. Obviously, the R1SMG mechanism has high utility although its the privacy budget is extremely limited, e.g.,

[4] Since covariance matrices are symmetric, the data consumer will perform post processing $\left(\mathcal{M}(f(\boldsymbol{x})) + \mathcal{M}(f(\boldsymbol{x}))^T\right)/2$ to obtain symmetric result. The privacy guarantee naturally holds due to the post-processing immunity [17].

(a) Deviation versus ε. (b) Accuracy versus ε.

Figure 6: Utility of the noisy covariance matrices obtained by various mechanisms. (a) The total deviation. (b) The classification accuracy measured on the projected testing dataset. ε used in the R1SMG mechanism is only $1/10^7$ of the others.

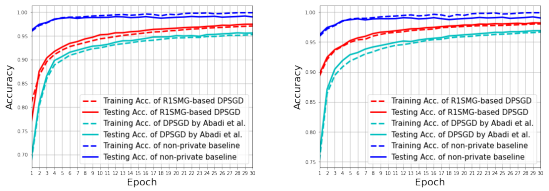
$\varepsilon < 10^{-7}$, which is also close to the non-private baselines (i.e., $\Delta = 0$ and 96.89% accuracy). This is because the R1SMG mechanism introduces perturbation noise of much smaller magnitudes in spite of very strict privacy guarantee, compared with the other mechanisms. Taking the MVG mechanism for example, according to Theorem 3, even when $\varepsilon = 1.6$ and $\delta = 10^{-7}$, MVG requires $||\sigma(\mathbf{\Sigma}^{-1})||_2||\sigma(\mathbf{\Psi}^{-1})||_2 \leq 0.011$ to achieve the desired privacy guarantee. This means that the covariance matrices will have very large singular values, which implies large expected accuracy loss (as discussed in Section 3) and causes the original data be overwhelmed by the additive noise. In fact, according to [11], for the MVG mechanism to have a decent performance on differentially private PCA, it requires $\varepsilon \geq 5$. Moreover, in this case study, the R1SMG mechanism even has similar utility performance of that of the task-specific mechanisms including PPCA, MOD-SULQ, and Wishart. In other words, under very limited ε, the R1SMG mechanism not only achieves very small Δ, but also gives high classification accuracy. This suggests that R1SMG is very promising in boosting the accuracy of high-dimensional differentially private query even if $\varepsilon \ll 1$. Note that in this study, the R1SMG mechanism also achieves the most stable accuracy, i.e., the accuracy loss introduced by it has leptokurtic and right-skewed histogram and empirical PDF, but the others still have bell-shaped empirical PDFs (similar to Figure 5). We omit the plots due to space limit.

7.3 Case Study III: Deep Learning with DP

In this case study, we conduct preliminary validation to assess the feasibility of replacing the classic Gaussian mechanism with the R1SMG in the DPSGD (differentially private stochastic gradient descent) optimization framework [3], and demonstrate that R1SMG can boost the utility (testing accuracy) of a differentially-private deep learning model and improve its training efficiency by reducing the number of epochs. Please note that this case study is not intended to be thorough or comprehensive, as differentially-private deep learning constitutes a distinct research direction in its own right.

As a proof of concept, we consider the MNIST [30] and CIFAR-10 [28] dataset, and compare our R1SMG-based DPSGD with the seminal work of DPSGD in deep learning (Abadi et al. CCS'16 [3]). For a given deep neural network, Abadi et al. introduce calibrated i.i.d. Gaussian noise ($\mathcal{N}(\mathbf{0}, \sigma^2 C^2 \mathbf{I})$) to the gradients computed on grouped batches of training data, where C is a norm clipping parameter to control the sensitivity (Algorithm 1 in [3]). They also developed the privacy accountant scheme to tightly bound the cumulative privacy loss for the entire training process. In particular, the total privacy budget (ε, δ) is determined by noise level σ, sampling ratio q, and the number of epochs E (so number of gradient descent steps is $T = E/q$).

In the experiment, we give our R1SMG-based DPSGD the same total privacy budget (ε, δ), C, q, and E as those of DPSGA in [3]. Then, we amortize (ε, δ) to all gradient descent steps in our R1SMG-based DPSGD, i.e., each step is assigned with $(\varepsilon_0, \delta_0)$. Although ε_0 might go beyond the upper bound discussed in Remark 1, it makes the comparison with DPSGD clear and straightforward. To be more specific, $(\varepsilon_0, \delta_0)$ is obtained by solving the following equations formulated using the strong composition theorem [19] considering $\frac{E}{q}$ repetitive executions of gradient descent.



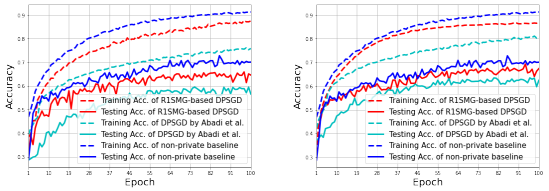
$$\begin{cases} \varepsilon = \sqrt{2\frac{E}{q}\ln\left(\frac{1}{\delta'}\right)}(q\varepsilon_0) + \frac{E}{q}(q\varepsilon_0)\left(e^{(q\varepsilon_0)} - 1\right) \\ \delta = \frac{E}{q}(q\delta_0) + \delta' \end{cases}, \quad (16)$$

where $q\varepsilon_0$ and $q\delta_0$ are due to privacy amplification via sampling [6, 26] (see discussion on page 3, right column of [3]). For example, based on the TensorFlow tutorial for DPSGD on MNIST [36], when $C = 1$, $\sigma = 1.1$, $q = \frac{256}{60000}$, and $E = 30$, it leads to $\varepsilon = 1.795$. Then, setting $\delta = 10^{-5}$, $\delta' = 10^{-10}$ and solving (16), we have $(\varepsilon_0, \delta_0) = (0.71, 3.33 \times 10^{-7})$. When $C = 1$, $\sigma = 0.5$, $q = \frac{256}{60000}$, and $E = 30$, it leads to $(16.983, 10^{-5})$-DP for DPSGD, which makes $(\varepsilon_0, \delta_0) = (5.42, 3.33 \times 10^{-7})$ for each gradient descent step in our R1SMG-based DPSGD.

Note that using strong composition theorem to assign amortized privacy budget to each step of our R1SMG-based DPSGD gives more favor to the classic Gaussian mechanism based DPSGD in the comparison. This is because strong composition is much looser than the privacy accountant scheme used in DPSGD (empirically validated by Figure 2 of [3]). Thus, the amortized $(\varepsilon_0, \delta_0)$ can be limited. Developing a tight composition framework for the R1SMG mechanism in SGD-based learning will be a separate research topic.

Even though the original DPSGD is given more favor in the comparison, our R1SMG-based DPSGD still outperforms it by achieving higher training and testing accuracy. We first show the comparison results on MNIST using the above parameters setups in Figure 7. In particular, Figure 7(a) and (b) show the training and testing accuracy on MNIST for the first 30 epochs achieved by various approaches when the entire learning process is $(1.795, 10^{-5})$-DP and $(16.983, 10^{-5})$-DP

(parameters discussed above), respectively. The blue lines and dashed lines in Figure 7 are the result of non-private SGD (the one uses original gradients calculated from the data).



(a) The entire process is $(1.795, 10^{-5})$-DP.

(b) The entire process is $(16.983, 10^{-5})$-DP.

Figure 7: Training and testing acc. on MNIST.

Compared with DPSGD, R1SMG-based DPSGD achieves higher training and testing accuracy in just a few epochs for the MNIST dataset. For example, when the total privacy budget is $(16.983, 10^{-5})$, our method achieves 95% accuracy on the testing dataset using 5 epochs, whereas DPSGD requires 14 epochs. Our R1SMG-based DPSGD also leads to performance that is closer to the non-private baseline, because even though the amortized privacy budget for each R1SMG-based DPSGD step is limited, the magnitude of the perturbation noise introduced by the R1SMG mechanism is much less than that required by the classic Gaussian in DPSGD.

(a) The entire process is $(2.673, 10^{-5})$-DP.

(b) The entire process is $(20.713, 10^{-5})$-DP.

Figure 8: Training and testing acc. on CIFAR-10.

Then, we conduct the experiments on CIFAR-10 dataset with the same parameter setups while using 100 epochs, i.e., $E = 100$. We also adopt the network architecture from the TensorFlow CNN tutorial [44]. The privacy budget for each step of R1SMG-based DPSGD, i.e., $(\varepsilon_0, \delta_0)$ is also decided by solving (16) numerically. In particular, when $\sigma = 1.1$ and $\sigma = 0.5$, the entire process of DPSGD is $(2.673, 10^{-5})$-DP and $(20.713, 10^{-5})$-DP, respectively, which make $(\varepsilon_0, \delta_0)$ become $(0.54, 10^{-7})$ and $(3.52, 10^{-7})$, respectively, for R1SMG-based DPSGD. The comparison results are shown in Figure 8. Clearly, our R1SMG-based DPSGD still outperforms DPSGD, i.e., both training and testing accuracy achieved by R1SMG-based DPSGD are closer to the non-private baselines compared with those achieved by DPSGD. In particular, R1SMG-based DPSGD improve the training efficiency by achieving a higher training accuracy (e.g., $> 80\%$) in much fewer epochs compared with the original DPSGD.

8 Related Work

Many works have attempted to improve the classic Gaussian mechanism. Here, we review some representative ones.

The analytic Gaussian mechanism proposed by Balle et al. [5] (see Theorem 2) improves the classic Gaussian mechanism by calibrating the variance of the Gaussian noise directly using the Gaussian cumulative density function instead of the tail bound approximation, and develop an analytical solution to the variance given specific choices ε and δ. Although this mechanism can reduce the magnitude of the noise when perturbing a scalar-valued quantity, it still suffers the curse of full-rank covariance matrices when applied to perturb high-dimensional query result (as discussed in Section 3).

Zhao et al. [48] investigate the classic Gaussian mechanism under high privacy budgets, i.e., $\varepsilon > 1$, and derive a closed-form upper bounds for the noise variance used in the analytic Gaussian mechanism. Their mechanism can achieve utility higher than the classic Gaussian mechanisms, but still lower than the analytic Gaussian mechanism.

Chanyaswad et al. [11] (see Definition 4 and Theorem 3) propose the MVG mechanism and develop the technique of directional noise to restrict the impact of the perturbation noise on the utility of a matrix-valued query function. However, to obtain the directional noise, one either needs a domain expert to determine the principal components of the queried data or has to calculate them via principal component analysis which consumes some privacy budget.

Some other variants of the classic Gaussian mechanism includes the Generalized Gaussian mechanism [33], which investigates noise calibration under the general l_p sensitivity, and the discrete Gaussian mechanism [9], which uses noise attributed to discrete Gaussian distribution to protect the privacy of query results in a discrete domain.

Our proposed R1SMG mechanism differs with the above mechanisms, as we explicitly require the covariance matrix of the additive noise to be rank-1. Thus, the R1SMG mechanism lifts the identified curse and boosts the utility of query results leading to guaranteed DP at much lower cost of accuracy loss.

9 Conclusions

In this paper, we developed a novel DP mechanism, i.e., R1SMG, to boost the utility and stability of differentially-private query results. We first identify the curse of full-rank covariance matrices in all existing Gaussian-based DP mechanisms. Then, we lift the curse by developing R1SMG which perturbs the query results using noise that follows a singular multivariate Gaussian distribution with a random rank-1 covariance matrix. We rigorously analyze the privacy guarantee of the R1SMG mechanism, and theoretically demonstrate that it can achieve much lower accuracy loss, particularly, on a lower order of magnitude by at least M or MN, and much higher accuracy stability as well, than the classic Gaussian, analytic Gaussian, and the MVG mechanisms.

A Proof of (e) in Equation (5)

Define $\sigma(\mathbf{\Sigma}) \overset{\text{def}}{=} [a_1, a_2, \ldots, a_M]$ and $\sigma(\mathbf{\Psi}) \overset{\text{def}}{=} [b_1, b_2, \ldots, b_N]$. Since $\mathbf{\Sigma}, \mathbf{\Psi} \in \mathbb{PD}$ and they are both symmetric, we have $a_m > 0, \forall m \in [1, M]$ and $b_n > 0, \forall n \in [1, N]$. Then, to prove (e) in (5), we essentially need to show that

$$\sqrt{\sum_{m=1}^{M} a_m^2} \times \sqrt{\sum_{n=1}^{N} b_n^2} \geq \frac{M}{\sqrt{\sum_{m=1}^{M} \frac{1}{a_m^2}}} \times \frac{N}{\sqrt{\sum_{n=1}^{M} \frac{1}{b_n^2}}}. \tag{17}$$

Apply harmonic mean-geometric mean inequality to $a_1^2, a_2^2, \ldots, a_M^2$, we have

$$\frac{a_1^2 + a_2^2 + \ldots + a_M^2}{M} \geq \left(a_1^2 \cdot a_2^2 \cdot \ldots \cdot a_M^2\right)^{\frac{1}{M}}. \tag{18}$$

Similarly, for $\frac{1}{a_1^2}, \frac{1}{a_2^2}, \ldots, \frac{1}{a_M^2}$, we have

$$\frac{\frac{1}{a_1^2} + \frac{1}{a_2^2} + \ldots + \frac{1}{a_M^2}}{M} \geq \left(\frac{1}{a_1^2} \cdot \frac{1}{a_2^2} \cdot \ldots \cdot \frac{1}{a_M^2}\right)^{\frac{1}{M}}. \tag{19}$$

Multiplying (18) and (19) gives

$$\frac{a_1^2 + a_2^2 + \ldots + a_M^2}{M} \times \frac{\frac{1}{a_1^2} + \frac{1}{a_2^2} + \ldots + \frac{1}{a_M^2}}{M}$$
$$\geq \left(a_1^2 \cdot a_2^2 \cdot \ldots \cdot a_M^2\right)^{\frac{1}{M}} \left(\frac{1}{a_1^2} \cdot \frac{1}{a_2^2} \cdot \ldots \cdot \frac{1}{a_M^2}\right)^{\frac{1}{M}} = 1.$$

Taking square root of the above, we have

$$\frac{\sqrt{\sum_{m=1}^{M} a_m^2}}{\sqrt{M}} \times \frac{\sqrt{\sum_{m=1}^{M} \frac{1}{a_m^2}}}{\sqrt{M}} \geq 1 \Leftrightarrow \sqrt{\sum_{m=1}^{M} a_m^2} \geq \frac{M}{\sqrt{\sum_{m=1}^{M} \frac{1}{a_m^2}}}.$$

By applying the same procedure on $[b_1, b_2, \ldots, b_N]$, we have $\sqrt{\sum_{n=1}^{N} b_n^2} \geq \frac{N}{\sqrt{\sum_{n=1}^{N} \frac{1}{b_n^2}}}$. Thus, (17) is proved, and the step (e) in (5) follows.

B $\mathbb{E}[\mathcal{L}]$ versus M for Various Mechanisms

Next, we empirically investigate the accuracy loss of the query results $f(\boldsymbol{x}) \in \mathbb{R}^M$ when M increases. In Figure 9, by assuming $\Delta_2 f = 1$, varying M from 10^2 to 10^6, and fixing $\delta = 10^{-10}$, we plot the expected accuracy loss introduced by the R1SMG, classic Gaussian, and analytic Gaussian mechanisms when $\varepsilon \in \{10^{-7}, 10^{-8}, 10^{-9}\}$. Note that we do not include MVG mechanism in the comparison, because (i) it requires the prior knowledge of $\gamma = \sup_{\boldsymbol{x}} ||f(\boldsymbol{x})||_F$, which depends on specific datasets and applications (e.g., see Theorem 3), and (ii) it will introduce more noise than the analytic Gaussian mechanism.

From Figure 9, we observe that, for both classic and analytic Gaussian mechanisms, the expected accuracy loss (i.e., $Tr[\sigma^2 \mathbf{I}_{M\times M}]$ and $Tr[\sigma_A^2 \mathbf{I}_{M\times M}]$) scales linearly with M, which validates our theoretical findings in Section 3. In contrast,

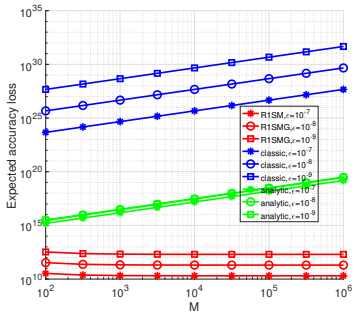

Figure 9: Expected accuracy loss of the R1SMG, classic Gaussian, and analytic Gaussian mechanisms under increasing query size when $\varepsilon \in \{10^{-7}, 10^{-8}, 10^{-9}\}$ and $\delta = 10^{-10}$.

as M increases, the expected accuracy loss incurred by the R1SMG mechanism (i.e., $Tr[\mathbf{\Pi}] = \sigma_*$) decreases and converges to $\frac{2(\Delta_2 f)^2}{\varepsilon}$. Thus, the R1SMG mechanism not only breaks the curse of full-rank covariance matrices, but also significantly improves the accuracy (utility) of the perturbed $f(\boldsymbol{x})$, as it is able to achieve (ε, δ)-DP by using much weaker noise even when the dimension of $f(\boldsymbol{x})$ increases.

C Potential Improvement of the MVG

When studying the MVG mechanism, we observe one potential solution to improve its privacy guarantee. In particular, one intermediate step in the proof of the MVG mechanism requires deriving an upper bound for

$$\clubsuit = Tr\Big[\mathbf{\Psi}^{-1}\mathbf{Y}^T\mathbf{\Sigma}^{-1}\Delta + \mathbf{\Psi}^{-1}\Delta^T\mathbf{\Sigma}^{-1}\mathbf{Y} + \mathbf{\Psi}^{-1}f(D_2)^T\mathbf{\Sigma}^{-1}f(D_2) - \mathbf{\Psi}^{-1}f(D_1)^T\mathbf{\Sigma}^{-1}f(D_1)\Big], \tag{20}$$

where $\mathbf{Y}$ stands for the output of the MVG mechanism and $\Delta = f(D_1) - f(D_2)$ (see [11] page 244, right column). Due to the negative sign in the fourth term, the authors simply bound its absolute value, i.e., $\left|Tr\left[\mathbf{\Psi}^{-1}f(D_1)^T\mathbf{\Sigma}^{-1}f(D_1)\right]\right|$, which results in a very loose upper bound related to the quadratic form in the Frobenius norm of the matrix query result (i.e, γ^2 in Theorem 3), and further compromises the utility.

In fact, the original proof of the MVG mechanism can be improved if we apply the transformation

$$Tr\left[\mathbf{\Psi}^{-1}f(D_2)^T\mathbf{\Sigma}^{-1}f(D_2) - \mathbf{\Psi}^{-1}f(D_1)^T\mathbf{\Sigma}^{-1}f(D_1)\right] =$$
$$Tr\left[\mathbf{\Psi}^{-1}\big(f(D_2)^T\mathbf{\Sigma}^{-1}\big(f(D_2) - f(D_1)\big) + \big(f(D_2) - f(D_1)\big)^T\mathbf{\Sigma}^{-1}f(D_1)\big)\right],$$

and rewrite $\clubsuit$ as

$$\clubsuit = Tr\Big[\mathbf{\Psi}^{-1}\big(\mathbf{Y} - f(D_2)\big)^T\mathbf{\Sigma}^{-1}\Delta + \mathbf{\Psi}^{-1}\Delta^T\mathbf{\Sigma}^{-1}\big(\mathbf{Y} - f(D_1)\big)\Big].$$

Then, we can bound $\clubsuit$ using singular values, and hence the quadratic form in the Frobenius norm of the query result can be completely removed. We do not follow the above steps to further develop an improved version of the MVG mechanism, because the improved version is still a "victim" of the identified curse of full-rank covariance matrices.

Relation Mining Under Local Differential Privacy

Abstract

Existing local differential privacy (LDP) techniques enable untrustworthy aggregators to perform only very simple data mining tasks on distributed private data, including statistical estimation and frequent item mining. There is currently no general LDP method that discovers relations between items. The main challenge lies in the curse of dimensionality, as the quantity of values to be estimated in mining relations is the square of the quantity of values to be estimated in mining item-level knowledge, leading to a considerable decrease in the final estimation accuracy. We propose LDP-RM, the first relation mining method under LDP. It represents items and relations in a matrix and utilizes singular value decomposition and low rank approximation to reduce the number of values to estimate from $O(k^2)$ to $O(r)$, where k is the number of all considered items, and $r < k$ is a parameter determined by the aggregator, signifying the rank of the approximation. LDP-RM serves as a fundamental privacy-preserving method for enabling various complex data mining tasks.

1 Introduction

Benefiting from local differential privacy (LDP) techniques [20], an untrustworthy aggregator is able to discover global knowledge from private data owned by distributed users without compromising privacy. Typically, an LDP technique comprises a **perturbation** algorithm and an **aggregation** algorithm. The perturbation algorithm perturbs private data to ensure privacy, and is employed by each user locally when responding to the aggregator's queries. The aggregation algorithm extracts global knowledge from all the perturbed responses provided by users, and is employed by the aggregator. However, existing LDP techniques are only capable of discovering simple global knowledge, such as statistical information [12,13,42], or popular items (e.g., emojis) [3,43].

Currently, there is no general method that discovers relations between or among items under LDP while some very recent LDP techniques can be applied to extract specific types of relations. Take the LDP technique that discovers frequent item-sets as an example [43]. An item-set represents co-occurrence relation of items. The estimated frequent item-sets are obtained through item-level perturbation and aggregation. However, this approach relies on a strong assumption that an item-set comprising two frequent items is also frequent. This assumption is problematic as shown by a counter example in Fig. 1 of Sec. 3.2.

To the best of our knowledge, we are the first to introduce the generic problem of relation mining under LDP. In this problem, we assume that each user possesses some private items and relations among those items are private information about the user. The untrustworthy aggregator is interested in globally useful statistics of relations, measured by two criteria: **support** and **confidence**. Support represents the relation's popularity and is defined as its frequency, while confidence denotes its reliability and is calculated as the ratio of the relation's support to the support of the items within the relation. Therefore, the goal of the aggregator is to uncover high-support and high-confidence relations.

The primary challenge in addressing this problem lies in the "Curse of Dimensionality". To discover relations with high support and high confidence, the aggregator needs to estimate the support and confidence of all potential relations. The quantity of values to be estimated in mining relation-level knowledge is the square of the quantity of values to be estimated in mining item-level knowledge [9], leading to a tremendous increase in the extent to which each user disturbs her data to ensure privacy. In LDP, a parameter named *privacy budget* (typically denoted as ε) is used to determine the privacy level. Its reciprocal determines the amount of noise that should be added to a response, and it must be split among multiple responses from the same user to prevent inference attacks [12]. The large number of relations to estimate results in excessive splitting of the privacy budget, necessitating an immense amount of noise to be added to user responses to ensure privacy. This ultimately leads to the failure of the entire relation mining task.

We propose LDP-RM, the first LDP technique that enables

*Corresponding author: Prof. Zhen Ling of Southeast University, China.

discovering high-support and high-confidence relations from distributed private data. This technique serves as a fundamental building block for data mining under LDP. With LDP-RM, the aggregator iteratively estimates the support of all relations from scratch, using a global matrix (referred to as the *aggregator matrix*) to save and update the estimations. Each row/column in this matrix corresponds to an item, and each element represents the support of a relation. To update the matrix, the aggregator collects perturbed reports constructed by distributed users. Each report can be abstracted as a user matrix that captures the user's private items and their relations. Directly protecting the privacy of the entire user matrix would inevitably split the privacy budget, leading to excessive noise and insufficient estimation accuracy. To address this issue, the **basic idea** of LDP-RM is to employ singular value decomposition [17] to compress the high-dimensional user matrix into a low-dimensional vector. By perturbing and reporting this vector instead of the user matrix, the amount of noise needed for privacy protection is significantly reduced.

LDP-RM works as follows. Without loss of generality, let k represent the number of all considered items. The aggregator begins by guessing an initial global matrix of size $k \times k$. Instead of directly aggregating and estimating the true global matrix of size $k \times k$, the aggregator estimates its projection onto the initial global matrix. This projection is represented as the *singular vector* (calculated using singular value decomposition), with a length of k. As a result, the number of values to estimate is reduced from k^2 to k. The aggregator then recovers the global matrix from the singular vector averaged over all users' data. If the aggregator estimates only the best rank-r approximation of the global matrix instead of the entire matrix, the number of values to estimate is further reduced to $r < k$. The **primary challenge** lies in performing singular value decomposition without possessing knowledge of the true global matrix. To address this challenge, LDP-RM employs an iterative scheme which updates the global matrix in each iteration. After several iterations, the aggregator obtains the final estimated global matrix and discovers high-support and high-confidence relations from it. Our experimental evaluation demonstrates the effectiveness of LDP-RM, and the ineffectiveness of the state-of-the-art LDP techniques — including SVIM [43], SVSM [43], CALM [50], and PCKV [18] — in mining relations.

Our major contributions can be summarized as follows:

- We are the first to introduce and investigate the problem of relation mining under LDP. This is a fundamental problem for carrying out complex data mining tasks on private data owned by distributed users.
- We propose LDP-RM, the first relation mining method under LDP. This method can be used to discover various kinds of relations of high support and high confidence, including but not limited to the co-occurrence of items.
- We conduct extensive experiments to validate the effectiveness of LDP-RM.

2 Background

In this section, we introduce local differential privacy and data mining under LDP. The notation used throughout this paper is summarized in Tab. 1.

2.1 Local Differential Privacy

Local differential privacy (LDP) is a model of differential privacy (DP) which offers robust privacy guarantees for distributed users [12]. Consider each user has a private value x from a given domain $\mathbf{X}$. In the local setting, each user applies an algorithm Ψ to perturb her individual input value $x \in \mathbf{X}$. The perturbed value $\Psi(x)$ is then sent to the aggregator. To ensure privacy, the algorithm Ψ should satisfy:

Definition 1 (ε-Local Differential Privacy)**.** *An algorithm $\Psi(\cdot)$ satisfies ε-local differential privacy (ε-LDP), where $\varepsilon \geq 0$, if and only if for any two values $x_1, x_2 \in \mathbf{X}$, we have:*

$$\forall T \in Range(\Psi) : \Pr(\Psi(x_1) = T) \leq e^{\varepsilon} \cdot \Pr(\Psi(x_2) = T),$$

where $Range(\Psi)$ denotes the range of Ψ.

The parameter ε is commonly known as the *privacy budget*, and a smaller ε guarantees a higher level of privacy. When the aggregator needs to estimate multiple values, it must be split among multiple reports from a user, in accordance with the *sequential composition theorem* [12]. Splitting the privacy budget can result in over-perturbed values provided by users, leading to a significant decrease in estimation accuracy. This problem can be mitigated by dividing users into groups, with the aggregator estimating only one value from each group to ensure that each user reports only once [4, 12, 32, 37, 43–45].

2.2 Data Mining under LDP

A data mining task discovers useful knowledge from large datasets. A data mining task under LDP operates within the confines of LDP constraints, which are imposed on distributed user data. Existing LDP techniques facilitate two primary types of data mining tasks: statistical estimation [12, 13, 42] and item mining [3, 43]. Taking the movie recommendation scenario as an example. Statistical-estimation can quantify the frequency of specific movie views. Item mining can identify the most popular movies.

In the most general scenario, consider n users, each possessing a private value x from a given domain $\mathbf{X}$. The aggregator aims to extract useful knowledge from users' private data without compromising privacy. A data mining task under LDP can be formalized as an LDP protocol $\mathcal{T}$, consisting of a pair of algorithms $\langle \Psi, \Phi \rangle$, defined as follows:

$$\mathcal{T}(\varepsilon) \triangleq \langle \Psi, \Phi \rangle. \tag{1}$$

Here Ψ denotes the perturbation algorithm employed by users to perturb local data to satisfy ε-LDP, and Φ denotes the

Table 1: Summary of Notations

Symbol	Meaning
x, $\mathbf{x}$, X, d	Item, user's set of items, set of all items, domain size of X
w, $\mathbf{w}$, $\mathbf{I}$	Relation, user's set of relations, user matrix
ε, $\Psi(\cdot)$, $\Phi(\cdot)$,	Privacy budget, perturbation algorithm, aggregation algorithm
$s(\cdot)$, $c(\cdot)$	Support of an item or a relation, confidence of a relation
k, k_s, k_c	Number of high-support items, number of high-support relations, number of high-confidence relations
n, n_1, n_2, n_3, T	Number of total users, number of users in the 1^{st}, 2^{nd}, 3^{rd} group, number of sub-groups/iterations
$\mathbf{Y}$, $\mathbb{Y}$	Candidate set of high-support items, that of high-support relations
$\mathbb{W}$	Candidate set of high-support and high-confidence relations
$\mathbf{M}_{agg}$, $\mathbf{M}_{gt}$, $\mathbf{M}'_{agg}$	Aggregator matrix, true matrix, updated aggregator matrix
θ, r, $\mathbf{M}_r$	Bias threshold, low rank, best rank-r approximation of the aggregator matrix
$\mathbf{u}$, $\mathbf{v}^\top$, $\mathbf{U}$, $\mathbf{V}^\top$, σ, Σ	Left-singular vector, transpose of right-singular vector, matrix of $\mathbf{u}$, $\mathbf{v}^\top$, singular value, matrix of σ
$\mathbf{P}$, $\widehat{\mathbf{P}}$, $\mathbf{S}$, $D_{\mathbf{S}}$, $\widehat{\mathbf{S}}$	Projection matrix, aggregation of $\mathbf{P}$, user report vector, domain of $\mathbf{S}$, estimated mean of $\mathbf{S}$
l, s_l, $\overrightarrow{s_l}$, $(\overrightarrow{s_l})^*$	Index of singular value in singular vector, pseudo singular value of index l, mapped s_l, perturbed $\overrightarrow{s_l}$
G, $C(\cdot)$, $C_H(\cdot)$	Hashed domain, count function, hash count function
ℓ, L, $u'(L)$	Padding length, padding length ℓ at the 90 percentile, update factor

aggregation algorithm employed by the aggregator to extract useful knowledge. Existing LDP protocols can be applied to perform statistical estimation tasks and item-level data mining tasks. However, a general method for mining relations between items under LDP remains elusive.

2.2.1 Statistical Estimation under LDP. Numerous LDP protocols have been proposed for various statistical estimation tasks. Our work pertains to two specific estimation tasks: mean estimation and frequency estimation.

In a mean estimation task, the aggregator aims to discover the averaged value $\bar{x}$ from all the n users:

$$\bar{x} \triangleq \frac{1}{n}\sum_{j=1}^{n} x^j, \tag{2}$$

where $x^j \in \mathbf{X} = [-1,1]$ denotes the normalized numeric value held by the j^{th} user. Prominent LDP protocols for mean estimation include Duchi [10], PM [39], HM [39], and others. This paper employs the HM protocol.

HM. HM stands for Hybrid Mechanism. A HM protocol takes as inputs a value $x \in \mathbf{X}$ and a privacy budget ε. It adaptively invokes the perturbation algorithm of PM and Duchi (denoted as Ψ_{PM} and Ψ_{Duchi} correspondingly), depending on the value of ε:

$$\Psi_{\text{HM}(\varepsilon)}(x) \triangleq \begin{cases} \Psi_{\text{PM}(\varepsilon)}(x), & \text{if } \varepsilon > 0.61; \\ \Psi_{\text{Duchi}(\varepsilon)}(x), & \text{otherwise .} \end{cases} \tag{3}$$

$$\Phi_{\text{HM}}(x) \triangleq \frac{1}{n}\sum \Psi_{\text{HM}(\varepsilon)}(x). \tag{4}$$

Appendix A gives a concise overview of PM and Duchi.

In a frequency estimation task, the aggregator aims to discover the number of users possessing a given value x. Let $\mathbf{x}^j \subseteq \mathbf{X} = \{1,2,...,d\}$ represent the set of categorical values held by the j^{th} user. The aggregator estimates the frequency of each item $x_i \in \mathbf{X}$, denoted as $s(x_i)$, by computing:

$$s(x_i) = \frac{1}{n}\sum_{j=1}^{n} \mathbb{1}(x_i, \mathbf{x}^j), 1 \le i \le d, \tag{5}$$

where $\mathbb{1}(x, \mathbf{x})$ is an indicator function, defined as:

$$\mathbb{1}(x, \mathbf{x}) \triangleq \begin{cases} 1 & \text{if } x \in \mathbf{x} \\ 0 & \text{if } x \notin \mathbf{x} \end{cases} \tag{6}$$

An LDP protocol employed for frequency estimation is also referred to as a Frequency Oracle (FO). Basic FOs, such as GRR [42], Rappor [13], OLH [42], OUE [42], JLRR [13], HRR [1], are applicable only in scenarios where each user possesses a single value. Our work is partially based on an item-level data mining LDP protocol (see Section 2.2.2) and, as a consequence, indirectly utilizes these protocols. A concise overview of GRR and OLH is provided in Appendix B.

2.2.2 Item Mining under LDP. Item mining under LDP aims to discover high-support items (a.k.a. heavy hitters) among the private items possessed by distributed users, and to estimate their frequency. In this context, each user possesses an item set $\mathbf{x} \subseteq \mathbf{X} = \{1,...,d\}$ rather than a single value. As a result, a basic FO cannot be directly applied. To address this issue, the set-valued item mining (SVIM) protocol [43] employs a Padding-and-Sampling-based Frequency Oracle (PSFO) as its core technique for identifying frequent items. Our work is partially based on this protocol.

SVIM. A SVIM protocol is specified by the following parameters: the number of users n, the number of output targets k, the value domain $\mathbf{X}$, and a privacy budget ε. Its perturbation algorithm utilizes PSFO in multiple rounds to determine a padding length ℓ and perturbs data according to ℓ. Its aggregation algorithm, denoted as Φ_{SVIM}, estimates the support

of each item in the value domain $\mathbf{X}$, and finally outputs the top-k frequent items (denoted as $\mathbf{Y}$) along with their estimated frequencies. Φ_{SVIM} is defined as:

$$\Phi_{\text{SVIM}(\mathbf{X},\varepsilon,n,k)} \triangleq \{(x, \Phi_{\text{PSFO}(\ell,\varepsilon)}(x)) | x \in \mathbf{Y}\}, \tag{7}$$

where $\Phi_{\text{PSFO}(\ell,\varepsilon)}(x)$ is the aggregation algorithm of PSFO which outputs the support of item x. We provide a concise overview of PSFO in Appendix C, and some more details of SVIM in Appendix D.

3 Relation Mining under LDP

In this section, we define the problem of relation mining under LDP, and discuss the challenges.

3.1 Problem Definition

While existing LDP techniques are unable to discover relation-level knowledge, such knowledge holds significant importance, particularly in domains such as social network analysis, healthcare informatics, finance, and marketing [30]. For instance, association rule mining, which uncovers co-occurrence relations among items, benefits offline retailers like Walmart in optimizing product placement [27]. Beyond association rules, other relations, including temporal relations, are harnessed by popular platforms like Amazon for product recommendations [31].

We consider an untrustworthy aggregator aiming to discover useful relations from private data owned by distributed users. The usefulness of a relation is often measured from two aspects, namely, support and confidence. The **support** of a relation w indicates its popularity and is defined as the proportion of users that have this relation among all n users:

$$s(w) \triangleq \frac{1}{n} \sum_{j=1}^{n} \mathbb{1}(w, \mathbf{w}^j), \tag{8}$$

where $\mathbf{w}^j$ denotes the set of relations possessed by the j^{th} user, and $\mathbb{1}(\cdot,\cdot)$ is the indicator function defined as in Equation (6). The **confidence** of a relation indicates its reliability and is defined as the ratio of the relation's support to the first item's support. Let (x_a, x_b) denote a relation between two items x_a and x_b. Its confidence can be calculated as:

$$c((x_a, x_b)) \triangleq s((x_a, x_b))/s(x_a). \tag{9}$$

In data mining under LDP, the criteria for determining high support or confidence differ from traditional data mining. In traditional data mining, predefined minimum thresholds can be employed to assess high support or confidence. As confidence computation inherently depends on support computation, a logical approach is to first identify high-support relations and subsequently select high-confidence ones. However, in the local context with an untrustworthy aggregator, they remain unknown beforehand. To tackle this challenge, existing LDP methods replace the support threshold with a parameter, denoted as k, and focus on discovering the top-k items or itemsets with high support [4, 6, 24, 32, 37, 43–45]. Similarly, in the context of relation mining under LDP, the aggregator's objective is to initially identify the top-k_s relations with high support, from which they can derive the final top-k_c relations among all possible relations.

Mathematically, consider a set of users $\mathbf{U} = \{u_1, u_2, ..., u_n\}$ and a set of items $\mathbf{X} = \{x_1, x_2, ..., x_d\}$, both known to the aggregator. Each user possesses a private set of items $\mathbf{x} \subseteq \mathbf{X}$ and a private set of relations $\mathbf{w} \subseteq \mathbf{X}^2$. The objective of relation mining under LDP is to first identify the top-k_s relations in terms of support, and then, from these k_s relations, find the top-k_c relations in confidence.

3.2 Challenges

To the best of our knowledge, no existing LDP methods can be applied to discover relation-level knowledge in general scenarios. A line of approaches aims to discover high-support item-sets [32, 43]. However, these are essentially item mining techniques, as they treat specific relations (i.e., co-occurrence relationships of items) as items and rely on basic FO protocols for statistical estimation. Furthermore, they are limited to statistics on high-support items or relations, neglecting the equally important criterion of confidence.

The primary challenge in addressing the problem of relation mining under LDP lies in the "Curse of Dimensionality". Given that both the set of individual items and that of individual relations are considered private, the aggregator must estimate the support for each item and that for each relation under the constraint of LDP. For estimating the support of each item, numerous item-level mining LDP protocols, such as SVIM, can be directly employed. However, estimating the support of relations by directly utilizing existing methods necessitates converting each 2-dimensional relation into a new 1-dimensional item (e.g., by using one-hot encoding) [43]. As a result, the quantity of values to be estimated becomes extremely large, leading to insufficient estimation accuracy.

An intuitive solution is to guess out high-support relations based on the support of items. Following this intuition, an existing approach called Set-Value itemSet Mining (SVSM) [43], which finds high-support co-occurrence relations, assumes that items are roughly independent of each other, so that the support of only those relations composed of high-support items needs to be estimated. However, this technique is not applicable to general relation mining tasks, as it can only discover certain co-occurrence relations when relatively low-support items are not strongly related to each other. In contrast, in a general relation scenario, the degrees of independence between any two items can vary significantly.

Furthermore, this intuitive approach presents challenges even in scenarios of association rule mining under LDP. This

	x_1	x_2	x_3	x_4	x_5	x_6
x_1	40	20	20	0	0	0
x_2	20	30	10	0	0	0
x_3	20	10	30	0	0	0
x_4	0	0	0	25	25	25
x_5	0	0	0	25	25	25
x_6	0	0	0	25	25	25

Figure 1: Number of users who possess x_{row} and x_{col}.

is because there is a conflict between mining high-support relations and mining high-confidence relations. Referring back to Equation (9), it is clear that, given the support of a relation, as the support of the item increases, the confidence of that relation decreases. The aggregator inevitably relies on high-support items to select high-support relations, this process tends to favor low-confidence relations, thus contradicting the goal of high-confidence relation mining.

We present an example to clarify this conflict. An association rule mining task is conducted under LDP with 6 items (denoted as x_1 to x_6), and 75 users. A 6×6 matrix representing the support of each item and relation is as illustrated in Fig. 1. Diagonal elements (in gray) signify the support of items, while other elements indicate the support of co-occurrence relations between their row- and column-labels. The aggregator's objective is to first identify the top-12 relations in support and then determine the top-6 relations in confidence as the final results. Correct results are marked in blue. However, if the aggregator utilizes the intuitive approach to select candidate relations, he will choose 12 relations (in orange) composed of high-support items, ultimately failing to discover any correct relations.

4 Method

In this section, we present LDP-RM and describe how it addresses the problem of relation mining under LDP.

4.1 Basic Idea

To address the "Curse of Dimensionality" in relation mining, LDP-RM must reduce the quantity of data that needs to be estimated. When dealing with binary relations defined among d items, there is a potential existence of $d \times (d-1)$ distinct relations. In such instances, one must recover a quantity of $O(d^2)$ support values, to accurately discover the relations with the highest support. If the mining task also extends to ternary relations or higher-order relations, the data recovery requirement escalates to $O(d^3)$ or beyond. This results in less accurate mining results. To facilitate understanding LDP-RM, this section delves into a simplified scenario that concentrates on binary relations. Later, in Sec. 6.1, we generalize LDP-RM to enable the mining of cascading relations involving more than two items.

By employing a widely adopted pre-estimation technique [43], we can significantly diminish the number of items that need to be considered. The aggregator initially estimates the support of all d items initially and subsequently identifies the top-k items in support (where $k < d$). By considering the relations only between top-k items instead of all items, the quantity of values to be estimated can be reduced from $O(d^2)$ to $O(k^2)$. Many existing LDP techniques [15, 37, 44] incorporate this approach into their mechanism design to confine the scope of the problem. Nevertheless, this pre-estimation procedure alone is insufficient to tackle the curse of dimensionality in relation mining under LDP.

Basic Idea. In what follows, we describe how LDP-RM further reduces the quantity of values to be estimated from $O(k^2)$ to below $O(k)$. LDP-RM organizes all support values into a matrix, and uses only a few singular values obtained through singular value decomposition (SVD) and low-rank approximation to represent the entire matrix. Each user puts her information into a **user matrix** of size $k \times k$, where rows/columns correspond to items. Off-diagonal/diagonal elements are binary (1 or 0), indicating possession of a relation/item by this user. We use **true matrix** to term the aggregation of all user matrices, and **aggregator matrix** to denote the aggregator's estimate on it. By using a variant of SVD on both the aggregator matrix, and each user matrix, a local vector of length k (i.e., the **singular vector**) can be obtained to indicate the projection from the user matrix onto the aggregator matrix. Consequently, the aggregator only needs to aggregate this vector of size k from each user to recover the $k \times k$ true matrix which is the aggregation of all the user matrices. Additionally, LDP-RM uses the best rank-r approximation of the aggregator matrix to decrease the size of users' private vectors from k to r, resulting in a further reduction in the number of values to be estimated. This reduces the problem of estimating the support of relations with a domain size of k^2 to estimating the mean value of a vector with length r (where $r < k$).

Technical Challenge. However, performing SVD in this context is challenging since neither the aggregator nor the user has prior knowledge of the true matrix. This creates a "catch-22" situation since neither party has information about the true matrix, which prevents distributed users from performing SVD and, consequently, prevents the aggregator from estimating the matrix.

Solution. To address this challenge, LDP-RM utilizes an iterative scheme, updating the estimation of the aggregator matrix to ultimately converge to the true matrix. Initially, the aggregator makes an educated guess regarding a global matrix, and sends it to a group of users. Each user in this group computes the compression of their private data onto the guessed global matrix, samples a singular value, and then introduces noise to this value before reporting it to the aggregator. The noised singular values from users are aggregated to reconstruct an estimated singular vector, utilizing LDP protocols

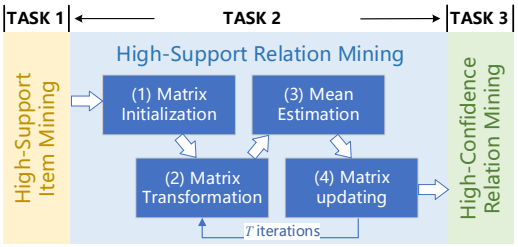

Figure 2: Workflow of LDP-RM

for mean estimation. This process enables the reconstruction of an improved estimated global matrix. With this matrix, the aggregator selects a new group of users to initiate a new iteration to finally obtain an accurate estimation of the true global matrix.

4.2 Details

We now detail the workflow of LDP-RM. A flowchart illustrating LDP-RM can be found in Fig. 2. In LDP-RM, the problem of RM under LDP is decomposed into the following three distinct tasks:

Task 1. "High-Support Item Mining", finds the top-k items in support and estimate their support.

Task 2. "High-Support Relation Mining" finds the top-k_s relations in support which constitute a candidate set.

Task 3. "High-Confidence Relation Mining" finds the top-k_c relations in confidence from the candidate set.

To save privacy budget, LDP-RM randomly divides all users into three groups corresponding to three tasks, with each user queried only once in each task. We denote the number of users in each group as n_1, n_2, and n_3, respectively.

4.2.1 TASK 1. High-Support Item Mining. In the first task, LDP-RM identifies the top-k items in support and estimates their support values. To achieve this, the aggregator interacts with the first group of users and employs the SVIM protocol. Each participating user perturbs their private items and randomly reports an item. Subsequently, the aggregator collects the reports and estimates the support of all items in the item domain $\mathbf{X}$ using the aggregate algorithm defined in Equation (7). The aggregator then selects the top-k items in support and adds them to a set denoted as $\mathbf{Y}$. This step aims to reduce the item domain's size from d to k and reduce the size of the relation domain from d^2 to k^2.

4.2.2 TASK 2. High-Support Relation Mining. In the second task, LDP-RM finds top-k_s relations in support from $\mathbf{Y}^2$, and estimates their support. To accomplish this task, the aggregator interacts with the second group of users through the following 4 stages: (1) Matrix Initialization. The aggregator initializes an aggregator matrix based on the top-k items in support. Each user then initializes their local user matrix. (2) Matrix Transformation. The aggregator performs singular value decomposition of the aggregator matrix. Each user subsequently transforms her private user matrix into a private singular vector. (3) Mean Estimation. Each user perturbs an element sampled from her private singular vector. The aggregator collects all perturbed reports and estimates the mean vector. (4) Matrix updating. The aggregator updates his aggregator matrix based on the mean vector. To accomplish the second task, stages 2 to 4 are performed for several rounds. The candidate set is constructed based on the final aggregator matrix. We now detail the four stages.

STAGE 1. Matrix Initialization. In this stage, the aggregator matrix and user matrices are initialized. The aggregator matrix represents the support of all item in $\mathbf{Y}$ and that of all relations in $\mathbf{Y}^2$, and a user matrix represents the user's possession of all items in $\mathbf{Y}$ and all relations in $\mathbf{Y}^2$. This stage is composed of two steps.

Step 1. Aggregator Matrix Initialization. This step is performed at the aggregator side. The aggregator constructs an aggregator matrix denoted as $\mathbf{M}_{agg}$. The diagonal elements represent the support of items, while the off-diagonal elements represent the support of relations. The initialization of the aggregator matrix is based on the assumption that items are independent of each other:

$$\widetilde{s}(x_a,x_b) = \begin{cases} \widehat{s}(x_a), & \text{if } x_a = x_b, \\ \widehat{s}(x_a)\widehat{s}(x_b), & \text{otherwise.} \end{cases} \tag{10}$$

where x_a and x_b are items in $\mathbf{Y}$, $\widehat{s}(\cdot)$ denotes the estimated support of an item and is obtained in Task 1, and $\widetilde{s}(\cdot,\cdot)$ represents the guessed support of a relation.

Step 2. User Matrix Initialization. In this step, the aggregator first sends $\mathbf{Y}$ (the set of top-k items in support) to the second group of users. Each user in this group constructs her user matrix of order $k \times k$ (denoted as $\mathbf{I}$) to indicate her possession of items in $\mathbf{Y}$ and that of relations in $\mathbf{Y}^2$. Each element in $\mathbf{I}$ is a binary value and is based on the user's private itemset $\mathbf{x}$, private relation set $\mathbf{w}$, and the global public set $\mathbf{Y}$:

$$\mathbf{I}_{\mathrm{Idx}(x_a),\mathrm{Idx}(x_b)} = \begin{cases} 1, & \text{if } (x_a,x_b) \in \mathbf{w} \text{ or} \\ & (x_a = x_b \text{ and } x_a \in \mathbf{x}) \\ 0, & \text{otherwise.} \end{cases} \tag{11}$$

where x_a and x_b are two items in $\mathbf{Y}$, $\mathrm{Idx}(\cdot)$ calculates a unique index number in [1,k] for each item in $\mathbf{Y}$.

STAGE 2. Matrix Transformation. In this stage, the aggregator performs singular value decomposition (SVD) [17] on the aggregator matrix $\mathbf{M}_{agg}$ and calculates a low rank approximation $\mathbf{M}_r$. Each user then calculates a singular vector $\mathbf{S}$, which is transformed from her user matrix $\mathbf{I}$ based on a variant of SVD. This stage comprises three steps.

Step 1. Singular Value Decomposition. In this step, the

aggregator performs SVD on $\mathbf{M}_{agg}$ as follows:

$$\mathbf{M}_{agg} = \mathbf{U}_k \mathbf{\Sigma}_k (\mathbf{V}_k)^\top = \sum_{i=1}^{k} \sigma_i \mathbf{u}_i (\mathbf{v}_i)^\top. \tag{12}$$

Where $\mathbf{U}_k$ and $\mathbf{V}_k$ are unitary matrices of order $k \times k$, $(\mathbf{V}_k)^\top$ is the conjugate transpose of $\mathbf{V}_k$. $\mathbf{u}_i$ is a column of $\mathbf{U}_k$, $(\mathbf{v}_i)^\top$ is a row of $(\mathbf{V}_k)^\top$, and they are called left- and right-singular vectors. $\mathbf{\Sigma}_k$ is a $k \times k$ diagonal matrix whose element σ_i is called the singular value of the decomposed matrix. All the singular values are non-negative real numbers, and are arranged in descending order from top-left to bottom-right.

Step 2. Low Rank Approximation. In this step, the aggregator specifies a positive integer r and calculates the best rank-r approximation of $\mathbf{M}_{agg}$, denoted as $\mathbf{M}_r$, defined as:

$$\mathbf{M}_r \equiv \arg\min_{\mathbf{M}} \|\mathbf{M}_{agg} - \mathbf{M}\|, \tag{13}$$

$$\text{s.t.: } \text{Rank}(\mathbf{M}) \leq \text{Min}(r, \text{Rank}(\mathbf{M}_{agg})). \tag{14}$$

Where $\|\cdot\|$ calculates the Frobenius norm of a matrix, $\text{Rank}(\cdot)$ calculates the rank of a matrix, $\text{Min}(\cdot,\cdot)$ identifies the smaller of two integers.

According to the Eckart-Young-Mirsky theorem [28] (described in Appendix E), the optimal rank-r approximation of $\mathbf{M}_{agg}$ under the Frobenius norm is given by:

$$\mathbf{M}_r = \mathbf{U}_r \Sigma_r \mathbf{V}_r^\top = \sum_{i=1}^{r} \sigma_i \mathbf{u}_i \mathbf{v}_i^\top. \tag{15}$$

Where $\mathbf{U}_r$ is a matrix of order $k \times r$, identical to $\mathbf{U}_k[1:r]$. And $\mathbf{V}_r^\top$ is a matrix of order $r \times k$, identical to $\mathbf{V}_k^\top[1:r]$.

Step 3. Singular Vector Generation. In this step, the aggregator first sends $\mathbf{U}_r$ and $\mathbf{V}_r$ to the users. Then, each user generates her singular vector, denoted as $\mathbf{S}$ of size r.

The calculation of the singular vector is as follows. Since $\mathbf{U}_r$ is not square, its inverse does not exist. However, the left-singular vectors $\mathbf{u}_1, ..., \mathbf{u}_r$ are all orthogonal vectors, and $\mathbf{U}_r$ has full column rank. Consequently, we utilize the Moore-Penrose generalized inverse of $\mathbf{U}_r$, given by:

$$(\mathbf{U}_r)^+ = ((\mathbf{U}_r)^\top \mathbf{U}_r)^{-1} (\mathbf{U}_r)^\top = (\mathbf{U}_r)^\top. \tag{16}$$

Similarly, $(\mathbf{V}_r)^\top$ has full row rank, and its Moore-Penrose generalized inverse is given by:

$$(\mathbf{V}_r)^{\top +} = \mathbf{V}_r ((\mathbf{V}_r)^\top \mathbf{V}_r)^{-1} = \mathbf{V}_r. \tag{17}$$

Based on the generalized inverse vectors, each user calculates her singular vector by:

$$\mathbf{S} = \text{Diagonal}(\mathbf{U}_r^\top \mathbf{I} \mathbf{V}_r) = [s_l]_r = \left[\mathbf{u}_l^\top \cdot \mathbf{I} \cdot \mathbf{v}_l\right]_r, \tag{18}$$

where $\text{Diagonal}(\cdot)$ calculates the diagonal of a matrix, $\mathbf{S}$ is a vector of size r. We name each element of this vector as the pseudo singular value, denoted as s_l, where $1 \leq l \leq r$.

STAGE 3. Mean Estimation. In this stage, the mean singular vector is estimated using a sampling mechanism proposed in [43] and a HM protocol proposed in [39]. Each user perturbs one pseudo singular value s_l sampled from her singular vector $\mathbf{S}$ and reports it to the aggregator. The aggregator then collects all perturbed reports and estimates the mean vector. This stage consists of four steps.

Step 1. Query Value Sampling. In this step, the aggregator samples a positive integer l from the range [1,r] for each user, and queries this user the l^{th} value (i.e., s_l) in her singular vector. The calculation of s_l is only related to $\mathbf{u}_l$ and $\mathbf{v}_l$ according to Equation (18), so the aggregator only needs to send l, $\mathbf{u}_l$ and $\mathbf{v}_l$ to the user, rather than the entire matrices $\mathbf{U}_r$ and $\mathbf{V}_r$.

Step 2. Value Domain Calculation. This step is performed at the user side. After receiving a query on a pseudo singular value s_l, the user calculates the domain of this value. This allows her to perturb the value later to meet the constraint of LDP. The domain of s_l is only related to $\mathbf{u}_l^\top$ and $\mathbf{v}_l$ and is independent of any value in the user matrix $\mathbf{I}$. If we represent $\mathbf{u}_l^\top$ as $\{u_{l1}, u_{l2}, \cdots, u_{lk}\}$, and $\mathbf{v}_l$ as $\{v_{l1}, v_{l2}, \cdots, v_{lk}\}^\top$, a sampled value s_l can be expanded as:

$$s_l = (\mathbf{u}_l)^\top \mathbf{I} \mathbf{v}_l = \sum_{a=1}^{k} \sum_{b=1}^{k} u_{la} \cdot \mathbf{I}_{a,b} \cdot v_{lb}. \tag{19}$$

Since each value in $\mathbf{I}$ is either 0 or 1, it is evident that the minimum possible value of a given pseudo singular value can be achieved when the following conditions are met:

$$\mathbf{I}_{a,b} = \begin{cases} 1, & \text{if } u_{la} \cdot v_{lb} \leq 0; \\ 0, & \text{otherwise.} \end{cases} \tag{20}$$

Thus we have:

$$\min(s_l) = \sum_{a=1}^{k} \sum_{b=1}^{k} \frac{u_{la} \cdot v_{lb} - |u_{la} \cdot v_{lb}|}{2}, \tag{21}$$

where $|\cdot|$ calculates the absolute value of a real number. Similarly, the maximum possible value is:

$$\max(s_l) = \sum_{a=1}^{k} \sum_{b=1}^{k} \frac{u_{la} \cdot v_{lb} + |u_{la} \cdot v_{lb}|}{2}. \tag{22}$$

Let $\text{D}_{\mathbf{S}}(s_l)$ denote the domain of the s_l, it is given by:

$$\text{D}_{\mathbf{S}}(s_l) = [\min(s_l), \max(s_l)]. \tag{23}$$

Step 3. Singular Value Perturbation. This step is performed at the user side. Firstly, each user calculates the mapped pseudo singular value $\overrightarrow{s_l}$, which is the mapping of s_l from $\text{D}_{\mathbf{S}}(s_l)$ to the range [-1,1]:

$$\overrightarrow{s_l} = 2 \times \frac{s_l - \min(s_l)}{\max(s_l) - \min(s_l)} - 1. \tag{24}$$

Afterward, to meet the constraint of LDP, the user applies the perturbation algorithm of the HM protocol to perturb $\overrightarrow{s_l}$ as:

$$(\overrightarrow{s_l})^* = \Psi_{HM(\varepsilon)}(\overrightarrow{s_l}), \tag{25}$$

and then reports the perturbed value $(\overrightarrow{s_l})^*$ to the aggregator.

Step 4. Mean Vector Estimation. This step is performed at the aggregator side. The aggregator collects all reported values sent from users in Step 3 and estimates a mean value for each pseudo singular value using the aggregation algorithm of the HM protocol:

$$\widehat{(\overrightarrow{s_l})^*} = r * \Phi_{HM}(\overrightarrow{s_l}) = \frac{r}{\eta}\sum_{j=1}^{\eta}(\overrightarrow{s_l}^j)^*, \tag{26}$$

where η is the number of users participating in the mean estimation of the same query value (i.e., received the same l in Step 1). The size of the singular vector (also the rank of approximation) is denoted by r, which is used to correct the sampling error. $(\overrightarrow{s_l}^j)^*$ represents the perturbed pseudo singular value uploaded by the j^{th} user. Subsequently, the aggregator remaps each estimated mean value from [-1,1] back to the domain $D_{\mathbf{S}}(s_l)$:

$$\widehat{s_l} = \min(s_l) + \left(\widehat{(\overrightarrow{s_l})^*} + 1\right)(\max(s_l) - \min(s_l))/2. \tag{27}$$

Finally, the aggregator obtains the mean singular vector:

$$\widehat{\mathbf{S}} = [\widehat{s_1}, \widehat{s_1}, ..., \widehat{s_r}] \tag{28}$$

STAGE 4. Matrix Updating. This stage is performed at the aggregator side. After estimating the mean singular vector $\widehat{\mathbf{S}}$, the aggregator estimates the aggregator matrix as follows:

$$\mathbf{M}'_{agg} = \mathbf{U}_r \,\mathrm{Diag}(\widehat{\mathbf{S}})\mathbf{V}_r^\top = \sum_{l=1}^{r}\widehat{s_l}\cdot\mathbf{u}_l\cdot\mathbf{v}_l^\top. \tag{29}$$

Where $\mathrm{Diag}(\widehat{\mathbf{S}})$ diagonalizes $\widehat{\mathbf{S}}$ into a diagonal matrix.

Note that $\mathbf{M}'_{agg}$ may not be an accurate estimation since the initial matrix $\mathbf{M}_{agg}$ (in Stage 1) is not precise. To address this issue, LDP-RM performs Stage 2 to Stage 4 iteratively, using $\mathbf{M}'_{agg}$ in the current iteration as the new initial matrix $\mathbf{M}_{agg}$ in the next iteration. If T iterations are employed, the n_2 users participating in the second task should be divided into T subgroups, each with n_2/T users. All n_2 users in the second group participate in Stage 1, while only one subgroup of users takes part in Stage 2 to 4 in each iteration. In the final (i.e., T^{th}) iteration, the final estimated aggregator matrix is obtained, and the aggregator selects the top-k_s relations in support and moves them to a candidate set, denoted as $\mathbb{Y}$.

4.2.3 TASK 3. High-Confidence Relation Mining. In the third task, LDP-RM identifies top-k_c relations in confidence from the candidate set $\mathbb{Y}$. The aggregator interacts with the third group of users and initiates an SVIM protocol. Each participating user randomly selects a private relation, perturbs it, and reports the perturbed value. The aggregator then estimates the support of all relations in $\mathbb{Y}$:

$$\Phi_{\mathrm{SVIM}(\mathbb{Y},\varepsilon,n_3,k_s)} = \{(\mathbf{w}, \Phi_{\mathrm{PSFO}(\ell,\varepsilon)}(\mathbf{w}))|\mathbf{w}\in\mathbb{Y}\}, \tag{30}$$

Based on the support of candidate relations in $\mathbb{Y}$ and the support of related items in $\mathbf{Y}$ (obtained in Task 1), the aggregator computes the confidence of each candidate relation. Finally, the aggregator selects the top-k_c relations in confidence from $\mathbb{Y}$ as the output of LDP-RM.

5 Analysis

In this section, we start with a proof that LDP-RM satisfies ε-LDP, then analyze the estimation error and bias of it.

5.1 Privacy

LDP-RM satisfies ε-LDP defined on users' items and relations. This is because, each task in LDP-RM involves the use of protocols that satisfy ε-LDP, namely, either a SVIM protocol or a HM protocol. Thus, LDP-RM satisfies ε-LDP. A rigorous proof is provided in Appendix F.

5.2 Utility

The utility of the results discovered by LDP-RM is primarily influenced by two factors: estimation error and bias.

Estimation Error. Estimation error is the difference between the true value and the estimated value. LDP-RM employs the HM protocol (which is built on PM and Duchi) to estimate the mean singular vector, and employs the SVIM protocol (which is built on PSFO, GRR and OLH) to estimate the support of items/relations. The L_∞ error of HM is bounded by $O_1 = O(\sqrt{r\log(r/\beta)}/\varepsilon\sqrt{n})$ with probability at least $1-\beta$, according to [39]. The L_∞ error of SVIM is bounded by $O_2 = O(\ell\sqrt{\log(\ell/\beta)}/\varepsilon\sqrt{n})$ with probability at least $1-\beta$. The proof can be found in Appendix H.

Estimation Bias. Estimation bias is the deviation from the true value during estimation. In LDP-RM, the aggregator is tasked with estimating the best rank-r approximation as opposed to the complete full-rank matrix. This inherently introduces a degree of bias in the process of recovering the true matrix. To mitigate this bias, one may contemplate the use of a larger value for the parameter r. However, it's important to note that opting for a larger value of r also implies an increased number of pseudo singular values that need to be estimated. Consequently, there exists a trade-off between diminishing the bias and minimizing the error. Given a bias bound denoted by θ provided by the aggregator, LDP-RM calculates the smallest possible value of r that satisfies this bound according to the Eckart-Young-Mirsky Theorem (described in Appendix E), as follows:

$$\min r, \text{ subject to: } \sum_{i=1}^{r}\sigma_i \Big/ \sum_{i=1}^{k}\sigma_i \geq \theta. \tag{31}$$

Compared to the estimation error, the bias has a minimal impact on the final results. LDP-RM strikes a balance by

selecting a relatively small r. The value of r can also be dynamically adjusted in different iterations, e.g., a smaller value in early iterations and a larger value in later iterations.

Biased Estimation Vs. Unbiased Estimation. We now explain why we employ a biased estimation method rather than an unbiased one. Consider an algorithm called HM-RM, which differs from LDP-RM in that each user in HM-RM generates a matrix $\mathbf{P} = \mathbf{U}_k^\top \mathbf{I}\mathbf{V}_k$ in Stage 2, rather than just a vector $\mathbf{S}$. If HM-RM is directly used, each user must perturb and report k^2 elements in $\mathbf{P}$, and the aggregator estimates a mean matrix $\widehat{\mathbf{P}}$ by using the HM protocol. This results in L_∞ error bounded by $O_3 = O(k\sqrt{\log(k^2/\beta)}/\varepsilon\sqrt{n})$ with probability at least $1-\beta$. We prove that HM-RM is unbiased in Appendix G. Our experiments in Sec. 7.2.1 and 7.2.2 demonstrate that the biased LDP-RM significantly outperforms the unbiased HM-RM.

5.3 Computational Overhead

The computational overhead of LDP-RM comprises three distinct components. This is because LDP-RM divides users into three groups.Moreover, within the second group (Task 2 participants), users are further subdivided into T subgroups across T iterations. Importantly, each user undergoes only one query by the aggregator, rendering the user-side computational overhead independent of task or iteration round.

Specifically, for **Task 1** and **Task 3**, LDP-RM employs two SVIM protocols with n_1 and n_3 users participating in these tasks, respectively. The user-side computational overhead for these two tasks amounts to $O(\log d)$ and $O(\log k_s)$, while the aggregator-side computational overhead is characterized by $O(n_1 \log d)$ and $O(n_3 \log k_s)$, respectively. For **Task 2**, n_2 users are involved, and each user computes a pseudo singular value s_l, resulting in a per-user computational overhead of $O(k^2)$. Subsequently, users employ the HM protocol to perturb and report s_l, incurring a computational overhead of $O(\log r)$. Consequently, the total computational overhead for each user in the second group is $O(k^2 + \log r)$. As the aggregator needs to conduct SVD and update the matrix in each iteration, incurring a computational overhead of $2k^2$, the aggregator-side computational overhead for Task 2 reaches $O(n_2(k^2 + \log r) + 2Tk^2)$. Thus, the cumulative aggregator-side computational overhead is given by:

$$O(n_1 \log d + n_2(k^2 + \log r) + 2Tk^2 + n_3 \log k_s). \quad (32)$$

We summarize the above analysis in Tab. 2. A recommended setting on all the parameters can be found in Tab. 4 of Appendix I. Typically, d and k_s are often large, whereas r, T and k are often small. With this setting, our proposed LDP-RM is slightly slower than SVSM [43] and PCKV [18], and superior to CALM [49], in computational overhead while LDP-RM is the only approach that can mine all types of relations.

6 Generalizing LDP-RM

In this section, we first propose an improvement to LDP-RM that enables the discovery of relations among more than two items. We then introduce an advanced frequency oracle on large domains that utilizes LDP-RM.

6.1 Mining Relations Comprising More Items

We now improve LDP-RM to identify cascading relations comprising more than two items, e.g., $((x_a, x_b), x_c)$. Modifications are made in Stage 1 and Stage 4 of Task 2. In Stage 1, after the aggregator identifies the top-k frequent items, he guesses the support of each possible relations by multiplying the support of any number of items. If the guessed support of a relation surpasses that of an item in $\mathbf{Y}$, the relation is treated as a new item and moved into $\mathbf{Y}$, while the item with the lowest estimated support is moved out from $\mathbf{Y}$. In Stage 4, before the aggregator updates the aggregator matrix $\mathbf{M}_{agg}$, he verifies whether a relation and an item exist such that the estimated support of the relation is larger than that of the item. If so, the set of high-support items $\mathbf{Y}$ is reconstructed by selecting the top-k frequent items/relations. After T iterations, the final top-k_c relations can consist of two items or more items.

6.2 Frequency Oracle on Large Domains

Consider a frequency estimation scenario under LDP where there is a large number of values to be estimated. In this context, LDP-RM can serve as a fundamental FO, which we refer to as SVD-FO. SVD-FO encodes a unidimensional item domain into a bidimensional one and utilizes LDP-RM for frequency estimation. Given an original item domain $\mathbf{X} = \{x_1, x_2, \cdots, x_d\}$, SVD-FO examines a virtualized domain $\mathbf{V}$, where $|\mathbf{V}| = \lceil d^{1/2} \rceil$. An one-to-one mapping $e(\cdot)$ from $\mathbf{X}$ to $\mathbf{V}^2$ is then employed to encode any item $x_i \in \mathbf{X}$ into a tuple $e(x_i) = (a,b) \in \mathbf{V}^2$. Subsequently, LDP-RM is applied to estimate the matrix $(\mathbf{M}_{a,b}) \in \mathbb{R}^{|\mathbf{V}| \times |\mathbf{V}|}$, in which each element $\mathbf{M}_{a,b}$ represents the frequency of an item $x_i = e^{-1}(a,b)$.

SVD-FO surpasses the state-of-the-art FO, specifically PSFO, in estimating item frequencies within high-dimensional contexts. This performance improvement stems from a reduction in the number of values to be estimated, decreasing from d to $r \times T < \lceil d^{1/2} \rceil \times T < d$, where r represents the approximation rank and T denotes number of iterations. However, in cases with a small domain size, SVD-FO may not necessarily outperform PSFO.

7 Evaluation

In this section, we first introduce the experiment setup including computing environment, compared methods, datasets and evaluation metrics, and then present results of experiments on LDP-RM in various data mining tasks.

Table 2: Computational Overhead of LDP-RM and Existing Techniques.

Methods	User Side			Aggregator Side
	Group ♯1 (n_1)	Group ♯2 (n_2)	Group ♯3 (n_3)	
LDP-RM	$O(\log d)$	$O(k^2+\log r)$	$O(\log k_s)$	$O(n_1\log d+n_2(k^2+\log r)+2Tk^2+n_3\log k_s)$
SVSM [43]	$O(\log d)$	$O(\log k_s)$		$O(n_1\log d+(n_2+n_3)\log k_s)$
CALM [50]	$O(\log d)$	$O(2^l)$		$O(n_1\log d+(n_2+n_3)2^l)$
PCKV [18]	$O(\log d)$	$O(\log k_s)$		$O(n_1\log d+(n_2+n_3)\log k_s)$

7.1 Experiment Setup

Environment. All experiments are conducted on a desktop with an Intel i7-1165G7 2.80GHz CPU and 16GB memory. Each experiment is performed 20 times, with mean and standard deviation reported.

Compared Methods. LDP-RM is the first method which addresses the problem of relation mining under LDP. We consider four compared methods, including **(1) SVIM** [43] which mines high-support items, **(2) SVSM** [43] which mines high-support itemsets, **(3) CALM** [50] which estimates marginal probabilities, **(4) PCKV** [18] which estimates support of a key and the mean value of that key, and **(5) HM-RM**, an unbiased relation mining method discussed in Sec. 5.2. All algorithms are implemented using Python 3.9.

Datasets. We conduct experiments on four public datasets.

(1) The IFTTT Dataset: We construct a binary relational dataset containing 354 non-repetitive items extracted from top-200 applets in IFTTT in 2023 [19]. One applet can be regarded as a relation which consists of two items. We consider 300,000 users in this dataset, and the items and relations possessed by each user is generated based on the popularity of each applet according to official statistics. This dataset is used to simulate a general scenario of relation mining.

(2) The Movie Dataset [29]: A movie viewing dataset containing 5,000 items and 400,000 users. Each user possesses temporal relations in the form of (x_a, x_b), signifying that after viewing movie x_a, the user subsequently watches movie x_b. This dataset is used to simulate a scenario of relation mining.

(3) The Modified IFTTT Dataset: A dataset modified from the IFTTT dataset which contains 354 items and 800,000 users. Within this dataset, relations are among items and are in the form of $((x_a, x_b), x_c)$. All relations are generated based on the relationship between IFTTT applets. This dataset is utilized to simulate the discovery of relations among items.

(4) The Retail Dataset [7]: A retail market basket dataset containing 2,603 items and 300,000 users. Each user possess several items. This dataset is used to simulate a scenario of association rule mining.

(5) The Kosarak Dataset [16]: A website click dataset containing 41,270 items and 990,002 users. This dataset is used to simulate a scenario of item mining on a large domain.

Evaluation Metrics. To measure estimation accuracy, we employ 3 different metrics. We denote the set of true relations with top-k_s support and top-k_c confidence as $\mathbb{W}_t$, and the set of estimated ones as $\mathbb{W}_e$. Consequently, $\mathbb{W}_t \cap \mathbb{W}_e$ represents the true positive instances (TP).

(1) F-Measure (F1) is a widely used metric to measure accuracy, which is defined as the harmonic mean of precision (denoted as P) and recall (denoted as R):

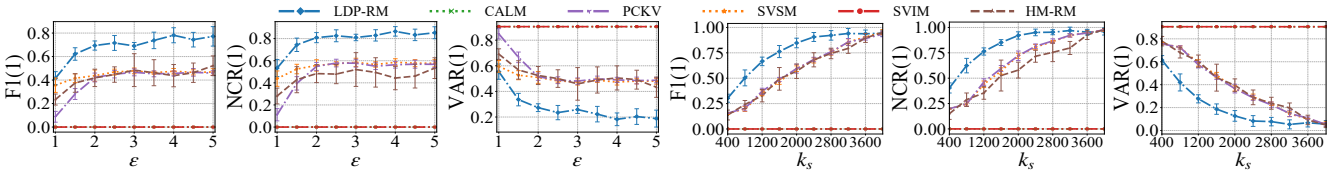
$$\mathrm{F1} \triangleq \frac{2}{1/P+1/R} = \frac{2PR}{P+R}, \tag{33}$$

$$\text{where } P \triangleq \frac{|\mathbb{W}_t \cap \mathbb{W}_e|}{|\mathbb{W}_e|}, R \triangleq \frac{|\mathbb{W}_t \cap \mathbb{W}_e|}{|\mathbb{W}_t|}. \tag{34}$$

(2) Normalized Cumulative Ranks (NCR) is a metric used to evaluate the level of accuracy achieved, which takes into consideration that the benefit of mining relations with higher confidence ranks should be greater than those with lower ranks. It is defined as:

$$\mathrm{NCR} = \sum_{\mathbf{w}\in\mathbb{W}_e\cap\mathbb{W}_t} q(\mathbf{w}) \Big/ \sum_{\mathbf{w}\in\mathbb{W}_t} q(\mathbf{w}), \tag{35}$$

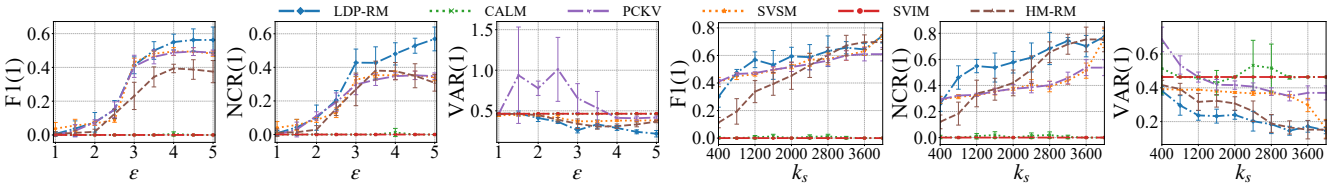
where $q(\cdot)$ is a quality function defined as follows. There are k_c relations in $\mathbb{W}_t$ which is the set of correct results. Consider a given relation $\mathbf{w}$. If $\mathbf{w}$ has the highest confidence, then $q(\mathbf{w}) = k_c$. If $\mathbf{w}$ has the second highest confidence, then $q(\mathbf{w}) = k_c - 1$, and so on. If $\mathbf{w} \notin \mathbb{W}_t$, then $q(\mathbf{w}) = 0$.



(3) Variance (VAR) is used to measure accuracy achieved on the confidence values of a set of relations by squared errors:

$$\mathrm{VAR} = \frac{1}{|\mathbb{W}_t|} \sum_{\mathbf{w}\in\mathbb{W}_t} (\rho(\mathbf{w}) - \varphi(\mathbf{w}))^2, \tag{36}$$

where $\rho(\mathbf{w})$ is the true confidence of the relation $\mathbf{w} \in \mathbb{W}_t$, and $\varphi(\mathbf{w})$ is the estimated confidence of $\mathbf{w}$. If $\mathbf{w} \notin \mathbb{W}_e$, we set $\varphi(\mathbf{w}) = 0$.



7.2 Experiments and Results

We conduct experiments in various data mining tasks, including mining of general relations comprising two items, more items, association rule mining, item mining and compare the performance of LDP-RM with non-private algorithms. We also conduct an ablation experiment to demonstrate the effectiveness of iterative process in LDP-RM.

(a) F1 on ε (b) NCR on ε (c) VAR on ε (d) F1 on k_s (e) NCR on k_s (f) VAR on k_s

Figure 3: Performance of LDP-RM and existing techniques in mining relations comprising 2 items from IFTTT dataset. Results of Experiment E1 are in (a), (b) and (c), that of E2 are in (d), (e) and (f). We set $k = 64, k_c = 32, \theta = 0.5, T = 5$ for both E1 and E2, with $k_s = 1600$ in E1, and $\varepsilon = 4$ in E2.

(a) F1 on ε (b) NCR on ε (c) VAR on ε (d) F1 on k_s (e) NCR on k_s (f) VAR on k_s

Figure 4: Performance of LDP-RM and existing techniques in mining relations comprising 2 items from Movie dataset. Results of Experiment E3 are in (a), (b) and (c), that of E4 are in (d), (e) and (f). We set $k = 64, k_c = 32, \theta = 0.5, T = 5$ for both E3 and E4, with $k_s = 1600$ in E3, and $\varepsilon = 4$ in E4.

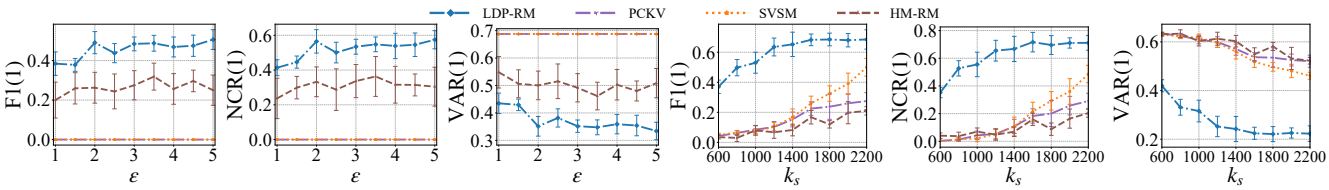
7.2.1 Experiments in mining relations between items. We conduct four experiments denoted as **E1** to **E4** on two datasets to validate the performance of LDP-RM in mining relations. The IFTTT dataset is used in **E1** and **E2**. The Movie dataset is used in **E3** and **E4**. Since relation mining require separate estimation of support for items and that for relations, we make the following settings to achieve a fair comparison among different methods. For LDP-RM and HM-RM, it accomplishes its Task 1, Task 2, and Task 3 by communicating with n_1, n_2, and n_3 users, respectively. For SVIM, SVSM, CALM, and PCKV, they communicate with n_1 users to estimate support of items, and with $n_2 + n_3$ users to estimate support of relations. For all methods, the ratio of n_1, n_2, n_3 is set to 30%, 35%, 35% respectively. The parameter setting in the following experiments are discussed in Appendix I.

(**E1**) The results on varying ε are illustrated in Figs. 3a, 3b, 3c. Among all methods, LDP-RM always performs the best. SVSM is better than the PCKV when $\varepsilon < 2$ because PCKV requires allocating an additional privacy budget for mean estimation. SVIM and CALM struggle to identify target relations due to the excessive value estimation requirements, resulting in insufficient privacy budget and user participation. The unbiased HM-RM is inferior to the biased LDP-RM, which validates our analysis in Sec. 5.2.

(**E2**) The results on varying k_s are illustrated in Figs. 3d, 3e, 3f. As k_s increases, F1 and NCR also increases, while VAR decreases. This is because a larger k_s means a smaller support threshold which decreases the difficulty in discovering high-support and high-confidence relations. Among all methods, LDP-RM always performs the best.

(**E3**) The results on varying ε are illustrated in Figs. 4a, 4b, 4c. All methods can discover only several target relations when $\varepsilon < 3$, because of insufficient privacy budget and insufficient users. When $\varepsilon > 3$, LDP-RM achieves better performance than other methods.

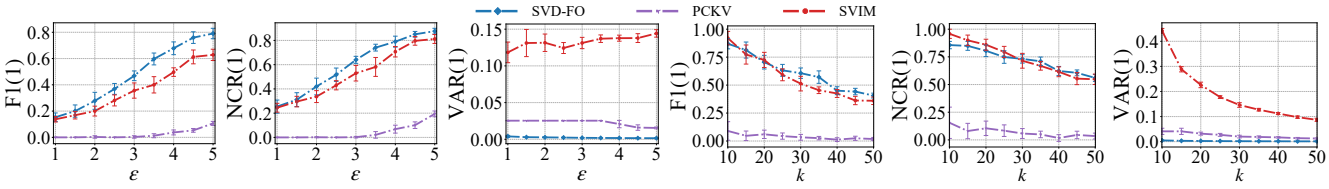
(**E4**) The results on varying k_s are illustrated in Figs. 4d, 4e, 4f. Compared with other methods, LDP-RM performs the best, especially on NCR.



7.2.2 Experiments in mining relations among items. The modified IFTTT dataset is used in these experiments. We use the same grouping strategy as in experiments **E1** and **E2**. Considering the ineffectiveness of SVIM and CALM in mining relations between items, we do not treat them as compared methods since the domain is larger.

(**E5**) The results on varying ε are illustrated in Figs. 5a, 5b, 5c. Among all methods, LDP-RM performs the best, followed by HM-RM. Hardly any high-support and high-confidence relations can be discovered by using other methods. It is because the effect of "Curse of Dimensionality" is more significant.

(**E6**) The results on varying k_s are illustrated in Figs. 5d, 5e, 5f. Compared with other methods, LDP-RM exhibits obvious advantages.



7.2.3 Experiments in mining association rules. The Retail dataset is used in these experiments. We use the same setting on grouping strategy as in experiments **E1** to **E6**.

(**E7**) This experiment is conducted directly on the Retail dataset, and the results is presented in Tab. 3 (left part). LDP-RM demonstrates comparable performance to SVSM in terms

(a) F1 on ε (b) NCR on ε (c) VAR on ε (d) F1 on k_s (e) NCR on k_s (f) VAR on k_s

Figure 5: Performance of LDP-RM and existing techniques in mining cascading relations (3 items) from modified IFTTT dataset. Results of Experiment E5 are in (a), (b) and (c), that of E6 are in (d), (e) and (f). We set $k = 64, k_c = 32, \theta = 0.5, T = 5$ for both E5 and E6, with $k_s = 1600$ in E5, and $\varepsilon = 4$ in E6.

(a) F1 on ε (b) NCR on ε (c) VAR on ε (d) F1 on k (e) NCR on k (f) VAR on k

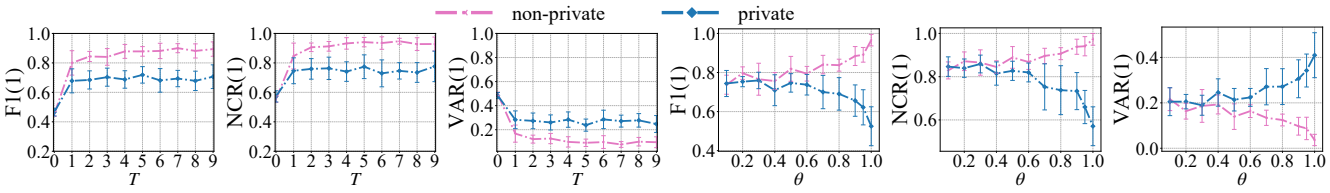
Figure 6: Performance of LDP-RM and existing techniques in mining frequent items from Kosarak dataset. Results of Experiment E9 are in (a), (b) and (c), that of E10 are in (d), (e) and (f). We set $\theta = 0.5, T = 5$ for both E9 and E10, with $k = 32$ in E9, and $\varepsilon = 4$ in E10.

Table 3: Performance of LDP-RM and existing techniques in mining association rules from Retail and Retail* dataset. We set $\varepsilon = 4, k = 64, k_s = 1600, k_c = 32, \theta = 0.5, T = 5$.

Method	Retail			Retail*		
	F1	NCR	VAR	F1	NCR	VAR
LDP-RM	0.558	0.640	0.246	0.546	0.654	0.180
SVSM	0.554	0.435	0.317	0.463	0.396	0.308
CALM	0.183	0.195	0.568	0.108	0.159	0.461
SVIM	0	0	0.603	0	0	0.491
PCKV	0	0	0.603	0	0	0.491
HM-RM	0.325	0.329	0.414	0.379	0.437	0.285

of F1, while exhibiting superiority in NCR and VAR. The reason for SVSM's commendable performance lies in the fact that the assumption of high-support relations being composed of high-support items remains valid within the original Retail dataset. CALM, SVIM, PCKV and HM-RM perform poorly.

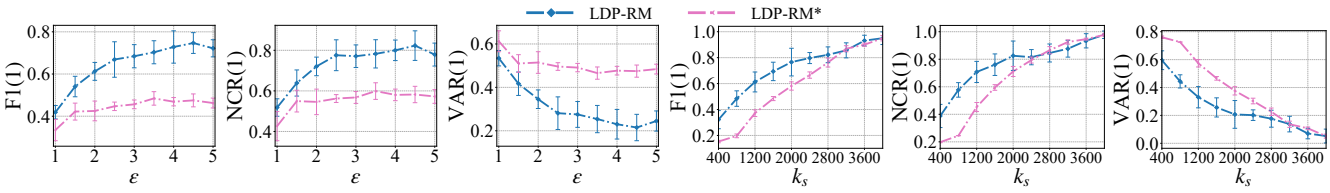
(**E8**) This experiment investigates the performance of different methods in association rule mining when the previous assumption in **E7** is not held. To relax this assumption, we slightly modify the Retail dataset by excluding data related to the top-8 items in support, since well-known relations comprising high-support items may not be the targets of the mining task. We denote the modified dataset as **Retail***. All parameters are set same as in **E7**, and the results is presented in Tab. 3 (right part). There is a significant decline in the accuracy achieved by SVSM, while the accuracy achieved by LDP-RM remains at an adequate level.



7.2.4 Experiments in item mining. The Kosarak dataset is used to evaluate the performance of SVD-FO (described in Sec. 6.2). To simulate the scenario of item mining in a large domain with a small number of users, we randomly select 50,000 users from the dataset. The number of users is comparable to the domain size $d = 41,270$. SVIM and PCKV, both employing PSFO, are selected for comparison.

(**E9**) The results on varying ε are illustrated in Figs. 6a, 6b, 6c. Among all methods, SVD-FO always delivers the best performance, while PCKV struggles to produce effective results. SVIM is slightly inferior to the SVD-FO in NCR and F1, exhibits a significantly larger VAR value. It is because SVIM requires directly estimating items in the large d domain while LDP-RM only needs to estimate items in the k_s ($k_s << d$) domain and the error is close to 0.

(**E10**) The results on varying k are illustrated in Figs. 6d, 6e, 6f. As k increases, F1 and NCR decreases and VAR increases. SVD-FO is comparable with SVIM in F1 and NCR, and performs the best in VAR.



7.2.5 Comparison of private and non-private algorithms. The IFTTT dataset is used to compare the performance of LDP-RM and that of its non-private variant ($\varepsilon = \infty$).

(**E11**) The results on varying number of iterations T are illustrated in Figs. 7a, 7b, 7c. For non-private LDP-RM, F1 and NCR consistently increase and VAR decreases as T increases. For private LDP-RM, the estimation accuracy does not always increase with T (when $T \geq 5$). This is because the number of users in each iteration decreases as T increases.

(a) F1 on T (b) NCR on T (c) VAR on T (d) F1 on θ (e) NCR on θ (f) VAR on θ

Figure 7: Ablation Experiments: Performance of private and non-private versions of LDP-RM in mining relations from IFTTT dataset. Results of Experiment E11 are in (a), (b) and (c), that of E12 are in (d), (e) and (f). We set $\varepsilon = 4$, $k = 64$, $k_s = 1600$, $k_c = 32$ for both E11 and E12 with $\theta = 0.5$ in E11, and $T = 5$ in E12.

(a) F1 on ε (b) NCR on ε (c) VAR on ε (d) F1 on k_s (e) NCR on k_s (f) VAR on k_s

Figure 8: Ablation Experiments: Performance of LDP-RM and its variant LDP-RM* that without iterative process in mining relations from IFTTT dataset. Results of Experiment E13 are in (a), (b) and (c), that of E14 are in (d), (e) and (f). We set $k = 64, k_c = 32, \theta = 0.5, T = 5$ for both E13 and E14, with $k_s = 1600$ in E13, and $\varepsilon = 4$ in E14.

(**E12**) The results on varying bias bound θ are illustrated in Figs. 7d, 7e, 7f. The rank of approximation r increases as θ increases, according to Equation (31). For non-private LDP-RM, F1 and NCR is nearly perfect when $\theta = 1$ (i.e., $r = k = 64$). For private LDP-RM, the accuracy starts to decrease when $\theta > 0.5$. This is because the larger the θ is, the more elements are needed to be estimated.

7.2.6 Comparison of iterative and non-iterative algorithms. The IFTTT dataset is used to illustrate the effectiveness of the iterative process. We denote the variant LDP-RM without iteration as LDP-RM*.

(**E13**) The results on varying ε are illustrated in Figs. 8a, 8b, 8c. LDP-RM significantly outperforms LDP-RM* owing to the fact that LDP-RM* relies on an imprecise global matrix that is entirely based on guesswork to produce results. In contrast, LDP-RM continually aggregates user information to update the matrix through T rounds of iterations.

(**E14**) The results on varying k_s are illustrated in Figs. 8d, 8e, 8f. It underscores the importance of the iterative process.

8 Related Work

We are the first to introduce and investigate the problem of relation mining under LDP. Consequently, there has been no prior research focused on this problem. Nonetheless, four lines of research are closely related to our work.

Frequent Item-set Mining under LDP. This line of research focuses on discovering high-support item-sets, with the state-of-the-art technique SVSM [43]. The limitations of using SVSM for relation mining are analyzed in Sec. 3.2 and verified in Sec. 7.2. In addition to SVSM, several other approaches have been proposed. Zhang et al. [49] mine frequent item-sets from perturbed items. Wang et al. [40] estimate the size distribution of frequent item-sets. Afrose et al. [2] mine frequent item-sets by splitting the privacy budget rather than grouping users. Ma et al. [24] utilize FP-tree in combination with Hadamard response to improve the accuracy of the results.

Marginal Release under LDP. This line of research concentrates on estimating marginal probabilities. The state-of-the-art technique, CALM [50], optimizes the trade-off between the number and length of marginals, taking into account the number of users, attributes, and privacy budget. Other techniques skillfully balance privacy and estimation accuracy, employing various techniques, such as Fourier Transformation [9] and Expectation Maximization [34].

Key-Value Collecting under LDP. This line of research focuses on estimating the support and mean value of a key. Ye et al. put forth three methods, namely PrivKV, PrivKVM, and PrivKVM+ [47]. Gu et al. propose a state-of-the-art technique called PCKV [18], which combines a sampling mechanism with GRR [42] and OUE [42], to improve estimation accuracy.

Relation Mining under DP. This line of research is under the constraint of DP in the centralized setting, not LDP. Traditional DP techniques perturb individual data by using the

Laplace mechanism [11], exponential mechanism [26], or some other mechanisms [14, 23]. These mechanisms destroy the relationship among the data values, rendering the perturbed data unsuitable for complex data mining tasks. Several researches have been proposed for relation mining. Li et al. [22] uses a trusted publisher to perturb the support of numerous high-support item-sets, and extracts the top-k subsets in support [5] from the perturbed data. To speed up computation in perturbation and extraction, some techniques such as transaction truncating [8, 36, 48], Markov Chain Monte Carlo [35], and binary estimation [46] have been proposed. Other techniques, such as frequent pattern tree [21] and sequence exponential mechanism [38], aim to save privacy budget. In addition to the techniques that focus on high-support relation mining under DP, Maruseac et al. [25] introduce a method that enables high-confidence relation mining.

9 Conclusion

It is a fundamental problem in performing complex data mining tasks on private data owned by distributed users. To address this problem, we propose LDP-RM, the first general relation mining method under LDP. By employing singular value decomposition and low rank approximation, it reduces the number of values to estimate, thereby improving the final estimation accuracy. Experimental evaluation demonstrates the effectiveness of LDP-RM in mining relations.

A The Duchi and PM Protocols

The Duchi and PM protocol are both utilized for mean estimation, where the j^{th} user possesses one value $x^j \in \mathbf{X} = [-1,1]$. Given an input $x \in \mathbf{X}$ and a privacy budget ε, the output is $y \in [-C,C]$, where $C = \frac{e^{\varepsilon/2}+1}{e^{\varepsilon/2}-1}$. the perturbation algorithms of them are defined respectively as follows:

$$\Pr\left[\Psi_{\mathrm{PM}(\varepsilon)}(x) = y\right] \triangleq \begin{cases} p, & \text{if } y \in [l(x), r(x)]; \\ p/e^{\varepsilon}, & \text{if } y \in [-C, l(x)) \cup (r(x), C]. \end{cases}$$

$$\Pr\left[\Psi_{\mathrm{Duchi}(\varepsilon)}(x) = y\right] \triangleq \begin{cases} q, & \text{if } y = (e^{\varepsilon}+1)/(e^{\varepsilon}-1); \\ 1-q, & \text{if } y = -(e^{\varepsilon}+1)/(e^{\varepsilon}-1), \end{cases}$$

Where $p = (e^{\varepsilon} - e^{\varepsilon/2})/(2e^{\varepsilon/2}+2)$, $q = (e^{\varepsilon}-1)/(2e^{\varepsilon}+2) + (1/2)$, $l(x) = (C+1)\cdot x/2 - (C-1)/2$, $r(x) = l(x) + C - 1$.

B The GRR and OLH Protocols

A frequency oracle (FO) protocol is formalized as a pair of algorithms $\langle \Psi, \Phi \rangle$, where Ψ is a perturbation algorithm which satisfies ε-LDP, and Φ is a aggregation algorithm which estimates the frequency of any value $x \in \mathbf{X}$, represented as:

$$\mathrm{FO}(\varepsilon) \triangleq \langle \Psi, \Phi \rangle.$$

Generalized Randomized Response (GRR). A GRR protocol [41] is a FO protocol used for the attribute with $d >= 2$ possible values. It is composed of a pair of algorithms: $\langle \Psi_{\mathrm{GRR}}, \Phi_{\mathrm{GRR}} \rangle$, defined as follows:

$$\forall_{y \in X} \Pr\left[\Psi_{\mathrm{GRR}(\varepsilon)}(x) = y\right] \triangleq \begin{cases} p = \frac{e^{\varepsilon}}{e^{\varepsilon}+d-1}, & \text{if } y = x; \\ q = \frac{1}{e^{\varepsilon}+d-1}, & \text{if } y \neq x. \end{cases}$$

$$\Phi_{\mathrm{GRR}(\varepsilon)}(x) \triangleq (C(x) - nq)/(p-q).$$

Where p (or q) denotes the probability that the original value is unchanged (or changed), $C(x)$ counts how many times x is reported, n is the total number of users.

Optimized Local Hashing (OLH). An OLH protocol [42] is a FO protocol that utilizes GRR and is composed of a pair of algorithms: $\langle \Psi_{\text{OLH}}, \Phi_{\text{OLH}} \rangle$. The reporting protocol Ψ_{OLH} maps an input value from a large domain $\mathbf{X}$ into a smaller domain G by first randomly selecting a hash function H from a predefined family of hash functions, then computing the hashed value $H(x)$. Next, a GRR protocol is used to perturb the hashed value. It has been proven in [42] that minimal variance is achieved when $|G| = \lceil e^{\varepsilon} + 1 \rceil$. The definitions of Ψ_{OLH} and Φ_{OLH} are as follows:

$$\Psi_{\text{OLH}(\varepsilon)}(\cdot) \triangleq \langle H, \Psi_{\text{GRR}(\varepsilon)}(H(\cdot)) \rangle,$$
$$\Phi_{\text{OLH}(\varepsilon)}(\cdot) \triangleq \frac{C_H(\cdot) - n/|G|}{e^{\varepsilon}/(e^{\varepsilon} + |G| - 1) - 1/|G|}.$$

Where $\Psi_{\text{GRR}(\varepsilon)}$ is a GRR protocol, $C_H(\cdot)$ counts the number of possible input values that share the same hash result with the user's input value $x \in \mathbf{X}$, n is the total number of users.

C The PSFO Protocol

A Padding-and-Sampling-based Frequency Oracle (PSFO) protocol [43] is specified by the following parameters: an item set $\mathbf{x} \in \mathbf{X}$, a padding length ℓ, and a privacy budget ε. The PSFO adaptively selects a GRR protocol $\langle \Psi_{\text{GRR}}, \Phi_{\text{GRR}} \rangle$ or an OLH protocol $\langle \Psi_{\text{OLH}}, \Phi_{\text{OLH}} \rangle$ to perform frequency estimation tasks. The choice depends on the domain size d and the padding length ℓ:

$$d < e^{\varepsilon}\ell(4\ell - 1) + 1. \tag{37}$$

A PSFO is as a pair of algorithms $\langle \Psi_{\text{PSFO}}, \Phi_{\text{PSFO}} \rangle$:

$$\Psi_{\text{PSFO}(\ell,\varepsilon)}(\mathbf{x}) \triangleq \begin{cases} \Psi_{\text{GRR}(\varepsilon)}(\text{PS}_{\ell}(\mathbf{x})), & \text{if (37) is held;} \\ \Psi_{\text{OLH}(\varepsilon)}(\text{PS}_{\ell}(\mathbf{x})), & \text{otherwise.} \end{cases}$$
$$\Phi_{\text{PSFO}(\ell,\varepsilon)}(x) \triangleq \Phi_{\text{FO}(\varepsilon)}(x) \cdot \ell,$$

where $\text{PS}_{\ell}(\mathbf{x})$ is a padding-and-sampling function that pads the item-set $\mathbf{x}$ to a set with a fixed length ℓ and then randomly samples an item x from it. When the number of items possessed by a user is smaller than ℓ, then $\ell - |\mathbf{x}|$ dummy items are added to the sampling process. Otherwise, $|\mathbf{x}| - \ell$ items are truncated. When $\ell = 1$, PSFO transforms to the basic FO.

D The SVIM Protocol

A Set-Valued Item Mining (SVIM) protocol [43] is used to find the top-k support items under LDP in the scenario where each user possesses an item set $\mathbf{x} \subseteq \mathbf{X} = \{1, ..., d\}$. SVIM outputs estimated support of top-k items, and involves the following parameters: the number of users, denoted as n, the number of output targets k, the value domain X, and a privacy budget ε. In brief, there are four steps in SVIM:

Step 1: Prune the Domain. The PSFO protocol is employed. Each user first uses the **PS** function to sample an item $x \in \mathbf{x}$ and perturbs it by using either a GRR (for small domains) or an OLH (for large domains) protocol. The user reports the perturbed value by $\Psi_{\text{PSFO}(1,\varepsilon)}(\mathbf{x})$. Then the aggregator estimates the support of each value $x \in \mathbf{X}$ by $\Phi_{\text{PSFO}(1,\varepsilon)}(x)$, and generates a candidate set Y that contains the top-$2k$ support items. The aggregator then sends Y to the users.
Step 2: Size Estimation. The OLH protocol is employed in this process. Upon receiving Y (in Step 1) from the aggregator, each user calculates the size of the intersection between their private set $\mathbf{x}$ and the candidate set Y, i.e., $|\mathbf{x} \cap Y|$, and reports the perturbed value to the aggregator using $\Psi_{\text{OLH}(\varepsilon)}(|\mathbf{x} \cap Y|)$. The aggregator then estimates the length distribution by $\Phi_{\text{OLH}(\varepsilon)}(\ell)$, for all $\ell \in [1, 2, ..., 2k]$, and finds the 90 percentile L. L is sent to the users.
Step 3: Candidates Estimation. The PSFO protocol is employed. Upon receiving Y (in Step 1) and L (in Step 2), each user calculates the intersection of their private set $\mathbf{x}$ and the candidate set Y (i.e., $\mathbf{x} \cap Y$). The intersection is then perturbed and reported by executing $\Psi_{\text{PSFO}(L,\varepsilon)}(\mathbf{x} \cap Y)$. The aggregator then makes an estimate of all $x \in \mathbf{X}$ by $\Phi_{\text{PSFO}(L,\varepsilon)}(x)$.
Step 4: Estimation Update. In this step, the error caused by the **PS** function used in PSFO protocol in Step 3 is corrected. In case that the number of items possessed by a user is greater than the number of samples (L), the support of these items would be underestimated. To address this problem, this estimation is corrected by multiplying an update factor denoted as $u'(L)$. Under the assumption that unreported items share a same distribution with the reported ones, $u'(L)$ is defined as:

$$u'(L) = \frac{\sum_{\ell=1}^{2k} \Phi_{\text{OLH}(\varepsilon)}(\ell)}{\sum_{\ell=1}^{2k} \Phi_{\text{OLH}(\varepsilon)}(\ell) - \sum_{\ell=L+1}^{2k} \Phi_{\text{OLH}(\varepsilon)}(\ell)(\ell - L)}.$$

After that, the aggregator can obtain the top-k support items, along with the estimation of their supports.

E Eckart-Young-Mirsky Theorem

The Eckart-Young-Mirsky Theorem [28] for low rank approximation is as follows.

Theorem 1 (Eckart-Young-Mirsky Theorem.)**.** *Let a matrix $\mathbf{M} \in \mathbb{R}^{m \times n}$ has a SVD-decomposition $\mathbf{M} = \boldsymbol{U}\Sigma\boldsymbol{V}^{\top}$, let $r < k = rank(M)$ and truncated matrix $\boldsymbol{M}_r = \sum_{i=1}^{r} \sigma_i \boldsymbol{u}_i \boldsymbol{v}_i^{\top}$. Then for any matrix $\mathbf{N}$ of rank r, it holds for Frobenius norm:*

$$\min_{\text{rank}(N)=r} \|\mathbf{M} - \mathbf{N}\|_F = \|\mathbf{M} - \mathbf{M}_r\|_F = \sum_{i=r+1}^{m} \sqrt{\sigma_i^2}.$$

Where $\mathbf{U}$ is an unitary matrix of order $m \times m$ and $\mathbf{V}^{\top}$ is an unitary matrix of order $n \times n$. $\mathbf{V}^{\top}$ is the conjugate transpose of $\mathbf{V}$. $\mathbf{u}_i$ is a column of $\mathbf{U}$, $\mathbf{v}_i^{\top}$ is a row of $(\mathbf{V})^{\top}$. Σ_k is a $m \times n$ diagonal matrix whose element σ_i is called the singular value. $\|\cdot\|_F$ denotes Frobenius norm.

F Proof that LDP-RM Satisfies ε-LDP

LDP-RM is proven to satisfy ε-LDP, as follows.

For the first task, the SVIM protocol is utilized, which has already been proven to satisfy ε-LDP [43]. For the second task, the rank of the approximation matrix is determined by the bounded bias threshold θ, and each user reports a pseudo singular value only once. The reported value is perturbed using the HM mechanism, which has also been proven to satisfy ε-LDP [39]. For the third task, the SVIM protocol, which satisfies ε-LDP, is used again. Benefiting from the property of post-processing of LDP [12], the calculation performed by the aggregator does not affect whether ε-LDP is satisfied. Overall, the sub-procedure in LDP-RM for each task satisfies ε-LDP, and since each user only participates in one task, the entire procedure of LDP-RM also satisfies ε-LDP.

G Proof that HM-RM is Unbiased

To prove that HM-RM is an unbiased method, it is only necessary to show that the aggregator matrix $\mathbf{M}'_{agg}$ can be estimated in an unbiased manner in Task 2, since the first and third task are accomplished using the unbiased SVIM protocol.

We assume that the user item-sets in different groups are identically distributed to that of all users. In HM-RM, the j^{th} user generates a matrix $\mathbf{P}^j = \mathbf{U}_k^\top \mathbf{I}^j \mathbf{V}_k$, and she needs to sample one element in the matrix to perturb and report. Since the HM protocol is unbiased, the aggregated mean estimation of $\mathbf{P}$, represented as $\widehat{\mathbf{P}}$, satisfies:

$$\mathbf{E}[\widehat{\mathbf{P}}] = \sum_j \mathbf{P}^j/n = \sum_j \mathbf{U}_k^\top \mathbf{I}^j \mathbf{V}_k/n$$

Let the true matrix be denoted as $\mathbf{M}_{gt}$. Because $\mathbf{U}_k$ and $\mathbf{V}_k$ are both orthogonal matrices, it satisfies $\mathbf{U}_k(\mathbf{U}_k)^\top = \mathbf{E}$. Similar with Equation (29), we have:

$$\begin{aligned}\mathbf{E}[\mathbf{M}'_{agg}] &= \mathbf{E}[\mathbf{U}_k \widehat{\mathbf{P}} \mathbf{V}_k^\top] = \mathbf{U}_k \mathbf{E}[\widehat{\mathbf{P}}](\mathbf{V}_k)^\top \\ &= \mathbf{U}_k(\mathbf{U}_k)^\top \sum_{j=1}^{n} \mathbf{I}^j \mathbf{V}_k(\mathbf{V}_k)^\top/n = \sum_{j=1}^{n} \mathbf{I}^j/n = \mathbf{M}_{gt}\end{aligned}$$

where $\widehat{\mathbf{P}}$ is the aggregated result of $\mathbf{P}$. In HM-RM, users can calculate and report the complete singular value matrix to the aggregator, allowing for support of relations to be obtained in only one iteration.

H L_∞ Error of SVIM

The L_∞ error of SVIM depends on that of PSFO, since PSFO is invoked many times in SVIM. Let P_x be the true support of x and P_x^* be the estimated support of x. We have $P_x^* = \Phi_{\text{PSFO}(\ell,\varepsilon)}(x)$. Since P_x^* is an unbiased estimation of P_x and it invokes GRR or OLH adaptively according to whether the condition of $d < \ell(4\ell-1)e^\varepsilon + 1$ is met, the variance of P_x^* is:

$$\text{Var}(P_x^*) = \begin{cases} n\frac{e^\varepsilon * \ell + d - 1}{(e^\varepsilon - 1)^2} & \text{if } d < \ell(4\ell-1)e^\varepsilon + 1; \\ n\frac{4\ell^2 e^\varepsilon}{(e^\varepsilon-1)^2} & \text{otherwise.} \end{cases}$$

For any given positive integer t, the probability that the L_∞-norm of the difference between P_x^* and P_x (denoted as $||P_x^* - P_x||_\infty$) is greater than t, is calculated as:

$$\begin{aligned}&||P_x^* - P_x||_\infty = Pr[||\frac{1}{n}\sum_{j=1}^{n}(\mathbb{1}(x)^* - \mathbb{1}(x))||_\infty \geq t] \\ &(\text{Let } y^* \triangleq 2\mathbb{1}(x)^* - 1 \in [-1,1], y \triangleq 2\mathbb{1}(x) - 1 \in [-1,1]) \\ &= Pr[||\frac{1}{n}\sum_{j=1}^{n}(y^* - y)||_\infty \geq 2t] \leq 2\exp(\frac{-(2nt)^2}{\frac{1}{n}\sum_{j=1}^{n} Var(y^*) + \frac{2nt}{3}}) \\ &(\text{according to Bernstein's inequality [33]}) \\ &= 2\exp(-\frac{4(nt)^2}{4n\frac{4\ell^2 e^\varepsilon}{(e^\varepsilon-1)^2} + \frac{2nt}{3}}) = O(exp(-nt^2(\varepsilon/l)^2)).\end{aligned}$$

Taking $t = O\left(l\sqrt{\log(l/\beta)}/(\varepsilon\sqrt{n})\right)$, we have that the L_∞ error is $O\left(l\sqrt{\log(l/\beta)}/(\varepsilon\sqrt{n})\right)$ with probability at least $1-\beta$.

Table 4: Parameter Setting Guideline.

Param.	Recommended setting
ε	4 (default), 2(high privacy protection restrictions)
k	64 (default), 128(large domain)
k_s	1600 (default), recommended range $(1000, 3000)$
k_c	32 (default), recommended range $(32, 64)$
T	5 (default)
θ	0.5 (default), flexible setting based on the dataset

I Parameter setting

The primary parameters of LDP-RM include ε, k, k_s, k_c, θ, T. ε determines the balance between privacy and utility, where a smaller ε implies higher privacy. k, k_s, and k_c continuously prune the relation domain, reducing it from d^2 to k^2 to k_s to k_c, aiding in identifying target relations. These parameters indirectly affect the trade-off between privacy and utility. If set too small, they risk overlooking relations with infrequent items. Conversely, if set too large, it requires estimating numerous relation frequency values, reducing accuracy. θ limits r-rank approximation, balancing estimation error and bias. T influences the number of iterations and user groups in Task 2, indirectly affecting the trade-off between error and bias. In our experiments, we set these parameters reasonably: $k = 64$, $k_s = 1600$, $k_c = 32$, $\theta = 0.5$, and $T = 5$. Based on our parameter tuning experience, we provide a recommended parameter configuration guideline, summarized in Tab. 4, as a reference for future LDP-RM applications.

Gradients Look Alike: Sensitivity is Often Overestimated in DP-SGD

Abstract

Differentially private stochastic gradient descent (DP-SGD) is the canonical approach to private deep learning. While the current privacy analysis of DP-SGD is known to be tight in some settings, several empirical results suggest that models trained on common benchmark datasets leak significantly less privacy for many datapoints. Yet, despite past attempts, a rigorous explanation for why this is the case has not been reached. Is it because there exist tighter privacy upper bounds when restricted to these dataset settings, or are our attacks not strong enough for certain datapoints? In this paper, we provide the first per-instance (i.e., "data-dependent") DP analysis of DP-SGD. Our analysis captures the intuition that points with similar neighbors in the dataset enjoy better data-dependent privacy than outliers. Formally, this is done by modifying the per-step privacy analysis of DP-SGD to introduce a dependence on the distribution of model updates computed from a training dataset. We further develop a new composition theorem to effectively use this new per-step analysis to reason about an entire training run. Put all together, our evaluation shows that this novel DP-SGD analysis allows us to now *formally* show that DP-SGD leaks significantly less privacy for many datapoints (when trained on common benchmarks) than the current data-independent guarantee. This implies privacy attacks will necessarily fail against many datapoints if the adversary does not have sufficient control over the possible training datasets.

1 Introduction

Differential Privacy (DP) is the standard framework for private data analysis [10]. Making an algorithm differentially private limits the success any attack can have in knowing whether any datapoint was or was not an input to the algorithm given just the outputs of the algorithm. To obtain this notion of indistinguishability the algorithm needs to perform a noisy analysis of the data. In the case of deep learning, the canonical private training algorithm is DP-SGD [1], where Gaussian noise is added to the gradients computed on training examples. Much work has gone into improving the privacy analysis of DP-SGD for a given amount of noise [17, 33, 34] in an effort to minimize the impact of noise on performance.

To reiterate, this current privacy analysis for DP-SGD is *data independent*: it assumes an upper-bound on how much *any* individual datapoint from *any* dataset can have their privacy leaked. It is furthermore now known to be tight; there exist specific pairs of datasets and models for which a privacy attack can match the upper-bound of DP-SGD [35]. Yet, when training on common benchmark datasets like CIFAR10, Carlini et al. [9] empirically saw that even strong privacy attacks perform significantly worse for many datapoints than the guarantees associated with DP-SGD. That is, when training on real-world data, there is a gap between what our strongest attacks can achieve and what our current data-independent privacy analysis of DP-SGD can tell us. Hence the question, why is there a gap? Is it because our attacks are still too weak for many datapoints, or is it because there exist tighter privacy upper bounds when restricted to these dataset settings? Past work attempted to answer this by analyzing specific privacy attacks [19, 31, 40], or studying a weakened notion of DP [44]. But all past work either have bounds limited in scope or with unproven assumptions. No work has yet derived tighter indistinguishability guarantees that are specific to the data being analyzed, analogous to how DP gives indistinguishability guarantees to prevent privacy attacks (for all possible datasets).

Our work provides the first per-instance DP analysis of DP-SGD, i.e., bounds on the distinguishability of outputted models that are specific to training on a given dataset or the dataset plus a point. This analysis bridges the theoretical gap between the tight data-independent analysis of DP-SGD and what is achievable when training on common deep-learning datasets. These new guarantees follow from an exploration of the role of *sensivity* in privacy analysis. Currently, to obtain data-independent privacy guarantees, a model trainer needs to bound how much *any* individual datapoint from *any* dataset can contribute to a gradient update—a quantity known as the algorithm's sensitivity. This is currently done by setting an

upper-bound ahead of time which is enforced during training by clipping the gradient computed on each datapoint to a norm below this preset sensitivity value. However, we highlight that this overestimates the sensitivity of DP-SGD to a *specific* datapoint in a *given* dataset when that datapoint's update is similar to the update given by many other datapoints in this dataset. In deep learning, many mini-batches in a dataset do produce similar gradients [25, 37, 39], hence such a case of overestimating sensitivity is common. Our per-instance (i.e., "data-dependent") DP analysis of DP-SGD leverages this phenomenon.

Let us first focus on a single update of DP-SGD. Intuitively, if many of the datapoints produced almost the same gradient, then with high probability we would have obtained the same updated model with or without one of these datapoints. Making this intuition rigorous, we introduce a class of distributions we call *sensitivity distributions*: broadly they capture the difference between updates computed from a given mini-batch to sampling another mini-batch. From this, we derive new bounds on the privacy leakage of a single DP-SGD update that incorporates how concentrated these distributions are at small values, i.e., have many mini-batches that produce almost the same gradient. Using this bound we can show that for many datapoints in common benchmark datasets, the individual per-step guarantee for that point can be magnitudes lower than the data-independent guarantee.

Building on our analysis for a single DP-SGD update, we give a per-instance bound on the *overall* privacy leakage of a *full DP-SGD run*. The current analysis considers the model that leaks the most privacy at every step (the worst-case model) and notes that summing the maximum per-step leakages bounds the overall privacy leakage of a DP-SGD run. Yet, the sensitivity distributions that we introduce are heavily dependent on the model being updated: e.g., there is a difference between gradients computed using a partially-trained model and a randomly-initialized model. Towards not relying on analyzing worst-case models, intuitively it should not matter what the privacy leakage of the worst-case models is if they are unlikely to be reached. More rigorously, we develop a new composition theorem which allows us to upper-bound the overall per-instance privacy leakage of using DP-SGD by the expected privacy leakage at each step during training.

These analytic results give a new framework to understand the privacy guarantees of DP-SGD for individual datapoints. However, it remains to verify whether this analysis is tight enough to show that many datapoints have better privacy when training on benchmark datasets. We thus turn to experimentation.[1] The crux of implementing our results is to repeat training several times to compute the expected per-step privacy leakage. Because this one-dimensional statistic is bounded by the existing worst-case privacy analysis, one achieves non-trivial estimates with few samples. Doing this:

1. We show that when training on common benchmark datasets, many data points have better per-instance privacy than what the current data-independent guarantee associated with DP-SGD tells us. For some datapoints, we observe more than a magnitude improvement in the privacy guarantee ε. This explains the prior results we motivated our work with: for many datapoints, attacks that can only observe the outputs from training with or without the datapoint will fail.
2. In our framework, we observe a disparity where correctly-classified points obtain better privacy guarantees than misclassified points. In other words, training algorithms that lead to high-performing models quantifiably leak less per-instance privacy for many points. This is as they reach states that have similar updates for large clusters of datapoints. We hypothesize that designing model architectures to be more performative may also make them more private.
3. In classical privacy analysis, training with higher mini-batch sampling rates leaks more privacy. However we find that for certain update rules, training with higher sampling rates can give better per-instance privacy because mini-batch updates concentrate on the dataset mean; this leads to many mini-batches with similar updates.

The consequences of our work are far reaching: having better per-instance DP guarantees has implications for unlearning, generalization, memorization and privacy auditing because of how DP formulates privacy by preventing distinguishability between the models trained with or without a datapoint. For unlearning, a strong per-instance DP guarantee implies that the models coming from training with a datapoint are indistinguishable to the models trained without it. We further discuss in the paper how per-instance DP guarantees can still be used to satisfy a private notion of unlearning, and provide a naive first algorithm which we hope motivates future work. For generalization and memorization, a strong per-instance DP guarantee implies that the models coming from training without a datapoint perform similarly to those that had trained with it. For privacy auditing, our work provides empirical upper-bounds to complement previous work on lower-bounds established by strong privacy attacks, allowing future work to test if such attacks are tight. We note however that privacy auditing can affect the data-independent privacy guarantee, and discuss mitigations and paths for future work in the paper. With our framework, one can now say a specific datapoint does not need to be unlearned, or that a datapoint will not be memorized. However, our work leaves open how to apply our analysis to obtain better data-independent privacy guarantees when possible.

2 Background

Here we describe the current data-independent privacy analysis of DP-SGD (Section 2.1) and the relevance of per-instance DP in explaining empirical privacy attacks in contrast to past

[1] The code is at https://github.com/cleverhans-lab/Gradients-Look-Alike-Sensitivity-is-Often-Overestimated-in-DP-SGD.

approaches (Section 2.2). We also discuss the implication of per-instance DP for unlearning and memorization in Section 2.2. Later, in Section 5.1, we describe past work on generalizing composition theorems and how they are not applicable for a better per-instance analysis of DP-SGD.

Machine Learning Notation We consider a learning setup where we have a dataset $X = \{x_1, \cdots x_n\}$ with datapoints from some space $\mathfrak{X}$ (e.g., images and their labels). Given a loss function $\mathcal{L} : \mathbb{R}^d \times \mathfrak{X} \to \mathbb{R}$, our objective is to minimize the loss $\frac{1}{n}\sum_{x_i \in X} \mathcal{L}(\theta, x_i)$ with respect to the parameters $\theta \in \mathbb{R}^d$ of some model. The canonical approach to do this for deep learning models is to use stochastic gradient descent (SGD). However, we consider having an additional requirement that the models we obtain should not leak the "privacy" of individual datapoints

2.1 DP-SGD Analysis

DP [10] is the de-facto definition of privacy used in ML. The typical definition used in machine learning is given below, where one thinks of M as the training algorithm:

Definition 2.1 ((ε, δ)-DP)**.** An algorithm M is said to be (ε, δ)-DP if for all neighbouring datasets X, X' (i.e. Hamming distance 1 apart), we have that

$$\mathbb{P}(M(X) \in S) \leq e^{\varepsilon}\mathbb{P}(M(X') \in S) + \delta$$

DP-SGD [1, 3, 38] is an (ε, δ)-DP version of stochastic gradient descent (SGD) which clips the individual gradients and adds Gaussian noise to the mini-batch update. Formally, given a dataset X, DP-SGD repeatedly computes the following deterministic update rule $U(X_B = \{x : x \sim X \ \ with \ \ probability \ \ \frac{L}{|X|}\}) = \sum_{x \in X_B} \nabla_\theta \mathcal{L}(\theta, x) / \max(1, \frac{||\nabla_\theta \mathcal{L}(\theta, x)||_2}{C})$ and then updates $\theta \to \theta - \eta \frac{1}{L}(U(X_B) + N(0, \sigma^2 C^2))$.

The current tightest privacy analysis of DP-SGD uses Rényi-DP (RDP) [33] which implies (ε, δ)-DP; the merits of first working with RDP is that it provides a tighter privacy analysis for releasing the composition of multiple steps in DP-SGD – where each step is an update computed on a different mini-batch X_B. An algorithm M is (α, ε)-Rényi DP if for all neighbouring datasets X, X' we have $D_\alpha(M(X)||M(X')) \leq \varepsilon$ where for two probability distributions P, Q we define the α-Rényi divergence as

$$D_\alpha(P||Q) := \frac{1}{\alpha - 1} \ln \mathbb{E}_{x \sim Q}(\frac{P}{Q})^\alpha$$

The RDP analysis follows two steps:

1. Per Step: Analyzing the privacy guarantee of each training step $\eta \frac{1}{L}(U(X_B) + N(0, \sigma^2 C^2))$, which is the same as $U(X_B) + N(0, \sigma^2 C^2)$ by the post-processing property of RDP (the output of a DP algorithm can be post-processed without degrading the DP guarantee provided).
2. Composition: Understanding the accumulated RDP guarantee of releasing all the updates.

The first part was analytically studied in Mironov et al. [34] and is called the sampled Gaussian mechanism. The accumulation step follows from the composition theorem for RDP [33]. In this paper, we provide new per-step and composition privacy analyses for DP-SGD that are *specific* to a pair of neighbouring datasets X, X'.

2.2 Motivation for Studying Per-Instance DP

In contrast to the classical analysis of DP-SGD, we will analyze its per-instance Rényi DP guarantees [43] – also known as "Individual Rényi DP" [15]. That is, the RDP guarantee specific to a *given* pair of neighbouring datasets.

Definition 2.2 (Per-Instance Rényi DP)**.** We say an algorithm M is (α, ε) per-instance Rényi DP for a pair of datasets $X, X' = X \cup x^*$ if

$$\max\{D_\alpha(M(X)||M(X')), D_\alpha(M(X')||M(X))\} \leq \varepsilon$$

Colloquially, when X is understood from context, we will specify the per-instance guarantee by saying an algorithm is (α, ε)-Rényi DP for a point x^* (which determines X').

Per-instance DP guarantees provide a privacy upper bound for an adversary trying to distinguish between a specific pair of datasets X, X' given the ouput of M on one of them, and not a bound for all neighbouring datasets like classical DP. However, this granularity allows for tighter analysis of each X, X' case. The tighter per-instance DP bounds we derive will allow us to say that for specific pairs of datasets $X, X' = X \cup x^*$, privacy attacks against x^* will fail when the adversary can only observe the outputs from X or X'. More generally, if there are strong per-instance guarantees for all the neighbouring datasets the adversary can observe, then they will still fail. Instantiating our analysis, we will show that on common benchmark datasets, an adversary trying to distinguish if a specific point was added or not will fail for many points.

Our work on upper bounding per-instance DP guarantees is contrasted with past work on rigorously explaining when privacy attacks against DP-SGD will perform worse than what is implied by the current (tight) data-independent analysis. One line of work has been to upper-bound the performance of specific attacks. Putting aside the limitation in only upper-bounding specific attacks, this line of work either lacks an individualized guarantee to explain the difficulty for individual points [31] or relies on a particular threat model to explain better privacy [40]. In the case improved individual upper-bounds were achieved [18], this was with bounds that can fail due to assumptions. In short, this line of work lacks the generality/strength of Definition 2.2 in explaining why *any* empirical privacy attack will perform worse in some data settings.

A more recent line of work has been to attempt to do individual (i.e., per-instance) DP accounting for DP-SGD [44].

However, Yu et al. [44] could not analyze the per-instance guarantees of DP-SGD and instead relied on a weaker guarantee that holds if intermediate models were not random (which is not true for DP-SGD). The main technical bottleneck to extend their approach to analyze DP-SGD, as also noted by Yu et al. [44], was how to effectively analyze composition when the intermediate models are random variables. Our work provides a new composition theorem to handle this technical issue, and in doing so provides proper per-instance DP guarantees without the assumptions present in Yu et al. [44].

Per-instance DP guarantees are also important beyond privacy. Memorization [13] is a per-instance quantity (only reasoning about a particular pair X, X'), and hence is bounded by Definition 2.2. Similarly, unlearning is a per-instance quantity, and a growing section of the literature uses per-instance DP guarantees to quantify unlearning [18]. Hence in providing per-instance DP bounds for DP-SGD, we have also quantified a set of points that will not be memorized nor need to be unlearned (as they are already unlearnt). We however remark that care must be taken to user per-instance guarantees without voiding other privacy guarantees, and discuss this for unlearning where the privacy guarantee is to be agnostic to the order of unlearning requests in Section 5.4. We refer the reader to Kulynych et al. [28] for a more general discussion on the utility of DP inequalities in studying properties of deep learning.

3 A Per-Instance Analysis of DP-SGD

We now present our new analysis of DP-SGD which removes the data-independent nature of the per-step and composition analyses currently used for DP-SGD. The impact of this new analysis is presented in Section 4, where we show that many datapoints have much better privacy than suggested by the current analysis of DP-SGD, explaining the failure of many privacy attacks in practice.

The technical contributions that led to this are two-fold. At the per-step level, we generalize the notion of sensitivity to what we term *sensitivity distributions*; given two datasets, sensitivity distributions capture how similar the updates between mini-batches from either dataset are. At the composition step, we generalize RDP composition to do accounting by the "expected" intermediate privacy losses during training as opposed to the largest possible intermediate privacy losses. Together, we can now study the data-dependent behaviour of DP-SGD.

3.1 Sensitivity Distribution Generalize the (ε, δ)-DP Analysis

We first turn to (ε, δ)-DP, which is not used to analyze DP-SGD for composition reasons, but allows for simpler expressions to demonstrate the improvements afforded by particular data-dependent random variables we call *sensitivity distributions*. In particular, in this section we will first consider the classical data-independent (ε, δ)-DP analysis of the sampled Gaussian mechanism M and show how one can generalize this analysis and obtain tighter per-instance (ε, δ)-DP guarantees.

Recall that for an update rule U, the Gaussian mechanism is defined as $A(X) = U(X) + N(0, \sigma)$. The sampled Gaussian mechanism is then defined as $M(X) = A(\mathbf{X_B})$ where $\mathbf{X_B}$ is a mini-batch constructed from a dataset X by sampling each datapoint $x \in X$ independently with probability $\mathbb{P}_x(1)$ (unless otherwise stated we think of X_B, not bold-face, as a specific mini-batch). Note, one assumes the sampling probability $\mathbb{P}_x(1)$ is only a function of x and not the full dataset X, e.g., some fixed constant. The classical data-independent (ε, δ)-DP analysis of the sampled Gaussian mechanism follows two steps. First, we derive the guarantee for just the Gaussian mechanism. To do so, one first assumes a data-independent sensitivity bound C_U on U: for all $X, X' = X \cup \{x^*\}$ we have $||U(X) - U(X')||_2 \leq C_U$. This can be achieved by clipping the output values of U to have a small norm. With this constant C_U one has that the Gaussian mechanism A gives the (ε, δ)-DP guarantee $\varepsilon = C_{\delta,\sigma} C_U$ for some constant $C_{\delta,\sigma}$ depending on δ and σ where σ is the standard deviation of the added Gaussian noise [2]. To then analyze the sampled Gaussian mechanism one would incorporate the privacy gain from not sampling x^* sometimes [4][24] to get the privacy guarantees of M as (ε', δ')-DP where $\varepsilon' = \ln(\mathbb{P}_{x^*}(1) e^{C_{\delta,\sigma} C_U} + \mathbb{P}_{x^*}(0))$ and $\delta' = \mathbb{P}_{x^*}(1)\delta$. Here $\mathbb{P}_{x^*}(0) = 1 - \mathbb{P}_{x^*}(1)$, and this gain in privacy by sometimes not using the datapoint is called privacy amplification by sampling.

Towards tightening this analysis into a per-instance analysis, let

$$\Delta_{U,x^*}(X_B) := ||U(X_B) - U(X_B \cup \{x^*\})||_2$$

then $\Delta_{U,x^*}(\mathbf{X_B})$ is a data-dependent random variable which we will call a *sensitivity distribution*: it captures the change in the distribution of mini-batches updates caused by adding a point x^* to the mini-batch. The classical data-independent analysis only (implicitly) uses sensitivity distributions via the data-independent bound $|\Delta_{U,x^*}(X_B)| \leq C_U \ \forall X_B$. Instead, we will show how to directly use the L_p norms $||\Delta_{U,x^*}(\mathbf{X_B})||_p = (\mathbb{E}_{X_B}(\Delta_{U,x^*}(X_B)^p))^{1/p}$ (or generally the L_p norm of some monotonic transformation of $\Delta_{U,x^*}(\mathbf{X_B})$) to obtain tighter per-instance privacy guarantees. Furthermore, when using $p < \infty$, this analysis will be able to translate the phenomenon that many mini-batches produce similar updates into better privacy guarantees (as the sensitivity distribution concentrates at smaller values and hence has smaller p-norms). To emphasize this ability, past work that studied sampling relied mainly on the intuition that by sampling a datapoint with low probability, we have any given step often does not leak privacy for that point as it was not used. This translates to better privacy guarantes. By using the L_p norms of sensitivity distributions with $p < \infty$ we make an additional observation, which is that if many of the other mini-batches produce the same update, then

[2] For example, one can take $C_{\delta,\sigma} = \frac{\sqrt{2\ln(1.25/\delta)}}{\sigma}$ [11].

effectively we have an even lower probability of an attacker observing a noticeable shift due solely to that point.

In particular, recall that to prove per-instance (ε,δ)-DP for a pair of datasets $X, X' = X \cup \{x^*\}$ we need to bound $\mathbb{P}(M(X') \in S) \leq e^{\varepsilon}\mathbb{P}(M(X) \in S) + \delta$ and $\mathbb{P}(M(X) \in S) \leq e^{\varepsilon}\mathbb{P}(M(X') \in S) + \delta$. As a proof-of-concept on the role of sensitivity distributions, we present an analysis for the first inequality in Corollary 3.1 [3]. Inspecting Corollary 3.1, we see that it approximately follows the formula given by the classical analysis except the role of C_U is replaced with a dependency on how concentrated $\Delta_{U,x^*}(X_B)$ is at small values (the L_p norm of an exponential applied to $\Delta_{U,x^*}(X_B)$). When enough mini-batches provide updates more similar than the upper-bound C_U, the per-instance guarantee of Corollary 3.1 will significantly beat the classical data-independent analysis, as demonstrated for MNIST and CIFAR10 in Appendix B.

Corollary 3.1. *For $p \in (1,\infty)$, let $a_p = \mathbb{P}_{x^*}(1)(\mathbb{E}_{x_B}(e^{C_{\delta,\sigma}\Delta_{U,x^*}(X_B)p}))^{1/p}$, $\varepsilon' = \ln(a_p^{\frac{1}{1-1/p}}\delta'^{\frac{-1}{p-1}} + \mathbb{P}_{x^*}(0))$ and $\delta'' = \mathbb{P}_{x^*}(1)\delta + \delta'$. Then, for $X' = X \cup \{x^*\}$ we have the following per-instance guarantee*

$$\mathbb{P}(M(X') \in S) \leq e^{\varepsilon'}\mathbb{P}(M(X) \in S) + \delta''$$

Proof Sketch: The proof of Corollary 3.1 follows two stages. First by expanding mini-batch sampling and applying Holder's inequality, we can show

$$\begin{aligned}\mathbb{P}(M(X') \in S) &\leq \mathbb{P}_{x^*}(1)\mathbb{E}_{X_B}(e^{C_{\delta,\sigma}\Delta_{U,x^*}(X_B)p})^{1/p}\mathbb{P}(M(X) \in S)^{1-1/p} \\ &\quad + \mathbb{P}_{x^*}(1)\delta + \mathbb{P}_{x^*}(0)\mathbb{P}(M(X) \in S) \quad (1)\end{aligned}$$

This is stated as Lemma A.1. One then analyzes the previous inequality in cases (first case is δ is upper-bounded, and else it is lower-bounded) to obtain an (ε,δ)-DP inequality. The full proof of Corollary 3.1 is in Appendix A.2.

3.2 Per-Instance Rényi-DP Analysis for DP-SGD

With now an understanding of the power of incorporating L_p norms of sensitivity distributions (upto some transformations) into DP analyses, we turn to analyzing the Rényi-DP guarantees of DP-SGD. Rényi-DP is more suited to compose the guarantees of each step of DP-SGD to obtain the guarantees for an entire training run. We first present per-step analyses for the sampled Gaussian mechanism, and then a new composition theorem to reason about the entire training run. We then discuss how to analyze DP-SGD for general update rules, i.e., not just the sum of gradients.

Our per-step analyses will focus on integer values of α for Rényi-DP. This is for simplicity, as Rényi divergences $D_\alpha(P||Q) := \frac{1}{\alpha-1}\ln\mathbb{E}_{x\sim Q}(\frac{P}{Q})^\alpha$ are increasing in their order α, hence we can bound the guarantee for any α by the guarantee for $\lceil\alpha\rceil$. In terms of notation, we will use $X_B{}^{\tilde{\alpha}} = (X_B{}^1, \cdots, X_B{}^\alpha)$ to denote α mini-batches from X (sampled independently if random). Analogously we use $X_B'{}^{\tilde{\alpha}}$ and X_B' for X'.

[3] We will later turn to Rényi-DP which provides both inequalities.

3.2.1 Per-Instance Rényi DP for the Sum Update Rule

In Section 3.1 we introduced the sensitivity distribution $\Delta_{U,x^*}(\mathbf{X_B}) = ||U(\mathbf{X_B}) - U(\mathbf{X_B} \cup \{\mathbf{x}^*\})||_2$ and showed how directly leveraging its L_p norms gives better per-instance DP analysis. In particular, how $p < \infty$ allows one to take advantage of expected sensitivity over mini-batches. However, for update rules of the form $U(X_B) = \sum_{x_i \in X_B} g(x_i)$ (i.e., the sum update rule typically used in DP-SGD) we have $\Delta_{U,x^*}(\mathbf{X_B})$ is always a constant: $\Delta_{U,x^*}(\mathbf{X_B}) = ||g(x^*)||_2$. Hence an analysis of the sampled Gaussian mechanism that used $\Delta_{U,x^*} := \sup_{X_B \sim X}\Delta_{U,x^*}(X_B)$ would effectively capture all L_p norms of the sensitivity distribution $\Delta_{U,x^*}(X_B)$ for the sum update rule. We state such a per-instance version of the classical RDP analysis of the sampled Gaussian mechanism below.

Theorem 3.2. *For integer $\alpha > 1$, the sampled Gaussian mechanism with noise σ and sampling probability $\mathbb{P}_{x^*}(1)$ for x^* is (α,ε) per-instance Rényi DP for $X, X' = X \cup x^*$ with:*

$$\varepsilon = \frac{1}{\alpha-1}\ln\Big(\sum_{k=0}^{\alpha}\binom{\alpha}{k}(1-\mathbb{P}_{x^*}(1))^{\alpha-k}\mathbb{P}_{x^*}(1)^k \exp\frac{\Delta_{U,x^*}^2(k^2-k)}{2\sigma^2}\Big)$$

Note that some key variables in Theorem 3.2 are the sampling rate $\mathbb{P}_{x^*}(1)$ (increasing it typically increases the bound), the standard deviation of noise σ (increasing it typically decreases the bound), and the sensitivity upper-bound over mini-batches Δ_{U,x^*} (increasing it typically increases the bound). The proof strategy is analogous to Mironov et al. [34] and replaces their sensitivity upper-bound with the per-instance bound Δ_{U,x^*} on the mini-batches.

Proof Sketch: The proof follows by noting the density function for $M(X')$ can be written as a convex combination of $M(X)$ and a translated version of $M(X)$. One then proceeds to apply the quasi-convexity of Rényi divergences, and direct calculations with the Gaussian density function and the symmetry between the terms (due to translation). The full proof of Theorem 3.2 is in Appendix A.3.

3.2.2 A Generalized Rényi-DP Composition

With now an analysis for the per-step guarantees from DP-SGD (which as currently implemented uses the sum update rule), we now resolve how to obtain a per-instance RDP bound for a full training run with DP-SGD without the limitations of past composition theorem (see Section 5.1 for a discussion on past composition bounds). In particular, we provide a composition theorem that bounds the overall per-instance privacy

leakage by the "expected" per-instance privacy guarantee at each step when training on a given dataset. This is presented in Theorem 3.3.

More technically, we once again generalize the classical analysis to look at arbitrary L_p norms, but now for the composition step. The classical Rényi DP composition theorem implicity uses the L_∞ norm of the distribution of per-step guarantees at each step (coming from the distribution of possible models at each step as training is random), and Theorem 3.3 generalizes this to arbitrary L_p norms of the exponential of the per-step guarantees (with some constants to scale). By using L_p norms with $p < \infty$ we take advantage of cases where many models have better privacy guarantees than the worst model.

Theorem 3.3. *Let $p \in (1,\infty)$ and consider a sequence of functions $X_1(x_1)$, $X_2(x_1,x_2)$, $X_3(x_2,x_3),\cdots X_n(x_{n-1},x_n)$ where X_i is a density function in the second argument for any fixed value of the first argument, except X_1 which is a density function in x_1. Consider an analogous sequence $Y_1(x_1),\cdots,Y_n(x_{n-1},x_n)$. Then letting $X = \prod_{j=1}^{n} X_j$ be the density function for a sequence $x_1,\cdots,x_n$ generated according to the Markov chain defined by X_i, and similarly Y, we have*

$$D_\alpha(X||Y) \leq \frac{1}{\alpha-1}\Big(\sum_{i=0}^{n-2}\frac{(p-1)^i}{p^{i+1}} \ln\big(\mathbb{E}_{X_1,\cdots X_{n-(i+1)}}\big(e^{(g_p^i(\alpha)-1)D_{g_p^i(\alpha)}(X_{n-i}||Y_{n-i})p}\big)\big)\Big) + \frac{1}{\alpha-1}\Big(\frac{p-1}{p}\Big)^{n-1}(g_p^{n-1}(\alpha)-1)D_{g_p^{n-1}(\alpha)}(X_1||Y_1) \quad (2)$$

where $g_p(\alpha) = \frac{p}{p-1}\alpha - \frac{1}{p}$ and g_p^i is g_p composed i times, where we defined $g_p^0(\alpha) = \alpha$.

Note some key variables in Theorem 3.3 are a flexible parameter p (which we'll soon describe leads to blow-up as it gets smaller), and the distribution of per-step guarantees $D_{g_p^i(\alpha)}(X_{n-i}||Y_{n-i})$ (the more concentrated at 0 they are, the smaller the upper-bound). The proof relies on using an induction argument to continually break up the composition and is presented below.

Proof. The proof follows by repeating a similar reduction as Theorem A.2. First note

$$\begin{aligned}
&\int (X_1\cdots X_n)^\alpha (Y_1\cdots Y_n)^{1-\alpha} dx_1\cdots dx_n \\
&= \int (X_1\cdots X_{n-1})^{\alpha-1/p}(Y_1\cdots Y_{n-1})^{1-\alpha} \\
&\quad \Big(\int X_n^\alpha Y_n^{1-\alpha} dx_n\Big)(X_1\cdots X_{n-1})^{1/p} dx_1\cdots dx_{n-1} \\
&\leq \Big(\int (X_1\cdots X_n)^{\frac{p}{p-1}\alpha-\frac{1}{p-1}}(Y_1\cdots Y_n)^{\frac{p}{p-1}(1-\alpha)} dx_1\cdots dx_{n-1}\Big)^{\frac{p-1}{p}} \\
&\quad \Big(\int \Big(\int X_n^\alpha Y_n^{1-\alpha} dx_n\Big)^p (X_1\cdots X_{n-1}) dx_1\cdots dx_{n-1}\Big)^{1/p} \quad (3)
\end{aligned}$$

where the first equality was from using the markov property, and the last inequality was from Holder's inequality with Holder constant p. Do note that, defining $g_p(\alpha) = \frac{p}{p-1}\alpha - \frac{1}{p-1}$, we have $\frac{p}{p-1}(1-\alpha) = 1 - g_p(\alpha)$. So now looking at the first term of the upper-bound we got, we are back to the original expression but with $\alpha \to g_p(\alpha)$ and $n \to n-1$, and an exponent to $\frac{p-1}{p}$. Note the second term is an expectation over the $n-1$ model state of the Markov chain. Do note $\int X_n^\alpha Y_n^{1-\alpha} dx_n$ is $e^{(\alpha-1)D_\alpha(X_{n-i}||Y_{n-i})}$ for a fixed $n-1$ model state (i.e., fixed x_{n-1}). So repeating this step on the first term until we are left only with an integral over x_1 we have

$$\begin{aligned}
&\int (X_1\cdots X_n)^\alpha (Y_1\cdots Y_n)^{1-\alpha} dx_1\cdots dx_n \\
&\leq \Big(\prod_{i=0}^{n-2}\big(\mathbb{E}_{X_1,\cdots X_{n-(i+1)}}\big((e^{(g_p^i(\alpha)-1)D_{g_p^i(\alpha)}(X_{n-i}||Y_{n-i})})^p\big)\big)^{\frac{(p-1)^i}{p^{i+1}}}\Big) \\
&\quad \big((e^{(g_p^{n-1}(\alpha)-1)D_{g_p^{n-1}(\alpha)}(X_1||Y_1)})^p\big)^{\frac{(p-1)^{n-1}}{p^n}} \quad (4)
\end{aligned}$$

So now noting

$$D_\alpha(X||Y) = \frac{1}{\alpha-1}\ln\Big(\int (X_1\cdots X_n)^\alpha (Y_1\cdots Y_n)^{1-\alpha} dx_1\cdots dx_n\Big)$$

we conclude by the previous expression that

$$\begin{aligned}
&D_\alpha(X||Y) \\
&\leq \frac{1}{\alpha-1}\Big(\sum_{i=0}^{n-2}\frac{(p-1)^i}{p^{i+1}} \ln\big(\mathbb{E}_{X_1,\cdots X_{n-(i+1)}}\big((e^{(g_p^i(\alpha)-1)D_{g_p^i(\alpha)}(X_{n-i}||Y_{n-i})p}\big)\big)\Big) \\
&+ \frac{1}{\alpha-1}\Big(\Big(\frac{(p-1)^{n-1}}{p^n}\Big)\ln\big((e^{(g_p^{n-1}(\alpha)-1)D_{g_p^{n-1}(\alpha)}(X_1||Y_1)})^p\big)\Big) \quad (5)
\end{aligned}$$

which completes the proof as the last term simplifies to the term stated in the theorem. □

Applying to DP-SGD. To interpret Theorem 3.3 in the context of DP-SGD, we can let X_i be the distribution of the $i'th$ model update (for a fixed $(i-1)'th$ model) when training on one dataset D, and similarly Y_i when training on a neighbouring dataset D'. Letting $Train_{DP-SGD}$ denote the Markov chain of the intermediate model updates when using DP-SGD, we have the maximum over the bound given by Theorem 3.3 on $D_\alpha(Train_{DP-SGD}(D)||Train_{DP-SGD}(D'))$ and $D_\alpha(Train_{DP-SGD}(D')||Train_{DP-SGD}(D))$ provides our per-instance RDP guarantee for DP-SGD.

Balancing the value of p. To understand the dependence on p in Theorem 3.3, consider for a moment $p = 2$. In this case, we observe that at the i'th step, we need to compute a Rényi divergence of order $\sim 2^i\alpha$. It is known that the Rényi divergence $D_c(P||Q)$ grows with c [42], and in the case of the Gaussian mechanism, this growth is linear with c [33].

Hence this exponential growth in the Rényi divergence order can prove impractical as a useful tool to analyze DP-SGD. However, as $p \to \infty$ we see that the growth on the order of the divergence shrinks.

Yet, by taking larger p values we are effectively taking larger L_p-norms of the per-step guarantees seen in training and so effectively turn to worst-case per-step analysis as $p \to \infty$. Hence it is desirable to choose p just sufficient for there to not be a significant blow-up in the order of the divergences for a given n. This can be done by analyzing how $g_p^i(\alpha)$ grows.

Fact 3.4. *If $p = O(n)$ then $g_p^i(\alpha) \leq 2\alpha \; \forall i \leq n$. In particular, $p = 3n$ works for sufficiently large n.*

The proof follows from direct calculations with the formula for $g_p(\alpha)$.

Proof. Note that $g_p(\alpha) \leq \frac{p}{p-1}\alpha$ hence $g_p^i(\alpha) \leq (\frac{p}{p-1})^i\alpha$. From this we see showing $\frac{p}{p-1}^n \leq 2$ for $p = O(n)$ will imply $g_p^i(\alpha) \leq 2\alpha \; \forall 1 \leq n$.

Note we can equivalently show $ln(\frac{p}{p-1}) = \ln(p) - \ln(p-1) \leq \frac{\ln(2)}{n}$. But if we take $p = 3n$ note $\ln(3n) - \ln(3n-1) \leq \frac{1}{3n-1}$ by the derivative of $\ln(x) \leq \frac{1}{3n-1}$ for $x \geq 3n-1$. So it suffices to show $\frac{1}{3n-1} \leq \frac{\ln(2)}{n}$, but this is true for sufficiently large n.

□

Estimating Theorem 3.3

In cases where one does not know the expectations used in Theorem 3.3 analytically, as is the case with DP-SGD when it is applied to deep learning, one can resort to empirically estimating the means. Our goal is to understand how much better our data-dependent guarantees are than the data-independent baseline for DP-SGD on common datasets. Hence, we wish to estimate the expression of Theorem 3.3 (or specifically the per-step contributions) with an error $c\varepsilon$ for $c < 1$ where ε is the data-independent guarantee (per-step).

The following fact focuses on estimating the $i'th$ per-step guarantee with an error relative to the worst-case per-step guarantee when $p = 3n$ as is used in our experiments. In particular, letting $f := (e^{(g_p^i(\alpha)-1)D_{g_p^i(\alpha)}(X_{n-i}||Y_{n-i})})^p$ we have the $i'th$ per-step guarantee is $\frac{1}{\alpha-1}\frac{(p-1)^i}{p^{i+1}}\ln(\mathbb{E}_{X_1,\cdots,X_{n-(i+1)}}f)$ and is less than the data-independent per-step privacy guarantee ε/n if $\mathbb{E}_{X_1,\cdots X_{n-(i+1)}}f \leq e^{(\alpha-1)3\varepsilon}$ for $p = 3n$. Hence we describe the number of samples needed to estimate $\mathbb{E}f$ with precision relative to $e^{(\alpha-1)3\varepsilon}$ (with high probability), which can be done in a constant number of samples relative to the data-independent bound.

Fact 3.5. *Let ε/n be the classical α-Rényi DP guarantee for the $i'th$ step, and ε'/n be the analogous 2α-Rényi DP guarantee for the $i'th$ step. Then for $l \geq \frac{-\ln(J)}{c^2}e^{6(\alpha-1)\varepsilon-3(2\alpha-1)\varepsilon'}$ and $p = 3n$ with n s.t $g_p^{n-1} \leq 2\alpha$, we have $\mathbb{P}(|\mathbb{E}^l f - \mathbb{E}f| \geq ce^{(\alpha-1)3\varepsilon}) \leq J$. Here $\mathbb{E}^l$ denotes the empirical mean over l samples.*

The proof follows from Hoeffding's inequality.

Proof. For the given choice of p and α we have $g_p^i \leq 2\alpha$ hence $D_{g_p^i(\alpha)}(X_{n-i}||Y_{n-i}) \leq D_{2\alpha}(X_{n-i}||Y_{n-i}) \leq \varepsilon'/n$ where ε' is determined by ε (when accounting for the increase due to the α-order). Hence we have that $f \leq e^{3(2\alpha-1)\varepsilon'}$.

By Hoeffding's inequality we can hence conclude $\mathbb{P}(|\mathbb{E}^l f - \mathbb{E}f| \geq ce^{3(\alpha-1)\varepsilon}) \leq e^{-\frac{e^{6(\alpha-1)\varepsilon}c^2 l}{e^{3(2\alpha-1)\varepsilon'}}}$. Now upper-bounding the right-hand side by J and rearranging to isolate for l, we can conclude the stated condition on l.

□

3.2.3 Per-Instance Rényi DP for General Updates

The results of Section 3.2.1 and Section 3.2.2 provide a complete per-instance RDP analysis of the current implementation of DP-SGD. In particular, with the per-step update rule being the sum of gradients. In this section we ask, how should we analyze per-step guarantees (and hence DP-SGD given our composition theorem) if the update rule is not the sum? In general, the worst-case sensitivity over mini-batches may be far higher than the expected sensitivity over mini-batches (unlike the sum update rule), meaning the analysis from Theorem 3.2 may be as bad as a data-independent analysis. For example, the typical update rule used in normal SGD is the mean update rule. However, $\Delta_{U,x^*}(X_B)$ for the mean update rule is the difference between the update for the datapoint x^* and the mean of the updates on X_B; this difference is not the same for all minibatches X_B and hence would be overestimated with the analysis of Theorem 3.2. One could resolve this issue of overestimating sensitivity by using the L_p norms $||\Delta_{U,x^*}(\mathbf{X_B})||_p = (\mathbb{E}_{X_B}(\Delta_{U,x^*}(X_B)^p))^{1/p}$ with $p < \infty$ in the RDP analysis of the sampled Gaussian mechanism, as was done in the (ε,δ)-DP case. However, we are not aware of an approach to do this for Rényi DP.

Instead, we show how a new sensitivity distribution comparing all mini-batches X_B in X to all mini-batches X'_B in $X' = X \cup \{x^*\}$, as opposed to just a single point x^* as done with $\Delta_{U,x^*}(X_B)$, is amenable to a Rényi-DP analysis of the sampled Gaussian mechanism that does not look at the maximum privacy leakage over mini-batches. If the distribution of all updates given by X is similar to the distribution of all updates given by X', then analysis with this new sensitivity distribution can be expected to beat the current data-independent analysis.

Specifically, given α minibatches sampled from X, ${X_B}^{\tilde{\alpha}} \sim X$, and a particular minibatch sampled from X', $X'_B \sim X'$, we define a new sensitivity distribution for α-Rényi DP as follows:

$$\Delta_{U,\alpha}({X_B}^{\tilde{\alpha}}, X'_B) := \sum_i ||U({X_B}^i)||_2^2 - (\alpha-1)||U(X'_B)||_2^2 - ||\Delta_\alpha({X_B}^{\tilde{\alpha}}, X'_B)||_2^2$$

where $\Delta_\alpha(X_B{}^{\tilde{\alpha}}, X'_B) = (\sum_i U(X_B{}^i)) - (\alpha-1)U(X'_B)$. When letting $X_B{}^{\tilde{\alpha}}$ and X'_B be random variables, $\Delta_{U,\alpha}$ effectively compares all the mini-batches in X' to all the α-tuples of mini-batches in X. The α-tuples appear here due to their equivalence with an expectation over mini-batches to the power of α which appears when analyzing α-Rényi divergences. As described earlier, comparing this to the previous sensitivity distribution $\Delta_{U,x^*}(X_B)$, we see that this new sensitivity will compare all mini-batches in X to all mini-batches in X' (and not just to a point x^*) and hence captures more "global" changes in updates due a datapoint x^*.

Theorem 3.6 states the Rényi diveregence of the sampled Gaussian mechanism M between two arbitrary datasets using $\Delta_{U,\alpha}$ through applying a transformation on its fixed X'_B marginal values and taking its expectation over X'_B. Taking the maximum of the bounds for $D_\alpha(M(X)||M(X'))$ and $D_\alpha(M(X')||M(X))$ from Theorem 3.6 where $X' = X \cup \{x^*\}$ gives a per-instance guarantee of M for X, X'.

Theorem 3.6. *Let $\alpha > 1$ be an integer. Given two arbitrary datasets X, X', the sampled Gaussian mechanism M with noise σ satisfies:*

$$D_\alpha(M(X')||M(X)) \leq \frac{1}{(\alpha-1)} \mathbb{E}_{X_B}(\ln(\mathbb{E}_{X'^{\alpha}_B}(e^{\frac{-1}{2\sigma^2}\Delta_{U,\alpha}(X'^{\tilde{\alpha}}_B, X_B)})))$$

Some key variables in Theorem 3.6 is the standard deviation of noise σ (increasing it decreases the upper-bound) and the sensitivity distribution $\Delta_{U,\alpha}(X_B{}^{\tilde{\alpha}}, X'_B)$ (the more concentrated at 0 it is, the smaller the upper-bound). The proof relies on convexity, which is always true for the second argument of the Rényi divergence $D_\alpha(A||B)$, and then direct calculations involving Gaussians.

Proof. For simpler notation, we use $\mu_X = U(X)$. We proceed by taking α to be an integer (to use an expansion similar to Section 3.3 in Mironov et al. [34]) and utilizing Theorem 12 in Van Erven and Harremos [42]. We will let $N_{X_B} = N(\mu_{X_B}, \sigma^2)$ where $\mu_{X_B} = U(X_B)$ as stated earlier.

We proceed to bound $D_\alpha(M(X')||M(X))$ for arbitrary X', X. Hence a completely analogous argument will allow us to also bound $D_\alpha(M(X)||M(X'))$ when X' is specifically $X \cup \{x^*\}$. First note

$$\begin{aligned} D_\alpha(M(X')||M(X)) &= D_\alpha(\sum_{X'_B} \mathbb{P}(X'_B) N_{X'_B} || \sum_{X_B} \mathbb{P}(X_B) N_{X_B}) \\ &\leq \sum_{X_B} \mathbb{P}(X_B) D_\alpha(\sum_{X'_B} \mathbb{P}(X'_B) N_{X'_B} || N_{X_B}) \end{aligned} \quad (6)$$

where the last inequality is from the fact the divergence is convex in the second argument (Theorem 12 in Van Erven and Harremos [42]).

Now note

$$\begin{aligned} & e^{(\alpha-1)D_\alpha(\sum_{X'_B} \mathbb{P}(X'_B) N_{X'_B} || N_{X_B})} \\ &= \int (\sum_{X'_B} \mathbb{P}(X'_B) \frac{1}{(\sigma\sqrt{2\pi})^d} e^{\frac{-1}{2\sigma^2}|x-\mu_{X'_B}|^2})^\alpha \\ &\quad (\frac{1}{(\sigma\sqrt{2\pi})^d} e^{\frac{-1}{2\sigma^2}|x-\mu_{X_B}|^2})^{1-\alpha} dx \\ &= \sum_{X'^{\tilde{\alpha}}_B} \mathbb{P}(X'^{\tilde{\alpha}}_B) \frac{1}{(\sigma\sqrt{2\pi})^d} \int e^{\frac{-1}{2\sigma^2}((\sum_{X'^i_B} |x-\mu_{X'^i_B}|^2) - (\alpha-1)|x-\mu_{X_B}|^2)} \end{aligned} \quad (7)$$

where we expanded $(\sum_{X'_B} \mathbb{P}(X'_B) \frac{1}{(\sigma\sqrt{2\pi})^d} e^{\frac{-1}{2\sigma^2}|x-\mu_{X'_B}|^2})^\alpha$ by noting each term in the product is just iterating through all α tuples of mini-batches from X'.

Note we can for now consider the integral in each dimension, as the overall integral is the product of each dimension. Also recall from the theorem statement that we define

$$\Delta_\alpha(X'^{\tilde{\alpha}}_B, X_B) = (\sum_i \mu_{X'^i_B}) - (\alpha-1)\mu_{X_B}$$

Hence (letting everything be one dimensional for now) we have

$$\begin{aligned} & (\sum_{X'^i_B} |x-\mu_{X'^i_B}|^2) - (\alpha-1)|x-\mu_{X_B}|^2 \\ &\quad = x^2 - 2\Delta_\alpha(X'^{\tilde{\alpha}}_B, X_B)x + \sum_i \mu^2_{X'^i_B} - (\alpha-1)\mu^2_{X_B} \\ &= (x - \Delta_\alpha(X'^{\tilde{\alpha}}_B, X_B))^2 + \sum_i \mu^2_{X'^i_B} - (\alpha-1)\mu^2_{X_B} - \Delta_\alpha(X'^{\tilde{\alpha}}_B, X_B)^2 \end{aligned} \quad (8)$$

Hence, we have

$$\begin{aligned} & \int e^{\frac{-1}{2\sigma^2}((\sum_{X'^i_B} |x-\mu_{X'^i_B}|^2) - (\alpha-1)|x-\mu_{X_B}|^2)} \\ &= e^{\frac{-1}{2\sigma^2}(\sum_i \mu_{X'^i_B}{}^2 - (\alpha-1)\mu^2_{X_B} - \Delta_\alpha(X'^{\tilde{\alpha}}_B, X_B)^2)} \int e^{\frac{-1}{2\sigma^2}(x-\Delta_\alpha(X'^{\tilde{\alpha}}_B, X_B))^2} \\ &\quad = \sigma\sqrt{2\pi} e^{\frac{-1}{2\sigma^2}(\sum_i \mu^2_{X'^i_B} - (\alpha-1)\mu^2_{X_B} - \Delta_\alpha(X'^{\tilde{\alpha}}_B, X_B)^2)} \end{aligned} \quad (9)$$

Note going back to the integral over all dimensions we get $= (\sigma\sqrt{2\pi})^d e^{\frac{-1}{2\sigma^2}(\sum_i ||\mu_{X'^i_B}||_2{}^2 - (\alpha-1)||\mu_{X_B}||_2^2 - ||\Delta_\alpha(X'^{\tilde{\alpha}}_B, X_B)||_2^2)}$.

Thus to conclude we get

$$\begin{aligned} D_\alpha(M(X')||M(X)) &\leq \sum_{X_B} \mathbb{P}(X_B) D_\alpha(\sum_{X'_B} \mathbb{P}(X'_B) N_{X'_B} || N_{X_B}) \\ &= \sum_{X_B} \mathbb{P}(X_B) \frac{1}{(\alpha-1)} \\ &\ln(\sum_{X'^{\tilde{\alpha}}_B} \mathbb{P}(X'^{\tilde{\alpha}}_B) e^{\frac{-1}{2\sigma^2}(\sum_i ||\mu_{X'^i_B}||_2^2 - (\alpha-1)||\mu_{X_B}||_2^2 - ||\Delta_\alpha(X'^{\tilde{\alpha}}_B, X_B)||_2^2)}) \end{aligned} \quad (10)$$

A completely analogous calculation gives the same bound with just X_B replaced with X'_B (and vice-versa) for $D_\alpha(M(X)||M(X'))$. Taking the max over both these divergences gives a bound on the per-step per-instance Rényi-DP guarantee.

□

Hence we now have a per-step RDP analysis for DP-SGD that takes advantage of when expected minibatch sensitivity to x^* is much better than the worst cast minibatch sensitivity. While this phenomenon is not useful for studying the sum update rule (what is currently used for DP-SGD) as every mini-batch has the same sensitivity to x^*, in Section 4.2 we show this analysis allows us to provide a tighter analysis of the mean update rule. Hence, this opens the possibility of future work deploying DP-SGD with different update rules.

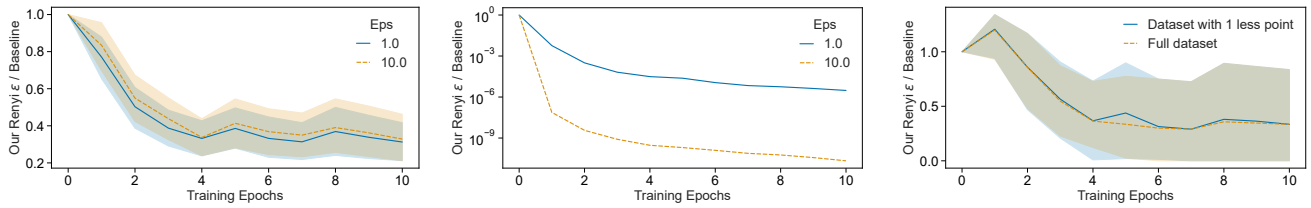
4 Empirical Results

In Section 3 we provided the first framework to analyze DP-SGD's per-instance privacy guarantees. This followed by providing new per-step analyses (Theorem 3.2 and 3.6), and a new composition theorem that relies on summing "expected" per-step guarantees (Theorem 3.3). We now highlight several conclusions our framework allows us to make about per-instance privacy when using DP-SGD. For conciseness, we defer a subset of the experimental results to Appendix B.

Experimental Setup. In the subsequent experiments, we apply our analysis on MNIST [29] and CIFAR-10 [27]. Unless otherwise specified, LeNet-5 [30] and ResNet-20 [21] were trained on the two datasets for 10 and 200 epochs respectively using DP-SGD, with a mini-batch size equal to 128, $\varepsilon = 10$, $\delta = 10^{-5}$, $\alpha = 8$ (in cases of Rényi DP), and clipping norm $C = 1.0$. All the experiments are repeated 100 times by sampling 100 data points to obtain a distribution/confidence interval if not otherwise stated. Regarding hardware, we used NVIDIA T4 to accelerate our experiments.

Data Access Assumptions We now clarify the data access assumptions needed to run our methods. Theorem 3.2 for the sum update rule only needs the individual datapoint x and the model, and the composition theorem only additionally needs the checkpoints obtained during training. Hence, as one only needs to compute Theorem 3.2 and then plug those values in our composition to obtain per-instance guarantees, computing the per-instance DP guarantee for DP-SGD does not require access to the underlying dataset but only the checkpoints and the point x^* in question (applicable for the results in Section 4.1). However, Theorem 3.6 requires sampling minibatches from the datasets, hence our approach to analyze the mean update rule requires further access to the whole dataset (applicable for the results in Section 4.2).

4.1 Many Datapoints have Better Privacy



Here we describe how our per-instance RDP analysis of DP-SGD, using Theorem 3.2 for the per-step analysis (with the update rule being the sum of gradients as is typically used) and Theorem 3.3 for the composition analysis, allows us to explain why per-instance privacy attacks will fail for many datapoints: many points have better per-instance privacy than the data-independent analysis. We further investigate the distribution of the per-instance privacy guarantees, and which points exhibit better per-instance privacy with our analysis.

Improved Per-Instance Analysis for Most Points We compare the guarantees given by Theorem 3.2 for the per-step guarantee in DP-SGD to the guarantee given by the data-independent analysis (see Section 3.3 in Mironov et al. [34]), and plot per-step contribution coming from our composition theorem. In particular, we take X to be the full MNIST training set, and randomly sample a data point x^* from the test set to create $X' = X \cup x^*$ (as mentioned earlier, we repeat the sampling of x^* 100 times to obtain a confidence interval). We train 10 different models on X with the same initialization and compute the per-step contribution from Theorem 3.3 between X and X' (using Theorem 3.2 to analyze the per-step guarantee from a given model) over the training run, shown in Figure 1a. We can see that our analysis of the per-step contribution decreases with respect to the baseline as we progress through training. This persists regardless of the expected mini-batch size, the strength of DP used during training, and model architectures; see Figure 6 in Appendix B. By Theorem 3.3 we conclude that $D_\alpha(Train_{DP-SGD}(X)||Train_{DP-SGD}(X'))$ is significantly less than the baseline for many data points.

To see our improvement over the max of $D_\alpha(Train_{DP-SGD}(X)||Train_{DP-SGD}(X'))$ and $D_\alpha(Train_{DP-SGD}(X')||Train_{DP-SGD}(X))$, i.e., the Rényi-DP guarantee, we computed the expectation when training on X and $X' = X \cup \{x^*\}$ for 10 training points x^* where X is now the training set of MNIST with one point removed and X' is the full training set. Our results are shown in Figure 1c where we see a similar decreasing trend relative to the baseline over training: we conclude by Theorem 3.3 that many datapoints have better per-instance Rényi DP than the baseline. In other words, we conclude many datapoints have stronger per-instance RDP guarantees than can be demonstrated through the classical data-independent analysis.

Long-Tail of Better Per-Instance Privacy. However, the previous figures only show the average effect over datapoints. In Figures 2a and 2b we plot the distribution of per-step guarantees over 500 data points in CIFAR10. The key observations are (1) there exists a long tail of data points with significantly better per-instance privacy than the baseline illustrated by the log-scale in Figures 2a and 2b, (2) such improvements mostly exist in the later half of the training process, and (3) such improvements are mostly independent of mini-batch size.

Correct Points are More Per-Instance Private. Next, we

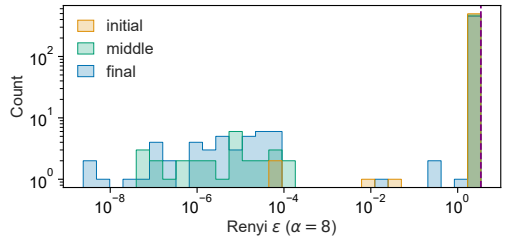
(a) Training with the datapoint $(X \cup \{x^*\})$

(b) Training with the datapoint $(X \cup \{x^*\})$ $(10^{th}$ percentile)

(c) Training with and without the datapont $(X \cup \{x^*\}$ and $X)$

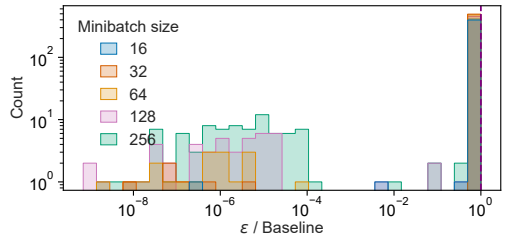
Figure 1: Per-step privacy contribution from our composition theorem (Theorem 3.3) using the per-step guarantee for the sum update rule (Theorem 3.2) as needed for DP-SGD, plotted as a fraction of the baseline data-independent per-step DP-SGD guarantee (Section 3.3 in Mironov et al. [34]). The x-axis represents the release of the intermediate models up to a given step in training. The y-axis represents the per-instance privacy leakage for a point given by the release of the model at that training step (relative to the data-independent guarantee); summing all the steps gives the overall privacy leakage of training. The different lines represent changing the Gaussian noise to train with different data-independent ε, δ-DP values. The expectations for Theorem 3.3 are computed over 10 trials. Figure 1a plots the average relative per-step contribution of 100 random points in MNIST for different strengths of the DP guarantee (i.e., different upper bounds ε) used when training on $X' = X \cup \{x^*\}$. The 10^{th} *percentile* is plotted in Figure 1b. Figure 1c plots expectation over 10 random points in MNIST when training on X' and X. We see from both subfigures our per-step contribution more tightly captures the per-instance privacy than the baseline as training progresses: using Theorem 3.3 one can conclude that many datapoints have better overall data-dependent privacy guarantees than expected by classical analysis. Note our analysis does worse at the first few steps of training as our composition theorem has a blow up in the order of the Rényi divergence for the per-step guarantee for early steps of training; if the sensitivity does not drop quickly enough our composition theorem accounts higher privacy leakage to early steps than the data-independent bounds.

turn to understanding what datapoints are experiencing better privacy when using DP-SGD. In Figure 3, we plot the per-step guarantees given by Theorem 3.2 for correctly and incorrectly classified data points at the beginning, middle, and end of training on CIFAR10 (and for MNIST in Figure 7 in Appendix B). We see that, on average, correctly classified data points have better per-step privacy guarantees than incorrectly classified data points across training. This disparity holds most strongly towards the end of training.



4.2 Higher Sampling Rates can give Better Privacy

We now highlight how our analysis, if it uses Theorem 3.6 for the per-step analysis, allows us to better analyze DP-SGD with other update rules (not the sum of gradients which is what the current implementation of DP-SGD uses and Section 4.1 analyzed). In particular, we will analyze the mean update rule and show how it has a privacy trade-off with sampling rate that is opposite to the trade-off for the sum update rule.



In normal SGD (with gradient clipping), one computes a mean for the per-step update $U(X_B) = \frac{1}{|X_B|} \sum_{x \in X_B} \nabla_\theta \mathcal{L}(\theta, x) / \max(1, \frac{||\nabla_\theta \mathcal{L}(\theta,x)||_2}{C})$. However, DP-SGD computes a weighted sum $U(X_B) = \frac{1}{L} \sum_{x \in X_B} \nabla_\theta \mathcal{L}(\theta, x) / \max(1, \frac{||\nabla_\theta \mathcal{L}(\theta,x)||_2}{C})$. Note the subtle difference between dividing by a fixed constant L (typically the expected mini-batch size when Poisson sampling datapoints) and by the mini-batch size $|X_B|$. This means for the sum the upper-bound on sensitivity is $\frac{C}{L}$, while for the mean the upper-bound on sensitivity is only C (consider neighbouring mini-batches of size 1 and 2). Hence using the mean update rule requires far more noise and so is not practical to use. We highlight how our per-instance analysis by sensitivity distributions provides better guarantees for the mean update rule.

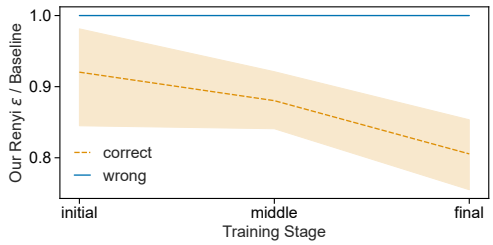
Better Analysis of the Mean Update Rule. Letting M now be the sampled Gaussian mechanism with the mean update rule, we compute the bound on $D_\alpha(M(X')||M(X))$ and $D_\alpha(M(X)||M(X'))$ given by Theorem 3.6, where we estimated the inner and outer expectation using 20 samples, i.e., 20 random $X_B'^\alpha$ (or X_B^α) for each of the 20 random X_B (or X_B'). We obtain Figure 4a and 4c by repeating this for 500 data points in CIFAR10 while varying the training stage. We observe that for both divergences, we beat the baseline analysis by more than a magnitude at the middle and end of training. We conclude Theorem 3.6 gives us better per-instance Rényi DP guarantees for the mean update rule.

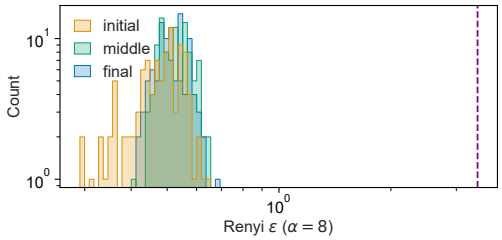
Per-Instance Privacy Improves with Higher Sampling Rate. Furthermore, counter-intuitively to typical subsample privacy amplification, in Figure 4c we see that our bound decreases with increasing expected mini-batch size: we attribute this to the law of large numbers, whereby increasing the expected mini-batch size leads to sampled mini-batches having similar updates more often and hence the sensitivity distribution concentrates at smaller values. An analogous result is shown for MNIST in Figure 8 (in Appendix B).

(a) Mini-batch Size = 128

(b) Varying Mini-batch Size

Figure 2: Distribution plots of our per-step guarantees for the sum update rule given by Theorem 3.2 for 500 datapoints in CIFAR10 with respect to: (a) different stages of training, and (b) varying mini-batch size. The x-axis represents the per-instance guarantee relative to the data-independent guarantee: i.e., the further the mass is to the left, the more our data-dependent guarantees improves upon the data-independent baseline. The purple dashed line represents the data-independent baseline. We observe a "long tail" of datapoints with magnitudes better privacy than expected in both plots, illustrated by the log scale on the x-axis.





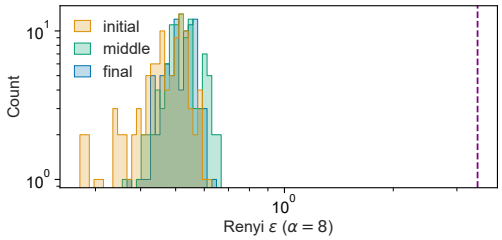


Figure 3: Per-step guarantees given by Theorem 3.2 for 500 datapoints in CIFAR10 across training stages with respect to correct or incorrect classifications. It can be seen that correctly classified datapoints are on average more private than incorrectly classified ones.

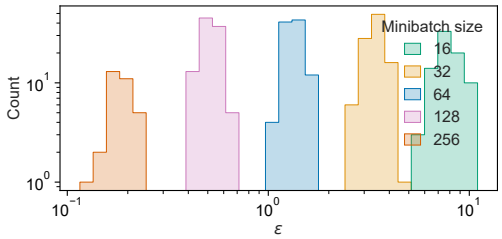
5 Discussion



Here we first discuss past work on composition theorems (Section 5.1) and the current computational trade-offs of our analysis which future work could improve (Section 5.2). We then discuss some theoretical questions based on observations from our analysis (Section 5.3). Lastly, we describe several applications of our analysis (Section 5.4).

(a) $D_\alpha(M(X')||M(X))$ Mini-batch Size = 128

(b) $D_\alpha(M(X)||M(X'))$ Mini-batch Size = 128

(c) $D_\alpha(M(X')||M(X))$ Varying Mini-batch Size

Figure 4: Distribution plots (log scale) of our per-step guarantees for the mean update rule (Theorem 3.6) for 500 datapoints in CIFAR10 with respect to different training stages and mini-batch sizes. Bounds on both $D_\alpha(M(X)||M(X'))$ and $D_\alpha(M(X')||M(X))$ are shown (the maximum of both is the per-instance Rényi-DP guarantee) for an expected mini-batch size of 128. From Figures 4a,4b, we conclude our per-step guarantees for the mean update rule (Theorem 3.6) gives better data-dependent guarantees for the mean update rule than classical analysis, and from Figure 4c that increasing the expected mini-batch size decreases our bound for this update rule (counter-intuitive to privacy amplification by subsampling).

5.1 Fully Adaptive Composition Theorems

One of the main technical contributions of this paper is generalizing the normal Rényi DP composition theorem (Proposition 1 in Mironov [33]), which sums worst-case per-step guarantees, to allow for better per-instance analysis. Other work have also generalized the composition theorem to have better per-instance analysis [15, 26], and called these new theorems Fully Adaptive Composition. For Rényi DP, Feldman and Zrnic [15] showed that composition can be done by considering the worst-case sum of the per-step guarantees from

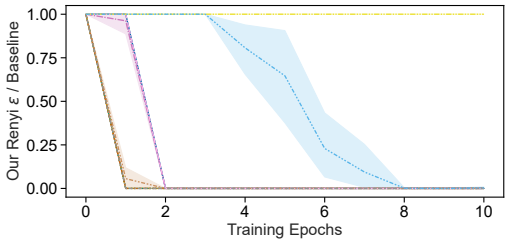


Figure 5: The expected reweighted per-step contributions which are summed for our composition theorem (Theorem 3.3) using Theorem 3.2 for the unweighted per-step guarantee for 10 different points in MNIST. The guarantees are computed once each epoch when training with the datapoint (i.e., on $X' = X \cup \{x^*\}$). The shaded region is the 95% confidence interval over 10 trials. As seen by the confidence intervals having a width a small fraction of the baseline value, with just 10 trials we are very confident in the estimates of the per-step contributions for most points.

a DP-SGD training run (Theorem 3.1 in Feldman and Zrnic [15]), as opposed to summing the worst-case guarantee at each step. Koskela et al. [26] state an analogous composition theorem for Gaussian DP. However, for DP-SGD, the degree of improvement provided by the worse-case sum compared to the normal composition is not clear. It could be that the worst-case sum is equal to the sum of the worst-case per-step guarantees, which is the case if the training run goes to worst-case states with non-zero probability at each step. Furthermore, it is hard to measure the worst-case sum to show this is not the case. Specifically, it requires measuring the L_∞ norm of a distribution, which without further assumptions beyond boundedness is much harder than the p-norms needed for our method. In short, we are the first to provide a per-instance composition theorem that can be used to determine better per-instance guarantees for DP-SGD.

5.2 Computational Limitations and Future Improvements

As explained in Section 3.2.2, there is a tension between preventing blow-up in our composition theorem (Theorem 3.3) and estimating the per-step contributions with few samples: both require manipulating a parameter p, with the former requiring large p and the latter requiring small p. We showed in Section 3.2.2 how the value of p we chose for our experiments strikes a balance where we can limit blow-up while still estimating the per-step contribution to the composition with few samples. This balance is further backed up by the confidence intervals for our estimates of the per-step contributions (see Figure 5). Nevertheless, we still require several training runs to compute the per-instance guarantee for a specific point.

Future work may be able to improve (analytically) the trade-off between blow-up and sample complexity for Theorem 3.3, and hence make it cheaper to compute the per-instance DP guarantees. Future work may also be able to derive composition theorems analogous to Theorem 3.3 which are easier to estimate. Similarly, Theorem 3.6 is computationally expensive to compute; we require computing several mini-batch updates at every step to estimate the expectations. Future work may be able to derive alternative per-step guarantees for general update rules that are easier to empirically estimate.

5.3 Theoretical Questions

In this paper we applied our analysis of DP-SGD to deep learning. In particular, our analysis led to data-dependent guarantees but stopped short of data-independent guarantees; the technical problem for deriving data-independent guarantees is bounding the "expected per-step guarantee" for all datasets. However, one can still apply our analysis of DP-SGD to classical machine learning. For example, theoretical work has shown improved data-independent privacy guarantees for convex losses [2]; the proof relied on the update rule being a contraction for convex losses. In contrast to this approach, our analysis can directly translate smaller gradient norms (in expectation) during training to better privacy guarantees. Hence, we believe an interesting future direction is applying our analysis to learning settings that permit direct calculations of sensitivity distributions and hence potentially derive data-independent guarantees.

In this direction, a particular phenomenon we wish to highlight is that by training with less noise we sometimes see a disproportional decrease in per-instance privacy consumption. This is shown in Figure 1b where training with the noise level for $\varepsilon = 10$ (data-independent bound) resulted in disproportionately smaller per-step privacy consumption than training with the higher noise level for $\varepsilon = 1$ (data-independent bound) for the 10th percentile of points with the smallest sensitivity. Stated another way, our analysis shows that for some datapoints more noise is not always better for privacy. In settings where sensitivity distributions can be explicitly calculated, one may be able to compute what this noise vs. per-instance privacy trade-off is.

5.4 Applications

In this paper, we focused on explaining how privacy attacks will fail for many datapoints if the adversary only observes typical datasets common to deep learning. This was done by providing a new per-instance DP analysis for DP-SGD. We now highlight other applications of our analysis.

Estimating Privacy A growing theme in private deep learning is empirically “estimating" privacy in different data settings, and is broadly encapsulated by privacy auditing [22, 35, 36, 45]. However, here estimating means obtaining lower bounds on privacy leakage (e.g., the parameter ε used in differential privacy). Our work presents a shift in how

we can go about estimating privacy. Our analysis provides per-instance *upper-bounds* that complement past lower-bounds, and when direct calculations of expected sensitivity distributions are not possible, one can still estimate our upper-bounds by repeating training. Future work can hence use our analysis to provide potentially matching empirical upper-bounds to previous empirical lower-bounds obtained with specific privacy attacks, and hence be able to conclude that these privacy attacks are optimal in more settings than just the worst-case.

However, it is possible that the result from auditing can be used in a way that increases the data-independent privacy leakage. Hence, to be more specific, we emphasize two use-cases of per-instance guarantees for auditing and when they retain data-independent differential privacy.

Internal Audit: The first is an internal audit, formally:

1. Input dataset D, auditing dataset D*, training algorithm T
2. Compute auditing statistics $S(D^*, T)$
3. Release $T(D)$

If T is a DP algorithm, we have the outputs of this protocol is private in the training dataset D. In our case, T is DP-SGD and our method provides tools to estimate S when S are per-instance guarantees for $x \in D^*$ (that are better than the data-independent guarantee).

Audit to Modify Training: However, if the audit affects the public release, then we can leak privacy. This leads to the second use-case, stated formally as:

1. Input D, reference algorithm T, final algorithm T'
2. Compute $S(D, T)$
3. Release $T'(D, S)$

An example of a possible T' is computing our per-instance guarantees as S, and then dropping all the least private points in the training set (in the hope of having better privacy guarantees and hence better utility vs. privacy); this is broadly captured by privacy filtering where one defines $T'(D,S) = T(D(S))$ where $D(S) \subset D$. However, note T' will now depend on the training dataset D through S. In this case, to preserve data-independent privacy, one needs to bound the sensitivity of T' to S and the sensitivity of S to D. How T' differs from T is not specified, giving a somewhat ill-posed problem. However, a specific privacy filtering algorithm was studied by Feldman and Zrnic [15] which relied on using per-step per-instance guarantees (not composition of steps). While in this paper we do not provide a filtering algorithm, we believe our composition theorem provides a new tool that future work may use in designing privacy filtering algorithms. However, we remark that at least for the filtering algorithm of Feldman and Zrnic [15], our composition theorem can be worse than their composition theorem; their algorithm enforces the almost every condition for their composition theorem which is then tighter than our composition theorem as it does not have divergence order blow-up for early steps (which ours does). This is in contrast to DP-SGD (see Section 5.1), highlighting the interdependence between algorithm and composition theorem choices.

Estimating Memorization Related to estimating privacy, a broad literature is concerned with measuring memorization [7, 8, 14, 41, 46]. The methodology for estimating memorization varies, but includes privacy attacks [8], or approximations of influence [7, 14]. Our work provides, to the best of our knowledge, the first approach to estimating memorization via upper bounds. Hence, our work may provide a complementary tool to past work on memorization.

Estimating Unlearning Unlearning a datapoint x^* is to obtain the model (distribution) coming from training on the dataset $D \setminus x^*$ given a model trained on the dataset D [6]. The only known methods to do this exactly for deep learning are variations of naively retraining on $D \setminus x^*$ [5]. Given the general intractability of exact unlearning, significant work has looked into *approximate unlearning*; approximate unlearning is to obtain the same model (distribution) as training with $D \setminus x^*$ up to some error in a predefined metric. A popular measure of approximate unlearning has been using per-instance DP guarantees [18], or only one of the per-instance DP inequalities [20][16] (which is implied by the former). However, the only known methods (to the best of our knowledge) to achieve this kind of guarantee for deep learning is to train with DP-SGD and use the data-independent DP bound as the unlearning guarantee. Our analysis allows for unlearning guarantees that are specific to individual points. While DP-SGD does not explicitly target specific points to have better unlearning guarantees, future work may be able to use our analysis to derive a modified version of DP-SGD that explicitly unlearns a subpopulation of the training set (hence future deletion requests for that subpopulation are already handled).

Another influential notion of unlearning is adaptive machine unlearning [20], which requires unlearning to also be private to the sequence of update requests; that is, regardless of the order in which people request for unlearning, one finally returns a model close to retraining without any of their data. Per-instance guarantees naturally leak information about the dataset, and so one might wonder if it is still possible to satisfy adaptive machine unlearning when using per-instance DP guarantees to unlearn. We now illustrate a specific unlearning algorithm using per-instance guarantees to not retrain when possible, which satisfies adaptive machine unlearning. However, this does not immediately give a more efficient unlearning algorithm than retraining. This is because checking the per-instance guarantees for each unlearning request is expensive with our current method. However, we hope this serves as motivation for future work on efficiently computing per-instance guarantees.

We now state a Rényi divergence version of adaptive machine unlearning; Rényi divergence implies the (ε, δ)-DP inequalities used in the original definition [20], while also being consistent with our paper. Note, we use u^i to de-

note the i^{th} unlearning request in a sequence (only deletion), $D^i = D \setminus \{\cup_{j=1}^{i} u^j\}$, and s for other hyperparameters.

Definition 5.1 (Rényi α,β,γ- adaptive unlearning)**.** We say R_A is a Rényi α,β,γ- adaptive unlearning algorithm for A if for all update request function $UpdReq$, initial datasets D, $t \geq 1$, and with probability $1-\gamma$ over the draw of unlearning requests $u^1,\cdots,u^t$ from $UpdReq$ we have $D_\alpha(R_A(D^{t-1},u^t,s^{t-1})||A(D^t)) \leq \beta$

Our adaptive unlearning algorithm using per-instance guarantees, which we will call Naive Per-Instance Unlearning (NPIU), is defined recursively over the sequence of unlearning requests. Intuitively, it checks if the current distribution of models is far away from the retraining distribution (via a triangle inequality), and if so it retrains from scratch. Formally:

1. If $\frac{\alpha-1}{\alpha-2}D_{2\alpha}(R_A(D^{t-2},u^{t-1},s^{t-2})||A(D^{t-1})) + D_{2\alpha-1}(A(D^{t-1})||A(D^t)) \leq \beta$ then $R_A(D^{t-1},u^t,s^{t-1}) = R_A(D^{t-2},u^{t-1},s^{t-2})$, i.e., keep same output as before
2. Else $R_A(D^{t-1},u^t,s^{t-1}) = A(D^t)$, i.e., retrain from scratch

Fact 5.2. *NPIU satisfies* $(\alpha,\beta,0)$*-adaptive unlearning.*

Proof. Consider any t, D, and update requests $u_1,\cdots,u_t$ (which defines the sequence of datasets). If the first condition is satisfied, then by Corollary 4 in [33] (the weak triangle inequality for Rényi Divergences) we have $D_\alpha(R_A(D^{t-2},u^{t-1},s^{t-2})||A(D^t)) \leq \frac{\alpha-1/2}{\alpha-1}D_{2\alpha}(R_A(D^{t-2},u^{t-1},s^{t-2})||A(D^{t-1})) + D_{2\alpha-1}(A(D^{t-1})||A(D^t)) \leq \beta$ hence $D_\alpha(R_A(D^{t-1},u^t,s^{t-1})||A(D^t) \leq \beta$ and so the unlearning criteria is satisfied at step t.

If not we have $R_A(D^{t-1},u^t,s^{t-1}) = A(D^t)$ and so $D_\alpha(R_A(D^{t-1},u^t,s^{t-1})||A(D^t)) = 0 \leq \beta$ meaning the unlearning criteria is once again satisfied at step t. Hence as we proved the condition holds for arbitrary t,D and sequence of update requests, the algorithm is $(\alpha,\beta,0)$ adaptive machine unlearning. This completes the proof.

□

Interpreting the algorithm in more detail, we have it checks if the per-instance guarantee $D_{2\alpha-1}(A(D^{t-1})||A(D^t))$ is small enough while recursively using information on what the per-instance guarantee was already with respect to D^{t-1}; if the sum of the guarantees is over the budget, it retrains from scratch. In particular, on accounting for the budget already used, note for each unlearning request one needs a divergence of two times the original order to implement the algorithm (see the first condition), which could be done by recursively applying Corollary 4 in [33] (as done in the proof) until one hits only divergences between $A(D^{i-1})$ and $A(D^i)$ for some i, where i is at least as large as the last time one hit the else condition and had to rerun A. Our results do not give efficient methods to measure these divergences (though computing different orders can reuse cached data such as checkpoints and gradients), but we hope unlearning motivates further work on efficiently computing per-instance guarantees.

An Alternative Framework for Forgeability However, underlying machine unlearning (as a legal requirement, e.g., the EU GDPR [32]) is the problem of whether an auditor can ever claim an entity did not unlearn a point. That is, can a model trainer claim to have trained without a point even if they in fact did? Forgeability [39] is a framework under which a model trainer can claim to have obtained their model by training on a dataset they did not in fact train on. To make a claim of training on a given dataset, forgeability relies on providing a valid Proof-of-Learning (PoL) [23] that uses the claimed dataset (different from what the model trainer originally used). Recall PoL is a sequence of checkpoints and minibatches for which the update from $i'th$ minibatch given the $i'th$ checkpoint leads to the $i+1'th$ checkpoint upto some error δ in a metric d. However, it is currently not known how to properly pick the threshold δ and metric d to define a "valid" update for a PoL (due to a lack of models for the backend noise during training), or how to make PoL efficient to verify without introducing additional security risks [12]. Hence the current framework for forgeability may not be robust until PoL is better understood.

As an alternative to using PoL, a per-instance DP guarantee tells us that it is very likely we would have obtained the same sequence of checkpoints with either of the two datasets. Hence, when an auditor claims a model trainer trained on a point (and the point has strong per-instance DP guarantees), the trainer can refute by submitting a dataset without the point and their original sequence of checkpoints and the details of their DP training implementation. Given this, an auditor that only has the information provided in the submitted proof can no longer distinguish between whether a trainer had or had not trained on the point.

6 Conclusion

Our work can be viewed as the first existential result showing better per-instance DP guarantees for deep learning when using DP-SGD. In doing so, we provided one resolution to an open problem in the field of privacy attacks against deep learning: why many privacy attacks fail in practice. However, further work is needed to convert our analysis into a fast algorithm to do privacy accounting. Our composition theorem requires computing several training runs, and the per-step analysis of Theorem 3.6 (which allows better analysis of the mean update rule) requires computing updates for many mini-batches at each step. Future work may be able to significantly reduce the cost associated with using these theorems, or propose alternative theorems that are more efficient to implement. Future work can also likely design algorithms that explicitly take advantage of sensitivity distributions, which we showed are implicit in DP-SGD in explaining its better per-instance privacy guarantees.

Acknowledgements

We would like to acknowledge our sponsors, who support our research with financial and in-kind contributions: Amazon, Apple, CIFAR through the Canada CIFAR AI Chair, DARPA through the GARD project, Intel, Meta, NSERC through the COHESA Strategic Alliance and a Discovery Grant, Ontario through an Early Researcher Award, and the Sloan Foundation. Anvith Thudi is supported by a Vanier Fellowship from the Natural Sciences and Engineering Research Council of Canada. Resources used in preparing this research were provided, in part, by the Province of Ontario, the Government of Canada through CIFAR, and companies sponsoring the Vector Institute. We would further like to thank Relu Patrascu at the University of Toronto for providing the compute infrastructure needed to perform the experimentation outlined in this work. We would also like to thank members of the CleverHans lab, Mahdi Haghifam, and our shepherd for their feedback on drafts of the manuscript.

A Proofs

A.1 Proof of Lemma A.1

Lemma A.1. *With the above notation, and $X' = X \cup \{x^*\}$, we have the per-instance inequality*

$$\begin{aligned}&\mathbb{P}(M(X') \in S)\\ &\leq \mathbb{P}_{x^*}(1)\mathbb{E}_{X_B}(e^{C_{\delta,\sigma}\Delta_{U,x^*}(X_B)p})^{1/p}\mathbb{P}(M(X) \in S)^{1-1/p}\\ &\quad + \mathbb{P}_{x^*}(1)\delta + \mathbb{P}_{x^*}(0)\mathbb{P}(M(X) \in S) \quad (11)\end{aligned}$$

Proof. First note sampling mini-batches from X' is equivalent to sampling a mini-batch X_B from X, then sampling x^* with probability $\mathbb{P}_{x^*}(1)$. Hence we have

$$\begin{aligned}\mathbb{P}(M(X') \in S) = \sum_{x_B}&(\mathbb{P}_{x^*}(1)\mathbb{P}(A(X_B \cup x^*) \in S)\\ &+ \mathbb{P}_{x^*}(0)\mathbb{P}(A(X_B) \in S))\mathbb{P}(X_B) \quad (12)\end{aligned}$$

Now note we have $\mathbb{P}(A(X_B \cup x^*) \in S) \leq e^{C_{\delta,\sigma}\Delta_{U,x^*}(X_B)}\mathbb{P}(A(X_B) \in S) + \delta$ by the (ε,δ)-DP guarantee of the Gaussian mechanism. So considering summing that over X_B we have $\sum_{X_B}\mathbb{P}(A(X_B \cup x^*) \in S)\mathbb{P}(X_B) \leq \sum_{X_B} e^{C_{\delta,\sigma}\Delta_{U,x^*}(X_B)}\mathbb{P}(A(X_B) \in S)\mathbb{P}(X_B) + \delta$. Now we apply Holder's inequality to get $\sum_{X_B} e^{C_{\delta,\sigma}\Delta_{U,x^*}(X_B)}\mathbb{P}(A(X_B) \in S)\mathbb{P}(X_B) \leq \mathbb{E}_{X_B}((e^{C_{\delta,\sigma}\Delta_{U,x^*}(X_B)})^p)^{1/p}\mathbb{E}_{x_B}(\mathbb{P}(A(x_B) \in S)^q)^{1/q}$. Note that $\mathbb{P}(A(x_B) \in S)^q \leq \mathbb{P}(A(x_B) \in S)$ for $q \geq 1$ as $\mathbb{P}(A(x_B) \in S) \leq 1$.

So we have

$$\begin{aligned}&\sum_{X_B}\mathbb{P}(A(X_B \cup x^*) \in S)\\ &\leq \mathbb{E}_{x_B}((e^{C_{\delta,\sigma}\Delta_{U,x^*}(X_B)})^p)^{1/p}\mathbb{E}_{x_B}(\mathbb{P}(A(x_B) \in S))^{1/q} + \delta \quad (13)\end{aligned}$$

So to conclude we have

$$\begin{aligned}&\mathbb{P}(M(X') \in S)\mathbb{P}(X_B)\\ &\leq \mathbb{P}_{x^*}(1)\mathbb{E}_{x_B}((e^{C_{\delta,\sigma}\Delta_{U,x^*}(X_B)})^p)^{1/p}\mathbb{E}_{x_B}(\mathbb{P}(A(x_B) \in S))^{1-1/p}\\ &\quad + \delta + \mathbb{P}_{x^*}(0)\mathbb{E}_{X_B}(\mathbb{P}(A(X_B) \in S)) \quad (14)\end{aligned}$$

Note $\mathbb{E}_{X_B}(\mathbb{P}(A(X_B) \in S)) = \mathbb{P}(M(X) \in S)$ which completes the proof.

□

A.2 Proof of Corollary 3.1

Proof. The following proof relies on independently analyzing two cases for what the value of δ could be to conclude the corollary statement (and is inspired by the proof of Proposition 3 in [33]).

Let $Q = \mathbb{P}(M(X) \in S)$ and note the first term in Lemma A.1 is then $(a_p^{\frac{1}{1-1/p}}Q)^{1-1/p}$. Now consider two cases: if $a_p^{\frac{1}{1-1/p}}Q > \delta'^{\frac{p}{p-1}}$ we have $(a_p^{\frac{1}{1-1/p}}Q)^{1-1/p} \leq a_p^{\frac{1}{1-1/p}}Q \cdot \delta'^{\frac{-1}{p-1}}$, and so the overall expression in Lemma A.1 is $\leq (a_p^{\frac{1}{1-1/p}}\delta'^{\frac{-1}{p-1}} + \mathbb{P}(0))Q + \mathbb{P}_{x^*}(1)\delta$.

Now else we have the first term is $\leq \delta'$ and the overall expression is $\leq \mathbb{P}_{\mathbf{x}^*}(0)Q + \mathbb{P}_{x^*}(1)\delta + \delta'$. Combining the two scenarios we see we always have $\mathbb{P}(M(X') \in S) \leq (a_p^{\frac{1}{1-1/p}}\delta'^{\frac{-1}{p-1}} + \mathbb{P}_{x^*}(0))\mathbb{P}(M(X) \in S) + \mathbb{P}_{x^*}(1)\delta + \delta'$, giving the stated condition.

□

A.3 Proof of Theorem 3.2

Proof. The proof is analogous to the results of Mironov et al. [34] with slight modifications to make it per-instance.

Recall that the density function for the sampled Gaussian mechanism $M(X)$ is

$$\sum_{X_B \subset D}\mathbb{P}(X_B)N(U(X_B), \sigma^2\mathbb{I}^d)$$

and for $X' = X \cup x^*$ it is

$$\begin{aligned}&\sum_{X'_B \subset X'}\mathbb{P}(X'_B)N(U(X'_B), \sigma^2\mathbb{I}^d)\\ &= \sum_{X_B \subset D}\mathbb{P}(X_B)(\mathbb{P}_{x^*}(0)N(U(X_B), \sigma^2\mathbb{I}^d)\\ &\quad + \mathbb{P}_{x^*}(1)N(U(X_B \cup x^*), \sigma^2\mathbb{I}^d)) \quad (15)\end{aligned}$$

By quasi concavity of the Rényi divergence we then have

$$\begin{aligned}
&D_\alpha(M(X)||M(X')) \\
&\leq sup_{X_B \subset X} D_\alpha(N(U(X_B),\sigma^2\mathbb{I}^d)||\mathbb{P}_{x^*}(0)N(U(X_B),\sigma^2\mathbb{I}^d) \\
&\qquad + \mathbb{P}_{x^*}(1)N(U(X_B \cup x^*),\sigma^2\mathbb{I}^d)) \\
&\leq sup_{X_B \subset X} D_\alpha(N(0,\sigma^2\mathbb{I}^d)||\mathbb{P}_{x^*}(0)N(0,\sigma^2\mathbb{I}^d) \\
&\qquad + \mathbb{P}_{x^*}(1)N(U(X_B \cup x^*) - U(X_B),\sigma^2\mathbb{I}^d)) \quad (16)
\end{aligned}$$

where we also used that Rényi divergences are translationally invariant. Now by noting the covariances are symmetric, we can apply a change of variables such that $U(X_B \cup x^*) - U(X_B) \to ||U(X_B \cup x^*) - U(X_B)||_2 e_1$ without changing the divergence. As now the change is only along one dimension of the product distribution, by additivity of Rényi divergences we conclude

$$\begin{aligned}
D_\alpha(M(X)||M(X')) &\leq sup_{X_B \subset D} D_\alpha(N(0,\sigma^2)||\mathbb{P}_{x^*}(0)N(0,\sigma^2) \\
&\quad + \mathbb{P}_{x^*}(1)N(||U(X_B \cup x^*) - U(X_B)||_2,\sigma^2)) \quad (17)
\end{aligned}$$

However as $||U(X_B \cup x^*) - U(X_B)||_2 \leq \Delta_{U,x^*}$ we can conclude (by change of variables and post-processing)

$$\begin{aligned}
D_\alpha(M(X)||M(X')) &\leq D_\alpha(N(0,\sigma^2)||\mathbb{P}_{x^*}(0)N(0,\sigma^2) \\
&\quad + \mathbb{P}_{x^*}(1)N(\Delta_{U,x^*},\sigma^2)) \quad (18)
\end{aligned}$$

Analogous calculations show

$$\begin{aligned}
&D_\alpha(M(X')||M(X)) \\
&\leq D_\alpha(\mathbb{P}_{x^*}(0)N(0,\sigma^2) + \mathbb{P}_{x^*}(1)N(\Delta_{U,x^*},\sigma^2)||N(0,\sigma^2)) \quad (19)
\end{aligned}$$

Now Theorem 5 in Mironov et al. [34] states that if P,Q are two differentiable distributions s.t $P(x) = Q(v(x))$ where $v(v(x)) = x$ and v is also differentiable, then for all $\alpha \geq 1$ and $q \in [0,1]$ $D_\alpha((1-q)P+qQ||Q) \geq D_\alpha(Q||(1-q)P+qQ)$. Now defining $Q = N(0,\sigma^2)$ and $P = N(\Delta_{U,x^*},\sigma^2)$ we have $v(x) = \Delta_{U,x^*} - x$ which is differentiable and $v(v(x)) = x$, and so conclude

$$\begin{aligned}
D(M(X)||M(X')) &\leq D_\alpha(N(0,\sigma^2)||\mathbb{P}_{x^*}(0)N(0,\sigma^2) + \\
&\quad \mathbb{P}_{x^*}(1)N(\Delta_{U,x^*},\sigma^2)) \\
&\leq D_\alpha(\mathbb{P}_{x^*}(0)N(0,\sigma^2) + \mathbb{P}_{x^*}(1)N(\Delta_{U,x^*},\sigma^2)||N(0,\sigma^2)) \quad (20)
\end{aligned}$$

As the last expression already bounds $D(M(X')||M(X))$, we proceed to bound it to get our desired guarantee.

Following the calculations of Section 3.3 in Mironov et al. [34] we use $\mu = \mathbb{P}_{x^*}(0)N(0,\sigma^2) + \mathbb{P}_{x^*}(1)N(\Delta_{U,x^*},\sigma^2)$, $\mu_0 = N(0,\sigma^2)$, and $\mu_{\Delta_{U,x^*}} = N(\Delta_{U,x^*},\sigma^2)$. We are thus interested in $D_\alpha(\mu||\mu_0) = \frac{1}{\alpha-1}\ln\int(\mu(w)/\mu_0(w))^\alpha\mu_0(w)$. Note $(\mu/\mu_0)^\alpha = \sum_{k=0}^{\alpha}\binom{\alpha}{k}(1-\mathbb{P}_{x^*}(1))^{\alpha-k}(\frac{\mu_{\Delta_{U,x^*}}}{\mu_0})^k$ and so plugging that into the previous integral, and then completing the square in the exponent for the Gaussian density function, we get

$$\begin{aligned}
D_\alpha(\mu||\mu_0) &= \frac{1}{\alpha-1}\ln\sum_{k=0}^{\alpha}\binom{\alpha}{k}(1-\mathbb{P}_{x^*}(1))^{\alpha-k} \\
&\quad \frac{1}{\sigma\sqrt{2\pi}}\int\exp\frac{-(x-k)^2 + (k^2\Delta_{U,x^*}^2 - k\Delta_{U,x^*}^2)}{2\sigma^2} \\
&= \frac{1}{\alpha-1}\ln\sum_{k=0}^{\alpha}\binom{\alpha}{k}(1-\mathbb{P}_{x^*}(1))^{\alpha-k}\exp\frac{\Delta_{U,x^*}^2(k^2-k)}{2\sigma^2} \quad (21)
\end{aligned}$$

This concludes the proof.

□

A.4 Proof of Theorem A.2

We first present a version of Theorem 3.3 that uses Cauchy-Schwarz, i.e., Holder's inequality with Holder constant $p = 2$. This we believe is easier to follow, and makes clearer the specific role of the Holder's constants in the proof of Theorem 3.3

Theorem A.2. *Consider a sequence of functions $X_1(x_1), X_2(x_1,x_2), X_3(x_2,x_3), \cdots X_n(x_{n-1},x_n)$ where X_i is a density function in the second arugment for any fixed value of the first argument, except X_1 which is a densitiy function in x_1. Consider an analogous sequence $Y_1(x_1), \cdots, Y_n(x_{n-1})$. Then letting $X = \prod_{j=1}^n X_j$ be the density function for a sequence $x_1, \cdots, x_n$ generated according to the Markov chain defined by X_i, and similarly Y, we have*

$$\begin{aligned}
&D_\alpha(X||Y) \\
&\leq \frac{1}{\alpha-1}(\sum_{i=0}^{n-2}\frac{1}{2^{i+1}}\ln(\mathbb{E}_{X_1,\cdots X_{n-(i+1)}}((e^{(g^i(\alpha)-1)D_{g^i(\alpha)}(X_{n-i}||Y_{n-i})})^2))) \\
&\qquad + \frac{1}{\alpha-1}((\frac{1}{2})^n\ln((e^{(g^{n-1}(\alpha)-1)D_{g^{n-1}(\alpha)}(X_1||Y_1)})^2)) \quad (22)
\end{aligned}$$

where $g(\alpha) = 2\alpha - 1$ and g^i means g composed i times, where $g^0(\alpha) = \alpha$

Proof. The proof relies on repeating the same reduction on the number of steps being considered. First note

$$\begin{aligned}
&\int(X_1\cdots X_n)^\alpha(Y_1\cdots Y_n)^{1-\alpha}dx_1\cdots dx_n \\
&\qquad = \int(X_1\cdots X_{n-1})^{\alpha-1/2}(Y_1\cdots Y_{n-1})^{1-\alpha} \\
&\qquad (\int X_n^\alpha Y_n^{1-\alpha}dx_n)(X_1\cdots X_{n-1})^{1/2}dx_1\cdots dx_{n-1} \\
&\leq (\int(X_1\cdots X_n)^{2\alpha-1}(Y_1\cdots Y_n)^{1-(2\alpha-1)}dx_1\cdots dx_{n-1})^{1/2} \\
&\qquad (\int(\int X_n^\alpha Y_n^{1-\alpha}dx_n)^2(X_1\cdots X_{n-1})dx_1\cdots dx_{n-1})^{1/2} \quad (23)
\end{aligned}$$

where the first equality was from using the markov property, and the last inequality was from Cauchy-Schwarz. So now looking at the first term, we are back to the original expression but with $\alpha \to g(a) = 2\alpha - 1$ and $n \to n-1$, and an exponent to $1/2$. Note the second term is an expectation over the $n-1$ model state of the Markov chain. Do note $\int X_n^\alpha Y_n^{1-\alpha}dx_n$ is $e^{(\alpha-1)D_\alpha(X_{n-i}||Y_{n-i})}$ for a fixed $n-1$ model state (i.e., fixed

x_{n-1}). So repeating this step on the first term until we are left only with an integral over x_1 we have

$$\int (X_1 \cdots X_n)^{\alpha} (Y_1 \cdots Y_n)^{1-\alpha} dx_1 \cdots dx_n$$

$$\leq \left(\prod_{i=0}^{n-2} \left(\mathbb{E}_{X_1,\cdots X_{n-(i+1)}} \left(\left(e^{(g^i(\alpha)-1)D_{g^i(\alpha)}(X_{n-i}||Y_{n-i})}\right)^2\right)\right)^{(\frac{1}{2})^{i+1}}\right)$$

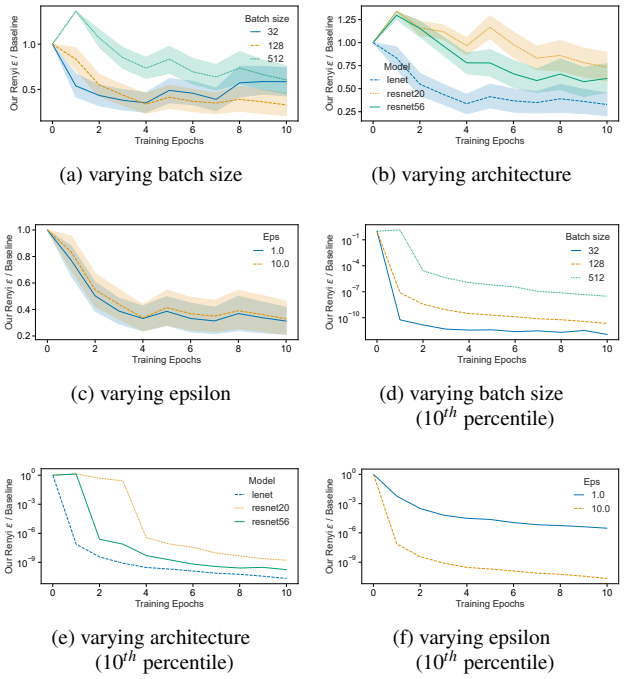
$$\left(\left(e^{(g^{n-1}(\alpha)-1)D_{g^{n-1}(\alpha)}(X_1||Y_1)}\right)^2\right)^{(\frac{1}{2})^n} \quad (24)$$

So now noting

$$D_{\alpha}(X||Y) = \frac{1}{\alpha-1} \ln\left(\int (X_1 \cdots X_n)^{\alpha} (Y_1 \cdots Y_n)^{1-\alpha} dx_1 \cdots dx_n\right)$$

we conclude by the previous expression that

$$D_{\alpha}(X||Y)$$



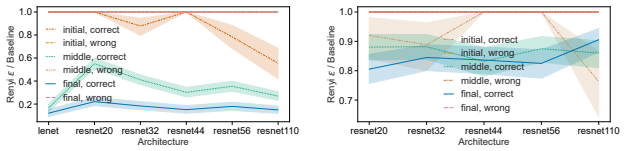
$$\leq \frac{1}{\alpha-1}\left(\sum_{i=0}^{n-2} \frac{1}{2^{i+1}} \ln\left(\mathbb{E}_{X_1,\cdots X_{n-(i+1)}} \left(\left(e^{(g^i(\alpha)-1)D_{g^i(\alpha)}(X_{n-i}||Y_{n-i})}\right)^2\right)\right)\right)$$

$$+ \frac{1}{\alpha-1}\left(\left(\frac{1}{2}\right)^n \ln\left(\left(e^{(g^{n-1}(\alpha)-1)D_{g^{n-1}(\alpha)}(X_1||Y_1)}\right)^2\right)\right) \quad (25)$$

which completes the proof. □

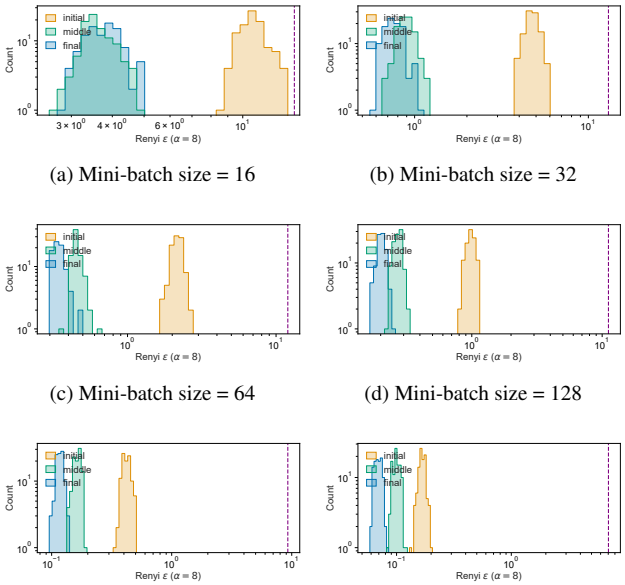
B Additional Empirical Results

We present additional experiments here.



(a) varying batch size (b) varying architecture

(c) varying epsilon (d) varying batch size (10^{th} percentile)

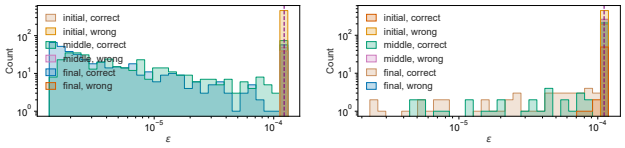


(e) varying architecture (10^{th} percentile) (f) varying epsilon (10^{th} percentile)

Figure 6: Expected privacy guarantees from Theorem 3.2 plotted as a fraction of the per-step DP-SGD guarantee over training. One can see that the ratio between our guarantee and the per-step DP-SGD guarantee (the baseline) decreases as training approaches the end, and this is consistent across different strengths of DP (i.e., ε set for the entire training), varying mini-batch size, and different model architectures.

(a) MNIST (b) CIFAR10

Figure 7: Per-step Rényi-DP guarantee given by Theorem 3.2 (divided by the baseline guarantee) plotted with respect to different model architectures trained on MNIST and CIFAR-10, at 3 stages of training. Consistently across different architectures and datasets, data points at later stages of training that are correctly classified have significantly better privacy guarantees than the baseline.



(a) Mini-batch size = 16 (b) Mini-batch size = 32

(c) Mini-batch size = 64 (d) Mini-batch size = 128

(e) Mini-batch size = 256 (f) Mini-batch size = 512

Figure 8: Distribution plots (log scale) of per-step guarantees given by Theorem 3.6 computed on LeNet-5 trained on MNIST with mean update rule and varying mini-batch sizes of $16, 32, 64, 128, 256, 512$. As specified by the legend labels, we group the plotted guarantees by whether the model is at the initial, middle, or final stage of the training. It can be seen that in all settings our guarantee is better than the baseline, which is represented by the dashed purple line. However, the guarantee distributions of points at the initial stage of training are closer to the baseline compared to the other distributions. Additionally, since a mean update rule is used, the bounds depend on the mini-batch size, and better bounds are achieved when the mini-batch size is large.

(a) MNIST (b) CIFAR10

Figure 9: Distribution plots of per-step guarantee given by Corollary 3.1 computed on MNIST and CIFAR10 with sum update rule with expected minibatch size 128, for different stages of training and correctly and incorrectly classified points. It can be seen that in all settings our guarantee is better than the baseline. However, the guarantee distributions of incorrectly classified points and points at the initial stage of training are closer to the baseline compared to the other settings.

DPAdapter: Improving Differentially Private Deep Learning through Noise Tolerance Pre-training

Zihao Wang[1]*, Rui Zhu[1]*, Dongruo Zhou[1], Zhikun Zhang[3], John Mitchell[2], Haixu Tang[1], and XiaoFeng Wang[1]
[1]*Indiana University Bloomington* [2]*Stanford University* [3]*Zhejiang University*

Abstract

Recent developments have underscored the critical role of *differential privacy* (DP) in safeguarding individual data for training machine learning models. However, integrating DP oftentimes incurs significant model performance degradation due to the perturbation introduced into the training process, presenting a formidable challenge in the differentially private machine learning (DPML) field. To this end, several mitigative efforts have been proposed, typically revolving around formulating new DPML algorithms or relaxing DP definitions to harmonize with distinct contexts. In spite of these initiatives, the diminishment induced by DP on models, particularly large-scale models, remains substantial and thus, necessitates an innovative solution that adeptly circumnavigates the consequential impairment of model utility.

In response, we introduce DPAdapter, a pioneering technique designed to amplify the model performance of DPML algorithms by enhancing parameter robustness. The fundamental intuition behind this strategy is that models with robust parameters are inherently more resistant to the noise introduced by DP, thereby retaining better performance despite the perturbations. DPAdapter modifies and enhances the sharpness-aware minimization (SAM) technique, utilizing a two-batch strategy to provide a more accurate perturbation estimate and an efficient gradient descent, thereby improving parameter robustness against noise. Notably, DPAdapter can act as a plug-and-play component and be combined with existing DPML algorithms to further improve their performance. Our experiments show that DPAdapter vastly enhances state-of-the-art DPML algorithms, increasing average accuracy from 72.92% to 77.09% with a privacy budget of $\varepsilon = 4$.

1 Introduction

Recent years have witnessed an exponential growth in applications of *deep neural networks* (DNNs) to various domains [14, 22, 44]. However, DNN models trained with standard pipelines can be attacked by an adversary that seeks to reveal the data on which the model was trained. For example, Carlini et al. [9] show that adversaries can generate and detect text sequences from the training set of a large transformer language model, while Balle et al. [5] demonstrate that powerful adversaries can reconstruct images from the training set of a classifier. Alongside other results [8, 31, 32], these studies indicate that models trained on sensitive datasets present a significant privacy risk.

Differential privacy (DP) [16] has been the golden standard for effective control of the risks of exposing training examples, and has already been adopted by various machine learning tasks for protection [15, 30, 34, 50]. A differentially private algorithm is a randomized algorithm providing a formal guarantee that any single example in the training set only has a limited impact on the output distributions of the algorithm. The privacy guarantee, denoted (ε, δ)-DP, is defined by two parameters (ε, δ), which we refer to as the *privacy budget*. The smaller these two parameters are, the closer the output distributions between the training sets that differ by a single example, and therefore the more difficult it becomes for an adversary to infer whether any single data point is included during training.

Challenges in Private Deep Learning. *Differentially private stochastic gradient descent* (DP-SGD) [1] stands out as a prevalent DPML technique. DP-SGD modifies the conventional mini-batch gradient calculation used in SGD by incorporating a privatized version, whereby the gradient of each training sample is clipped to a maximum norm. Subsequently, Gaussian noise, proportional to the clipping norm, is introduced to the sum of the clipped gradients, masking the influence of any individual example on the sum. However, the incorporation of the DP noise often comes with a notable degradation in the performance of trained models [1, 47]. In response, efforts to mitigate the adverse impact of DP on model utility have been made [38, 47, 51, 56]. Nonetheless, the detriment imposed by DP noise on differentially private models remains significant.

*The first two authors contributed equally to this work.

Our Solution. To mitigate the adverse impact of DP on model utility, prior research has underscored that transfer learning [37] from public data markedly enhances the model performance of DPML algorithms [26]. In our research, we went a step further. Specifically, we observed that the deep learning training process is highly sensitive to noise, with even a small amount of noise leading to a substantial impact on performance. However, this issue can be mitigated by the model pre-trained to minimize parameter sensitivity to noise, which we call *parameter robustness*, so as to control DP's performance impact. Therefore, we designed a new technique that pre-trains a model with its parameters robust to noise to enhance the performance of the downstream model fine-turned with DPML on private data.

A technique that could serve this purpose is *sharpness-aware minimization* (SAM), which augments parameter robustness [17, 49, 55] for the purpose of enhancing a model's generality. This technique, however, turns out to be less effective in controlling the performance impact of DPML, since it is not designed for maximizing parameter robustness. Concretely, SAM adds the worst-case perturbation to parameters before computing gradients and later removes the perturbation after each round of parameter updates. For this purpose, it calculates both the perturbation and gradients on a small batch of training samples. A problem is that although a small batch could be enough for improving a model's generality, it is inadequate for making an accurate estimate of the worst-case perturbation, thereby rendering the model parameters less robust than they could be. To address this issue, we enhanced SAM for our purpose with a new technique called DPAdapter, which utilizes two batches of training instances, a large one for a more accurate estimate of the perturbation and a small one for effective gradient descent to ensure convergence. We further theoretically analyzed why this approach improves parameter robustness against noise, thereby reducing DPML's performance impact on the downstream model fine-tuning.

Empiricaly Results. We implemented DPAdapter and evaluated its performance using a model pre-trained on CIFAR-100, which was then fine-tuned for classification tasks on CIFAR-10, SVHN, and STL-10 datasets. In these experiments, we utilized DPAdapter as the pre-training method and the CIFAR-100 dataset as the public dataset for the pre-training. The downstream tasks involve fine-tuning the pre-trained model with DPML. Our experimental results consistently show a stable improvement in the accuracy achieved by the downstream tasks, compared with those fine-tuned from the models without robustness enhancement. For instance, when the privacy budget is set to $\varepsilon = 4$ and DPML configured to DP-SGD (a popular setting), DPAdapter elevates the average accuracy across three downstream tasks to 77.09%. By comparison, when utilizing the pre-trained models without DPAdapter, the accuracy is 72.92%, over 4% below that of our approach. Note that all existing DPML enhancements could only achieve a performance gain no more than 3% [48] when the privacy budget is set to $\varepsilon = 4$. Also, many of them cannot work together, since they all focus on the downstream fine-tuning step. Our approach, however, is designed for more generic protection, independent of tasks, and compatible with these existing solutions, given its focus on the pre-training step.

Contributions. Our key contributions are outlined below:

• *New technique*. We developed DPAdapter, a new technique for enhancing parameter robustness, which leads to a general solution significantly outperforming yet compatible with existing techniques for controlling DPML's negative impacts.

• *Theoretical understandings*. We theoretically analyzed our solution to justify its effectiveness, unveiling intrinsic relations among parameter robustness, transferability, and DPML's performance impacts. Our analysis leads to new insights about how a pre-trained model can be designed to maximize the benefits of DPML.

• *Extensive empirical studies*. We conducted comprehensive empirical studies of DPAdapter on various downstream tasks and DPML algorithms under different privacy budgets. Our results show that our approach effectively enhances the performance of the downstream tasks fine-tuned by DPML.

2 Background

2.1 Differentially Private Machine Learning

Differential privacy [16] (DP) serves as a mathematical structure intended to quantify the assurance of privacy within data analysis, providing insights into the preservation of privacy when an individual's data becomes part of a publicly analyzed dataset. This concept typically involves a privacy budget, represented by ε, where a larger value signifies augmented privacy protection, and an optional failure probability, δ, defines the permissible deviation from impeccable privacy. Formally, we can define differential privacy as:

Definition 2.1 ((ε, δ)-DP)**.** *Given two neighboring datasets D and D' differing by one record, a mechanism $\mathcal{M}$ satisfies (ε, δ)-differential privacy if*

$$Pr[\mathcal{M}(D) \in S] \leq e^{\varepsilon} \cdot Pr[\mathcal{M}(D') \in S] + \delta,$$

where ε is the privacy budget, and δ is the failure probability.

Gaussian Mechanism. There are several approaches for designing mechanisms that satisfy (ε, δ)-differential privacy, among which the Gaussian mechanism is the most widely used one. It computes a function f on the dataset D in a differentially private manner, by adding to $f(D)$ a random noise. The magnitude of the noise depends on Δ_f, the *global sensitivity* or the ℓ_2 sensitivity of f. Such a mechanism $\mathcal{M}$ is given below:

$$\mathcal{M}(D) \quad = f(D) + \mathcal{N}\left(0, \Delta_f^2 \sigma^2 \mathbf{I}\right)$$

where $\Delta_f = \max_{(D,D'):D\simeq D'} ||f(D) - f(D')||_2$, $\mathcal{N}(0, \Delta_f^2\sigma^2\mathbf{I})$ denotes a multi-dimensional random variable sampled from the normal distribution with mean 0 and standard deviation $\Delta_f\sigma$, and $\sigma = \sqrt{2\ln\frac{1.25}{\delta}}/\varepsilon$.

DP-SGD. The integration of differential privacy into deep learning aims to build models that can learn from data without compromising the privacy of individuals within the dataset. Differentially private stochastic gradient descent (DP-SGD) [1] is the most widely used algorithm to enforce DP guarantee for the deep learning models. It adapts the standard SGD algorithm by introducing a few privacy-preserving modifications: *gradient clipping* and *noise addition*.

The gradient clipping operation aims to limit the sensitivity of each gradient, ensuring that a single data point does not unduly influence the model's learning process. Following gradient clipping, Gaussian noise is added to the clipped gradients before they are used to update the model parameters. This noise ensures that the exact values of the gradients—which could reveal sensitive information—are masked.

Our analysis is centered on gradient-level defenses, but it is crucial to note that methods like the Private Aggregation of Teacher Ensembles (PATE) [39] also show promise in balancing between privacy protection and model performance. Despite its potential, the applicability of PATE in federated learning [28] (which often involves continuously updated or streaming data) presents practical challenges, primarily due to the frequent necessity for retraining or re-aggregating teacher models. Federated learning serves as a clear example of a scenario where gradient-level defenses, such as DP-SGD, offer superior flexibility. DP-SGD naturally aligns with federated learning by seamlessly integrating privacy mechanisms into the model's training process, thus effectively managing real-time data updates. This inherent adaptability, combined with the challenges associated with implementing PATE in dynamic environments, highlights the reasons PATE-like strategies are not the focus of our analysis.

Privacy Budget Composition. On a broader spectrum, the overall privacy budget calculation of DP-SGD is established by demonstrating the privacy budget of each iteration under certain (ε, δ) values, followed by applying amplification by subsampling and composition throughout the iterations.

2.2 Adversarial Robustness and Model Parameter Robustness

Adversarial Training (AT). It is widely regarded as the most effective defense method against adversarial attacks [4, 6, 18, 40, 46]. AT essentially employs a "fight fire with fire" approach. It introduces adversarial examples into the training set, which are slight, carefully calculated modifications of the original inputs. These modifications are designed to mislead the model into making erroneous predictions. By learning from these adversarial examples, the model improves its ability to correctly classify such inputs in the future, thereby enhancing its overall resilience and robustness against adversarial attacks.

Parameter Robustness. It typically refers to the sensitivity of a model to small perturbations in its parameters. When discussing parameter robustness, we are interested in the model output (e.g., predictions on testing data) changes when its parameters are subjected to some level of noise.

Specifically, given a model f parameterized by θ and a test sample x, the robustness of the model with respect to its parameters can be defined as:

$$\rho(f) = \max_{\boldsymbol{x},\theta,\Delta} |f_{\theta+\Delta}(\boldsymbol{x}) - f_\theta(\boldsymbol{x})| / \|\Delta\|_2$$

where $\rho(f)$ represents the maximum change in the model's output. Δ is the noise added to the model parameters θ. $\|\cdot\|$ denotes a norm, for instance, the L2 norm.

This definition provides a measure of the potential variation in the model's output when its parameters undergo perturbation due to noise. A diminutive value of ρ is indicative of pronounced parameter robustness. Subsequently, we aim to *enhance* the parameter robustness of f, denoted by the objective of reducing the value of $\rho(f)$.

Robust Accuracy. We resort to *robust accuracy* as an evaluation metric for parameter robustness in the classification paradigm; Given a specific model f_θ, we introduce Gaussian noise, represented as $N(0, 0.1)$, uniformly across parameters spanning all layers. The resultant perturbed model is represented as $f_{\hat{\theta}}$. The model's performance, when faced with this perturbation, is then assessed. Consequently, the robust accuracy is computed over a dataset D and is delineated as:

$$\text{Robust Accuracy} = \frac{1}{|D|}\sum_{x\in D} I(f_{\hat{\theta}}(x) = y)$$

where I is the indicator function that returns 1 when the condition inside is true and 0 otherwise. A model exhibiting a higher robust accuracy indicates stronger parameter robustness, corresponding to a lower value of ρ.

The optimization of parameter robustness can be achieved through a technique known as *sharpness-aware minimization* (SAM) [17, 49, 55]. This method typically involves computing the worst-case perturbation on the parameters. The optimization then takes place on the model parameters subjected to this worst-case perturbation. The intention is to ensure that the model retains a significant portion of its performance, even when subjected to the worst-case perturbation. However, this technique is not designed to maximize parameter robustness but to achieve better generality. Consequently, it proves to be less effective in mitigating the performance impact of DPML (Section 5.2).

3 Problem Formulation and Key Observations

3.1 Problem Formulation

Threat Model. We consider a scenario where an attacker applies privacy attacks [5, 8, 9, 31, 32] to unveil the training data of a model. To defend against the attacks, the defender endeavors to build the model using differential privacy, which provably protects sensitive data while preserving its original utility. Additionally, the defender possesses a public dataset related to the private data, aligning with the standard assumption of transfer learning that the source and the target datasets follow similar but not identical distributions.

Problem Definition. Our aim is to build a pre-trained model that can be used for improving both the accuracy and privacy protection of the models trained for downstream tasks. Specifically, to build a pre-trained model that serves as a beneficial initialization for DP fine-tuning, we seek to answer two key questions: 1) what properties the pre-trained model should exhibit for the benefit of downstream models? and consequently 2) how the pre-training of the model should be executed to acquire these properties?

3.2 Motivation and Key Observations

Motivation. Our motivation to enhance the performance of the DPML algorithm using pre-trained models is rooted in our understanding of adversarial robustness training. The traditional adversarial training (AT) incrementally conditions the model to resist perturbations of its input. However, in the DPML algorithm, the noise is predominantly introduced into the gradients, or equivalently, into the model's parameters. Hence, we ask if there is any technique similar to AT that may condition the model to resist perturbations of its parameters. Obviously, if this can be achieved, the impact of the noise introduced by the DPML algorithm on the model performance could be minimized. It turns out, such an AT method has been proposed previously, referred to as the *sharpness aware minimization (SAM)*, which confers noise resilience to parameters Section 2.2. Based on the premise, we introduce two working hypotheses.

We first consider a specialized transfer learning scenario where the training datasets for the upstream and downstream tasks are i.i.d. (independent and identically distributed); for instance, each of these training datasets represent a random sub-sample of an overarching dataset. Under this scenario, we propose the first hypothesis:

Hypothesis 1. *Assuming the datasets A and B are randomly sampled from the same distribution, if a pre-trained model built from the dataset A possesses enhanced parameter robustness, the model fine-tuned on the dataset B using the DPML algorithm under a fixed privacy budget will yield better performance.*

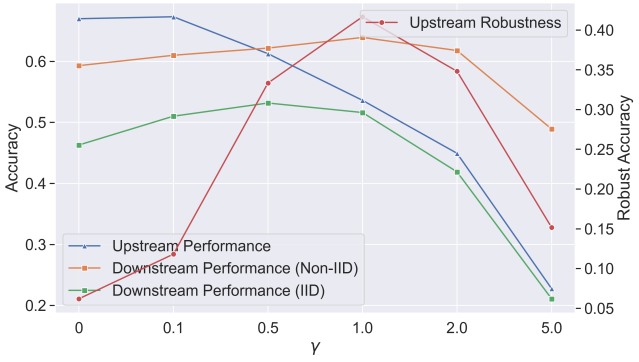


Figure 1: Impact of perturbation magnitude on AMP.

Next, we extend our hypothesis into a more general transfer learning scenario, where the upstream and downstream datasets are not identical but related, for example, when the upstream training data comes from ImageNet and the downstream data is sourced from CIFAR-10. Under this scenario, we have our second hypothesis.

Hypothesis 2. *Assuming the datasets A and B are sampled from two different but similar distributions, respectively, if a pre-trained model built from the dataset A exhibits strong parameter robustness, the model fine-tuned on the dataset B using the DPML algorithm under a fixed privacy budget will yield better performance.*

Rationales. Hypothesis 1 is quite intuitive. Drawing parallels from AT — which can counteract the effects of adversarial examples by introducing noise into the input — we anticipate that SAM can similarly mitigate the implications of the noise added to parameters by the DPML algorithm. Hypothesis 2, on the other hand, is inspired by prior work [42]. It has been observed that pre-trained models, when subjected to AT, can impart some degree of their acquired adversarial robustness to downstream models via transfer learning. This led us to a deeper contemplation: Can the parameter robustness garnered through SAM training also be transferred to downstream tasks through transfer learning? If this transfer of parameter robustness is indeed feasible, then, based on Hypothesis 1, it could potentially alleviate the performance degradation in downstream training using the DPML algorithm.

Empirical Validation. To evaluate our hypotheses, we utilized state-of-the-art Adversarial Model Perturbation (AMP) methodologies. Our models were exposed to an array of AMP intensities, producing pre-trained models that span a spectrum of parameter robustness. We then measured their parameter robustness by assessing the model accuracy on testing data after perturbation, and analyzed their performance in conjunction with DP-SGD.

Specifically, to validate Hypothesis 1, we examined a scenario where both upstream and downstream training data were sourced from the CIFAR-100 dataset, with the upstream

data constituting 90% of the CIFAR-100 training dataset and the downstream data constituting the remaining 10%. As depicted in Figure 1, the x-axis signifies the parameter γ in AMP, which modulates the intensity of parameter robustness. By adjusting γ, we derived pre-trained models of various levels of robustness (indicated by the red line). This robustness peaks with increasing γ and then starts to wane. Correspondingly, the green line, which illustrates the accuracy of the model's performance after downstream optimization using DP-SGD, displays an initial rise followed by a decline, mirroring the trajectory of parameter robustness. This result suggests that if the upstream and downstream training datasets both follow an i.i.d. distribution, the parameter robustness of upstream model is directly correlated with the performance of the downstream fine-tuned model.

For Hypothesis 2, we used the upstream training data comprising the same 90% of the CIFAR-100 dataset, while the downstream training data was entirely from the CIFAR-10 dataset. Still referencing Figure 1, the blue line indicates the performance (accuracy) of the downstream model after DP-SGD optimization. Consistent with the results above, the blue line showcases an initial increase in performance of the downstream model followed by a significant drop, which is highly consistent with the pattern of the parameter robustness. This result suggests that in a transfer learning scenario, the parameters robustness of an upstream pre-trained model can influence the performance of the downstream model trained using the DPML algorithm. Additionally, we observed a gradual decline in the accuracy of the upstream model with an increase in its parameter robustness, indicating a trade-off between the parameter robustness and the accuracy of the model. If the accuracy of the upstream model drops too significantly, it can detrimentally impact the performance of the downstream model. Taking these observation into account, we outline our design objectives below, aiming to illustrate our intent of devising a cost-effective strategy to build a pre-trained model that strikes a balance between two goals, i.e., to increase the parameter robustness while maintaining the high accuracy of the pre-trained model.

We further explore the transferability of parameter robustness in the context of transfer learning. In specific, we used CIFAR-100 as the upstream training dataset, and employed the CIFAR-10, SVHN, and STL-10 datasets, respectively for downstream training. We first trained the model on the upstream data with five different intensities of Adversarial Model Perturbation (AMP) characterized by the values $\gamma = 0, 0.1, 0.2, 0.5$, and 1.0. This procedure yielded five sets of pre-trained models, each with distinct robust accuracies. Subsequently, we performed transfer learning from each of these five distinct pre-trained models on the downstream data. Upon the completion of training, the robust accuracy of models on the downstream dataset was computed. Figure 2 shows the high between the robust accuracies of the pre-trained models (x-axis) and the robust accuracy of downstream models

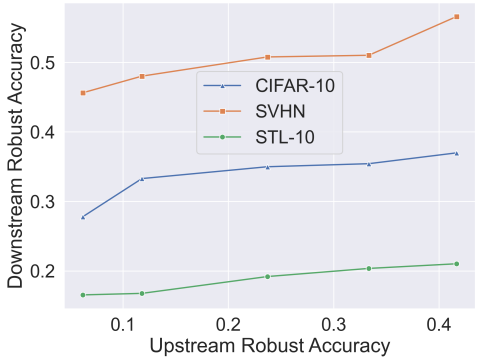

Figure 2: The relationship between the parameter robustness of the pretrained models and that of the models fine-tuned on the downstream tasks.

(y-axis). In general, it can be observed that the pre-trained models with higher robust accuracy tend to maintain their enhanced robust accuracy during the transfer learning for the downstream tasks. This observation underscores the inherent transferability of parameter robustness in a transfer learning context.

Design Goals. Based on the results from the toy examples as illustrated above, our objective is to build a pre-trained model that achieves two primary goals: robustness and effectiveness, which we elaborate below.

• *Robustness*. As observed earlier, we aim for our pre-trained model to exhibit strong parameter robustness (for instance, a smaller value of ρ). This ensures that when the downstream model employs the DPML algorithm, the influence on its performance is minimal.

• *Generality*. While striving for pronounced parameter robustness in the pre-trained model, it is imperative that the model's inherent performance remains commendable. Should we solely emphasize parameter robustness, the model may exhibit an extremely low value of ρ—indicating high robustness—but low accuracy. For instance, $f(x;\theta+\Delta) = f(x;\theta) \neq y$. As illustrated in Figure 1, when γ exceeds 1, the pre-trained model's performance may deteriorate considerably. As a result, the DPML algorithm employed for downstream training might not inherit sufficient effective features from the pre-trained model, leading to a diminished outcome. Hence, it is equally pivotal for the pre-trained model to retain high performance as compared to enhance its parameter robustness.

4 DPAdapter

In essence, the design of DPAdapter is rooted in the two observations mentioned earlier. Our objective is for the pre-trained model to achieve higher parameter robustness while maintaining its performance. Given the observation that parameter robustness can be transferred when the model is passed down-

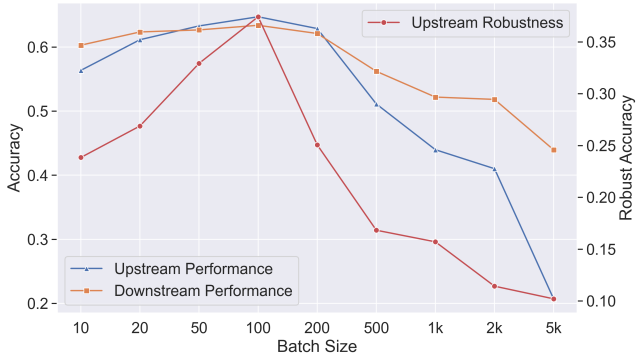

Figure 3: Impact of different batch sizes on AMP.

stream, the fine-tuning DPML algorithms can operate under the same privacy budget. This, in turn, minimizes the impact on performance.

4.1 Design Challenge

We observe that while AMP can enhance parameter robustness, leading to an improvement in the DP-SGD performance of downstream fine-tuned models, the extent of this robustness enhancement is quite limited. This, in turn, results in only a marginal performance boost. As we illustrated in Section 5.4 using AMP as an example, the effect of existing model parameter adversarial training on enhancing the parameter robustness of pre-trained models is not significant. Consequently, the impact on the performance of downstream DPML algorithms is also marginal. This is primarily because the existing methods aimed at improving parameter robustness were primarily designed to enhance model generalization. Since they were not explicitly designed for robustness enhancement, the gains in parameter robustness tend to be limited. While these methods can indeed be adjusted to prioritize robustness by increasing the perturbation magnitude at the expense of generalization, such a trade-off is often costly. As depicted in Figure 1, a high perturbation magnitude not only fails to bring much-added robustness but also makes the model challenging to converge. Given these challenges, we introduce DPAdapter, a novel approach to help pre-trained models achieve higher parameter robustness and minimize the adverse impact on performance when downstream models employ DPML algorithms.

4.2 Design Intuition

As highlighted in the "Challenge" section above, traditional methods of enhancing parameter robustness often result in a significant trade-off between parameter robustness and model performance. We've observed that these conventional methods of improving parameter robustness primarily leverage schemes akin to SGD for adversarial training. During a single optimization iteration, the batch used to compute the perturbation and the batch used to calculate the gradient direction for optimization are the same. However, the rationale behind this approach has not been extensively discussed. In fact, taking the AMP as an example, as depicted in Figure 3, when a large batch size is chosen, the model's training becomes suboptimal due to the utilization of this large batch. On the contrary, if the batch size is too small, computing the perturbation based on such limited data leads to inaccurate perturbations, subsequently compromising the robustness of the training. Note that a recent study suggests employing a linear scaling rule to adjust the learning rate based on the modified batch size [20]; specifically, the learning rate should be multiplied by k when using a batch size of kN. Consequently, in this experiment, we also adhere to this setting to approximate the optimal learning rate for each batch size.

Based on these observations, we decided to decouple the batches used for computing perturbations and those for calculating parameter gradients during the optimization process. For computing perturbations, we chose a batch size larger than what is typically required for regular training. The reasoning is that perturbation computations don't necessarily benefit from being stochastic. Ideally, the entire dataset would be used to compute the perturbation. However, due to computational resource constraints, using the complete dataset for this purpose is challenging. Hence, we opt for a compromise by selecting a relatively larger batch size for the perturbation computations. In contrast, for batches used to compute model optimization gradients, we chose sizes that are conducive to model optimization, ensuring we avoid sizes that are excessively large or small that could impair model performance.

4.3 Methodology Overview

Figure 4 illustrates the overall workflow of DPAdapter. To efficiently achieve the parameter robustness of pre-trained models, DPAdapter employs a Min-Max optimization, iterating over four steps of model updating as presented below.

Step 1: Warming-up. The pre-trained model initiates with a warming-up phase using standard training techniques to ensure the accuracy (ACC) meets the targeted benchmark. We refer to the model post-warming-up as f_θ.

Step 2: Worst-case Model Perturbation. We select an enlarged batch of training data, denoted as $\mathcal{B}_1$. We then compute the direction of the gradient that maximizes the loss of this batch under the current model parameters. Subsequently, we perturb the model parameters along this direction with the intention of impairing the model's predictive capability on this large batch of data when subjected to such perturbation. We denote the perturbation as Δ, and the model after perturbation as $f_{\theta+\Delta}$.

Step 3: Update on the Perturbed Model. To enhance the model's resilience to perturbations in its parameters (param-

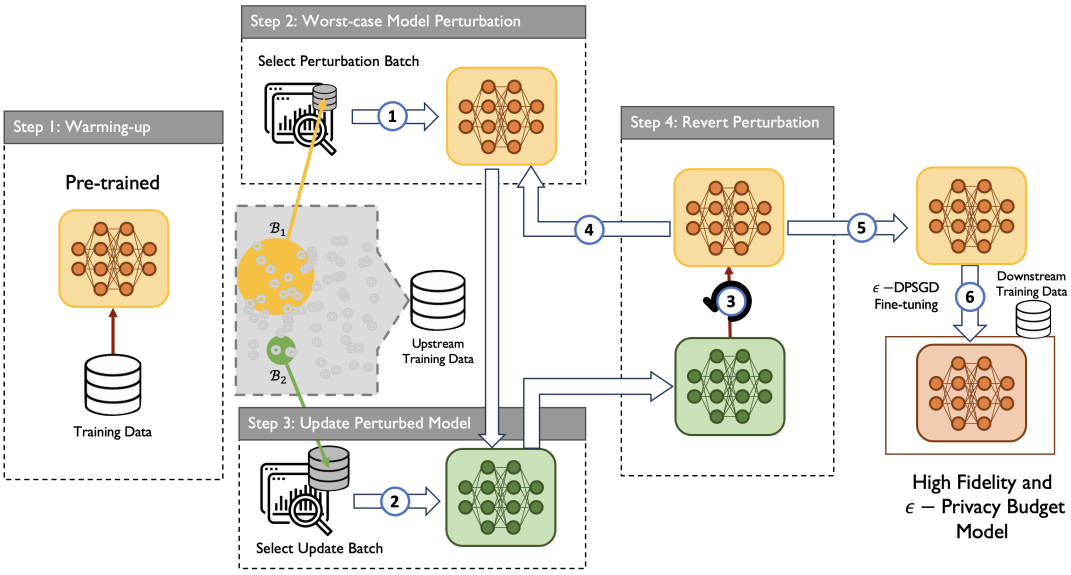

Figure 4: Overview of the DPAdapter approach.

eter robustness), we optimize the perturbed model with the goal of maintaining good performance even when the model is subjected to such perturbations. We select a standard-sized batch of training data, represented as $\mathcal{B}_2$. We then perform regular training using stochastic gradient descent (SGD) on $\mathcal{B}_2$. The updated model is denoted as $f_{\theta+\Delta+\alpha}$, where α represents the weight update resulting from the SGD.

Step 4: Revert Perturbation. In Step 3, we have already enhanced the model's resilience to parameter perturbations. As a result, there's no longer a need to retain the noise applied to the parameters in Step 2, as doing so would only degrade our model's accuracy. Therefore, in this step, we revert the update of the model weight made in Step 2: the final model is represented as $f_{\theta+\Delta+\alpha-\Delta} = f_{\theta+\alpha}$.

Our workflow operates iteratively. Upon completion of Step 4, the process loops back to Step 1. In each iteration, distinct batches of training data are randomly selected for both $\mathcal{B}_1$ and $\mathcal{B}_2$. The algorithm takes the total number of iterations as an input, ensuring that training concludes after the specified number of iterations.

Remark. It is important to highlight the distinction between our approach and conventional techniques aimed at enhancing a model's generality by improving parameter robustness, such as AMP [55]. Specifically, AMP optimizes using the same $\mathcal{B}_2$ and $\mathcal{B}_1$.

The key innovation in our method lies in the strategic batch selection during two different optimization processes: the worst-case perturbation computation and the SGD gradient computation. By ensuring that the batch size for $\mathcal{B}_1$ is relatively large, we obtain a more precise and general perturbation. In contrast, a standard batch size is used for $\mathcal{B}_2$ to facilitate optimal training with SGD. Such nuanced improvements enable our pretrained model, DPAdapter, to achieve heightened parameter robustness, resulting in significant enhancements when downstream DPSGD is applied.

4.4 Design Details

We now delve into a detailed presentation of the DPAdapter algorithm, focusing primarily on Steps 2 and 3. These steps are comparatively more complex: while Step 1 involves standard training and Step 4 simply involves a subtraction to remove noise from the parameters. Notably, it's Steps 2 and 3 that distinctly set DPAdapter apart from other SAM algorithms.

First, like any typical SAM algorithm, we define a *norm ball* $\mathbf{B}(\boldsymbol{\mu};\gamma)$, as a region around a given point $\boldsymbol{\mu}$ in the parameter space Θ (i.e., $\boldsymbol{\mu} \in \Theta$) with the radius of γ ($\gamma \geq 0$):

$$\mathbf{B}(\boldsymbol{\mu};\gamma) := \{\boldsymbol{\theta} \in \Theta : \|\boldsymbol{\theta} - \boldsymbol{\mu}\| \leq \gamma\} \tag{1}$$

Recall that a typical SAM loss is designed upon the norm ball $\mathbf{B}(\theta;\gamma)$:

$$\mathcal{L}_{\text{SAM}}(\boldsymbol{\theta}) := \max_{\Delta \in \mathbf{B}(\mathbf{0};\gamma)} \frac{1}{|\mathcal{D}|} \sum_{(\boldsymbol{x},\boldsymbol{y}) \in \mathcal{D}} \ell(\boldsymbol{x},\boldsymbol{y};\boldsymbol{\theta}+\Delta) \tag{2}$$

where $\mathcal{D}$ represent the training dataset. The training loss, denoted by ℓ, varies based on the task at hand: for classification tasks, it is typically the cross-entropy, while for regression tasks, it is often the least squares. The perturbation Δ is the worst-case model perturbation

Worst-case Model Perturbation. In this section, we detail the computation of Δ used to obtain $f_{\theta+\Delta}$ in Step 2. The worst-case model perturbation, Δ, is strategically designed to induce the model parameters θ to achieve the fastest reduction in loss

on the dataset:

$$\Delta_{\mathcal{B}_1} = \arg\max_{\Delta \in \mathbf{B}(\boldsymbol{\theta};\gamma)} \frac{1}{|\mathcal{B}_1|} \sum_{(\boldsymbol{x},\boldsymbol{y})\in\mathcal{B}_1} \ell(\boldsymbol{x},\boldsymbol{y};\boldsymbol{\theta}+\Delta) \tag{3}$$

Recall that in DPAdapter, $\mathcal{B}_1$ denote the batch of data use as to compute the worst-case model perturbation. γ denotes the radius of the norm ball and acts as a hyperparameter that governs the degree of parameter robustness training. The robustness of the model's parameters is directly influenced by this radius: a larger γ implies that the model can tolerate more noise in the parameter space, as determined by DPAdapter. Consequently, a greater γ results in a model with enhanced parameter robustness.

Update Perturbed Model. In this section, we detail the computation of α used to obtain $f_{\theta+\Delta+\alpha}$ in Step 3. Since in practice, the optimization is typically carried out using mini-batches. In this case, the $\mathcal{L}_{\text{DPAdapter}}$ can be approximated using a mini-batch $\mathcal{B}_2$:

$$\begin{aligned}\mathcal{L}_{\text{DPAdapter}}(\boldsymbol{\theta}) &\approx \max_{\Delta_{\mathcal{B}_1}\in\mathbf{B}(\mathbf{0};\gamma)} \frac{1}{|\mathcal{B}_2|} \sum_{(\boldsymbol{x},\boldsymbol{y})\in\mathcal{B}_2} \ell(\boldsymbol{x},\boldsymbol{y};\boldsymbol{\theta}+\Delta_{\mathcal{B}_1}) \\ &:= \mathcal{J}_{\text{DPAdapter},\mathcal{B}_1,\mathcal{B}_2}(\boldsymbol{\theta})\end{aligned} \tag{4}$$

Hence, at this point, the model's update is given by

$$\alpha = \eta_2 \nabla \mathcal{J}_{\text{DPAdapter},\mathcal{B}_1,\mathcal{B}_2}(\boldsymbol{\theta}) \tag{5}$$

where η_2 represents the optimization step size. It is crucial to highlight the primary distinction between DPAdapter and other SAM algorithms, which lies in Equation 3 and Equation 4. In other SAM algorithms, such as those cited in [17, 49, 55], the batch used to compute the worst-case perturbation, denoted as $\mathcal{B}_1$, is the same as the batch utilized for computing the update. We argue that by separately selecting $\mathcal{B}_1$ and $\mathcal{B}_2$, the trained model can achieve a balance between parameter robustness and overall model performance in Section 5.4.

The specifics of the DPAdapter algorithm can be found in Algorithm 1. Importantly, in alignment with other SAM algorithms such as [17, 49, 55], the finalized model utilizes the parameters denoted as $\boldsymbol{\theta}^*_{\text{DPAdapter}}$. These parameters are employed for model inference (or prediction) without the need for additional perturbations.

As mentioned earlier, the training process of DPAdapter is divided into two primary stages: The perturbation computation and the update computation.

• **Perturbation Computation**. Line 5 to Line 9 in Algorithm 1. This phase is responsible for calculating the worst-case perturbation, $\Delta_{\mathcal{B}_1}$, based on the prevailing conditions.

• **Update Computation**. Line 10 to Line 12 in Algorithm 1. In this phase, the $\Delta_{\mathcal{B}_1}$ derived from the previous perturbation computation step is used to determine the parameter optimization gradient, $\nabla \mathcal{J}_{\text{DPAdapter},\mathcal{B}_1,\mathcal{B}_2}$. Following this, the model parameters are updated.

Algorithm 1 DPAdapter Training

Require: Training set $\mathcal{D} = \{(\boldsymbol{x},\boldsymbol{y})\}$, perturbation batch size m_1, update batch size m_2, loss function ℓ, perturbation computation learning rate η_1, update learning rate η_2, norm ball radius γ, number of update iteration K.

1: **while** $k < K$ **do**
2: Draw $\mathcal{B}_1 = \{(\boldsymbol{x}_i,\boldsymbol{y}_i)\}_{i=1}^{m_1}$ from training set $\mathcal{D}$
3: Draw $\mathcal{B}_2 = \{(\boldsymbol{x}_i,\boldsymbol{y}_i)\}_{i=1}^{m_2}$ from training set $\mathcal{D}$
4: Set perturbation: $\Delta_{\mathcal{B}_1} \leftarrow \mathbf{0}$
5: Calculate the perturbation:
$\Delta_{\mathcal{B}_1} \leftarrow \eta_1 \arg\max_{\Delta\in\mathbf{B}(\boldsymbol{\theta}_k;\gamma)} \frac{1}{|m_1|}\sum_{(\boldsymbol{x},\boldsymbol{y})\in\mathcal{B}_1} \ell(\boldsymbol{x},\boldsymbol{y};\boldsymbol{\theta}_k+\Delta)$
6: **if** $\|\Delta_{\mathcal{B}_1}\|_2 > \gamma$ **then**
7: Normalize perturbation: $\Delta_{\mathcal{B}_1} \leftarrow \gamma\Delta_{\mathcal{B}_1}/\|\Delta_{\mathcal{B}_1}\|_2$
8: **end if**
9: Add the perturbation to parameters:
$\boldsymbol{\theta}_k \leftarrow \boldsymbol{\theta}_k + \Delta_{\mathcal{B}_1}$
10: Compute update gradient:
$\nabla \mathcal{J}_{\text{DPAdapter},\mathcal{B}_1,\mathcal{B}_2} \leftarrow \sum_{i=1}^{|\mathcal{B}_2|} \nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{x}_i,\boldsymbol{y}_i;\boldsymbol{\theta}_k)/m_2$
11: Update on the perturbed model :
$\boldsymbol{\theta}_{k+1} \leftarrow \boldsymbol{\theta}_k - \eta_2 \nabla \mathcal{J}_{\text{DPAdapter},\mathcal{B}_1,\mathcal{B}_2}$
12: Revert perturbation: $\boldsymbol{\theta}_{k+1} \leftarrow \boldsymbol{\theta}_{k+1} - \Delta_{\mathcal{B}_1}$
13: Increment iteration: $k \leftarrow k+1$
14: **end while**

Training can be executed for a specified number of epochs K, or it can continue until the parameter loss stabilizes, which indicates the completion of the training process.

4.5 Theoretical Analyses

In this section, we aim to provide a theoretical explanation of why DPAdapter achieves improvements in the DPML algorithm. Specifically, our theoretical examination revolves around two key points:

1. Understanding the rationale behind the separate selection of $\mathcal{B}_1$ and $\mathcal{B}_2$, particularly emphasizing why the batch size of $\mathcal{B}_2$ should be large.

2. Elucidating how enhancing the robustness of pretrained parameters can ensure superior performance in downstream training, given the same privacy budget.

The first point is theoretically proven in Theorem 1, while the second is validated in Theorem 2.

To give a basic idea, through Theorem 1, we aim to theoretically demonstrate that, upon selecting an appropriate $\mathcal{B}_1$ conducive to optimization and holding it constant, we can bound the difference between the actual loss and the maximum lower bound (Infimum) of the loss. Essentially, as the magnitude of $\mathcal{B}_2$ increases, the upper bound on the expected convergence rate of the model obtained through DPAdapter also increases.

In theorem 2, we prove that given a model training by DP-SGD, the expected difference between the model's loss and

the maximum lower bound of the achievable loss (termed as DP-SGD's performance) is positively proportional to ρ. Specifically, a lower value of ρ (indicating stronger parameter robustness) in the model initial stage, results in a lower loss when optimized using DP-SGD.

Next, we delineate the setup for our theoretical framework. We first analyze the convergence behavior of our proposed algorithm. We show that by using a different update batch (where $|\mathcal{B}_1| \neq |\mathcal{B}_2|$). We summarize our algorithm as follows. Let $L_i(\boldsymbol{\theta}) := \ell(f_{\boldsymbol{\theta}}(\boldsymbol{x}_i), \boldsymbol{y}_i)$. For any batch of the data $\mathcal{S} \subseteq \mathcal{D}$, let $L_{\mathcal{S}}$ be the average of $L_i, i \in \mathcal{S}$. Then our algorithm is as follows. Starting from the initial parameter $\boldsymbol{\theta}_0$, for each iteration t, we have

$$\boldsymbol{\theta}_{t+1} = \boldsymbol{\theta}_t - \eta_2 \cdot \nabla L_{\mathcal{B}_2}(\boldsymbol{\theta}_t + \Delta_t),\ \Delta_t := \eta_1 \cdot \nabla L_{\mathcal{B}_1}(\boldsymbol{\theta}_t). \quad (6)$$

Equation 6 is essentially the same as Algorithm 1 in Section 4.3 without the perturbation normalization step (line 6-8 in Algorithm 1). Meanwhile, we need the following assumptions.

Assumption 1. *f is β-smooth w.r.t. $\boldsymbol{\theta}$, i.e., $\|\nabla f_{\boldsymbol{\theta}}(\boldsymbol{x}) - \nabla f_{\boldsymbol{\theta}'}(\boldsymbol{x})\|_2 \leq \beta \|\boldsymbol{\theta} - \boldsymbol{\theta}'\|_2$.*

Assumption 2. *ℓ is β_1-Lipschitz continuous w.r.t. $\boldsymbol{x}$ i.e., $|\ell(\boldsymbol{x}, \boldsymbol{y}) - \ell(\boldsymbol{x}', \boldsymbol{y})| \leq \beta_1 |\boldsymbol{x} - \boldsymbol{x}'|$.*

Assumption 3. *ℓ is β_2-smooth w.r.t. $\boldsymbol{x}$, i.e., $|\nabla_{\boldsymbol{x}} \ell(\boldsymbol{x}, \boldsymbol{y}) - \nabla_{\boldsymbol{x}} \ell(\boldsymbol{x}', \boldsymbol{y})| \leq \beta_2 |\boldsymbol{x} - \boldsymbol{x}'|$.*

Assumption 4. *∇L_i is $\hat{\sigma}^2$-variance bounded gradient, i.e., $\mathbb{E}_i \|\nabla L_i(\boldsymbol{\theta}) - \nabla L_{\mathcal{D}}(\boldsymbol{\theta})\|_2^2 \leq \hat{\sigma}^2$. Here $\mathbb{E}_i$ denotes the expectation over $i \in 1, \ldots, n$.*

Assumption 5. *$L_{\mathcal{D}}$ satisfies the μ-PL-condition, i.e., $\|\nabla L_{\mathcal{D}}(\boldsymbol{\theta})\|_2^2 \geq 1/\mu \cdot (L_{\mathcal{D}}(\boldsymbol{\theta}) - \inf_{\hat{\boldsymbol{\theta}}} L_{\mathcal{D}}(\hat{\boldsymbol{\theta}}))$.*

We also formally define the parameter robustness in Section 2.2 as follows:

$$\rho(f) = \max_{\boldsymbol{x}, \boldsymbol{\theta}, \Delta} |f_{\theta+\Delta}(\boldsymbol{x}) - f_{\theta}(\boldsymbol{x})| / \|\Delta\|_2.$$

For simplicity, we use $\rho := \rho(f)$ with a slight abuse of notation. Then we have the following theorem.

Theorem 1 (Informal)**.** *With proper selection of parameters, our algorithm enjoys the following gradient norm bound:*

$$\frac{1}{T} \sum_{t=1}^{T} \mathbb{E}(L_{\mathcal{D}}(\boldsymbol{\theta}_t) - \inf_{\hat{\boldsymbol{\theta}}} L_{\mathcal{D}}(\hat{\boldsymbol{\theta}})) \leq \mu \cdot \left(\frac{L_{\mathcal{D}}(\boldsymbol{\theta}_0)}{T} + \frac{\hat{\sigma}^2}{16\hat{\beta}} (1/|\mathcal{B}_2| + 1/|\mathcal{B}_1|) \right),$$

where $\hat{\beta} = (\rho^2 \beta_2 + \beta\beta_1)$.

We note that the significance of increasing the perturbation batch size, $|\mathcal{B}_1|$, directly influences the gradient norm bound and, consequently, the convergence rate of our algorithm. Elevating $|\mathcal{B}_1|$ effectively lowers this bound by diminishing the noise-to-signal ratio in our gradient estimations, leading to more precise and efficient optimization steps. This strategy is particularly crucial within the context of differential privacy, where striking a balance between privacy protection and algorithmic efficacy is paramount. By judiciously selecting a larger $|\mathcal{B}_1|$, we enable a smoother and more accurate convergence process, highlighting the importance of careful batch size configuration in achieving optimal learning outcomes under privacy constraints.

The detailed theorem and proof are deferred to Appendix A.1. Theorem 1 suggests that selecting a large perturbation batch size $|\mathcal{B}_1|$ makes our algorithm have a better convergence rate, indicating better performance while using a large batch of perturbations $|\mathcal{B}_1|$.

We have another analysis of the noise tolerance and the DP-SGD performance. Then we have our theorem.

Theorem 2 (Informal)**.** *Given (ε, δ), with proper selection of parameters, let $\boldsymbol{\theta}_{out}$ be the final output of DP-SGD, then DP-SGD is (ε, δ)-DP and enjoys the following utility bound:*

$$\mathbb{E}(L_{\mathcal{D}}(\boldsymbol{\theta}_{out}) - \inf_{\boldsymbol{\theta}} L_{\mathcal{D}}(\boldsymbol{\theta})) \leq C \cdot \frac{\rho \sqrt{\rho^2 \beta_2 + \beta\beta_1}}{|\mathcal{D}|\varepsilon},$$

where $C = c \cdot \mu\beta_1 \sqrt{d \log(|\mathcal{D}|/\delta) \log(1/\delta) L_{\mathcal{D}}(\boldsymbol{\theta}_0)}$, c is some positive constant, d is the dimension of parameter $\boldsymbol{\theta}$.

The detailed algorithm, theorem, and proof are deferred to Appendix A.2. Theorem 2 suggests that the parameter robustness ρ indeed affects the final utility.

5 Evaluation

5.1 Experimental Setup

Datasets. We use the following five datasets in our evaluation.

• *CIFAR-10* [25]: This dataset contains 50,000 training images and 10,000 testing images. Each image has a size of $32 \times 32 \times 3$ and belongs to one of 10 classes.

• *CIFAR-100* [25]: This dataset contains 50,000 training images and 10,000 testing images. Each image has a size of $32 \times 32 \times 3$ and belongs to one of 100 classes.

• *SVHN* [36]: In this dataset, each image represents a digit from the house numbers in Google Street View. The size of each image is $32 \times 32 \times 3$. Each image belongs to one of the 10 digits. This dataset has 73,257 training images and 26,032 testing images.

• *STL-10* [13]: This dataset contains 5,000 training images and 8,000 testing images. Each image has a size of $96 \times 96 \times 3$ and belongs to one of 10 classes.

• *Tiny ImageNet* [27]: This dataset contains 100,000 training images and 10,000 testing images. Each image has a size of $64 \times 64 \times 3$ and belongs to one of 200 classes.

In this paper, CIFAR-100 and Tiny ImageNet serves as a public dataset used for pre-training, while CIFAR-10, SVHN, and STL-10 serves as the private data/tasks.

Pre-training Procedure. In our experiments, we utilize CIFAR-100 as our pre-training dataset and employ DPAdapter to train a ResNet20 model [22] as the pre-trained model. We compute the mean and standard deviation on the training set to normalize the input images. We adopt cross-entropy as the loss function ℓ and utilize the SGD optimizer with momentum, incorporating a step-wise learning rate decay. Specifically, the model is trained for $K = 1,000$ epochs, with the outer learning rate η_2 initialized at 0.1 and divided by 10 after 500 and 750 epochs. The momentum is set to 0.9, and the weight decay is set to 1×10^{-4}. The inner batch size m_1 is set to 5,000, with the inner learning rate η_1 set to 1.0; the outer batch size m_2 is set to 50. For perturbation magnitude, we adopt $\gamma = 2.0$ by default.

Fine-tuning Procedure. Given a pre-trained model, we utilize it to train private downstream classifiers for the remaining three datasets: CIFAR-10, SVHN, and STL-10. We employ the parameters of the pre-trained model as the initial parameters of the downstream classifier, which is then trained on the downstream dataset.

We use Rényi DP to accumulate the overall privacy budget and precompute the required noise scale (σ in DP-SGD) numerically [1, 35]. We maintain $\delta = 10^{-5}$ and utilize different privacy budgets: $\varepsilon = \{1, 4\}$. The clipping threshold for all algorithms is fixed at 4, except when an algorithm employs special clipping strategies. The cross-entropy loss function and the DP-SGD optimizer with momentum are adopted when training a downstream classifier. The model is fine-tuned for 100 epochs, with the learning rate initialized at 0.01 and momentum set to 0.9. The batch size is configured to 256.

DPML Algorithms. According to the different optimization methods that the downstream model could adopt, we consider three types of DP algorithms in addition to vanilla DP-SGD:

• *GEP* [52]: Yu et al. observed that in vanilla DP-SGD, the amount of noise increases with the model size and proposed a solution, GEP [52], to reduce the gradient dimension before adding noise. GEP first calculates an anchor subspace, which contains some gradients of public data, using the power method. Subsequently, it projects the gradient of private data into the anchor subspace, resulting in a low-dimensional gradient embedding and a small-norm residual gradient. These two components are independently processed with the DP mechanism and then combined to update the original weight.

• *AdpAlloc* [53]: It proposes a dynamic noise-adding mechanism, eschewing the practice of maintaining a constant noise multiplier σ throughout every training epoch in vanilla DP-SGD. Instead of utilizing a static variance in the Gaussian mechanism, it replaces it with a function of the epoch: $M(d) = f(d) + \mathbf{N}(0, S_f^2 \cdot \sigma_t^2)$, where the value of σ_t is contingent upon the final privacy budget, epoch, and schedule function. The schedule function delineates the adjustment of the noise scale throughout training. Yu et al. proposed several pre-defined schedules. For our evaluation, we select *Exponential Decay*, which demonstrated the best average performance in [53]. The mathematical expression for *Exponential Decay* is $\sigma_t = \sigma_0 e^{-kt}$, where $k(k > 0)$ represents the decay rate and σ_0 denotes the initial noise scale.

• *AdpClip* [2]: An adaptive clipping threshold mechanism is utilized, setting the clip threshold to a specified quantile of the update norm distribution at each epoch. Formally, the clipping threshold C_t in epoch t can be computed as $C_t = C_{t-1} \cdot \exp\left(-\eta_C(\overline{b} - \gamma)\right)$, where $\gamma \in [0, 1]$ is a quantile to be matched, $\overline{b} \triangleq \frac{1}{m} \sum_{i \in [m]} \mathbb{I}_{x_i \leq C}$ represents the empirical fraction of samples with a value at most C, and η_C is the learning rate with a default value of 0.2, as indicated in [2].

5.2 Effectiveness of DPAdapter

In this section, we empirically validate the overall effectiveness of DPAdapter and conduct ablation studies to illustrate the effectiveness of each component.

Setup. We conduct experiments using four different DPML algorithms across three distinct private downstream tasks (CIFAR-10, SVHN, and STL-10), under four different pre-training settings: (i) From Scratch: utilizing randomly initialized weight values (i.e., no pre-training); (ii) Standard Pre-training [15, 26]: conducting pre-training on the CIFAR-100 dataset using standard training procedures; (iii) Vanilla Sharpness-Aware Minimization (SAM): pre-training with AMP [55], employing the optimal perturbation magnitude $\gamma = 1.0$ and the optimal batch size $m = 100$; (iv) DPAdapter: pre-training with the proposed DPAdapter, using hyper-parameters described in Section 5.1.

Observations. Table 1 illustrates the downstream accuracy for various settings. In general, we observe that the proposed DPAdapter substantially enhances the downstream accuracy in all settings. For instance, when the privacy budget is set to $\varepsilon = 1$ and the DPML algorithm is configured to vanilla DP-SGD, DPAdapter elevates the average accuracy across three downstream datasets to 61.42%. In contrast, when utilizing models pre-trained normally, the accuracy is only 56.95%, marking an improvement of over 4%. When the DPML algorithm is AdpClip, DPAdapter boosts the accuracy from 42.67% to 52.54%, representing a near 10% improvement.

We note that, compared to training from scratch, a normally pre-trained model consistently yields an improvement in downstream accuracy. This finding aligns with previous work which noted that transfer learning from public data significantly enhances the accuracy of DPML algorithms [26]. Further, we note that employing vanilla SAM to provide pa-

Table 1: Comparison of the performance of training from scratch, standard pre-training, vanilla SAM, and DPAdapter across various downstream tasks under different privacy budgets.

rameter robustness can additionally enhance downstream accuracy. For example, when the privacy budget is designated as $\varepsilon = 1$ and the DPML algorithm is configured to AdpAlloc, using a standard pre-trained model improves the average downstream accuracy by 1.71%. Meanwhile, applying vanilla SAM can further augment the average downstream accuracy by 6.09% (compared with standard pre-training), achieving an additional gap that is over three times larger than the previous gap achieved by standard pre-training. This underscores the significance of leveraging parameter robustness to enhance DPML algorithms.

Moreover, we observe that employing DPAdapter consistently achieves higher downstream accuracy compared to using vanilla SAM. For instance, when the privacy budget is set to $\varepsilon = 4$ and the DPML algorithm is configured to GEP, applying vanilla SAM enhances the average downstream accuracy by 0.74% compared with standard pre-training. Meanwhile, applying DPAdapter can further increase the average downstream accuracy by 2.20% (compared with vanilla SAM). When the privacy budget is $\varepsilon = 1$, applying vanilla SAM improves the average downstream accuracy by 2.54%; DPAdapter, in contrast, achieves an improvement of 6.28% compared with standard pre-training. This emphasizes the importance of leveraging decoupled batches to further enhance parameter robustness.

We can also observe that GEP is particularly suitable for DPAdapter, potentially due to the specific challenges posed by DPML, notably the "curse of dimensionality". This phenomenon indicates that as the model dimension increases, the required noise addition also escalates, significantly impacting model performance. GEP mitigates this challenge by reducing dimensionality and applying noise in a lower-dimensional space, effectively diminishing the adverse effects of noise on model performance. In contrast, DPAdapter focuses on enhancing each dimension's resilience to noise, thereby maintaining model performance even as noise increases in larger dimensions. The integration of GEP and DPAdapter appears especially effective for high-dimensional models, leveraging their distinct methodologies. This synergy arises from their complementary approaches to managing noise and dimensionality, showcasing how combining these strategies can address the challenges of pre-trained models more efficiently.

5.3 Impact of Perturbation Magnitude

Recall that DPAdapter fundamentally accumulates parameter robustness by introducing adversarial perturbation during the training process, the magnitude of which is determined by the γ term. To comprehend how DPAdapter influences the performance of downstream tasks, we assess DPAdapter utilizing various γ settings. In this experiment, we fix the privacy budget at $\varepsilon = 1$ and the DPML algorithm is configured to vanilla DP-SGD.

Observations. Figure 5 illustrates the fluctuations in upstream performance, upstream parameter robustness, and the performance of various downstream tasks when applying DPAdapter with different γ values, representing the perturbation magnitude. We observe that the downstream accuracy

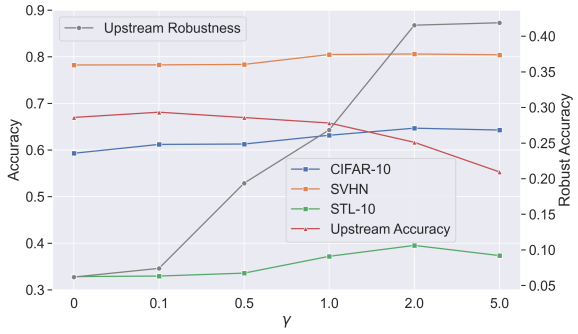

Figure 5: Impact of perturbation magnitude on DPAdapter.

trend largely aligns with the trend of upstream parameter robustness, while demonstrating a nearly inverse relationship with the level of upstream accuracy. This observation suggests that parameter robustness is the principal factor through which DPAdapter enhances downstream accuracy. Given that the trends of upstream accuracy and downstream accuracy exhibit nearly inverse patterns with changes in γ, we can essentially rule out the possibility that upstream accuracy is the predominant contributor to downstream accuracy.

Note that when γ is further increased to 5.0, the upstream accuracy experiences a slight increase while the performance across different downstream tasks all decline. This could be attributed to the scenario where the enhancement in parameter robustness becomes constrained and the decline in upstream accuracy becomes significant. The advantages conferred by improved parameter robustness are unable to offset the disadvantages brought about by the reduction in upstream accuracy, since upstream accuracy also contributes to downstream accuracy through enhanced generalization ability. This underscores the vital necessity of maintaining a balance between parameter robustness and generalization ability.

In this experiment, for the first time, we identify and establish a connection between parameter robustness and the performance of DPML algorithms, marking one of the key contributions of this paper.

5.4 Comparison with Vanilla SAM

Setup. In this experiment, we consider four perturbation magnitudes: 0.1, 0.5, 1.0, and 2.0. The DPML algorithm is fixed at vanilla DP-SGD and the privacy budget is fixed at $\varepsilon = 1$. The results of using the vanilla SAM are denoted by blue triangles, while the results of the proposed DPAdapter are denoted by red diamonds. The result of using a normally pre-trained model is denoted as a purple rectangle.

Observations. Figure 6 illustrate the influence of perturbation magnitude on both vanilla SAM and DPAdapter. The x-axis represents the robust accuracy, which measures parameter robustness, while the y-axis indicates the accuracy, reflecting model performance. We observe that models using standard pre-training typically appear in the bottom-left region, demonstrating a weak robustness and generalization trade-off, identified as crucial for DPML algorithms in Section 5.3. Conversely, the results derived from the proposed DPAdapter predominantly reside in the top-right region, showcasing an enhancement over the vanilla SAM. This implies that DPAdapter can further refine the robustness-generalization trade-off compared to vanilla SAM, which may elucidate its consistent ability to amplify the performance of DPML algorithms with the most substantial improvements.

Table 2: The impact of public dataset and model architecture.

Public Dataset →		CIFAR-100		Tiny ImageNet	
Model Arch. ↓	Pre-training Method ↓	$\varepsilon = 1$	$\varepsilon = 4$	$\varepsilon = 1$	$\varepsilon = 4$
ResNet20	Standard	0.3282	0.5695	0.3129	0.5460
	DPAdapter	**0.3951**	**0.6364**	**0.3671**	**0.6031**
ViT-B	Standard	0.4331	0.4929	0.5499	0.6118
	DPAdapter	**0.4480**	**0.5200**	**0.5730**	**0.6374**

Table 3: Compatibility of DPAdapter with Downstream Enhancements.

DPML Algorithm ↓	Pre-training Method ↓	$\varepsilon = 1$	$\varepsilon = 4$
DP-SGD	Standard	0.3282	0.5695
	DPAdapter	**0.3951**	**0.6364**

	DPAdapter	**0.4109**	**0.6432**

5.5 Impact of Public Dataset and Model Architecture

Setup. In this experiment, we explore the effects of public dataset selection and model architecture on DPAdapter. We evaluate two public datasets: Tiny ImageNet and CIFAR-100, alongside two model architectures: ResNet20 and ViT-B. The downstream task is fixed as STL-10. For the fine-tuning of ViT-B, all layers except the linear ones are frozen. The outer learning rate, η_2, is set to 0.05 for experiments involving Tiny ImageNet.

Observations. The results, as shown in Table 2, reveal the influence of public dataset selection and model architecture on the effectiveness of DPAdapter. Overall, DPAdapter enhances test accuracy across all configurations, showcasing its adaptability. Notably, Tiny ImageNet appears to be more compatible with ViT-B, whereas CIFAR-100 is better suited for ResNet20. This discrepancy may be attributed to the resolution differences between the datasets, given that ViT-B segments an image into 16x16 tiles.

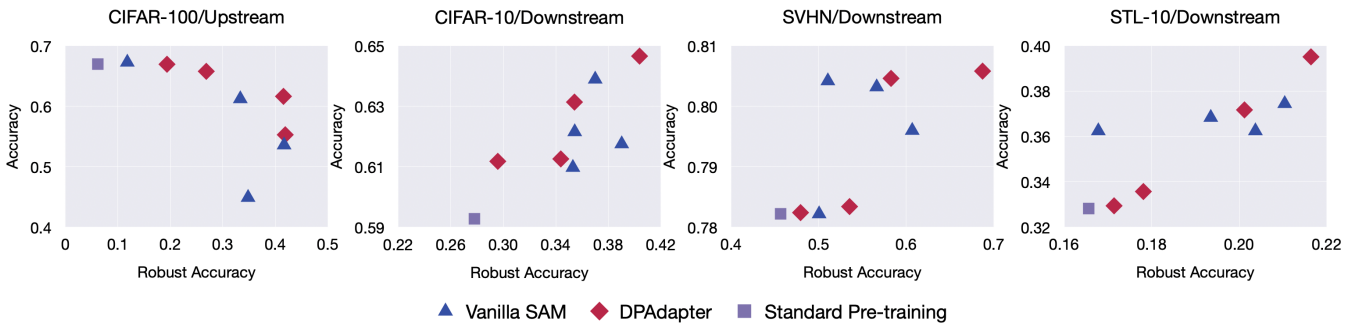

Figure 6: The results of DPAdapter and vanilla SAM under different perturbation magnitudes.

5.6 Compatibility with Other Enhancements

Setup. In this experiment, we investigate the compatibility of DPAdapter with downstream enhancements, focusing on the state-of-the-art DP-SGD enhancement method, mixed ghost clipping (MGC), as proposed in recent research [7]. We designate STL-10 as the downstream task and CIFAR-100 as the public dataset for this evaluation.

Observations. The results, as presented in Table 3, reveal that both DPAdapter and MGC effectively improve test accuracy. When combined, they achieve even better test accuracy, indicating that DPAdapter is highly compatible with downstream enhancements. Furthermore, it is noted that DPAdapter consistently offers a more significant enhancement compared to MGC. Specifically, the accuracy improvement attributed to MGC is around 1% for both $\varepsilon = 1$ and $\varepsilon = 4$ scenarios. In contrast, DPAdapter consistently yields an enhancement of over 6% across all cases, demonstrating its superior efficacy in enhancing model performance.

6 Discussion

The current design of DPAdapter is specifically targeted towards supervised learning and cannot be directly applied to unsupervised learning techniques like contrastive learning [11, 12, 21]. Thus, the attacker in our scenario needs to have a labeled dataset for pre-training, which might pose a challenge in certain specialized fields.

Moreover, while our discussion and implementation center on a single-party scenario, it is worth noting that our framework is adaptable to both single-party and multi-party situations. In a multi-party context, the private data originates from multiple sources. Consequently, private fine-tuning processes can be facilitated through federated learning [28].

7 Related Work

Parameter Robustness. Numerous studies have shown that enhancing parameter robustness effectively narrows the generalization gap, leading to improved model generalizability [17, 29, 55]. In this paper, we categorize these efforts under the umbrella of sharpness-aware minimization (SAM) approaches. However, all of these studies utilize the additional benefits conferred by parameter robustness, i.e., generality, without directly leveraging the property of parameter robustness itself. In contrast, the proposed DPAdapter is among the first strategies that directly utilize parameter robustness to benefit private learning. This introduces a fresh perspective on the potential applications of the parameter robustness property. Several pieces of research [41, 45] have incorporated SAM into DP algorithms to improve test accuracy. Yet, their protection is applied during the fine-tuning phase, whereas DPAdapter implements protection in the pre-training phase. It is important to recognize that each approach brings its own advantages, and combining DPAdapter with these methods could potentially boost accuracy further. Therefore, the protection offered at the pre-training stage deserves special attention for its unique contributions.

Pre-trained Model as a Service. Adversarial training [19, 33] is recognized as a standard method for developing empirically robust classifiers in supervised learning. The core concept involves generating adversarial examples from training instances during the training process and augmenting the training data with these examples. Several studies [10, 23, 24, 43] have generalized adversarial training for the pre-training of robust models in self-supervised learning. Generally, the approach first generates adversarial examples that result in significant loss, which are then used for model pre-training. However, previous studies have focused solely on offering input robustness as a service, neglecting to offer parameter robustness, which is the primary contribution of this paper.

8 Conclusion

In this study, we unveiled DPAdapter, a groundbreaking technique engineered to augment parameter robustness, thereby navigating the traditionally adversarial relationship between Differential Privacy (DP) noise and model utility in Deep Learning. By meticulously reallocating batch sizes for

perturbation and gradient calculations, DPAdapter refines Sharpness-Aware Minimization (SAM) algorithms, delivering enhanced parameter robustness and, consequently, mitigating the impact of DP noise. Our comprehensive evaluations across several datasets substantiate DPAdapter's capability to substantially bolster the accuracy of DPML algorithms on various downstream tasks, thereby highlighting its potential as a pivotal technique in future privacy-preserving machine learning endeavors.

Appendix

A Theoretical Results

A.1 Proof of Theorem 1

We first restate Theorem Theorem 1 as follows.

Theorem 3 (Formal version of Theorem 1)**.** *Denote* $\hat{\beta} := (\rho^2\beta_2 + \beta\beta_1)$. *Select step sizes* $\eta_1 = \eta_2 = 1/(4\hat{\beta})$. *Then Algorithm 1 enjoys the following utility bound:*

$$\frac{1}{T}\sum_{t=1}^{T}\mathbb{E}(L_{\mathcal{D}}(\boldsymbol{\theta}_t) - \inf_{\hat{\boldsymbol{\theta}}} L_{\mathcal{D}}(\hat{\boldsymbol{\theta}})) \leq \mu \cdot \left(\frac{L_{\mathcal{D}}(\boldsymbol{\theta}_0)}{T} + \frac{\hat{\sigma}^2}{16\hat{\beta}}(1/|\mathcal{B}_2| + 1/|\mathcal{B}_1|)\right).$$

To prove Theorem 3, we need the following lemma which estimates the Lipschitz constant and smoothness constant of L_i.

Lemma A.1. *For each i,* L_i *is* $\beta_1\rho$*-Lipschitz continuous and* $(\rho^2\beta_2 + \beta\beta_1)$*-smooth.*

Proof. We have for all $\boldsymbol{\theta}, \boldsymbol{\theta}'$,

$$\begin{aligned}
|L_i(\boldsymbol{\theta}) - L_i(\boldsymbol{\theta}')| &= |\ell(f_{\boldsymbol{\theta}}(x_i), y_i) - \ell(f_{\boldsymbol{\theta}'}(x_i), y_i)| \\
&\leq \beta_1 |f_{\boldsymbol{\theta}}(x_i) - f_{\boldsymbol{\theta}'}(x_i)| \\
&\leq \beta_1\rho\|\boldsymbol{\theta} - \boldsymbol{\theta}'\|_2,
\end{aligned}$$

and

$$\begin{aligned}
&\|\nabla L_i(\boldsymbol{\theta}) - \nabla L_i(\boldsymbol{\theta}')\|_2 \\
&= \|\nabla_x \ell(f_{\boldsymbol{\theta}}(x_i), y_i)\nabla f_{\boldsymbol{\theta}}(x_i) - \nabla_x \ell(f_{\boldsymbol{\theta}'}(x_i), y_i)\nabla f_{\boldsymbol{\theta}'}(x_i)\|_2 \\
&\leq \|\nabla_x \ell(f_{\boldsymbol{\theta}}(x_i), y_i)\nabla f_{\boldsymbol{\theta}}(x_i) - \nabla_x \ell(f_{\boldsymbol{\theta}'}(x_i), y_i)\nabla f_{\boldsymbol{\theta}}(x_i)\|_2 + \|\nabla_x \ell(f_{\boldsymbol{\theta}'}(x_i), y_i)\nabla f_{\boldsymbol{\theta}}(x_i) - \nabla_x \ell(f_{\boldsymbol{\theta}'}(x_i), y_i)\nabla f_{\boldsymbol{\theta}'}(x_i)\|_2 \\
&\leq \|\nabla f_{\boldsymbol{\theta}}(x_i)\|_2 |\nabla_x \ell(f_{\boldsymbol{\theta}}(x_i), y_i) - \nabla_x \ell(f_{\boldsymbol{\theta}'}(x_i), y_i)| + |\nabla_x \ell(f_{\boldsymbol{\theta}'}(x_i), y_i)| \|\nabla f_{\boldsymbol{\theta}}(x_i) - \nabla f_{\boldsymbol{\theta}'}(x_i)\|_2 \\
&\leq \rho^2\beta_2\|\boldsymbol{\theta} - \boldsymbol{\theta}'\|_2 + \beta_1\beta\|\boldsymbol{\theta} - \boldsymbol{\theta}'\|_2.
\end{aligned}$$

Therefore, L_i is $\beta_1\rho$-Lipschitz continuous and $(\rho^2\beta_2 + \beta\beta_1)$-smooth. □

We now begin to prove Theorem 3.

Proof of Theorem 3. The proof is adapted from [3]. First, by Lemma A.1 we know that L_i is $\beta_1\rho$-Lipschitz continuous and $(\rho^2\beta_2 + \beta\beta_1)$-smooth. By Lemma 13 in [3], we have

$$\mathbb{E}\langle \nabla L_{\mathcal{B}_2}(\boldsymbol{\theta}_t + \eta_2 \cdot \nabla L_{\mathcal{B}_1}(\boldsymbol{\theta}_t)), \nabla L_{\mathcal{D}}(\boldsymbol{\theta}_t)\rangle \geq (1 - \hat{\beta}\eta_2)\|L_{\mathcal{D}}(\boldsymbol{\theta}_t)\|_2^2 - \frac{\hat{\beta}^2\eta_2^2\hat{\sigma}^2}{2|\mathcal{B}_1|}. \tag{7}$$

By Lemma 14 in [3], denote $\boldsymbol{\theta}_{t+1/2} := \boldsymbol{\theta}_t + \eta_2 \cdot \nabla L_{\mathcal{B}_1}(\boldsymbol{\theta}_t)$, then we have for all $\eta_1 \leq 1/(2\hat{\beta})$ and $\eta_2 \leq 1/(2\hat{\beta})$,

$$\begin{aligned}
\mathbb{E}L_{\mathcal{D}}(\boldsymbol{\theta}_{t+1}) &\leq \mathbb{E}L_{\mathcal{D}}(\boldsymbol{\theta}_t) + \eta_1^2\hat{\beta}\hat{\sigma}^2/|\mathcal{B}_2| - \eta_1^2\hat{\beta}\mathbb{E}\|\nabla L_{\mathcal{D}}(\boldsymbol{\theta}_t)\|_2^2 - \eta_1(1 - 2\eta_1\hat{\beta})\mathbb{E}\langle \nabla L_{\mathcal{D}}(\boldsymbol{\theta}_{t+1/2}), \nabla L_{\mathcal{D}}(\boldsymbol{\theta}_t)\rangle \\
&\quad + \eta_1^2\hat{\beta}\mathbb{E}\|\nabla L_{\mathcal{D}}(\boldsymbol{\theta}_{t+1/2}) - \nabla L_{\mathcal{D}}(\boldsymbol{\theta}_t)\|_2^2 \\
&\leq \mathbb{E}L_{\mathcal{D}}(\boldsymbol{\theta}_t) + \eta_1^2\hat{\beta}\hat{\sigma}^2/|\mathcal{B}_2| - \eta_1^2\hat{\beta}\mathbb{E}\|\nabla L_{\mathcal{D}}(\boldsymbol{\theta}_t)\|_2^2 - \eta_1(1 - 2\eta_1\hat{\beta})\mathbb{E}\langle \nabla L_{\mathcal{D}}(\boldsymbol{\theta}_{t+1/2}), \nabla L_{\mathcal{D}}(\boldsymbol{\theta}_t)\rangle \\
&\quad + \eta_1^2\hat{\beta}\mathbb{E}\|\boldsymbol{\theta}_{t+1/2} - \boldsymbol{\theta}_t\|_2^2 \\
&= \mathbb{E}L_{\mathcal{D}}(\boldsymbol{\theta}_t) + \eta_1^2\hat{\beta}\hat{\sigma}^2/|\mathcal{B}_2| - \eta_1^2\hat{\beta}\mathbb{E}\|\nabla L_{\mathcal{D}}(\boldsymbol{\theta}_t)\|_2^2 - \eta_1(1 - 2\eta_1\hat{\beta})\mathbb{E}\langle \nabla L_{\mathcal{D}}(\boldsymbol{\theta}_{t+1/2}), \nabla L_{\mathcal{D}}(\boldsymbol{\theta}_t)\rangle \\
&\quad + \eta_1^2\hat{\beta}^3\eta_2^2\mathbb{E}\|\nabla L_{\mathcal{B}_1}(\boldsymbol{\theta}_t)\|_2^2 \\
&\leq \mathbb{E}L_{\mathcal{D}}(\boldsymbol{\theta}_t) + \eta_1^2\hat{\beta}\hat{\sigma}^2/|\mathcal{B}_2| - \eta_1^2\hat{\beta}(1 - 2\hat{\beta}^2\eta_2^2)\mathbb{E}\|\nabla L_{\mathcal{D}}(\boldsymbol{\theta}_t)\|_2^2 - \eta_1(1 - 2\eta_1\hat{\beta})\mathbb{E}\langle \nabla L_{\mathcal{D}}(\boldsymbol{\theta}_{t+1/2}), \nabla L_{\mathcal{D}}(\boldsymbol{\theta}_t)\rangle \\
&\quad + 2\eta_1^2\hat{\beta}^3\eta_2^2\hat{\sigma}^2/|\mathcal{B}_1|.
\end{aligned}$$

Algorithm 2 Random round DP-SGD

Require: Training set $\mathcal{D} = \{(\boldsymbol{x}, \boldsymbol{y})\}$, loss function $L_i := \ell(f_{\boldsymbol{\theta}}(\boldsymbol{x}_i), \boldsymbol{y}_i)$, privacy parameter (ε, δ), learning rate η.

1: Randomly draw $R \sim \mathbb{P}$, where

$$\mathbb{P}(R = k+1) := \frac{1}{|\mathcal{D}|^2}, k = 0, 1, \ldots, |\mathcal{D}|^2 - 1.$$

2: **for** $t = 0, \ldots, R-1$ **do**

3: Uniformly randomly draw i from $1, \ldots, |\mathcal{D}|$

4: Draw $z_t \in \mathbb{R}^d$ from the following Gaussian distribution:

$$z^t \sim \mathcal{N}(0, 4\beta_1^2 \rho^2 \log(3|\mathcal{D}|/\delta) \log(2/\delta) \cdot \mathbf{I}) \tag{9}$$

5: Update $\boldsymbol{\theta}_{t+1} := \boldsymbol{\theta}_t - \eta \cdot (\nabla L_i(\boldsymbol{\theta}_t) + z_t)$

6: **end for**

Ensure: $\boldsymbol{\theta}_{\text{out}} = \boldsymbol{\theta}_R$

Then substituting Equation 7 and setting $\eta_1 = \eta_2 = 1/(4\hat{\beta})$, we have

$$\begin{aligned}
&\mathbb{E}L_{\mathcal{D}}(\boldsymbol{\theta}_{t+1}) - \mathbb{E}L_{\mathcal{D}}(\boldsymbol{\theta}_t) \\
&\leq \hat{\sigma}^2/(16|\mathcal{B}_2|\hat{\beta}) - 1/(16\hat{\beta}) \cdot 7/8 \cdot \mathbb{E}\|\nabla L_{\mathcal{D}}(\boldsymbol{\theta}_t)\|_2^2 - 1/(8\hat{\beta}) \cdot (3/4 \cdot \mathbb{E}\|\nabla L_{\mathcal{D}}(\boldsymbol{\theta}_t)\|_2^2 - \hat{\sigma}^2/(32|\mathcal{B}_1|)) + \hat{\sigma}^2/(128\hat{\beta}|\mathcal{B}_1|) \\
&\leq \hat{\sigma}^2/(64\hat{\beta}|\mathcal{B}_1|) + \hat{\sigma}^2/(16\hat{\beta}|\mathcal{B}_2|) - 1/(8\hat{\beta}) \cdot \mathbb{E}\|\nabla L_{\mathcal{D}}(\boldsymbol{\theta}_t)\|_2^2.
\end{aligned}$$

Therefore, we have

$$\frac{1}{T}\sum_{t=1}^{T} \mathbb{E}\|\nabla L_{\mathcal{D}}(\boldsymbol{\theta}_t)\|_2^2 \leq \frac{L_{\mathcal{D}}(\boldsymbol{\theta}_0)}{T} + \frac{\hat{\sigma}^2}{16\hat{\beta}}(1/|\mathcal{B}_2| + 1/|\mathcal{B}_1|). \tag{8}$$

Finally, by using the PL-condition we have $\|\nabla L_{\mathcal{D}}(\boldsymbol{\theta}_t)\|_2^2 \geq 1/\mu \cdot (L_{\mathcal{D}}(\boldsymbol{\theta}_t) - \inf_{\boldsymbol{\theta}} L_{\mathcal{D}}(\boldsymbol{\theta}))$. Substituting it into (8) concludes the proof. □

A.2 Proof of Theorem 2

We present the random round DP-SGD proposed in [54] as Algorithm 2. Compared with the standard DP-SGD [1], the main difference is the random selected round number R here. The use of a random round number is only due to the need of theoretical proof. Next, we state the formal version of Theorem Theorem 2 as follows.

Theorem 4 (Formal version of Theorem 2)**.** *Select the step size* $\eta = \min\{1/(\rho^2\beta_2 + \beta\beta_1), D_f/(\sigma|\mathcal{D}|)\}$*, where*

$$D_f := \sqrt{2(L_{\mathcal{D}}(\boldsymbol{\theta}_0) - \min_{\boldsymbol{\theta}} L_{\mathcal{D}}(\boldsymbol{\theta}))/(\rho^2\beta_2 + \beta\beta_1)},$$

$$\sigma := 2\beta_1\rho\sqrt{1 + \frac{d\log(3|\mathcal{D}|/\delta)\log(2\delta)}{\varepsilon^2}},$$

then we have the following utility bound:

$$\mathbb{E}(L_{\mathcal{D}}(\boldsymbol{\theta}_{out}) - \inf_{\boldsymbol{\theta}} L_{\mathcal{D}}(\boldsymbol{\theta})) \leq C \cdot \frac{\rho\sqrt{\rho^2\beta_2 + \beta\beta_1}}{|\mathcal{D}|\varepsilon},$$

where $C = c \cdot \mu\beta_1\sqrt{d\log(|\mathcal{D}|/\delta)\log(1/\delta)L_{\mathcal{D}}(\boldsymbol{\theta}_0)}$*, c is some positive constant, d is the dimension of parameter* $\boldsymbol{\theta}$*.*

Proof of Theorem 4. First, by Lemma A.1, we have L_i is $\beta_1\rho$-Lipschitz continuous and $(\rho^2\beta_2 + \beta\beta_1)$-smooth. Then according to Theorem 5 in [54], we have the following utility bound:

$$\mathbb{E}\|\nabla L_{\mathcal{D}}(\boldsymbol{\theta}_{\text{out}})\|_2^2 \leq c \cdot \left(\frac{\beta_1\rho\sqrt{\rho^2\beta_2 + \beta\beta_1}\sqrt{d\log(|\mathcal{D}|/\delta)\log(1/\delta)L_{\mathcal{D}}(\boldsymbol{\theta}_0)}}{|\mathcal{D}|\varepsilon}\right), \tag{10}$$

where c is some positive constant. Meanwhile, random round DP-SGD is (ε, δ)-DP due to Theorem 4 in [54]. Finally, by using the PL-condition we have $\|\nabla L_{\mathcal{D}}(\boldsymbol{\theta}_{\text{out}})\|_2^2 \geq 1/\mu \cdot (L_{\mathcal{D}}(\boldsymbol{\theta}_{\text{out}}) - \inf_{\boldsymbol{\theta}} L_{\mathcal{D}}(\boldsymbol{\theta}))$. Substituting it into Equation 10 concludes the proof. □

Double Face: Leveraging User Intelligence to Characterize and Recognize AI-synthesized Faces

Matthew Joslin Xian Wang Shuang Hao
University of Texas at Dallas
{matthew.joslin, xxw161030, shao}@utdallas.edu

Abstract

Artificial Intelligence (AI) techniques have advanced to generate face images of nonexistent yet photorealistic persons. Despite positive applications, AI-synthesized faces have been increasingly abused to deceive users and manipulate opinions, such as AI-generated profile photos for fake accounts. Deception using generated realistic-appearing images raises severe trust and security concerns. So far, techniques to analyze and recognize AI-synthesized face images are limited, mainly relying on off-the-shelf classification methods or heuristics of researchers' individual perceptions.

As a complement to existing analysis techniques, we develop a novel approach that leverages crowdsourcing annotations to analyze and defend against AI-synthesized face images. We aggregate and characterize AI-synthesis artifacts annotated by multiple users (instead of by individual researchers or automated systems). Our quantitative findings systematically identify where the synthesis artifacts are likely to be located and what characteristics the synthesis patterns have. We further incorporate user annotated regions into an attention learning approach to detect AI-synthesized faces. Our work sheds light on involving human factors to enhance defense against AI-synthesized face images.

1 Introduction

Recent advances in deep neural networks have significantly improved AI synthesis techniques such as Generative Adversarial Networks (GANs) that automatically produce realistic-appearing images [1, 2, 3]. Despite positive applications [4, 5, 6], increasingly realistic models are being abused in online fraud and mischief, which causes severe trust and security threats. Especially, the abuses of AI-synthesis techniques generate images of *nonexistent yet photorealistic* persons to deceive users or spread propaganda.

Deceptive content historically used low-quality content or plagiarized others' images, whose origins are easier to identify (such as by reverse image search [7]). But AI-synthesis techniques allow miscreants to circumvent existing defenses by generating realistic-appearing and unique face images. Recently, we have witnessed a surge in real-world incidents. For example, an AI-synthesized photo was used in a suspected spy's LinkedIn profile as part of espionage efforts [8], a fake political candidate on Twitter (set up by a high school student) was created with the portrait image of a nonexistent person that AI algorithms produced [9], and groups of AI-generated profile photos of fake accounts were found on Facebook distributing polarization [10].

Challenges. Unfortunately, so far, techniques to counter AI-synthesized facial images are limited. Existing detection approaches [11, 12, 13, 14, 15] mostly train off-the-shelf classifiers, susceptible to the risk of picking superficial features [16]. While some research [17, 18] suggested specific facial parts as detection features, the features were based on the heuristics of individual researchers, limited to the individual perception or assumptions. We lack a systematic understanding of what detectable AI artifacts are more prevalent quantitatively in such images, specifically what regions are suspicious and what specific patterns resemble synthesis.

Our approaches and findings. In this paper, we develop a complementary novel approach that uses crowdsourcing intelligence to characterize and defend against AI-synthesized face images. We derive and analyze AI-synthesis artifacts annotated by multiple users (instead of by individual researchers or automated systems), which provides new insights to investigate and identify AI-synthesized images. While an individual user has limited capability, the annotations of multiple users will aggregate in finding constantly marked artifact regions (example user annotations in Figure 1, where heat color indicates the number of annotations aggregated for a position). We focus on human face synthesis, as this poses high practical threats in social engineering attacks [10, 19, 20]. Research in neuropsychology has shown that the human visual system is sensitive to face perception [21, 22], which has natural advantages for the analysis of face images.

Our work systematically identifies *where the synthesis artifacts are likely to be located* and *what characteristics the*

synthesis patterns have. We design a user study that prompts users to visually draw suspicious regions on AI-synthesized face images, and input text to describe annotated regions. While prior work [23, 24, 25] has explored crowdsourcing studies to analyze AI-synthesized images, these studies used designs limited to only binary questions or rating questions. Instead, our design (drawing regions and inputting text to describe suspicious regions) allows deep quantitative analysis of what specific artifacts often occur in AI-synthesized images and how these results can be leveraged for detection.

Our analysis compares and quantifies 15 different regions, including facial and non-facial regions. For comparative analysis, we include a control group of real images in experiments. For AI-synthesized images, we use the images generated by StyleGAN2 [3] and StyleGAN3 [26], which are widely used in practice [27, 28] and have been reported in real-world incidents [29, 9]. We discover what synthesis artifacts are prevalent and distinct from real images as opposed to prior work which only suggested the existence of artifacts [18, 17]. We summarize our main findings on AI-synthesized face images. (1) Facial regions show various degrees of artifacts despite exhibiting AI synthesis defects. Ear and hair regions in synthesized images are more likely to exhibit defects that users discern, ranging from 2.3 to 4.3 times higher likelihood compared to the control group of real images. On the other hand, other regions, such as nose and eye, present less effectual artifacts to distinguish synthesized images without showing statistical significance. In general, we observe that the facial regions distant from the central face area lead to increasing levels of distinguishable artifacts. (2) Non-facial regions show consistently high likelihoods of AI synthesis artifacts. Non-facial objects of hat, earring, eyeglass, or clothes are frequently annotated as suspicious regions in synthesized images, with an overall 6.6 times higher likelihood compared to the control group of real images. We find that non-facial regions have higher probabilities to exhibit synthesis artifacts compared to facial regions. (3) The prevalent pattern of artifacts in synthesized images is blur, e.g., correlated with ear, eyeglass, and clothes regions. Additionally, the facial and non-facial regions show other unique patterns, such as skin anomalies in facial regions and unknown objects in non-facial regions. The patterns in suspicious regions in synthesized images are generally different from the control group of real images. Our findings provide new insights into synthesis artifacts to characterize and recognize AI-synthesized faces. Based on the results, we compile actionable suggestions for content moderators to screen AI-synthesized images empirically.

Furthermore, with the intelligence of user annotations, we investigate the potential of enhancing the detection of AI-synthesized faces. We adopt an attention learning approach, which guides inference to the regions of interest. The artifact regions from crowdsourcing annotations provide attention guidance during the training of the detection model. We include eight synthesis models in detection experiments, spanning GAN, autoencoder, and diffusion models. The evaluation on AI-synthesized faces shows that the detection guided by user annotations outperforms the state-of-the-art detection approaches [30, 15, 17], and achieves comparatively high generalization performance. We further evaluate common evasions on the synthesized images, and observe that the detection with user annotations retains high robustness against evasions.

Figure 1: Examples of user annotations on AI-synthesized face images. Multiple users draw bounding boxes to locate suspicious regions. We use heat color to indicate the number of annotations aggregated for a position (red color parts have high annotation numbers). The aggregation of multiple user annotations focuses on key artifact regions.

To summarize, we make the following contributions in this paper.

- We take a novel analysis perspective and perform an empirical study to characterize artifacts that users commonly perceive in AI-synthesized face images. We develop a crowdsourcing annotation approach to systematically aggregate multiple user annotations that locate suspicious regions and extract artifact patterns.
- We characterize what synthesis artifacts and patterns are prevalent in AI-synthesized face images. We find that facial regions distant from the center (such as ear and hair) are more likely to exhibit synthesis artifacts, and non-facial regions consistently show high likelihoods of defects (compared to facial regions). The prevalent pattern of artifacts in synthesized images is blur. Our findings provide empirical insights to recognize AI-synthesized faces.
- We incorporate an attention learning method with user annotations to detect AI-synthesized faces. The experiments show our approach outperforms the state-of-the-art detection approaches in accuracy and remains robust against

evasions. The results demonstrate the potential benefits of human intelligence to defend against synthesized face images.

2 Background

We introduce the background of AI-synthesis techniques that automatically generate face images, and describe general human visual system which is evolved to recognize and perceive faces.

2.1 AI-synthesis Techniques and Models

AI techniques with neural networks are used to generate photorealistic-looking photos of people who do not exist in reality. Among various open-source synthesis techniques, Generative Adversarial Networks [31] (GANs) achieve the state-of-art performance and efficient computation, in which two neural networks compete to improve quality iteratively. A series of GAN models are developed to achieve high synthesis effects. ProGAN [1] added neural network layers and learned progressively to generate large-resolution images. StyleGAN [32] (based on ProGAN) introduced finer latent representation and style information, and provided a dataset of real human faces FFHQ which became a common training set for later models. StyleGAN2 [3] (based on StyleGAN) simplified dataflow and overcame previously noticed weaknesses. MSG-GAN [33] (based on StyleGAN2) was developed to improve the stability of synthesizing high-resolution images. StyleGAN3 [26] (based on StyleGAN2) used continuous representation for detail transformation. Anyres-GAN [34] (based on StyleGAN3) sampled patches to synthesize images at arbitrary scales. In addition, other AI-synthesis approaches have been developed for producing high-quality images. For example, StarGAN v2 [35] performed an image-to-image translation using multiple modules to generate images with diverse styles. Nouveau Variational Autoencoder (NVAE) [36] learned a latent encoding through a variational autoencoder (VAE) and generated images using the decoder. Latent Diffusion Model (LDM) [37] employed a denoising autoencoder to model images as a diffusion process from a latent vector.

In our user study (Section 4), we use face images generated from StyleGAN2 and StyleGAN3, the milestone GAN models which have attained high popularity in practice [27, 28]. Anecdotes have shown that face images generated from StyleGAN2 were used to deceive users [9]. The image quality of StyleGAN3 is similar with StyleGAN2 (in terms of FID, Frechet inception distance) as presented by the original work [26]. The difference is that StyleGAN3 has changes in internal representations to address texture sticking and improve the equivariance metrics. In detection experiments (Section 6), we include more models to examine detection generalization (including various GAN models, and autoencoder and diffusion models).

2.2 Human Perception Sensitivity on Faces

Humans use vision perception as a primary sensory means and have dedicated neurobiological capability to recognize faces. A significant amount of neural signals are for visual information processing. Prior research has shown that human visual system is specialized for the recognition of faces [38, 22]. For socialization, humans evolve to be capable of quickly extracting traits of faces and identifying face differences. Humans are sensitive to processing facial information [38]. For vision tasks, humans have advantages to achieve high-quality results.

On the other hand, human attention is more attracted by face images. Photographic face images promote affection and social attraction of users [39]. Social networks and service websites typically have user accounts to set with profile photos. Displaying profile face photos is an important factor to influence decision making online, such as friend request acceptance [40, 41] or online purchasing [42, 43]. Therefore, face images have become a target of attackers to manipulate and falsely gain users' trust to perform malicious activities.

3 Design Overview and Research Questions

AI-synthesized face images have been increasingly abused by miscreants to falsely gain users' trust in social engineering attacks, such as creating fake social media profiles (real-world incidents [8, 9, 19, 10]). Existing detection approaches mostly rely on black-box classifiers or heuristics of researchers' individual perception [11, 12, 13, 17, 30, 15]. In contrast, we develop a novel method to leverage user perceptions to systematically characterize and defend against AI-synthesized face images. We derive and analyze AI-synthesis artifacts annotated by multiple users (instead of by individual researchers or automated systems). Our quantitative analysis answers the following research questions.

RQ1. Do AI-synthesized face images contain artifacts that users commonly perceive?

RQ2. Where in the AI-synthesized face images are the synthesis artifacts located?

RQ3. What patterns do the perceived artifact regions exhibit in AI-synthesized images?

RQ4. How can user perceptions be used to facilitate detecting AI-generated face images?

Figure 2 shows the design overview of our study, and the corresponding components that investigate the research questions. We conduct a user study that collects crowdsourcing annotations to find and characterize commonly perceived synthesis artifacts (Section 4 and Section 5). Specifically, for each face image, users are requested to rate the face fidelity

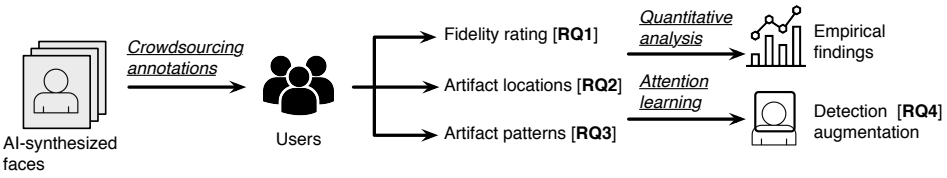

Figure 2: Design overview of our study. The analysis aims to answer the research questions **RQ1** to **RQ4** described in Section 3.

(for **RQ1**), draw bounding boxes to locate suspicious regions (for **RQ2**), and input textual fields to describe annotated regions (for **RQ3**). Our study design focuses on annotating and extracting suspicious regions, which is different from prior crowdsourcing work [23, 24, 25], since our goal is to find and characterize suspicious regions of synthesis artifacts. As described in Section 2.2, humans have dedicated visual capabilities of face perception [21, 22], so crowdsourcing has advantages for analysis of face images. Note that we aggregate multiple users' annotations (not just a single user) to extract commonly perceived artifacts and prune outlier mistakes. Based on the aggregated user annotations, we qualitatively compare and characterize various artifacts in AI-synthesized face images. The findings provide new insights of empirically recognizing synthesized faces (we discuss suggestions for content moderators in Section 7). To further leverage user annotations in automated detection, we incorporate an attention learning mechanism (Section 6) to detect AI-synthesized face images (for **RQ4**). While attention mechanisms traditionally adjust network architecture to optimize feature weights [44, 45, 46], attention from input data provides guidance information [47]. We use an attention learning approach to combine the attention from human annotations and the features learned from neural networks. The detection improvement demonstrates the capability of user annotations to facilitate recognizing AI-synthesized faces.

4 Methodology of Crowdsourcing Annotations

We describe the design of crowdsourcing annotations and the user study to extract AI-synthesis artifacts recognized by multiple users. In this work, we develop crowdsourcing annotations to quantitatively identify and characterize artifact regions that users commonly perceive.

4.1 User Study Settings

We conduct user study experiments on the crowdsourcing platform, Amazon Mechanical Turk (MTurk). We develop a web annotation interface (details in Section 4.2) which accommodates MTurk participants to draw suspicious regions on the images and describe artifact patterns. We provide an instruction page which only informs participants how to use the annotation tool and explains that the images may be fake from AI generation, rather than providing detailed instructions on how to find synthesis artifacts or what suspicious artifacts look like (to avoid biasing users' own perception). Human users are equipped with the visual system to naturally capture abnormal regions on face images. To elicit comprehensive analysis, we add a control group of real images in the experiments (comparison results in Section 5). Each participant will be assigned a sequence of synthesized images and real images (as the control group) for annotations. The images will be displayed in random order.

Face images for crowdsourcing annotations. For crowdsourcing annotations, we use publicly available models of StyleGAN2 [3] and StyleGAN3 [26], which are widely used AI-synthesis models for human portraits and have high star and fork rankings in practice [27, 28] (we include more synthesis models for detection experiments in Section 6.2). Moreover, face images generated by StyleGAN2 and StyleGAN3 have been witnessed in real-world incidents or attacks [29, 9]. The two synthesis models facilitate comparison and understanding of how AI synthesis has improved. We randomly generated 100 synthesized images from StyleGAN2 and 100 synthesized images from StyleGAN3. For the control group of real images, we randomly sampled 100 images from the FFHQ dataset [32], as FFHQ is the basis of real images for training most of the recent face models. The images have high quality with 1024×1024 resolution. We manually examine and present the distribution of the gender and ethnicity of the faces in Appendix A.

4.2 Crowdsourcing Annotation Designs

We develop the annotation interface for MTurk participants to mark and describe the artifacts that they perceive on each image. Figure 3 shows the example annotation webpage that we design. The annotation webpage displays the images for annotation and contains instructions to participants. The instructions inform participants how to use the annotation tool and describe the scenario rather than providing detailed instructions on what to look for in the AI-synthesized images, to avoid annotation biases. The language of the instructions is kept concise and intuitive, which allows regular users to comprehend the task and use their own judgment to explore suspicious regions.

In the procedure of the task, the participant first agrees online a consent form. The participant is then guided through an instruction page. The instruction page includes an inter-

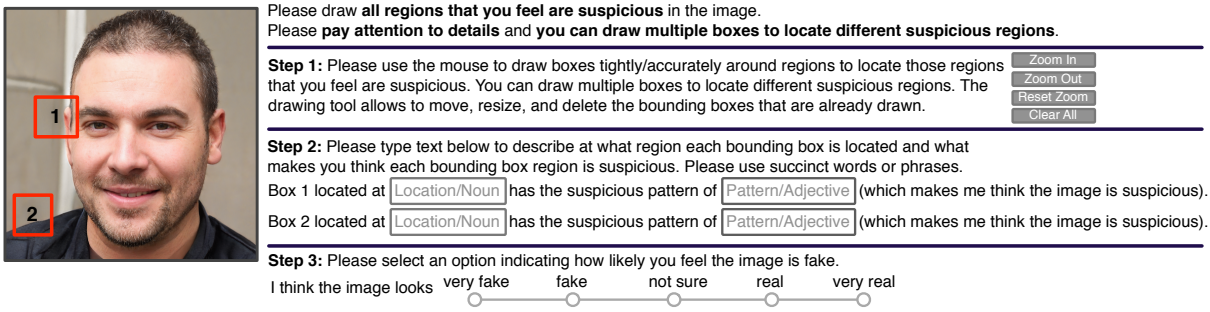

Figure 3: The crowdsourcing annotation webpage that we develop to instruct users through the scenario and annotate the displayed image. **Step 1** requests users to draw on top of the image and carefully size and position the bounding boxes to capture suspicious regions. Upon drawing, the boxes are assigned indexes for reference in **Step 2** where users are requested to complete the prompt on where the box is located and describe what is suspicious with the region (the rows are dynamically updated according to the number of drawn boxes). Finally, **Step 3** asks the users to select from the rating choices to indicate how fake the image appears.

face to get familiar with the drawing tool, which requests the participant to use the mouse to draw boxes and move or resize the drawn boxes. This also proves the participant can understand instructions and draw boxes through the webpage interface. Next the participant will start the main task of annotating images. The annotation task of each image includes the following three steps.

Step 1: Drawing bounding boxes to locate artifact regions. We request participants to use their mouses to draw a set of bounding boxes on the displayed image to mark which regions they consider suspicious (such as the red boxes drawn in Figure 3). The main purpose of drawn boxes is to visually collect and aggregate artifact regions that participants perceive. When the cursor is moved on the image, crosshairs with extended lines are displayed to track position and assist drawing accuracy. The orders of the drawn boxes of each participant are indexed (to be referred in Step 2). We do not place any restrictions on how many boxes participants may draw (allowing participants to draw no boxes) and how large the boxes can be. Relaxing such constraints gives participants full flexibility to reflect their perceived suspicious regions (more analysis in Section 5.1). We provide a set of operations on the webpage interface to facilitate accurate drawing, including moving, resizing, and deleting boxes, and zooming into the image to closely examine an area.

Step 2: Adding text to describe artifact regions. When each bounding box is drawn, we dynamically add text fields on the webpage and request participants to input text to describe the box region. The main purpose of text description is to allow participants to express how they think about suspicious regions in fake images. We use the collected information to characterize and derive artifact taxonomy (more analysis in Section 5.4). To keep the task intuitive for participants, we format the questionnaire as filling two fields in a sentence. Figure 3 shows examples displayed to participants: "`Box 1 located at` Location `has the suspicious pattern of` Pattern `which makes me think the image is suspicious.`" Participants fill text in the two fields of `Location` and `Pattern`. The `Location` field corresponds to what region/object in the image the participants meant to mark (e.g., ear, teeth). The `Pattern` field requests to describe the artifacts in the participants' own words. The open text fields allow participants to flexibly explain perceived observations. When the participant draws a box, a corresponding text question for the box will be added on the web interface (if a bounding box is deleted by the participant, the text question will also disappear). For example, in Figure 3, the participant draws two bounding boxes, and the participant will be prompted with two questions to describe the location and pattern of the drawn boxes respectively. For each box drawn on the image, we mandate the participant to enter at least one character in the corresponding description fields before allowing the task to proceed to the next image (i.e., the button for the next image becomes available to click after the condition is met). The description inputs also help participants to re-examine and justify the annotated box regions.

Step 3: Rating image fidelity. The participants are requested to rate the image's overall fakeness on a predefined five-level Likert scale [48] of "`I think the image looks very fake`", "`looks fake`", "`not sure`", "`looks real`", and "`looks very real`". As shown in Figure 3, the participants click one of the radio buttons for rating (initially no button is selected). We use the ratings to assess the users' overall perception how real or fake an image appears. Selection from descriptive ratings is explanatory to users, compared to direct numerical ratings [48]. If a participant selects a rating level towards fakeness, including "`looks very fake`" and "`looks fake`", we will mandate the participant to draw at least one box on the image to mark suspicious regions, before

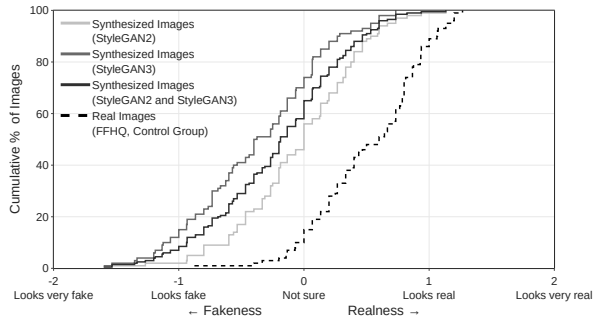

Figure 4: Distribution of the average fakeness rating. The x-axis is the average fakeness rating computed by converting the five-level descriptive Likert scale to integers from -2 to 2. We use an average score of 0 (level of "not sure") to separate perceptions between fake and real categories. On average over multiple users, 89% real images are rated towards real and 65% of synthesized images are rated towards fake.

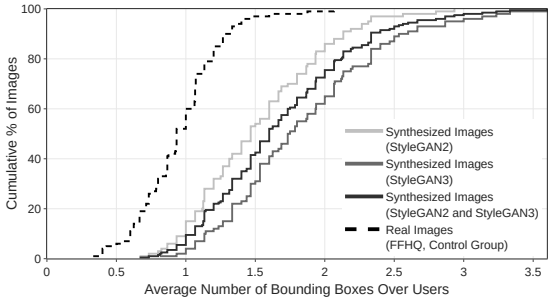

Figure 5: Distribution of the average number of boxes drawn by users for each image. We observe that 52% of real images have less than one annotation drawn on average, while 94% of synthesized images have one or more annotations.

allowing the task to proceed to the next image (if the condition is not met, clicking the button for the next image will not proceed and the webpage will display a text warning to participants).

After a participant completes the steps as described above for an image, the button to proceed to the next image becomes available and the participant clicks to start annotating another image. The top of the webpage will show the number of total images in this task and the sequence number of the current image, facilitating participants to track the progress of the task. At the end of the procedure, the participant can fill in demographic questions optionally.

Figure 1 shows examples of bounding boxes that participants draw by using our MTurk webpage interface to annotate AI-synthesized face images. Multiple participants draw bounding boxes to locate suspicious regions. The heat color indicates the number of annotations aggregated for a position (red color parts have high annotation numbers). As example text that participants input to describe suspicious regions for the synthesized images in Figure 1, the top left face image got descriptions such as location "ear" with pattern "abnormal", the top right image was marked location "eyeglass" with pattern "incomplete" or "bent", the bottom left face had "hair" annotated as "deformed", and the bottom right image had location "earring" described with pattern "blur". We perform in-depth analysis to characterize user annotations in Section 5.

4.3 Recruitment for User Study

We recruited participants on MTurk between June and September 2023 for crowdsourcing annotations. Our study was conducted with the approval of the institutional review board (IRB). We did not collect any personal identifiable information (PII) from the participants. The participants first completed the consent form before starting tasks (as described in Section 4.2). We carefully protected the anonymity of the participants. We provided options for participants to opt out of the experiments (we did not receive any opt-out requests). More details on ethics considerations are in Section 7. We conducted a small pilot experiment to ensure that the instructions and interface are clear for participants. For new participants, the first two images were used as an exercise to get familiar with the annotation procedure and will not be counted in the results.

Each image is annotated by 15 unique participants. We recruited U.S. workers who have successfully completed at least 5,000 tasks and had an approval rating greater than 98% (this setting is similar to or above the ones used in prior studies [49, 50] to recruit high-quality participants). We deployed an attention check question to verify that participants carefully complete the tasks. In addition, at the instruction page of tasks, we requested that participants completed a step to both draw boxes on an image and then move or resize the boxes, to verify that the participants could understand instructions and were capable to use the drawing tools. Participants typically took 1-1.5 minutes to complete one image. We paid the participants $0.25 for each image annotated. We designed the experiment with a power analysis [51] with a power of 0.8 using binomial proportion tests at significance level of 0.05 and a standard effect size 0.4. In total, we recruited 185 MTurk participants to annotate images in our experiments. We present demographic statistics optionally input by participants in Appendix B.

5 Characterization and Findings

In this section, we present detailed analysis of the crowdsourcing annotation results. We examine user perception capabilities, aggregate regions commonly annotated by multiple users, and extract artifact patterns to characterize AI-synthesized faces (**RQ1**–**RQ3**).

5.1 Overall Perception on AI-synthesized Images

We characterize the overall perception of human users for AI-synthesized portraits (**RQ1**). For comparison (as described in Section 4), we introduce a control group by adding real images to each set of annotation tasks. From our annotation results, we analyze and compare how users perceive synthesized and real images.

Overall fidelity ratings. We request participants to rate the fakeness level that they perceive for each image (Step 3 in Section 4.2). We convert the five-level descriptive Likert scale to integers from -2 to 2 (any evenly distributed numerical values will lead to the same analysis results). Figure 4 shows the distribution of images' average fakeness ratings. The x-axis indicates the average fakeness level over participants for an image. The y-axis means the cumulative percentage of the images. By using an average score of 0 (level of "`not sure`") to separate perception between fake and real categories, we observe that on average (over multiple participants) 89% real images are rated towards real and 65% of synthesized images (56% for StyleGAN2 and 74% for StyleGAN3) are rated towards fake. The observation suggests that human visual system genuinely recognizes differences between AI-synthesized face images and real face images.

Bounding box numbers. We further examine the number of bounding boxes that participants draw on the images. We provide participants full flexibility to decide how many boxes to annotate suspicious regions on an image (Step 1 in Section 4.2). Figure 5 shows the distribution of the average number of boxes per image drawn by participants. The x-axis represents the average number of boxes over participants for an image. The y-axis displays the cumulative percentage of the images. We observe that 52% of real images have less than one annotation drawn on average, while 6% of synthesized images (9% for StyleGAN2 and 3% for StyleGAN3) have less than one annotation. Moreover, just 1% of real images show more than two annotations on average; on the other hand, 24.5% of synthesized images (15% for StyleGAN2 and 34% for StyleGAN3) have more than two annotations. The results show that participants carefully examine images and annotate more frequently in synthesized portraits than in the control group of real portraits.

> **Takeaway 1**: On average, users recognize the differences in AI-synthesized face images from the control group of real ones, and draw more boxes to annotate suspicious regions in the synthesized images.

5.2 Extracting Aggregate Regions

In the crowdsourcing experiment, we collected boxes drawn by users (Step 1 in Section 4.2) which indicate individual's perceived suspicious parts on AI-synthesized images. Figure 1 shows examples of user annotations on synthesized face images (where the heat color indicates the number of annotations aggregated). We focus on analyzing the regions that are constantly marked by multiple users, to characterize commonly recognized synthesis artifacts (in Section 5.3 and Section 5.4). We also use the extracted regions as annotation masks to augment detection of AI-synthesized face images (in Section 6).

Algorithm 1 Extraction of aggregate regions

Input: A list L_{boxes} contains the bounding boxes that all users drew for an image. Each item M_{box} in L_{boxes} is a matrix (same dimensions as the image) marking the bounding box area denoted with 1 and all other positions with 0.
The operations $+$, $-$, and Σ are point-wise matrix operations.
The procedure constants *MinAgree* (a minimum agreement level of a region) and *AgreePercent* (a percentage used to ensure a relatively similar level agreement across a region).
Output: The list of extracted aggregate regions $L_{regions}$ for the image.

```
1:  L_regions ← list();
2:  M_aggregate ← Σ_{L_boxes} M_box;
3:  while (findMax(M_aggregate) ≥ MinAgree ) do
4:      PeakValue ← findMax(M_aggregate);
5:      AgreeLevel ← max(MinAgree, AgreePercent × PeakValue);
6:      M_mask ← extractGreaterOrEqual(M_aggregate, AgreeLevel);
7:      L_candidates ← findConnectedComponents(M_mask);
8:      for M_candidate in L_candidates do
9:          if findMax(M_candidate) < PeakValue then
10:             L_candidates ← deleteUpdate(L_candidates, M_candidate)
11:         end if
12:     end for
13:     M_region ← outputMinSizeItem(L_candidates)
14:     L_regions ← appendUpdate(L_regions, M_region);
15:     for M_box in L_boxes do
16:         if intersect(M_box, M_region) then
17:             L_boxes ← deleteUpdate(L_boxes, M_box);
18:             M_aggregate ← M_aggregate − M_box;
19:         end if
20:     end for
21: end while
22: return L_regions;
```

We develop Algorithm 1 to extract aggregate regions from bounding boxes that multiple users draw. The input is the list of bounding boxes submitted by users for an image, L_{boxes}. The output is the list of extracted regions, $L_{regions}$. The algorithm iteratively extracts the top aggregate region in each round.

1. At the beginning of the round (Line 3), we examine how many layers of annotations are stacked across the bounding boxes that multiple users drew independently (agreement level). We proceed the extraction if the agreement level in the remaining multi-layer masks is not lower than $MinAgree$. We set the practical $MinAgree$ value as four annotations (greater than 25% of participants for each image in our experiment).

2. We extract the region that has the most annotations for this round (Lines 4-14).

   (a) To separate regions (Lines 4-6), we require the agreement levels of the points included are

Figure 6: Example regions extracted by Algorithm 1 on AI-synthesized face images. The bounding boxes that users annotated on these images are shown in Figure 1.

not lower than *AgreePercent* of the peak value, in addition to *MinAgree*. We set the practical *AgreePercent* value as 50%.

(b) We use a union-find strategy [52] to extract connected components based on the multi-layer masks as candidates (Line 7). We filter the candidate regions by requiring to include the peak value (Lines 8-12).

(c) To break the tie of multiple candidate regions, we select the candidate with the smallest extracted size (Line 13) and add it as the extracted region for this round (Line 14). The strategy prioritizes choosing compact regions.

3. We exclude the selected bounding boxes, which intersect with the currently extracted region, from the aggregate masks (Lines 15-20), to prepare for the next round extraction.

Example extraction results are shown in Figure 6 (where the original bounding boxes that users drew are shown in Figure 1). Aggregation of multiple user annotations points to artifact regions.

Numbers and sizes of extracted regions. Table 1 presents statistics of the extracted regions. We first examine the average number of extracted regions over images. The average number of extracted regions on AI-synthesized images is 2.10, and the average number of extracted regions in the control group of real images is 0.96. The synthesized images have extracted regions 2.19 times more on average than the control group of real images (ratio $2.10/0.96 = 2.19$). We further analyze the average region size percentage to the full image size. The average size of extracted regions on AI-synthesized images is 2.17% of the image size, and the average size of extracted regions on the control group of real images is 2.45% of the image size. The differences have statistical significance with low p-value ($p < 0.001$). The finding shows that the annotation aggregation results focus on detailed regions in the images.

Table 1: Average numbers and size percentages of the regions extracted from annotation aggregations. The rows represent image sets. The columns indicate region statistics.

Image Set		*Average Region Number*	*Average Size Percent %*
Synthesized	*StyleGAN2*	1.83	2.14
	StyleGAN3	2.37	2.19
Synthesized Images (StyleGAN2 and StyleGAN3)		2.10	2.17
Real Images (FFHQ, Control Group)		0.96	2.45

Takeaway 2: The extracted regions that multiple users annotate as suspicious in synthesized images occur with higher incidence and focus on detailed regions.

5.3 Characterizing Artifact Locations

Based on the extracted regions (from Algorithm 1) that multiple users collectively marked, we examine `Location` text input by the users (Step 2 in Section 4.2) to identify where in the AI-synthesized face images the synthesis artifacts are located (**RQ2**). We use natural language processing techniques to analyze user input text. We apply the widely-used lexical database WordNet [53] to parse the user location text. We extract lexical parent categories from WordNet to filter candidate noun words referring to objects. The terms that specify human body regions are grouped based on the established categorization list [54]. We further group similar words that have common hypernyms in WordNet for the non-body region words. Our analysis extracts 15 categories that frequently occur in user annotations, including ten facial categories and five non-facial categories (as the x-axis in Figure 7).

We note that some categories such as "`nose`" or "`mouth`" occur in all face images, but other categories such as "`earring`" occur in only subset of the images. To account for how often these categories appear, we manually review images and count numbers with the accessories that occur. We measure the conditional probability of a given location category being marked by users (i.e., the count of being marked divided by the count of images with the location appearing in the images). We apply the two-sample one-sided hypothesis testing (binomial proportion test) [55] to assess whether the synthesized and real images exhibit statistically significant differences for annotated locations. The difference is considered statistically significant when p-value is low ($p < 0.05$).

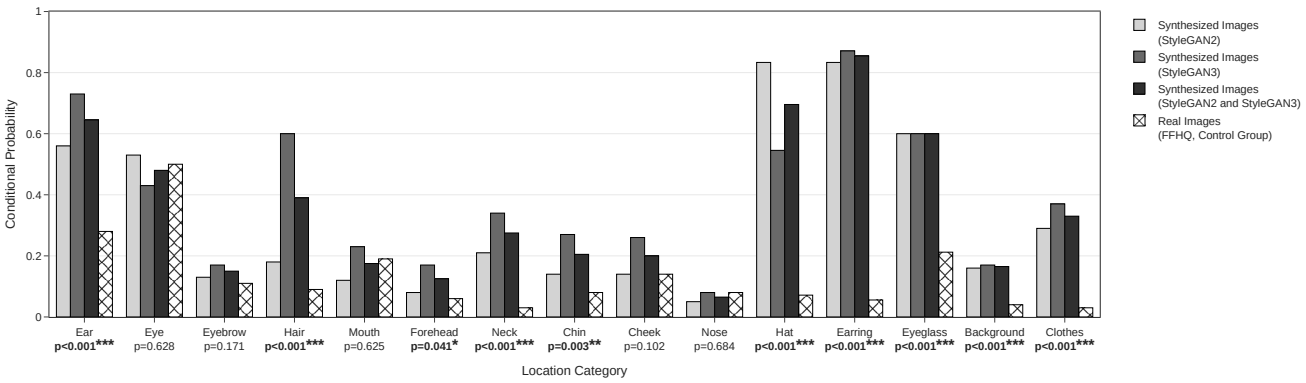

Figure 7: Conditional probabilities of the locations marked by users. The facial categories include ear, eye, eyebrow, hair, mouth, forehead, neck, chin, cheek, and nose. The non-facial categories include hat, earring, eyeglass, background, and clothes. The values below the x-axis labels represent p-value. Significance level is indicated as * ($p < 0.05$), ** ($p < 0.01$), and *** ($p < 0.001$).

Figure 7 shows conditional probabilities for different location categories. The x-axis presents the location categories. The values below the category labels represent p-value. The y-axis shows the conditional probabilities of the categories. We observe that the synthesized images show higher conditional probabilities of location annotations than the control group of real images with statistical significance ($p < 0.05$), which indicates distinct artifacts in AI-synthesized images.

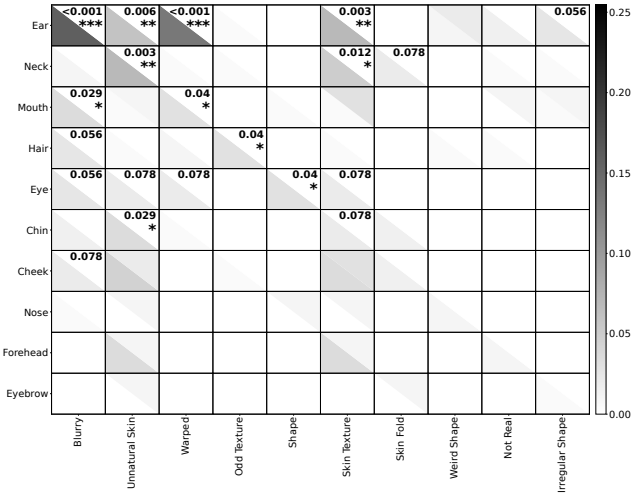
Facial location characterization. In Figure 7, we observe that facial regions show diverse degrees of probabilities to exhibit AI artifacts. Regions of "ear" and "hair" are more likely to exhibit defects that users discern. Specifically, the likelihood of "ear" extracted as suspicious regions in the synthesized images is 2.32 times higher than in the control group of real images (ratio $0.65/0.28 = 2.32$, $p < 0.001$), and the likelihood of "hair" in the synthesized image is 4.33 times higher than in the control group of real images (ratio $0.39/0.09 = 4.33$, $p < 0.001$). We note that these areas distant from the central face area have high levels of distinguishable artifacts. On the other hand, the regions of "nose", "eye", and "mouth" have relatively low probabilities of being annotated or result in similar likelihood (without a statistically significant difference) between synthesized and real images, though prior studies [18, 17] suggested artifacts in such regions. In Section 5.4 we further characterize the region patterns and find pattern differences between synthesized and real images. The observations on facial regions show that certain facial regions have high likelihoods with artifacts to distinguish AI-generated images.

Takeaway 3: Facial regions show various degrees of artifacts. Regions of "ear" and "hair" are more likely to exhibit defects in synthesized images, about 2.3 to 4.3 times higher likelihood compared to real images. Other regions such as "nose" and "eye" present less effectual artifacts to distinguish synthesized images.

Non-facial location characterization. We observe in Figure 7 that non-facial objects, including "hat", "earring", and "clothes", show consistently high likelihoods of synthesis artifacts, and annotations in the control group of real images typically do not converge on these regions. The likelihood of "hat" as suspicious regions from user annotations in the synthesized images is 9.72 times higher than in the control group of real images (ratio $0.69/0.071 = 9.72$, $p < 0.001$), the likelihood of "earring" in the synthesized images is 15.18 times higher than in the real images (ratio $0.85/0.056 = 15.18$, $p < 0.001$), and the likelihood of "clothes" in the synthesized images is 11.00 times higher than in the real images (ratio $0.33/0.03 = 11.00$, $p < 0.001$). With the conditional probabilities calculated over all non-facial categories, the non-facial regions in synthesized images overall have 6.6 times higher likelihood of being annotated as suspicious compared to the control group of real images. The observations show that non-facial regions frequently contain artifacts in AI-synthesized images, presumably due to the variety of the locations and styles of these objects which may cause the model to undertrain on properly rendering the regions. Examining these non-facial regions will facilitate recognition of AI-synthesized face images.

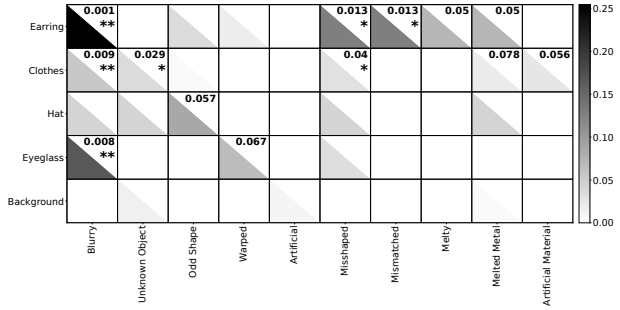
Takeaway 4: Non-facial regions, such as "hat", "earring", and "clothes", show consistently high likelihoods in synthesized images to contain artifacts. Non-facial regions overall have 6.6 times higher likelihood of being recognized as suspicious in synthesized images compared to real images.

5.4 Characterizing Artifact Patterns



We analyze user inputs for the Pattern prompt (Step 2 in Section 4.2) to understand what visual characteristics highly correlate with specific regions being annotated. We seek to

answer the question what synthesis patterns are commonly found in AI-synthesized portraits (**RQ3**). We correlate the relationship between the pattern descriptions and location descriptions from the user annotations to characterize artifact attributes.



We calculate the conditional probabilities of the description words occurring given the location tokens extracted in Section 5.3. A high probability indicates that the token pair has high correlation, i.e., the annotated location is frequently described as the specific pattern. For the textual descriptions in the `Pattern` fields, we remove stop words, lemmatize the words to their canonical forms, and generate the unigram and bigram tokens. In addition, we calculate p-value via the two-sample one-sided hypothesis testing [55] to measure significance of differences between synthesized images and the control group of real images. We select the most discriminative description tokens ranked by the p-value, and show the top 10 description tokens for the location categories in Figure 8. In each square grid of Figure 8, the bottom left triangle shows the conditional probability from the synthesized images, and the top right triangle shows the conditional probability from the control group of real images (for comparison). The numbers in the grids represent p-value in the hypothesis testing. The $p < 0.05$ indicates statistical significance, and for ease of visualization, we show the p-value that is less than 0.1 in Figure 8. We observe that users perceive different patterns for similar locations marked in the synthesized and real images. We separate the facial and non-facial location categories (based on Section 5.3) for characterization.

Facial pattern characterization. We find differences in the patterns for locations marked in the synthesized and real images. For facial locations in Figure 8(a), we observe the prevalent description in synthesized images is "`blurry`" (1st column from left). Specifically the regions showing "`blurry`" with statistical significance are "`ear`" ($p < 0.001$) and "`mouth`" ($p < 0.05$). We also find that the pattern "`unnatural skin`" (2nd column) has high correlation with facial regions in synthesized images, including "`ear`" ($p < 0.01$), "`neck`" ($p < 0.01$), and "`chin`" ($p < 0.05$). The observations demonstrate the difficulties to synthesize intricate facial details. In addition, although users may mark same regions in synthesized and real images, such as "`eye`" or "`mouth`" (Section 5.3), we observe pattern differences between synthesized and real images ($p < 0.05$), e.g., "`eye`" in synthesized images appears abnormal "`shape`" (5th column) and "`mouth`" in synthesized images tends to be "`blurry`" (1st column).

Non-facial pattern characterization. The correlations between non-facial regions and descriptive patterns are illustrated in Figure 8(b). Similar to facial regions, we find that the main synthesis pattern is "`blurry`" (1st column from left) correlated with non-facial regions, including "`earring`" ($p < 0.01$), "`clothes`" ($p < 0.01$), and "`eyeglass`" ($p < 0.01$). We also observe specific non-facial patterns of "`unknown object`" (2nd column) with "`clothes`" ($p < 0.05$) and "`mismatched`" (7th column) with "`earring`" ($p < 0.05$), which suggests that the synthesis patterns in non-facial regions at statistically significant rates do not correspond to objects that users can recognize.

(a) Conditional probabilities of pattern descriptions for facial regions (ear, eye, eyebrow, hair, mouth, forehead, neck, chin, cheek, and nose).

(b) Conditional probabilities of pattern descriptions for non-facial regions (hat, earring, eyeglass, background, and clothes).

Figure 8: Conditional probabilities of `Pattern` tokens input by the users correlated with the `Location` categories. In each square, the bottom left triangle shows the probability from the synthesized images, and the top right triangle shows the probability from the control group of real images (for comparison). The plots show the top correlation pairs ordered according to p-value. Significance level is indicated as * ($p < 0.05$), ** ($p < 0.01$), and *** ($p < 0.001$).

Takeaway 5: The prevalent artifact pattern in synthesized images is "`blurry`", e.g., correlated with "`ear`", "`eyeglass`", and "`clothes`" regions. In addition, the facial and non-facial regions show other unique synthesis patterns, specifically skin anomalies in facial regions and unknown objects in non-facial regions.

6 Detection of AI-synthesized Faces

With the intelligence of user annotations, we investigate the potential of enhancing the detection of AI-synthesized faces. We use an attention learning approach to incorporate user annotated regions, and evaluate detection accuracy.

6.1 Guided Attention Method for Detection

From our user study, we gather human annotations that collectively locate artifact regions in AI-synthesized face images. We further investigate how to use annotated data to improve detection (**RQ4**). Existing detection of AI-synthesized images typically trains black-box neural networks for classification [13, 56, 57], which have the risk of selecting superficial features. On the other hand, carefully designed heuristic approaches identify explicit features [58, 17, 59], but may suffer from scaling or generalizing to other synthesis methods. We aim to combine the strengths of the two sides. We use the set of human annotated images to guide the detection model and focus on the useful feature regions.

Using Algorithm 1 in Section 5.2, we extract attention mask annotated by users on synthesized images, which ensures that only high agreement regions are used to guide the model learning. As users mark suspicious regions in our study, the extracted mask locates artifacts in AI-synthesized images. With image dimension $H \times W$, the pixel-level annotation mask is represented as $M \in \mathbb{R}^{H \times W}$ (normalized between 0 and 1), where each element indicates the weight of user annotation for an image position. We adopt attention learning to integrate human annotation mask M when training the model. Li et al. [47] developed a method to provide direct guidance on the attention. The model attention map is calculated via Grad-CAM (Gradient-weighted Class Activation Mapping) [60] as $A \in \mathbb{R}^{H \times W}$ (normalized between 0 and 1), whose values highlight the discriminative image regions that the model has learned in training. To enforce extra attention as guidance, a mean squared error loss between A and M is introduced as in Equation (1).

$$\mathcal{L}_{extra}(A,M) = \frac{1}{H \cdot W} \sum_{i=0}^{H-1} \sum_{j=0}^{W-1} (A_{ij} - M_{ij})^2 \qquad (1)$$

This loss term $\mathcal{L}_{extra}(A,M)$ is integrated with a weighting parameter into the final loss function for training the model. By minimizing the loss, Equation (1) makes the learned attention map A close to the user mask M, which guides the network to pay attention to the user marked regions. We add the loss to provide extra supervision in the training. The attention learning combines the heuristics from human annotations and the features learned from neural networks.

6.2 Detection Experiments and Evaluation

We perform experiments to investigate the effects of adding human annotations to guide attention and compare with other detection methods. The classification neural network that we use is the ConvNeXt [62]. Our training data contains 10,000 synthetic face images (5,000 from StyleGAN2 and 5,000 from StyleGAN3) and 10,000 FFHQ real face images. To provide the extra guidance, we include 200 user annotated images (from our user study experiment) with masks extracted by Algorithm 1. These 200 images are included to train all methods (only our approach uses the human annotation masks). The training data size has similar magnitude and ratio compared to the prior attention learning framework study [47].

To evaluate detection generalization, our testing data spans images generated from a variety of generation methods, with publicly released image sets or pre-trained models to synthesize high-quality images of 1024×1024 resolution. In addition to StyleGAN2 [3] and StyleGAN3 [26] (which also generate the training images in our experiments), we perform testing on earlier and later GAN models, including StyleGAN [32] (predecessor of StyleGAN2), MSG-GAN [33] (successor of StyleGAN2), and Anyres-GAN [34] (successor of StyleGAN3). We also test other models, including StarGAN v2 [35], NVAE [36], and LDM [37]. Each testing experiment consists of 1,000 synthesized face images compared with a fixed set of 1,000 FFHQ real face images.

We run training and evaluation on a NVIDIA TITAN RTX GPU with 24GB of RAM. All images are resized to 224×224, since the ConvNeXt model is pretrained on this resolution [62] and it is close to the practical profile image resolution on social media platforms [63, 64, 65]. In training, we use the Adam optimizer [66] and set the weights of the loss components as 1 for the classification loss and 5 for the guided supervision loss.

Detection accuracy. To evaluate the performance of our method, we compare with the state-of-the-art approaches that were recently developed on AI-generated image detection, including LGrad [30], UniversalFakeDetect [15], and an expert-based detection [17]. The experiments were trained on the same data as our approach. We measure detection accuracy using the F-score [61] and show the evaluation results in Table 2. The rows represent detection approaches. The columns show the evaluation results on images generated by various synthesis models. With the evaluation on StyleGAN2 and StyleGAN3 image sets, our approach of guided attention achieves an F-score over 0.970, outperforming the other approaches (and showing improvement via ablation, more details below). To evaluate generalization across images from other synthesis models (Anyres-GAN, MSG-GAN, StyleGAN, StarGAN v2, NVAE, LDM), our approach yields an overall F-score of 0.927, compared to LGrad with 0.556, UniversalFakeDetect with 0.841, and expert-based detection with 0.835. In addition to improving detection on StyleGAN

Table 2: Breakdown of detection accuracy across the AI-synthesized image testing datasets. The accuracy values show F-scores [61]. *Testing Setup* indicates whether or not evasions were applied to the AI-generated images for testing. *Training Method* denotes what type of training was used for the detection approach. *Same Models as Training* datasets used a train-test split across StyleGAN2 and StyleGAN3 images. *Other StyleGAN Related Models* datasets were testing images generated by other models related to StyleGAN (including both predecessor and successor models). *Other Models* datasets were testing images generated by other synthesis models. The last column shows the arithmetic average across all testing datasets for each detection.

Testing Setup		*Training Method*	*Same Models as Training*		*Other StyleGAN Related Models*			*Other Models*			
			StyleGAN2	StyleGAN3	Anyres-GAN	MSG-GAN	StyleGAN	StarGAN v2	NVAE	LDM	Average

related images, our approach also generalizes to improve detecting images generated by other synthesis models (StarGAN v2, NVAE, and LDM). Our attention approach achieves statistically significant performance improvements over each of the other approaches ($p < 0.001$ using the two-sample, binomial proportion test). The results show that our approach achieves high detection accuracy and competent generalization performance.

Ablation analysis. To examine the efficacy of incorporating user annotations in detection, we perform an ablation experiment to investigate how much the annotations in training contributes to the detection performance. For the attention ablation setting, we remove the attention component in the loss function and evaluate on the same image sets. Table 2 includes the F-score values of the attention ablation experiment. Without attention in the training, the detection results show lower accuracy, and the overall performance is 0.823. The improvement contribution of attention based on annotations overall is 10.4% (0.823 compared to 0.927). The attention detection with user annotations performs better than the ablation setting with statistical significance ($p<0.001$ using a two-sample, binomial proportion test). The results demonstrate that incorporating annotations considerably improves the detection performance.

Detection robustness. We further examine robustness and evaluate common evasions on the synthesized images, including blurring, cropping, and JPEG compression. We apply evasions only on the synthesized images, not on the real images (i.e., real images are unchanged, since evasions will only be performed by adversaries on synthesized images). For the blurring we use a Gaussian blur with a kernel size of 13 and a standard deviation of 2. For cropping, we randomly crop out up to 10% of the image (i.e., retaining 90% of the image). For JPEG compression, we use a quality level of 75%. Table 2 shows the F-score accuracy under various evasions. Our approach consistently achieves high accuracy across evasions, compared to the other three approaches. LGrad experiences significantly degraded performance since it depends on the gradient pre-processing susceptible to small changes in the pixel values. UniversalFakeDetect uses a predefined feature space, and its accuracy under evasions largely remains lower compared to our approach. Expert-based detection forces the detection to focus on a fixed region based on heuristics and the performance under evasion is still lower than our approach. We observe that detection guided with attention that incorporates human annotations learns inherent features and remains robust against evasions.

Takeaway 6: Attention-guided detection with human annotations achieves high accuracy compared with prior detection approaches, and retains high robustness against evasions.

7 Discussion

We provide discussion based on our findings and experiments, including ethics considerations, suggestions to defend against synthesized faces, and limitations and future work.

Ethics considerations. Our user study was performed with the approval of our institutional review board (IRB). The IRB approval established specific guidelines addressing ethical considerations, such as collecting data securely and obtaining user's consent. We diligently adhered to these guidelines throughout our research to protect the study participants. In our experiments, we carefully avoided collecting any personal identifiable information (PII) from participants and all results are presented in aggregate statistics. We also provided participants options to opt-out of the experiments (we did not receive any opt-out requests). We complied with established ethical norms in our data analysis and result presentation, including securing data storage and maintaining participant anonymity and privacy.

We consider that the value in developing potential defenses against AI-synthesized images outweighs the potential risks, although research into the artifact characteristics of AI-synthesized faces could be used to improve the quality of AI synthesis techniques. Our findings provide higher actionable insights for content moderators than for miscreants. Online moderators can easily operationalize our findings by scrutinizing the suggested regions (more details below) or using attention enhance detection that we describe to identify AI-synthesized images. On the other hand, our identified synthesis artifacts are difficult to rectify for miscreants, since the artifacts are inherent from systemic limitations in AI-synthesized images.

Suggestions for content moderators to recognize AI-synthesized faces. While individual users may have limited capability to distinguish between AI-synthesized content and real images, aggregating across user responses allows for clear identification and localization of artifacts. The aggregated user annotations provide deeper levels of insight into the artifacts by accumulating individual user intelligence. Based on the crowdsourcing insights, our findings suggest regions and patterns to identify AI-synthesized images. First, in AI-synthesized face images, accessories such as earring and eyeglass or specific facial details such as ear and hair likely show anomalies. Second, anomaly patterns in AI-synthesized images are typically misshaped boundaries, unnatural skin, and unrecognizable objects, which are different from suspicious attributes in real images. Content moderators can focus on these regions and patterns that we summarize when screening large numbers of suspicious images to improve the efficiency of identifying AI-synthesized faces. Our findings can also help to educate general users on typical attributes of AI-synthesized faces to avoid being deceived.

Deployment scenarios. Our approach can be deployed in various ways to assist stakeholders defending against the abuse of synthesized images. (1) Our work of user annotations provides quantitative findings about artifacts in AI-synthesized images. Expert researchers can use our approach to study quantitatively specific synthesis areas for rigorous analysis, in addition to applying heuristics. (2) Content platforms can deploy our approach and leverage collective annotation intelligence from the moderation team to build effective detection systems with attention learning. This will mitigate disinformation propagation and AI-based deception on the platforms. (3) Our approach can also be incorporated with other detection approaches, to enable a multi-layered defense strategy. Longitudinal deployment will facilitate continual analysis and detection on AI-synthesized images.

User's trust in real images. Traditionally, the user's assumption for facial images has been that the faces are real, but the continued growth in AI-synthesized content threatens to challenge users' trust. We included a control group of real images in our experiments. While participants can distinguish between AI-generated content and real face images, many still choose the level of "`looks real`" instead of "`very real`". By checking real images with lower trust scores, we find these images contain less common elements such as unusual clothing, dyed hair, or out of the ordinary poses or expressions. The decreased trust of real images with unfamiliar contents suggests users may first begin to suspect content which does not conform to their common definition. The findings are in line with prior work [49, 24] on online user trust. The effect on user's trust in real images needs additional efforts to counter the negative impact brought by AI-synthesized images especially for marginalized groups.

Limitations and future work. A limitation is we focus on face images synthesized by AI techniques. Face images are often used to establish trust and abused by miscreants to deceive users. With attacks expanding, other non-facial images may also present potential misuse in security areas such as product review spam or disinformation. Our approach can be adapted to analyze other categories of synthesized images. Another limitation is our analysis is mainly on GAN models (given its wide abuse in practice), though we include multiple models in the user study and detection experiments. A prospective work direction is to expand analysis on future or more synthesis techniques, as new synthesis models are developed. We anticipate our analysis approach can be applied to find more synthesis characteristics. A potential extension of our work is to use our human-in-the-loop approach to continue adapting to other modalities such as audio or video.

We acknowledge that our results may not fully transfer to

an unprompted setting. We provided brief prompts to allow participants to understand the task, as our goal is to use crowdsourcing characterizing AI-synthesis artifacts. Research to investigate user studies identifying AI-synthesized images under different types of prompting is a promising future research area.

8 Related Work

We describe previous studies on detection of AI-synthesized images and user studies for synthesized face images, and highlight the differences from our work.

Detection and identified artifacts of AI-synthesized images. Existing studies to detect AI-synthesized images and artifacts mainly rely on two strategies, black-box classification or specific pattern heuristics. Classification-based approaches [11, 12, 67, 15] typically train another deep neural network on real and synthesized images, which performs automated learning for detection. A group of work [13, 68, 69, 70] attempted to augment images with different evasions during training to improve the classifier's robustness. Other work investigated using an ensemble of classifiers [14, 71] to supplement individual model's performance. Finally, another body of work explored other feature spaces such as different color representations [72], frequency domain [73], or gradient [30]. However, these classification approaches for detection risks learning superficial features [16].

Heuristic-based approaches used a wide range of specific observations or assumptions about synthesis artifacts such as color, frequency, or facial features, but are limited to the individual perception or heuristics of researchers. Prior studies [59, 74, 75] examined inconsistent colors in synthesized images. Some studies [76, 77, 78, 56, 79] derived signals from noise patterns and frequency analysis generated by GANs. Another line of prior work [58, 17] suggested specific facial parts as features to distinguish AI-synthesized face images.

In contrast, our work complements prior detection and analysis. We use crowdsourcing intelligence to systematically find and characterize AI-synthesis artifacts annotated by multiple users (instead of by individual researchers or automated systems). Our findings reveal new characteristics in AI-synthesized images, and our detection with attention guidance combines strengths of heuristics from human annotations and automated detection from neural network classification.

User studies on AI-synthesized face images. Recent research has conducted user studies to understand users' behaviors and trust on AI-synthesized faces. Mink et al. [49] established social network profiles with AI-synthesized portraits and performed user studies to investigate what factors affect users' trust. Guo [25] proposed alternate analysis platforms for evaluating human performance on identifying AI-synthesized faces. Other work [23, 24, 80] analyzed whether users can distinguish between AI-synthesized and real faces. These studies inspire our work. However, previous work has focused on the victim's perspective and used relatively simplistic designs.

Our work, on the other hand, quantitatively examines where and how users perceive artifacts and is the first to leverage user perception as means to detect and characterize AI-synthesized face images. Our user study designs to use crowdsourcing annotations to locate and examine suspicious regions in synthesized images, with the main goal to characterize artifacts in AI-synthesized images. Based on aggregated human annotations, we extract characteristics of synthesis artifacts and demonstrate the potential of involving human factors to defend against AI-synthesized faces.

9 Conclusion

In this paper, we develop a novel approach that leverages crowdsourcing annotations to systematically characterize and recognize AI-synthesized face images. Existing detection and analysis mostly relies on black-box classifiers or heuristics of researchers' individual perception. In contrast, we design a user study to aggregate and characterize AI-synthesis artifacts annotated by multiple users (rather than individual researchers or automated systems). Based on quantitative results, we find that facial regions distant from the center (such as ear and hair) and non-facial regions are more likely to exhibit synthesis artifacts. The prevalent pattern of artifacts in synthesized images is blur. Our findings provide empirical insights for online moderators or general users to recognize AI-synthesized faces. Furthermore, we incorporate user annotated regions into an attention learning approach to detect AI-synthesized faces. Evaluation comparing with prior approaches shows that our approach achieves high detection accuracy and remains robust under evasions. Our results demonstrate the human-in-the-loop potential to defend against AI-synthesized images.

A Statistics on Images

To examine the distribution of the images, we manually labeled the gender and ethnicity of the faces. While the images were randomly sampled, the gender and ethnicity show similar trend. For the gender of images, 53% of synthesized images (54% of real images) were female and 47% of synthesized images (46% of real images) were male. For the ethnicity of images, 67% of synthesized images (62% of real images) were White, 4% of synthesized images (4% of real images) were Hispanic or Latino, 5% of synthesized images (3% of real images) were African American, 11% of synthesized images (20% of real images) were Asian, and 13% of synthesized images (11% of real images) were uncertain.

B Additional Statistics on Participants

We aggregate the statistics based on participants who answered demographic questions optionally. The optional demographic questions include the participant's age range, education, gender, and ethnicity. The ages of the participants were in a range of 20 to 64 with a median range of 35-39. Most participants had post-secondary education with 77% having received a bachelor degree or above. For the gender of participants, 44.85% were female and 55.15% were male (we provided the non-binary option and the option was not selected). For the ethnicity of participants, 79.46% were White, 2.70% were Hispanic or Latino, 2.16% were African American, 2.16% were Asian, and 13.52% were uncertain.

SoK: The Good, The Bad, and The Unbalanced: Measuring Structural Limitations of Deepfake Media Datasets

Seth Layton, Tyler Tucker, Daniel Olszewski, Kevin Warren, Kevin Butler, and Patrick Traynor
University of Florida

Abstract

Deepfake media represents an important and growing threat not only to computing systems but to society at large. Datasets of image, video, and voice deepfakes are being created to assist researchers in building strong defenses against these emerging threats. However, despite the growing number of datasets and the relative diversity of their samples, little guidance exists to help researchers select datasets and then meaningfully contrast their results against prior efforts. To assist in this process, this paper presents the first systematization of deepfake media. Using traditional anomaly detection datasets as a baseline, we characterize the metrics, generation techniques, and class distributions of existing datasets. Through this process, we discover significant problems impacting the comparability of systems using these datasets, including unaccounted-for heavy class imbalance and reliance upon limited metrics. These observations have a potentially profound impact should such systems be transitioned to practice - as an example, we demonstrate that the widely-viewed best detector applied to a typical call center scenario would result in only 1 out of 333 flagged results being a true positive. To improve reproducibility and future comparisons, we provide a template for reporting results in this space and advocate for the release of model score files such that a wider range of statistics can easily be found and/or calculated. Through this, and our recommendations for improving dataset construction, we provide important steps to move this community forward.

1 Introduction

Deepfake media, known colloquially as deepfakes, are videos, images, and speech that are generated from deep learning models to appear as if they represent genuine snapshots of reality. Whether focused on a specific individual or attempting to create realistic but untargeted humans, these increasingly sophisticated attacks have been enabled by the confluence of powerful GPU hardware and machine learning models. With significant potential for misuse in areas ranging from financial fraud [1] and damage to brands [2] to politics [3], the ability to detect such attacks will become increasingly important. Such a need is already a reality, as some prominent individuals claim that public statements may be deepfakes and not authentic [4].

Researchers attempting to enter this space are confronted with a surprising challenge: determining which datasets they should use to most meaningfully compare against other defenses. We argue that because detecting deepfake media is an instance of the anomaly detection problem, baselines from that many-decades-old field should guide the construction and selection of datasets in this new one. Through this lens, we provide the first systematization of the deepfake media space, the generation techniques used to create samples, metrics to evaluate detectors, and how datasets are constructed. Through this systematization, we observe significant deviations from classical anomaly detection, yielding several challenges and highlighting the need for guidelines of use.

In so doing, we make the following contributions:

- **Categorize Existing Deepfake Media Datasets:** A wide array of deepfake media datasets exist; however, selecting an appropriate dataset is non-trivial and important. We systematize the current space of deepfake media according to their generation techniques, evaluation metrics, and class distribution.
- **Identify Limitations in Deepfake Media Datasets:** Identifying deepfake media is an instance of the anomaly detection problem. As such, we use popular anomaly detection datasets to form a baseline for comparison. From this baseline, we demonstrate significant deviations in underlying assumptions including performance metrics and class distributions. We then show that these differences result in the overstating of detector performance.
- **Provide Best Practices:** We discuss guidelines for both current and future datasets to facilitate more meaningful measurements and comparisons. These include presenting a range of base rates to deal with real-world measurement uncertainty, acknowledgment and justification of dataset imbalances, and characterization using appro-

priate metrics. Additionally, we make available a metric reporting template to facilitate comparison.

Of crucial importance, our systematization demonstrates that recognition of the base-rate fallacy [5] and the use of limited metrics are significant problems in this emerging community. Failing to understand and correct such methodological issues will not only result in overstated performance, but will make the transition to deployed systems more difficult. As such, we believe that our recommendations will not only make the current state of the art more realistic, but that our artifacts will make future work more comparable and replicable.

The remainder of this paper is as follows: Section 2 systematizes deepfake media and uses popular datasets from anomaly detection to establish a baseline; Section 3 measures the impact on stated performance that results from these significant differences; Section 4 includes discussion and practical applications to better contextualize the performance of deepfake media detectors; Section 5 offers recommendations to both dataset designers and researchers attempting to enter this space; and Section 6 provides concluding remarks.

2 Systematization of Deepfake Media

Synthetic media includes forms of altered content, whether by simple alterations (i.e., cheapfakes) or sophisticated generation techniques (i.e., deepfakes). Recent advances in deep learning democratized deepfakes, making their creation inexpensive and automated. Moreover, while cheapfakes demanded considerable time and expertise for modest results, deepfakes produce remarkably authentic content surpassing what previous methods could accomplish.

2.1 Setup

To investigate the state of deepfake media research, we identify three distinct domains: video, image, and speech. For each domain, we collect the most popular datasets based on Google Scholar citations. Then, we analyze each corresponding dataset by generation technique, how the authors report baseline model performance, and the class distribution of fake to real signals. Contextualizing datasets in this way reveals community trends in deepfake media research from a security perspective. Additionally, as deepfake media detection may be classified as anomaly detection at its core, we use the network intrusion detection (NIDS) field and datasets as a baseline for reasoning; as this is a mature and well-established subcommunity of anomaly detection. We gather the suggested metrics and class distributions from 15 widely-cited networking IDS datasets [6–20] surveyed by Ring et al. [21].

2.2 Deepfake Media

To better understand the types of deepfake media we provide a brief overview of the major categories.

Video: Deepfake video samples are not always fully generative, instead they often rely on a source video including a real human subject. From that video, models will perform face and landmark (facial features) detection before sending encoded individual frames into an ML algorithm and decoding the result as an image of the target subject's face. Finally, the model places that image or "mask" over the subject's face and performs a smoothing procedure around the mask's boundary.
Image: Deepfake image generation follows a similar procedure as deepfake video generation; however, deepfake images may be fully generative and retain a high quality as they do not have to produce a consistent temporal result.
Speech: Deepfake speech is any speech not explicitly spoken by a human. Common forms include voice modulation, voice replaying, voice conversion, audio deepfakes, and speech generation. Deepfake speech generation ranges from fully generated, where the input is a specific text to voice conversion which converts the sample of speech from one individual to make it sound like a different individual.

None of the deepfake media described in this section is inherently malicious, however, the potential for adversarial, or non-consensual, uses has spurred the design of datasets for the creation of detection mechanisms by the community.

2.3 Dataset Characterization

We gather a range of the most popular deepfake datasets from the community to assist future researchers when contributing to the space. We classify each dataset into eight categories. We show a condensed version of the systematization of deepfake media in Table 1, where we focus on generation techniques, metrics, and class distributions. However, an in-depth breakdown of each dataset is provided on our companion website (Tables 7, 8, 9, and 10).[1]

Generation Technique: We analyze the spectrum of generation techniques, and we use these techniques to understand trends inter and intra-domain.
Metric(s): We gather all the metrics that are suggested for each dataset, or used to report baseline model performance. We use these metrics and test their efficacy.
Deepfake/Real Ratio: We use the deepfake/real ratio to calculate the assumed base-rate of incidence for deepfakes. This gives a metric to help contextualization for each dataset.
Deepfake Sample Counts: Deepfake sample counts are split into their respective partitions if these partitions exist. We use the deepfake sample counts as the assumed incidence counts for deepfake media in the datasets. If a dataset contains different variations, we aggregate the total number of deepfake samples in all variations.
Real Sample Counts: Real sample counts are split into their respective partitions (e.g., train/test/validation) if these

Table 1: A systematization of deepfake datasets. For the class distribution sections, a heatmap indicates the density of datasets that meet the column criteria in the greater group of datasets.

partitions exist. We use the real sample counts as the assumed prevalence for real media in the datasets. If a dataset contains different variations, we aggregate the total number of real samples in all variations.

Has Baseline Model: A dataset requires some form of baseline model to showcase its efficacy and give researchers a bar for comparison. We use this category to highlight any dataset that does not provide this foundational component.

Weighted Citations: We use the collected datasets to showcase the disparity in dataset popularity in the space. To view a dimension of dataset popularity, we collect the total number of citations that accompany a dataset publication. If there are multiple publications for one dataset, we use the combined total citations from each of the publications (e.g., ASVspoof 2019 has two publications [43, 65]).[2] To obtain an equal comparison, we weight the total citations from each publication by the number of days since publication and multiply that by 365 to get the number of citations per year (i.e., $weighted\_citations = \frac{total\_number\_of\_citations}{days\_since\_publication} * 365$).

Year: We use the year to understand the staying power of a dataset and to separate datasets with multiple iterations.

In Table 1, we group datasets by domain, public availability, and baseline model availability. Each column is a category for classification and the number in a cell represents the total number of datasets in that group that meet the requirement. The generation techniques and evaluation metrics are grouped into the most popular themes, where the remaining are classified as "other". The training and testing class distributions are broadly split into five categories with "N/A" meaning no specific class split is suggested for the set. For most of the datasets, there is no training/test split suggested, so we assume the same class distribution in the train and test sets. Additionally, if a dataset contains multiple versions, we use the aggregate total of each class.

[2] We understand that a citation does not necessarily mean usage of the cited dataset, yet this gives a good measure of awareness of each dataset.

2.4 Generation Techniques

Deepfake samples can be generated using one or more approaches (e.g., GANs, convolutional autoencoders). To investigate the prevalence of select techniques in inter-domain and intra-domain datasets, we include every generation technique that contributed to each dataset.

Categorizing Generation Techniques: We observe over a dozen approaches for each domain, ranging from sourcing samples from other datasets to implementing various types of GANs. While early datasets relied on domain-specific generation techniques (e.g., text-to-speech and voice conversion for deepfake speech, and face-swapping apps for deepfake images), newer datasets settle on ML-based generation techniques to produce high-quality samples. We therefore observe a convergence of generation techniques into GANs and autoencoders often used in conjunction with domain-specific tasks (e.g., voice conversion for deepfake speech). Table 1 shows that GANs and NNs substantially dominate the generation space, yet the other category is the largest, suggesting an increasingly complex landscape for generation algorithms. These approaches allow deepfake media generation to compete with increasingly complex models.

2.5 Detection Performance Metrics

Every deepfake media dataset is designed as a platform for training and evaluating classifiers. Accordingly, they generally include a baseline model and compare its performance to existing models in the space. To achieve a direct comparison, however, work in this space needs to report similar metrics. To explore this, we offer a list of every metric included in the deepfake media and network IDS datasets gathered.

Categorizing Metrics: Datasets in each deepfake domain report several metrics: eight for speech and twelve for both image and video. Speech classification reporting is dominated by Equal Error Rate (EER), inspired by the metric's role in the ASVspoof competitions beginning in 2015. While some datasets include additional metrics (e.g., ADD 2023 includes F1-Score), the community standard remains EER.

Unlike the deepfake speech domain, the deepfake image and video domains do not exhibit an overwhelmingly dominant metric. In both domains, the most popular metric is accuracy followed by Area Under the ROC curve (AUROC). However, at least half of the datasets in all domains only report a *single* performance metric. This approach enables comparison between classifiers using that metric, but is generally insufficient in fully contextualizing classifier performance [66].

Furthermore, examining Table 1 and contextualizing all deepfake media datasets shows that EER is the dominant metric. Yet, *no* network IDS datasets analyzed use EER as a metric. Additionally, precision and recall are among the top metrics in NIDS, but see little usage in deepfake datasets.

2.6 Class Distribution

A base-rate for a given class in a population describes the percentage of samples that belong to that class. This simple yet impactful metric contextualizes the performance of a classifier on a dataset. For example, assume that we are interested in the base-rate of deepfakes for all samples in the wild. In this setting, if we observe that 100 samples online are deepfakes compared to a total of 10 million available samples, we can state that the base-rate for deepfakes is 0.001%. If the base-rate is not explicitly stated for a dataset, we must assume that the base-rate was chosen to be the distribution of the classes present in a dataset. Stated concisely, *classifier performance has no context without an accompanying base-rate*.

Categorizing Class Distributions: Unlike traditional anomaly detection, no studies exist to provide a base-rate of deepfake media on the internet. Therefore, even dataset designers aware of the base-rate fallacy [5] (i.e., misinterpreting performance results based on incorrect statistical assumptions) do not have references for constructing their split of fake and real samples. We expand on the base-rate fallacy on our companion website. Nevertheless, we highlight in Table 1 that splits skew toward the fake class in all domains of deepfake media, suggesting that media on the internet is *primarily fake*. Furthermore, the heatmap in Table 1 shows that deepfake media and NIDS have *inverted* class distributions.

To further expand, Figure 1 breaks down the class distribution of each dataset (train/test and dataset versions are split). Of the three deepfake domains, deepfake speech suggests a base-rate of deepfakes at 88%. Additionally, observing the 90th percentile in network IDS and the 10th percentile in the deepfake video and speech datasets shows minimal overlap at the extremes. As such, anomaly detection problems are exercises in *finding a needle in a haystack*; whereas deepfake media datasets such as ASVspoof2021 seemingly ask practitioners to *find hay in a needlestack.*

3 Examining Deepfake Dataset Construction

Figure 1 shows that speech deepfakes have the most skewed class distribution when compared to anomaly detection. To produce the most faithful representation of model performance, we require the following baseline reproducibility criteria [67] to be met for our experiments: the dataset must be publicly available, contain an explicitly defined train and test split, propose an explicitly defined baseline model, and suggest standard comparison metrics. No video or image deepfake dataset meets these requirements. We therefore focus our experiments on the most skewed and reproducible deepfake media category: speech deepfakes. For the remainder of this deep analysis, we focus on speech deepfake datasets to understand the limitations of operating on the *extreme assumption* of a base-rate environment where the total amount of fake samples substantially outweighs the total amount of

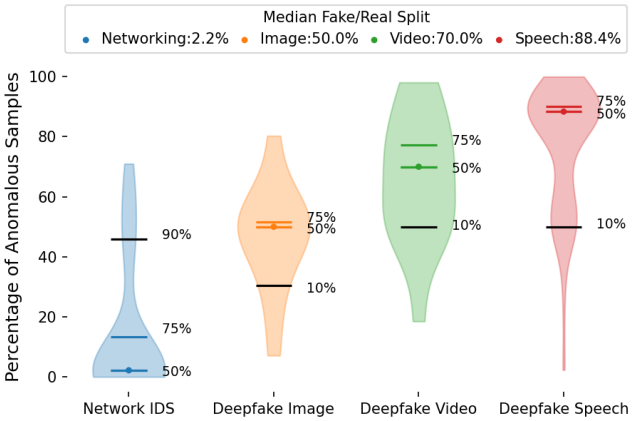

Figure 1: The Ratio of malicious samples to benign samples in 15 network IDS datasets, 23 deepfake speech datasets, 14 deepfake video datasets, and 9 deepfake image datasets. Each group is represented by a violin in the plot above and the quartiles are denoted as the horizontal lines.

real samples. However, in Section 4.1 we show that the issues presented and described here are generalizable.

Deepfake Detection vs. Speaker Verification: In the case of deepfake speech, there are two different categories of datasets: deepfake detection and speaker verification. These are inherently two different tasks, but both employ a form of deepfake speech detection. Speaker verification requires prior knowledge of a specific individual to test if future unseen speech is that specific person. Deepfake detection focuses on whether a sample of speech is *reasonably* human-generated and does not require specific knowledge of any individual. For this paper, we focus on deepfake datasets and detection.

Dataset Down-Selection: There are myriad datasets to use in the space of deepfake speech, therefore the task of selecting the correct dataset is non-trivial. The choice of dataset has a major impact on the final model and results. As such, a filtering process must occur to eliminate datasets that are not useful based on context. One of the most important factors in selecting a dataset is comparability (i.e., if a new technique produces results, is it possible to 1:1 compare that technique with previous results). To showcase this, we filter our list of 23 speech deepfake datasets using 5 simple filters to find suitable datasets. First, we focus on deepfake datasets exclusively to align with the scope of our work. Second, we select publicly available datasets, as comparability only works if a dataset can be used by all. Third, we select datasets that contain an explicit train/test(/validation) split to ensure different models train on the same data. Fourth, we select datasets that have suggested metrics, or use metrics in a custom baseline model, as again for a 1:1 comparison the same metrics must be reported. Finally, we select only datasets that have a comparative baseline model associated. A 1:1 comparison ensures

Dataset Name	Weighted Citations	Train Split	Has Metrics	Has Baseline

Table 2: All publicly available deepfake speech datasets. The highlighted cells indicate datasets that meet all the following criteria: is a deepfake dataset, is publicly available, has a train/test split, and suggests comparison metric(s).

that the community may meaningfully compare results. Without this, it is difficult to compare, or even reproduce results. Table 2 showcases the filter in action; the highlighted rows are the only remaining datasets after applying these five filters.

For the remainder of this paper, we examine the efficacy and value of the ASVspoof 2021 (English) dataset, however, we provide insight into the CFAD (Chinese) dataset where results are interesting or deviate from ASVspoof 2021.

3.1 Setup

We show that ASVspoof and CFAD are the only datasets that meet our set of down-selection criteria. Thus, we examine the ASVspoof 2021 deepfake dataset (i.e., ASV_{trn}, ASV_{dev}, and ASV_{eval}) and the CFAD dataset (i.e., $CFAD_{trn}$, $CFAD_{dev}$, and $CFAD_{eval}$). One minor change we implement is the combination of both test sets in CFAD (test seen and test unseen). As CFAD contains a segment for detecting the generation algorithm used in deepfake speech, the test seen set is defined as samples that were generated with a technique that was used for $CFAD_{trn}$ samples. Conversely, test unseen is defined as samples that were not generated with a technique that was used for $CFAD_{trn}$ samples. The combination of these two test sets comprises the entirety of $CFAD_{eval}$.

In conventional anomaly detection, the positive class represents the most important, the events that should trigger an alarm, and the minority. Despite this, ASVspoof considers real speech as the positive class. To align with anomaly detection, we invert the labels such that deepfake speech is the positive class. We use all baseline models from ASVspoof 2021 (RawNet2, LFCC-LCNN, LFCC-GMM, and CQCC-GMM) and the best two baseline models from CFAD (RawNet2 and LFCC-LCNN) which we define as M_{ASV-RN}, M_{ASV-LL}, M_{ASV-LG}, M_{ASV-CG}, $M_{CFAD-RN}$, and $M_{CFAD-LL}$, respectively. Additionally, we implement the SSL-wav2vec2.0 (M_{ASV-SW}) deepfake detector [68] as it has the best-reported performance, to our knowledge, on ASV_{eval}.

3.2 Research Questions

We create four research questions and conduct experiments to answer each of them.

3.2.1 Reproducibility

The first step in comparison with any model is to verify the reported results. Towards this, we investigate the reproducibility of baseline detection models in our first research question:

RQ1 · Are performance results from baseline detection models on deepfake datasets reasonably reproducible?

We begin by retraining the models mentioned in Section 3.1 to verify their reproducibility which is a growing concern in machine learning [67]. Toward this, we implement each model directly from GitHub without modification [69–71]. We retrain the ASVspoof models using ASV_{trn} and the CFAD models using $CFAD_{trn}$ with default parameters. Using the trained models, we determine per-class probabilities for predictions against ASV_{eval} and $CFAD_{eval}$, respectively.[3] We evaluate the reproducibility of each model by measuring suggested metrics against the reported values of the baseline models.

We show the results of this reproducibility test in Table 3. We show that for 5 of 7 models, our retraining meets or exceeds the reported metrics for that model. The reported EERs for the four ASVspoof baseline models and our measured EERs are all within 4.32% (relative). However, we measured EER for M_{ASV-SW} as 4.14% which is relatively 52.3% worse than the reported 2.85%.

As the CFAD results are reported individually for both test sets (seen/unseen) we must weigh the two results and combine them into a single EER value for comparison to our measured results. We use the formula: $EER = \frac{x*EER_{seen}+(1-x)*EER_{unseen}}{2}$, where x is the ratio of samples in the test seen set and $1-x$ is the ratio of samples in the test unseen set. We show a matched measurement to the reported EER for $M_{CFAD-LL}$. However, we show a substantially better measured EER for $M_{CFAD-RN}$ than what is reported. This highlights an interesting reproducibility issue with our measured results substantially outperforming the reported values. In this case, the disparity between measured and reported favors the authors of the original work, as we do not produce worse results. A deeper investigation into LFCC-LCNN and RawNet2, as these models are used by both datasets, allows an expected value comparison. The similarity of measured and reported EERs for M_{ASV-LL} and M_{ASV-RN} shows that our measured value of $M_{CFAD-RN}$ is similar to $M_{CFAD-LL}$, which leaves the reported value of 23.9% EER for $M_{CFAD-RN}$ as the outlier. This outlier, and the measured M_{ASV-SW} results, suggest that reproducibility in the space may be an issue (**RQ1**).

[3] For each model (except $M_{ASV-RN}/M_{CFAD-RN}$) we apply a sigmoid function to the model's scoring function output. $M_{ASV-RN}/M_{CFAD-RN}$ already calculate per-class probabilities and no additional processing is necessary.

Model	Type	EER	TPR	FPR	Sample Prediction Cosine Similarity
M_{ASV-CG}	M	25.4%	44.9%	13.1%	0.195
	R	25.3%	−−	−−	−−
M_{ASV-LG}	M	25.5%	44.2%	8.80%	0.206
	R	25.6%	−−	−−	−−
M_{ASV-LL}	M	22.9%	94.7%	41.7%	0.468
	R	23.5%	−−	−−	−−
M_{ASV-RN}	M	22.1%	95.9%	36.2%	0.551
	R	22.4%	−−	−−	−−
M_{ASV-SW}	M	4.14%	99.9%	26.9%	−−
	R	2.85%	−−	−−	−−
$M_{CFAD-LL}$	M	9.36%	90.9%	10.8%	−−
	R	9.69%	−−	−−	−−
$M_{CFAD-RN}$	M	10.9%	88.4%	9.49%	0.379
	R	23.9%	−−	−−	−−

Table 3: Measured vs. Reported (M/R) reproducibility results from retraining the 5 ASVspoof2021 and 2 CFAD models. All models are retrained and tested against the original train and test sets. Reported values labeled as −− are not provided or derivable from reported metrics.

For the remainder of the paper, we default to using our measured results instead of reported metrics.

3.2.2 Efficacy of Reported Metrics

We hypothesize that current deepfake datasets are *not* sufficiently robust to allow for meaningful evaluation of detection mechanisms. To investigate this claim, we define our second research question:

RQ2 · Do limited, and often singular, metrics as the sole performance measure sufficiently represent the behavior of deepfake detection models?

The main metrics used in the deepfake detection space are Equal Error Rate (EER), Accuracy, Precision, Recall, F1-Score, and AUROC. We show in Table 9 on our companion website that EER is the substantial majority with ~90% of speech deepfake datasets using EER and ~50% exclusively implementing EER, including ASVspoof 2021 and CFAD.

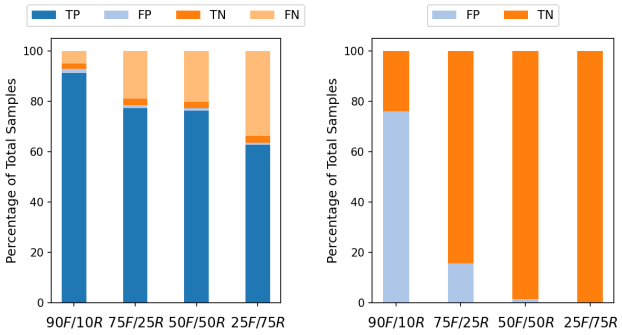
The efficacy of single performance metrics (e.g., EER) has been shown to be inherently flawed. For example, prior work [66] shows that since EER characterizes a family of ROC curves, the performance of a model may change significantly between the possible prediction thresholds, effectively obfuscating results. While ASVspoof 2021 acknowledges that EER is considered deprecated by the ISO/IEC standards [72], EER remains the only universal metric for speech deepfakes.

To understand the meaningfulness of EER, and verify the inability of this limited metric to report performance, we calculate the true positive and false positive rates, and EER for all

models defined in Section 3.1. We compare the foundational metrics of each model to investigate whether performance is obfuscated by using EER as a comparison metric.

Table 3 shows that models with similar EER values may have vastly different metrics (i.e., TPR and FPR). Inspecting M_{ASV-LG} and M_{ASV-LL} (highlighted rows in Table 3) which have similar EER values of 25.5% and 22.9% highlights this issue. M_{ASV-LG} has a TPR of 44.2% whereas M_{ASV-LL} has a substantially better TPR of 94.7%; however, M_{ASV-LG} with an FPR of 8.80% considerably outperforms M_{ASV-LL} with an FPR of 41.7%. Thus, similar EER values do not necessarily represent the underlying performance of a model.

Additionally, we examine the predictions from the five baseline ASVspoof 2021 models on each ASV_{eval} sample to understand how models with similar EERs classify samples. As a broad example, two models exhibiting 90% accuracy over a test set, do not necessarily incorrectly predict the same 10% of samples. For the ASVspoof 2021 baseline models, we measure the total number of samples that the models agreed upon. All five models agree on 34.1% of samples, at least 4/5 models agree on 54.9% of samples, and at least 3/5 models agree on 100% of samples. We show that it is relatively rare for all five models to agree on a specific sample. To further highlight the issue, we take the two baseline models with the closest EER values (i.e., M_{ASV-LG} and M_{ASV-CG}) and calculate the cosine similarity between the list of predictions (ordered based on predicted sample name). The cosine similarity for these two models is 0.831, indicating that two models with an EER difference of 0.1% predict differently on individual samples. Furthermore, we select the "best" model from each dataset as a baseline and compute the cosine similarity between it and the other models for that dataset. We show in the right-most column in Table 3 that there is little agreement between these models.



We show that the most used comparison metric (EER) does not honestly report the results of a model and thus, masks intrinsically different performance profiles (**RQ2**).

3.2.3 Class Distribution in Datasets

Class imbalance in training and evaluation sets may obscure experimental results [73], which exacerbates the misrepresentation caused by unidimensional performance metrics. This leads us to define our third research question:

RQ3 · Does the composition of current deepfake datasets bias classification results?

To examine whether the distribution of classes can create unintentionally biased detectors, we propose two methods to test bias based on ASV_{trn}/$CFAD_{trn}$ and ASV_{eval}/$CFAD_{eval}$. Prior research [74] has shown that such imbalances exist in other datasets and create bias, thus it is necessary to measure whether bias impacts these datasets. Both tests vary the ratio

(a) M_{ASV-LL}, test set ASV_{eval}. (b) M_{ASV-LL}, test set RO_{asv}.

Figure 2: To show bias in the training and test sets of deepfake datasets, we examine M_{ASV-LL} with four different training distributions. Note the reduction in true positives, and consequently, the reduction in false positives. Results for M_{ASV-RN}, M_{ASV-SW}, $M_{CFAD-RN}$, and $M_{CFAD-LL}$ may be found on our companion website, Figure 10 and Figure 11.

of deepfake to real speech in the training set to determine the effect of class distribution changes on two evaluation sets.

- **[Test 1]** Tests bias in the evaluation set and varies the training data by augmenting ASV_{trn} with additional real samples and tests against ASV_{eval}. Additionally, we repeat this with $CFAD_{trn}$ against $CFAD_{eval}$.
- **[Test 2]** Tests bias in the training set using the varied models from **[Test 1]** and replaces the evaluation set with entirely real-speech sets RO_{asv} or RO_{cfad}.

We adopt the notation $D_{xF/yR}$ for class distribution, where x/y is the ratio of fake to real speech.

Test 1: ASV_{eval} contains approximately 97% deepfakes and is thus highly imbalanced towards the fake class. To understand any biases inherent in this composition, we retrain the two best baseline models (M_{ASV-RN} and M_{ASV-LL}) and the overall best model (M_{ASV-SW}) with varying class distributions.[4] We test the following class distributions: $D_{90F/10R}$, $D_{75F/25R}$, $D_{50F/50R}$, and $D_{25F/75R}$. We then evaluate each model against the default ASV_{eval} set. To avoid bias by downsampling the overrepresented deepfake class and thus reducing the total number of training samples, we augment the number of real samples in ASV_{trn}. We sub-sample speech from LibriSpeech train-clean-100 [75] to match the distribution of ASV_{trn}.

$CFAD_{eval}$ contains 66% deepfake samples and is not as imbalanced as ASV_{eval}, but is still skewed towards more deepfakes. We retrain the two best baseline models from CFAD ($M_{CFAD-RN}$ and $M_{CFAD-LL}$) with the same training class distributions as ASVspoof.[5]. We then evaluate each model against the default $CFAD_{eval}$ set. We augment the real

[4]The default parameters and epochs are unaltered for each model and training class distribution combination for all datasets.

[5]We downsample the deepfake speech class for $D_{90F/10R}$ and $D_{75F/25R}$

samples in $CFAD_{trn}$ with real-only Chinese speech from the WeNetSpeech Podcast Train set [76] to match distributions.

Specifically, for the real-speech subset of each dataset, we match the sample durations, number of speakers, number of utterances per speaker, and the ratio of female to male speakers. Section 2 on our companion website gives an in-depth breakdown of the augmentation technique and shows the length distribution of the real samples in ASV_{trn}/Librispeech and $CFAD_{trn}$/WeNetSpeech.

Figure 2a shows the true positives, false positives, true negatives, and false negatives for M_{ASV-LL} trained with four different training distributions. For space concerns we only show the results of one model, however, the trends follow for all models and are shown on our companion website in Figures 10 and 11. Additionally, Table 4 on our companion website shows metrics for each combination of training distributions and evaluation sets.

We show that as the training set class distribution moves further away from the testing distribution (i.e., a right move on the x-axis in Figure 2) the overall model performance decreases. To be precise, increasing the number of real speech samples in the training set does not independently improve the ability of the model to predict real speech samples, it also reduces the performance on deepfake speech.

With a simple shift in training distributions, a model's performance changes on the same test set. To put it concisely, a model must train with a similar class distribution to the evaluation set to have performant results. We show that the test sets ASV_{eval} and $CFAD_{eval}$ both contain bias and overstate the performance of a model.

Test 2: To test bias in the training sets ASV_{trn} and $CFAD_{trn}$, we explore a scenario where there are *no* deepfakes in an evaluation set. As the ASV_{eval} set only contains approximately 3% real-class samples, and oversampling or augmenting these samples may add bias to this test, we collect almost 150,000 samples from four publicly available real-speech corpora (TIMIT [77], LJSpeech [78], World English Bible [79], and LibriSpeech train-clean-360 [75]) and label the resulting dataset RO_{asv}. Similarly, we collect real-only Chinese speech samples from WeNetSpeech Meeting Test [76] and label the resulting dataset RO_{cfad}. We use the samples in these real-only evaluation sets to simulate different class distributions than ASV_{eval} and $CFAD_{eval}$ to investigate bias in training.

Figure 2b shows the false positives and true negatives for M_{ASV-LL} with the 4 different training distributions. For brevity, we only show the results of one model, however, the trends follow for all models. See our companion website for the results of other models. This demonstrates the overwhelming number of false positives for $D_{90F/10R}$ in an all-real evaluation set; in fact, all models have a higher false positive rate than a true negative rate. Moving from $D_{90F/10R}$ to $D_{25F/75R}$ dramatically reduces false positive predictions. This further exemplifies the bias of the ASV_{trn} and $CFAD_{trn}$ sets. Models trained on $D_{90F/10R}$ are only effective on a test set with a similar class distribution. Adding a minor amount of the underrepresented class when training reduces bias.

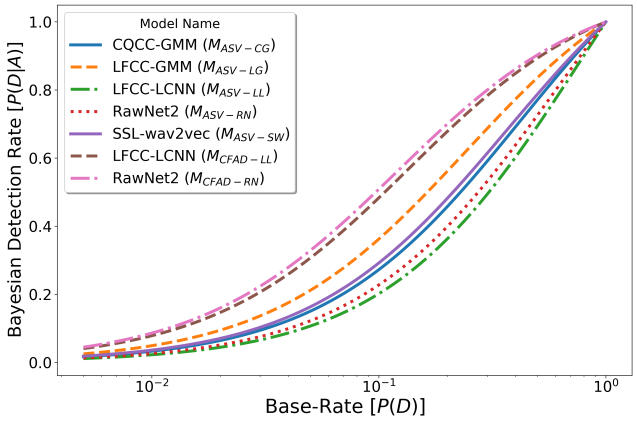


Figure 3: We calculate BDR as a function of the base-rate for all baseline models using the respective test set. Base-rates range from 0.01% (i.e., an approximation based on network IDS measurements), to 100% (i.e., every sample is a deepfake). Referencing the five ASVspoof models in the context of BDR, we observe that M_{ASV-LG} performs the best at every base-rate threshold despite having a substantially worse EER than M_{ASV-LG} (25.5% vs. 4.14%).

We evaluate bias in the ASVspoof 2021 and CFAD train and test datasets with two tests (i.e., changing the underlying training class distributions, and testing the baseline models against an all-real speech set). We show that due to the class distributions, train and test sets impose a bias on the performance of detectors built on these datasets **(RQ3)**.

3.2.4 Characterizing Model Efficacy

As stated previously, classifier performance has no context without an accompanying base-rate. Despite this, no deepfake dataset provides a base-rate to contextualize model results. With this, we define our final research question:

RQ4 · How do current deepfake datasets perform in a base-rate-aware environment?

Abstracting away from the dataset and the class distribution in each set, we examine how framing the output of any given model within the context of a base-rate tests the robustness of that model. Contextualizing a model in the scope of a specific base-rate does not change the underlying performance of that model on any specific evaluation set; however, it may expose the limitations of that performance. We calculate the true and false positive rates for all models retrained in Section 3.2.1. Then, we calculate the Bayesian Detection Rate (BDR) as a function of the base-rate. BDR is defined as:

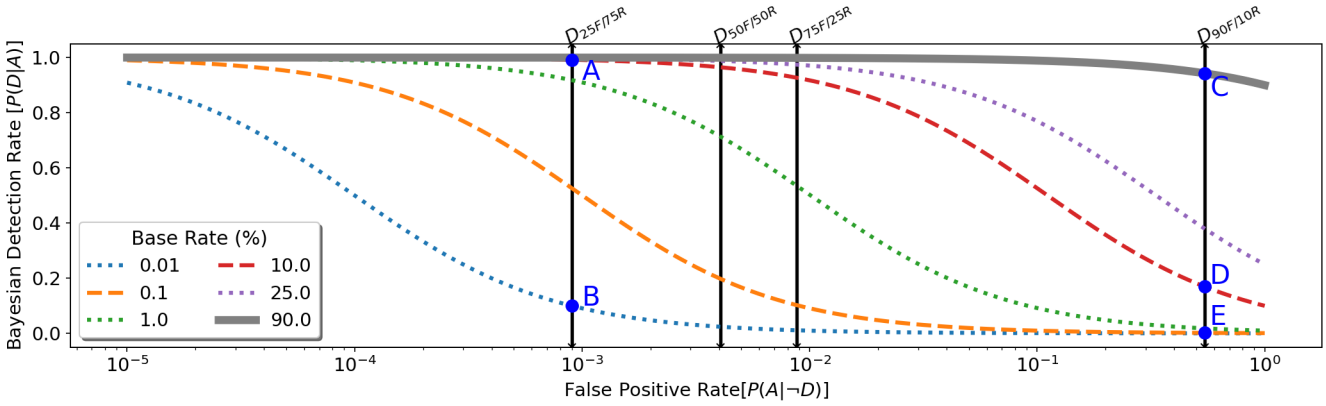

Figure 4: We calculate RawNet2's BDR as a function of the base-rate where the vertical lines represent the measured false positive rates for each class distribution against RO_{asv}. The intersections show where a class distribution maps to a BDR at different base-rates. This mapping gives a visual representation of how the base-rate impacts performance in a real-world scenario, effectively allowing the selection of the best model based on a use case.

$$BDR = P(D|A) = \frac{P(D) \cdot P(A|D)}{P(D) \cdot P(A|D) + P(\neg D) \cdot P(A|\neg D)}, \quad (1)$$

where D is a sample of deepfake media, A is an alarm, $P(D)$ is the probability of encountering a sample of deepfake media, $P(A)$ is the probability of an alarm, $P(D|A)$ is the probability of a sample of deepfake media given an alarm, and $P(A|D)$ is the probability of an alarm given a sample of deepfake media. We provide an in-depth breakdown of BDR on our companion website.

As neither ASVspoof 2021 nor CFAD explicitly state any base-rate assumptions and the base-rate for deepfake media in the wild is unknown, we use a range of base-rates (90%, 75%, 50%, 25%, 10%, 1%, 0.1%, 0.01%). This simulates how well a specific model performs in multiple scenarios.

Figure 3 shows the BDR for the seven baseline models trained with the original training sets at varying base-rates. Referring back to Table 3 shows that M_{ASV-SW} has an EER value that is 83.8% better than M_{ASV-LG}; however, Figure 3 highlights that the BDR of M_{ASV-SW} is strictly worse than M_{ASV-LG} *at every threshold*. Additionally, as the base-rate approaches either extreme, the BDR of every model converges.

Furthermore, to showcase how the BDR helps evaluate the performance of a model, we examine M_{ASV-RN} against the real-only test set without loss of generality, as the training class distribution changes (see Table 4 on our companion website). For M_{ASV-RN}, the correct classification of true negatives increases from 45.60% to 99.91% and the false positive classifications decrease from 54.40% to 0.09%. This is a relative false positive decrease of 99.83% and suggests substantial performance improvements. However, these results do not contextualize the output of the detector within the scope of any base-rate and, as such, overstates the performance of the model. To understand this overstatement, we plot the training class distribution for M_{ASV-RN} against a range of base-rates in Figure 4.[6] For example, point A shows M_{ASV-RN} trained with $D_{25F/75R}$ operating in an environment where 10% of samples are deepfakes. For all base-rates above 10% at point A (i.e., base-rate lines 25% and 90%), nearly all predictions of fake speech made by the model are truly fake samples. Shifting to point B, we show the same model and training distribution as point A, in an environment where the expected encounter with deepfakes is 0.01%. Predictions of deepfake speech made by the model at point B have a 10% probability of truly being fake. Following down to point E shows the original $D_{90F/10R}$ M_{ASV-RN} has a nearly 0% probability of being correct when predicting fake samples. Additionally, point C is the ASVspoof base-rate.

Finally, we evaluate the impact of threshold manipulation on the performance of a model with respect to BDR – as taking the standard 0.5 probabilistic threshold for predictions may not result in the most robust model given a specific context. To achieve this, we take M_{ASV-RN} trained and tested on the original ASV_{trn}/ASV_{eval} sets and set the predictive threshold such that the false positive rate is 1%. Using the default predictive threshold of 0.5, M_{ASV-RN} has a false positive rate of 36.2% and a true positive rate of 95.9%. If we change the threshold to 0.99, the false positive rate drops to 0.99% and the true positive rate drops to 53%. Calculating the BDR from the 0.5 and 0.99 thresholds gives 0.26% and 4.9%, which shows that the model with the better false positive rate has a better BDR (i.e., 20x better). This highlights

[6] The true positive rate is undefined as there are no deepfakes in the RO_{asv} set and we assume a perfectly accurate 1.0 detection rate.

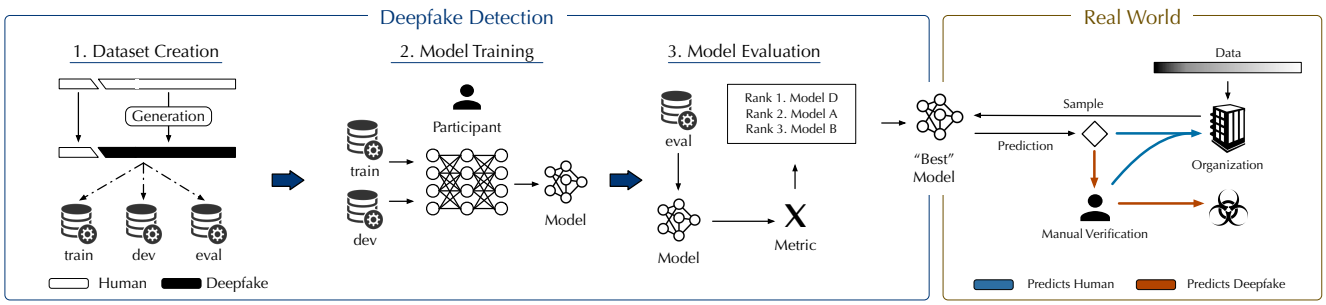

Figure 5: A generalized ecosystem for deepfake dataset creation, including detector benchmarking and a scenario where a detector is used in the real world. To start, a dataset is created and split into training, development, and evaluation subsets (1). These subsets are provided and, using the training set, algorithms are produced based on their lowest metric on the development set (2). The final algorithms are ranked based on their metric over the evaluation set (3). A model may then be selected by an organization based on the ranking. In the real world, all samples classified as a deepfake must be manually reviewed so as not to allow false positives to impact operations and user experience.

the importance of the false positive rate on the BDR and the trade-off (i.e., reduction in the true positive rate) that may be required to achieve this improvement. We show that setting thresholds such as keeping the false positive rate at 1% improves BDR, but the trade-offs must be acknowledged.

We show that every model tested is susceptible to degrading BDR performance when contextualized with a decreasing base-rate and that BDR is mostly affected by the false positive rate. This contextualization may have substantial performance implications as we observe in Figure 4 **(RQ4)**.

3.2.5 Summary of Results

Through our experiments on ASVspoof 2021 and CFAD, we demonstrate the limitations of current deepfake datasets. We show that reproducibility may be an issue with comparisons **(RQ1)**, single metrics (EER), and class imbalance lead to overstated model performance **(RQ2, RQ3)**, and base-rate contextualization (currently undefined for deepfakes) is necessary to meaningfully evaluate a model **(RQ4)**.

4 Discussion

4.1 Larger than Speech Deepfakes

While we focus on speech deepfake datasets, the issues presented in this paper generalize to a greater issue. We do not examine the inherent properties of the data present in any dataset, instead, *we demonstrate that the overall structures inherently lead to misinterpreting results*. While the speech deepfake datasets are substantially more skewed towards the fake class than the video and image datasets, the same issues reported will impact these datasets as well. To demonstrate this, we explore the research questions defined in Section 3.2 on a sample dataset from the image deepfake domain.

There are no image or video deepfake datasets that meet the reproducibility criteria defined in Section 3. However, CIFAKE [37] is only missing concrete baseline model implementation details. As such, we make general assumptions about the missing hyperparameter details of the baseline model. We note that this is not a direct implementation of the baseline system of CIFAKE; but rather a "best-effort" re-implementation. We show (in a detailed analysis on our companion website) that the trends outlined in Section 3.2 follow for the image deepfake domain. While reproducibility is strongly hindered by a lack of explicit documentation **(RQ1)**, training and test distributions impose a bias on the performance of the model **(RQ3)**, and contextualizing with an appropriate base-rate degrades model performance **(RQ4)**.

4.2 Transition to Practice

Deepfake media datasets are collections of human-originated and synthetically generated videos/images/speech for use in machine learning with the explicit task of discrimination between real/fake samples. Unlike other datasets within Security (e.g., network traffic), multiple deepfakes can be generated from one seed input. Thus, class imbalance is an inherent problem within deepfake dataset creation. These datasets enable disparate algorithms and models to benchmark their performance based on specific metrics. This comparison allows for an academically created algorithm to be adopted into practice. Figure 5 shows the general structure of dataset creation, benchmarking, and transitioning to practice. Motivated by this pipeline, we show two practical real-world scenarios.

4.2.1 Speech Deepfakes: A Call Center

To visualize the current issues of speech deepfake datasets, we examine parallel real-world scenarios (SCN_A and SCN_B). Each scenario is a call center that selects a model from ASVspoof 2021 according to public ranking results (i.e., EER). The call center receives a stream of calls that must be classified as real or deepfake before being transferred to the greater organization. Additionally, every detected deepfake speech sample is manually verified to check for fraudulent activity. The call centers in both scenarios receive identical streams of 4,400 [80] total monthly calls. The base-rate of deepfake calls in this environment is 1 in 1,074 (i.e., ~4 total deepfake calls in a month), a rate derived from real-world call center fraud benchmarks [81]. In SCN_A, M_{ASV-SW} is selected as this model is the top performer based on EER. In SCN_B, M_{ASV-LG} is selected, as this is the simplest model.

Examining SCN_A, M_{ASV-SW} has a near-perfect true positive rate, and correctly detects all 4 deepfake calls. However, the model incorrectly identifies 1,182 real calls as a deepfake. Calculating the Bayesian Detection Rate for this model in this specific environment gives $BDR = 0.34\%$. This means that roughly 1 in 333 calls detected as a deepfake are *actually* deepfakes. The employee tasked with manually verifying potentially fraudulent calls is overwhelmed.

Now examining SCN_B, M_{ASV-LG} results in 2 out of 4 deepfake calls being correctly detected and 38 real calls incorrectly identified as a deepfake. Calculating the BDR for this model in this specific environment gives $BDR = 0.47\%$. This suggests that 1 in 200 calls detected as a deepfake are *actually* deepfakes. As the number of false positives is much lower, the manual verification of potentially fraudulent calls is not quite as overwhelming in this scenario.

Organizations have different risk management systems and thus may prioritize individual metrics in different ways. For example, a call center may prefer a model that minimizes manual verification workload (an increase in this workload leads to a direct increase in manhours and expenses) to avoid alarm fatigue [82]. In this example, M_{ASV-LG} achieves superior performance. However, if minimizing the total number of fraudulent calls that bypass the call center is more important, M_{ASV-SW} is the better-performing model.

This scenario highlights the trade-offs often neglected when selecting detection models using a single metric. The context is key, therefore every model ***must*** be contextualized to select appropriate metrics. We observe in this example that failure to do so can translate to alarm fatigue, though negative outcomes can also include financial loss or degradation of public relations. Finally, we note that both models produce poor BDR values in this setting, highlighting the need for more robust classifiers in deepfake detection.

4.2.2 Image Deepfakes: Social Media

We theorize a secondary scenario with real-world impact. For this scenario, we first evaluated the CIFAKE baseline model; however, this model follows the trends from the previous scenario. Instead, we select the DFFD image deepfake baseline model as it is the only one with the appropriate TPR and FPR metrics reported as seen in Table 7 on our companion website. This scenario highlights the issue with single performance metrics and shows that even BDR alone is fallible. For this scenario, we use the same model at two different thresholds (i.e., TPR 90% at FPR 0.1% and TPR 83% at FPR 0.01%). We define these two models as M_1 and M_2. Each deepfake image detector is tasked with detecting fake news in social media where any deepfake image is considered fake news.

Models M_1 and M_2 are tasked with providing an end user with a prediction on whether an image is a deepfake or real. The end user may then decide to fact-check this particular piece of media. As such, fake news in this scenario is relatively inexpensive in that it has low "immediate risk" and a model falsely identifying media as a deepfake has low impact. On the other hand, a model must be able to accurately predict every piece of fake news correctly to ensure complete coverage. The base-rate of fake news on social media is unknown; however, Allcott et al. [83] find that from a list of fake news websites over half of all images proved to be fake news. Following this, the models are only tasked with predicting on media that is hosted on previously known fake news sites. As such, we will assume a high base-rate for fake news on social media as 1 in 2. We assume that each model sees the same 1,000 samples of media (i.e., 500 real samples and 500 fake news samples).

Calculating the BDR for M_1: $BDR = 99.89\%$ and the BDR for M_2: $BDR = 99.99\%$. In this scenario M_1 flags fewer samples correctly than M_2 as M_2 has a higher BDR. However, when contextualized to this scenario M_1 is the clear best performer. To highlight this, consider M_2 which detects 415 of the 1,000 samples as fake news and does not misclassify any real samples as fake news. On the other hand, M_1 detects 450 of the 1,000 samples as fake news and also does not misclassify any real samples as fake news. As neither model misclassified any real samples as fake news and M_1 detected ~10% more fake samples than M_2, the model with the lower BDR (i.e., M_1) is the best model for this scenario. Additionally, as a false positive in this scenario is considered low-risk, the choice of M_1 stands, even as the number of processed images grows and misclassifications appear.

4.3 Ethical Consideration

Serious ethical considerations arise when researching deepfake generation, datasets, and defenses; each deserving its own ethics discussion. As we analyze deepfake datasets, we contextualize the ethics of dataset generation, collection, and propagation using the Menlo Report's [84] pillars: *Respect*

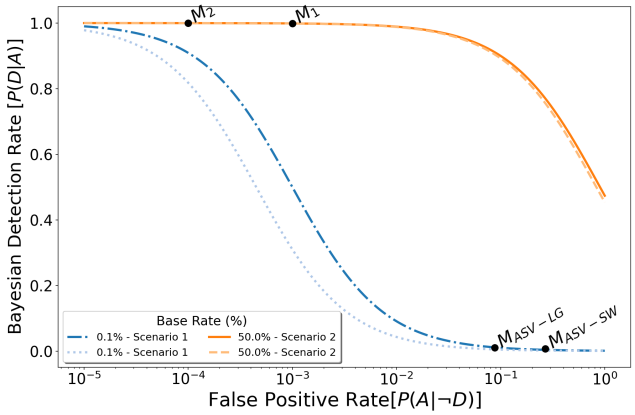

Figure 6: Scenarios from Sections 4.2.1 and 4.2.2 plotted against their base-rates and BDRs. We show that major improvements in model performance are required in the base-rate environment similar to the call-center scenario.

for Persons, *Beneficence*, *Justice*, and *Respect for Laws*.

Respect for Persons: Research involving human subjects should properly disclose the risks of the research to each participant. Whether collecting deepfakes in-the-wild or generating deepfakes from participants, researchers should make their best effort to identify and obtain consent from subjects. Further, when providing deepfake datasets for reproducibility and future research, subjects should have a clear understanding of how this data can be used.

Beneficence: Minimizing harm to subjects while maximizing the overall benefit of the research becomes increasingly difficult as various types of deepfakes can have adverse effects on the subjects of deepfakes. For example, deepfake pornography has extremely negative effects on victims [85]. Researchers have to be particularly careful in building datasets designed to encourage the development of these defenses. Publishing datasets, especially containing sensitive information, can create harmful effects for the subjects.

Justice: Each person deserves equal consideration in the course of a study. Deepfake datasets should clearly define how their populations were collected and identify inherent biases arising from this process. Researchers should consider how they can provide accurate representation of populations, especially of vulnerable and marginalized communities. Specifically, considering *who is left out* when creating a deepfake dataset allows for a more ethically sound foundation.

Respect for Laws: Including in-the-wild samples in a dataset and propagating that dataset is, at best, non-consensual and at worst, illegal [86]. Unfortunately, laws and public policy surrounding the creation and use of deepfakes has yet to be enacted at a wide scale [87]. Future policy changes and laws could greatly affect how deepfake datasets are created.

Of the forty-five deepfake datasets we surveyed, only eleven discussed ethical considerations of their dataset with none mentioning the Menlo Report. Moreover, some of these deepfake datasets train using corpora that predate deepfakes; thus, participant consent in these corpora does not include deepfake ethical considerations. While these datasets offer a foundation for deepfake research, a more thorough community discussion on the ethics of creating deepfake datasets and how the community builds upon them is necessary.

5 Recommendations for Future Datasets

5.1 Metrics

Metric Selection: Many metrics may be appropriate when applied within a specific context, but not all metrics are applicable within every context. There is *no single metric* that fully represents the performance of a model.

In general, for class-imbalanced datasets precision-recall curves and AUPRC has been shown to more accurately describe the performance of the minority class. However, the use of this metric is critical. The minority class is usually the class of import, or the class a detector is created to detect, but in the case of speech deepfake datasets, the important class is the overwhelming majority. Therefore, simply applying AUPRC to view the performance of deepfake detection in these datasets will produce non-meaningful results. The baseline for a precision-recall curve and AUPRC is the percentage of samples in the viewed class, which for example is 97% in the ASVspoof 2021 evaluation set. The difference between a perfect detector and the baseline is only 3%.

Most deepfake datasets suggest using EER and accuracy as simple performance evaluators, but both fail to honestly and completely measure model performance. While convenient as a means of providing an easy comparison, this approach largely results in meaningless results. More critically, it subsequently hinders the ability to adopt these detection models in the real world and hides the need for even better detectors.

To combat this, we recommend that future datasets suggest the use of an ensemble of metrics such as the precision-recall curve and AUPRC for the minority class (if the minority class is the important class), false positive rate, true positive rate, ROC curve/AUROC, and the BDR. Additionally, we recommend posting the raw scores output from the model, such that future researchers may calculate *any* metric for comparison. This approach ensures that model results may be contextualized to fully evaluate performance.

Metric Reporting Template: We create and publish a boilerplate template to be used for future detection mechanisms. We provide a concise example of this in Table 4 and a full example in Table 4 on our companion website shows this template as populated by the scores files from all models trained throughout Section 3.2. Using this template allows for a quick comparison of class distributions in training and test sets and

														BDR							
														Base-Rates							
	Trn Set	Trn Distro	Eval Set	Eval Distro	EER	TPR	FPR	TNR	FNR	Prec	Recall	F1	AUPRC	*0.01*	*0.1*	*1*	*10*	*25*	*50*	*75*	*90*

Table 4: Concise template of dataset statistic and metric reporting.

quantifies the performance as multiple base-rates. This template facilitates the mapping of any detector onto a figure similar to Figure 4, which creates a visual representation of base-rate performance.

5.2 Consider the Base-Rate

We show the importance of contextualizing the outputs of detectors within base-rates. The baseline models examined in this paper perform reasonably well within the scope of a base-rate that matches the distributions of the evaluation set but break down when tasked with inferring other distributions.

As an in-depth evaluation to measure the base-rate of deepfakes in the wild is an open research problem, there are a few potential stop-gaps for contextualizing datasets within base-rates. None of these suggestions change any requirements of datasets, as this is a post-processing step to change the viewing angle of each compared detector. As we show in Section 4.2, detectors that have substantially worse EER values may perform better in a base-rate-aware scenario. The first, and the most straightforward option, is to consider a range of base-rates that cover class imbalance in both classes similar to our experiments in Section 3.2.4. A second option is to justify the class distribution being presented in a dataset, generally in the form of a clearly defined use case. We recommend setting additional base rates at an order of magnitude above and below that of the evaluation set (i.e., for a 1% base-rate, provide three base-rates of 0.1%, 1%, and 10%).

Deepfake datasets should provide base-rate assumptions to put all results into an appropriate context. Doing so will allow for contending models to follow an explicit threat model while also providing interested organizations with the information necessary to decide if a model is appropriate for their setting. Currently, such datasets only offer extraordinarily high base-rates of deepfake samples in their datasets.

5.3 Dataset Class Imbalance

Dataset class imbalance is not a new issue in machine learning and is often a product of the difficulty of capturing samples of the minority class [88–90]. However, due to the issues highlighted in Section 4.2, deepfake datasets suggest that real samples are difficult to gather. Regardless, many techniques exist to alleviate the impact of class imbalance from simple resampling [91–93] to data augmentation [94–96] and data generation [97, 98]. Class imbalance is not inherently negative; however, leaving class imbalance unacknowledged leads to misrepresentation of results. A simple solution would be to increase the amount of human-generated media in future datasets, regardless if doing this increases the complexity of curating. This allows for a balanced dataset and a reduction of misinterpretation of model performance.

5.4 Comparing Via Contextual Importance

Comparison & Context: To reduce the chasm between detection mechanism development and real-world deployment, a more representative method of comparing model performance must be adopted. Towards this goal, strict contextualization allows for meaningful comparison of model efficacy. First, datasets should suggest an ensemble of metrics for comparators to optimize. Second, these datasets should define a use case or scenario for contextualization. Third, these metrics must then be weighted by importance. Finally, multiple base-rates should be selected for contextualization to cover any differences in measured base-rates and in-the-wild realities.

Using the call center scenario from Section 4.2.1 as an example, we showcase a simple comparison example for completeness. As the base-rate in this scenario is measured as 0.001%, three base-rates should be selected: 0.0001%, 0.001%, and 0.01%. As one possible approach, we propose a weighted ranking by setting a maximum allowed FPR and filtering models based on this threshold. The remaining models may then be ordered by decreasing TPR and/or BDR values.

Use Case: Understanding the base-rate of incidence of an attack is tantamount to clearly defining a use case. In Section 4.2, we outline scenarios with explicitly defined base-rates. Additionally, we quantify the penalty of false positives and false negatives in the form of manual reviewer fatigue and correctness. We show in these examples that traditional comparisons between models are meaningless in this context. This shows that the use case is the most important criterion to consider when designing datasets.

5.5 Using Contextless Datasets

While we suggest guidelines for the creation of future security-aware datasets, there exists the issue of the current datasets and their usefulness. Towards this, our methodology for dataset creation may be applied. First, when publishing results, make an ensemble of metrics and the raw scores file available. Second, select a wide range of base-rates to test the detection performance. If the base-rate is known, then select an order of magnitude above and below. However, if the base-rate is unknown then select a wide range of base-rates such as we do in Section 3.2.4 (e.g., (90%, 75%, 50%, 25%, 10%, 1%, 0.1%, 0.01%)). Following these steps will allow for a more meaningful comparison with future work.

6 Conclusion

Deepfake media (e.g., video/image/speech deepfakes) represents a growing threat to our trust in information. Mechanisms that facilitate community interaction and spur innovation for the detection of deepfakes are necessary. However, the confluence of data in this space makes the selection of datasets non-trivial and these datasets inadvertently promote unrealistic outputs. To understand this, we systematize the space of deepfake media and compare that to anomaly detection in the form of network intrusion detection. Through this systematization, we demonstrate the vast discrepancy between the class distribution of these two fields. Specifically, we examine the speech deepfake datasets as they are the overwhelming outliers in class distribution. We examine the most popular datasets and show that this imbalance creates bias and vastly over-represents model performance. Such bias is hidden by the use of limited metrics, specifically EER, as the sole metric for comparison and the lack of consideration of base-rates. We apply the models examined in a real-world base-rate-aware scenario to show significant performance issues in the form of false positives and alert fatigue. We thus recommend that raw model score files be published for evaluating future methods, that the context in which a model is deployed be well-defined, and that models be evaluated across varying base-rates. The failure to follow these recommendations risks entrenching inaccurate metrics used by multiple research communities, to the ultimate detriment of all detection-based research.

Can I Hear Your Face? Pervasive Attack on Voice Authentication Systems with a Single Face Image

Nan Jiang[†], Bangjie Sun[†], Terence Sim[†], and Jun Han[‡]

[†]*National University of Singapore,* [‡]*KAIST*

Abstract

We present *Foice*, a novel deepfake attack against voice authentication systems. *Foice* generates a synthetic voice of the victim from *just a single image* of the victim's face, *without requiring any voice sample*. This synthetic voice is realistic enough to fool commercial authentication systems. Since face images are generally easier to obtain than voice samples, *Foice* effectively makes it easier for an attacker to mount large-scale attacks. The key idea lies in learning the partial correlation between face and voice features, and adding to that a face-independent voice feature sampled from a Gaussian distribution. We demonstrate the effectiveness of *Foice* with a comprehensive set of real-world experiments involving ten offline participants and an online dataset of 1,029 unique individuals. By evaluating eight state-of-the-art systems, including WeChat's Voiceprint and Microsoft Azure, we show that all these systems are vulnerable to *Foice* attack.

1 Introduction

Voice authentication is being adopted more widely as an alternative to traditional password-based security measures for social media platforms [13], telebanking [6], and personal smart devices [2, 9, 10]. However, recent advancements in voice deepfake techniques have enabled the generation of synthetic voices that are sufficiently convincing to bypass even the most advanced voice authentication systems. For example, recent deepfake attacks have reportedly compromised the voice authentication systems of platforms such as WeChat, Microsoft Azure's voice authentication API, and Amazon Alexa [16, 57].

The state-of-the-art voice deepfake attacks, however, typically necessitate the attackers to obtain voice recordings of the victim. This assumption inherently limits and confines the pervasiveness of these attacks. As a result, targets are often limited to celebrities whose voice samples are widely available online. However, there have been minimal efforts to enhance the pervasiveness of the voice deepfake attacks to a wider range of victims.

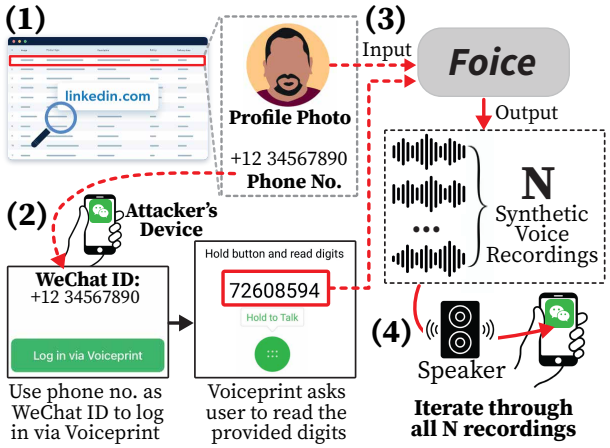

Figure 1: Figure depicts an example attack scenario of *Foice*. The attacker (1) obtains the victim's photo along with the corresponding phone number (often used as WeChat ID) from online social media such as LinkedIn; (2) attempts to log in to victim's WeChat via Voiceprint (voice authentication) system on the attacker's device; (3) inputs the victim's photo and WeChat's provided digits to *Foice* to generate N synthetic voice recordings where the speaker is speaking the provided digits; and (4) manages to successfully authenticate and log in as the victim on WeChat by sequentially playing each of the N synthetic recordings through an external speaker.

In light of this, we pose the following question: *is it possible to design a more pervasive voice deepfake attack that eliminates the need for direct access to the victim's voice recordings, thus increasing the attack scalability by broadening the target to a wider range of victims?* To address this, we propose *Foice*, a novel voice deepfake attack that can synthesize a victim's voice leveraging ***only a single photograph (i.e., face image) without requiring voice recordings*** of the individual. Such images are easily accessible, especially with the proliferation of social media platforms such as Instagram, Facebook, and LinkedIn. The feasibility of *Foice* stems from

the inherent biological correlation between facial attributes (e.g., gender, age, facial bone structure, mouth, and lips) and voice features (e.g., volume, pitch, timbre, pace, and vocal range). This correlation becomes clear when we intuitively gauge an individual's voice from their physical appearance – for instance, predicting a deeper tone from a more robust individual while expecting a higher pitch from someone with a slender build. Figure 1 illustrates how *Foice* launches an attack on WeChat's Voiceprint, namely its voice authentication system, by leveraging the biological correlation. The attacker (1) obtains the victim's photo along with the corresponding phone number (often used as WeChat ID) from online social media such as LinkedIn; (2) attempts to log in to the victim's WeChat via the Voiceprint (voice authentication) system on the attacker's device; (3) uses the victim's photo and WeChat's provided digits to generate N synthetic voice recordings where the victim is speaking the provided digits; and (4) manages to successfully authenticate and log in as the victim on WeChat by sequentially playing each of the N synthetic recordings through a speaker.

Designing *Foice* presents significant challenges, primarily due to the intricate relationships between facial and voice features. Specifically, facial features influence only a portion of voice features (e.g., pitch), while the remaining (e.g., timbre) are influenced by internal physiological structures, like the vocal cords, which are not discernible from facial appearance (see §2.3). To bridge this gap, we design a generative deep-learning model to generate a search space containing all the potential voice features that cannot be derived from the face image. To launch the attack on the victim, *Foice* extracts a portion of voice features from the victim's face image (i.e., *face-dependent* features). The attacker then takes N samples of *face-independent* features from the search space and combines them with the *face-dependent* features to obtain N synthetic voice recordings. By increasing the number N, the attacker has a higher chance of obtaining a synthetic recording that sounds similar to the victim, hence successfully compromising the voice authentication systems.

We evaluate *Foice* to demonstrate its feasibility through comprehensive real-world experiments. We evaluate *Foice*'s attack performance on authentication systems of commodity products, including WeChat's Voiceprint as well as smart assistants such as Siri [9], Google Assistant [10], and Bixby [2], by inviting ten participants. We also evaluate *Foice* on the state-of-the-art cloud services, including Microsoft Azure [8], iFlyteck [7], VGGVox [43], and DeepSpeaker [35], with a public dataset of 1,029 unique individuals. Our results demonstrate that **all** the tested authentication systems and voice assistants are vulnerable to *Foice* attack. In particular, *Foice* successfully bypasses all ten invited participants' WeChat Voiceprint system. On average, about 30% of the synthetic recordings for each participant are successful in the attack. In addition to demonstrating the effectiveness of *Foice* attack, we quantify how a face image contributes to the success of *Foice* attack. Finally, we evaluate the feasibility of augmenting the conventional voice deepfake attack with *Foice*. Our results demonstrate that *Foice* significantly improves the attack's performance by threefold.

These findings highlight the urgent need for heightened awareness to safeguard against novel voice deepfake attacks, such as *Foice*. Through this study, we also hint at a new avenue of information leakage, namely how a person's face potentially reveals how they sound. We hope that this paper would stimulate further exploration within the security community regarding the threats posed by the correlation of biometric information.

2 Background

We introduce the background of voice deepfake, voice authentication systems, and the correlation between a speaker's face and voice.

2.1 Voice Deepfakes

The state-of-the-art voice deepfake utilizes a short voice recording of the victim to synthesize another recording with a similar vocal style but with new content. A typical example of a voice deepfake circulating on social media is to manipulate the content of the U.S. president's speech while keeping a similar vocal style. Figure 2 depicts an overview of how the state-of-the-art voice deepfake operates. Specifically, the voice deepfake produces a new voice recording in two steps.
(1) Voice Feature Extraction. Given a voice recording, the voice deepfake first extracts a *voice feature vector*, which captures and numerically represents the speaker's unique *voice features*, such as pitch, timbre, and pronunciation. Intuitively, when we listen to two different speakers saying the same sentence (e.g., "Hello, how are you?" as depicted in Figure 2(a)), we can easily differentiate between them due to their unique *voice features*. The voice deepfake utilizes a deep-learning model, namely the *Speaker Encoder* to extract the *voice feature vector*, which captures relevant *voice features* of the speaker that can distinguish him/her from other speakers, regardless of the speech content.
(2) Voice Synthesis. Subsequently, the voice deepfake synthesizes a new voice recording with the extracted *voice feature vector* and a text input (e.g., "Hey, Google!" as depicted in Figure 2(b)). The voice deepfake utilizes another deep-learning model, namely the *Synthesizer*, to perform this task. Specifically, the *Synthesizer* first generates audio signals whose waveform is primarily determined by the text input. It then modifies the audio signals based on the *voice features* described in the *voice feature vectors*.

Different from the state-of-the-art voice deepfake, *Foice* only utilizes a face image of the speaker to generate the *voice feature vectors* (see §4.3 and §4.4). We observe that both *Foice*

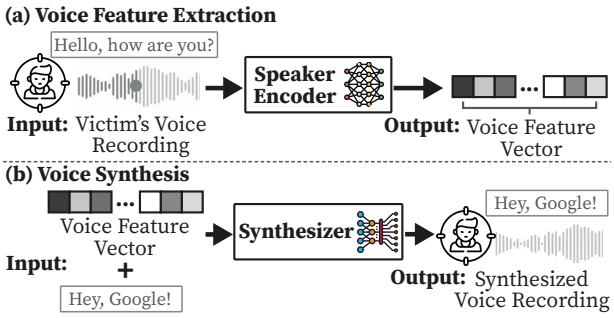

Figure 2: Figure depicts an overview of how voice deepfake operates. (a) depicts the *Voice Feature Extraction* step, where the *Speaker Encoder* extracts the *voice feature vector* from a voice recording. (b) depicts the *Voice Synthesis* step, where the *Synthesizer* uses the *voice feature vector* and a text input to synthesize a new voice recording.

and the voice deepfake yield similar vocal styles when using the face images and voice recordings, respectively (see §5.2).

2.2 Voice Authentication

Voice authentication is often incorporated into many online applications, such as social media platforms (e.g., WeChat), and telebanking, as an authentication method. Modern voice assistants, such as Siri, Google Assistant, and Bixby, also require voice authentication when they are activated by the user (e.g., "Hey, Google" when activating Google Assistant). In general, existing voice authentication solutions consist of two phases, namely the *Enrollment Phase* and the *Authentication Phase*. During the *Enrollment Phase*, the system provides several digits or sentences and enrolls the user's voice. In the *Authentication Phase*, the system records the user's voice again and compares the recorded voice with the enrolled voice to obtain a similarity score. The authentication is successful when the score is above a certain threshold.

However, we notice that the existing systems are vulnerable to voice deepfake attacks due to two reasons.

(1) Low Threshold. For the user's convenience, voice authentication systems usually configure a considerably low threshold of around 0.5 to 0.6 (e.g., Microsoft and iFlytek APIs) [7, 8]. This is to ensure that users can successfully authenticate themselves in noisy environments, such as restaurants and cafes, with background noises (e.g., speech from other people).

(2) Unlimited Number of Attempts. Many voice authentication systems do not restrict the number of authentication attempts for the user's convenience. For example, WeChat does not limit the number of *unsuccessful* login attempts. However, there is a limitation on the number of *successful* daily logins [13].

Foice exploits the aforementioned vulnerability to successfully bypass real-world voice authentication systems even

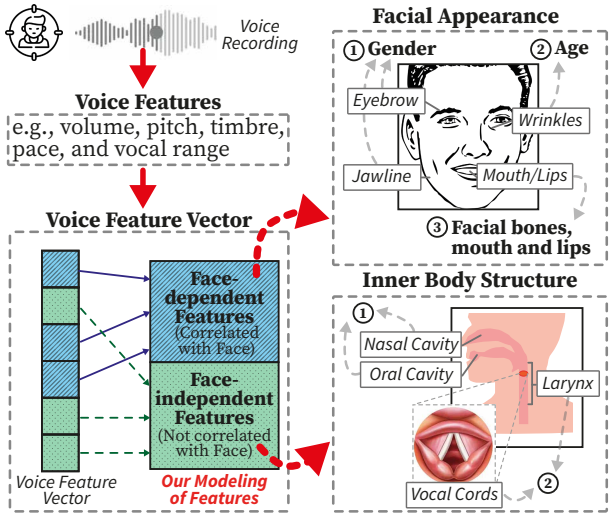

Figure 3: Figure depicts an example of the *voice feature vector* extracted from a voice recording, which captures the speaker's *voice features*. Based on our modeling, the *voice feature vector* consists of *face-dependent* and *face-independent* features, which are affected by the speaker's facial appearance or inner body structure, respectively.

with a single face image from the victim.

2.3 Correlation Between Face and Voice

Recall that existing voice deepfake utilizes the *voice feature vector* to capture and numerically represent *voice features*, including volume, pitch, timbre, pace, and vocal range, all of which constitute the uniqueness of the person's voice (see §2.1). Importantly, a subset of values in the *voice feature vector* is correlated with the person's ***facial appearance*** [47] (i.e., *face-dependent* features). The remaining feature values are largely affected by the person's ***inner body structure*** that produces the sound [49] (i.e., *face-independent* features). Figure 3 illustrates our modeling of *face-dependent* and *face-independent* features and their correlations with the speaker's facial appearance and inner body structure, respectively.

Facial Appearance. Facial appearance, including gender, age, the shape of the mouth, facial bone structure, and thin or full lips, may affect how the person's voice sounds (i.e., the *face-dependent* features) [47]. We present three examples as depicted in Figure 3 (*Facial Appearance*). ① Gender: Males typically have a more prominent eyebrow ridge and broad jawline compared to females while having a lower voice pitch. This is because hormone levels (i.e., the major factor determining gender) during puberty affect both face morphology and voice pitch [55]. ② Age: Age significantly affects a person's face and voice due to physiological and structural changes that occur over time. As people age, we can observe wrinkles and fine lines, especially around the eyes, forehead, and mouth. At

the same time, their *vocal cords* (i.e., a pair of muscular structures located in the voice box within the human throat) may become less flexible and thinner, resulting in a higher pitch in both men and women [42]. ③ Facial bones, mouth, and lips: Facial bone structure, the shape of the mouth, and thin or full lips may interfere with the sound wave propagating from the *vocal cords* to the mouth [23]. For example, people with thin lips may find it more challenging to articulate labial sounds (i.e., sounds like *'p', 'b', 'm', and 'w'* involving movement of lips). It is because they have less lip tissue to create the necessary closure or friction [15].

Inner Body Structure However, a significant portion of the *voice feature vector* is not correlated with the face (i.e., the *face-independent* features). Instead, it is largely affected by the inner body structure, such as the *nasal cavity*, *oral cavity*, and *larynx*. Figure 3 (*Inner Body Structure*) depicts two examples. ① The nasal cavity and oral cavity: The *nasal* and *oral cavities* are hollow spaces or passages in the head that extend from the nose or mouth, respectively, to the back of the throat. The shape and size of these cavities affect how the sound waves resonate and are modified, which, in turn, influences the timbre or quality of a person's voice [27]. ② The larynx: *The larynx*, commonly known as the voice box, plays a vital role in speech production. It is located in the neck. The *larynx* contains the *vocal cords*, which are two pairs of folds made up of muscle and tissue. The shape, size, and tension of the *vocal cords* significantly affect the timbre of the voice [51].

Key Takeaway. The *voice feature vector* describing a person's voice consists of the *face-dependent* (i.e., correlated with face) and *face-independent* (i.e., not correlated with face) features. Leveraging this observation, *Foice* first utilizes information in the face image to extract the *face-dependent* features (see §4.3). However, as the face image provides almost no insight into the inner body structure, it is challenging for *Foice* to obtain the *face-independent* features. To overcome this challenge, *Foice* designs a deep-learning model to generate a *search space* containing all the possible *face-independent* features subject to different inner body structures (see §4.4).

3 Threat Model

We highlight the attacker's goals and capabilities and further present *Foice*'s assumptions. The *goal* of the attacker is to compromise voice authentication in order to gain unauthorized access to the victim's accounts on platforms such as social media or gain access to personal voice assistants like Siri or Bixby. To achieve this goal, the attacker possesses the *capability* to acquire at least one facial image of the victim along with their credentials (such as email addresses, often used as account IDs). This information is extracted from publicly available data on online platforms such as Instagram, Facebook, and LinkedIn. Moreover, we assume that the attacker is capable of crawling through multiple online platforms to gather information from a broad cross-section of potential victims, making *Foice* a scalable attack. To execute the attack successfully, the attacker is also capable of collecting a large training dataset. This dataset includes a large collection of facial images of different speakers paired with their corresponding ground truth voice data (see §4.1).

4 System Design

We now present an overview of *Foice*'s design in §4.1, followed by details of each module from §4.2 to §4.5.

4.1 System Overview

Foice produces a set of synthetic voice recordings of the victim from a single face image leveraging the biological correlation between facial appearance and voice features (see §2.3). The attacker could iterate through all synthetic recordings to authenticate and log in as the victim to voice authentication systems. As depicted in Figure 4, *Foice* is divided into the *Training* and *Attack* phases.

❶Training Phase. The *Training Phase* is a one-time phase where the attacker utilizes online public datasets, containing face images and corresponding voice recordings, to train deep-learning models to learn the correlation. Specifically, *Foice* first processes the online public dataset in the *Data Processing* module (§4.2) to remove noise in face images, such as head orientations and background scenes, and extract ground truth voice feature vectors from voice recordings. Recall from §2.3 that the voice feature vector consists of *face-dependent* (i.e., correlated with face) and *face-independent* (i.e., not correlated with face) features. For clarity, we use F_{dep} and F_{indep} for these two kinds of features. In the *Face-dependent Voice Feature Extractor* module (§4.3), *Foice* utilizes processed face images and the ground truth voice feature vector to learn the relationship between F_{dep} and facial appearances. Subsequently, in the *Face-independent Voice Feature Generator* module (§4.4), *Foice* learns to identify F_{indep} by removing F_{dep} from the ground truth voice feature vector. It then generates a ***search space*** enumerating all possibilities of F_{indep}.

❷Attack Phase. Subsequently, in the *Attack Phase*, the attacker inputs one face image of the victim and takes N random samples from the search space to obtain ***N* synthetic voice recordings**, which are played iteratively to the authentication system until gaining access. Specifically, *Foice* first processes the face image in the *Face Processing* module (§4.2.1). *Foice* then utilizes the trained model in the *Face-dependent Voice Feature Extractor* module (§4.3) to extract F_{dep} of the victim from the processed face image. In the *Face-independent Voice Feature Generator* module (§4.4), *Foice* combines N samples from the search space with F_{dep} to reconstruct a set of N voice feature vectors of the victim. Finally, *Foice* converts N reconstructed vectors and a text input into N synthetic voice recordings, respectively, in the *Voice Synthesizer* module (§4.5).

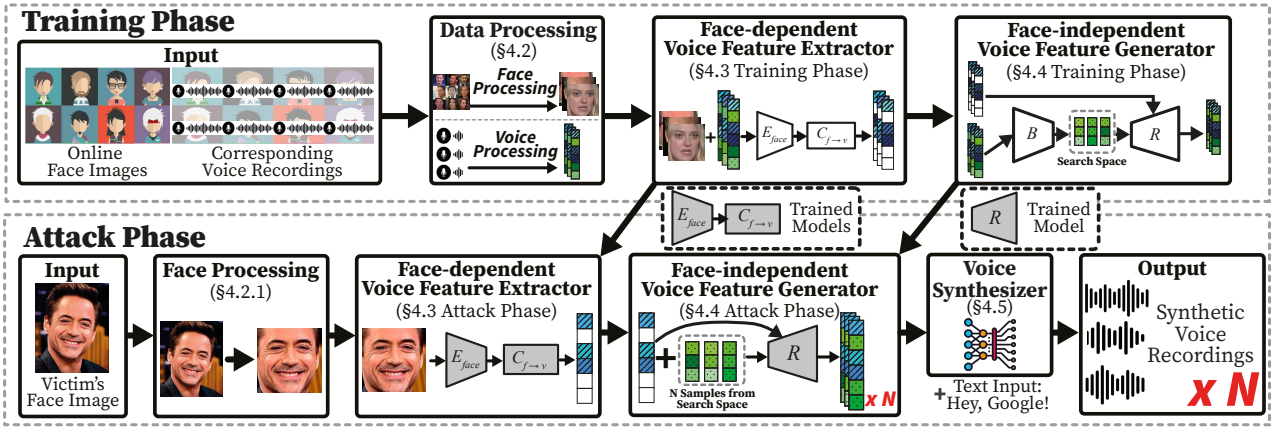

Figure 4: Figure depicts *Foice*'s system design. *Foice* is divided into *Training Phase* and *Attack Phase*. During the *Training Phase*, the attacker utilizes online public face images and corresponding ground truth voice recordings to train deep-learning models in the *Face-dependent Voice Feature Extractor* (§4.3) and *Face-independent Voice Feature Generator* (§4.4). During the *Attack Phase*, the attacker inputs the victim's face image to *Foice* to synthesize *N* number of voice recordings of the text that the attacker chooses (e.g., "Hey, Google!") in an attempt to bypass the victim's voice authentication or voice assistant systems (e.g., Google Assistant). The attacker iterates through the *N* synthetic voice recordings until gaining access.

4.2 Data Processing

Data processing module processes the online public dataset containing face images and corresponding voice recordings. It consists of two sub-modules. First, the *Face Processing* sub-module (§4.2.1) removes noise from the face image, such as the background scene and head orientation. Second, the *Voice Processing* sub-module (§4.2.2) takes as input a voice recording and outputs the voice feature vector that can uniquely identify a speaker.

4.2.1 Face Processing

Figure 5(a) illustrates the processing pipeline of this sub-module. *Foice* processes face images in two steps.

Face Cropping and Normalization. In this step, *Foice* removes background scenes and normalizes head orientations and face sizes in the input face image. Specifically, we detect and crop the face appearing in the image using a face detection model. Then, the cropped face is normalized to ensure that each face has approximately the same size and is rotated so that two eyes lie on a horizontal line.

Face Blurriness Assessment. Subsequently, *Foice* evaluates the image quality of the cropped and normalized face and discards blurry face images from the dataset. Specifically, *Foice* evaluates the clarity and sharpness of the face image by obtaining a *quality score*, which we compute based on the observation that a sharp image generally contains a large number of edges. Here, we apply the *Sobel* edge detection [32] on the face to detect all the edges. Examples of images with different *quality scores* are listed in Figure 14. We only keep images with scores above a threshold (i.e., empirically set to 100). However, we note that *Foice* attack is still effective when taking blurry faces (i.e., those below the threshold) as input (see §5.5.3).

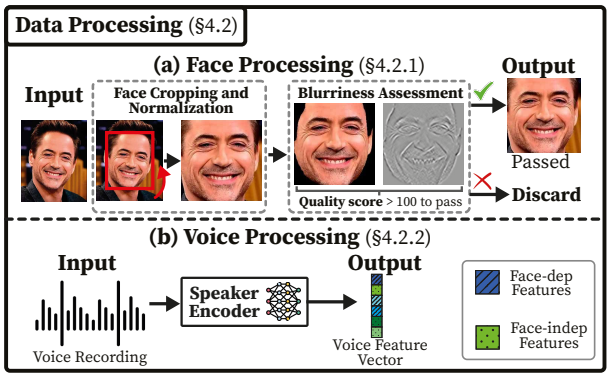

Figure 5: Figure depicts the pipeline of *Foice*'s *Data Processing* module (§4.2). (a) depicts the *Face Processing* (§4.2.1) which removes noise like head orientations and background scenes from the face images and filters out blurry images. (b) depicts the *Voice Processing* module (§4.2.2) which extracts the voice feature vector from the voice recording.

4.2.2 Voice Processing

Foice only utilizes this sub-module in its *Training Phase*. Figure 5(b) depicts the audio processing pipeline. We leverage a deep-learning model, namely the *Speaker Encoder* (see §2.1), to extract a voice feature vector from a voice recording. The extracted voice feature vector serves as the *ground truth* to facilitate the training of deep-learning models in §4.3 and §4.4.

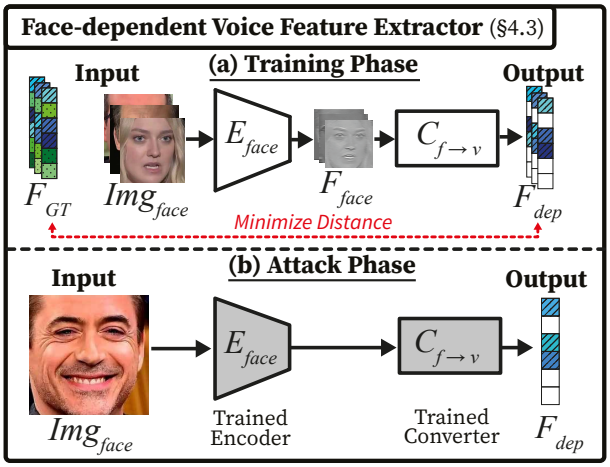

Figure 6: Figure depicts the pipeline of the *Face-dependent Voice Feature Extractor* module (§4.3). Specifically, it extracts relevant facial features from the processed face images and then converts them to *face-dependent* features in the voice feature vector.

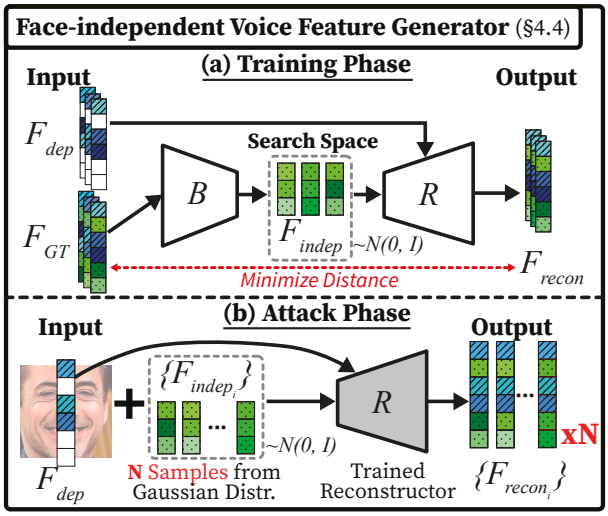

Figure 7: Figure depicts the pipeline of the *Face-independent Voice Feature Generator* module (§4.4). Specifically, it generates a search space of all possible *face-independent* features subject to different inner body structures by analyzing the dataset. It then combines both *face-dependent* and *face-independent* features to reconstruct the voice feature vectors of the victim, ultimately generating N reconstructed voice feature vectors.

4.3 Face-dependent Voice Feature Extractor

In this module, *Foice* aims to extract the *face-dependent* features, F_{dep}, from a processed face image. Figure 6 depicts the module pipeline in the *Training* and *Attack* phases.

Training Phase. In this phase, *Foice* trains a deep-learning model using processed face images, Img_{face}, and corresponding ground truth voice feature vectors, F_{GT}, from online public datasets (i.e., training dataset). The training objective is first to identify the facial features in face images that are correlated to the voice of the speaker, and then convert the relevant facial features to partial voice features, namely F_{dep}, as the model output. Figure 6(a) depicts the deep-learning models, namely an *Encoder*, $E_{face}(\cdot)$, and a *Converter*, $C_{f\to v}(\cdot)$[1]. Specifically, $E_{face}(\cdot)$ learns to identify relevant facial features from Img_{face} leveraging convolutional neural networks (CNN) such as ResNet [29]. $C_{f\to v}(\cdot)$ learns to convert facial features to F_{dep}.

$$F_{face} = E_{face}(Img_{face}), \qquad F_{dep} = C_{f\to v}(F_{face}),$$

where F_{face} denotes the facial features extracted by $E_{face}(\cdot)$.

To ensure that the extracted F_{face} correlates with the speaker's voice features, we train the two models jointly. We design the loss function to maximize the similarity (or minimize the distance) between F_{dep} and F_{GT}, such that

$$\min_{E_{face}(\cdot), C_{f\to v}(\cdot)} Err(F_{dep}, F_{GT}),$$

where $Err(\cdot,\cdot)$ denotes distance-based loss function. We note that our training scheme is effective in extracting *face-dependent* features with the following Observation 1. We present an empirical analysis of this observation in §A.2.1.

[1] See §A.1 for model architecture and implementation.

Observation 1. Following the training scheme in §4.3, *Foice* can extract *face-dependent* voice features, such as voice gender, from a single face image.

Attack Phase. The attacker inputs the victim's face image to the trained *Encoder*, $E_{face}(\cdot)$, and the *Converter*, $C_{f\to v}(\cdot)$, to extract F_{dep} of the victim. Figure 6(b) depicts the pipeline. Note that the attacker can input face images that are ***unseen*** in the *Training Phase*, hence attacking a wider range of victims.

4.4 Face-independent Voice Feature Generator

In this module, *Foice* aims to obtain the victim's *face-independent* features, F_{indep}. However, this is extremely challenging because F_{indep} are largely affected by the victim's inner body structure (see §2.3) which a face image provides almost no insight into. To overcome this challenge, the core idea is to analyze the known ground truth voice feature vectors, F_{GT}, of speakers in the public online dataset (i.e., training dataset) to generate a ***search space*** which enumerates all possible F_{indep}. Figure 7 illustrates this core idea. To launch the attack on the victim, the attacker can take N samples from the search space and combine them with the *face-dependent* features, F_{dep}, extracted from the face image to obtain a set of N reconstructed voice feature vectors, $\{F_{recon_i}\}$, *where* $i \in [1,N]$. By increasing N, the attacker has a higher chance of obtaining a F_{recon_i} sufficiently similar to the victim's F_{GT}. We now present how *Foice* generates the search space in the *Training*

Phase and how the attacker could use *Foice*'s model to attack a victim in the *Attack Phase*.

Training Phase. In this phase, we train a deep-learning model, which learns how to generate a search space from F_{dep} and F_{GT} of speakers in the training dataset. However, there are two main challenges.

First, separating F_{indep} from F_{GT} is non-trivial. To overcome this challenge, we design a *bottleneck* in the model (inspired by AutoVC [46]) to reduce the dimension of F_{GT} until it only contains F_{indep} (i.e., with as little F_{dep} as possible). The *bottleneck* is analogous to a "funnel" that filters out F_{dep} from F_{GT}. This is feasible by selecting a proper size of the "narrow opening of the funnel", or the dimension of the output of the *bottleneck*.

Second, the F_{indep} of speakers in the training dataset form **discrete** data points. It is still difficult to generalize to new speakers who are not in the dataset. For example, a victim's F_{indep} may be different from all speakers in the dataset and *Foice*'s search space should still contain it. To address this issue, we ensure that the search space adheres to a continuous distribution (i.e., standard Gaussian distribution). Intuitively, we may find the victim's F_{indep} by interpolating between discrete data points in the dataset.

Figure 7(a) depicts the details of our model design. Specifically, the *Bottleneck*, $B(\cdot)$, takes F_{GT} as input and outputs F_{indep} that has a smaller dimension and follows the continuous standard Gaussian distribution. Subsequently, the *Reconstructor*, $R(\cdot,\cdot)$, combines F_{indep} and F_{dep} to obtain the reconstructed voice feature vector, F_{recon}.

$$F_{indep} = B(F_{GT}), \qquad F_{recon} = R(F_{indep}, F_{dep})$$

We train the deep-learning model by minimizing a custom loss function to achieve two training objectives. First, to ensure that the search space is continuous, we minimize the KL-divergence loss (i.e., a standard loss often used to force feature vectors to follow the standard Gaussian distribution). Second, to ensure that $R(\cdot,\cdot)$ can accurately reconstruct voice features, we minimize the reconstruction error (i.e., the difference between F_{GT} and F_{recon}). Hence, the custom loss function is:

$$\min_{B(\cdot),R(\cdot,\cdot)} Err(F_{GT}, F_{recon}) + KL[P_{F_{indep}}(\cdot) \parallel \mathcal{N}(0,I)],$$

where $KL(\cdot \parallel \cdot)$ denotes the KL-divergence loss, $Err(\cdot,\cdot)$ represents the reconstruction error (e.g., distance-based loss function), and $P_{F_{indep}}(\cdot)$ denotes the probability density function of F_{indep}.

Note that *Foice* only utilizes $B(\cdot)$ in the *Training Phase* to obtain accurate extraction of F_{indep} from F_{GT} to train $R(\cdot,\cdot)$. We note that our bottleneck structure and training scheme are effective in extracting *face-independent* features with the following Observation 2, and we present an empirical analysis of this observation in §A.2.2.

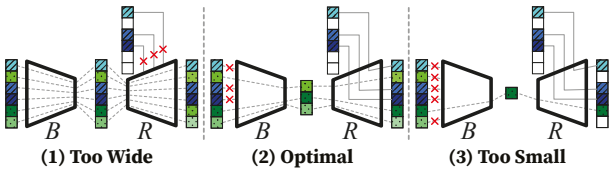

Figure 8: Figure depicts the implications of the bottleneck dimension to *Foice* when it is (1) too wide, (2) optimal, and (3) too small. *Foice* selects the optimal dimension.

Observation 2. By adjusting the bottleneck dimension, *Foice* is able to produce *face-independent* voice feature vectors that contains little *face-dependent* voice features.

The Rationale Behind Observation 2. Figure 8 depicts three scenarios to demonstrate the implications to *Foice* if the bottleneck dimension is (1) too wide, (2) optimal, and (3) too small. ***(1) Too wide:*** When the bottleneck dimension is too wide (i.e., as wide as F_{GT}), the bottleneck tends to copy F_{GT} directly to its output, F_{indep}, and the reconstructor could simply utilize F_{indep} as its output, F_{recon}, to achieve a minimal reconstruction loss (i.e., the difference between F_{GT} and F_{recon}). However, the search space in this case is overly large (i.e., as large as the entire voice feature vector space). ***(2) Optimal:*** When the bottleneck dimension decreases, F_{indep} is forced to discard some portion of it. To minimize the reconstruction loss, F_{indep} will first discard information preserved in F_{dep}. When the bottleneck dimension reaches the optimal, F_{indep} contains just the right amount of information and involves as few *face-dependent* features as possible in order to minimize the reconstruction loss. ***(3) Too small:*** When the bottleneck dimension is too small, F_{indep} starts to lose *face-independent* features in this case, leading to large reconstruction errors. As a result, the attacker may not be able to find the voice feature vector associated with the victim in the search space.

Attack Phase. Figure 7(b) depicts how the attacker can utilize F_{dep} of the victim and *Foice*'s trained model to obtain a set of voice feature vectors of the victim, $\{F_{recon_i}\}$, *where* $i \in [1,N]$. Specifically, the attacker first samples N random vectors as $\{F_{indep_1}, \ldots, F_{indep_N}\}$ from the standard Gaussian distribution, $\mathcal{N}(0,I)$. Then the attacker leverages the trained $R(\cdot,\cdot)$ to combine each F_{indep_i} with F_{dep} previously extracted from the victim's face image (see §4.3).

$$F_{indep_i} \sim \mathcal{N}(0,I), \qquad F_{recon_i} = R(F_{indep_i}, F_{dep}),$$

where $i \in [1,N]$. Finally, the attacker obtains $\{F_{recon_1}, \ldots, F_{recon_N}\}$ and then generates N synthetic voice recordings in the *Voice Synthesizer* module (§4.5).

4.5 Voice Synthesizer

Foice now takes as input a set of N reconstructed voice feature vectors, F_{recon}, and text of a given content (e.g., "Hey, Google!"). *Foice* then outputs ***N* synthetic voice recordings**

of the victim speaking the given content. Specifically, *Foice* adopts the deep-learning model used in the state-of-the-art voice deepfake system (see §2.1). Finally, the attacker enumerates through all synthetic voice recordings to authenticate and log in as the victim to voice authentication systems.

5 Evaluation

Through comprehensive real-world experiments, we seek to answer the following questions: ❶ Is *Foice* attack effective against diverse modern implementations of speaker authentication systems and voice assistants? (see §5.2) ❷ Can *Foice* provide more voice information other than age and gender? (see §5.3) ❸ Can we combine *Foice* and the existing voice deepfake system to improve the attack's effectiveness? (see §5.4) ❹ How do different experimental conditions affect the effectiveness of *Foice*? (see §5.5) ❹ How does *Foice* behave when converting facial features into voice features? (see §5.6)

5.1 Experiment Setup

We now present the experiment setup to evaluate *Foice*.

5.1.1 Voice Authentication System Selection

We evaluate *Foice* on various state-of-the-art voice authentication systems and off-the-shelf voice assistants, listed in Table 1. The list provides a representative collection of systems that can be acquired and implemented for experiments.

Voice Authentication Systems. We select two types of voice authentication systems for our evaluation - *on-device systems* and *cloud services*. First, we choose commercial on-device voice authentication systems installed on commodity smartphones. In addition, we experiment on *commercial* cloud authentication services, such as the voice authentication API from Microsoft and iFlytek, and deep learning models proposed in *academic* papers, such as VGGVox and DeepSpeaker, which could be deployed as cloud services. We select the official GitHub implementation of VGGVox [11] and DeepSpeaker [3], which are pre-trained on VoxCeleb2 [21] and LibriSpeech dataset [45], respectively. Cloud services may exhibit superior authentication capabilities compared to on-device systems. This is because on-device systems are designed to be lightweight due to limited computing resources on the edge device. In contrast, cloud services can utilize large deep-learning models without such constraints.

Voice Assistants. Initially designed for automatic speech recognition (i.e., conversion from speech recordings to written text), voice assistants are increasingly integrating voice authentication for personalized user services. This paper primarily focuses on voice assistants incorporating voice authentication. Consequently, we select and experiment with off-the-shelf systems - e.g., Siri, Google Assistant, and Bixby.

Authentication Mechanism. The aforementioned systems work by **verifying** the user's identity. Each system has exactly one enrolled speaker and checks if an input voice is uttered by the enrolled speaker or not. Specifically, by comparing the enrolled voice with the input voice, the system computes a match score to indicate how closely they match each other. If the match score exceeds a pre-defined threshold, then the system accepts the input as a match; otherwise, it rejects the input voice (see §2.2). The *on-device systems* (i.e., WeChat, Siri, Google Assistant, and Bixby) have fixed thresholds that users cannot modify. Cloud services are initially configured with default thresholds, yet users can adjust the threshold based on their specific usage scenarios. This paper assesses cloud services across various threshold values, with the threshold configuration discussed in §5.2.2. It is worth taking note that while the main purpose of voice assistants like Siri, Google Assistant, and Bixby is to recognize activation words such as "Hey, Google", these systems also include the above-mentioned authentication measures to verify the speaker's identity.

5.1.2 Benchmark Voice Deepfake System

We utilize the state-of-the-art voice deepfake system with public code and pre-trained models as our benchmark. Specifically, we select SV2TTS [31] because it outperforms other state-of-the-art voice deepfake systems due to its outstanding performance in generalizing to *unseen* speakers. SV2TTS takes as input a single voice recording from the victim and outputs one synthetic recording. We use a well-known GitHub implementation [1] pre-trained on the VoxCeleb and LibriSpeech datasets.

5.1.3 Speaker Dataset

We use three different speaker datasets, namely VoxCeleb1 [43], VoxCeleb2 [21], and a custom dataset, that contain face images and associated voice recordings for our experiments. We use each speaker's face image as the input to *Foice* to produce multiple synthetic voice recordings. We also input the corresponding voice recording to the benchmark voice deepfake model (i.e., SV2TTS) to generate a synthetic voice recording as the baseline.

VoxCeleb. VoxCeleb1 and VoxCeleb2 are public datasets containing YouTube videos. In particular, VoxCeleb1 contains over 100,000 videos for 1,251 celebrities, and VoxCeleb2 contains over a million videos from 6,112 celebrities. Each speaker in the dataset has multiple face images and voice recordings. There is no shared speaker identity between these two datasets. Both datasets demonstrate relatively equal representation of genders, with male gender accounting for 55% in VoxCeleb1 and 61% in VoxCeleb2, respectively. However, the videos are collected in many noisy environments – e.g., red carpets, outdoor stadiums, and lecture halls. Con-

Category	System	System Type	Commercial/ Academic	Eval. Param.		Overall Success Rate			Average Individual Success Rate (Foice)
				#Spk.	Threshold	SV2TTS [31]	Foice	Augmentation Attack (Foice + SV2TTS)	
 On-Device System	WeChat	Authentication	Commercial	10	—	50.0%	**100%**	—	29.7%
	Siri	Voice Assistant	Commercial	10	—	50.0%	**70.0%**	—	40.9%
	Google Assistant	Voice Assistant	Commercial	10	—	50.0%	**60.0%**	—	10.3%
	Bixby	Voice Assistant	Commercial	10	—	30.0%	**50.0%**	—	3.6%
 Cloud Service	Microsoft API	Authentication	Commercial	597	0.1 - 0.8	0% - 86.9%	0% - 95.0%	**0% - 99.6%**	0% - 29.5%
	iFlytek API	Authentication	Commercial	1021	0.1 - 0.8	0% - 100%	0% - 100%	**0% - 100%**	0% - 99.5%
	VggVox	Authentication	Academic	1029	0.1 - 0.8	2.9% - 97.8%	8.9% - 99.3%	**26.1% - 99.9%**	2.3% - 84.6%
	DeepSpeaker	Authentication	Academic	1029	0.1 - 0.8	0.2% - 99.5%	0.5% - 100%	**2.4% - 100%**	1.0% - 99.4%

Table 1: Table depicts the four on-device systems and four cloud services tested in our experiment. We present the evaluation parameters for each system, the overall success rate of *SV2TTS* [31], *Foice*, and *Augmentation Attack* (i.e., *Foice* + *SV2TTS*), and the average individual success rate achieved by *Foice*.

sequently, voice recordings in the dataset may contain background conversations, laughter, speech overlap, and diverse ambient noise. Similarly, face images experience variations in pose, lighting conditions, and blurriness due to motion. We use VoxCeleb2, a larger dataset, for training and VoxCeleb1 for evaluation of *Foice* on cloud-based authentication services.

Custom Dataset. We evaluate the real-world implications of *Foice* on on-device authentication systems by creating our own dataset of ten participants with different ages (six in their 20s; two in their 30s; one in their 40s; one in their 50s) and genders (seven male and three female). Each participant utilizes the Voice Memo app on the iPad Air (4th generation) for recording. In a quiet meeting room, they read two sentences from the Rainbow Passage [26]. This voice recording is input to SV2TTS to generate a synthetic voice recording, which serves as our benchmark. We also collect a profile photo from each participant as the input to *Foice*. We conduct the experiments and data collection by adhering to our university's Institutional Review Board (IRB) approval (see §A.4). Table 3 summarises the dataset employed to train and evaluate *Foice*.

5.1.4 Performance Metrics

We define the following three metrics to evaluate *Foice*:

Overall Success Rate: Percentage of *speakers* with at least one synthetic voice recording that passes the authentication (or successfully activate the voice assistant).

Individual Success Rate: Percentage of *synthetic voice recordings* of a particular person that passes the authentication (or successfully activate the voice assistant).

Foice Individual Success Rate: Fraction of voice cloned from a single face image that can pass the verification. A higher individual success rate indicates that the participant is more likely to be attack by *Foice*.

The overall success rate captures the general view of the security vulnerability of the target authentication system. In contrast, the individual success rate indicates the chances of attacking a victim successfully.

5.2 Can *Foice* Attack Real-world Systems?

We present our experiment results on eight modern voice authentication systems and voice assistants as listed in Table 1

5.2.1 Analysis of On-device Systems

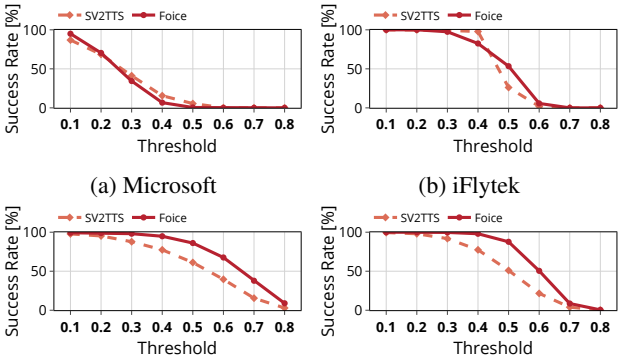
Users interact with on-device systems (i.e., WeChat, Siri, Google Assistant, and Bixby) by engaging in direct conversation with the device microphones. To resemble real-world scenarios, we recruit ten participants in our experiments.

Data Preparation. We evaluate the effectiveness of *Foice* and SV2TTS attacks on these systems. Specifically, we use our custom dataset (see §5.1.3) to generate synthetic voice recordings of each participant using both *Foice* and SV2TTS. Ultimately, for each speaker, we generate 100 synthetic voice recordings using *Foice* and one synthetic recording using SV2TTS. This is due to *Foice*'s ability to produce multiple synthetic voice recordings from a single face image (see §4.4), whereas SV2TTS can generate only a single synthetic recording from a single voice input (see §5.1.2).

Experiment Setup. Each participant enrolls their voice with a dummy account on each system. Subsequently, we use a laptop speaker to directly play the synthetic voice recordings to the smartphone hosting the on-device system. The smartphone is positioned next to the laptop, with the smartphone's microphone facing directly towards the speaker. We consider an attack successful if the synthetic voice recording can log in to the WeChat account or activate the voice assistant.

Results of WeChat. As depicted in Table 1, *Foice* yields an overall success rate of 100%. In other words, all the participants have at least one *Foice*-generated synthetic voice recording that can successfully log in to the WeChat account protected by their voice. In addition, *Foice* achieves an average individual success rate of 29.7%. This indicates that, on average, approximately 30 out of 100 synthetic recordings of each participant can successfully log in to WeChat. Given that WeChat allows ***unlimited*** login attempts, this result shows that *Foice* poses a significant threat to WeChat's Voiceprint.

By comparison, SV2TTS only achieves an overall success rate of 50%. This is because the synthetic voice recordings generated by SV2TTS exhibit audible noise. Some are even unintelligible to the human ear, rendering the authentication impossible. It appears that SV2TTS is sensitive to noise in the input audio. Although we recorded the input voice in a *quiet* and *empty* meeting room (see §5.1.3), we still observed echos in the recording, which could be the primary cause of the noisy output. This poses a notable disadvantage for attackers utilizing SV2TTS because noise-free audio is not easily available. Also, removing noise from audio is still a difficult research problem [22].



Results of Siri, Google Assistant, and Bixby. Table 1 summarizes the overall success rate and average individual success rate. Overall, *Foice* yields an overall success rate ranging from 50% to 70% across all the three voice assistants while the highest success rate for SV2TTS is 50%. Again, this is due to the presence of noise in SV2TTS' outputs, causing the voice assistant to be unable to recognize the activation words. In addition, we note that the *voice synthesizer* (see §4.5) struggles to accurately pronounce specialized vocabulary. For example, "Siri" tends to be pronounced as "sigh ree". In turn, this impacts the success rate of both *Foice* and SV2TTS. As the technology of voice synthesizers improve, so should the performance of both *Foice* and SV2TTS.

5.2.2 Analysis of Cloud Services.

We also evaluate *Foice* on two state-of-the-art cloud-based commercial voice authentication APIs (Microsoft and iFlytek) and two academic proposals (VGGVox and DeepSpeaker). Unlike on-device systems, cloud services accept inputs through their software interface rather than through a microphone. This allows us to conduct a large-scale experiment using a public dataset.

Data Preparation. We experiment on the VoxCeleb1 dataset. **(1) Enrollment.** We filter out blurry face images (see §4.2.1) and select high-quality voice recordings using NISQA [41] (i.e., a deep learning model evaluating the audio quality). In total, we have a dataset with 1,029 speakers (out of a total of 1,251 speakers; see §5.1.3). Table 1 summarizes the number of enrolled speakers. Not all speakers are successfully enrolled to Microsoft and iFlytek due to poor-quality recordings (i.e., audio signal-to-noise ratio below 2dB). **(2) Authentication.** We generate synthetic voice recordings using both *Foice* and SV2TTS. *Foice* takes as input one face image, whereas SV2TTS uses a *new* voice recording (i.e., not used for enrollment) as input. The generated recordings are then sent to each cloud service for authentication.

Threshold. Cloud services rely on an adjustable threshold (a numerical value between 0 and 1) to decide if two recordings are from the same speaker (see §2.1). Table 1 lists the threshold values used for evaluation. Although Microsoft and iFlytek recommend fixed thresholds for their systems, we vary said thresholds to investigate their overall performance.

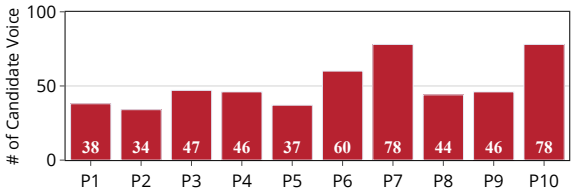
(a) Microsoft (b) iFlytek

(c) VGGVox (d) DeepSpeaker

Figure 9: (a) to (d) depict the overall success rate across a range of thresholds from 0.1 to 0.8 for four tested cloud services, respectively.

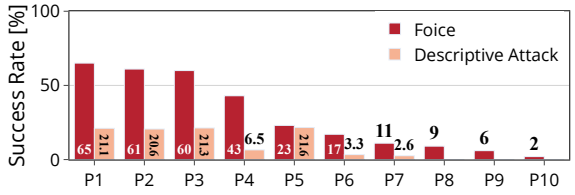
System	Default/Optimal Threshold	Overall Success Rate		Average Individual Success Rate
		SV2TTS [31]	*Foice*	
Microsoft	0.5	**5.5%**	0.5%	1%
iFlytek	0.6	2.0%	**5.7%**	3.3%
VGGVox	0.6	39.6%	**67.6%**	15.4%
DeepSpeaker	0.5	51%	**87.7%**	32.7%

Table 2: Table depicts the default/optimal thresholds of four tested cloud services and the overall success rate of *SV2TTS* and *Foice*, respectively. In addition, it presents the average individual success rate achieved by *Foice*.



Results. Figure 9 depicts the attack success rate across a range of thresholds from 0.1 to 0.8. *Foice* achieves comparable results as SV2TTS in attacking Microsoft and iFlytek. Surprisingly, *Foice* yields higher success rates than SV2TTS in attacking VGGVox and DeepSpeaker across all the thresholds. ***We note that regardless of differences in system design and implementation, all systems are susceptible to Foice when the threshold is set at their default or optimal value*** as summarized in Table 2. The optimal threshold of VGGVox and DeepSpeaker is set to minimize their equal error rate. It is possible to guard against *Foice* by setting a higher threshold, but this will result in higher false rejects, impairing usability. On the other hand, setting a lower threshold can significantly increase *Foice*'s success, as Figure 9 shows. In addition, we observe that academic models exhibit greater vulnerability than commercial systems. This could be due to insufficient training resources (e.g., training data, computing power) or an inadequate optimization strategy.

5.3 Does *Foice* Leverage Voice Information Beyond Gender and Age?



Foice leverages the correlation between face and voice to extract *face-dependent* features, such as gender and age (see

Dataset	#Speaker	#Instances	Details
Train Set	4108	1273017	Part of **VoxCeleb2** [21] used for training *Foice*
Test-1 Set	1029	1029	Part of **VoxCeleb1** [43] used for testing Microsoft, iFlytek, VGGVox, and DeepSpeaker
Test-2 Set	10	10	Data from **recruited participants** used for testing WeChat, Siri, Google Assistant, and Bixby

Table 3: Table summarises the datasets for training and testing. "#Speaker" specifies the total number of speakers. "#Instances" specifies the total number of face images. "Details" highlights the source and purpose of each dataset.

(a) Number of candidate voice recordings

(b) *Foice* vs. *Descriptive Attack*

Figure 10: (a) depicts the number of candidate recordings obtained from the dataset for each participant. (b) depicts the individual success rate of *Foice* and *Descriptive Attack* on WeChat's Voiceprint, respectively.

§4.3). However, apart from the face image, the attacker could gather the victim's gender and age from other sources (e.g., healthcare databases). Hence, we aim to investigate the following: (1) Can a voice deepfake attack be launched using only descriptive features (e.g., gender and age)? (2) Does *Foice* leverage more information other than gender and age?

Descriptive Attack. As such, we define a *Descriptive Attack* that only leverages descriptive information (i.e., age and gender) as a baseline. To launch the attack, the attacker searches from a large-scale voice dataset for speakers of similar age and the same gender as the victim. Subsequently, these speakers' voice recordings are input to voice deepfake systems (e.g., SV2TTS) to generate candidate synthetic voice recordings. Finally, the attacker attempts to compromise the authentication system using all the candidate recordings.

Data Preparation. We utilize VoxCeleb2, on which *Foice* is trained, as the dataset for the *Descriptive Attack*. We ensure that *Foice* and *Descriptive Attack* are implemented with the same dataset. To attack a victim, we search for voice recordings with similar age (i.e., age difference no larger than two years) and the same gender from VoxCeleb2. For example, if the attacker wants to attack a 30-year-old male speaker, all the male speakers between the ages of 28 and 32 are selected. Figure 10(a) provides an overview of the number of candidate recordings for each participant.

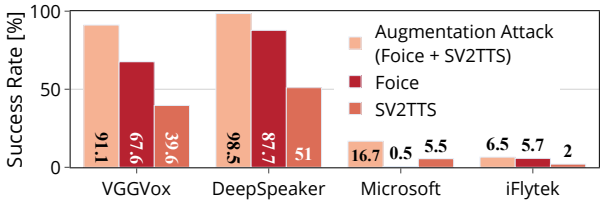


Figure 11: Figure depicts the overall attack success rate of *Augmentation Attack* (i.e, *Foice* + *SV2TTS*), *Foice*, and *SV2TTS*, for four tested cloud services (with the default or optimal threshold), respectively.

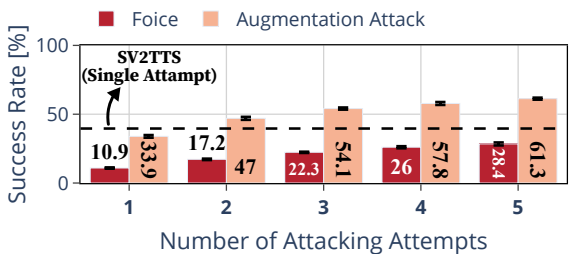
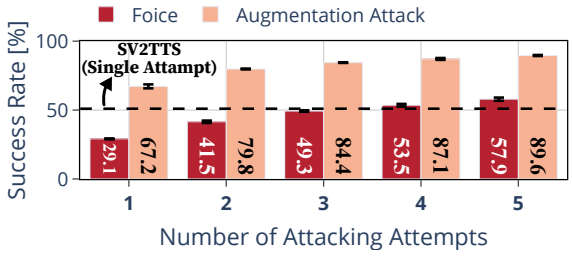


Descriptive Attack* vs. *Foice*.** We evaluate the *Descriptive Attack* on WeChat with the same experiment setup in §5.2.1. Figure 10(b) compares the individual success rate (i.e., the success rate in attacking a specific speaker) of *Foice* and *Descriptive Attack*. *Foice* outperforms the *Descriptive Attack* across all the participants. *Foice* yields an average individual success rate of 29.7%, and the *Descriptive Attack* has an average individual success rate of 9.7%. These results indicate that ***Foice leverages voice information beyond age and gender for voice synthesis. Moreover, we can observe from Figure 10(a) that even if VoxCeleb2 contains recordings from 6,112 speakers, each participant has less than 100 candidate synthetic recordings. On the other hand, *Foice*'s capability in enumerating all the possible voice recordings is not constrained by the training dataset.

5.4 Can *Foice* Augment Existing Voice Deepfake Systems?



Recall that existing voice deepfake systems (e.g., SV2TTS) can only generate one synthetic recording given one voice input. This section investigates if *Foice* can be used to augment SV2TTS attack to improve the attack performance.

Augmentation Attack. We assume that the attacker can obtain a short voice recording (i.e., less than a minute) and a face image of the victim. To launch the attack, the attacker averages the voice feature vector generated by SV2TTS with each of the N vectors produced by *Foice*. Then, the attacker generates N synthetic voice recordings from the averaged feature vectors. Finally, the attacker enumerates through all synthetic recordings to compromise the authentication system.

Evaluation of *Augmentation Attack*. We conduct a large-scale experiment with commercial APIs and academic models, utilizing the VoxCeleb1 dataset. We follow the same experiment setup in §5.2.2, where each speaker has 100 synthetic

(a) VGGVox

(b) DeepSpeaker

Figure 12: Figure depicts the *Foice*'s overall success rate with varying numbers of attacking attempts on (a) VGGVox and (b) DeepSpeaker, respectively.

voice recordings output by the *Augmentation Attack*. Figure 11 depicts the overall success rate of SV2TTS and *Augmentation Attack* when targeting voice authentication systems using either the default or optimal threshold. *Augmentation Attack* outperforms SV2TT and *Foice* across all the four evaluated systems. ***This finding highlights the effectiveness of Foice in augmenting existing voice deepfake attacks.***

5.5 How Robust is *Foice*?

We evaluate the practicality of *Foice* over several different conditions. In total, our experiments target 1,029 speakers from the VoxCeleb1 dataset (see §5.2.2 Experiment Setup) on VGGVox and DeepSpeaker. We choose the optimal threshold of 0.5 and 0.6 for VGGVox and DeepSpeaker, respectively.

5.5.1 Impact of Limiting Attack Attempts

Some real-world authentication systems, such as mobile banking apps, generally allow three to five login attempts for improved security. We evaluate *Foice* and *Augmentation Attack*'s performance in attacking academic models (e.g., VGGVox and DeepSpeaker) with **a maximum of five attack attempts**. Figure 12 depicts the results. The success rate grows with the number of attempts for both VGGVox and DeepSpeaker. With a single face image, *Foice* is effective with only five attempts, yielding a success rate of 29.4% for VGGVox and 58.6% for DeepSpeaker. With a face image and a short voice recording, the *Augmentation Attack* outperforms the single-attempt voice-only attack (e.g., SV2TTS) with less than five attempts.

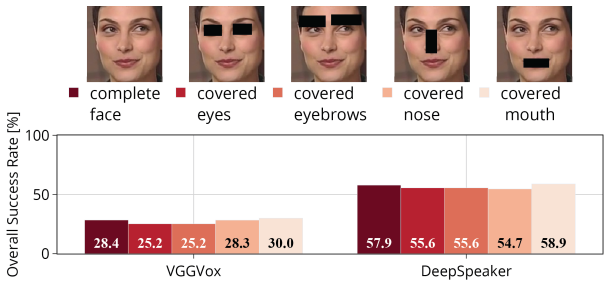


Figure 13: Figure depicts *Foice*'s overall success rate with *varying missing facial features* in the face images on VGGVox and DeepSpeaker, respectively.

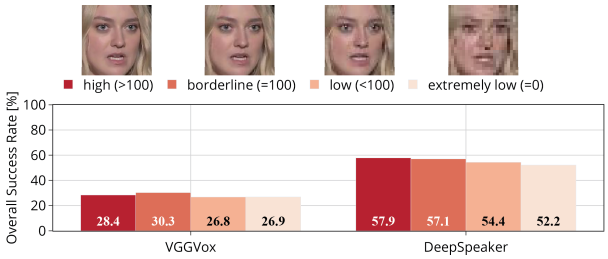

Figure 14: Figure depicts *Foice*'s overall success rate with *varying resolutions of face images* on VGGVox and DeepSpeaker, respectively.

The *Augmentation Attack* achieves a success rate above 50% across both systems with only five attempts. ***These results demonstrate the potential of Foice in realizing a practical attack that limits the number of attack attempts.***

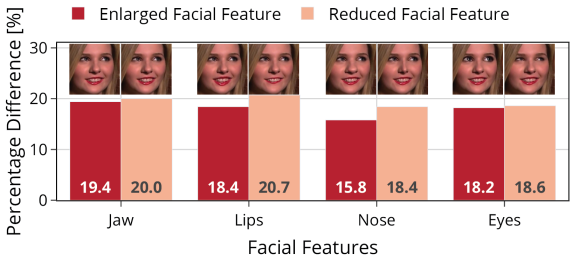
5.5.2 Impact of Image Occlusion

The attack performance may be constrained by image occlusion – e.g., wearing sunglasses or masks. We cover critical facial features, such as eyebrows, eyes, nose, and mouth as depicted in Figure 13. We evaluate *Foice*'s performance with five attack attempts. For both VGGVox and DeepSpeaker, we observe a decrease in the success rate when the eyes, eyebrows, and nose are covered. In contrast, there is a subtle increase in the success rate when the mouth is covered. We attribute this to the varying mouth shapes in our training images due to people speaking. Hence, mouth might be considered by *Foice* as noise since the same speaker could have different mouth shapes. With a cleaner dataset, *Foice*'s performance may improve as it may utilize mouth features as well. ***Overall, Foice is robust to image occlusion.***

5.5.3 Impact of Image Resolution

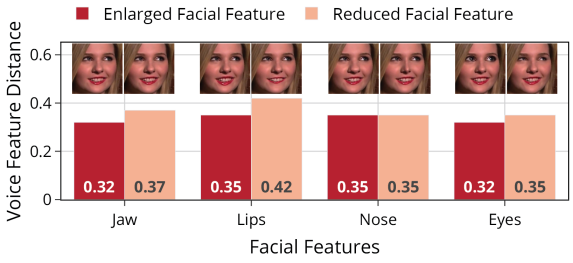
The attacker might not always obtain high-resolution face images of the victim. To explore the impact of image resolution, we down-sample the face image evaluated in §5.2.2 to different resolutions. By assessing the resolution using

our *Face Blurriness Assessment* algorithm (see §4.2.1), we categorize images into four resolution levels: high resolution (score > 100), borderline resolution (score ≈ 100), low resolution (score < 100), and extremely low resolution (score ≈ 0). Figure 14 shows the success rate of *Foice* with five attack attempts. We observe that the success rate increases with the image resolution. *Foice* achieves a surprisingly high success rate on both systems, even when taking the extremely low-resolution image as input. We conjecture that *Foice* mainly relies on the overall face structure rather than detailed features (e.g., texture) to derive voice features. As a result, *Foice* nearly remains unaffected when we blur the face image. ***The results indicate that Foice is effective even when taking the blurry face as input.***



5.6 How Do Facial Features Affect the Output?

We now investigate the behavior of *Foice*'s *Face-dependent Voice Feature Extractor* (see §4.3) by analyzing how facial features affect its output. Our analysis involves altering various facial features (e.g., eyes, noses, jawlines, and lips) through enlargement or reduction in the input face image. Subsequently, we evaluate the resulting audio output to compare voice features with those obtained from the ground truth audio.



Data Preparation. We select 50 speakers (25 males and 25 females) randomly from the VoxCeleb1 dataset. Using Adobe Photoshop, we then change the size of facial features such as eyes, noses, jawlines, and lips in each image (see Figure 15). Subsequently, we employ *Foice*'s *Face-dependent Voice Feature Extractor* (see §4.3) and *Voice Synthesizer* (see §4.5) to convert these modified images into audio outputs.

Voice Features. We calculate voice features, including pitch (i.e., highness or lowness of a sound), formant frequency (i.e., timbre), spectral centroid (i.e., the brightness of a sound), and spectral bandwidth (i.e., the sharpness of a sound), from each generated audio file. We quantify the pitch difference between the synthetic audio, x, and the speaker's actual voice, y, using percentage difference, $PD = |\frac{x-y}{y} \times 100\%|$. We then compare PD when enlarging or reducing the size of facial features to calculate the delta, $\Delta = |PD_{enlarge} - PD_{reduce}|$, which indicates pitch sensitivity to changes in facial features. We use Euclidean distance for the remaining voice features to quantify the difference as they are high-dimensional.

Results. We observe notable effects on pitch and formant frequency with modifications to facial features. However, changes in facial features have minimal impact on other voice attributes (i.e., spectral centroid and spectral bandwidth). Figure 15a illustrates the effect on pitch, while Figure 15b depicts the effect on formant frequency, resulting from enlarging and reducing facial features in the image. In Figure 15a, it is evident that *Foice*'s deep-learning model associates **lips** and **noses** with pitch. For instance, enlarging and reducing noses result in a percentage difference of 15.8% and 18.4%, respectively, with the largest delta of 2.6%. Similarly, modifying

(a) Pitch

(b) Formant Frequency

Figure 15: Figure depicts the impact on (a) Pitch and (b) Formant Frequency with enlarged and reduced facial features in the face image.

lips yields the second-largest delta of 2.3%. This aligns with the biological association between facial features and voice features (see §2.3). In Figure 15b, we also notice a similar pattern where lips emerge as the most influential facial feature, followed by jawlines. When enlarging and reducing lips, we observe a feature distance of 0.35 and 0.42, respectively, with the largest delta being 0.07. Similarly, modifying jawlines results in the second-largest delta of 0.05. Jawlines exert a more pronounced effect on formant frequency compared to the nose because formant frequencies represent the resonant frequencies of the vocal tract, which can be influenced by the width or narrowness of jawlines. Therefore, it is clear that *Foice* can effectively extract pertinent facial features and convert them into pitch and formant frequencies, which are crucial features often used in speaker identification [48].

6 Discussion

We present relevant discussion points of *Foice* in this section.

Deployment Considerations. We note that there is an increasing trend of incorporating voice authentication into real-world systems [2,9,10,13]. Hence, it is not difficult to imagine voice authentication replacing password-based authentication to improve user experience. For example, many instant messaging services, including Facebook Messenger and WhatsApp, could employ voice authentication in the near future for increased usability [12]. Furthermore, we note that existing authentication systems may adopt multi-factor authentication (MFA) to enhance their security. For example, voice biomet-

rics and one-time passwords (OTP) are often used as MFA factors for telebanking [6] and WeChat also adopts multiple factors to protect users' accounts. Hence, if *Foice* is to be deployed to gain unauthorized access to the victim's account, we envision that *Foice* would compromise the voice factor while leveraging additional attack methods to compromise other factors (e.g., password and OTP) [34].

Improving *Foice*'s Performance. While we demonstrate the effectiveness in launching *Foice* attack on commercial systems, there is still room for improvement. First, we can enhance *Foice*'s processing pipeline such as improving noise reduction methods to normalize facial expressions and lip movements in face images (see §4.2). Second, we can incorporate diverse information from the victim. For example, we can combine face images with the victim's voice samples (see §5.4) or utilize 3D face photos, to capture additional details of the victim's face structures [24, 39]. Furthermore, as a proof-of-concept, *Foice* only adopts a simple architecture for the deep-learning models (see §A.1). Further optimization of the model architecture would contribute to further improving *Foice*'s performance.

Countermeasures. One simple countermeasure is to restrict the number of login attempts to authentication systems. However, we note that the tested systems are still vulnerable to *Foice* with a maximum of five login attempts (see Figure 12 in §5.5.1). Hence, we envision two potential countermeasures. First, integrating *deepfake voice detection* methods [20, 38, 54] into authentication systems could mitigate problems that may arise from attacks like *Foice*. Second, authentication systems could also incorporate *liveness detection* methods [14, 40, 53] to determine the source of the input voice signal, such as whether it originates from a human voice or a pre-recorded voice playback. However, it is important to note that these two directions have not been incorporated into real-world systems. Hence, additional measures need to be implemented and deployed to adequately safeguard against voice deepfake attacks such as *Foice*.

7 Related Work

We present related works of the attacks on voice authentication systems and voice synthesis using face information.

Attacks on Voice Authentication Systems. There are two categories of attacks compromising voice authentication systems. First, an *adversarial attack* exploits the vulnerabilities of machine learning algorithms of the authentication system to produce erratic predictions [17–19, 36, 52, 58, 60]. However, for an *adversarial attack* to be successful, one must know either the implementation details of the authentication system or the victim's voice samples. On the contrary, *Foice* does not require this knowledge. Second, a *voice deepfake attack* leverages deep learning models to generate synthetic voice recordings that sound like the victim's voice [50, 57]. *Foice* is motivated by the *voice deepfake attack*, but only utilizes a single face image of the victim.

Voice Synthesis using Face Information. Recent studies investigate the correlation between face and voice. A family of works investigates the possibility of reconstructing voice from the associated face [28, 33, 37, 56, 59], and vice versa [25, 30, 44]. However, face images lack some essential voice features, making accurate face-to-voice conversion extremely challenging. Previous methods mostly rely on voice cues in the face, but we propose a new method to generate missing voice features and our approach significantly improves voice reconstruction performance compared to prior methods (see §A.3). Furthermore, prior works fail to underscore the **security implications**. For example, *Face2Speech* [28], *FaceVC* [37], *SP-FaceVC* [56] and *Face-TTS* [33] evaluate audio quality of synthetic voice recordings and how well the recordings match the corresponding face images. However, none of these works evaluates the similarity between the speaker's ground truth and synthesized voices while the similarity is the key to attacking voice authentication systems. Lastly, another family of works investigates the use of video to generate voice recordings [59]. *Foice*, on the other hand, only utilizes a single face image.

8 Conclusion

We present *Foice*, a novel pervasive and scalable voice deepfake attack that uniquely leverages only ***a single face image of the victim***. Hence, *Foice* addresses the limitation of state-of-the-art voice deepfake attacks that require the victim's voice samples, which might not always be readily available. By exploiting the correlation between facial and voice features, which originate from physiological structures, we design *Foice* to synthesize voice recordings. We demonstrate the feasibility of *Foice* through comprehensive real-world experiments, involving ten offline participants and an online dataset of 1,029 unique individuals, and testing on eight state-of-the-art voice authentication systems, such as WeChat and Microsoft Azure. We urge the research community and vendors of voice authentication systems to be alert to this new threat and to develop corresponding countermeasures.

A Appendix

A.1 Implementation

We demonstrate the effectiveness of *Foice* in extracting voice features from the face image via a proof-of-concept implementation. We adopt the existing *Synthesizer* structure and only focus on implementing *Face-dependent Voice Feature Extractor* and *Face-independent Voice Feature Generator*. Figure 16 depicts *Foice*'s model structure. More details can be found in the GitHub repository https://github.com/SeCATrity/Foice.

A.2 Why does *Foice* Work?

In this section, we provide empirical evidence for **Observation 1** and **Observation 2** (see §4.3 and §4.4).

A.2.1 Observation 1: *Face-dependent* Features Extracted

We demonstrate the efficacy of *Foice* in extracting *face-dependent* feature vector from a single face image. Specifically, we investigate whether this vector reveals the **gender** information of the speaker. We utilize vector morphing, a commonly used technique to prove the existence of semantic information in the feature vector. By interpolating *face-dependent* vectors between two gender groups (i.e., male and female) and generating corresponding synthetic recordings, we investigate the voice gender of these recordings (i.e., whether the recording sounds like a male or a female voice).

Vector Morphing. Specifically, we take the weighted average of a *face-dependent* voice feature vector $VFeat_{ori}$ from the original gender (e.g., male) and a feature vector $VFeat_{opp}$ from the opposite gender (e.g., female):

$$F_{morphed} = (1-\omega) \times F_{ori} + \omega \times F_{opp},$$

where $\omega \in [0,1]$ denotes the morphing coefficient. A higher ω pulls $F_{morphed}$ closer to the opposite gender. For example, $\omega = 1$ results in a synthetic recording that sounds like the opposite gender, while $\omega = 0$ results in a recording that sounds like the original gender. Then, we utilize the state-of-the-art voice gender classifier [5] to conduct gender classification on the generated synthetic voice recordings.

Results. Figure 17 depicts the classification accuracy computed from the original and predicted gender label across different morphing coefficients. We observe that the accuracy (i.e., male, female, and overall) decreases smoothly with the increase of ω. These results suggest that the interpolated vector (i.e., the vector between the two gender groups) also captures semantic voice gender information. We highlight that we can derive voice gender information from a single face image with a proof-of-concept implementation (see §A.1). More accurate *face-dependent* voice features could be captured with a carefully designed structure (see §6).

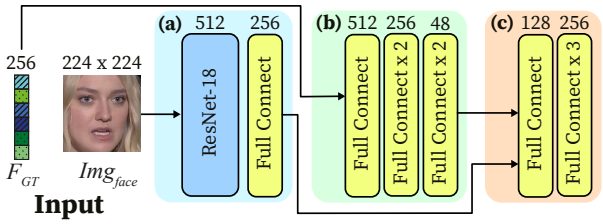

Figure 16: Figure depicts *Foice*'s deep-learning models for training. (a) depicts the *Encoder* and *Converter*. (b) depicts the *Bottleneck*, and (c) depicts the *Reconstructor*.

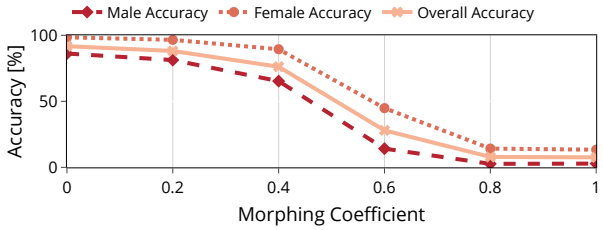

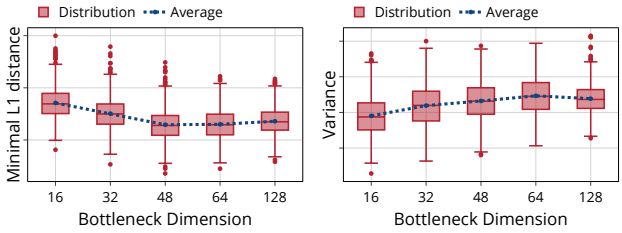

Figure 17: Figure depicts the empirical results of voice morphing. Specifically, the gender classification accuracy decreases as the morphing coefficient increases, indicating that the face-dependent voice features contain gender information.

A.2.2 Observation 2: Adjusting Bottleneck Dimension

Recall that we can find an optimal bottleneck dimension such that the search space contains only *face-independent* features (see Figure 8). We investigate the impact of varying bottleneck dimensions on (1) the size of the search space and (2) whether the search space contains a sufficiently similar *face-independent* feature vector to the victim's ground truth.

(a) Embedding similarity (b) Embedding diversity

Figure 18: (a) depicts the similarity of the voice features in the search space across varying dimensions. (b) depicts the voice features' variations and the search space size across varying dimensions.

Method	Overall Success Rate	
	VGGVox	DeepSpeaker
Face-TTS	0.97%	3.79%
Foice w/o Generator	10.9%	29.1%
Foice	67.6%	87.7%

Table 4: Table compares the attack performance of *Foice* with Face-TTS. VGGVox and DeepSpeaker are evaluated using their optimal threshold depicted in Table 2.

Experiment Setup. We experiment on VoxCeleb2 [21]. For each speaker in the dataset, we utilize the generated search space and the *face-dependent* feature vector to reconstruct 100 voice feature vectors, $\{F_{recon_1}, \ldots, F_{recon_{100}}\}$ (see §4.4). Since the *face-dependent* feature vector for each speaker is fixed by the input image, the space of the reconstructed voice feature vector exhibits the property of the search space. Then, we compute the L1 distance between each F_{recon_i} and the corresponding ground truth F_{GT}. For each speaker, we utilize the minimal L1 distance to evaluate the capability of a search space in producing a close enough F_{recon_i}. To evaluate the search space size, we use the standard deviation of the L1 distances to measure the variance of the search space.

$$Dist_{min} = \min_{i \in [1,100]} (\|F_{recon_i} - F_{GT}\|_1),$$

$$Var = \sqrt{\frac{\sum_{i=1}^{100} (F_{recon_i} - F_{GT})^2}{100}}$$

Lower $Dist_{min}$ means the attacker can find a voice feature vector that closely resembles the ground truth voice feature within 100 searching attempts. At the same time, larger Var indicates a larger variance in the search space. Hence, more samples are needed to find the target F_{GT}.

Results. Figure 18 depicts how different dimensions of the bottleneck affect the minimal L1 distance and the variance of the search space. We observe in Figure 18(a) that when the dimension increases, $Dist_{min}$ first decreases. This is because the search space contains more *face-independent* voice features such that the attacker can find voice feature vectors increasingly similar to the victim's ground truth. However, $Dist_{min}$ saturates when the bottleneck dimension reaches optimal because all the *face-independent* features are captured. In contrast, Figure 18(b) depicts an increasing trend in Var when increasing the dimension, indicating an increasing search space size. We attribute this to the increasing amount of voice features, including the *face-dependent* and the *face-independent*, encoded in the search space. In particular, dimension 48 yields a relatively small search space containing voice feature vectors sufficiently close to the ground truth. Hence, *Foice* selects the optimal dimension of 48.

A.3 Comparison with the Related Work

We compare *Foice* against Face-TTS [33], the latest closely related work. Like *Foice*, Face-TTS takes as input a text transcription and a face image, and generates a speech sample using a diffusion model conditioned on the input face image to model speaker characteristics. For evaluation, we utilize the official implementation and pre-trained weights provided by the authors [4], ensuring consistency and reproducibility in our experiments. In addition, we evaluate *Foice* without the Generator (see §4.4), which only relies on the *face-dependent* features for voice synthesis, to demonstrate the effectiveness of *Foice* in extracting *face-dependent* voice features from the face image. In total, our experiments target 1,029 speakers from the VoxCeleb1 dataset on VGGVox and DeepSpeaker. We choose the optimal threshold of 0.5 and 0.6 for VGGVox and DeepSpeaker, respectively. We evaluate the attack performance of *Foice* and Face-TTS using the *Overall Success Rate* (see §5.1.4), which represents the proportion of speakers in the dataset that can be attacked. We summarize the results in Table 4. Without the Generator, *Foice* achieves a success rate significantly higher, by an order of magnitude, than Face-TTS on both VGGVox and DeepSpeaker. With the Generator, *Foice* achieves an overall success rate that exceeds that of Face-TTS by 60 times on VGGVox and 30 times on DeepSpeaker. **These results demonstrate that *Foice* outperforms the state-of-the-art method by (i) extracting more relevant and accurate *face-dependent* voice features from the face image; (ii) and generating supplementary voice features that augment the *face-dependent* feature.**

A.4 Ethics

This study is approved by our university's Institutional Review Board (IRB). We carefully designed the experiments to protect the privacy of our participants. The photos and voice recordings collected are anonymized and securely stored on our servers. We use dummy accounts and the voices enrolled are deleted immediately after the completion of the experiments. We have responsibly disclosed the identified vulnerabilities to the affected company to ensure timely remediation.

dp-promise: Differentially Private Diffusion Probabilistic Models for Image Synthesis

Abstract

Utilizing sensitive images (e.g., human faces) for training DL models raises privacy concerns. One straightforward solution is to replace the private images with synthetic ones generated by deep generative models. Among all image synthesis methods, diffusion models (DMs) yield impressive performance. Unfortunately, recent studies have revealed that DMs incur privacy challenges due to the memorization of the training instances. To preserve the existence of a single private sample of DMs, many works have explored to apply DP on DMs from different perspectives. However, existing works on differentially private DMs only consider DMs as regular deep models, such that they inject unnecessary DP noise in addition to the forward process noise in DMs, damaging the model utility. To address the issue, this paper proposes Differentially Private Diffusion Probabilistic Models for Image Synthesis, dp-promise, which theoretically guarantees approximate DP by leveraging the DM noise during the forward process. Extensive experiments demonstrate that, given the same privacy budget, dp-promise outperforms the state-of-the-art on the image quality of differentially private image synthesis across the standard metrics and datasets.

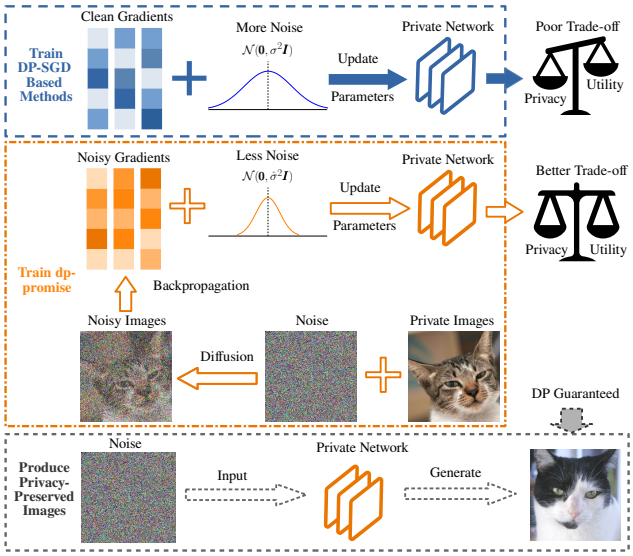

Figure 1: Comparison between dp-promise and other DP-SGD-based approaches for differentially private image synthesis using DMs.

1 Introduction

Nowadays, it is widely acknowledged that the performance of deep neural networks (DNNs) greatly benefits from large-scale training data. However, in numerous sensitive domains relying on image data, such as face recognition and medical image processing, the collection or release of a large-scale dataset often proves exceedingly challenging due to privacy issues [26, 64]. Intuitively, a straightforward solution to mitigate the risk of privacy leakage is using synthetic images, following the same distribution as the private images, to train those models. Nevertheless, recent works [6, 21] discovered that synthetic images produced by generative models, including generative adversarial networks (GANs) and diffusion models (DMs), still leak the privacy of the private data. Since DMs are more powerful than GANs in synthetic image generation, we target at preserving the privacy of training data for DMs in this paper [10].

Differential privacy [15], as a de facto privacy standard, is commonly used in preserving the individual privacy of a private dataset [41]. Specifying in machine learning tasks, differentially private stochastic gradient descent (DP-SGD) [1] incorporates gradient clipping and noise injection during the stochastic gradient descent process to ensure the privacy of training data. Later, DPDM [11] applies DP-SGD during the training procedure of DMs and then generates differentially private synthetic data. In a more recent study [17], Ghalebikesabi et al. pre-train DMs with public data and then

*Equal contribution.

fine-tune the pre-trained DMs with DP-SGD on private data. On top of DPDM, DP-LDM [37] explores the usage of latent DMs (LDMs) [44] to reduce the number of network parameters and training time while achieving similar privacy-utility trade-offs as DPDM.

Though the aforementioned studies have demonstrated the remarkable performance of DMs in differentially private image generation, they might have injected unnecessary noise when achieving DP. As shown in the upper dashed-dotted block of Figure 1, existing DPDM solutions, in general, injected both DM noise and DP noise into the DM's forward process based on the schemes of DM and DP-SGD, respectively. However, we observed that the gradients, calculated based on the DM noise-injected images, are "noisy" gradients having the same effect as DP-SGD gradients for a particular privacy budget. Hence, it is possible to achieve the same DP as the existing solutions with less DP noise injected. That is, we could inject the same amount of DP noise as the existing solutions, where partial DP noise was implemented by the DM noise. This way, we could enhance the model utility while ensuring the same DP guarantee as the existing works.

To achieve this goal, we propose a novel framework, Differentially Private Diffusion Probabilistic Models for Image Synthesis (dp-promise), which promotes the model utility by reducing the injected noise based on the theoretical analysis of the privacy guarantee provided in the DM's forward process. Specifically, dp-promise splits the normal DM forward process $[1,T]$ into two phases. In Phase I, we train DMs at $[S,T]$, where the training is conducted using a non-private optimization algorithm as usual DMs and DP noise are implemented by injecting DM noise into the images. In Phase II, we train DMs at $[1,S-1]$, where we ensure DP through DP-SGD since images at this stage do not contain enough DM noise. Furthermore, we incorporate various improvements over existing work to achieve a better trade-off between privacy and utility, e.g., freezing unnecessary layers before fine-tuning to reduce noise injection. Resulting from the above, the comprehensive experiments on four famous image datasets (MNIST, Fashion-MNIST, CelebA, and CIFAR-10 used by existing works [11, 17–19]) confirm that, given the same privacy budget, the synthetic images generated by dp-promise outperform the state-of-the-art methods roughly from 5% (compared with [17]) to 99% (compared with [19]) under commonly used performance metrics.

Our main contributions are summarized as follows.

- We propose a novel differentially private diffusion model framework, dp-promise, which provides an enhanced privacy-utility trade-off by employing a two-phase DM training process to reduce the overall noise injection.
- We provide a rigorous theoretical study on the relationship between DM noise and DP guarantees for dp-promise, making dp-promise the first work to take advantage of DM noise to achieve (approximate) DP.
- We conduct experiments on four benchmarking image datasets, including MNIST, Fashion-MNIST, CelebA, and CIFAR-10. The experimental results demonstrate that dp-promise achieves a non-trivial improvement (roughly from 5% to 99%) over state-of-the-art methods.

2 Related Work

In this section, we present a review of the related work in the field of differentially private generative models for image synthesis. We classify state-of-the-art into feature matching-based [18,19,32,52] and diffusion model-based approaches [8, 11, 17, 34, 37]. Note that there are also many works achieving DP on Generative Adversarial Networks (GANs) [7,25,33,36, 51,53,59]; however, those DP-GANs did not show promising image generation quality due to issues like mode collapse [38], hence, we do not take DP-GANs as baselines in this paper.

Approaches based on feature matching. Feature matching-based approaches utilize generative models to match the feature distributions of original data with those of generated data. Specifically, these approaches train these generative models by minimizing the Maximum Mean Discrepancy (MMD), a metric quantifying the distance between two feature distributions. To achieve DP, feature matching-based approaches inject noise into the features of the original data distribution. DP-MERF [18] trains the network by minimizing the distance of the mean embeddings between the real data and the generated data distribution, where Gaussian noise was injected into the mean embeddings of the real data distribution to achieve DP. DP-HP [52] employs hermit polynomial features instead of random Fourier features as in DP-MERF to estimate kernel mean embeddings more effectively. PEARL [32] considers training models using private embeddings constructed by a characteristic function. DP-MEPF [19] uses the perceptual feature of public data to fit a generator distribution.

Approaches based on diffusion models. Diffusion model-based approaches mainly rely on DP-SGD to achieve DP on top of diffusion models for image synthesis. DPDM [11] demonstrates how to train score-based generative models with DP-SGD and proposes a training strategy named noise multiplicity to improve performance. Both DPGEN [8] and Liu et al. [34] employ energy-based generative models trained on differentially private scores, which are constructed by randomized responses. DP-Diffusion [17] utilizes DMs pre-trained on extra public data and then fine-tunes the DMs on private data. More recently, DP-LDM [37] pre-trains latent DMs (LDMs) and fine-tunes attention modules.

Limitation. For approaches based on feature matching, e.g., DP-MERF [18] and DP-MEPF [19], they are unable to generate clear images due to noise injection on the feature of the original data distribution and then directly train the network on the noisy features to achieve DP. For approaches based

Table 1: Notation and definition.

Notation	Definition
$t \in \{1,2,\ldots,T\}$	diffusion time-steps
β_t, α_t	pre-defined diffusion noise scale
$\boldsymbol{x} \in \mathbb{R}^d$	data point in d-dimensional space
$D_{\text{priv}} = \{\boldsymbol{x}_i\}_{i=1}^n$	private dataset with n items
D_{pub}	public dataset
$\boldsymbol{z}_\theta$	neural network with parameters θ
$1 \le S \le T$	the time-step boundary between Phase I and Phase II
m_1, m_2	the batch size of Phase I and Phase II, respectively
N_1, N_2	the number of iterations in Phase I and Phase II, respectively
η_1, η_2	the learning rate in Phase I and Phase II, respectively
$\texttt{PoissionSample}_p$	Poisson sub-sampling with probability p
clip_C	clipping function with clipping constant C
σ	DP-SGD noise scale
K	the number of samples for noise augmentation
T'	the number of sampling steps
ρ	the variance hyper-parameter of sampling
w	the guidance scale of sampling

on DMs, e.g., DPDM [11] and DP-Diffusion [17] integrate DP-SGD to the training of the network in DMs but ignore the inherent privacy features within DM. Additionally, DPDM performs poorly on higher-dimensional datasets (e.g., 64×64 CelebA), and DP-Diffusion does not conduct experiments on higher-dimensional datasets.

3 Preliminaries

In this section, we present the preliminaries for this paper, including a brief introduction to DMs and the definition and properties of DP variants. Table 1 gives the definition of all the notations used in this paper.

3.1 Diffusion Models

Diffusion models (DMs) aim to learn the latent structure of a dataset by modeling the way in which data points diffuse through their latent (pixel, if in image generation task) space [50]. In a nutshell, DMs are implemented in two architectures: discrete diffusion models (denoising diffusion probabilistic models, DDPMs [22, 47]) and continuous diffusion models (score-based diffusion models [50]). In fact, the two architectures use different mathematical tools for modeling DMs, with one based on probabilistic forms and the other on stochastic differential equations (SDEs). Several works [48, 50] show that DDPM is an equivalent form of score-based DMs. Because of the high quality of image generation [40], in this paper, we use DDPM as the architecture for DMs.

Denoising diffusion probabilistic models (DDPMs) [22,47] contain a forward diffusion process and a reverse diffusion process. In the forward process, we slowly inject Gaussian noise into the original image through a series of T steps. Then, in the reverse process, we aim to learn models that reconstruct the real/original image from noisy images produced in the forward process. Formally, given an original data point $\boldsymbol{x}^{(0)}$, the forward process can be represented as a Markov chain $\{\boldsymbol{x}^{(0)}, \boldsymbol{x}^{(1)}, \ldots, \boldsymbol{x}^{(T)}\}$, where $\boldsymbol{x}^{(t)}$, at diffusion time-step $t \in \{1,2,\ldots,T\}$, was produced by injecting carefully scaled Gaussian noise into $\boldsymbol{x}^{(t-1)}$ using noise scale $\{\beta_t\}$. For the entire forward process, the posterior $q(\boldsymbol{x}^{(1)}, \boldsymbol{x}^{(2)}, \ldots, \boldsymbol{x}^{(T)} | \boldsymbol{x}^{(0)})$ holds that

$$q(\boldsymbol{x}^{(t)} | \boldsymbol{x}^{(t-1)}) = \mathcal{N}(\boldsymbol{x}^{(t)}; \sqrt{1-\beta_t}\boldsymbol{x}^{(t-1)}, \beta_t \boldsymbol{I}), \tag{1}$$

$$q(\boldsymbol{x}^{(1)}, \boldsymbol{x}^{(2)}, \ldots, \boldsymbol{x}^{(T)} | \boldsymbol{x}^{(0)}) = \prod_{t=1}^{T} q(\boldsymbol{x}^{(t)} | \boldsymbol{x}^{(t-1)}). \tag{2}$$

It is worth noting that, as the time-step t approaches T, the noisy data $\boldsymbol{x}^{(t)}$ approximates a standard normal distribution due to the cumulative impact of the injected noise. By utilizing the inherent properties of the Gaussian distribution, we have

$$q(\boldsymbol{x}^{(t)} | \boldsymbol{x}^{(0)}) = \mathcal{N}(\boldsymbol{x}^{(t)}; \sqrt{\alpha_t}\boldsymbol{x}^{(0)}, (1-\alpha_t)\boldsymbol{I}), \tag{3}$$

where $\alpha_t = \prod_{s=1}^{t}(1-\beta_s)$. Following Equation (3), the noisy data at time-step t can be calculated as

$$\boldsymbol{x}^{(t)} = \sqrt{\alpha_t}\boldsymbol{x}^{(0)} + \sqrt{1-\alpha_t}\boldsymbol{z}, \tag{4}$$

where random noise $\boldsymbol{z} \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I})$.

In DMs, the reverse process is also defined as a Markov chain $\{\boldsymbol{x}^{(T)}, \boldsymbol{x}^{(T-1)}, \ldots, \boldsymbol{x}^{(0)}\}$. We leverage Denoising Diffusion Implicit Models (DDIMs) [48] as the reverse process to predict the noise distribution between two adjacent time-steps t and $t-1$, then recover $\boldsymbol{x}^{(t-1)}$ from $\boldsymbol{x}^{(t)}$ by removing the noise. To do so, we first learn models $\boldsymbol{z}_\theta$ to predict noise injected between $\boldsymbol{x}^{(0)}$ and $\boldsymbol{x}^{(t)}$, $t \in \{1,2,\ldots,T\}$, then derive the mean of the predicted distribution as

$$\hat{\boldsymbol{\mu}}_\theta(\boldsymbol{x}^{(t)}, t) = \sqrt{\alpha_{t-1}}\tilde{\boldsymbol{x}}^{(0)} + \sqrt{1-\alpha_{t-1}-\hat{\Sigma}_t^2} \cdot \boldsymbol{z}_\theta(\boldsymbol{x}^{(t)}, t), \tag{5}$$

where $\hat{\Sigma}_t = \rho\sqrt{(1-\alpha_{t-1})/(1-\alpha_t)}\sqrt{\beta_t}$, $\tilde{\boldsymbol{x}}^{(0)} = (\boldsymbol{x}^{(t)} - \sqrt{1-\alpha_t}\boldsymbol{z}_\theta(\boldsymbol{x}^{(t)}, t))/\sqrt{\alpha_t}$, and the hyper-parameter ρ controls variance during sampling procedure. After having $\hat{\boldsymbol{\mu}}_\theta(\boldsymbol{x}^{(t)}, t)$, we will predict the noise distribution immediately as $\hat{p}_\theta(\boldsymbol{x}^{(t-1)} | \boldsymbol{x}^{(t)}) = \mathcal{N}(\boldsymbol{x}^{(t-1)}; \hat{\boldsymbol{\mu}}_\theta(\boldsymbol{x}^{(t)}, t), \hat{\Sigma}_t^2 \boldsymbol{I})$.

To train the neural network, the parameters θ are optimized by the following objective

$$\arg\min_{\theta} \mathbb{E}_{t,\boldsymbol{x}^{(0)},\boldsymbol{z}}\left[\|\boldsymbol{z}-\boldsymbol{z}_\theta(\sqrt{\alpha_t}\boldsymbol{x}^{(0)}+\sqrt{1-\alpha_t}\boldsymbol{z},t)\|_2^2\right], \quad (6)$$

where t is uniformly selected from $\{1,2,\ldots,T\}$, $\boldsymbol{x}^{(0)} \sim D$, and $\boldsymbol{z} \sim \mathcal{N}(\boldsymbol{0},\boldsymbol{I})$. In practice, to reconstruct the desired data from noise, denoted as $\hat{\boldsymbol{x}}^{(T)} \sim \mathcal{N}(\boldsymbol{0},\boldsymbol{I})$, we iteratively generate the synthetic data as follows

$$\begin{aligned}\hat{\boldsymbol{x}}^{(t-1)} = \sqrt{\alpha_{t-1}}\frac{\hat{\boldsymbol{x}}^{(t)}-\sqrt{1-\alpha_t}\boldsymbol{z}_\theta(\hat{\boldsymbol{x}}^{(t)},t)}{\sqrt{\alpha_t}}+ \\ \sqrt{1-\alpha_{t-1}-\hat{\Sigma}_t^2}\cdot\boldsymbol{z}_\theta(\hat{\boldsymbol{x}}^{(t)},t)+\hat{\Sigma}_t\boldsymbol{\xi},\end{aligned} \quad (7)$$

where t ranges from T to 1, and $\boldsymbol{\xi} \sim \mathcal{N}(\boldsymbol{0},\boldsymbol{I})$. Note that in DDIM, the synthetic data generation process can be accelerated by sampling in a small subset of time-steps $\{\tau_1,\tau_2,\ldots,\tau_{T'}\}$ instead of the entire diffusion time-steps as in DDPM.

3.2 Differential Privacy

Differential privacy (DP) mathematically ensures the indistinguishability between the computing outcomes on two datasets with or without an arbitrary individual.

Definition 1 ((ε,δ)-differential privacy [14]). *A randomized mechanism $\mathcal{M}$ satisfies (ε,δ)-DP, if for any two neighboring datasets $D \simeq D'$ and all $S \subseteq Range(\mathcal{M})$, it holds that*

$$\Pr[\mathcal{M}(D) \in S] \leq \exp(\varepsilon)\Pr[\mathcal{M}(D') \in S] + \delta. \quad (8)$$

In Definition 1, the neighboring datasets D and D' can be transformed into each other by adding or removing a single item, ε is the privacy budget bounding the divergence of the output distribution between two neighboring datasets, and δ is negligible on the number of items in D measuring the probability that the above constraint is violated. When $\delta = 0$, (ε,δ)-DP becomes ε-DP, which is the first and strict definition of DP introduced by Dwork et al. [15].

Generally, a common approach to achieving ε-DP or (ε,δ)-DP is to inject noise following Laplace or Gaussian distribution into the original input/output/computing process. The magnitude of noise injection is related to the sensitivity of the function, f, for the computation. We provide the definition of ℓ_2-sensitivity as below

Definition 2 (ℓ_2-sensitivity [15]). *Given a function $f : \mathcal{D} \to \mathbb{R}^k$, for all $D \in \mathcal{D}$, the ℓ_2-sensitivity of f is*

$$S_f := \max_{D \simeq D'} \|f(D) - f(D')\|_2, \quad (9)$$

where $\|\cdot\|_2$ denotes ℓ_2-norm of the vector.

In practice, we say $\tilde{f}$ satisfies (ε,δ)-DP if we inject scaled Gaussian noise $\mathcal{N}(0,S_f^2\sigma^2\boldsymbol{I})$ into each component in a non-private f, where S_f is the ℓ_2-sensitivity of f and $\sigma \geq \sqrt{2\ln(1.25/\delta)}/\varepsilon$. The Gaussian mechanism is

$$\tilde{f}(D) := f(D) + \mathcal{N}(0,S_f^2\sigma^2\boldsymbol{I}). \quad (10)$$

Dong et al. [12] propose a variant of DP named Gaussian Differential Privacy (GDP). Let ϕ be a rejection rule used for testing the hypothesis to distinguish between two distributions P and Q. The trade-off function $F(P,Q) : [0,1] \to [0,1]$ is defined as $F(P,Q)(\alpha) := \inf_\phi\{1-\mathbb{E}_Q[\phi] : \mathbb{E}_P[\phi] \leq \alpha\}$, where $\mathbb{E}_P[\phi]$ is Type I error, and $1-\mathbb{E}_Q[\phi]$ is Type II error. Let $G_\mu := F(\mathcal{N}(0,1),\mathcal{N}(\mu,1))$, where $\mu \geq 0$. In practice, G_μ has a close-form expression as $G_\mu(\alpha) = \Phi(\Phi^{-1}(1-\alpha)-\mu)$, where Φ denotes the Cumulative Distribution Function (CDF) of standard normal distribution and Φ^{-1} is the inversion of Φ. Based on the trade-off function F, we have the definition of GDP as follows.

Definition 3 (Gaussian differential privacy (GDP) [12]). *A randomized mechanism $\mathcal{M}$ is said to satisfy μ-GDP if any two neighboring datasets D and D'*

$$F(\mathcal{M}(D),\mathcal{M}(D')) \geq G_\mu. \quad (11)$$

For the Gaussian mechanism, GDP provides a more straightforward case compared to (ε,δ)-DP. Given a specific noise scale σ, the following theorem demonstrates that the privacy budget of the Gaussian mechanism under GDP:

Theorem 1 (Gaussian mechanism on GDP [12]). *Given a noise scale σ, the Gaussian mechanism satisfies $1/\sigma$-GDP.*

An important DP (including GDP) property is post-processing, which ensures the DP for post-processing of an output of a DP mechanism.

Proposition 1 (Post-processing of DP [16]). *For any data-independent function g defined over the image of the randomized mechanism $\mathcal{M}$, if $\mathcal{M}$ is (ε,δ)-DP, then $g \circ \mathcal{M}$ satisfies (ε,δ)-DP, where $\circ$ denotes the composition operation.*

When applying DP on machine learning area to train privacy-preserved models, differentially private stochastic gradient descent (DP-SGD) [1] is the most common technique, which injects DP noise into the gradients. This way, the trained model will be differentially private. Then, based on the post-processing, all predictions made by such a model will be differentially private as well. However, one challenge for DP-SGD is to bound the global sensitivity due to no limit on the size of the gradients. To overcome this issue, DP-SGD clips each gradient to bound the global sensitivity of gradients, then injects Gaussian noise into each clipped gradient. Note that this process can be viewed as a Gaussian mechanism.

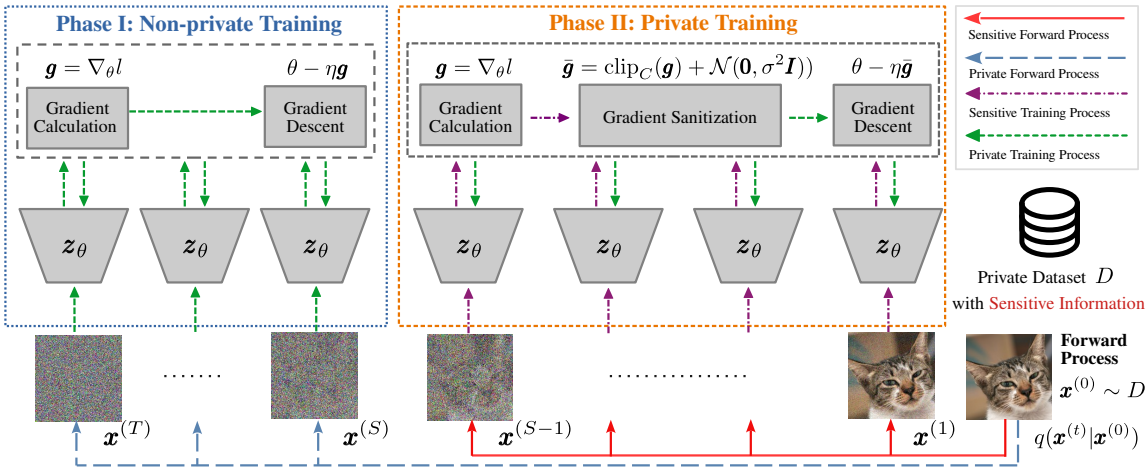

Figure 2: Framework of dp-promise, which aims to provide privacy guarantees to private data during the training of DMs. "Sensitive" means there is a risk of privacy leakage, and "Private" means privacy guarantees exist.

4 Threat Model

In this paper, we define white-box privacy adversaries against DMs as entities seeking to infer the existence of a particular image [13] or reconstruct a set of images [6] belonging to the DMs training data, given access to the images generated by DMs and the model parameters of the trained DMs. To preserve the privacy of the training data of DMs, we construct differentially private DMs, ensuring the synthetic data generated by DMs is differentially private.

Formally, we aim to train a differentially private diffusion model $\mathcal{G}$ with a neural network z_θ on a private dataset $D_{\text{priv}} = \{x_1, x_2, \ldots, x_n\}$. Given random noise r, the generated data by the DP DMs $\hat{x} \leftarrow \mathcal{G}(r)$ is differentially private. Note that we assume the model is publicly accessible, meaning that the adversaries have full access to both the diffusion model $\mathcal{G}$ and the corresponding neural network z_θ. We give the details of $\mathcal{G}$ and z_θ in Section 3.1.

Next, we provide the definition of the white-box membership inference.

Definition 4 (White-box membership inference attacks)**.** *Let $\mathcal{A}$ be a white-box adversary, $\mathcal{D}$ be data distribution, A be training algorithm, and $\mathcal{G}$ be a diffusion model with a neural network z_θ. The white-box membership inference attack is*

0. *$\mathcal{A}$ has full access to $\mathcal{G}$ and z_θ.*
1. *Select a private dataset $D_{priv} \in \mathcal{D}$.*
2. *Train $\mathcal{G}$ on D_{priv} with algorithm A as $\mathcal{G}_{A,D_{priv}} = A(\mathcal{G}, D_{priv})$.*
3. *Flip a coin to decide whether $b = 0$ or $b = 1$.*
4. *Sample $x \in D_{priv}$ if $b = 0$, $x \in \mathcal{D}$ if $b = 1$.*
5. *Attack is successful if $\mathcal{A}(x, \mathcal{G}_{A,D_{priv}}, \mathcal{D}) = b$, and fails otherwise.*

Note that DP limits the effect of any point in the private dataset to final computation results, thereby reducing the success rate of membership inference attacks [60].

5 Our Approach: dp-promise

In this section, we first introduce the motivation and propose a framework that ensures approximate DP in DMs. Then we describe the details of each component of dp-promise. Finally, we conduct a rigorous theoretical analysis for privacy guarantees of dp-promise.

5.1 Method Overview

The motivation of this work is mainly based on the observation that existing differentially private diffusion models [11, 17, 37] inject wasteful noise. That is, training DMs with DP-SGD injects DP noise on top of DM noise, which would result in duplicate noise injection and then damage the model utility. To address this problem, we propose Differentially Private Diffusion Probabilistic Models for Image Synthesis (dp-promise), which utilize DM noise when implementing DP. Figure 2 depicts the framework of dp-promise.

To take advantage of DM noise, we split the traditional DM training (recovering raw images by removing predicted noise) into two phases - Phase I non-private training (achieving DP by normal DM noise) and Phase II private training (achieving DP by DP-SGD). In Phase I, we follow the normal DM training during time-steps $[S, T]$. Recall Equation (4) in Section 3.1, the noisy images are produced by injecting scaled Gaussian noise, which could be treated as the Gaussian mechanism for achieving GDP. Then, based on the post-processing property, all following DM training operations in Phase I

are DP immediately. Proposition 2 gives a formal proof to connect the DM noise and DP guarantee. Following Phase I training, in Phase II, we apply DP-SGD to DM training during time-steps $[1, S-1]$ using DP-SGD to ensure DP guarantees directly. Overall, dp-promise ensures DP in the two phases while avoiding injecting DP noise during Phase I to save the privacy budget. Hence, dp-promise could provide better model utility without compromising the DP guarantee. Algorithm 1 describes the complete process of dp-promise.

Proposition 2. *Equation (4) satisfies* $2\sqrt{d\alpha_t/(1-\alpha_t)}$*-GDP.*

Proof. Let $\hat{\boldsymbol{x}} := \boldsymbol{x} + \mathcal{N}(\boldsymbol{0}, ((1-\alpha_t)/\alpha_t)\boldsymbol{I})$ be the procedure of generating noisy data in Equation (4). For any two data points $\boldsymbol{x}$ and $\boldsymbol{x}' \in \mathbb{R}^d$, we can derive that $\max_{\boldsymbol{x},\boldsymbol{x}'} \|\boldsymbol{x} - \boldsymbol{x}'\|_2 = 2\sqrt{d}$. Therefore, the sensitivity of the process is bounded by $2\sqrt{d}$. Following the Theorem 1, we can derive that the procedure of generating noisy data satisfies $2\sqrt{d\alpha_t/(1-\alpha_t)}$-GDP. □

Next, we give an example to show how dp-promise achieves DP on an image dataset. In this paper, we consider processing within the domain of images. Let $D_{\text{priv}} = \{\boldsymbol{x}_i \in \mathbb{R}^d\}_{i=1}^n$ represent a private dataset, where we define the number of channels, height, and width of an image as *channel*, *height* and *width*, respectively. Consequently, $d = channel \times height \times width$ represents the dimensions of an image. Following the configuration detailed in [22], we employ a linear transformation for each pixel in the image, converting integer values within the range of $\{0, 1, \ldots, 255\}$ to the interval $[-1, 1]$.

Remark 1. *In practice, given a time-step* $t \in \{1, 2, \ldots, T\}$*,* $\{\alpha_1, \alpha_2, \ldots, \alpha_T\}$ *is a pre-defined decreasing sequence such that* α_1 *is close to* 1 *and* α_T *is close to* 0*. (e.g., with parameters like* $T = 1{,}000$*,* $\{\beta_1, \beta_2, \ldots, \beta_T\}$ *is selected from* 10^{-4} *to* 2×10^{-2} *linearly). Considering a high-dimensional image domain (e.g., a color image with* 32×32 *resolution and* 3 *channels, resulting in* $d = 3{,}072$*). Following Proposition 2, we can achieve significant DP guarantees when* $t \to T$ *and* $\gamma_t \to 0$ *(e.g., with parameters following above, resulting in* $\alpha_t = 0.0004$ *when* $t = 900$*). In contrast, when* $t \to 0$*,* $\gamma_t \to \infty$*, there is almost no privacy guarantee.*

In line with the analysis in Remark 1, it is evident that substantial DP guarantees are already established at the large time-steps.

5.2 Method Details

In this section, we give a detailed description of the two phases of dp-promise, then introduce several techniques applied in dp-promise for privacy and utility enhancement.

Two-phase training in dp-promise. We split the whole DMs training process (from time-steps 1 to T) at a given time-step $S \in \{1, 2, \ldots, T\}$. Since the key in the DMs training is to learn and remove the injected noise to generate the original image from a group of noisy images with different amounts of noise injected, we define Phase I as time-step $[S, T]$ and Phase II as time-step $[1, S-1]$.

Algorithm 1: dp-promise framework.

Input: private dataset $D_{\text{priv}} = \{\boldsymbol{x}_i \in \mathbb{R}^d\}_{i=1}^n$, diffusion steps T, time-step boundary S, learning rate η_1 and η_2, batch size m_1 and m_2, number of iterations N_1 and N_2, clipping constant C, neural network $\boldsymbol{z}_\theta$, DP-SGD noise scale σ, number of samples for noise augmentation K.

// Phase I: training non-privately during time-step $[S, T]$

1 **for** *number of iterations* N_1 **do**
2 $\quad I \sim \texttt{PoissonSample}_{m_1/n}(\{1, 2, \ldots, n\})$
3 $\quad$ **for** $i \in I$ **do**
4 $\quad\quad t_i \sim \mathcal{U}(\{S, S+1, \ldots, T\}), \boldsymbol{z}_i \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I})$
5 $\quad\quad l_i \leftarrow \|\boldsymbol{z}_i - \boldsymbol{z}_\theta(\sqrt{\alpha_t}\boldsymbol{x}_i + \sqrt{1-\alpha_t}\boldsymbol{z}_i, t_i)\|_2^2$
6 $\quad \theta \leftarrow \theta - \eta_1 \cdot \frac{1}{|I|} \sum_{i \in I} \nabla_\theta l_i$

// Phase II: training privately during time-step $[1, S-1]$

7 **for** *number of iterations* N_2 **do**
8 $\quad I \sim \texttt{PoissonSample}_{m_2/n}(\{1, 2, \ldots, n\})$
9 $\quad$ **for** $i \in I$ **do**
10 $\quad\quad$ **for** $k = 1, 2, \ldots, K$ **do**
11 $\quad\quad\quad t_{ik} \sim \mathcal{U}(\{1, 2, \ldots, S-1\}), \boldsymbol{z}_{ik} \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I})$
12 $\quad\quad\quad l_{ik} \leftarrow \|\boldsymbol{z}_{ik} - \boldsymbol{z}_\theta(\sqrt{\alpha_t}\boldsymbol{x}_i + \sqrt{1-\alpha_t}\boldsymbol{z}_{ik}, t_{ik})\|_2^2$
$\quad\quad$ *// Aggregate and clip gradient*
13 $\quad\quad \bar{\boldsymbol{g}}_i \leftarrow \text{clip}_C(\frac{1}{K}\nabla_\theta \sum_{k=1}^K l_{ik})$
$\quad$ *// Add Gaussian noise to gradient*
14 $\quad \theta \leftarrow \theta - \eta_2 \cdot \frac{1}{|I|}(\sum_{i \in I} \bar{\boldsymbol{g}}_i + C\sigma \cdot \boldsymbol{\xi}), \boldsymbol{\xi} \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I})$

Output: trained parameters θ and output privacy budget by Theorem 2.

In Phase I, the main purpose is to leverage the injected DM noise to achieve DP. In the implementation, we first use Poisson sub-sampling to construct a mini-batch with probability m_1/n, where m_1 is the batch size of Phase I (step 2 of Algorithm 1). Then, we follow the normal DM training process to learn the noise injection distribution (steps 3 to 6 of Algorithm 1, please refer to Section 3 for details).

In Phase II, since the amount of DM-injected noise is not enough to achieve DP, we further apply DP-SGD [1] to guarantee DP. Formally, we use Poisson sub-sampling to construct a mini-batch with probability m_2/n, where m_2 is the batch size of Phase II. For $\boldsymbol{x}_i \sim D$, $t_i \sim \mathcal{U}(\{1, 2, \ldots, S-1\})$, and $\boldsymbol{z}_i \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I})$, the parameters θ are updated as follows

$$\theta \leftarrow \theta - \eta_2 \cdot \frac{1}{|I|}\left(\sum_{i \in I} \text{clip}_C(\nabla_\theta l_i) + C\sigma \cdot \boldsymbol{\xi}\right), \qquad (12)$$

where $\boldsymbol{\xi} \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I})$, η_2 is learning rate in Phase II, and σ

is DP-SGD noise scale. The clipping function is defined as $\text{clip}_C(\boldsymbol{g}) = \boldsymbol{g}/\max\{1, \|\boldsymbol{g}\|_2/C\}$, where the clipping constant C (>0) controls the magnitude of the gradient norm.

Dockhorn et al. [11] state that injecting extra noise into gradients leads to an increase in the variance of the gradient norm, resulting in a notable information loss after clipping gradients. Inspired by this point, we utilize the average per-instance loss computed over K times. That is, for each data point $\boldsymbol{x}_i$, we calculate the loss as $\tilde{l}_i = \frac{1}{K}\sum_{k=1}^{K} l_{ik}$, where $l_{ik} = \|\boldsymbol{z}_{ik} - \boldsymbol{z}_\theta(\sqrt{\alpha_t}\boldsymbol{x}_i + \sqrt{1-\alpha_t}\boldsymbol{z}_{ik}, t_{ik})\|_2^2$, $t_{ik} \sim \mathcal{U}(\{1,2,\ldots,S-1\})$, and $\boldsymbol{z}_{ik} \sim \mathcal{N}(\boldsymbol{0},\boldsymbol{I})$. In practice, we calculate the gradient $\boldsymbol{g}_{ik} = \nabla_\theta l_{ik}$ at each iteration and then use the average to estimate per-instance gradients as $\nabla_\theta l_i = \frac{1}{K}\sum_{k=1}^{K}\boldsymbol{g}_{ik}$.

Privacy amplification by sub-sampling. During the training of differentially private DL models, sub-sampling is a common technique to enhance the DP guarantees [3, 31, 55, 65]. Specifically, sub-sampling involves applying the randomized mechanism to select a subset rather than the entire set. Since some instances are excluded from the chosen subset, sub-sampling prevents the privacy leakage of sensitive information associated with these excluded instances. dp-promise utilizes Poisson sub-sampling to select the mini-batch for Phase I and Phase II. Following the description in [55], we denote a sub-sampling procedure with a probability p as $\texttt{PoissonSample}_p$, and the definition is

Definition 5 (Poisson sub-sampling)**.** *Let S denote a set. $\texttt{PoissonSample}_p$ selects a subset from S. For each element in S, the selection is determined by an independent Bernoulli trial with probability $0 < p < 1$.*

By utilizing Poisson sub-sampling to construct the mini-batch at each training step, we can get privacy amplification through sub-sampling, reducing the overall privacy budget in two phases. We provide a detailed analysis of how sub-sampling amplifies privacy in Lemma 3, Section 5.3.

Pre-training on public data. Pre-training is a widely used strategy to improve the performance of DP generative models [17, 19, 57]. Intuitively, we assume that the public dataset used in pre-training does not contain any sensitive information. Thus, training on the public dataset does not incur privacy costs. Let D_{pub} represent a publicly available dataset. We denote the pre-training integrated process as $\mathcal{M} = \mathcal{M}_{D_{\text{priv}}} \circ \mathcal{M}_{D_{\text{pub}}}$, where we first pre-train on D_{pub} and then fine-tune on D_{priv}. The privacy guarantee of $\mathcal{M}$ is determined by the privacy guarantee of $\mathcal{M}_{D_{\text{priv}}}$. In dp-promise, the consumed privacy budgets are directly related to the number of training iterations since each iteration will consume an amount of privacy budget (i.e., more training iterations incur a higher privacy budget). Hence, we employ pre-training to accelerate the training process and reduce the number of training iterations. Additionally, even in the presence of a noticeable distribution shift between the public and private datasets, the experiments have demonstrated that pre-training remains effective. In practice, the time-step, as an input to the network, is encoded in an embedding layer with learnable parameters. Training the entire network with DP-SGD would introduce unnecessary noise into these parameters. Therefore, we freeze these layers before the fine-tuning process to reduce information loss.

Algorithm 2: Sampler.

Input: sampling step T', variance hyper-parameter ρ, trained neural network $\boldsymbol{z}_\theta$, target label y (for conditional generation).

$\hat{x}^{(\tau_{T'})} \sim \mathcal{N}(\boldsymbol{0},\boldsymbol{I})$

for $\tau_t = \tau_{T'}, \tau_{T'-1} \ldots, \tau_1$ **do**

  $\boldsymbol{\xi} \sim \mathcal{N}(\boldsymbol{0},\boldsymbol{I})$ if $t > 1$ else $\boldsymbol{\xi} = 0$

  if *unconditional generation* **then**

    $\hat{\boldsymbol{x}}^{(\tau_{t-1})} = \sqrt{\alpha_{\tau_{t-1}}}\frac{\hat{\boldsymbol{x}}^{(\tau_t)} - \sqrt{1-\alpha_{\tau_t}}\boldsymbol{z}_\theta(\hat{\boldsymbol{x}}^{(\tau_t)}, \tau_t)}{\sqrt{\alpha_{\tau_t}}} + \sqrt{1-\alpha_{\tau_{t-1}} - \hat{\Sigma}_{\tau_t}^2}\cdot\boldsymbol{z}_\theta(\hat{\boldsymbol{x}}^{(\tau_t)}, \tau_t) + \hat{\Sigma}_{\tau_t}\boldsymbol{\xi}$

  else if *conditional generation* **then**

    $\hat{\boldsymbol{x}}^{(\tau_{t-1})} = \sqrt{\alpha_{\tau_{t-1}}}\frac{\hat{\boldsymbol{x}}^{(\tau_t)} - \sqrt{1-\alpha_{\tau_t}}\hat{\boldsymbol{z}}_\theta(\hat{\boldsymbol{x}}^{(\tau_t)}, \tau_t, y)}{\sqrt{\alpha_{\tau_t}}} + \sqrt{1-\alpha_{\tau_{t-1}} - \hat{\Sigma}_{\tau_t}^2}\cdot\hat{\boldsymbol{z}}_\theta(\hat{\boldsymbol{x}}^{(\tau_t)}, \tau_t, y) + \hat{\Sigma}_{\tau_t}\boldsymbol{\xi}$

Output: synthetic sample $\hat{\boldsymbol{x}}^{(\tau_0)}$.

Sampling. dp-promise leverages DDIM sampler [48] to accelerate the sampling process in the DM training. Given a sample step T', we linearly choose a subset $\{\tau_1, \tau_2, \ldots, \tau_{T'}\}$ from the complete time-steps set. In unconditional generation, we start with a random noisy data point $\hat{\boldsymbol{x}}^{\tau_{T'}} \sim \mathcal{N}(\boldsymbol{0},\boldsymbol{I})$ and iteratively generate synthetic data from $\tau_{T'-1}$ to τ_0 by Equation (7). In conditional generation, we employ classifier-free guidance [23] in the sampling process of DMs.

For downstream tasks involving classifier training, it is necessary to utilize label information as a condition to guide the training process. Nevertheless, if original labels are directly inputted in Phase I, the label information will propagate through gradients into the model due to no additional noise added to gradients, which may pose a risk of privacy leakage. To address this issue, we do not use input label information in Phase I but use the labels in Phase II. Since the gradient information is perturbed by additional noise in Phase II, we cannot directly propagate the private information in the labels into the model. During the sampling process, the role of labels is to guide the model to generate data for the corresponding label. We utilize both the conditional and unconditional prediction results with a guidance scale w as $\hat{\boldsymbol{z}}_\theta(\boldsymbol{x}^{(t)}, t, y) = (1+w)\boldsymbol{z}_\theta(\boldsymbol{x}^{(t)}, t, y) - w\boldsymbol{z}_\theta(\boldsymbol{x}^{(t)}, t)$. The entire sampling procedure is presented in Algorithm 2.

5.3 Privacy Analysis

To calculate the overall privacy budget consumption, we provide a theoretical analysis for dp-promise. In this paper, we employ the Gaussian differential privacy (GDP) [12] as the foundation for theoretical analysis and utilize sub-sampling technology to amplify the DP guarantees. As a result, we provide an approximate bound of the privacy budget under (ε, δ)-DP for Algorithm 1.

Next, we introduce the conversion between GDP and (ε, δ)-DP. Specifically, for any fixed probability δ, μ-GDP can be transformed into $(\varepsilon_{\delta,\mu}, \delta)$-DP, where $\varepsilon_{\delta,\mu}$ is constrained by a condition detailed in the following lemma

Lemma 1 (GDP to DP conversion [12])**.** *A randomized mechanism $\mathcal{M}$ is μ-GDP if and only if $\mathcal{M}$ is $(\varepsilon, \delta(\varepsilon))$-DP for all $\varepsilon \geq 0$, where*

$$\delta(\varepsilon) = \Phi(-\frac{\varepsilon}{\mu} + \frac{\mu}{2}) - \exp(\varepsilon)\Phi(-\frac{\varepsilon}{\mu} - \frac{\mu}{2}). \tag{13}$$

Given a randomized mechanism $\mathcal{M}$, which is assembled as the composition of k randomized mechanisms $\mathcal{M}_i, \mathcal{M}_{i+1}, \ldots, \mathcal{M}_k$. If each $\mathcal{M}_i$ satisfies GDP, it naturally follows that $\mathcal{M}$ also maintains GDP. Formally, we provide the composition of GDP as follows

Lemma 2 (Composition on GDP [12])**.** *The k-fold composition of μ_i-GDP $(0 \leq i \leq k)$ mechanisms satisfy $\sqrt{\mu_1^2 + \cdots + \mu_k^2}$-GDP.*

dp-promise utilizes a sub-sampling technique to strengthen DP guarantees. Specifically, we employ Poisson sub-sampling to select a subset from the dataset, and then we apply a private algorithm to this selected subset. Next, we describe the privacy amplification provided by GDP as follows

Lemma 3 (Sub-sampling on GDP [3])**.** *Let a randomized mechanism $\mathcal{M}$ satisfy μ-GDP, and $\mathcal{M} \circ \texttt{PoissonSample}_p$ denote the privacy amplification by Poisson sub-sampling with probability p. Suppose p is related to N such that $p\sqrt{N} \to v$, the N-fold composition of $\mathcal{M} \circ \texttt{PoissonSample}_p$ asymptotically satisfies $\hat{\mu}$-GDP as $N \to \infty$, where*

$$\hat{\mu} = v\sqrt{\exp(\mu^2) - 1} = p\sqrt{N(\exp(\mu^2) - 1)}. \tag{14}$$

For any randomized mechanism $\mathcal{M}$ that satisfies μ-GDP, we can apply $\texttt{PoissonSample}_p$ to obtain a new mechanism denoted as $\mathcal{M} \circ \texttt{PoissonSample}_p$. Following Lemma 3, we can derive the new mechanism that satisfies $\hat{\mu}$-GDP. To ensure DP guarantees for both Phase I and Phase II, we present Lemma 4 and Lemma 5, respectively.

Lemma 4. *Given a time-step boundary S for splitting Phase I and Phase II, a batch size m_1, the size of the private dataset n, the data dimensions d, the pre-defined diffusion noise scale α_S, and the number of iterations N_1, Phase I in Algorithm 1 asymptotically satisfies μ_1-GDP, where*

$$\mu_1 = \frac{m_1}{n}\sqrt{N_1(\exp(4d\alpha_S/(1-\alpha_S)) - 1)}. \tag{15}$$

Proof. Let $\mathcal{M}_1$ denote the mechanism in Phase I such that $\mathcal{M}_1(\boldsymbol{x}) := \boldsymbol{x} + \mathcal{N}(\boldsymbol{0}, ((1-\alpha_t)/\alpha_t)\boldsymbol{I})$, where $t \in \{S, S+1, \ldots, T\}$. Following Proposition 2, we can derive that $\mathcal{M}_1$ satisfies $2\sqrt{d\alpha_S/(1-\alpha_S)}$-GDP. For a private dataset D, we denote the sequence of $\mathcal{M}_1(\boldsymbol{x}_i)$ as $\mathcal{M}_1(D) := D + \mathcal{N}((1-\alpha_t)/\alpha_t)\boldsymbol{I})$. For any two neighboring datasets $D = \{\boldsymbol{x}_i\}_{i=1}^n \cup \{\boldsymbol{x}'\}$ and $D' = \{\boldsymbol{x}_i\}_{i=1}^n$, where $\boldsymbol{x}' \notin D'$, the sensitivity can be bounded as $\max_{D,D'} \|D - D'\| = 2\sqrt{d}$. Following Theorem 1, the sequence of $\mathcal{M}_1(\boldsymbol{x}_i)$ satisfies $2\sqrt{d\alpha_S/(1-\alpha_S)}$-GDP. Moreover, we use Poisson sub-sampling to amplify differential privacy. Following Lemma 3, given sub-sampling probability $p_1 = m_1/n$, Phase I asymptotically satisfies $p_1\sqrt{N_1(\exp(4d\alpha_S/(1-\alpha_S)) - 1)}$-GDP. □

In Phase I, α_S is a constant related to the selection of S. As S increases, the value of α_S decreases. In particular, $\alpha_t = \prod_{s=1}^t (1-\beta_s)$, where we set β_t to linearly increase from $\beta_1 = 10^{-4}$ to $\beta_T = 2 \times 10^{-2}$. For different data dimensions, as the data dimension d increases, a larger value of S is needed to ensure practical privacy guarantees. In contrast, for low-dimensional data, practical privacy guarantees can be achieved without selecting larger values of S. We show the selection for the value of S in Section 6.

Lemma 5. *Given a DP-SGD noise scale σ, a batch size m_2, the size of the private dataset n, and the number of iterations N_2, Phase II in Algorithm 1 satisfies μ_2-GDP, where*

$$\mu_2 = \frac{m_2}{n}\sqrt{N_2(\exp(1/\sigma^2) - 1)}. \tag{16}$$

Proof. Let $\mathcal{M}_2$ denote the mechanism in Phase II (based on Equation (12)) such that $\mathcal{M}_2(D) = g(D) + C\sigma \cdot \mathcal{N}(\boldsymbol{0}, \boldsymbol{I})$, where $g(D) = \sum_{i \in I} \text{clip}_C(\nabla_\theta l_i)$. For two neighboring datasets $D = \{\boldsymbol{x}_i\}_{i=1}^n \cup \{\boldsymbol{x}'\}$ and $D' = \{\boldsymbol{x}_i\}_{i=1}^n$, where $\boldsymbol{x}' \notin D'$, the sensitivity of g is

$$\begin{aligned}
&\max_{D,D'} \left\| g(D) - g(D') \right\|_2 \\
=&\max_{D,D'} \left\| \sum_{i=1}^n \text{clip}_C(\nabla_\theta l_i) + \text{clip}_C(\nabla_\theta l') - \sum_{i=1}^n \text{clip}_C(\nabla_\theta l_i) \right\|_2 \\
=&\max_{D,D'} \left\| \text{clip}_C(\nabla_\theta l') \right\|_2 = C,
\end{aligned}$$

where $\nabla_\theta l'$ is the gradient with respect to $\boldsymbol{x}'$. Following Theorem 1, $\mathcal{M}_2$ satisfies $1/\sigma$-GDP. Subsequently, we use Poisson sub-sampling to amplify differential privacy. Following Lemma 3, given sub-sampling probability $p_2 = m_2/n$, Phase II asymptotically satisfies $p_2\sqrt{N_2(\exp(1/\sigma^2) - 1)}$-GDP. □

In Phase II, the noise scale σ controls the magnitude of the injected noise (with more noise injected providing greater privacy guarantees for the DMs). The clipping constant C controls the sensitivity of gradients. Changing the clipping constant will not affect the privacy guarantees when other parameters remain unchanged. This is because adjusting the clipping constant simultaneously affects both the overall noise added in Phase II and the sensitivity of gradients, thereby maintaining the final privacy guarantee unchanged.

Following the composition property on GDP (Lemma 2), we compose the overall privacy budget consumption of the two phases, as detailed in Lemma 4 and Lemma 5, respectively. Additionally, we employ the conversion to convert the privacy budget from GDP to (ε, δ)-DP for comparative analysis. Next, we provide the formal privacy guarantees for dp-promise as follows

Theorem 2 (Differential privacy for dp-promise)**.** *Algorithm 1 asymptotically satisfies $(\varepsilon, \delta(\varepsilon))$-DP, it holds that*

$$\delta(\varepsilon) = \Phi(-\frac{\varepsilon}{\mu} + \frac{\mu}{2}) - \exp(\varepsilon)\Phi(-\frac{\varepsilon}{\mu} - \frac{\mu}{2}), \tag{17}$$

$$\mu = \sqrt{\mu_1^2 + \mu_2^2}, \tag{18}$$

where μ_1 is defined in Equation (15) and μ_2 is defined in Equation (16).

Proof. Algorithm 1 contains two phases. Following composition on GDP via Lemma 2, we can derive that Algorithm 1 asymptotically satisfies $\sqrt{\mu_1^2 + \mu_2^2}$-GDP. Then, following Lemma 1, we can obtain the final privacy budget $(\varepsilon, \delta(\varepsilon))$. □

According to the condition provided in Theorem 2, in practice, we can also calculate a privacy budget ε_δ by a given δ. Note that the results we obtained from the theoretical analysis are approximate compositions based on the Central Limit Theorems (CLT) of f-DP [12]. Nevertheless, Dong et al [12] and Bu et al. [3] demonstrate that the approximation derived from CLT is close to the exact composition results in their experiments. Furthermore, two commonly used DP-ML frameworks, i.e., TensorFlow Privacy[1] and Opacus [61], both support the implementation of the GDP accountant, which is based on the approximate results from CLT [3, 12]. Additionally, Dong et al. [12] emphasized that the exact computation of privacy guarantees under compositions is computationally hard, thus tractable approximations are important. Eventually, we utilize the differentially private DMs to generate synthetic data. The following corollary of Theorem 2 presents the DP guarantees for synthetic data generated by dp-promise.

Corollary 1. *Given a private dataset D_{priv} and a fixed probability δ, let $\mathcal{G}$ represent the diffusion model, such that the neural network z_θ trained by Algorithm 1. Let $X = \mathcal{G}(R)$ represent the diffusion model map a noise set $R \in \mathcal{R}$ to a synthetic dataset $X \in \mathcal{X}$, where $\mathcal{R}$ and $\mathcal{X}$ are noise space and data space, respectively. For any $R \in \mathcal{R}$, there is $\varepsilon_\delta > 0$ such that the synthetic dataset asymptotically satisfies $(\varepsilon_\delta, \delta)$-DP.*

Proof. The noise set R is independent of the private dataset D_{priv}. Following the Theorem 2, the privacy in parameters of the neural network is asymptotically bounded by $(\varepsilon_\delta, \delta)$-DP. Additionally, there is no data-dependent parameter in the sampling procedure of DMs. According to the post-processing property of DP, the synthetic dataset generated by $\mathcal{G}$ asymptotically satisfies $(\varepsilon_\delta, \delta)$-DP. □

6 Experimental Evaluation

In this section, we evaluate dp-promise to demonstrate the performance in generating differentially private data. To show the effectiveness of dp-promise, we compare dp-promise against the state-of-the-art differentially private generative models on image data.

6.1 Experiment Setup

Datasets. Our experiments are conducted on four well-known image datasets for comprehensive evaluation, i.e., MNIST [30], Fashion-MNIST [58], CelebA [35], and CIFAR-10 [29]. Specifically, MNIST [30] and Fashion-MNIST [58] are two widely used datasets in the field of differentially private image synthesis. Both MNIST and Fashion-MNIST contain a total of 70,000 grayscale images, each with a resolution of 28×28 pixels, comprising handwritten digits and fashion products with 10 distinct object classes, respectively. MNIST and Fashion-MNIST are divided into two parts: 60,000 images for training and 10,000 images for testing. In the experiments, 60,000 training images are utilized in the training procedure. Furthermore, we also investigate two more complex and high-dimensional datasets, namely CelebA [35] and CIFAR-10 [29]. CelebA contains 202,599 color images with a resolution of 64×64 pixels, and CIFAR-10 comprises 60,000 color images, each with a resolution of 32×32 pixels.

Baselines. Our proposed method, dp-promise, is compared with various baseline models, including DP-SGD DM, DP-MERF [18], DPDM [11], DP-MEPF [19], and DP-Diffusion [17]. Note that DPGEN [8] is excluded from the comparison due to an incorrect privacy analysis [11]. PATE-based methods (e.g., G-PATE [36]) rely on data-dependent privacy, thereby making the PATE-based methods incomparable to dp-promise.

- **DP-SGD DM**: This is a naive method where DP-SGD is directly applied to fine-tuning a pre-trained DM. For DP-SGD DM, we first pre-train DMs using public data and then fine-tune the DMs with private data. Note that

[1] https://github.com/tensorflow/privacy

Figure 3: The synthetic data generated by DP-MERF, DPDM, DP-MEPF, DP-SGD DM, and dp-promise under $\varepsilon = 10$ and $\delta = 10^{-5}$ on MNIST and Fashion-MNIST. The original data is presented in the last row.

we maintain the model architecture and parameters as close to dp-promise as possible.

- **DP-MERF [18] & DP-MEPF [19]**: We executed the official code provided by the authors of DP-MERF[2] and DP-MEPF[3] to obtain the results. For DP-MEPF, we consider both features ϕ_1 and ϕ_2 within DP-MEPF. Note that DP-MEPF utilizes public data.
- **DPDM [11]**: We executed the official code[4] provided by the authors. Note that the original DPDM conducted experiments without public data pre-training and had two distinct settings - DPDM (FID) and DPDM (Acc), which focus on sample quality and downstream utility, respectively. For fair comparisons of experiments with public data pre-training, we made necessary modifications, such as parameters based on the official code to adapt pre-training settings, denoted as DPDM (Pub).
- **DP-Diffusion [17]**: Due to no publicly available code of DP-Diffusion [17] and no experimental results on MNIST, Fashion-MNIST, and CelebA datasets, we manually reproduced DP-Diffusion following all provided information from [17] and reported the results on the high-dimensional CelebA dataset and the more challenging CIFAR-10 dataset.

Evaluation metrics. To demonstrate the performance of dp-promise in differentially private synthetic image generation, we conduct a comprehensive analysis using both sample quality and downstream utility. To compare sample quality with other approaches, we present quantitative results that include the Fréchet Inception Distance (FID) [20] and Inception Score (IS) [45]. These two metrics are commonly used to evaluate the quality and diversity of images generated by the generative model. Informally, FID is computed based on the distance between the feature distributions extracted from generated images and real images, and the Inception Score is calculated as the exponential mean of the probability distribution extracted from generated images. To measure the utility of synthetic data in downstream tasks, following existing studies [5, 11, 18, 24], we utilize a range of classifiers, including multi-layer perceptron (MLP), convolutional neural network (CNN), and eleven additional scikit-learn [28] classifiers (e.g., logistic regression, decision tree, etc.). In particular, we train each classifier on synthetic data and then evaluate the trained classifiers on real data to measure the performance in downstream tasks using classification accuracy. We report the accuracy of MLP, CNN, and the average accuracy of the other eleven scikit-learn classifiers.

6.2 Implementation

Model architectures and implementation. In the experiments, we use the PyTorch framework [43]. Specifically, we employ the Opacus framework [61] to implement the DP-SGD algorithm. Then, we build neural networks us-

ing a U-Net architecture, which is based on the improved DDPM [40] repository[5], and we train the network using Adam [27] optimizer. In dp-promise, we set diffusion steps to $T = 1,000$ and linearly assign values from 10^{-4} to 2×10^{-2} for $\{\beta_1, \beta_2, \ldots, \beta_T\}$. Similar to recent works [2, 11, 17], we use a large batch size and small clipping constant during the private training procedure to enhance the sample quality. We show the values of all the hyper-parameters in the "Training" paragraph. Following existing work [11, 49], we use the exponential moving average (EMA) of neural network parameters, which is a common practice in traditional DMs.

Training. For MNIST, we initiate pre-training of DMs with 1.6M parameters using Fashion-MNIST as the public dataset. The network contains 32 base channels, channel multipliers $(1,2,2)$, and attention resolution 7. We pre-train this network with a learning rate of 2×10^{-4} and 50 epochs at batch size 128. In the experiments on Fashion-MNIST, we pre-train DMs with 6.5M parameters on CIFAR-10. In this case, we transformed each image into grayscale and resized the images into 28×28 pixels, matching the size of Fashion-MNIST. The network has 64 base channels, channel multipliers $(1,2,2)$, and attention resolution 7 in the neural network. Pre-training is performed with a learning rate of 2×10^{-4} and $1,000$ epochs at batch size 128. Subsequently, we fine-tune these pre-trained models on MNIST and Fashion-MNIST using dp-promise. The fine-tuning process involves time-step boundary $S = 900$, learning rate $\eta_1 = 3 \times 10^{-4}, \eta_2 = 6 \times 10^{-4}$, batch size $m_1 = 32, m_2 = 4,096$, and the number of iterations $N_1 = 3 \cdot n/m_1, N_2 = 50 \cdot n/m_2$. We apply noise augmentation with $K = 32$ and a clipping constant of $C = 10^{-2}$. For the selection of S, due to the high-dimensional data we need to handle, it is necessary to choose a large S to ensure that Phase I does not consume an excessive amount of privacy budget. In the sampling procedure, we consider conditional generation with sampling parameters $T' = 200$, $\rho = 1$, and $w = 0$.

For CelebA and CIFAR-10 on 32×32 resolution, we initiate the pre-training of DMs with 35M parameters on ImageNet [9] as the public dataset, where each image is resized into 32×32 resolution, matching the dimensions of CelebA and CIFAR-10. The network includes 128 base channels, channel multipliers $(1,2,2,2)$, and attention resolution 16. Pre-training is performed with a learning rate of 2×10^{-4} and 50 epochs at batch size 128. For CelebA, we fine-tune the network using dp-promise with a time-step boundary $S = 925$, learning rate $\eta_1 = 3 \times 10^{-4}, \eta_2 = 3 \times 10^{-4}$, batch size $m_1 = 32, m_2 = 4,096$, the number of iterations $N_1 = 2 \cdot n/m_1, N_2 = 50 \cdot n/m_2$, noise augmentation $K = 4$, and clipping constant $C = 10^{-2}$. For CIFAR-10, we apply parameters including learning rate $\eta_1 = 3 \times 10^{-4}, \eta_2 = 3 \times 10^{-4}$, batch size $m_1 = 32, m_2 = 4,096$, the number of iterations $N_1 = 3 \cdot n/m_1, N_2 = 50 \cdot n/m_2$, noise augmentation $K = 4$, and clipping constant $C = 10^{-2}$. In the sampling procedure, we consider unconditional generation with sampling parameters $T' = 200$, $\rho = 1$, and $w = 0$.

Evaluation. For evaluation of sample quality, we use the code and Inception network at `tensorflow_gan` repository[6] to compute FID and Inception Score. We use 60,000 synthetic images and then compute the Inception Score and FID with the origin training dataset. For the evaluation of downstream quality, we build the MLP and CNN classifiers based on the

Figure 5: Synthetic data generated by DPDM, DP-MEPF, and dp-promise under various privacy budgets with fixed $\delta = 10^{-5}$ on CelebA (left) and CIFAR-10 (right). The original images are displayed in the first column for each dataset.

DPDM repository. On MNIST and Fashion-MNIST, we randomly split 60,000 synthetic samples into a 50,000 training set and a 10,000 validation set. Then we train all classifiers using Adam optimizer with 50 epochs, batch size 128, and a learning rate of 3×10^{-4}. Finally, we select the classifier that achieves the highest accuracy on the validation set and then test the classifier on the real data.

6.3 Experimental Results

MNIST and Fashion-MNIST. Following the previous literature on differentially private generative models [11, 18, 24], we compare the sample quality and downstream utility for dp-promise in comparison to existing methods. We perform on MNIST and Fashion-MNIST, considering fixed privacy budgets $\varepsilon = \{0.2, 1, 10, \infty\}$ with a fixed probability $\delta = 10^{-5}$, where $\varepsilon = \infty$ represents the non-private settings. Note that we vary privacy budgets ε from 0.2 to 10, as this range is commonly employed in practical applications like DP-FL [62, 63], DP-SGD [4, 46, 56], DP-DL [42], DPML [39] and Vote-Histogram [54].

In Figure 3, we present the visualization results of synthetic data generated by various approaches on both MNIST and Fashion-MNIST. We can observe that dp-promise generates high-fidelity samples under a standard privacy guarantee (e.g., $\varepsilon = 1$). The aggregated results for sample quality and downstream utility of synthetic data are summarized in Table 2. Specifically, on MNIST, dp-promise outperforms all baselines on almost all metrics in downstream utility and sample quality. On Fashion-MNIST, dp-promise achieves a lower FID compared to other approaches under all privacy budgets while achieving downstream prediction accuracy similar to DP-MEPF and DPDM under a strong privacy guarantee (e.g., $\varepsilon = 0.2$). For DPDM with public data settings, pre-training enables DPDM to enhance sample quality, but we find there is no significant improvement in downstream utility. dp-promise still outperforms DPDM with public data pre-training in most settings. Note that CIFAR-10 and Fashion-MNIST have a significant visual difference, making it challenging to trans-

fer knowledge under a large distribution shift. Nonetheless, dp-promise achieves higher downstream classification accuracy under standard privacy guarantees (e.g., $\varepsilon = \{1, 10\}$). In comparison with DPDM, dp-promise simultaneously achieves high sample quality and downstream utility across one setting, in contrast to the distinct settings in DPDM.

To explore the privacy-utility trade-off of different methods, we vary the privacy budget ε from 0.2 to 10 for DP-MERF, DP-MEPF, and dp-promise, and then report the downstream utility and sample quality on MNIST and Fashion-MNIST. As shown in Figure 4, under the standard privacy budgets (e.g., $\varepsilon = 1, 10$), we observe that dp-promise consistently outperforms all of the other approaches, and dp-promise shows lower sample quality degradation. Moreover, under a higher privacy budget, dp-promise achieves performance that is close to the non-private setting, highlighting the effectiveness in preserving both utility and privacy.

CelebA and CIFAR-10. To demonstrate the usability of dp-promise on more complex datasets beyond MNIST and Fashion-MNIST, we compare the sample quality of dp-promise, DPDM (FID), DP-MEPF, DPDM (Pub), and DP-Diffusion on CelebA and CIFAR-10 under fixed privacy budgets $\varepsilon = \{1, 5, 10\}$. We set $\delta = 10^{-6}$ and $\delta = 10^{-5}$ for CelebA and CIFAR-10, respectively.

The visualization results of these approaches on CelebA and CIFAR-10 are presented in Figure 5. We can observe that dp-promise is able to generate realistic samples under

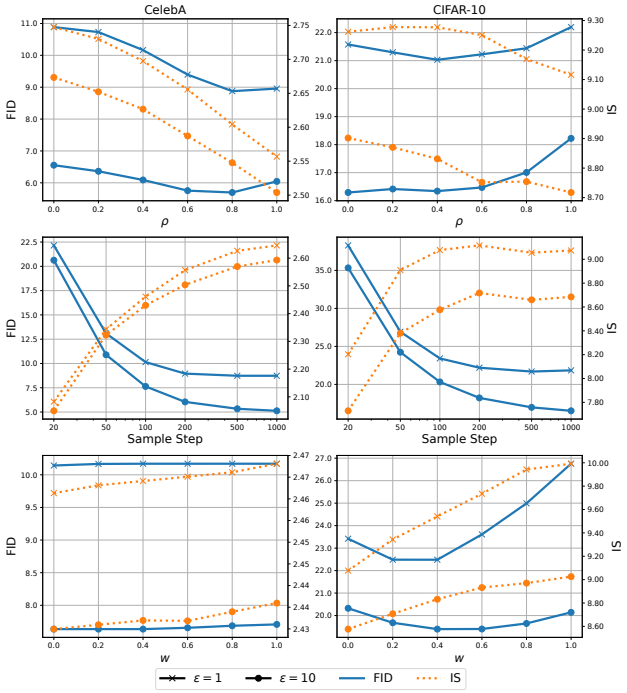

Figure 6: The influence of sampling hyper-parameters on CelebA (left column) and CIFAR-10 (right column). Three rows represent randomness ρ, sample step T', and guidance scale w, respectively.

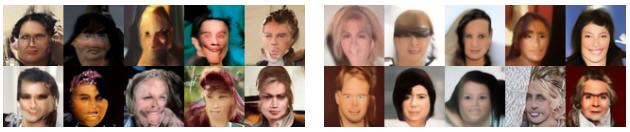

a standard privacy budget (e.g., $\varepsilon = \{1, 10\}$). We report the sample quality in Table 3. It is shown that dp-promise can generate samples that are close to original images, achieving a lower FID and higher Inception Score compared to the baselines.

Effect of Phase I. To investigate the impact of Phase I on sample quality and downstream utility, we conducted ablation experiments on Phase I. For the experimental settings, we adjusted S to 800 and retained most of the previous experimental settings on MNIST and Fashion-MNIST under $\varepsilon = 10$ and $\delta = 10^{-5}$. Note that the purpose of reducing the value of S here is to increase the ratio of Phase I over all time-steps while increasing the privacy budget of Phase I. As shown in Table 4, Phase I enhances the sample quality and downstream utility. This is attributed to the network in DMs needing to fully learn the reverse process from 1 to T. Therefore, it is necessary to train the network from S to T. However, since most denoising steps are in Phase II, the network cannot solely learn the reverse process through Phase I. It still needs to learn the denoising steps with smaller noise through Phase II while also providing privacy guarantees.

Effect of hyper-parameters for sampling. In this experiment, we investigate the impact of hyper-parameters for sampling on the sample quality of dp-promise. We perform on CelebA and CIFAR-10 under a fixed privacy budget of

Figure 7: Synthetic data generated by DPDM and dp-promise under $\varepsilon = 10$ and $\delta = 10^{-6}$ on CelebA with a resolution of 64×64 pixels.

$\varepsilon = \{1, 10\}$. For randomness ρ, we vary ρ from 0 to 1 while keeping fixed sample step $T' = 200$ and guidance scale $w = 0$. In the first row of Figure 6, we observe that stochastic sampling leads to a lower FID, indicating improved sample quality. However, there is a slight decrease in the Inception Score, suggesting a minor loss in the diversity of the sample. This indicates that stochastic sampling is more robust when dealing with an imprecise neural network in DMs. For sample step T', we vary T' from 20 to 1,000 while keeping fixed $\rho = 1$ and guidance scale $w = 0$. In the second row of Figure 6, the results show that increasing the sample step results in better sample quality with more sampling time. Therefore, we choose $T' = 200$ as the sample step to balance the sample quality and sampling time. Note that DPDM uses a more advanced sampler and considers $T' = 1,000$ as the sample step, consuming a significant amount of time to generate samples. For the guidance scale, we vary w from 0 to 1 while keeping fixed $T' = 200$ and $\rho = 1$. In the third row of Figure 6, we notice that as the guidance scale increases, both FID and Inception Score also improve. This suggests that using a higher guidance scale results in samples with greater diversity. These findings help us understand how different hyper-parameters influence the sample quality of dp-promise and enable us to make choices to balance quality and efficiency in practice.

Higher resolution results. To explore the performance on higher-dimensional datasets, we consider experiments on CelebA with 64×64 resolution under $\varepsilon = \{1, 5, 10\}$. We initiate the pre-training of DMs with 35 million parameters on ImageNet [9] as the public dataset, where each image is resized into 64×64 resolution. The network includes 128 base channels, channel multipliers $(1, 2, 2, 2)$, and attention resolution 16. Pre-training is performed with a learning rate of 2×10^{-4} and 50 epochs at batch size 128. We fine-tune the network with time-step boundary $S = 950$, learning rate $\eta_1 = 3 \times 10^{-4}, \eta_2 = 3 \times 10^{-4}$, batch size $m_1 = 32, m_2 = 4,096$ for $\varepsilon = 10$, batch size $m_1 = 16, m_2 = 4,096$ for $\varepsilon = \{1, 5\}$, the number of iteration $N_1 = 1 \cdot n/m_1, N_2 = 15 \cdot n/m_2$, noise augmentation $K = 4$, and clipping constant $C = 10^{-2}$. In the sampling procedure, we consider unconditional generation with parameters $T' = 200$, $\rho = 1$, and $w = 0$. Since DPDM with public data pre-training is closest to dp-promise in technique and performance, we conduct experiments compared to DPDM (Pub). As shown in Table 5 and Figure 7, dp-promise advances the performance of sample quality. Compared with DPDM, dp-promise generates faces with more fidelity.

7 Conclusion

In this paper, we propose dp-promise, a novel framework to train differentially private DMs. dp-promise contains a two-phase training process that takes advantage of DMs to reduce information loss during private training. Moreover, we provide a rigorous theoretical analysis for dp-promise. The experiments demonstrate a non-trivial improvement over the existing state-of-the-art on typical benchmarks. Furthermore, dp-promise is able to perform under various privacy budgets and on more challenging datasets (e.g., CelebA and CIFAR-10). In summary, this work establishes a connection between DMs and privacy and demonstrates that DMs are a superior choice for differentially private image synthesis.

Comparing the experimental results from higher-dimensional datasets and lower-dimensional datasets, dp-promise shows a performance drop on the higher-dimensional datasets. In the future, we will work on approaches that can provide consistent performance on both higher- and lower-dimensional data.

DMAAUTH: A Lightweight Pointer Integrity-based Secure Architecture to Defeat DMA Attacks

Xingkai Wang, Wenbo Shen✉, Yujie Bu, Jinmeng Zhou, and Yajin Zhou

Zhejiang University

Abstract

IOMMU has been introduced to thwart DMA attacks. However, the performance degradation prevents it from being enabled on most systems. Even worse, recent studies show that IOMMU is still vulnerable to sub-page and deferred invalidation attacks, posing threats to systems with IOMMU enabled.

This paper aims to provide a lightweight and secure solution to defend against DMA attacks. Based on our measurement and characterizing of DMA behavior, we propose *DMAAUTH*, a lightweight pointer integrity-based hardware-software co-design architecture. DMAAUTH utilizes a novel technique named *Arithmetic-capable Pointer AuthentiCation* (APAC), which protects the DMA pointer integrity while supporting pointer arithmetic. It also places a dedicated hardware named Authenticator on the bus to authenticate all the DMA transactions. Combining APAC, per-mapping metadata, and the Authenticator, DMAAUTH achieves strict byte-grained spatial protection and temporal protection.

We implement DMAAUTH on a real FPGA hardware board. Specifically, we first realize a PCIe-customizable SoC on real FPGA, based on which we implement hardware version DMAAUTH and conduct a thorough evaluation. We also implement DMAAUTH on both ARM and RISC-V emulators to demonstrate its cross-architecture capability. Our evaluation shows that DMAAUTH is faster and safer than IOMMU while being transparent to devices, drivers, and IOMMU.

1 Introduction

Direct memory access (DMA) is a technique of computer systems that allows the peripheral device to access the main memory directly. DMA does not require CPU involvement during memory access and thus significantly reduces CPU occupancy. Therefore, DMA has been widely used on almost all computer systems, including large servers, personal computers, and mobile smartphones [12, 31].

However, the performance gain of DMA also comes with a price. DMA exposes the physical memory directly to the devices, bypassing all MMU-based protection (i.e., paging). All devices plugged into the host arbitrarily read/write the physical memory [9, 34]. To defeat DMA attacks, the Input/Output Memory Management Unit (IOMMU) has been introduced, which maps the physical memory to I/O virtual addresses (IOVAs) and gives the IOVAs to the peripheral devices [11]. Hence, the device cannot access the physical memory directly, and the access scope is limited to the mapped I/O pages. IOMMU is effective in defending against DMA attacks and has become the de facto approach for DMA protection.

However, recent research shows that IOMMU is not enabled on most systems, including Windows, Linux, and FreeBSD, due to performance concerns caused by IOVA translation and the slow IOTLB invalidation [12, 31]. Even when the IOMMU is enabled, the system protected by the IOMMU still suffers from both *spatial* and *temporal* attacks [3]. The page-grained-mapping nature of IOMMU allows a malicious device to access kernel objects that coexist on the same page with I/O buffers, leading to *spatial* sub-page attacks. The deferred IOTLB invalidation allows the device to access unmapped pages in the deferred time windows, leading to *temporal* deferred-invalidation attacks. Hence, how to defeat DMA attacks efficiently and thoroughly remains an open question.

To answer this question, this paper aims to provide a solution to address DMA security problems, which, in the meantime, is lightweight enough to be applied in an actual production environment. To achieve this goal, we first characterize the DMA behavior from devices of different types to see whether existing integrity-based or baggy-bounds-based methods are applicable. Our results show that 75.2% of requests are via DMA pointers plus an offset (termed the *pointer arithmetic*). At the same time, the number of coexisting mapped buffers is small (≤ 435), and the size ranges from 1B to about 520KB, while 68.7% of the buffer sizes are neither multiple-page-sized nor 2^n-sized. These results indicate that the existing methods are not feasible.

Based on measurement results, we propose *DMAAUTH*, a lightweight hardware-software co-design architecture that achieves byte-grained bound checking and strict temporal

✉ Corresponding author.

integrity on DMA pointers. DMAAUTH can thus defeat the DMA attacks that IOMMU suffers from, including the sub-page attacks and the deferred-invalidation attacks. In our design, a dedicated hardware named *Authenticator* is placed on the bus to authenticate all the DMA transactions, with the signature on the DMA pointers and corresponding metadata maintained by the OS kernel.

We face two challenges when designing and implementing DMAAUTH. First, the kernel loses control of DMA pointers once they are passed to the peripheral devices. In other words, devices can fake DMA pointers for memory access. Even with IOMMU, the malicious device can still forge an out-of-bound pointer to launch sub-page attacks or reuse outdated pointers to launch temporal attacks [3]. Second, protecting the pointer integrity while supporting the pointer arithmetic is difficult. Our characterization shows that benign devices frequently add offsets to given pointers and then dereference them for DMA. However, the existing pointer integrity-based techniques sign the whole pointer [28, 54] and are incompatible with peripheral pointer arithmetic.

To resolve the above challenges, we propose a new technique termed *Arithmetic-capable Pointer Authentication* (APAC), which leverages the pointer signing/authentication to grant the kernel complete control over the DMA pointers. APAC only signs the high bits and leaves the lower bits for arithmetic, overcoming the pointer arithmetic challenges. On top of APAC, DMAAUTH introduces per-mapping metadata and combines them to achieve spatial and temporal protection.

To evaluate the efficiency and effectiveness of the proposed techniques, we implement DMAAUTH on a real FPGA hardware board. Specifically, we first implement a fully functional SoC with customizable PCIe support on FPGA as our baseline. Based on our SoC, we implement the hardware Authenticator and integrate it into the PCIe bus to authenticate all PCIe DMA transactions. To enforce the protection, we protect the Linux DMA APIs to drive the Authenticator and realize DMAAUTH protection without changing device drivers. Additionally, DMAAUTH was also developed for RISC-V and ARM QEMU to demonstrate its cross-architecture capability.

We conduct both security and performance evaluations of DMAAUTH. The security evaluation shows that DMAAUTH can defeat all six types of DMA attacks, including the sub-page and the deferred-invalidation attacks. The performance evaluation on real hardware shows that DMAAUTH introduces a 1.0% throughput degradation and a 1.8% CPU runtime consumption overhead, outperforming the deferred IOMMU scheme by reducing throughput degradation and CPU overhead by 82.1% and 68.9%, respectively.

The contributions of this paper are summarized as follows.

- We characterize the DMA of different devices, providing a knowledge base of the DMA behavior.
- We propose a novel technique named APAC, which is the first pointer integrity protection scheme that supports pointer arithmetic.
- We propose a lightweight pointer integrity-based secure architecture named *DMAAUTH*, combining APAC and per-mapping metadata to thwart various DMA attacks.
- We develop a full-fledged PCIe-customizable SoC on real FPGA hardware, serving as a foundation for future architecture and system research.
- We implement DMAAUTH on real FPGA hardware based on our SoC. We also implement an emulator version of DMAAUTH for both RISC-V and ARM to show its cross-architectural capability. Our evaluation shows that DMAAUTH outperforms IOMMU in terms of both security and efficiency.

2 Background

2.1 DMA Workflow

DMA is a mechanism that transfers data without the full participation of the CPU to liberate it from the heavy burden of copying or moving data. Historically, DMAs were only configured by CPUs, but afterward, DMAs can also be issued by peripherals directly or via bus controllers. We use the Linux kernel as an example to illustrate the lifetime of a DMA transfer. We divide the whole process into three stages.

Pre-transfer is handled by the CPU and OS kernel. The `dma_map` API is called to map the kernel virtual address into the corresponding DMA pointer. `dma_alloc` API performs similar functionality but allocates a buffer in advance. Then, the kernel sends the DMA pointer to the peripheral and yields the CPU. If the IOMMU is enabled, the kernel is also responsible for maintaining the table for IOMMU address translation.

In-transfer is taken over by the peripheral and I/O bus. The peripheral launch DMAs and perform the actual data transfer via the bus. When finished, the peripheral informs the CPU by writing a message in memory or via interruption.

Post-transfer is handled by the CPU and OS kernel again. The DMA buffer is recycled using `dma_unmap` and `dma_free` API series. In compliance, the device should not reaccess the buffer. The IOMMU mapping for the buffer is also removed . Finally, `dma_free` also frees the DMA buffer after unmapping.

2.2 IOMMU

IOMMU was introduced into modern SoCs in the early 2000s to map only the specified pages to the device, preventing malicious devices from accessing unmapped memory [10]. However, IOMMU is still vulnerable due to the assumption that all the peripherals are parts of the trusted computing base (TCB) in OS implementations.

Memory management. IOMMUs use page tables to translate I/O virtual addresses (IOVAs) into physical addresses, similar to how MMUs translate virtual addresses. For each access from the peripheral using IOVA, the IOMMU hardware walks

through its page table level by level and reaches the corresponding physical address. This scheme provides analogous protection capability as the MMUs; devices cannot access pages without mapping entry in the IOMMU page table but can still access contents residing on the same page, resulting in spatial *sub-page vulnerability*.

IOTLB cache. To accelerate the translation , an I/O translation look-aside buffer (IOTLB) is used to cache mappings from IOVAs to physical addresses. However, in the typical implementations, the consistency between the IOTLB and the IOMMU page table has to be maintained by the OS kernels via flushing the IOTLB after unmapping buffers [1, 4, 6, 21]. Such flushes introduce significant overhead and are thus usually deferred by default to provide an acceptable performance. This allows peripherals to access unmapped pages in a time window, causing temporal *deferred invalidation vulnerability*.

PCIe ATS. To provide even better performance than the IOTLB integrated into IOMMU, SoC manufacturers provide address translation service (ATS) for trusted PCIe devices. Instead of translating the IOVA to the physical address on each peripheral memory access, the IOMMU informs the peripheral of the physical address after the translation. Then, the PCIe peripheral can choose to store the mapping from the IOVA to the physical address in its address translation cache (ATC), and it can launch DMA transactions using physical addresses directly [4, 6, 21]. But this mechanism exposes entire physical memory directly, causing *bypass vulnerability*. To make things worse, the Linux kernel trusts all the PCIe devices except those explicitly listed as external ports in the Advanced Control and Power Interface (ACPI) [15, 52]. This allows all the PCIe devices plugged into the motherboard to use the ATS and access the main memory via bare physical addresses, positioning the entire system in danger.

2.3 DMA Attack

Computer system interconnects various components, including the powerful main processing units (such as CPU, GPU, and NPU), along with other accessory peripherals, which can be produced and marketed by untrustable manufacturers.

In the early years, without IOMMU protection, systems allowed all the peripherals to manipulate the main memory arbitrarily. During this period, DMA attacks were plain and powerful. Unlocking the OSes and executing arbitrary code is reachable via overwriting critical data in Windows [8], macOS [9, 13], FreeBSD [13], and Linux kernels [13, 14].

As discussed, IOMMU provides basic protection, preventing direct attacks. However, the high overhead introduced by IOMMU prevents the OSes from adopting it. Linux distributions often turn off the IOMMU protection by default, as did the different Windows editions [31]. The vulnerability of Linux further poses millions of Android devices in danger [12]. This fact reveals the demand for a more lightweight mechanism that can be applied in actual systems. Further research discovered that even when the IOMMU is enabled, the *sub-page vulnerability* and *deferred-invalidation vulnerability* still render the system vulnerable to DMA attacks [3, 31], urging researchers to design more secure protections.

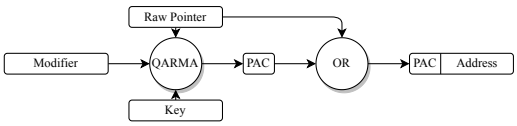

Figure 1: ARM Pointer Authentication. A hash signature is calculated by the QARMA encryption engine and embedded in the high bits of a pointer.

2.4 Pointer Authentication

Pointer authentication (PA) was first introduced into ARM v8.3 to ensure the integrity of pointers in AArch64 instruction set architecture (ISA). PA is an ISA extension that provides extra instructions for creating and authenticating authorized pointers. As shown in Figure 1, a signature is calculated based on the *pointer* value to authenticate, a 128-bit secret *key*, and a 64-bit *modifier*. Changing one of the three values results in a difference in the signature, preventing forgery of pointers. In this paper, we add a new pointer authentication instruction to meet specific pointer format requirements, but the methodology is the same as the ARM PA extension.

Signing a pointer. The ARM PA provides different keys for the different data categories: two for data pointers, another two for code pointers, and one for general data. For instance, to create a data pointer with a signature, `pacda <pointer>, <modifier>` is used. This instruction specifies the secret key using `d` for data pointers and `a` for the first key. The output signed pointer is stored in the original pointer's register.

Authenticating a pointer. To authenticate a pointer, the instruction `autda <pointer>, <modifier>` is used to recalculate the signature and strip it down from the pointer if the signature is valid. If the signature is invalid, it will be kept on the high bits of the pointer. This results in an illegal pointer and causes translation exceptions when dereferenced.

PA is the basis for many novel security-related works to ensure pointer integrity [22, 28, 47, 55]. As the effectiveness and performance of PA have been tested in many scenarios, developers and researchers have been working on transporting the mechanism to other platforms [47, 51, 62].

3 Threat Model and Assumptions

In this paper, the attacker fully controls a DMA-capable accessory peripheral device. The attacker can read/write the main memory via DMA requests. When the IOMMU is absent, the attacker can forge fake DMA pointers and access all physical memory directly. When the IOMMU is enabled, the attacker

exploits the sub-page vulnerability and deferred-invalidation vulnerabilities to access all mapped pages. The attacker aims to attack the OS kernel by launching DMA attacks, including memory dumping, kernel DoS, data pointer tampering, control flow hijack, information leaking, etc.

In this paper, we consider two system settings: the one with no IOMMU and the one with IOMMU enabled. We assume the main processing units(CPUs and computing accelerators, such as GPU), main memory, and the bus are trusted, and so are the enabled IOMMU. The OS kernel and device drivers running on the CPUs are trusted and use kernel DMA APIs correctly, as are the firmware running on the accelerators.

4 Characterizing DMA Behavior

We first characterize the DMA behavior of peripherals to guide the design of protection architectures.

4.1 System Setup

To monitor all the DMA buffers in the Linux kernel, we add logging logic to all the `dma_alloc` and `dma_map` series APIs of the Linux v6.1 kernel. Thus, all the DMA buffers' information can be recorded during the runtime, including the lower and upper bounds of the buffer, the device holding the buffer, and how many times the buffer has been mapped.

We intercept DMA transactions from different I/O buses, including PCI, PCIe, USB host controller interfaces (HCIs), etc. For each access, the start address, the length, and the access type will be recorded for further analysis. The Linux API modification only adds logging logic and does not impact the original DMA behavior. We use Buildroot to setup Linux with the following common peripherals: Intel E1000E NIC (`e1000e`), NVMe disk (`nvme`), Intel I/O Controller Hub 9 (`ich9`), QEMU Enhanced Host Controller Interface (`usb-ehci`), and other common USB peripherals like tablet, disks, keyboard and mouse are connected via the HCI interfaces. Once the emulation starts, our modification in the kernel and the emulator records all allocation, mapping, and accesses related to DMA, providing a better understanding of the DMA behavior.

We utilize two widely adopted network and storage benchmarking tools, `iperf3`[1] and `fio`[2], to generate authentic DMA traffic and furnish realistic workloads for characterization. On the one hand, `iperf3` conducts UDP send and receive operations with packet sizes ranging from 16B to 1460B, alongside TCP upload and download tests featuring window sizes ranging from 1KB to 1MiB. On the other hand, `fio` executes random and sequential read/write operations with block sizes spanning from 4KB to 4MiB.

[2] https://github.com/axboe/fio

4.2 Access Characteristics

DMA consists of two parts: the mapping performed by the kernel and the data transfer conducted by peripherals. We analyze both parts to characterize DMA.

4.2.1 DMA Mapping Statistics

We analyzed the collected data to determine how many mapped buffers coexist in the memory. As shown in Table 1, the peripherals use a limited number of mapped buffers at the same time. We also read the driver source code of these devices to understand this behavior. The devices usually use I/O rings to hold descriptors for coexisting mapped buffers. Similar characterizing study for GPUs has been conducted [25] and reveals that the number of buffers used simultaneously by GPUs is also limited ($\leq$ 34 per kernel) and indexed by 14 bits. DAMN [33] shows the mapped *pages* are less than 12K.

Finding-1: Peripherals devices use a small number of coexisting I/O buffers (<500), despite that a large number of buffers had been mapped then unmapped (>5M).

We also analyzed the size of the mapped buffers, as shown in Figure 2. We find that the sizes of the mapped buffer vary significantly from 1 to 524288 bytes. The size of the buffers is very irregular. Only 30.2% of the buffers are multiple of page size, and only 28.1% are 2^n sized.

Finding-2: Peripherals' buffer sizes vary greatly, most of which are neither multipage-sized nor 2^n-sized.

The varied and irregular buffer sizes expose sub-page vulnerabilities and introduce obstacles to applying page-grained or 2^n-grained protection schemes like Baggy Bounds [2].

4.2.2 DMA Transfer Statistics

As shown in Table 1, peripheral devices often perform DMA transfer via the given DMA pointers plus an offset (termed pointer arithmetic). These accesses are mainly caused by the *I/O ring* scheme, in which the mapped buffers' descriptors are stored in a dedicated memory area. The device is responsible for reading the data from the area and launching DMA to the buffers specified by the descriptors.

Finding-3: Peripherals tend to apply pointer arithmetic on the given DMA pointers, accounting for 75.2% of all.

In our setup, these accesses are mainly fetching metadata from TX and RX buffers. In this scenario, the device continuously reads DMA-pointer-size data from a large buffer (usually one or more pages) for further DMA operations.

5 DMAAUTH Design

5.1 Goals and Challenges

To defeat DMA attacks and allow easy adoption by existing systems, DMAAUTH needs to meet the following design goals.

Table 1: DMA memory statistics.

Device Information		Pointer Arithmetic Statistics			Mappings Statistics	
Device	DMA Interface	With Offset	Total Access	Ratio	Coexisting Mappings	Total Mappings
NVMe SSD	PCIe (`nvme`)	4406751	5943096	74.1%	154	1487516
SCSI HDD	AHCI (`ich9-ahci`)	40	67	59.7%	13	15
Mouse and Tablet	EHCI (`ich9-ehci`)	40690	40956	99.4%	6	54
Keyboard	UHCI (`ich9-uhci`)	5066871	6629284	76.4%	5	32
USB Stick	EHCI (`usb-ehci`)	35086	35372	99.2%	5	33
E1000E NIC	PCIe (`e1000e`)	11230518	14985786	74.9%	271	3744537
Total	/	20779956	27634561	75.2%	435	5232187

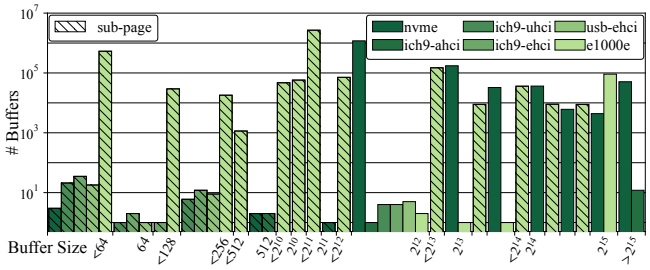

Figure 2: Sizes of the mapped buffers. The huge difference and irregularity of the sizes of the mapped buffers indicate that different buffers are used in highly different ways.

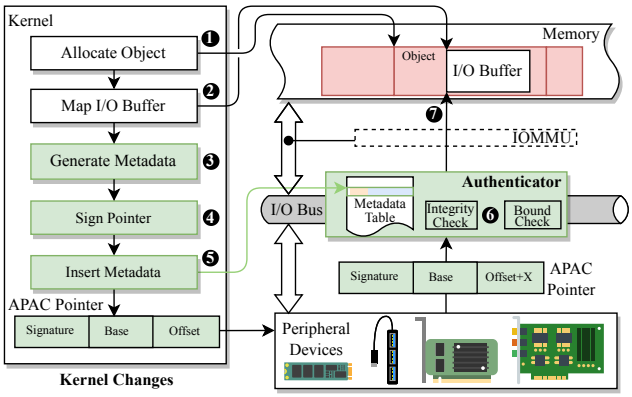

Figure 3: DMAAUTH workflow. Green-colored blocks are DMAAUTH components. DMAAUTH contains two parts: kernel changes and an Authenticator hardware on the I/O bus to intercept and check all DMA requests. DMAAUTH works with or without IOMMU.

Goal-1: Security. DMAAUTH must defeat both spatial and temporal DMA attacks. Particularly, DMAAUTH needs to defeat all sub-page attacks and deferred-invalidation attacks. Moreover, DMAAUTH must provide the same security guarantees without IOMMU or with ATS enabled.

Goal-2: Transparency. For easy adoption, DMAAUTH should require minimum changes on the OS kernels. Moreover, it should be fully transparent to the peripheral devices, device drivers, and the IOMMU DMA address translation process to provide excellent compatibility.

Goal-3: Lightweight. DMAAUTH should have minimum overhead to be adopted in the actual production environment.

To achieve the above goals, we need to resolve the following challenges to achieve DMAAUTH.

Challenge-1: No control on DMA pointers. The kernel loses control of the pointers once they are passed to the peripherals via MMIO. In other words, a malicious device can generate fake pointers arbitrarily and use them for memory access via DMA. Without IOMMU, the fake pointer can point to any physical address. Even with IOMMU, the malicious device can still forge out-of-bound pointers to access the kernel objects on the same page, leading to sub-page attacks [3].

Challenge-2: Pointer arithmetic compatibility. It is challenging to protect the integrity of the DMA addresses and support the pointer arithmetic. Our study in §4 shows that even benign devices frequently add an offset to the DMA pointers given by kernel drivers and use the new pointer with offset for DMA. Traditional pointer integrity-based technique is not compatible with pointer arithmetic. In other words, all these offset pointers will fail the pointer integrity check and are considered illegal. Therefore, we need to propose a new technique that can protect DMA pointer integrity and, at the same time, is compatible with pointer arithmetic.

5.2 Design Overview

To defend against DMA attacks, it is essential for the kernel to gain control of these DMA pointers, even after passing them to the device. To achieve this, inspired by ARM pointer authentication (PA), our key insight is that the kernel can sign all DMA pointers with secret keys that are inaccessible to the devices. When receiving DMA requests, the hardware Authenticator on the I/O bus checks the signature of DMA pointers. The devices don't have secret keys and thus cannot forge signed pointers. Therefore, the kernel has complete control of the DMA pointers and overcomes Challenge-1.

Unfortunately, ARM PA cannot be used directly due to the pointer arithmetic requirements. As shown in §4, devices often add or subtract an offset from a legal pointer and use it

to access memory. ARM PA signs the whole pointer and does not allow any changes to the pointer. As a result, the pointers with pointer arithmetic fail the integrity check, disabling legal memory accesses. To solve this problem, we propose a partial pointer authentication technique named *Arithmetic-capable Pointer Authentication (APAC)*, which only signs the high bits and leaves the low bits for arithmetic, resolving Challenge-2.

Combining the above design and the technique, we propose DMAAUTH, which is a hardware-software co-design for defending against DMA attacks. More specifically, DMAAUTH uses the APAC technique to sign DMA pointers on the kernel side before passing them to peripheral devices. DMAAUTH also places the *Authenticator* hardware on I/O buses to intercept all DMA memory accesses, as shown in Figure 3. As APAC supports pointer arithmetic, DMA memory accesses by de-referencing the signed pointer directly or with offsets can pass the integrity checks, and the memory accesses are permitted. The forged DMA pointers or beyond-range offsets fail the integrity check, and the memory accesses are denied.

DMAAUTH workflow. DMAAUTH works with or without IOMMU. We use Figure 3 to illustrate how DMAAUTH works with and without IOMMU. Firstly, the kernel prepares the APAC pointer in the *pre-transfer* stage. ❶ When a device requires memory, the OS kernel allocates an object for I/O purposes, but only part of the object (the block mark I/O Buffer in Figure 3) should be allowed to be accessed by the device. But the rest of the object, along with the mapped page (colored red in Figure 3), is exposed to the peripheral, leading to sub-page attacks [3]. ❷ After memory allocation, the kernel explicitly maps the buffer to the page and gets the DMA pointer, which is a physical address without IOMMU, and an IOVA if IOMMU is enabled. ❸ According to the mapped buffer, the protected kernel generates the per-mapping metadata, which contains the bounds of the mapped buffer and a random identifier. ❹ Next, the protected kernel signs the DMA pointer using the whole metadata, to protect both the pointer and the metadata. The signed *APAC pointer* is then ready to be passed to the device. ❺ The metadata is stored in the corresponding entry, ready to be referred to by the DMAAUTH hardware. All metadata is kept in the Authenticator's dedicated memory, which can never be leaked even if the peripheral hijacks the data flow, providing extra resilience.

Then, the peripheral takes over the *in-transfer* stage and uses either the guarded pointer directly or with offsets as DMA addresses. ❻ When intercepting the DMA memory accesses, the Authenticator on the I/O bus first fetches the metadata, then uses the whole metadata entry to authenticate the pointer signature to determine whether the pointer is forged by a malicious peripheral or has been outdated. Moreover, the Authenticator further uses the bounds in the metadata to check whether the access is within legal ranges. ❼ Authenticator strips off the signature from the APAC pointer, forming a legal physical address or IOVA to proceed with the requested data access for the peripheral if the pointer passes the integrity and bound checks. This authentication process requires no participation of the CPU and the OS kernel. When the peripheral finishes the actual data transfer, the OS kernel continues the *post-transfer* stage and cleans the mappings.

Fulfill design goals. For security, DMAAUTH encodes the signature of the pointer into the high bits to form the *APAC pointer*, which is used to enforce the pointer integrity (§5.3). Moreover, DMAAUTH uses the bounds to defeat spatial attacks (e.g., sub-page attacks) and the identifier to defeat temporal attacks (e.g., deferred-invalidation attacks), as detailed in §5.4. Therefore, DMAAUTH outperforms IOMMU and defeats more DMA attacks. Besides, the key of DMAAUTH is stored in dedicated registers rather than memory and hence cannot be stolen by peripherals, thwarting pointer forgery attacks even when the adversary has access permission to the metadata. Once the metadata is stored in the Authenticator, it can never fetched and leaked to the peripheral, providing extra exploit tolerance. Therefore, DMAAUTH achieves Goal-1.

For transparency, when using table-gathered metadata, DMAAUTH requires less than 100 LoC changes in the Linux kernel and does not need to change the device driver at all. §6 shows that the Authenticator can be easily inserted between I/O buses and the memory to form a protected SoC design. Moreover, DMAAUTH is fully compatible with IOMMU. Therefore, DMAAUTH realizes Goal-2. DMAAUTH can be applied to different CPU architectures, such as ARM, RISC-V, and AMD64, as long as the QARMA is implemented.

For lightweight, §7.2 shows that DMAAUTH outperforms the deferred IOMMU scheme by ~80% in throughput and ~70% in CPU consumption, making it a better solution to be applied to the actual production environment.

5.3 Arithmetic-capable Pointer Authentication

As mentioned, we propose a novel pointer authentication technique named *Arithmetic-capable Pointer Authentication* (APAC) to protect the pointer integrity while allowing pointer arithmetic. The basic idea of APAC is to sign only the high bits and leave the lower bits for pointer arithmetic. In the following, we give details on the APAC-pointer format and the signing/authentication steps.

Pointer format. As shown in Figure 4, the APAC pointer consists of the following fields.

- A *signature* field holds the S-bit signature of the pointer.
- A *base* field to hold the 2^n-aligned lower bound of the mapped buffer.
- An *offset* field to hold the low bits of the addresses, acting as the offset within the buffer.

The *signature* length is S bits defined by SoC designers. The rest L bits are used to store the physical address, where $S+L=64$. The *offset* length is decided at the DMA mapping site. The protected DMA mapping API gets the size and DMA address of the mapped buffer, up-rounds the size to 2^n, and uses the n as the *offset* length stored in the metadata.

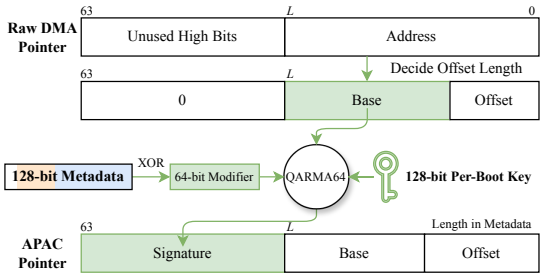

Figure 4: APAC pointer format. The signature of the pointer is calculated with the *base*, the *metadata* generated at mapping time, and the encryption *key*. The *offset* bits are not used for pointer authentication, thus supporting pointer arithmetic.

Pointer signing. The kernel performs the pointer signing during device memory allocation. As shown in Figure 4, After deciding the *offset* length, the DMAAUTH-protected kernel uses the *base* bits to sign and authenticate a pointer while skipping the *offset* bits. In this way, the devices can perform pointer arithmetic, which only changes the *offset* bits and doesn't impact the signature. Therefore, APAC pointers support pointer arithmetic while protecting the pointer integrity.

More specifically, the protected kernel takes the *base* field as the input of the QARMA encryption engine to generate the pointer signature. The other two inputs are the identifier in the per-mapping metadata and an encryption key. Note that the 128-bit metadata is transformed into a 64-bit modifier by XORing the high 64 bits and the low 64 bits to fit into the QARMA64 input. Next, DMAAUTH trunks the signature into *S* bits and embeds it into unused high bits of the DMA pointer. After these steps, the APAC pointer is ready to be transferred to the peripheral device for DMA purposes.

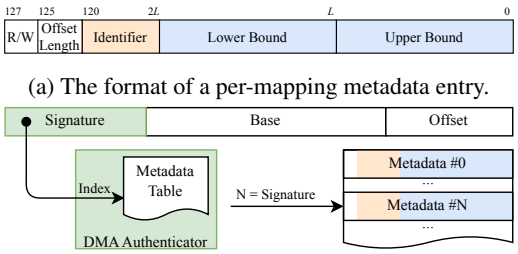
Pointer authentication. Pointer authentication is conducted by the DMA hardware when the peripherals launch the DMA memory access using the APAC pointers. DMAAUTH uses the signature in the pointer to locate and fetch the metadata from memory (detailed in §5.4). Once the metadata is fetched, the Authenticator gets the offset length and starts to authenticate the pointer to find out whether the pointer is forged by a peripheral, out-of-bound, or accessing unmapped memory.

If the peripheral device adds a legitimate offset to the APAC pointer, the *base* area of the pointer stays the same, and hence so is the signature re-calculated by the Authenticator. Once the pointer arithmetic results in overflow or underflow of the *offset* field, it will change the *base* of the APAC pointer. As a result, the whole pointer fails the authentication, and illegal memory access is denied. Using the APAC technique, the kernel has complete control over the DMA pointers.

Key management. DMAAUTH stores the key in both the CPU and the DMAAUTH hardware. In the CPU, DMAAUTH adds a key register to hold the key for the kernel to generate DMA pointers' signatures. In the Authenticator, the key is also stored to authenticate APAC pointers. During each boot time, a random value is generated and stored in the CPU key register using specialized instructions and in the key register of Authenticator hardware via MMIO write. Once initialized, these two registers holding the keys can never be accessed.

Physical address confidentiality. When using DMAAUTH only, the APAC pointer is based on a physical address. The confidentiality of the physical address can be achieved by adding a random offset to the physical address before signing the APAC pointer. The random offset is stored in the metadata and is used to recover the physical address when the APAC pointer is authenticated. When both DMAAUTH and IOMMU are enabled, confidentiality is guaranteed by the IOMMU.

5.4 Per-Mapping Metadata



The kernel gains full control over the DMA pointers with the APAC technique. However, the unused bits in the pointer are not enough to encode a pointer's bounds information. While these bounds information are essential for spatial protection. To resolve this problem, our key observation is that the kernel uses memory DMA mapping/unmapping APIs to grant/revoke memory from devices. Therefore, we propose generating metadata for each memory mapping and storing the bounds in the metadata for spatial protection. Moreover, we also store a unique per-mapping identifier in the metadata to provide temporal protection. Note that we propose using per-mapping metadata rather than per-buffer metadata, as the latter cannot differentiate two mappings on the same buffer, leading to temporal attacks.

With the per-mapping metadata, when signing the DMA pointers, DMAAUTH fetches the metadata and uses it as the modifier for generating the signature. When the device accesses memory with APAC pointers, the Authenticator checks the signature to defeat any temporal attacks. Moreover, while performing the integrity check, DMAAUTH hardware further fetches the bounds from the metadata and performs a bound check to defeat any spatial attacks. Here resides the challenge to maintain and locate the corresponding metadata of an APAC pointer. In the following, we first discuss the metadata format and then give the metadata positioning scheme.

5.4.1 Metadata Format

Each metadata is 128-bit, consisting of 5 fields in Figure 5a.

- The *R/W* permission field. This field contains two bits and encodes three permission types: read-only, write-only, and bidirectional. The Authenticator checks this field to thwart unprivileged read or write on the mapped buffers for each DMA.
- The *offset length* field marks the length of *offset* field in the APAC pointer, which is 5-bit, supporting 4GiB buffer size. This field informs the DMAAUTH hardware

(a) The format of a per-mapping metadata entry.

(b) Metadata positioning. DMAAUTH uses the signature embedded in the APAC pointer to index the metadata in the metadata table.

Figure 5: Metadata format and the positioning scheme.

of the length of *base* field that should be taken into the authentication when using the pointer for DMA.
- The *identifier* is a $(121-2L)$-bit random number generated when the kernel sets up the mapping. This field also resolves signature hash collisions of APAC pointers.
- The L-bit *lower bound* of the mapped buffer.
- The L-bit *upper bound* of the mapped buffer.

The two bound fields provide byte-level bounds for at most L-bit physical address, allowing mapping any part of the physical memory region for the peripheral devices.

5.4.2 Metadata Positioning

As mentioned, the Authenticator intercepts the DMA and performs integrity and bound checking. Then, the APAC pointer is used to locate the metadata of the corresponding mapped buffer. Our key observation is that the number of the coexisting mapped DMA buffers is small (≤ 435 in Table 1.), which is suitable to be held in a dedicated metadata table.

As shown in Figure 5b, we integrate dedicated storage in the Authenticator to hold the metadata table and make the metadata table *write-only* to avoid metadata leakage. The APAC pointer holds S-bit signature and uniquely locates the metadata in the table, which holds 2^S metadata entries.

In the *pre-transfer* stage (§2.1), the DMAAUTH-protected kernel is responsible for filling the metadata of a newly mapped buffer into the metadata table and avoiding index collision. If the identifier causes index collision, another random identifier is generated. Finally, the metadata is written to the corresponding entry in the metadata table via MMIO.

Then, in the *in-transfer* (§2.1), the Authenticator uses the signature in the APAC pointer to index the metadata and uses it to authenticate the pointer and check the bounds.

Select signature length. SoC designers can easily customize the size of the metadata table to achieve a balance between circuit cost and supported coexisting buffers. For embedded devices that don't have to support massive coexisting buffers, the signature length can be set to 10. The corresponding metadata table holds 2^{10} entries, requiring only 16KiB extra SRAM storage. For desktop SoCs, the metadata table can be set to 2^{16} entries and requires 1MiB SRAM, which is small compared to the L3 cache (128MiB for Ryzen 7950X3D). For server SoCs, whose L3 cache is even larger (1.1GiB for EPYC 9684X), DMAAUTH can have up to 22-bit signature with 2^{22} entries, leaving 42 bits to support 4TiB DRAM.

Advantages. For each DMA memory access, the Authenticator requires only one extra memory access to authenticate an APAC pointer. In contrast, the common IOMMU has to access the main memory four or five times for each address translation. As a result, DMAAUTH has a significantly better performance compared with IOMMU-protected systems, as will be elaborated in §7.2. Moreover, DMAAUTH requires less than 100 LoC changes in the Linux kernel and requires no change on the device driver at all. Therefore, DMAAUTH is totally transparent to the driver developers.

5.5 Working Together with IOMMU

DMAAUTH is designed to be fully transparent to the IOVA translation process and thus is compatible with IOMMU.

IOVA translation. As shown in Figure 3, the Authenticator is placed closer to the peripherals than the IOMMU. The IOVA-based APAC pointers are generated the same way as physical-address-based APAC pointers. In the *pre-transfer* procedure, the metadata generation and pointer signing are conducted *after* the mapping is created by walking the IOMMU page table. In the *post-transfer* procedure, the signature is checked and stripped off by the Authenticator *before* being sent to the IOMMU for IOVA translation. The hardware and software co-design of the DMAAUTH is interposed *between* the IOMMU mapping-creating process and the IOMMU hardware translation process without changing the input of both two processes. In this way, we ensure the transparency to the IOMMU.

Providing ATS. The Authenticator hardware is designed to intercept the ATS request(§2.2) sent by the peripherals and return a corresponding APAC physical pointer. In the *pre-transfer* procedure, this requires the kernel to add the metadata of both the physical address and IOVA to the metadata table. To correctly translate an APAC IOVA to an APAC physical address, we use another table for signature translation.

The underlying limitation is that the mapped buffer using ATS has to be continuous in both the IOVA space and physical address space. This is already guaranteed in the `dma_map` APIs in order to use IOMMU. We just need to instruct the `dma_alloc` APIs to allocate physically contiguous memory using the `kmalloc` instead of `vmalloc`.

6 DMAAUTH Implementation

DMAAUTH contains the Authenticator implementation and the kernel changes, as shown in Figure 3. We implement two versions of the Authenticator: the FPGA-based hardware

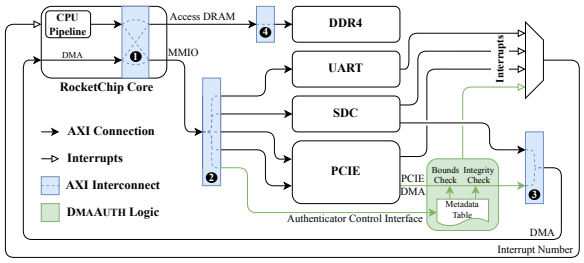


Figure 6: Hardware architecture of DMAAUTH. The green parts in the picture are the control and data path of the Authenticator. The blocks are connected via AXI protocol and are scheduled to transfer data by the AXI interconnects.

version and the QEMU-based emulator version. We implement DMAAUTH on Linux v6.1 kernel and implement the Authenticator to achieve fine-grained and transparent protection against malicious DMA-capable peripherals. The FPGA Authenticator is implemented with ~1500 lines of Verilog/Chisel. The emulator version adds ~200 lines of C code. The kernel changes are ~100 LoC with zero change on the device drivers.

We select the PCIe bus as our protected target for its high scalability and performance. We first construct a fully functional RISC-V SoC with PCIe 3.0 x8 based on the RocketChip core [7] as our baseline. We add pointer signing instruction `pacdma` to the core and Authenticator in Verilog to the bus, forming the DMAAUTH secure SoC prototype.

6.1 Authenticator Implementation

PCIe-customizable SoC implementation. To realize DMAAUTH on real FPGA, we first implement a fully-fledged RISC-V SoC with customizable PCIe support.The simplified schematic diagram is shown in Figure 6. The PCIe IP is officially supported by Xilinx and can be easily customized in Vivado GUI, making our design scalable for future research. However, the IP's lack of document support hinders it from being adopted by open-source SoC designs. We reverse-engineered the Xilinx PetaLinux[3] to configure the PCIe IP correctly, connect it to our SoC, and create the device tree.

The components in our design are connected using the AXI protocol, which is responsible for the *data transfer dispatching* and *cross-clock domain synchronization*. For data transfers, the AXI Interconnect ❶ receives access from the CPU and the DMA and determines whether it is access to the main memory or MMIO space, according to the address. If the address resides in the main memory region, the access is taken over by ❹ to read/write the main memory; otherwise, the access is determined as MMIO and guided to perform read/write access to the device registers by ❷. As the threat in our model, the PCIe device sends DMA requests to ❸, which can further forward the access to ❹ to access the DRAM.

[3] https://digilent.com/reference/software/petalinux

Synchronization between clock domains is also challenging since the design requires three different clock sources: CPU core clock, DDR4 clock, and PCIe clock. In particular, the PCIe clock requires a higher-quality differential signal, so we provide the signal with an external clock generator soldered on an FMC adapter. We use ❹ to synchronize between the CPU core and DDR4 DRAM. The synchronization between the CPU core and the PCIe is ensured by ❷ and ❸.

We use the `DefaultConfig` of the RocketChip generator, which has one `BigCore` with 16 KiB, 4-way set-associative instruction and data caches. The connection between the PCIe IP and the memory is limited to 100MHz with 64-bit data width to fully expose the throughput overhead introduced by the Authenticator. By intentionally making the host slower than the peripherals, we ensure that DMAAUTH acts as the system's bottleneck, facilitating a fair evaluation of its performance impact.

FPGA-based Authenticator implementation. As shown in Figure 6, the Verilog-implemented Authenticator is placed between the PCIe IP and next-level AXI interconnect to intercept and check all the DMA pointers from the PCIe bus. We decide to use 10-bit signature and 2^{10} metadata table entries because the single RocketChip core is more suitable for the peripherals in Table 1, which requires only ≤ 435 entries.

Firstly, the Authenticator has an AXI subordinate interface for the CPU to control it with MMIO. When the CPU accesses a specified range of addresses, it can write the key of the Authenticator and the metadata in the corresponding metadata entry in the metadata table, an FPGA block memory (BRAM) in our implementation. Notice that the CPU cannot directly read the metadata and key using MMIO to avoid metadata and key leakage. Especially, reading the occupied metadata entry returns `0x1`, and otherwise `0x0`, to allow the CPU and the kernel to resolve signature hash collision.

The Authenticator has another AXI subordinate interface to receive transactions from the PCIe IP. When the PCIe devices put Transaction Layer Packets (TLP) on the bus, the PCIe transforms the TLP into AXI access and then forwards it to the Authenticator. Notice that since the APAC pointers are transferred from the host to the peripherals, the peripherals use APAC pointers as target TLP addresses to perform DMA, and so are the AXI addresses sent by the PCIe IP.

Once the APAC pointer reaches the Authenticator, the authentication and bound checking described in step ❻ in Figure 3 is performed. The Authenticator has an AXI manager interface, which is responsible for forwarding the legitimate AXI transaction to the next-level AXI interconnect to perform DMA (step ❼ in Figure 3) and an interrupt signal to notify the CPU when the Authenticator detects a malicious DMA transaction. Once the interrupt is sent to the CPU, the corresponding trap handler in the protected kernel will further control the PCIe IP, forcing the peripheral to go offline.

We pipeline the authentication and data beats to reduce throughput overhead. Specifically, an AXI read burst consists

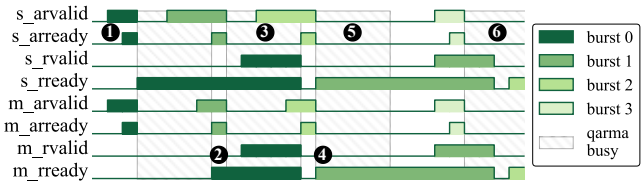

Figure 7: DMA read data transfer of the Authenticator. The diagram shows four AXI data bursts. The Authenticator receives DMAs launched by peripherals from the ports starting with `s` and forwards them to the next level via the `m` ports.

```
1 MemTxResult dma_memory_rw(AddressSpace *as, dma_addr_t addr, void
  ↪ *buf, dma_addr_t len, DMADirection dir, MemTxAttrs attrs) {
2   dma_barrier(as, dir);
3   dma_auth(addr, len, metadata);// Check signature and bounds.
4   addr = lower_54_bits(addr); // Strip the signature.
5   return dma_memory_rw_relaxed(as, addr, buf, len, dir, attrs);
6 }
```

Figure 8: APAC authentication in QEMU emulation. The signature is removed to make DMAAUTH transparent to the lower-level DMA logic.

of two processes: address handshake and data beats, which can be overlapped and pipelined as shown in Figure 7.

We apply two AXI-related optimizations. First, when the peripheral starts address handshake by setting `s_arvalid`, the Authenticator sets `s_arready` to finish it if the QARMA engine is not busy, as indicated at ❶ in Figure 7. The `m_rready` is set to allow the data beats when the authentication is finished at ❷. Thus, clock cycles between ❶ and ❷ are used to prepare the required data. Second, the authentication of burst 1 (❸) is finished during the data beats of burst 0, and hence the `m_rready` can be set once the previous data beats are finished at ❹. So does the authentication of burst 2 and burst 3 (❺, ❻). These two optimizations pipeline bursts for rapid transfer.

IOMMU baseline implementation. To ensure fair comparison in evaluation, we introduce IOMMU to our SoC baseline. The RISC-V Foundation recently released its IOMMU specification [1]. But the standard hasn't been implemented in the RocketChip generator [7]. We extend the IOMMU on CVA6 [59] to our SoC and keep only a 1-level device table and a 3-level page table in order to ensure the baseline has the minimum translation latency required by the specification.

We config the IOMMU to have 256 IOTLB entries to ensure that the IOTLB pressure will not be the bottleneck for the system. The AXI-related optimizations are also applied to pipeline handshakes and data beats to achieve better performance. Additionally, the IOTLB flush will not block the CPU, saving ~2000 cycles CPU time [3, 5] for each flush.

After the above optimization, the IOMMU has only 5.6% overhead on transfer throughput and 5.8% CPU time overhead using deferred invalidation. This overhead is lower than commercially applied IOMMUs, which have ~10% overhead in throughput and ~10% in CPU time [33]. The IOMMU baseline without any logic other than address translation and IOTLB caching has the lower-bound overhead and is used as the baseline for the performance comparison with DMAAUTH.

QEMU-based Authenticator Implementation. We also implement the Authenticator on RISC-V and ARM64 QEMU to show its cross-architecture compatibility and IOMMU compatibility. QEMU uses `dma_memory_rw` to perform DMA data transfer. This API is responsible for translating the DMA pointer (IOVA when IOMMU is enabled) into a physical address and read/write memory using it. *Before* the translation, authentication logic checks the access and strips off the signature on the high bits, as shown in Figure 8.

PAC Extension. To accelerate the APAC pointer signing process, we introduce pointer signing instruction extension `pacdma` to the RocketChip. `pacdma rd, rs1, rs2` takes the `rs1` as the pointer and `rs2` as the modifier to generate the APAC pointer and stores it to `rd`. The `rs1` is preprocessed to remove the *offset* part, and the `rs2` is preprocessed by XORing the higher 64 bits and lower 64 bits of the metadata. The QARMA engine is pipelined into 5 clock cycles to meet timing constraints and embedded as Rocket custom coprocessor.

6.2 Kernel Changes

The Linux kernel provides relatively uniform APIs for DMA operations, bringing convenience to our implementation. In general, the kernel uses the `dma_map` series APIs to grant access permission to the peripherals explicitly. As shown in Figure 9, the function checks whether the IOMMU is enabled and dispatches the DMA operation (Line 3-6) to call the direct helper function or creates an IOMMU mapping entry for IOVA translation. This dispatching corresponds to step ❷ in Figure 3. The driver uses the `dma_unmap` APIs to withdraw the access right from the peripheral. These functions also check whether the IOMMU is enabled and remove the translation entry from the IOMMU page table if IOMMU is enabled, as shown in Figure 10 (Line 5-8). Drivers utilize these APIs, so no modification of the driver source code is required.

Create Mapping. The `dma_map` takes an existing buffer as input and returns the corresponding DMA pointer as output. We let the API perform all the originally required operations. But before returning, the raw DMA pointer (physical address or IOVA) is signed with helper function `dma_auth_map` using the highlighted calls on Line 7 of Figure 9.

This metadata generation and pointer signing procedure is encapsulated in the helper function `dma_auth_map`. As depicted in Figure 3, the per-mapping metadata is generated (step ❸) in line 11 before calculating the APAC pointer (step ❹) in line 14. The helper function is also responsible for regenerating the identifier to resolve collision in the metadata table. Finally, in line 15, the metadata is inserted into the metadata table to be checked by Authenticator (step ❺).

```
1  dma_addr_t dma_map_page_attrs(struct device *dev, struct page
   ↪ *page, size_t offset, size_t size, enum dma_data_direction
   ↪ dir, unsigned long attrs) {
2    ...
3    if (dma_map_direct(dev, ops)) // No IOMMU, direct map.
4      addr = dma_direct_map_page(dev,page,offset,size,dir,attrs);
5    else // IOMMU enabled, add mapping in IOMMU page table.
6      addr = ops->map_page(dev, page, offset, size, dir, attrs);
7    addr = dma_auth_map(dev, addr, size, attrs);
8    return addr;
9  }
10 dma_addr_t dma_auth_map(struct device *dev, dma_addr_t addr,
   ↪ size_t size, unsigned long attrs) {
11   struct metadata *metadata = dma_auth_metadata(addr,size,attrs);
12   uint64_t base = dma_auth_mask(addr, metadata->offset_length);
13   while (dma_auth_slot_taken(apac >> 54)) // If slot occupied.
14     apac = dma_auth_apac(base, reshuffle_identifier(metadata));
15   dma_auth_write_metadata(metadata, apac >> 54);
16   return apac;
17 }
```

Figure 9: Generate an APAC pointer. The DMA pointer generated by the corresponding mapping function is an input to produce the signature with newly generated metadata.

```
1  void dma_unmap_page_attrs(struct device *dev, dma_addr_t addr,
   ↪ size_t size, enum dma_data_direction dir, unsigned long
   ↪ attrs) {
2    const struct dma_map_ops *ops = get_dma_ops(dev);
3    addr = dma_auth_unmap(addr); // R/W=0, shuffle identifier.
4    ...
5    if (dma_map_direct(dev, ops))//IOMMU disabled,direct unmap.
6        dma_auth_unmap_page(dev, addr, size, dir, attrs);
7    else if (ops->unmap_page) // IOMMU enabled, clear mapping.
8        ops->unmap_page(dev, addr, size, dir, attrs);
9  }
```

Figure 10: Withdraw access right. After resetting the R/W bits and changing the identifier, any DMA corresponding to the metadata will be considered to be outdated and malicious.

Withdrawing Access Right. The access right towards the mapped buffer should be withdrawn immediately from the peripherals when unmapping the buffer, as shown in Line 3 of Figure 10. To achieve this goal, we disable all access using the outdated APAC pointer by resetting the R/W bits and rerandomizing the identifier. Without both the read and write permission, the peripheral has no access right to the unmapped memory region. This invalidation takes effect immediately, resolving the temporal vulnerability caused by the deferred invalidation. The direct unmap process or IOMMU-related unmap is called to clean up the mapping (Lines 5-8).

7 Evaluation

In this section, we evaluate the security and performance of DMAAUTH. The result shows that DMAAUTH defeats various DMA attacks while introducing low-performance overhead.

7.1 Security Evaluation

We evaluate the security capability of DMAAUTH using six DMA attacks of different types, including the sub-page and deferred-invalidation attack, as shown in Table 2. The evaluation results show that DMAAUTH can defeat all of them.

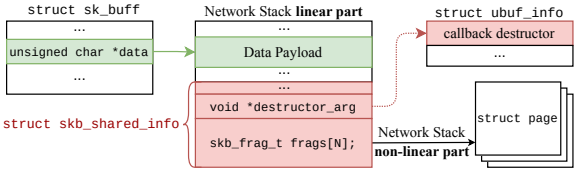

Figure 11: Memory layout of `sk_buff` structure. This data structure has been frequently exploited for sub-page attacks.

Table 2: Security evaluation.

Attack Information		Security Analysis		
Attacks	Type	Bare	IOMMU	Ours
❶ Full Memory Dump	Arbitrary Read	✗	✓	✓
❷ Denial of Service	Sub-page Write	✗	✗	✓
❸ Data Pointer Tampering	Sub-page Write	✗	✗	✓
❹ Control Flow Hijack	Sub-page Write	✗	✗	✓
❺ Information Leak	Sub-page Read	✗	✗	✓
❻ Access Unmapped	Temporal	✗	✗	✓

For the evaluation, we set up three settings based on Linux 6.1: one without IOMMU protection, one with IOMMU enabled, and one with DMAAUTH. We use an emulated malicious E1000E, which is adopted as the base of the Thunderclap platform to perform DMA attacks [31].

7.1.1 Defeating Spatial Attacks

We define a system to hold *spatial security* if the peripheral can only access the memory area that is mapped for it, i.e., realizing byte-level bounds to mitigate sub-page vulnerability.

Cases ❷ ❸ ❹ ❺ are the sub-page attacks that can be performed when IOMMU is enabled. All these attacks are implemented based on the structure `sk_buff`, a core implementation of the Linux network subsystem. As shown in Figure 11, the `sk_buff` struct carries data in its `data` field, which should be mapped to the NIC in streaming DMA. Different from previous works believing `sk_buff` is not an attack surface, further research [3] revealed that the `data` field of `sk_buff` has its memory organization with a linear part and a non-linear part. The descriptor of the non-linear part is stored immediately after the linear part in physical memory. These metadata structures are exposed to the NIC, making the DMA attack more powerful. In the following, we discuss these attacks in detail.

Case ❶: Full memory dump. The malicious device can easily dump the whole memory for the system without DMA protection. With IOMMU, the device can only access the mapped page, and this attack is defeated. DMAAUTH signs and authenticates all the DMA pointers and strictly restricts the pointers to their bounds, defeating the attack.

Case ❷: Denial of service. This attack is straightforward for a malicious NIC. It simply needs to blindly overwrite the entire page where the DMA buffer is located. Our experiments show that the host kernel always panics and crashes due to overwriting critical data pointers, even with the IOMMU.

Case ❸ Data pointer tampering and ❹ control flow hijack are similar. While the former one corrupts data pointers, while

the latter corrupts the function pointer. More specifically, for the control flow attack, the attacker first forges a fake `ubuf_info` structure in a writable area, holding a callback pointer with a code pointer to the intended malicious gadget. Next, the attacker overwrites the pointer in `skb_shared_info` with the address of the fake structure. This way, the attacker can launch a control flow hijack to execute any kernel code. Sadly, these two attacks cannot be defeated by IOMMU.

Case ❺: Information leak. In this case, the attacker can exploit data pointers in `struct skb_shared_info` to leak important information, such as the kernel heap base and the base of the `vmemmap` segment. This information can bypass kernel ALSR. Again, IOMMU cannot prevent this leakage.

In our experiments, DMAAUTH can defeat the attacks in ❷ ❸ ❹ ❺. More specifically, the out-of-bounds reads and writes of DMA buffers are blocked by DMAAUTH's byte-level granularity (compared to the page-grained IOMMU). In this way, DMA is strictly restricted to the mapped buffer.

7.1.2 Defeating Temporal Attacks

As mentioned in §2.2, the OS kernels may sacrifice the IOTLB consistency to reach better performance in practice because of the unacceptable overhead introduced by IOTLB flushing [5, 26, 29, 50]. This brings deferred invalidation vulnerability to the system. As for the system without IOMMU protection, no temporal protection is provided, and the peripheral can access a specific memory area at any time.

Case ❻: Access unmapped memory areas. After a deferred invalidation, peripherals can still access the unmapped pages in a time window. Even if the driver checks all critical data after unmapping, there would still be a time window that malicious peripherals can tamper with some critical metadata after the checking. If the unmapped memory area is reallocated for other objects, the peripheral can also access the newly allocated object to perform further attacks. When using the strict mode, IOMMU can defeat such attacks but will introduce unacceptable performance overhead.

With DMAAUTH, the metadata update takes effect and invalidates the outdated APAC pointer immediately by re-randomizing the identifier and resetting R/W bits, and achieves temporal security with or without IOMMU.

7.1.3 Defeating Pointer Forgery and Substitution

The malicious peripheral may try to forge a valid pointer to bypass the pointer authentication conducted by the DMAAUTH. But without the 128-bit key stored in dedicated DMAAUTH and CPU registers, it can only try to break the authentication by iterating different signatures in brute force, which has a success rate of $\frac{1}{2^S}$ and requires 2^{S-1} attempts on average. Any failed attempts in the brute force break will trigger an exception to the CPU, notifying to disable the malicious device.

The substitution attack is prevented because the outdated APAC pointer is invalidated since unmapping. Because our metadata table is write-only, the attacker cannot obtain the metadata to perform substitution. The write-only metadata, random identifier, and R/W bits realize defense in depth.

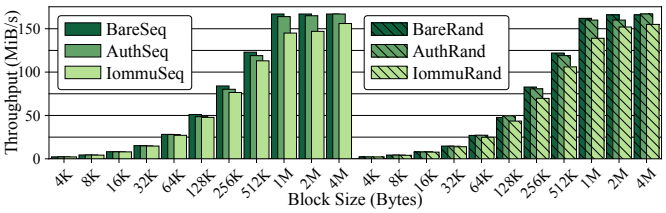
7.2 Overhead Evaluation

We evaluate the performance of the DMAAUTH based on our FPGA prototype elaborated in §6.1. We use an FMC adapter to connect our SoC to the real peripherals: an E1000E NIC and an NVMe SSD. The workload used in performance evaluation is the same as §4. We also compare the hardware overhead of DMAAUTH with the IOMMU[4]. We noticed that the Rocketchip random generator is the bottleneck and causes large performance degradation, so we use `jiffies` as the random source to reduce the overhead.

7.2.1 NVMe SSD Performance

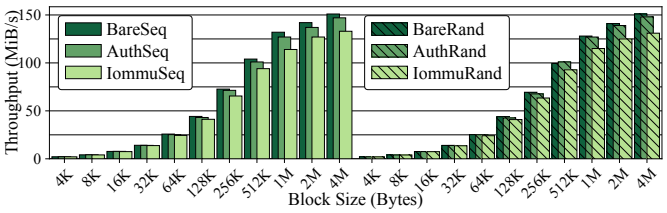
The NVMe SSDs are ubiquitous nowadays and are widely used in data centers and personal computers. We test the performance influence of DMAAUTH on the SAMSUNG 970 EVO Plus. With the tool `fio`, we test the sequential and random read/write performance with basic block sizing from 4KB to 4MiB by sending 1GiB of data in total with four threads.

Throughput evaluation. The throughput evaluation is based on the transfer speed the SSD can reach under different base block sizes. The results in Figures 12a and 12b reveal that the DMAAUTH introduces 1.4% overhead on average.



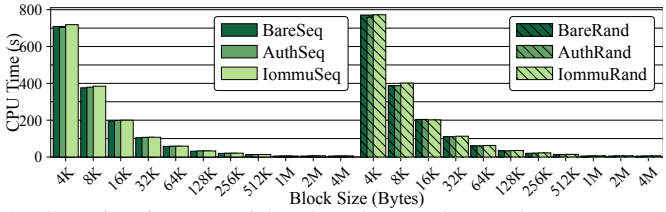
CPU runtime evaluation. DMAAUTH also introduces CPU runtime overhead for the metadata generation and APAC signing processes. We evaluate the cost by measuring the CPU time required to finish. The results in Figures 12c and 12d reveal that DMAAUTH introduces 1.0% extra CPU time.

7.2.2 Network Card Performance

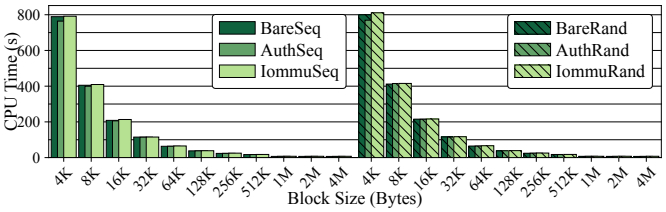


The Intel E1000E NIC has been proved to be an attack surface for DMA attacks [3]. We use a real E1000E card (Intel 82574) to test the performance influence of DMAAUTH on network cards. We use the network benchmark tool `iperf3` to send UDP packets from 16 to 1460 bytes to test UDP transfer performance; we also use this tool to perform TCP transfer tests in TCP window sizes ranging from 1KB to 128KB to reveal the performance degradation on the TCP stack.

Throughput evaluation. The TCP transfer throughput is shown in Figure 13a. The UDP transfer throughput is shown in Figure 13b. The DMAAUTH introduces 1.2% overhead in TCP throughput and $< 0.1\%$ overhead in UDP throughput.



[4] https://github.com/zero-day-labs/riscv-iommu



(a) Throughput in sequential and random read test. The DMAAUTH's average overhead is 1.3%, which is 82.7% less than IOMMU. The worst-case overhead of DMAAUTH is 8.6%.

(b) Throughput in sequential and random write test. The DMAAUTH incurs an average 1.4% overhead and is 79.3% less than IOMMU. The worst-case overhead brought by DMAAUTH is 3.8%.

(c) CPU time in sequential and random read test. The DMAAUTH operates with an average 1.1% overhead and is 81.9% smaller than IOMMU. The worst-case overhead introduced by DMAAUTH is 8.6%.

(d) CPU time in the sequential and random write test. The DMAAUTH carries an average 0.9% overhead, which is 81.2% less than IOMMU. DMAAUTH's worst-case overhead is 5.3%.

Figure 12: Performance evaluation on NVMe SSD. Combining the read and write test, the DMAAUTH introduces a 1.4% overhead in throughput and 1.0% overhead in CPU runtime on average, which are 81.0% and 81.6% less than IOMMU respectively.

Table 3: Hardware Resource Overhead.

Component	LUTs	FFs	BRAM
Bare SoC	69073	58605	58.5
DMAAUTH	4127 (5.9%)	4306 (7.3%)	4.0 (6.83%)
IOMMU	28432 (41.1%)	19477 (33.2%)	0

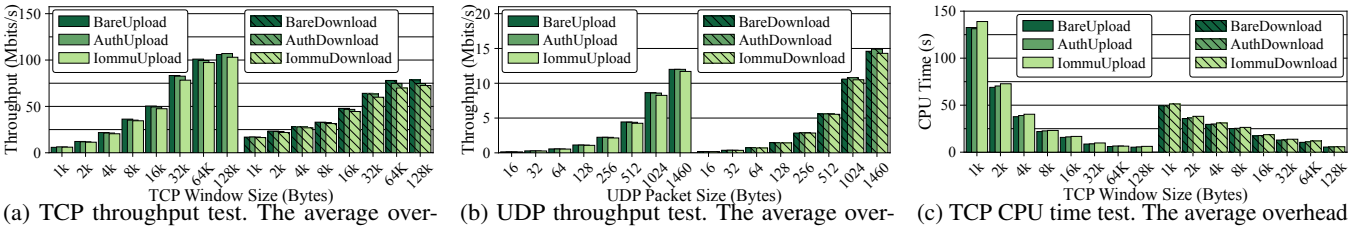
CPU runtime evaluation. We evaluate the CPU runtime head by measuring the CPU time required to finish transferring 1Gbits data. In the UDP transfer speed test, the CPU time equals the total transfer time, so it can be revealed in Figure 13b. The TCP runtime overhead is shown in Figure 13c. The DMAAUTH introduces 2.6% overhead in CPU time.

7.2.3 Comparison with IOMMU

As illustrated in §6.1, the IOMMU baseline ported to our SoC has 5.6% throughput overhead and 5.8% CPU runtime overhead, which is faster than the commercially applied SoCs' IOMMUs for its simplicity [11, 33]. Our evaluation shows that DMAAUTH only introduces an average 1.0% throughput degradation based on the NVMe SSD and E1000E NIC. The CPU runtime overhead is 1.8%. When the IOMMU operates in the deferred mode, DMAAUTH is 82.1% faster in throughput and 68.9% faster in CPU runtime.

We use Vivado[5] 2022.1 to synthesize the RTL and report circuit overhead and extra static power consumption as shown in Table 3. The DMAAUTH introduces 5.9% LUTs, 7.3% FFs, and 6.83% BRAMs overhead, while the IOMMU introduces 41.1% LUTs, and 33.2% FFs overhead when having 4 IOTLB, 4 DDTC and 4 PDTC entries in LUTs. DMAAUTH's BRAM overhead is due to the metadata table, which is used to store the per-mapping metadata.

[5] https://www.xilinx.com/products/design-tools/vivado



The SoC equipped with the DMAAUTH consumes 0.575W static power, which is 0.012W higher than the bare SoC. The extra power usage is about 2.1% of the bare SoC.

DMAAUTH requires on-chip storage for the metadata table, and the IOMMU requires on-chip storage to cache IOTLB and PTE. The SoC designer can adjust the size of the metadata table considering the number of DMA mappings according to the chip use case, as described in §5.4.2, to make the overhead acceptable compared with L3 cache or other on-chip storage. For the IOMMU, the size of the IOTLB and PTE cache should also be carefully chosen by SoC designers to balance the performance and overhead.

8 Related Work

DMA protection. DMA attacks have emerged for decades, but this threat is sometimes considered an out-of-scope problem or future work requiring research [16, 41, 45, 48, 57].

For systems with the basic protection of IOMMUs, there are works to thwart existing attacks using dedicated space for I/O operations [32], but this approach disables zero-copy and introduces significant performance overhead (20% CPU time and up to 25% throughput overhead). DAMN [33] kept zero-copy and reached better performance (10% throughput overhead). Kernel bypassing is enabled by DAMN to reach less CPU time than bare systems that disable such bypassing. However, the comparison when the bare system enables kernel bypassing is not conducted. DAMN's approach requires dedicated modification for each peripheral type and brings unacceptable manual workloads, making it not realistic to be applied in real-world OSes. These methods provide the same security guarantees as DMAAUTH but have larger overhead.

(a) TCP throughput test. The average overhead is 1.21% and is 76.5% smaller. The worst-case overhead of DMAAUTH is 4.8%.

(b) UDP throughput test. The average overhead $< 0.1\%$ while the IOMMU has a 3.1% overhead. The worst-case overhead is 1.8%.

(c) TCP CPU time test. The average overhead is 2.6%, which is 65.5% less than IOMMU. DMAAUTH's worst-case overhead is 9.0%.

Figure 13: Performance evaluation on E1000E NIC. Combining the TCP and UDP test, the DMAAUTH introduces 0.6% overhead in throughput and 2.6% overhead in CPU time on average, which are 85.3% and 65.5% less than IOMMU, respectively.

Fundamental modifications to IOMMUs are also proposed to realize find-grained protection. The novel hardware architecture is positioned into CHERI to enforce strong protection against DMA attacks [30]. But this requires radical modification towards existing hardware, and has not become available. Apple Inc. introduced byte-level protection into its IOMMU standard Device Address Resolution Map (DART) [42]. However, these solutions lack Linux support and face temporal vulnerabilities. Modifying hardware to make memory regions inaccessible for peripherals [35] is viable for embedded systems but not for time-tested complex OSes. AI-based methods are also introduced to defeat DMA attacks [19] but bring false positives and cannot provide deterministic protection. There have also been static and dynamic analysis tools detecting spatial and temporal vulnerabilities to help the developers improve memory hygiene [3].

Pointer integrity. Pointer integrity mechanisms are widely adopted in protecting embedded systems [43, 62], user space programs [28, 60], or the OS kernels [55]. It was first used to ensure control flow integrity by thwarting attackers from tampering with code pointers via software approaches [24, 43, 60, 62]. As new security features were introduced into modern computer systems, an increasing number of mechanisms were used to ensure pointer integrity, e.g., memory tagging [18] and pointer authentication [22, 28, 47]. Researchers are working on pointer integrity mechanisms to ensure better security [20].

However, the DMA attacks confront us with a distinct scenario: the CPU shall not participate in the actual data transfer procedure, making the methods mentioned above unavailable. These methods don't support pointer arithmetic and are thus incompatible with existing peripherals.

Memory protection. Corrupting memory was the oldest attack in the development of computer science and gave birth to various delicate exploit techniques and well-designed protection countermeasures [49, 58, 61].

To provide spatial protection, some mechanisms associate bound metadata with the objects and perform bound checking when conducting pointer arithmetic to restrict the pointer in the object [2, 27, 44, 56]. Some others are pointer-based and encode metadata into the pointers, using fat pointers [23, 39, 53] to store bound information or store it separately [17, 37], and check bounds when dereferencing the pointers.

Temporal vulnerabilities are mitigated by associating the allocation metadata with the allocated object [40, 46] or the output pointer [36, 38], but recording the metadata for each object fails to detect outdated pointer dereferences if the same memory area is reallocated for other objects.

Our mechanism is inspired by these memory-protection schemes, but it is not limited only to spatial or temporal. To provide spatial protection, it integrates the bound information in the metadata and uses redundant spatial information (*length* field) to provide extra protection and resilience. Also, each APAC pointer is associated with a mapped buffer and a write-only identifier via the signature encoded in the high bits to defeat temporal attacks and substitution attacks.

9 Conclusion

In this paper, we propose a lightweight pointer integrity-based security architecture named DMAAUTH, which achieves byte-grained protection on DMA memory and thus can defeat various DMA attacks, including the sub-page and the deferred-invalidation attacks. According to the findings from our characterization of DMA behavior, we design the novel Arithmetic-capable Pointer Authentication technique to ensure pointer integrity while allowing pointer arithmetic.

To verify the feasibility and performance of DMAAUTH, we realize the dedicated hardware Authenticator on the FPGA-based RISC-V SoC we implemented, which supports customizable PCIe. We also implement the Authenticator on the RISC-V and ARM QEMU to show DMAAUTH's cross-architecture capability. The implementation and evaluation prove that DMAAUTH outperforms IOMMU in both security and performance observably while staying transparent to IOMMU and device drivers.

Bending microarchitectural weird machines towards practicality

Ping-Lun Wang, Riccardo Paccagnella, Riad S. Wahby, and Fraser Brown
Carnegie Mellon University

Abstract

A large body of work has demonstrated attacks that rely on the difference between CPUs' nominal instruction set architectures and their actual (microarchitectural) implementations. Most of these attacks, like Spectre, bypass the CPU's data-protection boundaries. A recent line of work considers a different primitive, called a *microarchitectural weird machine* (μWM), that can execute computations almost entirely using microarchitectural side effects. While μWMs would seem to be an extremely powerful tool, e.g., for obfuscating malware, thus far they have seen very limited application. This is because prior μWMs must be hand-crafted by experts, and even then have trouble reliably executing complex computations.

In this work, we show that μWMs are a practical, near-term threat. First, we design a new μWM architecture, Flexo, that improves performance by 1–2 orders of magnitude and reduces circuit size by 75–87%, dramatically improving the applicability of μWMs to complex computation. Second, we build the first compiler from a high-level language to μWMs, letting experts craft automatic optimizations and non-experts construct state-of-the-art obfuscated computations. Finally, we demonstrate the practicality of our approach by extending the popular UPX packer to encrypt its payload and use a μWM for decryption, frustrating malware analysis.

1 Introduction

Modern processors achieve impressive performance through astonishing complexity. In the last two decades, however, it has become clear that this complexity threatens to completely undermine memory isolation, which is crucial for nearly every aspect of software security. This realization followed the discovery of numerous microarchitectural attacks capable of leaking sensitive information—in the worst case, an entire program's memory—even in the absence of software bugs [3–8, 13, 15, 21, 26, 31, 34, 39–54, 57–60, 64, 66–69, 72, 76–78, 80, 82, 84, 85, 87, 89, 90, 92, 94–100, 104, 105, 109–111, 113, 116–118, 126–128, 130, 133–136, 139–141].

These attacks stem from the difference between the abstraction the processor is *intended* to expose and the abstraction that its implementation *actually* exposes—a gap that is primarily the result of complexity in service of performance. As an example, a recent wave of microarchitectural attacks relies on the fact that the CPU may transiently execute code that, per the semantics of the instruction set architecture (ISA), it should not [13, 21, 52, 57, 66–69, 77, 80, 84, 85, 97–100, 105, 113, 116–118, 127, 128, 139]. While the ISA guarantees that architectural state (e.g., the contents of registers and memory) does not reflect such transient execution, it makes no promises about implicit, microarchitectural state (e.g., the contents of the cache or the internal state of the CPU's branch prediction machinery). Crucially, although this microarchitectural state is not exposed by the ISA, programs can nevertheless modify and observe this state (e.g., through timing measurements that reveal cache residency). The result is that the *actual* processor architecture is a strict superset of the *intended* one (i.e., the ISA)—and that superset can give attackers superpowers.

A processor's superset-of-ISA functionality is an instance of the *weird machine* paradigm [11, 17, 35, 36] which considers, for a given system, a "weird system" that extends the system's intended behavior with its unintended but observable behavior. This paradigm formalizes the notion that an attacker's interaction with a system is bound by its *actual* implementation, not by the designer's intent. For CPUs, the past two decades have demonstrated empirically that securing the ISA is insufficient: it is the entire weird system—the ISA plus observable microarchitecture—that must withstand attacks.

One recent line of work [38, 62, 63, 123, 125] explores *microarchitectural weird machines* (μWMs)—code gadgets that perform computation purely through microarchitectural side effects.[1] μWMs resist analysis, both because they leave little or no trace in the CPU's architectural state and because they are essentially invisible to conventional debuggers (as one

[1] Calling this code a weird machine is arguably an abuse of terminology: strictly speaking, the code executes *on* the computational substrate exposed by the weird superset of the ISA that is inherent in the CPU's microarchitecture. We nevertheless follow colloquial usage and call the code gadgets μWMs.

example: single-stepping through a μWM destroys the computation). At first blush, such stealthy computation seems as if it should lead to attacks at least as powerful as prior work focused on crossing data-protection boundaries (e.g., Spectre [68] and Meltdown [77]); indeed, prior work predicted that μWMs would see widespread use in applications like malware obfuscation. To date, however, their only applications have been clever but somewhat narrow: obfuscating simple computations like 160-bit XOR and 2-block SHA-1 [38], and improving cache side-channel attacks [62, 63].

This motivates our research question: *is there any reason to worry that μWMs can be made practical?*—and thus, is there any reason to invest effort in developing countermeasures? By practical, we mean two specific criteria, neither of which has been satisfied by prior work. First, it should be possible to build μWMs that reliably compute *complex* functions with reasonable performance across a range of microarchitectures. Second, such μWMs should be broadly usable, not limited to a handful of experts who painstakingly hand-craft weird functionality. In this paper we address these challenges, then answer our motivating question in the affirmative by building a malware packer that uses μWMs to hinder analysis (§6).

In prior work, reliability of μWMs on complex computations is a thorny issue: a μWM's reliability tends to fall off precipitously as the size of the computation increases. While prior work has explored techniques for detecting and correcting errors, these tend to dramatically increase a computation's execution time even when no error occurs. Our μWM design (§3), somewhat unintuitively, starts with a more costly *differential* logic encoding (i.e., one in which each bit is represented by the difference between two "wires"). Although this seems like it should make scaling more difficult, it has the effect of making error detection and logical inversion nearly free—and since these were by far the *most costly* primitives in prior work (§2.2), the result is dramatically improved scaling.

This μWM design, which we call Flexo, is also far more generic than prior work: rather than implementing a family of small logic gates, we give a design that can compute *any* N-input boolean function (N is determined by the CPU; our testbed machines can handle 4-input functions; §3.1, §5). This makes our design particularly suitable as a compilation target, a fact we leverage in our first-of-its-kind μWM compiler (§4). Our compilation toolchain, which extends LLVM [73], consumes C/C++ code and emits an assembly Flexo implementation. Beyond making Flexo accessible to non-experts, our compiler makes it possible to create μWM-specific optimization passes; we implement one as a proof of concept.

In summary, we make the following contributions:

- We propose a new circuit design for μWMs that reduces circuit size by 75–87%, resulting in 1–2 orders of magnitude speedup. Our design enables bit-wise error detection and correction—in one case improving a circuit's accuracy from 0.3% to 99.9%—while imposing almost no overhead for circuits with high uncorrected accuracy.
- We design a compiler that can turn high-level C/C++ code into a μWM and use it to compile the SHA-1 hash and the AES and Simon ciphers into μWMs.
- We present a weird machine packer that uses Flexo to obfuscate UPX's [88] unpacking process. Our packer encrypts the packed executable, which a μWM later decrypts at runtime. The packer currently supports AES and Simon decryption modules, which we implement in under six hundred lines of C—but our compiler makes it easy to build different obfuscated encryption schemes.

2 Background and related work

This section discusses transient execution (§2.1), upon which we (and others) build microarchitectural weird machines (§2.2). We discuss related work on circuit compilers in Section 4, and likewise for binary packers in Section 6.

2.1 Transient execution

Transient execution occurs when a processor executes *transient instructions* that are never committed to the architectural state [22]. Even though they do not change architectural state, transient instructions can leave traces in the microarchitectural state (e.g., the cache), and these traces can be observed by an attacker using microarchitectural side channels [3–8, 15, 26, 31, 34, 39–51, 53, 54, 58–60, 64, 72, 76, 78, 82, 87, 89, 90, 92, 94–96, 104, 109–111, 126, 130, 133–136, 140, 141]. This behavior is the foundation of *transient execution attacks* [13, 21, 52, 57, 66–69, 77, 80, 84, 85, 97–100, 105, 113, 116–118, 127, 128, 139], in which attackers exploit transient execution to access and leak program data. We adopt prior work's terminology and define the *transient window* as the period of time during which a processor executes transient instructions (e.g., following a branch misprediction or a fault). The *length* of a transient window depends on the time required for the processor to realize that the instructions executed within it were, in fact, transient and should be discarded.

As a concrete example of transient execution—in fact, the kind that our compiler targets (§4)—consider transient execution due to return address misprediction [69, 80]. The return stack buffer (RSB) is a small per-core structure that predicts the target of `ret` instructions. The RSB stores the address of each instruction that follows a `call` instruction, predicting that the calls will return to the addresses it has stored. The prediction is *usually* correct—except when a function overwrites its return address during execution. In such cases, the processor transiently executes at the (mispredicted) address stored in the RSB until it knows the function's real return address. The length of the transient window, therefore, depends on the time the function takes to compute and load its

actual return address. By computing that return address using different sequences of high-latency instructions, an attacker can tune the length of the transient window.

2.2 Microarchitectural weird machines

Microarchitectural weird machines (μWMs) run computations that are, in theory, invisible to architectural state: they use cache residency information to store values, and transient execution and microarchitectural side channels to compute on those values.[2] The first μWM [38] relied on Intel TSX for transient execution and could obfuscate 160-bit XOR and 2-block SHA-1. However, it was relatively slow (26.5 min to run 2-block SHA-1) and leaked about 40% of its intermediate values to architectural state. Subsequent work improved μWMs' construction and expanded their applications [62, 63, 125]. Wang et al. [125] show that any transient primitive (e.g., exceptions and branch predictors) can create μWMs, and that both x86_64 and ARM CPUs can execute them. Kaplan [62] and Katzman et al. [63] build μWMs that amplify cache side-channel signals, and Katzman et al. [63] also present μWMs that are much faster (923 ms to run 2-block SHA-1) and stealthier (leaking about 1% of intermediate values to architectural state) than prior work.

Computational model μWMs compute on *weird registers*, registers stored in microarchitectural state. Each weird register can store a binary value and is associated with a cache line. The value of a weird register is determined by the *cache residency* of its cache line: if its line is in the cache, the weird register value is '1'; if not, the weird register value is '0'. In other words, weird registers are memory addresses that store values in microarchitectural (i.e., cache) state, rather than using main memory to store values in architectural state.

To set the value of a weird register to '1,' a μWM must bring the register's cache line into the cache by loading or storing its memory address. To set the value of a weird register to '0', a μWM must remove its cache line from the cache by flushing its memory address (e.g., using `clflush`[3]).

μWMs use transient execution to execute code gadgets that modify the values of weird registers. These gadgets (or "weird gates" or "circuits") implement boolean functions with one or more input registers and a single output register. In the following, we give examples of basic gates that, e.g., set the value of an output weird register when both input registers are '1.' In these examples, the input registers always have an all-zeros architectural value (i.e., the value in main memory), and the output weird register's microarchitectural value is initially '0' (i.e., flushed from cache).

`AND` and `OR` gates Prior work [63, 125] builds `AND` and `OR` gates by exploiting the time difference between (fast) cache hits and (slow) cache misses. Listing 1, for example, shows a weird gate that computes output `Out[0]` as `In1[0] AND In2[0]`—so `Out[0]` ends up in the cache (i.e., as '1') only if `In1[0]` and `In2[0]` were in the cache (i.e., were '1') to begin with. To execute this code, the processor checks the cache for both weird registers, and fetches them if they are not there. It uses the architectural values of these registers to compute the address of `Out[0]`, which it then fetches into cache. Therefore, if the transient window is shorter than the cache miss latency, the output weird register will end up in cache *only if* both input registers are already in cache; otherwise, the processor will not have time to pull the output register into cache (i.e., set its value to '1') before transient execution ends. Building a correct gate requires controlling the length of the transient window; see the prior section for more detail on controlling this length.

```
1 Out[In2[In1[0]]] = 0;
```

```
1 Out[In1[0]] = 0;
2 Out[In2[0]] = 0;
```

Listing 1: The `AND` gate (left) and the `OR` gate (right). The output is initially not in the cache, and the inputs have architectural values set to zero. These gates are executed in transient execution.

`NOT` gate Prior work [62, 63, 125] uses μWMs to implement the `NOT` gate in Listing 2, with input weird register `In[0]` and output register `Out[0]`. This gate controls the length of the transient window so that the processor only fetches the output into the cache when the input *is not* in the cache. The first step (not pictured) is training the branch predictor to take the false branch at line one and jump straight to line two. Then, when the weird gate executes, the branch predictor mispredicts the branch and transiently executes line two. If `In[0]` is in cache ('1'), the processor can resolve the branch target quickly. This *does not* give the processor time to pull `Out[0]` into cache, since `delay` is a function that takes more time than a cache hit (but less than a cache miss) to compute. In contrast, when `In[0]` is not in cache (i.e., '0'), the processor has time to bring `Out[0]` into cache (i.e., make it '1').

```
1 if (In[0] == 0) return; // trained to go to line 2
2 Out[delay(0)] = 0; // cache hit < delay < cache miss
```

Listing 2: The `NOT` gate. The output is initially not in the cache, and the input has the architectural value set to zero.

Executing more complex logic in a single transient window So far we have discussed executing a single, one- or two-input gate per transient window. In practice, it is more efficient to execute as much weird computation as possible within a single transient window. For example, Listing 3 uses an `AND` gate

[2] Note that constructions that do not rely on the cache (as mentioned in [38]) or on transient execution (as shown in [137]) are also possible.

[3] Or e.g., `DC CIVAC + DSB SY` on ARM.

and an OR gate to compute Out[0] = (In1[0] ∧ In2[0]) ∨ In3[0] within one transient execution.

```
1 Out[In1[In2[0]]] = 0;
2 Out[In3[0]] = 0;
```

Listing 3: A composed AND and OR gate. The output is initially not in the cache, and the inputs have architectural values set to zero. This gate is executed in transient execution.

Unfortunately, with the constructions discussed in this section, it is impossible to compose inverting and non-inverting gates (e.g., AND and NOT) within one transient execution. While non-inverting gates use a fixed transient window length that is slightly shorter than the cache miss latency, inverting gates have a window length that depends on their inputs. Therefore, choosing a specific transient window length for the *composition* of both gates would break one gate or the other. As a result, building most complex functionality has in all prior work required executing weird computations in many distinct transient windows of distinct length.

3 New circuit construction

We propose a new weird circuit construction, Flexo, for computing arbitrary N-input, one-output boolean functions within a single transient execution. The number of inputs, N, is architecture-dependent; the x86_64 machines we evaluate in this paper support 4-input functions (§3.1, §5).

Flexo uses a *differential* (or *dual-rail*) encoding [115, Ch. 9], wherein a logical value is represented as the *difference* between two "wire" values. Here, a wire is exactly a weird register, and its value is stored as cache residency information. At first glance, using twice as many wires seems wasteful—and for simple boolean functions like AND and OR, it is. But when expressing more complex functionality, the benefits of our generic, high-level computational primitive outweigh the costs (§5). Specifically, Flexo improves:

- **Performance**. Prior work implements complex functionality by composing a small set of simple gates (e.g., AND, OR, and NOT [38, 62, 63, 125]); in general, such compositions span multiple transient executions. Implementing the same functionality with Flexo uses *fewer*, more complex gates, each taking a single transient execution. Empirically, this yields smaller, faster circuits. For example, all prior work computes 2-input XOR by composing (at least) five transient executions; Flexo computes 4-input XOR in a *single* execution.
- **Accuracy**. Since circuits built from Flexo gates are more concise than existing constructions, they are less susceptible to errors caused by microarchitectural noise. Further, even when errors happen, Flexo's differential encoding makes them easy to detect (and thus correct!): since only two of the four possible configurations for a gate's output value are valid, the other two configurations indicate an error in the gate's execution (§3.2).
- **Flexibility**. Because Flexo can implement *any* N-to-1 boolean function (for our testbeds, $N = 4$; §5), it is an easier compilation target than prior designs: our compiler synthesizes a set of 4-input truth tables, then implements them directly. We discuss further in Section 4.

Looking ahead, Section 5 shows that Flexo reduces circuit size by 75–87%, contributing to its 17% higher accuracy and 25× faster runtime compared to the prior state of the art [63]. In this section, we define our encoding (§3.1), then outline how this encoding makes error detection simple (§3.2) and how we optimize Flexo gates (§3.3) for accuracy.

3.1 Differential encoding

We use a classical differential encoding, which represents a logical boolean value (i.e., `true` or `false`) as the difference of two wire values (recall that our wire values are stored in weird registers; §2.2). One wire suffices to encode a boolean value: when the wire has a high value (H), we usually say it encodes `true`, and likewise for a low value (L) and `false`. In contrast, a differential encoding represents a boolean value w with two wire values, w_- and w_+, such that $w_- \neq w_+$. To represent $w =$ `false`, we choose $w_-w_+ =$ HL, and likewise $w =$ `true` is represented as $w_-w_+ =$ LH. Since there are four possible states for the combination of two wires (i.e., $w_-w_+ \in \{\mathsf{HH}, \mathsf{HL}, \mathsf{LH}, \mathsf{LL}\}$), w_-w_+ can also represent two *invalid* states (i.e., when $w_- = w_+$).

Representing boolean functions with differential encodings Consider a boolean function $o = f(i_1, \ldots, i_N)$, where $o, i_1, \ldots, i_N \in \{\texttt{true}, \texttt{false}\}$. We can think of a differential gate computing f as a pair of boolean expressions, one that computes each of the differential output wires, i.e., $o_- = f_-(i_{1-}i_{1+}, \ldots, i_{N-}i_{N+})$ and $o_+ = f_+(i_{1-}i_{1+}, \ldots, i_{N-}i_{N+})$, where $f_+ = f$ and $f_- = \neg f$.

Deriving expressions for f_+ and f_- is straightforward: first, expand the logical expressions for f and $\neg f$ to minterm canonical form (i.e., to a sum of products). Next, replace each non-negated variable v with that variable's v_+ wire, and each negated variable w with that variable's w_- wire. The result is a pair of inversion-free expressions that compute o_-o_+. Logical manipulations like these are used extensively by electronic design automation (EDA) toolchains, e.g., tools used to program field-programmable gate arrays (FPGAs) [19, 79, 129]; our compiler (§4) uses Yosys [129] for this procedure.

As a concrete example of differential encoding, consider the AND gate $o = f(i_1, i_2) = i_1 \wedge i_2$. We have that $\neg f(i_1, i_2) = \neg(i_1 \wedge i_2) = \neg i_1 \vee \neg i_2$, where the latter expression is the minterm canonical form, meaning that the following pair of

```
Out_p[In1_p[In2_p[0]]] = 0;
Out_m[In1_m[0]] = 0;
Out_m[In2_m[0]] = 0;
```

Listing 4: A differential μWM for AND. o_+ and o_- correspond to Out_p and Out_m, and likewise for i_1, In1 and i_2, In2.

```
Out_p[In1_p[In2_m[0]]] = 0; // XOR(1, 0) = 1
Out_p[In1_m[In2_p[0]]] = 0; // XOR(0, 1) = 1
Out_m[In1_p[In2_p[0]]] = 0; // XOR(1, 1) = 0
Out_m[In1_m[In2_m[0]]] = 0; // XOR(0, 0) = 0
```

Listing 5: A differential μWM for XOR. o_+ and o_- correspond to Out_p and Out_m, and likewise for i_1, In1 and i_2, In2.

expressions implements the differential gate in terms of the differential inputs: $o_+ = i_{1+} \wedge i_{2+}$ and $o_- = i_{1-} \vee i_{2-}$. Listing 4 shows our implementation of gate as a μWM using the basic AND and OR gadgets from Listing 1 (§2.2).

As a slightly more complex example, consider XOR, i.e., $o = f(i_1, i_2) = (i_1 \vee i_2) \wedge \neg(i_1 \wedge i_2)$. Following the process above, we have $o_+ = (i_{1+} \wedge i_{2-}) \vee (i_{1-} \wedge i_{2+})$, $o_- = (i_{1+} \wedge i_{2+}) \vee (i_{1-} \wedge i_{2-})$. Listing 5 shows our implementation of this gate, which computes XOR in a *single* transient execution—something that no prior work has been able to achieve.

How many inputs can Flexo support? As with all μWMs, the complexity limit for Flexo gates is dictated by the length of the CPU's transient window. Compared to prior work, however, Flexo is much less sensitive to the logical function being calculated. In particular, prior work uses a cascade of gates to implement functionality that inverts inputs or intermediate states (§2.2). In most cases, such compositions span multiple transient windows, reducing speed and accuracy. In contrast, as described above, Flexo's differential encoding lets it compute logical functions directly as a sum of products of the differential input values.

Speaking generally, the cost to evaluate a sum of products depends on the number of terms and the number of variables per term. Every N-to-1 boolean function f has at most 2^N minterms in total between the f_+ and f_- expressions (i.e., at most one term per truth table entry), where each term depends on at most N variables (i.e., an input or its negation).[4] The XOR gate (and its generalization to N inputs, which computes the sum of inputs mod 2) is an example of a maximal-cost gate: for any N, N-input XOR has 2^N minterms in total between f_+ and f_-, with N variables per minterm.

[4] A simple counting argument shows that, as N grows, most N-to-1 functions must be close to the maximum size. This is why we consider generic N-to-1 functions: while it might be possible to squeeze a bit more performance out of Flexo by considering a subset of, say, $(N+1)$-to-1 functions, most of the time we expect that the payoff will be small. We leave detailed investigation and further optimization to future work.

Thus, if a given CPU supports Flexo's XOR on N inputs, Flexo can compute any N-input function. Our experiments show that the eight x86_64 testbed architectures on which we evaluate (§5, Table 1) can correctly evaluate at most a 4-input XOR (and thus, any 4-input boolean function) in a single transient execution. Other microarchitectures may differ.

3.2 Bit-wise error detection and correction

Flexo's differential encoding gives bit-wise error detection "for free," and lets us build accurate error correction that does not impose high overhead. Prior work [38, 63] implements error correction with majority-of-five voting, which requires re-running a circuit five times to produce a final, error-corrected output. In this approach, however, error correction does not scale with the accuracy of the underlying circuit: it imposes unnecessary overhead for already-accurate circuits and may not run enough error-correction rounds to correct inaccurate circuits. Flexo overcomes these limitations by dynamically re-executing a circuit *only* when it detects an error. Section 5 shows that this approach has small overhead ($\approx 1.8\%$) for circuits with good accuracy yet can correct extremely low accuracy—in one case, improving a circuit with 0.3% uncorrected accuracy to 99.9%.

Error detection Since our differential encoding only allows two valid output states (HL and LH), the other two states (HH and LL) signal an error in the circuit's execution. This can happen when a prefetcher fetches both wires in the cache, or when both wires are evicted from the cache. While all invalid states indicate an error, not all errors cause invalid states. Immediately below, we discuss the way we overcome this limitation with a careful application of majority voting.

Error correction When Flexo detects an error in the output bits of a circuit, it needs to re-run that circuit to correct the error. The naive approach is to re-run the circuit until a single run produces a completely valid set of output bits; for a three-output circuit, this means that one run must produce three valid outputs. For better performance, though, we save the results of every valid output bit over the repeated circuit executions—and only re-run the circuit until there *exists* a valid bit for every output. If one run of a three-output circuit produces two valid bits and another produces the third, for example, we can stop re-running the circuit: we have saved three valid output bits over the course of the two runs.

While differential encoding can detect errors leading to invalid outputs HH or LL, it cannot detect errors that lead to valid (but incorrect) outputs. This could happen, for example, if the overall result of a computation should be HL, but some errors cause the computation to incorrectly output LH. To address this problem, we run a majority vote for each output bit in the circuit. On each run, for each valid output bit, we record whether that bit is zero or one. Once each output is either zero or one $> 50\%$ of the time, we return the majority's

choice for each output and stop re-running the circuit.[5] In contrast to prior work, this means that in principle our circuits' runtime is unbounded. In practice, however, a circuit with reasonable accuracy ($> 10\%$) only needs a few—in our experiments, at most seven—re-runs to produce the output, while circuits with much lower accuracy ($< 1\%$) can incur much larger overhead (100–250×).

3.3 Optimizing the memory layout

Prior work shows that microarchitectural features such as the prefetcher affect μWM's accuracy. Katzman et al. [63] report that enabling the prefetcher reduces the accuracy of their circuits by 41–52%. Evtyushkin et al. [38] and Kaplan [62] also discuss the accuracy-related effects of weird registers' placement and alignment in memory.

These observations motivate us to optimize Flexo's memory layout to reduce these microarchitectural effects. For Flexo, the two most important factors for accuracy are (1) the spacing between successive weird registers (i.e., the size of the gaps between two weird registers' memory addresses), and (2) the mapping from circuit wires to cache lines. Our evaluation (§5) demonstrates that Flexo's accuracy remains high *without* disabling the prefetcher—in fact, Flexo gives higher accuracy with the prefetcher enabled than prior state of the art does with the prefetcher disabled [63].[6]

Setting the spacing between weird registers As noted above, the memory layout of weird registers is a key design parameter. If weird registers R1 and R2 have memory addresses that are too close together, the prefetcher might fetch (say) R2 into the cache as a side effect of the weird machine's fetching R1, thereby corrupting the value in R2. Similarly, if registers R1 and R2 both map to the same cache set in a set-associative cache, computing on one register might cause the other's eviction, which also leads to corruption.

Kaplan [62] suggests separating weird registers by 4160 ($4096+64$) bytes: a ≥ 4096-byte offset puts weird registers on different pages, defeating the prefetcher, and the additional 64-byte offset ensures that most weird registers map to a different cache set. But a separation this large is not suitable for large circuits: when the number of active pages exceeds the size of the translation lookaside buffer, the resulting page table thrashing adds more noise to the circuit's execution. In our evaluation (§5), we use 1088-byte ($1024+64$) gaps for the smallest circuit (the 4-bit ALU). For the larger circuits (SHA-1, AES, and Simon), which require more weird registers, we use either 576- or 488-byte (512 ± 64) gaps.

[5] Flexo's compiler (§4) makes it easy to tune runtime versus accuracy by specifying the number of votes required when choosing an output value.

[6] Requiring the prefetcher to be disabled makes a μWM less practical: modern CPUs' prefetchers can only be disabled with root or BIOS access, and the prefetcher is generally enabled by default because it boosts performance.

Randomizing weird register memory layout To reduce the effect of the prefetcher for large circuits (which, as discussed immediately above, must use smaller register-to-register gaps), Flexo also randomizes the mapping of weird registers to memory addresses before *each* execution.

To do so, Flexo accesses weird registers via an indirection table $\mathcal{R}$ defining a permutation on $\{0,\ldots,k-1\}$ for k weird registers. When the gap between weird registers is g bytes and the base memory address of the weird register file is b, the address of (zero-indexed) weird register j is given by $b+g\cdot\mathcal{R}(j)$. $\mathcal{R}$ is implemented as a length-k array of integers; before execution, Flexo shuffles $\{0,\ldots,k-1\}$ into the array.

4 A compiler for Flexo

To execute a program using a μWM, a programmer must express that program as a boolean circuit. Transforming a high-level computation into a (well-performing) circuit and implementing that circuit as a μWM is both difficult and error-prone—especially for complex programs like cryptographic computations. To address this, we build the first compiler that generates μWMs. Our compiler consumes C or C++ and targets the differential encoding presented in Section 3; as we discuss below, this is an easier target than prior encodings.

Our compiler makes it easy to create efficient weird machines. For example, the source code for our SHA-1 hash function is 274 lines of code, whereas prior work [63] requires around two thousand lines to implement the same circuit from low-level logic gates. This convenience does not sacrifice performance: our compiler-generated implementation of one SHA-1 round is about 25× faster than prior work (§5). As further evidence that μWM compilers can improve both performance *and* usability, we implement three proof-of-concept optimization passes and configuration hooks:

- Error detection hooks let us build Section 3's error correction mechanism in 21 lines of code.
- The compiler lets us configure the length of the transient window (§2.1), which makes it easy to fine-tune μWMs for a given microarchitecture.
- An optimization pass makes generated circuits more resilient to prefetching and cache eviction.

In this section, we outline prior work that inspired our compiler, and then give an overview of our compilation pipeline. Our compiler is implemented in 2245 lines of C++ code.

Background: circuit compilers and high-level synthesis While prior work suggests building compilers that target μWMs [125], this work, to our knowledge, is the first such implementation. Still, compiling from programming languages to circuits is an important research topic in several distinct fields. High-level synthesis (HLS) creates a hardware description from a programming language (often, C or C++);

see [32] for a survey. In contrast to our compiler, which produces purely combinational circuits (discussed below), the key challenge in HLS is efficiently handling stateful circuits (e.g., flip-flops or latches). HLS techniques may nevertheless prove valuable in future work (§7), particularly with regard to optimization.

Further afield, compilers target the circuit-like representations [91] used by cryptographic primitives like multi-party computation [2, 14, 20, 24, 55, 56, 81], fully homomorphic encryption [121], and probabilistic proof systems [18, 29, 70, 93, 106, 107, 122]. These compilers transform high-level programs into boolean or arithmetic circuits, which, as in μWMs, are almost always purely combinational. Similarly, program verifiers [9, 10, 25, 27, 28, 30, 61, 65, 71, 74, 112, 119, 120, 131] target logical formulas (which are isomorphic to combinational circuits). Both verifiers and cryptographic compilers allow programmers to use control flow (via standard flattening techniques (e.g., as in [25])) and memory operations (via domain-specific representations). Future μWMs may build on such techniques to support a richer input language.

μWM compiler overview Figure 1 shows the process by which our compiler constructs a weird machine from a C or C++ function. First, the programmer provides an input file and annotates the functions that should be compiled to weird machines. Each annotated function is processed by an LLVM pass that translates it into a Verilog [1] description. This pass treats function bodies as the circuit's computation, function arguments as the input and output wires of the circuit, and the function's return value as an error detection bit (§4.1).

The compiler uses Yosys [129], an off-the-shelf EDA tool, to synthesize the Verilog into a set of truth tables with at most 4 inputs. For each such truth table, the compiler generates an assembly implementation of a Flexo gate. Finally, the compiler optimizes the memory layout of the weird machines and splices them into the original LLVM IR file. Appendix A shows the output of each compilation stage.

Input program requirements Since μWMs are ultimately boolean circuits, compiler input programs must not contain:

- *Intermediate loads or stores*: The compiler only permits load operations on input variables and store operations of output variables, with constant load or store addresses.
- *Control flow*: Function bodies cannot contain branches, function calls, or loops.
- *Unsupported operations*: Only arithmetic, comparison, logical, bitwise, assignment, and ternary operators are allowed (e.g., no address-of operator).

Future work can avoid these restrictions using known techniques (see above). Even with these limitations, our compiler supports complex computations like SHA-1 and AES (§5).

Finally, our compiler implements special semantics for arguments and return values of the functions it translates. A

```
#define ROL(x, n) (((x) << (n)) | ((x) >> (32 - (n))))

void __weird__sha1_round(
    unsigned* input,
    unsigned* output, unsigned* error_output
) {
    unsigned a = input[0];
    unsigned b = input[1];
    unsigned c = input[2];
    unsigned d = input[3];
    unsigned e = input[4];
    unsigned w = input[5];
    unsigned k = 0x5A827999;

    unsigned f = (b & c) | ((~b) & d);
    unsigned temp = ROL(a, 5) + f + e + w + k;

    output[0] = temp;
    output[1] = a;
    output[2] = ROL(b, 30);
    output[3] = c;
    output[4] = d;
}
```

Listing 6: An example input program to our compiler. This program implements one round of SHA-1.

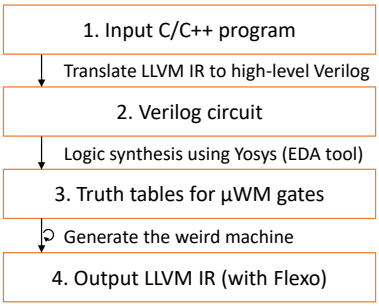

Figure 1: The compiler pipeline. In the first stage, the compiler executes clang's frontend with the `-emit-llvm` flag to emit LLVM IR code.

μWM's input values are function arguments (which can be pointers or integral types), as are its outputs (which must be pointers; see §4.1). Specifying a `bool` function return type directs the compiler to emit extra error detection code: the function returns true if any output wire yields an error.

4.1 The compilation pipeline

Our compiler converts input programs (e.g., Listing 6) into boolean circuits in several pipeline stages, shown in Figure 1.

From LLVM IR to Verilog circuit In this stage, the compiler translates LLVM IR into a high-level Verilog circuit. It treats function arguments as input and output buses; an input is an argument whose value is only ever *read*, and an output is one whose value is only ever *written*. The restric-

tions on input programs discussed above make the LLVM IR to Verilog conversion step straightforward. For example, the compiler converts arithmetic instructions into the corresponding Verilog operators and converts memory instructions into assignments between wires or buses.

In addition to specifying a global boolean return value that is set if an error occurred, the programmer can specify error bits for individual outputs, which can be used to implement custom error correction. To implement the error correction described in Section 3, for example, we write code that checks each output's error flag, saves valid values, and conditionally re-executes the circuit.

From Verilog to truth tables Our compiler guarantees that the Verilog it generates encodes purely combinational logic (i.e., free of memory elements like flip-flops and latches). The Verilog can thus be translated into truth tables using standard logic synthesis techniques [101, Ch. 12]. Our compiler uses Yosys [129], an open-source synthesis tool that targets FPGAs; this is convenient because Flexo's arbitrary 4-input gates (§3) closely resemble an FPGA's lookup tables (LUTs). The output from Yosys is a set of 4-input truth tables, which would normally be used to program an FPGA's LUTs; our compiler instead uses them to construct a μWM.

We note that Flexo's ability to implement any 4-input boolean function makes this step substantially easier while improving the quality of the result. In principle, one could use Yosys to target the set of gates supported by prior work (e.g., `AND`, `OR`, and `NOT` [38, 62, 63, 125]). However, extracting good performance from such a circuit would be challenging because it would require the synthesis process to account for the speed, size, and accuracy of a composition of heterogeneous gates. In contrast, the performance of Flexo's 4-input gates is essentially oblivious to the logical function being computed, and its basic unit of computation is much richer than prior work's. This dramatically simplifies the synthesis process and completely eliminates a (difficult) optimization pass.

From truth tables to Flexo The final pipeline stage converts the prior stage's truth tables into Flexo gates and emits an assembly implementation of the μWM. To do so, the compiler uses the Quine-McCluskey logic minimization algorithm [83] to construct the f_+ and f_- expressions as sums of products, then implements those expressions using basic `AND` and `OR` gadgets (§2.2; Listings 4 and 5, §3.1).

The compiler then generates assembly to prepare the circuit's inputs (i.e., by transferring the values from architectural to microarchitectural state), to read the circuit's outputs into architectural state (i.e., by measuring cache residency information for each output value), and to trigger transient execution for each gate (via return address misprediction; §2.1). The compiler's approach to triggering transient execution gives it precise control over the length of the transient window. This is a parameter that the user can set, giving a convenient knob for tuning the μWM to a particular microarchitecture.

The compiler optimizes the μWM's memory layout to improve accuracy in the face of prefetching and cache evictions (§3.3): it controls the spacing between successive weird registers (to avoid prefetching and correlated evictions), and emits code that randomizes weird registers' memory locations before each execution (to further counteract the prefetcher). Finally, the compiler splices the optimized assembly code into the LLVM IR file and generates a standard executable.

5 Evaluation

We now evaluate Flexo via the following questions:

1. How does Flexo compare to state-of-the-art prior work in speed and accuracy? (§5.1)

2. How large of a Flexo circuit can execute correctly across different microarchitectures? (§5.2)

3. How does Flexo perform on larger computations (i.e., SHA-1 and AES) using composed circuits? (§5.3)

We find that Flexo significantly reduces the circuit size and performs one to two orders of magnitude faster than the state of the art. Furthermore, Flexo is the first μWM that can perform reliably ($\geq$97.8% accuracy) across different microarchitectures even for complex computations like SHA-1 and AES, allowing us to build an end-to-end application: a weird machine–based packer (§6).

Throughout this section, we construct circuits for Flexo using the compiler described in Section 4. These circuits are compiled from at most a few hundred lines of C or C++, and constructing the circuits requires no manual edits. This stands in stark contrast to prior work, in which all circuits must be hand crafted by experts.

Testbeds We evaluate Flexo on eight different AWS EC2 machine types (Table 1), all running Ubuntu 22.04; we use one of these machines (Skylake) to reproduce the results of state-of-the-art prior work (§5.1). Our testbed machines cover several of the latest x86_64 microarchitectures from AMD and Intel. (In the rest of this section we refer to these machines using their microarchitectures, e.g., "Skylake.")

Because we run our experiments in a public cloud environment, other tenants are able to inject noise into the CPU's shared microarchitectural states. While our experiments suggest that this noise has little effect on our results (see Appendix B for details), achieving high accuracy on shared machines increases our confidence that Flexo is suitable for deployment in real-world settings.

Experimental method To measure Flexo's runtime and accuracy on a given circuit, we compile (§4) a binary that evaluates the circuit one thousand times on random inputs and reports the number of correct executions and total time. We then repeatedly execute that binary for forty-three hours

Microarchitecture	Instance Type	Processor
Zen 1	t3a.xlarge	AMD EPYC 7571
Zen 2	c5a.xlarge	AMD EPYC 7R32
Zen 3	c6a.xlarge	AMD EPYC 7R13
Zen 4	m7a.xlarge	AMD EPYC 9R14
Skylake	c5n.xlarge	Intel Xeon 8124M
Cascade Lake	m5n.xlarge	Intel Xeon 8259CL
Icelake	m6in.xlarge	Intel Xeon 8375C
Sapphire Rapids	m7i.xlarge	Intel Xeon 8488C

Table 1: The AWS EC2 instances and processors we use to perform our evaluation.

without error correction and one hundred hours with error correction, and then we report the median from these executions.

This measurement approach is similar to prior work. Running the same circuit repeatedly amortizes away constant measurement offsets. Reporting the median of several executions avoids outlier cases where the μWM fails because of an unlucky combination of microarchitectural and architectural state (e.g., page alignment, cache state, noise from other processes or tenants, etc.).

When preparing a binary for a given microarchitecture, we first run a sweep to determine the transient window length that gives the best accuracy or the shortest runtime. We build circuits with fifty different transient window lengths by adjusting the number of division instructions used when triggering transient execution (§2.1). For circuits without error correction, we choose the transient window length that gives the best accuracy; for circuits with error correction, we choose the one with the shortest runtime among those with an accuracy of at least 95%. This process does not require expert hand-tuning, but as in prior work it means that our binaries are specific to a target microarchitecture. In Section 6, we show that a single μWM-enhanced packer binary works on all the Intel machines from our testbed, meaning that non–microarchitecture-specific binaries can still have good performance; in Section 7, we discuss ideas to further enhance our compiler's ability to create generic, multi-microarchitecture binaries.

5.1 How does Flexo compare to prior work?

We compare the accuracy and execution time of our circuits to those from Gates of Time (GoT) [63], state-of-the-art prior work building μWMs. We find that, across a variety of circuits, Flexo performs approximately 25–49× faster and 4–17% more accurately than GoT with error correction, and approximately 5–10× faster and 18–39% more accurately than GoT without error correction.

Reproducing GoT's results We evaluate both projects on the Skylake machine. Although we do not use exactly the same CPU as GoT (their CPU is unavailable on AWS EC2), our CPU uses the same core microarchitecture as the one used in their evaluation. Further, our reported results for GoT are similar to those reported in GoT. Specifically, Tables 2 and 3 give similar results to [63, §4.1–4.2] with prefetchers enabled.

4-bit ALU

	GoT [63]	Flexo	Improvement
Wires	336	62	-81.55%
Gates	250	32	-87.20%
Accuracy	81.00%	98.90%	+17.90%
Runtime (μs)	134.37	13.58	9.89×
With error correction			
Accuracy	96.00%	100.00%	+4.00%
Runtime (μs)	673.48	13.82	48.73×

Table 2: Comparison of the circuit size, accuracy, and runtime of GoT [63] and Flexo for the 4-bit ALU.

SHA-1 round function

	GoT [63]	Flexo	Improvement
Wires	2976	1061	-64.35%
Gates	2208	544	-75.36%
Accuracy	57.00%	95.80%	+38.80%
Runtime (μs)	1161.91	219.12	5.30×
With error correction			
Accuracy	83.00%	100.00%	+17.00%
Runtime (μs)	5771.13	233.32	24.73×

Table 3: Comparison of the circuit size, accuracy, and runtime of GoT [63] and Flexo for one round of SHA-1.

We evaluate two circuits from GoT: a 4-bit arithmetic logic unit (ALU) and one round of the SHA-1 hash function. We choose these computations because they are of practical interest and cover a range of circuit sizes (SHA-1 is about 10× larger than the 4-bit ALU). To evaluate GoT's performance, we execute the shell script in their artifact,[7] reporting median accuracy and runtime. We compare both error-corrected and non-error-corrected GoT and Flexo circuits.

Results without error correction The top portion of Table 2 compares GoT's 4-bit ALU performance to that of Flexo. Flexo reduces the circuit size by 87.20% compared to GoT, which leads to a 9.89× speedup. At the same time, Flexo improves the circuits' accuracy from 81% to 98.9% without relying on error correction or detection. Flexo also reduces the SHA-1 circuit size by 75.36% (with a 5.3× speedup) and increases accuracy by 38.8% (Table 3).

[7] https://github.com/0xADE1A1DE/GoT/blob/main/circuits/run_experiment_all_with_prefetcher.sh. This script executes the circuit one hundred times to measure accuracy and runtime, and repeats this ten thousand times to collect the median.

Results with error correction The bottom portions of Table 2 and 3 compare error-corrected GoT to error-corrected Flexo. Table 2 and 3 show that, with error correction, Flexo achieves perfect accuracy with tiny performance penalty. Our bit-by-bit error correction mechanism (§3.2) increases the accuracy while maintaining high performance, yielding only 1.76% (ALU) or 6.48% (SHA-1) longer runtime.

While error-corrected GoT also enjoys much higher accuracy, its runtime is 48.73× and 24.73× slower than Flexo for ALU and SHA-1, respectively. This is because GoT implements error correction using majority voting: it executes the same circuit five times, and then outputs the most common result. While this improves the circuit's accuracy, it also increases the runtime by ≈5× compared to the un-corrected version. In contrast, Flexo re-runs the circuit (correction) *only* when it detects an error (§3.2), and thus incurs minimal overhead when the circuit is already accurate.

5.2 How large can a Flexo circuit be?

Scaling μWMs to large circuits is challenging. As the circuit grows, it needs more storage for the values of wires and may start incurring self-evictions in the cache. Using more cache lines might also increase interference from hardware prefetchers. This results in less accurate circuits. For example, when the circuit in Section 5.1 grows by ≈10×—from a 4-bit ALU to the SHA-1 circuit—GoT's accuracy degrades by 24%.

In this section, we show that Flexo's design can handle much larger circuits than those in prior work. We do so by executing four circuits across a range of sizes: in addition to the simple 4-bit ALU and the first round of SHA-1 from the prior section, we evaluate circuits implementing one round of AES encryption and the entire Simon block cipher [12], which are five and eight times larger than the SHA-1 circuit, respectively. We evaluate the accuracy and runtime of Flexo on the eight machines in Table 1, finding that Flexo supports a wide range of CPU microarchitectures and that its error correction mechanism dramatically increases accuracy—in one case, from under 0.3% to over 99.9%.

Circuit implementation The ALU and SHA-1 implementations are the same ones reported in Section 5.1.

To build one round of AES encryption with a 128-bit key, we implement its four operations, which are *SubBytes*, *ShiftRows*, *MixColumns*, and *AddRoundKey* (214 lines of C). The most challenging operation is *SubBytes*, which requires computing a multiplicative inverse over GF(2^8). While *SubBytes* is usually implemented as a lookup table (i.e., the AES S-box), this approach would be inefficient in Flexo. We instead use the method of Canright et al. [23] and Satoh et al. [102] to compute a multiplicative inverse directly.

We also implement Simon [12], a lightweight block cipher designed for microcontrollers. We use the variant with 32-bit blocks and a 64-bit key. Because this cipher is so simple, we can execute the entire cipher in one circuit (50 lines of C).

Results Table 4 shows the results of the four test circuits on our eight testbed machines. We find that Flexo can compute large circuits (> 4k gates) with very high accuracy (≥ 99.3%) on all testbed machines, demonstrating that it supports complex computations that prior μWMs could not handle. As Tables 2 and 3 demonstrate, Flexo's circuit construction (§3) results in ≈4–8× smaller circuits than prior work, meaning that a 4k-gate Flexo circuit supports significantly more complex functionality than prior work with that number of gates.

For ALU and SHA-1, most of our testbed machines give high accuracy even without error correction (EC). The AES circuit, in contrast, is ≈5× as large as SHA-1 and its accuracy is much lower. But even when its accuracy is as low as 1.4% (on Zen 3 and Zen 4), EC can still correct all errors at the cost of longer runtime (≈7×).

Simon is the largest circuit, and most AMD CPUs give very low accuracy. For Zen 3, we must reduce the circuit size from 4322 gates to 3282 gates by reducing the number of rounds in the cipher (from 32 to 25) in order to generate correct outputs. In other words, the maximum size of a Flexo circuit for Zen 3 is ≈3k gates. Beyond this size accuracy drops to zero, at which point error correction cannot help. Other Zen machines still give nonzero accuracy when computing the full 32 rounds. In these cases, even when accuracy is as low as 0.3%, error correction still improves it to 99.9%, although the performance penalty is high (≈298×).

5.3 How does Flexo perform on composed circuits?

A standard technique for running large computations in μWMs is to stitch several smaller circuits together via *architectural* computations. While this approach is helpful, it does not entirely address the problem of scaling μWMs to large computations, for two reasons. First, it exposes more of the computation in architectural states, which may increase the likelihood of detection—so fewer stitches (i.e., larger μWM circuits; §5.2) is better for stealth. Second, as a natural consequence of composing circuits with imperfect accuracy, the accuracy and/or speed of the overall computation suffers.

In this section, we evaluate Flexo's accuracy and runtime when composing several circuits. In particular, we use the single round SHA-1 and AES circuits as building blocks to compose a complete SHA-1 hash function and AES encryption. As in prior work, we stitch these circuits together by using architectural computation to transform the outputs of one circuit into the inputs of the next one.

Results Table 5 shows the results of the SHA-1 hash function with two input blocks and the AES encryption with one block and a 128-bit key. The SHA-1 hash function is composed of 160 small circuits (one circuit per round, 80 rounds per block), while the AES encryption comprises 19 small circuits (ten rounds and nine round keys).

Circuit		4-bit ALU		SHA-1 (1 round)		AES (1 round)		Simon (1 block)

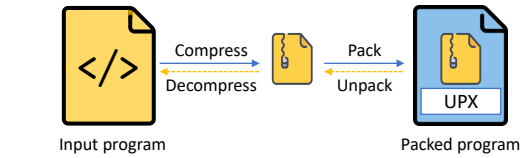
Table 4: The accuracy and runtime of Flexo with or without error correction (EC) on different CPUs. The runtime is in microseconds. *For Zen 3, we reduce the number of encryption rounds from 32 to 25 since it cannot correctly compute Simon encryption with more than 25 rounds. The circuit for 25 rounds has 6528 wires and 3282 gates.

	SHA-1		AES	
	Acc.	Runtime	Acc.	Runtime
Zen 1	99.00%	55.95	99.80%	347.72
Zen 2	99.30%	45.07	99.70%	204.16
Zen 3	97.80%	46.85	99.90%	206.72
Zen 4	99.60%	53.84	100.00%	215.39
Skylake	99.60%	44.68	100.00%	265.91
Cascade Lake	99.80%	43.68	100.00%	218.68
Icelake	99.80%	38.51	100.00%	239.33
Sapphire Rapids	98.00%	48.28	99.80%	210.47

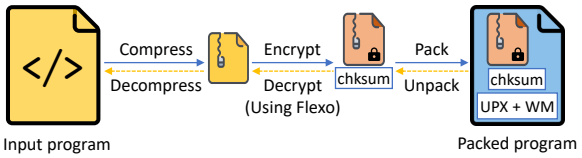
Table 5: The accuracy and runtime of the SHA-1 hash function and the AES encryption of Flexo with error correction on different CPUs. The runtime is in milliseconds.

We find that Flexo is able to achieve high accuracy ($\geq$ 97.8%) for both computations. For comparison, the GoT authors report 95.1% accuracy for two blocks (i.e., 160 one-round circuits) of SHA-1 [63, §4.2].[8] Runtime is also better than in prior work: composing 160 GoT SHA-1 round circuits with error correction (using the single-round runtime from §5.1) would be more than 20$\times$ slower than our SHA-1 results.



[8]The GoT measurement appears to require disabling the prefetcher to give better accuracy. As discussed in Footnote 6, this may not be possible for a user-level attacker because it requires root or BIOS access.

6 A weird machine packer



In this section we modify UPX [88], a binary packer [114] that is among the most widely used for malware [86], by obfuscating its unpacking process in order to make analysis more difficult. Our modified UPX uses a Flexo decryption stage during unpacking (and a corresponding encryption stage when packing; this is not obfuscated because it is never run on a victim machine) using Simon [12] or AES (§5.2).

Prior work [38, 125] also obfuscates malware with a μWM, but the obfuscation is limited to simple XOR operations and requires expertly hand-crafted μWM designs. Evtyushkin et al. [38] report that computing `XOR` on twenty bytes of data takes around 500 ms; Flexo takes less time to compute AES-CTR decryption on that amount of data. This work also demonstrates for the first time that using a μWM to obfuscate large computations is feasible for a non-expert: as mentioned in the prior section, our implementations of Simon and AES comprise 119 and 402 lines of C, respectively, and our compiler is able to automatically add it to UPX. We also modify the original UPX project with 412 lines of C++ to add an encryption stage during the encryption process and invoke the weird machine during unpacking.

Background: program obfuscation Program obfuscation makes a program more difficult to understand by increasing its complexity without changing its functionality [132]. Developers may use obfuscation to protect intellectual property [37], enforce software licensing [103], prevent tamper-

(a) UPX

(b) Our μWM packer (UPX + Flexo)

Figure 2: The packing (right arrows) and unpacking process (left arrows) of UPX and our weird machine packer.

ing [138], defeat anti-virus protection, or raise the cost of malware analysis [114].

Many program obfuscation techniques focus on making static and dynamic analysis more difficult. Anti-debugger, anti-sandbox, and anti-VM techniques let programs change behavior when they detect a dynamic analysis tool [108], and control flow flattening [124], junk code [75], and constant data encoding [132] make static analysis harder. Packers make malware less visible to static analysis tools by compressing an executable, then creating a new executable that contains the compressed data along with the code to unpack and run it.

These obfuscation techniques, however, happen in architectural states, and their computations and states are visible. While ExSpectre [123] aims to hide these tracks in transient executions, they can only move the computations into transient executions, and their states are still stored architecturally. In contrast, our Flexo-based packer hides both computation and program state in the microarchitecture.

μWM packers Figure 2 gives an overview of the packing and unpacking processes for our μWM packer. At a high level, unmodified UPX (Fig. 2a) compresses the original binary and creates a self-unpacking executable. Our μWM packer (Fig. 2b) makes three changes: first, it computes a set of checksums after compressing the data; second, it encrypts the compressed data; and third, in addition to the encrypted data, it injects the checksums and the decryption μWM into the self-unpacking executable. For the encryption scheme, users can choose AES or Simon in counter mode depending on their requirements.[9] Since Simon is simpler, it generally runs faster; AES, on the other hand, makes unpacking more complex, which may improve obfuscation.

During unpacking, the μWM decrypts the payload, then the unpacking code checksums the result, retrying decryption if there is a mismatch with the packed checksums. Finally, the UPX runtime decompresses the program and executes it.

The net result is that our μWM packer makes analysis even more difficult than standard packing. Performing unpacking steps in μWMs, for example, foils existing static analysis tools that depend on running a standard unpacker before analyzing code [16]. Flexo also breaks existing dynamic deobfuscation techniques that rely on emulation or single-stepping through the unpacking process. Such techniques interrupt transient execution, which causes unpacking to fail.

[9] Users can also utilize our compiler to implement a different encryption scheme for the packer.

	Simon	AES	Single binary
Zen 1	909.67	355.63	
Zen 2	64.66	242.17	
Zen 3	304.72	259.49	
Zen 4	2008.87	263.98	
Skylake	79.37	354.48	81.15
Cascade Lake	58.92	300.12	109.40
Icelake	146.58	306.12	146.58
Sapphire Rapids	50.13	268.35	60.14

Table 6: Our unpacker's median runtime in seconds using Simon and AES ciphers across the testbed CPUs (§6). The rightmost column is the runtime of the Icelake-specific binary using Simon on all Intel microarchitectures.

How fast is the unpacking process? We evaluate our packer on the `ls` binary from Ubuntu 23.04 (132 kiB uncompressed, 58 kiB compressed) using the testbed machines in Table 1. For each machine, our unpacker injects a Flexo decryption circuit with the same transient window length used in Section 5. We run the unpacker 100 times and calculate the median runtime, and Table 6 shows the results for Simon and AES. In summary, AES gives similar speed on all machines, roughly five minutes. On Zen 2 and Intel machines, Simon is faster: it finishes unpacking within eighty seconds, i.e., 2.1–5.3× faster than AES.

Can we create a cross-microarchitecture packed binary? The rightmost column of Table 6 shows the runtime of the Icelake-specific binary with Simon μWM on all four Intel microarchitectures. While the results are slower than with microarchitecture-specific binaries, the slowdown is always less than 2×, showing that Flexo can target multiple architectures simultaneously.

7 Conclusion and future work

This work started by asking whether μWMs should be considered a practical threat, or if they are likely to remain limited to simple computations and accessible only to a small group of experts. Our results show that μWMs have orders of magnitude more potential as a computational primitive than previously known, and that non-experts assisted by a compiler

can craft μWMs with state-of-the-art performance. History has shown that, beyond some minimum viability threshold, attack techniques tend to become more powerful over time. Considering both their extremely clever application to cache side-channel attacks in prior work [62, 63] and the performance and broad applicability demonstrated here, we believe μWMs are now well beyond that threshold. We thus conclude that μWMs merit further study, both to understand their limits and to develop detection methods and countermeasures. To that end, we offer a few specific suggestions:

Circuit optimizations Flexo circuits (and μWM circuits more generally) are very different from traditional circuits: the wires (weird registers) are volatile, which means their values are destroyed after a read, and the size of a logic gate is determined by the number of minterms of its boolean function. In contrast, traditional circuits can read from a wire multiple times without additional cost, and the size of a lookup table in FPGA circuits is determined by the number of inputs instead of the number of minterms. This raises interesting questions with regard to optimizations: (1) should we account for the cost of reusing wires in a circuit, and if so, how? and (2) how can we minimize the number of transient windows required by a weird circuit (e.g., by packing as many minterms as possible into each window)? Accounting for these special characteristics may result in much more efficient circuits.

Hiding and detecting weird machines Although μWMs frustrate program analysis by hiding computational states, behaving differently when debugged, and expressing high-level computations as low-level logic gates, their implementations are still visible in the program's code. While it would be a challenge, an analyst could reverse engineer the assembly code of a μWM to reconstruct the computation.

It may be possible to further hinder this type of analysis by hiding μWMs in dead code that is usually ignored by binary analysis tools—or even by camouflaging real μWMs with dummy ones. Of course, this is most helpful if the defender's goal is *understanding* the μWM—it is likely much easier to *detect* binaries containing μWMs (say, in a malware scanner). As μWM obfuscation becomes more of a threat, good detection and analysis techniques will become more important. These may include, for example, using hardware performance counters [33] and checking if a program's execution differs between normal execution and single-step debugging.[10]

Runtime calibration for transient windows To improve performance and accuracy, our compiler can generate binaries with different transient window lengths depending on the target microarchitecture (§4–§6). With additional engineering work, however, we could extend our compiler to produce binaries that calibrate transient window length at runtime. Our evaluation shows that this *one* parameter suffices to retarget Flexo across a wide range of microarchitectures, indicating that such runtime calibration is plausible because it does not involve a complex multi-parameter optimization.

Microarchitecture-specific μWMs In Section 6, we showed that Flexo binaries compiled for a specific microarchitecture can port to other microarchitectures. Such cross-microarchitecture binaries are useful because they do not require tailoring to individual machines, enabling attackers to build obfuscated, portable malware that can infect as many machines as possible. An intriguing alternative direction would be to explore the design of compilers for μWMs that work *only* on specific microarchitectures, by leveraging properties or optimizations that are unique to those microarchitectures. These microarchitecture-specific binaries would be useful for targeted attack scenarios, where an attacker may want their malware to activate only on the specific target machines. Such binaries could also raise the analysis cost by requiring analysts to examine them on specific microarchitectures.

[10] Recall that single-step debugging breaks μWMs, e.g., by affecting its transient execution and timing behaviors.

A Compiler input and output

Listing 7 shows how the compiler translates an 8-bit `XOR` from C code (a) into: LLVM IR (b); a Verilog circuit (c); truth tables (d); and assembly (e).

B How does noise from co-tenants on shared machines affect Flexo?

In Section 5, we evaluated the performance of Flexo's circuits by repeatedly running each binary for 100 hours in the AWS EC2 public cloud environment. To assess the impact of noise due to other tenants who may have been co-located with our instances, we now analyze if the runtime and accuracy of our binaries changed during that time window.

Figures 3 and 4 show the accuracy and runtime of Flexo over the 100-hour time window. For all these plots, each data point is the moving median of ten accuracy/runtime samples.

From these plots, we can see that most circuits are very stable on all the machines. We only see temporal variations on the AMD Zen 1 and Zen 3 machines. For AMD Zen 1, the accuracy for all circuits is stable. However, the runtime of the Simon and AES circuits exhibits notable variances, displaying what appears to be a periodic pattern occurring approximately every 24 hours. For AMD Zen 3, the Simon and SHA-1 circuits have larger variances in accuracy, and the Simon and AES circuits have larger variances in runtime. Nevertheless, the accuracy of these circuits is still very high (usually around 97–98%) even in the presence of noise.

```
bool __weird__xor(
    uint8_t in1, uint8_t in2, uint8_t* out
) {
    out[0] = in1 ^ in2;
    return false;
}
```

Abstract

Microarchitectural side-channel attacks have shaken the foundations of modern processor design. The cornerstone defense against these attacks has been to ensure that security-critical programs do not use secret-dependent data as addresses. Put simply: do not pass secrets as addresses to, e.g., data memory instructions. Yet, the discovery of data memory-dependent prefetchers (DMPs)—which turn program data into addresses directly from within the memory system—calls into question whether this approach will continue to remain secure.

This paper shows that the security threat from DMPs is significantly worse than previously thought and demonstrates the first end-to-end attacks on security-critical software using the Apple `m`-series DMP. Undergirding our attacks is a new understanding of how DMPs behave which shows, among other things, that the Apple DMP will activate on behalf of any victim program and attempt to "leak" *any* cached data that resembles a pointer. From this understanding, we design a new type of chosen-input attack that uses the DMP to perform end-to-end key extraction on popular constant-time implementations of classical (OpenSSL Diffie-Hellman Key Exchange, Go RSA decryption) and post-quantum cryptography (CRYSTALS-Kyber and CRYSTALS-Dilithium).

1 Introduction

For over a decade, modern processors have faced a myriad of microarchitectural side-channel attacks, e.g., through the caches [64, 92], TLBs [43, 79, 83], branch predictors [6, 36], on-chip interconnects [32, 65, 86], memory management units [44, 51, 82], speculative execution [52, 55], voltage-frequency scaling [78, 88, 89] and more.

The most prominent class of these attacks occurs when the program's memory access pattern becomes dependent on secret data. For example, cache and TLB side-channel attacks arise when the program's data memory access pattern becomes secret dependent. Other attacks, e.g., those monitoring on-chip interconnects, can be viewed similarly with respect to the program's instruction memory access pattern. This has led to the development of a wide range of defenses—including the ubiquitous constant-time programming model [53, 62], information flow-based tracking [42, 80, 95], and more—all of which seek to prevent secret data from being used as an address to memory/control-flow instructions.

Recently, however, Augury [84] demonstrated that Apple M-series CPUs undermine this programming model by introducing a Data Memory-dependent Prefetcher (DMP) that will attempt to prefetch addresses found in the contents of program memory. Thus, in theory, Apple's DMP leaks memory contents via cache side channels, even if that memory is never passed as an address to a memory/control-flow instruction.

Despite the Apple DMP's novel leakage capabilities, its restrictive behavior has prevented it from being used in attacks. In particular, Augury reported that the DMP only activates in the presence of a rather idiosyncratic program memory access pattern (where the program streams through an array of pointers and architecturally dereferences those pointers). This access pattern is not typically found in security critical software such as side-channel hardened constant-time code—hence making that code impervious to leakage through the DMP. With the DMP's full security implications unclear, in this paper we address the following questions:

Do DMPs create a critical security threat to high-value software? Can attacks use DMPs to bypass side-channel countermeasures such as constant-time programming?

1.1 Our Contribution

This paper answers the above questions in the affirmative, showing how Apple's DMP implementation poses severe risks to the constant-time coding paradigm. In particular, we demonstrate end-to-end key extraction attacks against four state-of-the-art cryptographic implementations, all deploying constant-time programming.

Analyzing DMP Activation Patterns. We start by re-examining the findings in Augury [84], here we find that Augury's analysis of the DMP activation model was overly

restrictive and missed several DMP activation scenarios. Through new reverse engineering, we find that the DMP activates on behalf of potentially *any* program, and attempts to dereference *any* data brought into cache that resembles a pointer. This behavior places a significant amount of program data at risk, and eliminates the restrictions reported by prior work. Finally, going beyond Apple we confirm the existence of a similar DMP on Intel's latest 13th generation (Raptor Lake) architecture with more restrictive activation criteria.

Breaking Constant Time Cryptography. Next, we show how to exploit the DMP to break security-critical software. We demonstrate the widespread presence of code vulnerable to DMP-aided attacks in state-of-the-art constant-time cryptographic software, spanning classical to post-quantum key exchange and signing algorithms. Our key insight is that while the DMP only dereferences pointers, an attacker can craft program inputs so that when those inputs *mix* with cryptographic secrets, the resulting intermediate state can be engineered to look like a pointer if and only if the secret satisfies an attacker-chosen predicate. For example, imagine that a program has secret s, takes x as input and computes and then stores $y = s \oplus x$ to its program memory. The attacker can craft different x and infer partial (or even complete) information about s by observing whether the DMP is able to dereference y. We first use this observation to break the guarantees of a standard constant-time swap primitive [54] recommended for use in cryptographic implementations. We then show how to break complete cryptographic implementations designed to be secure against chosen-input attacks.

Summary of Contribution. We contribute the following.

1. **Reverse Engineering Apple and Intel DMPs.** We reverse engineer the DMP found on Apple CPUs and discover new activation criteria (Section 4).
2. **Developing DMP Exploitation Techniques.** Using our new understanding of the DMP, we develop a new type of victim-agnostic chosen-input attack and associated attack primitives (e.g., eviction set construction) that does not require the attacker and victim to share memory. We use these primitives to mount a proof-of-concept attack on constant-time swap operations (Section 5).
3. **Breaking Constant-Time Cryptography.** Undergirded by our chosen-input attack framework, in Sections 6 and 7 we develop end-to-end key-extraction attacks on constant-time implementations of classical cryptography (OpenSSL Diffie-Hellman Key Exchange and Go RSA decryption) and post-quantum cryptography (CRYSTALS-Kyber and CRYSTALS-Dilithium).

1.2 Disclosure

We disclosed to Apple, OpenSSL, Go Crypto, and the CRYSTALS team. Apple is investigating our PoC. OpenSSL reported that local side-channel attacks (i.e., ones where an attacker process runs on the same machine) fall outside of their threat model. The Go Crypto team considers this attack to be low severity. The CRYSTALS team agreed that pinning to the Icestorm cores without DMP could be the short-term solution and hardware fixes are needed in the long term.

2 Background

Cache Architecture. Modern processors use a hierarchy of caches to reduce memory access latency. Typically, higher-level caches are smaller and faster to access, while lower-level caches are larger but slower to access. For example, the Apple processors we study in this paper have two cache levels, a core-private L1 and a shared L2. These caches are set-associative, meaning that they contain a fixed number of cache sets, each of which can fit a fixed number of cache lines. Cache lines are the basic unit for cache transactions. Multi-level caches have an inclusion policy that determines how the presence of a cache line in one level affects its presence in other levels. Most of our experiments were conducted on the Apple M1's 4 Firestorm (performance) cores, which are the only ones to have a DMP. Each Firestorm core has a 128 KByte, 8 way set-associative L1 data cache with 64 Byte cache lines and these 4 Firestorm cores share a 12 MByte, 12 way set-associative L2 data cache with 128 Byte cache lines. The shared L2 cache is inclusive of the L1 caches, i.e. every cache line present in the L1 is also present in the L2 [94].

Cache Side-Channel Attacks. In a cache side-channel attack, an attacker infers a victim program's secret by observing the side effects of the victim program's secret-dependent accesses to the processor cache. These attacks typically consist of three steps, during which the attacker (i) brings the cache into a known state, (ii) lets the victim execute, and (iii) checks the state of the cache to learn information about the victim's execution during step (ii). Two techniques commonly used to mount cache side-channel attacks are Flush+Reload [92] and Prime+Probe [64]. In Flush+Reload, an attacker that shares memory with a victim flushes individual shared cache lines and later reloads them to figure out if the victim accessed them. In Prime+Probe, the attacker builds an *eviction set* of addresses that map to the same cache set as the victim's target cache line, primes the cache set with the eviction set, and later probes it to figure out whether the victim accessed the target line / displaced a line in the eviction set.

Classical Prefetchers. Prefetchers are a hardware optimization used to hide memory access latency. Prefetchers live in the memory system, typically between the L1 and L2 or between the L2 and DRAM, and work by pre-loading data into the cache before it is requested by the core. In particular, given a program memory access pattern, *classical prefetchers* try to predict the next addresses the program will access based on its access pattern (an address trace) thus far.

Classical Prefetcher Security Implications. Several prior works have analyzed the security implications of classical

prefetchers [17, 26, 27, 31, 76, 91, 98]. These works demonstrate that, through unintended interactions with prefetchers, victim programs can create cache state changes that can be measured by the attacker to leak information. Fortunately, leakage through these attacks is limited to the victim's access pattern and can be mitigated through constant-time programming practices that ensure the program memory access pattern does not depend on secrets.

Data Memory-Dependent Prefetchers (DMPs). DMPs are a class of prefetchers designed to prefetch irregular memory access patterns. In contrast to classical prefetchers, which only take the memory access pattern as an input, DMPs also take into account the *contents* of data memory directly to determine what to prefetch. The computer architecture literature and industry patents proposed several types of DMPs [7, 8, 16, 24, 29, 50, 84, 96, 97], which differ in the irregular access patterns that they are designed to speed up (e.g., linked-list traversals, sparse matrix traversals).

DMP Security Implications. Vicarte et al. were the first to perform an analysis of the security implications of DMPs [72]. In the worst case, they found that proposed (but not known to be implemented) indirect memory prefetchers could be used to build universal read gadgets that leak a program's entire memory, similar to Spectre [52, 60]. More recently, Augury demonstrated that modern Apple processors employ a type of DMP referred to as an Array-of-Pointers (AoP) DMP [84]. We describe this DMP's behavior in more detail in Section 4.1.

3 Threat Model and Setup

In this paper we assume a typical microarchitectural attack scenario, where the victim and attacker have two different processes co-located on the same machine.

Software. For our cryptographic attacks, we assume the attacker runs unprivileged code and is able to interact with the victim via nominal software interfaces, triggering it to perform private key operations. Next, we assume that the victim is constant-time software that does not exhibit any (known) microarchitectural side-channel leakage. Finally, we assume that the attacker and the victim do not share memory, but that the attacker can monitor any microarchitectural side channels available to it, e.g., cache latency. As we test unprivileged code, we only consider memory addresses commonly allocated to userspace (EL0) programs by macOS.

Hardware. Unless otherwise specified, we focus on Apple hardware. The M1-based experiments of Section 4 are run on a Mac Mini with an Apple M1 running macOS 13.5. For our investigation into the M2/M3 microarchitecture, we used a Mac Mini with an Apple M2 (running macOS 14.2.1) and a MacBook Pro with an Apple M3 (running macOS 14.2). Finally, when investigating Intel's DMP implementation, we used an Intel Core i9-13900K (Raptor Lake) CPU, running Ubuntu 23.04 with kernel version 6.2.0.

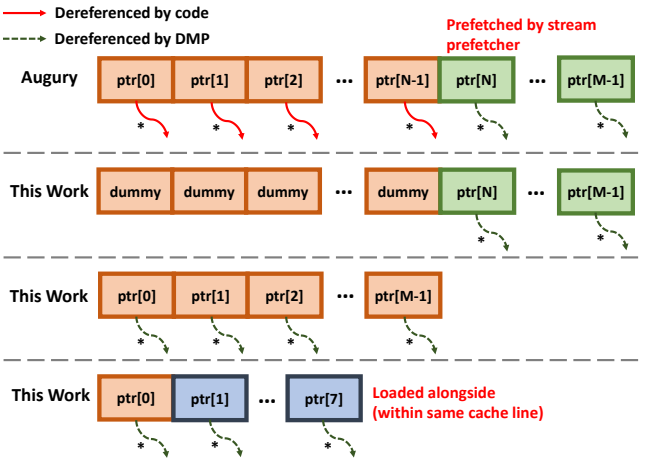

Figure 1: We compare memory access patterns and subsequent prefetches. The first row represents the activation pattern reported by Augury [84]: a streaming dereference access pattern causes the DMP to dereference out-of-bounds pointers. In the second row, we show that architectural/program-level dereferences are unnecessary; we see DMP activations even when the training array contains non-pointer values. In the third row, we show that the DMP even dereferences the in-bounds pointers that are architecturally accessed (but, again, not dereferenced). Finally, the last row shows that a single access to a memory location results in all pointers stored in the incident cache line being dereferenced.

4 Microarchitectural Characterization

4.1 Revisiting DMP Data Access Patterns

In this section, we investigate the access patterns required to activate the M1 DMP. We show that the M1 DMP dereferences more pointers and with fewer program assumptions than was claimed by Augury [84]. Figure 1 summarizes the subsection's findings.

Augury. We begin by reviewing the M1 DMP activation pattern and methodology described in Augury. Augury's code, summarized in Listing 1 (left), first allocates an array (`aop`) of length M and fills `aop` with pointers to memory addresses that correspond to unique L2 cache lines. Next, it evicts these cache lines from the L2 via cache thrashing (by loading an array eight times the size of the cache). The code then accesses (loads) and dereferences the first N elements of the `aop`, where $N \leq M$. We call `aop[0]`, ..., `aop[N-1]` the in-bounds pointers and `aop[N]`, ..., `aop[M-1]` the out-of-bounds pointers.

Augury inferred the DMP's activity by adding code after the loop to time how long it would take to dereference pointers in the `aop`. We call these test accesses. The main finding was that the latency of test accesses for out-of-bounds pointers in some index range $[N, N+\delta)$ corresponded to L2 cache hits. This is noteworthy because the code itself never dereferenced pointers located after `aop[N]`. Augury attributed this behavior

to a new form of prefetcher, with prefetch distance δ.

```
uint64_t* aop[M];
// Fill aop with pointers
// to unique addresses
// or random values

for (i=0; i<N; i++) {
    *aop[i%N];
}

// Measure latency to
// set of test addresses
```

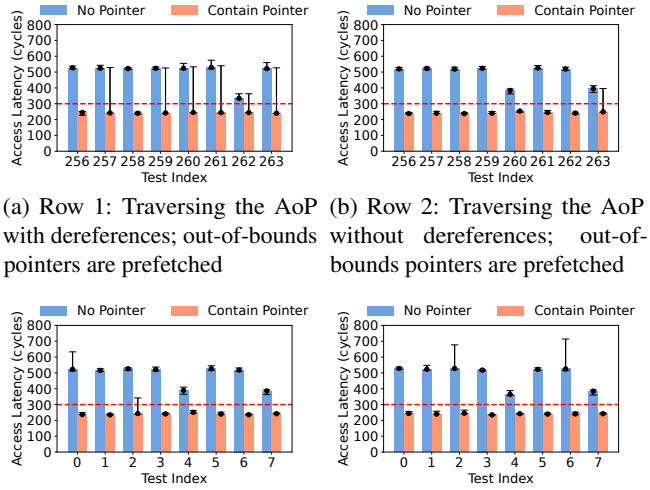
```
uint64_t* aop[M];
// Fill aop with pointers
// to unique addresses
// or random values

for (i=0; i<N; i++) {
    aop[i%N];
}

// Measure latency to
// set of test addresses
```

Listing 1: Left: The DMP activation code pattern studied by Augury [84]. Right: The DMP activation pattern studied in this work. For both, assume $N \leq M$. Both code patterns fill the `aop` before the loop begins and use a mod operation to inhibit speculative execution.

Observing DMP Activations. We reproduce Augury's experiments by setting $N = 256$ and $M = 264$, choosing a set of test pointers, and then either filling the out-of-bounds region with those pointers or random values. When the pointers are present, a test access (dereference) to one takes ~ 250 cycles,[1] as shown in Figure 2a. When the pointers are not present, the same test accesses take significantly longer. A cutoff of 300 cycles (red dash line) cleanly differentiates between the two cases and thus DMP activations. This corresponds to the L2 hit time and matches Augury's findings, consistent with $\delta \geq 8$.



Avoiding Architectural Pointer Dereferencing. To determine if the architectural pointer dereferences are required to trigger DMP activations we use the code in Listing 1 (right), where the in-bounds region does not contain pointers nor does the `aop` traversal loop perform any pointer dereferences. Again, we either fill the out-of-bounds region with test pointers or random values. See Figure 1 (second row).

As seen in Figure 2b, when the out-of-bounds region contains pointers, test accesses are < 300 cycles despite no architectural dereferences occurring to the in-bounds pointers. From this, we deduce that architectural dereferences are not required for the DMP to activate, i.e., that the DMP will prefetch out-of-bounds pointers without them.

In-bounds DMP Dereferencing. We then further check if the in-bounds pointers are *also* dereferenced by the DMP as they are no longer architecturally dereferenced in Listing 1 (right). This is the memory access pattern outlined in Figure 1 (third row), where we iterate over an array containing valid pointers without performing any dereferences.

Figure 2c shows that for $N = 8$, we can still consistently differentiate between the two cases. This indicates that if the `aop` contains data which can be interpreted as valid pointers, merely iterating over it is sufficient to activate the DMP.

One Load, Single Pointer. Finally, we consider how general the memory access pattern can be by performing a *single* data load and no architectural dereference, as shown in Figure 1 (fourth row). Even though the program only loads one `aop` index, other pointers in the same cache line are also brought into the cache. Figure 2d shows that with a single load,[2] we observe similar results to traversing the entire ($N = 8$) `aop` in Figure 2c. We further repeat the experiment but vary the number of pointers in the cache line from 1 to 8. In all cases, we observe DMP activations/dereferences for all pointers in `aop`, indicating that even a single pointer can trigger the DMP.

(a) Row 1: Traversing the AoP with dereferences; out-of-bounds pointers are prefetched

(b) Row 2: Traversing the AoP without dereferences; out-of-bounds pointers are prefetched

(c) Row 3: Traversing the AoP without dereferences; in-bounds pointers are prefetched

(d) Row 4: One load to AoP; pointers within the incident cache line are prefetched

Figure 2: Median, minimum, and maximum test access latencies (over 32 samples for each bar) using the access patterns of Figure 1. The x axis corresponds to the test access latency for the pointer at the corresponding index in the `aop` in case it contains the pointer. Blue bars (No Pointer) are for when the test pointer is not in the `aop` array, while red bars (Contain Pointer) are for when the pointer is in the array.

4.2 DMP Activation Criteria

Having established what memory access patterns activate the DMP, this section investigates *where data must reside in the memory hierarchy* to be DMP-searched for pointers. We show that the DMP dereferences pointers specifically on L1 cache fills and features two mechanisms to prevent redundant prefetches: a history filter and a do-not-scan hint. In this section, we make use of standard eviction sets, i.e., eviction sets for individual cache sets. We generate these eviction sets using standard techniques from prior work [85].[3]

History Filter. We start by rerunning the experiments from

[1] We collect timing measurements by configuring and reading performance counters (`PMC2-PMC7`) for cycle counting via `kperf`.

[2] Replacing the load with the store instruction, we find that none of pointers in the accessed cache line are dereferenced.

[3] This is in contrast with Augury, which, as we mentioned in Section 4.1, relied on cache thrashing to precondition the cache.

Section 4.1 using standard L2 eviction sets to evict both the `aop` array and the L2 cache lines that are pointed to by pointers in the `aop` array. We call these L2 lines the *target lines*.

We observe that the DMP only reliably dereferences each pointer once, on the first access to its `aop` entry. That is, even if the previously prefetched target line is evicted from the cache, along with its `aop` entry, the DMP no longer activates when seeing that pointer in the future. This observation suggests that the decision to dereference a pointer is made based on not only the program's access pattern but also some additional mechanism. An Apple patent suggests that this mechanism might be a history filter that "attempts to identify whether a given memory pointer candidate likely corresponds to a candidate that has been recently prefetched, in which case the given candidate may be discarded as a likely duplicate" [47]. The same patent suggests that this filter may be organized as a direct-mapped 128-entry or 256-entry structure.

History Filter Reverse Engineering. To corroborate the history filter hypothesis, we design a new experiment where `aop` only contains a single pointer `ptr`. First, we access `aop`, causing the DMP to dereference `ptr`. We then evict `aop` and the target line for `ptr` from the cache using standard eviction sets. Next, we read S unique pointers stored in a different array, causing the DMP to inspect and dereference S additional pointers. Finally, we re-access `aop` and check if this second access causes the DMP to dereference `ptr`. We run the experiment 100 times for each value of S and report the success rate (i.e., the percentage of times that the DMP activated on the second `aop` access) in Figure 3.

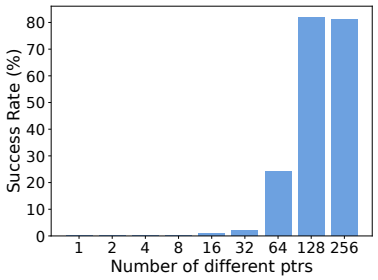


Figure 3: The percentage of experiments where the DMP re-activates when `ptr` is re-accessed (Success Rate, y-axis), as a function of the number of unique pointers accessed in between the first and second access to `ptr` (x-axis). Observe that Success Rate increases with the number of unique intermediate pointer accesses.

We observe that the DMP only reliably re-activates on `ptr` when $S \geq 128$. This behavior is likely due to the limited capacity of the history filter. That is, accessing S unique pointers results in the record of `ptr`'s target getting evicted from the filter when $S \geq 128$. We hypothesize that Augury's methodology was not affected by the history filter because its aggressive cache thrashing technique (i.e., accessing an array eight times the size of the cache) had a side effect of also flushing the history filter.

We further find that the history filter is a per-core structure and is reset if a core remains idle for an extended period of time. Specifically, the DMP reliably re-activates even when $S = 0$ if we (i) reschedule our experiment to a different core between the first and the second `aop` access or (ii) run the experiment on one core but leave the core idle for 100μs or more between the first and the second `aop` access.

L1 and L2 Cache Fills. The above observations indicate that the DMP activates when an `aop` entry is accessed from DRAM and the record of its target is not present in the history filter. Next, we investigate at which stage of a DRAM fetch the DMP scans the data for pointers. Recall that the M1 has an L2 line size of 128 Bytes and an L1 line size of 64 Bytes. With each pointer containing 8 Bytes, L2 lines can thus be split into "lower" and "upper" halves, each of which is an independent L1 line that can store $64/8 = 8$ pointers. When a program accesses either the lower or upper half, the accessed L1 line will be filled into both the L1 and L2 caches, while the other half will only be filled into the L2 cache.[4] In order to differentiate between L1 and L2 fills, we populate a L2 line size-aligned `aop` with 16 unique pointers and run the experiment from Listing 1 (right) in Section 4.1 with $N = 1$ and $M = 16$. Before each repetition, we use cache thrashing (as in Section 4.1) to evict the `aop` and its target lines from both the cache and the history filter.

Figure 4 (top) summarizes our findings, repeating each experiment 100 times and using the 300 cycle threshold from Section 4.1 for L2 cache hits. Here, we observe that when the program accesses `aop[0]`, the DMP only dereferences `aop[0]`, $\cdots$, `aop[7]`. We run 7 more variants of this experiment, varying the single `aop[i]` access from $i = 1, \cdots, 7$ and observe the same behavior for each choice of i. Next, we run 8 more variants of the same experiment, this time making a single access to `aop[i]` for $i = 8, \cdots, 15$. In this case, we observe that `aop[8]`, $\cdots$, `aop[15]` are all dereferenced for each choice of i, as shown in Figure 4 (bottom). We conclude that when filling an L2 cache line from DRAM, the DMP dereferences all pointers in the specific L1 line that is accessed, and not those in the other half of the L2 line.

We run 8 more variants of the above experiment. For these, before making an access to `aop[i]` for $i = 0, \cdots, 7$, we first make an access to `aop[8]`. We then repeat this setup while exploring the opposite case: before making an access to `aop[i]` for $i = 8, \cdots, 15$, we first make an access to `aop[0]`. As discussed above, the first access brings `aop[i]` from DRAM to the L2 cache and `aop[i]` further moves to the L1 cache with the second access. We observe that the DMP reliably dereferences the contents of the L1 line containing `aop[i]`. This means that L2 to L1 fills can also activate the DMP.

Do-not-scan Hint. The above experiments suggest that

[4] We empirically verify this by subsequently timing an access to the other half and observing that its access latency corresponds to the that of an L2 hit.

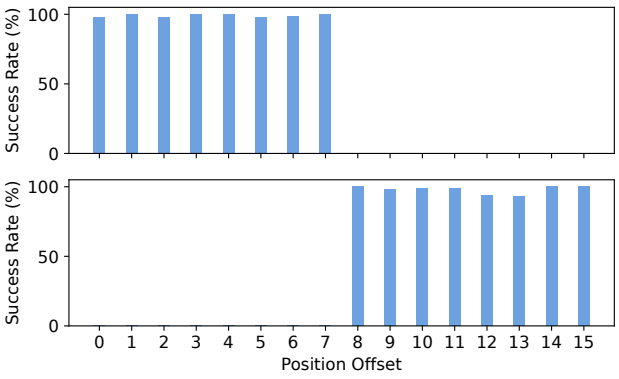

Figure 4: Which pointers in an L2 line are dereferenced when an access is made to data in that line? Top: the code accesses `aop[0]`. Bottom: the code accesses `aop[8]`. We conclude that the DMP dereferences pointers in the specific L1 line (either the upper or lower half of the L2 line) the code accessed.

the DMP searches for pointers in L1 cache lines during L1 fills, regardless of whether the L1 line is fetched from DRAM or the L2. To corroborate this hypothesis, we design another variant of the single-pointer experiment from Section 4.1. The experiment starts by loading the `aop` into the L1 and subsequently using eviction sets to either (i) evict the `aop` from the L1 or (ii) evict the `aop` from both the L1 and L2. In both cases, the experiment also evicts the target line from the cache and accesses a separate set of 256 pointers to evict the record of the target line from the history filter. Finally, the experiment re-accesses `aop` and tests if this second `aop` access causes the DMP to re-dereference `ptr`.

Interestingly, we observe that the DMP does not re-dereference `ptr` when the experiment re-accesses `aop` and `aop` was only evicted from the L1. However, when the `aop` is also evicted from the L2, the DMP re-dereferences it. This means that even if the previously prefetched target line is evicted from both the cache *and* the history filter, the DMP does not dereference that pointer again unless its `aop` entry is also evicted from both the L1 and L2. This behavior matches a mechanism also described in the previously referenced Apple patent [47], where the L2 sets a "do-not-scan" hint on L1 cache fills to prevent a previously scanned L1 cache line from being redundantly re-scanned. Fortunately, in our experiments, evicting the `aop` from both the L1 and the L2 is sufficient to clear the "do-not-scan" hint on the `aop`.

4.3 Restrictions on Dereferenced Pointers

In the previous section, we learned that the DMP activates on L1 fills and dereferences the pointers inside it if and only if those pointers' targets are not in the history filter and the filled line is not marked with the "do-not-scan" hint. We now investigate *what* pointers can be dereferenced by the DMP. For this, we again use Listing 1 (right) with $N = 1$ and $M = 1$ and rely on cache thrashing to ensure that the `aop` is uncached. We then try testing different pointer values in the `aop`, and checking for DMP activations.

4GByte Prefetch Region. We begin by investigating if the DMP requires there to be a relationship between the address of the `aop` entry and the value of the `aop` entry (i.e., the pointer). We call the address of the `aop` entry the entry's/pointer's position. To understand what the requirements are for one pointer to be dereferenced, we carry out a series of experiments that vary a pointer's position and value. See one such experiment in Figure 5 which shows that the pointer's position and value must be related for DMP activation to occur. Overall, we discover that the DMP only dereferences a pointer if the `aop` entry and target line are in the same 4 GByte-aligned region (Figure 6). In other words, that the upper 32 bits of their addresses match. Apple's patent [47] mentions similar pointer detection heuristic.

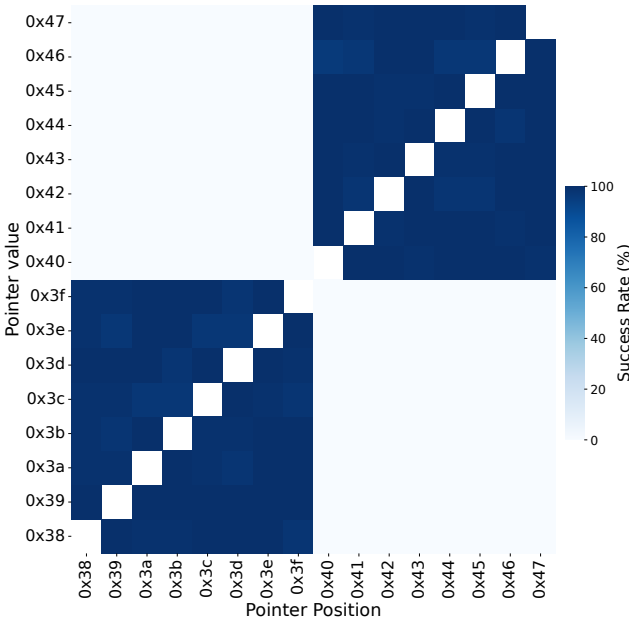

Figure 5: For various combinations of pointer position and value, when does the DMP dereference the pointer? Here, we sweep within the region between `0x380000000` and `0x480000000`. The white diagonal shows the degenerate case when the pointer's value equals its position, which is invalid. The lower 28 bits of the addresses are omitted for brevity.

Top Byte Ignore. The address space standards in ARMv8 direct the processor to ignore the top byte of the virtual address [2]. To learn whether the DMP follows this specification, we perform a series of experiments flipping different upper bits in a valid pointer. We then perform a test access to check whether, after these bit flips, the DMP still dereferences the original pointer. Figure 7 shows the results. We perform 16 experiments, where each flips a bit in the address starting at bit 48 and ending at bit 63. We observe that the DMP does not

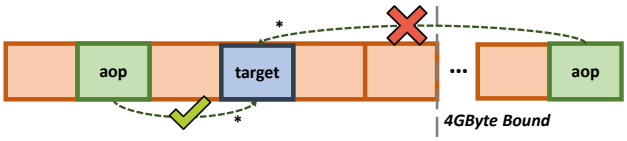

Figure 6: Outline of the placement of the target line and the `aop` entry. Following the observation from Figure 5, if the `aop` entry and target line straddle a 4GByte boundary, the DMP won't dereference the pointer.

dereference the original pointer if a bit in the range $[48, 55]$ is flipped. However, if a bit in the range $[56, 63]$ is flipped, the original pointer gets dereferenced. We conclude that the DMP ignores the upper 8 bits of a pointer when dereferencing it, which matches the "Top-Byte-Ignore" in ARMv8.

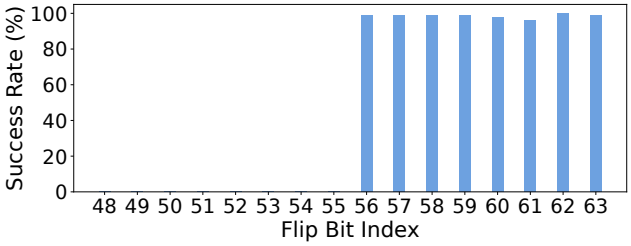

Figure 7: Activation success rate for a pointer when it is accessed by the program, after having one bit flipped between bit 48 to 63.

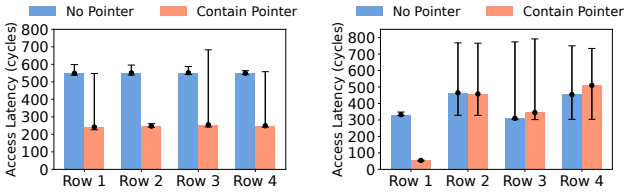
Auxiliary next-line prefetch. Finally, we investigate the amount of data prefetched when the DMP dereferences a pointer. We test this by performing a test access to not only a pointer's target line, but also to nearby lines. Apart from the target line, we also observe L2 hits to cache lines immediately next to the target line. We hypothesize that this is due to a next-line prefetcher being triggered alongside the DMP, which matches the adjacent-line prefetch behavior described in Apple's patent [47].

4.4 A Model for the DMP's Behavior

We now summarize the previous two subsections and make several new observations.



Step 1: Observing Cache Line Data. The DMP scans the data in an L1 line when that line is filled to the L1, if the line is not marked with the "do-not-scan" hint (i.e., the line has not been scanned since it was brought into the cache; Section 4.2). The DMP performs the scan by checking each pointer size-aligned chunk (the first 64 bits, second 64 bits, etc.) in the cache line.[5]

Step 2: Address Check. Next, the DMP applies additional checks and filters to each chunk (candidate pointer) to see if it should be dereferenced. Bits [63:56] are ignored (Section 4.3). Further, per Section 4.3, the cache line that stores the pointer (its position) must be in the same 4 GByte ($\log_2$ 4 GByte $=$ 32 bits)-aligned region as the cache line that the pointer points to (its target). In other words, the DMP checks whether bits [55:32] of the candidate pointer match the corresponding bits of the address of the target cache line. Finally, the DMP checks if the candidate pointer is present in the history filter (Section 4.2). If bits [55:32] match and the pointer is not in the history filter, the DMP attempts to prefetch two L2 lines. Specifically, it first prefetches the cache line targeted by the 64-bit chunk, ignoring the top byte value. Next, it triggers the CPU's next line prefetcher and fetches the neighboring cache line also into the CPU's L2 cache (Section 4.3). Both prefetched addresses are then inserted to the history filter.

As part of the prefetching process, the DMP looks up the translation lookaside buffer (TLB) and triggers page table walks to obtain the physical address corresponding to each candidate pointer (which is a virtual address [33]). On a TLB miss, the DMP inserts the missing translations into the TLB.[6]

4.5 Other Microarchitectures

We investigated the DMP behavior on other microarchitectures including the Apple M2/M3 and Intel's 13th Generation (Raptor Lake) CPUs, and display results in Figures 8a and 8b. As the Apple M3 behaves similarly to the M2, we omit its figure. In these two figures, the x-axis refers to the four access patterns shown as the rows in Figure 1, while the y-axis is the access latency for test accesses. For simplicity, we only show latencies for test accesses to the first pointer in each pattern. The Intel i9-13900K (Raptor Lake) shows a distinguishable timing difference only for the first access pattern from Figure 1, whereas the M2/M3 activates on all the patterns discussed previously. We conclude that while DMPs are present on Raptor Lake machines, they require different activation patterns. Finally, we leave the systematic investigation and exploration of Intel's DMPs to future work.

(a) Apple M2 (b) Intel Raptor Lake

Figure 8: We test four access patterns shown in Figure 1 on Apple M2 (left) and Intel 13th generation Raptor Lake (right).

[5] Pointers in `aop` should be 64-bit aligned, which is also discussed in [84].

[6] Prior work [84] also observes that the M1 DMP fills TLB entries for pointers in the `aop`.

5 Attacking Constant-Time Conditional Swap

To mitigate microarchitectural side channels, cryptographic code follows the constant-time programming principle: A secret should not determine which instructions to execute, which memory to access, or be used as input for variable-time instructions [11, 13, 14, 21–23, 62].

We now show how the DMP can break cryptographic security even when code is written to follow the constant-time principle. To introduce ideas and attacker tools, this section showcases a Proof-of-Concept (PoC) attack on a core constant-time cryptographic primitive [54] called `ct-swap` which conditionally swaps the contents of two arrays `a` and `b` based on a secret bit `secret`. We start with `ct-swap` to simplify the presentation. Later sections will reuse the ideas and processes described here to break real cryptographic code.

Constant Time Swap Overview. Listing 2 swaps the contents of array `a` and `b` based on the value of `secret` in a constant-time manner. The underlying swap operation for each 64-bit entry is borrowed from OpenSSL.[7] To achieve constant-time behavior, Line 4 in Listing 2 first extends `secret` to be a machine-sized word; i.e., `0x0000000000000000` or `0xFFFFFFFFFFFFFFFF` based on the value of `secret`. Next, for each loop iteration, Line 6 of Listing 2 computes a masked `delta` between the contents of the current elements of `a` and `b`. Finally, Lines 7 and 8 actually conditionally swap the contents of the two elements, based on the value of `secret`.

```
1  void ct-swap(uint64_t secret, uint64_t *a, uint64_t *b,
2          size_t len) {
3      uint64_t delta;
4      uint64_t mask = ~(secret-1);
5      for (size_t i = 0; i < len; i++) {
6          delta = (a[i] ^ b[i]) & mask;
7          a[i] = a[i] ^ delta;
8          b[i] = b[i] ^ delta;
9      }
10 }
```

Listing 2: Code snippet of constant-time swap. The contents of `a` and `b` is conditionally swapped based on `secret`.

5.1 Attack Overview and Challenges

Emulating realistic attack scenarios, we assume that `ct-swap` runs in a victim process, separate from the attacker's address space. We assume a simple but common protocol between victim and attacker, where the victim takes input from the attacker to populate the `ct-swap`'s `a` and `b` arrays and then executes `ct-swap`. The outcome of the swap is never directly revealed, nor is the value of `secret`. The attacker can learn page offsets (not randomized by ASLR) of array `a` and `b` by investigating the victim's program in advance. The attacker process' goal is to extract the value of `secret` from the victim, using microarchitectural side channels and the DMP.

Chosen-Input Attack. We now overview how the attacker uses the DMP to extract `secret`. At a high level, the attacker populates one of `ct-swap`'s arrays (`a` or `b`—let us assume it chooses `b`) with a pointer `ptr` of its choosing, and then arranges for the DMP to dereference the contents of the other array (`a`) during the conditional swap computation. Then, the attacker uses conventional cache side-channel analysis to observe whether `ptr` was dereferenced by the DMP due to `ct-swap`'s computation over `a`, which in turn reveals whether the swap occurred and therefore the value of `secret`.

Overcoming DMP Activation Criteria. To correctly attribute the DMP's activation to `ptr` being moved from `b` to `a`, the attacker must ensure that the DMP's activation criteria are only satisfied when accessing `a` (and not `b`). Based on Section 4.2, one necessary prerequisite to activate the DMP on an `aop` load is to evict the `aop` from the L2 cache. Thus, we need a means to evict `a`[8] (but not `b`).

Overcoming Address Space Separation. Yet, since the attacker runs in a separate process from the victim and without any shared memory, we must replace the Flush+Reload in Section 4 with Prime+Probe. In particular, we must build an eviction set to detect whether `ptr` was dereferenced by the DMP inside the victim process. However, it is not clear how to build eviction sets for `ptr`'s target line (or `a` mentioned above),[9] as we cannot time accesses to these since they are located inside the victim's address space.

5.2 Compound Eviction Set Construction

We now present a novel technique—compound eviction set generation—which solves the above problem by using `ct-swap`'s access to `a` as well as DMP dereferences to `ptr` to simultaneously build eviction sets for both elements.

Establishing a Timing Source. To start, we need to distinguish between L2 hits and misses. However, as the attacker is running without elevated privileges, it is unable to access nanosecond-accurate timers on Apple CPUs, instead being limited to the system's 42 ns timer. Unfortunately, we empirically find that this timer is not sufficient to reliably mount Prime+Probe attacks. We sidestep this issue by using the multi-thread timer approach of [46, 69, 73]. Here, the main idea is to use a dedicated counting thread, which constantly increments a shared variable with the attacker process in a tight loop. By loading the value of the shared variable, the attacker

[7] `constant_time_cond_swap_64`: https://github.com/openssl/openssl/blob/1751185154ab1f1a796e0f39567fe51c8e24b78d/include/internal/constant_time.h.

[8] Triggering the DMP also requires that `a` is refilled after it is evicted. We rely on the victim to perform this refill. For example, `ct-swap` reads `a` in a loop, which will cause each cache line making up `a` to be accessed (refilled) multiple times (`len` > 1).

[9] We assume that the base addresses of `a` and `b` have different page-offset bits, so that the eviction set for `a` would not evict `b`, which also holds for later attacks.

process is thus able to obtain high resolution timestamps, allowing us to distinguish L2 hits from misses.

Generating Standard Eviction Sets. Next, we need to generate a large number of standard L2 eviction sets, i.e., eviction sets targeted to individual L2 sets. The M1 has 8192 (2^{13}) L2 cache sets, indexed with 6 (upper) bits from the physical page frame and 7 (lower) bits from the page offset. We generate standard eviction sets for all these L2 sets by extending the technique used in Section 4.2 (detailed in Appendix A).

Generating Compound Eviction Sets. With all standard L2 eviction sets in hand, we now need to test which of these are capable of evicting the target of `ptr`. As described in Section 5.1, this is non-trivial because observing the dereference of `ptr` via DMP activations requires an eviction set for `a` which we cannot create with standard techniques.

To solve this problem, we will build and test what we call *compound eviction sets*, which simultaneously evict both the target of `ptr` and `a`. We build candidate compound eviction sets as pairs (EV_a, EV_{ptr}) of standard L2 eviction sets, where EV_a (respectively EV_{ptr}) is an eviction set whose page-offset bits are compatible with `a` (respectively `ptr`).

We proceed as follows. First, the attacker will place `ptr` in both `a` and `b`. This is so that dereferences to `a` can occur regardless of the secret value. Next, the attacker tests whether each candidate compound set, denoted (EV_a, EV_{ptr}), can evict both `a` and `ptr`'s target by priming all lines in EV_{ptr} and continuously traversing EV_a, and then probing/timing EV_{ptr}. If the probe results in an L2 miss, the target of `ptr` filled the cache and displaced a line in EV_{ptr}. This simultaneously implies that EV_a evicted `a` because evicting `a` is the only way that the DMP would have dereferenced `ptr`. If the probe results in all L2 hits, either EV_a or EV_{ptr} were not eviction sets for `a` or `ptr`, respectively.

The complexity of compound eviction set finding is proportional to the number of possible candidates. With the knowledge of page offsets of `a` and `ptr`, the attacker can reduce the number of potential L2 sets each of them maps to from 8192 to 64. Meanwhile, EV_a only needs to be a superset of the standard eviction. We group 8[10] standard eviction sets as one EV_a in our PoCs, which leads to 512 candidates overall. We run our compound eviction sets construction algorithm 10 times and the mean time for all L2 eviction set generation is 263.9 seconds, while 113.6 seconds for finding the compound eviction set. Overall, we find that we are able to reliably construct these compound eviction sets using the above-described technique, allowing us to proceed to using the DMP in order to recover `secret` from within `ct-swap`'s address space.

5.3 Proof-of-Concept Results

With the compound eviction set (EV_a, EV_{ptr}) for `a` and `ptr`'s target in hand, we now demonstrate a proof-of-concept attack on `ct-swap` to learn the secret `secret`. For all proof-of-concept attacks, we use three attacker processes. The first process establishes a TCP connection with the victim process and transmits the value of `ptr` to the victim. The victim process upon receiving `ptr` subsequently executes `ct-swap(a,b,secret)` where `a` is some dummy value, `b` is full of multiple copies of `ptr`, and `secret` is a hardcoded value. In parallel, we use the second attacker process to continuously traverse EV_a, evicting `a` from the CPU's L2 cache during the execution of Line 7 of Listing 2. Finally, the third attacker process provides a high-resolution timing source via a counting thread that constantly increments a shared variable.

After transmitting the value of `ptr` to the victim, our first attacker process uses the Prime+Probe channel built on EV_{ptr} to monitor the DMP activation. We perform 3200 attack trials,[11] for both values of `secret`. Figure 9 summarizes our findings, with the timing distributions for `secret=1` and `secret=0` being clearly distinguishable.

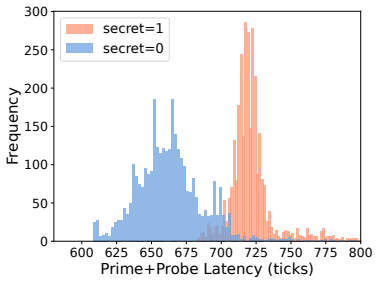


Figure 9: Prime+Probe latency of constant-time swap subroutine. If `ptr` shows up in `a` (`secret=1`), the attacker observes a high latency; otherwise (`secret=0`) it observes a low latency.

6 Attacking Classical Cryptography

We demonstrate that Go's RSA implementation and OpenSSL's Diffie-Hellman Key Exchange (DHKE) implementation, despite being constant-time, can leak secrets via the DMP side-channel. Both systems are otherwise secure against malicious inputs, but feature subroutines that activate the DMP based on the secret key. We draw inspiration from prior chosen-ciphertext side-channel attacks [4, 5, 9, 19, 20, 39, 40, 48, 53, 61, 90, 93], and adapt those techniques for the specific implementations considered in this section.

6.1 Go's RSA Encryption

Our targeted RSA implementation uses Montgomery multiplication, which implicitly blinds the RSA secret key except

[10] The group size is not "the bigger the better", since EV_a needs to evict array `a` before the victim loads `a`.

[11] Based on Section 4.2, the attacker has to reset the history filter to achieve re-dereferences to the same `ptr`. In our PoC, while the methods discussed in Section 4.2 could help, we experimentally find that the TCP socket code used in the victim process to receive inputs from the attacker generates a sufficient amount of traffic to reset the history filter.

during a single, necessary modular operation.[12] We find that an attacker can craft ciphertexts to exploit this modular operation and extract a partial RSA secret key by observing DMP activations.[13] They can then use the standard Coppersmith method to recover the entire RSA secret key [30, 71].

Go's RSA (1.20+) encryption overview. RSA is a public-key cryptosystem. Go (1.20+) RSA implementation follows the specification in RFC 8017 [63]. RSA has a public exponent e (65537 in Go's RSA). An RSA secret key consists of two primes p and q, and an integer d such that $ed \equiv 1 \bmod (p-1)(q-1)$. An RSA public key is $(N = p*q, e)$. Without loss of generality we assume $p > q$. Go's RSA uses the Chinese remainder theorem (CRT) to accelerate decryption.

PoC overview. In our PoC, we target Go's RSA-2048 (1.20). Similarly to [93], our threat model assumes that the victim (server) generates a pair of static public and secret keys. The attacker sends a ciphertext to the victim, and the victim decrypts the ciphertext using its secret key.[14] The public N is 2048 bits long, and the secret p and q are about 1024 bits long. Factoring N into p and q breaks RSA-2048. In our PoC, the attacker extracts the 560 most significant bits of p by observing DMP activations, and then uses the Coppersmith method to break RSA-2048.

DMP-vulnerable subroutine in Go's RSA. Listing 3 shows the DMP-vulnerable subroutine in Go's RSA `Decrypt`. `Decrypt` takes in an RSA secret key and a ciphertext c, and outputs a plaintext $m = c^d \bmod N$. Due to CRT, `Decrypt` breaks this exponentiation into two: $m = c^{D_p} \bmod p$ and $m = c^{D_q} \bmod q$, where D_p and D_q are CRT-related parameters.

The first step of $m = c^{D_p} \bmod p$ is to compute $t_0 = c \bmod p$. A key observation is that if $c < p$, t_0 remains as c. On the other hand, if $c \geq p$, t_0 becomes $c - l*p$, which is unpredictable because l is an unknown integer. Suppose c contains a `ptr`:

- If $c < p$, $t_0 = c$ contains the `ptr` and activates the DMP.
- If $c \geq p$, $t_0 \neq c$ is random and does not activate the DMP.

In this case, we can extract p bit by bit by observing DMP activations resulting from loading t_0. This allows us to treat t_0 as the AoP `a` in Section 5.[15]

Challenge ciphertext construction. Next, we show how to construct c to extract the 560 most significant bits of p (one at a time). In Figure 10, assume the attacker has already recovered the $n-1$ most significant bits of p and targets the n-th bit. Since p is 1024-bit, the attacker sets the leading 1024 bits of the 2048-bit c to be 0. They set the next $n-1$ bits of c to be the recovered $n-1$ bits of p, and the n-th bit of c to be 1. Then, the attacker sets the remaining bits of c to be all 0, except the lower 448 bits that are filled with 7 64-bit `ptrs`. The 16 bits immediately before the `ptrs` are always set to 0 and unused.

```
1 // m = c ^ Dp mod P
2 m  = bigmod.NewNat().Exp(t0.Mod(c, P), // t0 = c mod P
3 priv.Precomputed.Dp.Bytes(), P)
4 // m2 = c ^ Dq mod Q
5 m2 = bigmod.NewNat().Exp(t0.Mod(c, Q), // t0 = c mod Q
6 priv.Precomputed.Dq.Bytes(), Q)
```

Listing 3: DMP-vulnerable subroutine in Go's RSA (1.20) `Decrypt`. c is the attacker's challenge ciphertext that contains a `ptr`. t_0 functions as the AoP `a` in Section 5 because $t_0 = c \bmod p$ would activate the DMP if and only if $c < p$. Attacker can then extract p adaptively by observing DMP activations.

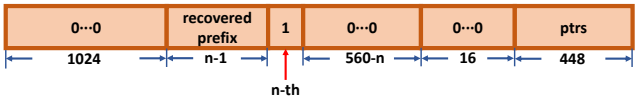

Figure 10: Challenge ciphertext construction to leak the n-th most significant bit of the p in Go's RSA-2048.

Assuming $p > q$, if the attacker observes no DMP activation from $t_0 = c \bmod p$, they can conclude that $c \geq p$ and the n-th bit of p is 0 with $1 - \frac{1}{2^{576-n}} \approx 1$ probability. On the other hand, if the attacker observes the DMP activation, they can conclude that $c < p$ and the n-th bit of p must be 1. Since $\frac{1}{2^{576-n}}$ becomes non-negligible as n approaches 576, we stop the attack at $n = 560$.

Experimental result. We now use the previous ciphertext construction strategy and the Coppersmith method to extract the full RSA secret key.[16] When targeting each of the 560 top bits of p, we collect 32 Prime+Probe latency data points to mitigate background noise. The median of the collected data is then compared to a profiled threshold: 742 ± 38 ticks when c triggers the DMP activation versus 664 ± 124 ticks when c does not trigger. We repeat the experiment targeting bit n if the collected data are outliers due to system noise. The end-to-end attack takes 49 minutes on average to finish. More details about compound eviction set generation and noise tolerance for Go's RSA are in Appendix B.

6.2 OpenSSL Diffie-Hellman Key Exchange

Our targeted OpenSSL DHKE implementation utilizes a window-based exponentiation algorithm. This creates a vulnerability given DMP: if an attacker crafts a malicious public key and correctly guesses the target window of the secret key, a multiplication subroutine will generate a `ptr` value. The attacker can then exploit DMP activations to adaptively extract the DH secret key.

[12] Updates to Go 1.20 cryptography: https://words.filippo.io/dispatches/go-1-20-cryptography/

[13] In Sections 6 and 7, DMP activation particularly refers to DMP dereferences to the attacker-chosen `ptr`.

[14] The attack does not apply to the RSA signature scheme because signatures are calculated as $s = h^d \bmod N$, where h is the message hash. Since hash is a one-way function, the attacker does not have precise control of h.

[15] t_0 is a Go `bigmod.Nat` whose internal representation is an array of 64-bit integers (on 64-bit machine).

[16] The implementation of the Coppersmith method used by our paper: https://github.com/mimoo/RSA-and-LLL-attacks

Cryptography	Online Time (minutes) ❶	❷	❸	Offline Time (minutes)
RSA-2048	5	18	26	∼0
DH-2048	5	6	127	∼0
Kyber-512	6	10	43	286
Dilithium-2	5	13	577	274

Table 1: Experimental results of four cryptographic attack PoCs. We show the mean of three runs of each PoC. Online time refers to the required time for a co-located attacker process, which includes ❶ standard eviction sets generation; ❷ compound eviction set finding; ❸ DMP leakage. Offline time is the post-processing (e.g. lattice reduction) time to complete secret key recovery. We do not include the time for the offline signature collection phase of Dilithium-2.

OpenSSL DHKE (1.1.1q) overview. DHKE allows two parties, Alice and Bob, to agree on a shared secret over an insecure channel [34]. The public parameters are a prime p and a generator g that generates a cyclic order-q subgroup of $\mathbb{Z}_p^*$. DHKE requires p to be a safe prime such that $q = \frac{p-1}{2}$.[17] Alice and Bob generate their own secret keys $x \in \mathbb{Z}_q$ and $y \in \mathbb{Z}_q$. Alice sends her public key g^x mod p to Bob and Bob sends his g^y mod p to Alice. They both compute the shared secret $(g^x)^y$ mod $p = (g^y)^x$ mod p. The security of DHKE relies on the computational Diffie–Hellman (CDH) assumption that given g^x mod p, g^y mod p, and g, it is computationally difficult to compute g^{xy} mod p.

PoC overview. Following [41,61], our threat model assumes that the victim (server) and attacker (client) do a DH key exchange. The victim (server) generates a random 2048-bit DH public parameter p and shares it with the attacker (client). The victim generates its own static secret key s. The attacker sends a challenge public key c to the victim, who computes c^s mod p using the OpenSSL window-based exponentiation. The window size w is 6. The attacker extracts s window after window by observing DMP activations.

DMP-vulnerable subroutine in OpenSSL DHKE. The victim breaks s into k windows $s_0\|s_1\|...\|s_{k-1}$ with each window of size w. Listing 4 shows a simplified version of the algorithm that computes c^s mod p window by window, where we replace most of the code with descriptive comments and only highlight the DMP-vulnerable subroutine `bn_mul_mont_fixed_top`. To start with, a variable `tmp` is initialized to c^{s_0}. At the end of each while loop iteration i (i starts from 1), `tmp` $= c^{s_0\|...\|s_i}$.

During iteration i, an invariant holds after Line 5: `tmp` $= (c^{s_0\|s_1\|...\|s_{i-1}})^{2^w}$. If the attacker already recovered the prefix $s_0\|s_1\|...\|s_{i-2}$, they can guess s_{i-1} and construct c strategically. If their guess is correct, `tmp` will contain a `ptr` after Line 5, triggering the DMP. Consequently, the subroutine `bn_mul_mont_fixed_top` is DMP-vulnerable, and `tmp` is the AoP `a` in Section 5.

```
1 // tmp = c^(s0)
2 while (bits > 0) {
3   for (i = 0; i < w; i++)
4     if (!bn_mul_mont_fixed_top(&tmp, &tmp, &tmp, mont, ctx))
5       goto err;
6   // bits -= w;
7   // tmp = tmp * c^(si)
8 }
```

Listing 4: `bn_mul_mont_fixed_top` is our DMP-vulnerable subroutine in OpenSSL DHKE (1.1.1q). The secret key s is broken into k windows $s_0\|s_1\|...\|s_{k-1}$ with a window size w. An attack who knows $s_0\|s_1\|...\|s_{i-2}$ can guess s_{i-1} and construct c such that if the guess is correct, `tmp` contains `ptr` after Line 5. The attacker can then extract s adaptively.

Challenge public key construction. Next, we show how to construct the challenge public key c. All multiplication is in Montgomery form, so every operand is pre-multiplied with a public constant R. Assume the attacker already recovered $s_0\|s_1\|...\|s_{i-2}$. To target s_{i-1}, the attacker makes a guess of its value and constructs c by solving the equation

$$(c^{s_0\|s_1\|...\|s_{i-1}})^{2^w} \cdot R \equiv \texttt{tmp} \mod p \quad (1)$$

where the 2048-bit attacker-controlled output buffer `tmp` contains a `ptr`.

Let E denote the exponent $(s_0\|s_1\|...\|s_{i-1}) * (2^w)$. We start by assuming that the exponent E is an odd number.

If E is an odd number, we first move R to the right-hand side of the equation by doing an inverse:

$$c^E \equiv R^{-1} \cdot \texttt{tmp} \mod p \quad (2)$$

Since p is a safe prime, $gcd(p-1, E) = 1$ (E is odd), the modular inverse E^{-1} ($E^{-1} \cdot E \equiv 1 \mod (p-1)$) exists due to Fermat's little theorem, and c can be solved as $(\texttt{tmp} \cdot R^{-1})^{E^{-1}}$ mod p [39].

However, $E = (s_0\|s_1\|...\|s_{i-1}) * (2^w)$ is an even number. An even number can be factorized as an odd number multiplied by 2^n. In order to convert an even number to an odd number, we need to eliminate the 2^n. Tonelli-Shanks algorithm explains how to calculate the modular square root for n times, but only half of the elements in $\mathbb{Z}_p^*$ are quadratic residues, which means that a given number might not have recursive modular square roots of depth-n [74,81] . This problem can be overcome because `tmp` has 32 64-bit elements and only one needs to be the `ptr`. We can adjust any of the other 31 64-bit elements to ensure that $\texttt{tmp} \cdot R^{-1}$ mod p has recursive modular square roots of depth-n. Once the 2^n factor is eliminated, we can apply the odd-E case outlined above.

Experimental result. For a target window i, there are only 2^w (64) possible values of s_i. For each guess of s_i, we collect 32 Prime+Probe latency data points to mitigate background noise. We repeat an experiment if the collected data contains

[17] Why Diffie-Hellman prefers safe primes: https://www.johndcook.com/blog/2017/01/12/safe-primes-sylow-theorems-and-cryptography/

outliers due to system noise. We compare the median of our collected data with a profiled threshold to determine if our guess of s_i is correct. After testing all 64 values, we expect to observe 1 high Prime+Probe latency (correct guess) and 63 low Prime+Probe latencies (incorrect guesses). If the number of positive and negative measurements deviates from this, we redo the experiment for this window. When the challenge public key c triggers the DMP, the Prime+Probe latency is 701 ± 65 ticks, compared to 641 ± 10 when it does not. The experiment takes 2.3 hours to complete, and we extract the victim secret key s. Appendix B provides further details about compound eviction set generation and noise tolerance for OpenSSL DHKE.

7 Attacking Post-Quantum Cryptography

We demonstrate that the implementation of two CRYSTALS cryptographic primitives, Kyber and Dilithium, though designed to be constant-time, can leak secrets via the DMP side channel.[18] Kyber is an IND-CCA2-secure (secure against adaptive chosen-ciphertext attack) NIST-selected key encapsulation mechanism (KEM) [12]. Dilithium is a NIST-selected digital signature scheme [57]. Both Kyber and Dilithium rely on the hardness of Module-LWE (MLWE).

Notation: R denotes the ring $(\mathbb{Z}[x]/x^n+1)$. R_q denotes the ring $(\mathbb{Z}_q[x]/x^n+1)$. R_q^k denotes the space of length-k vectors whose elements are in R_q. $R_q^{k\times l}$ denotes the space of $k \times l$ matrices whose elements are in R_q. For a polynomial p, $p[i]$ denotes the i-th coefficient of p. For a vector $\mathbf{v}$, $\mathbf{v}[i]$ denotes the i-th polynomial of $\mathbf{v}$, and $\mathbf{v}[i][j]$ denotes the j-th coefficient of $\mathbf{v}[i]$. For a vector $\mathbf{v} \in R_q^k$ (or matrix $\mathbf{A} \in R_q^{k\times l}$), $\mathbf{v}^T$ (or $\mathbf{A}^T$) denotes its transpose. $\lceil x \rfloor$ denotes rounding x to the closest integer, rounding up in the case of ties. B_η and S_η denote the centered binomial and uniform random distribution respectively. A number sampled from B_η or S_η is within the range $[-\eta, \eta]$. When we say that $\mathbf{v} \in R_q^k$ is sampled from B_η (S_η), we mean that each coefficient of polynomials in $\mathbf{v}$ is sampled from B_η (S_η). B_τ denotes the set of sparse polynomials in R where τ coefficients are either -1 or 1 and the rest are 0.

7.1 Kyber

Kyber decapsulation relies on a decryption subroutine. Decryption failure leaks the Kyber secret key [35, 66–68, 75]. While Kyber does not expose decryption failures to the attacker, the attacker can use the DMP side channel to construct a decryption failure oracle and then extract the secret key.

Kyber overview. A KEM uses a public key encryption (PKE) scheme to secure symmetric key material. Kyber builds upon a PKE scheme called Kyber.CPAPKE, which is chosen-plaintext secure (CPA-secure). Kyber is a Fujisaki-Okamoto (FO) transformation of the underlying Kyber.CPAPKE, which turns a CPA-secure PKE into a IND-CCA2-secure KEM [38].

Kyber.CPAPKE key generation samples the secret key $\mathbf{s}, \mathbf{e} \in R_q^k$ from B_{η_1}, with η_1 being a small integer. The public key consists of $\mathbf{t} \in R_q^k$ and a random $\mathbf{A} \in R_q^{k\times k}$, where $\mathbf{t} = \mathbf{A}\mathbf{s} + \mathbf{e}$.[19] Leaking either $\mathbf{s}$ or $\mathbf{e}$ breaks Kyber.

Kyber.CPAPKE encryption takes in the public key $(\mathbf{t}, \mathbf{A})$, a 256-bit message M, and a seed r as the source of randomness. $M = M_0 M_1 ... M_{255}$ is converted to a polynomial $m_p \in R_q$, where $m_p(x) = \sum_{i=0}^{255} M_i * \lceil \frac{q}{2} \rfloor * x^i$. Then, it samples $\mathbf{r} \in R_q^k$ from B_{η_1}, $\mathbf{e_1} \in R_q^k$ from B_{η_2}, and $e_2 \in R_q$ from B_{η_2}, with η_1 and η_2 being small integers. It computes $\mathbf{u} = \mathbf{A}^T\mathbf{r} + \mathbf{e_1}$, and $v = \mathbf{t}^T\mathbf{r} + e_2 + m_p$. The ciphertext is $(\mathbf{u}, v)$.

Kyber.CPAPKE decryption takes in the ciphertext $(\mathbf{u}, v)$, and the secret key $(\mathbf{s}, \mathbf{e})$. It computes $v - \mathbf{s}^T\mathbf{u} = m_p + \mathbf{e}^T\mathbf{r} + e_2 - \mathbf{s}^T\mathbf{e_1}$. Coefficients in m_p are either 0 or $\lceil \frac{q}{2} \rfloor$. Coefficients in $\mathbf{e}^T\mathbf{r} + e_2 - \mathbf{s}^T\mathbf{e_1}$ are small integers. Decryption recovers the plaintext M by rounding each coefficient of $v - \mathbf{s}^T\mathbf{u}$ to 1 if the coefficient is closer to $\lceil \frac{q}{2} \rfloor$ than to 0; and to 0 otherwise.

Decryption failure occurs with negligible probability when processing normal ciphertexts. Let M' denote the decrypted plaintext. If decryption fails, resulting in $M'_i \neq M_i$ (the i-th bit is flipped), this happens only if the i-th coefficient of the error vector $(\mathbf{e}^T\mathbf{r} + e_2 - \mathbf{s}^T\mathbf{e_1})[i] \geq \lceil \frac{q}{4} \rfloor$.

PoC overview. We target the Kyber-512 reference implementation, where $n = 256$, $q = 3329$, $k = 2$, $\eta_1 = 3$, and $\eta_2 = 2$. Our threat model assumes that the victim (server) and attacker (client) want to derive a shared secret using Kyber. The victim (server) generates a pair of static Kyber secret and public keys. The secret $\mathbf{s}$ has two ($k = 2$) polynomials, each with 256 coefficients. The attacker guesses a value for $\mathbf{s}[i][j]$ and then crafts a plaintext M containing a `ptr`. They encrypt M using the victim's public key and send the ciphertext to the victim for decryption.

DMP-vulnerable subroutine in Kyber. Kyber's DMP-vulnerable subroutine is `indcpa_dec`, the CPAPKE decryption function. It decrypts the challenge ciphertext that encrypts a plaintext M containing a `ptr`, and stores the decrypted M' into a buffer `buf`. If the decryption is successful, $M' = M$ and `buf` contains `ptr`. Otherwise, $M' \neq M$ and `buf` does not contain `ptr`.

Kyber is CCA secure. Decapsulation would reject a malformed ciphertext without exposing $M' = M$ or $M' \neq M$ to the attacker. However, the attacker can learn decryption failure or success by observing whether `ptr` is dereferenced by the DMP. This behavior is not an implementation issue but fundamental to the FO transform. As a result, subroutine `indcpa_dec` is DMP-vulnerable and `buf` is the AoP `a` in Section 5.

[18] CRYSTALS: Cryptographic Suite for Algebraic Lattices https://pq-crystals.org/index.shtml

[19] The security level of Kyber scales with k. A MLWE matrix from $R_q^{k\times k}$ is analogous to a $nk \times nk$ matrix in LWE.

Challenge ciphertext construction. We demonstrate how to construct a ciphertext $(\mathbf{u}, v)$ that allows the attacker to build a decryption failure oracle using DMP activations. Recall:

$$\begin{aligned} \mathbf{u} &= \mathbf{A}^T\mathbf{r} + \mathbf{e_1} \\ v &= \mathbf{t}^T\mathbf{r} + e_2 + m_p \end{aligned} \tag{3}$$

Suppose the attacker attempts to learn the first coefficient of the first polynomial in $\mathbf{s}$: $\mathbf{s}[0][0]$. They prepare a plaintext M with a `ptr` in $M_{0...63}$ and fill the rest with 0s: $M = \texttt{ptr}||00...00$. They manipulate other variables to ensure the following: if $0 < \mathbf{s}[0][0]$, $(\mathbf{u}, v)$ decrypts to M; otherwise, it decrypts to M' with the first bit flipped ($M'_0 = M_0 \oplus 1$). To achieve this, they can set $\mathbf{r} = (0,0)$ (a length-2 vector of degree-0 polynomials), $e_2 = \lceil \frac{q}{4} \rfloor$ (a degree-0 polynomial), and $\mathbf{e_1} = (1,0)$. This results in a ciphertext of $\mathbf{u} = (1,0)$, $v = m_p + e_2$.

Decryption computes $v - \mathbf{s}^T\mathbf{u}$:

$$\begin{aligned} v - \mathbf{s}^T\mathbf{u} &= m_p + e_2 - \mathbf{s}^T\mathbf{e_1} \\ &= m_p + e_2 - (\mathbf{s}[0], \mathbf{s}[1])^T(1,0) \\ &= m_p + \lceil \frac{q}{4} \rfloor - \mathbf{s}[0] \end{aligned} \tag{4}$$

The first entry of $v - \mathbf{s}^T\mathbf{u}$ is $m_p[0] + \lceil \frac{q}{4} \rfloor - \mathbf{s}[0][0]$, containing a deliberately introduced large error $\lceil \frac{q}{4} \rfloor - \mathbf{s}[0][0]$. Decryption would fail if $\lceil \frac{q}{4} \rfloor - \mathbf{s}[0][0] \geq \lceil \frac{q}{4} \rfloor$. The ciphertext construction ensures that decryption failure depends on the value of $\mathbf{s}[0][0]$:

- If $\lceil \frac{q}{4} \rfloor - \mathbf{s}[0][0] < \lceil \frac{q}{4} \rfloor$ $(0 < \mathbf{s}[0][0])$, $M' = M = \texttt{ptr}||00...00$, and `buf` activates the DMP.
- If $\lceil \frac{q}{4} \rfloor - \mathbf{s}[0][0] \geq \lceil \frac{q}{4} \rfloor$ $(0 \geq \mathbf{s}[0][0])$, $M' \neq M$ because the first bit is flipped ($M'_0 = M_0 \oplus 1$), and `buf` cannot activate the DMP.

The attacker can learn the exact value of $\mathbf{s}[0][0]$ by tuning e_2 and observing DMP activations. To trigger DMP activation on `buf` (e.g., eviction set construction), we employ the same method as the chosen-input attack from Section 5.1.

We now present a simplified version of our attack. Kyber includes an extra compression and decompression step. In [25], we detail how to overcome the compression when constructing the challenge ciphertext.

The secret key has $256 \times 2 = 512$ coefficients. Ideally, the attacker should be able to apply the same process above to target any coefficient of $\mathbf{s}$. However, due to findings in Section Section 4.3, the DMP cannot leak every coefficient of $\mathbf{s}$: If we break $\mathbf{s}$ into chunks of 64, the leading 8 and trailing 7 bits are not recoverable via the DMP. As a result, 392 out of 512 coefficients can be recovered by observing DMP activations. We feed the recovered 392 coefficients as 392 hints into the lattice reduction tool from May et al., to recover the entire secret key [59]. In [25], we provide more details about why certain coefficients are not recoverable, and how we use the lattice reduction tool.

Experimental result. In our PoC, there are 392 recoverable secret coefficients. We construct 8 challenge ciphertexts to adaptively learn each coefficient, as its potential value ranges from -3 to 3. See [25] for why we need 8 ciphertexts. For each ciphertext, we collect 32 Prime+Probe latency data points to mitigate background noise. We repeat the experiment if the data we collect contains outliers due to system noise. We compare the median of our collected data with a profiled threshold to determine the activation status of the DMP. When the ciphertext triggers the DMP (decryption succeeds), the Prime+Probe latency is 713 ± 22 ticks, compared to 616 ± 14 ticks when it does not (decryption fails). The experiment takes 59 minutes to complete. After that, we spend another 5 hours on lattice reduction to extract the entire secret key. More details about compound eviction set generation and noise tolerance for Kyber are in Appendix B.

7.2 Dilithium

Dilithium relies on the "Fiat-Shamir with Aborts" [57], and its security depends on the privacy of its nonce $\mathbf{y}$ [56]. Dilithium is secure against chosen-message attacks, meaning a polynomial-time attacker cannot learn secret information by observing signatures. However, Dilithium might generate data in $\mathbf{y}$ that resembles a pointer. By monitoring DMP activations, an attacker could obtain knowledge of $\mathbf{y}$, derive linear equations involving the secret key, and ultimately extract the entire secret key. Prior research has explored similar attacks that exploit side channels to learn intermediate values during Dilithium signing, allowing secret key reconstruction [15, 28, 49, 58, 77, 87].

Dilithium overview. *Dilithium key generation* samples the secret key $\mathbf{s_1} \in R_q^l$ from S_η and $\mathbf{s_2} \in R_q^k$ from S_η, with η being a small integer. The public key consists of $\mathbf{t} \in R_q^k$ and a random $\mathbf{A} \in R_q^{k \times l}$, where $\mathbf{t} = \mathbf{A}\mathbf{s_1} + \mathbf{s_2}$. Leaking either $\mathbf{s_1}$ or $\mathbf{s_2}$ breaks Dilithium. Dilithium also has a public key compression, which we discuss in [25].

Dilithium signature generation uses rejection sampling to generate digital signatures [56]. In Algorithm 1 we present a simplified version that focuses on the part relevant to our attack. The algorithm generates a signature $(\mathbf{z}, c)$ of a message M using the secret key $\mathbf{s}_1$. $\mathbf{z}$ is initialized to $\perp$ (Line 2). In a while loop, the algorithm samples a private nonce $\mathbf{y}$, which is a length-l vector of polynomials with coefficients randomly sampled from $[-\gamma_1, \gamma_1]$ (Line 4). Then, the algorithm samples a random c from B_τ, and c depends on M (Line 5). c is a sparse polynomial with exactly τ number of 1 or -1, and the non-zero entries have randomized positions. The algorithm computes $\mathbf{z} = \mathbf{y} + c\mathbf{s}_1$ (Line 6), but will only accept $(\mathbf{z}, c)$ if it leaks no secrets, and reject $(\mathbf{z}, c)$ otherwise. Note that $\mathbf{y}$ must be kept private. Leaking $\mathbf{y}$ leaks $\mathbf{s}_1 = \frac{\mathbf{z}-\mathbf{y}}{c}$. Leaking partial information of $\mathbf{y}$ might also compromise $\mathbf{s}_1$ [18].

PoC overview. The victim (a Dilithium signing server) generates a pair of Dilithium secret and public keys. Our threat

1 Sign($\mathbf{s}_1$,M)
2 $\mathbf{z} := \perp$
3 **while** $\mathbf{z} = \perp$ **do**
4 $\quad \mathbf{y} \leftarrow S^{\ell}_{\gamma_1}$ // A length-l vector of random and small polynomials
5 $\quad c \in B_\tau$ // A sparse polynomial (depending on M) with τ number of 1 or -1
6 $\quad \mathbf{z} := \mathbf{y} + c\mathbf{s}_1$
$\quad$ // Reject $\mathbf{z}$ (set $\mathbf{z}$ to $\perp$) if $\mathbf{z}$ leaks information about the secret key
7 $\quad$ **return** $(\mathbf{z}, c)$
8 **end**

Algorithm 1: The main body of the Dilithium sign algorithm is a while loop that creates a signature $(\mathbf{z}, c)$ of message M under the secret key $\mathbf{s}_1$. The algorithm returns $(\mathbf{z}, c)$ if it does not leak any secret information.

model assumes that the victim is a signing server. The attacker can choose arbitrary messages and request digital signatures from the victim. The attacker can parse the signatures offline and replay certain messages later.

We target CIRCL's implementation of deterministic Dilithium-2 (written in Go), where $n = 256$, $q = 8380417$, $k = l = 4$, $\gamma_1 = 2^{17}$, $\eta = 2$, and $\tau = 39$ [37].[20] Dilithium is deterministic when the private nonce $\mathbf{y}$ in Algorithm 1 is generated with deterministic randomness. Our attack is motivated by the observation: *the server might naturally produce data that resembles a* `ptr` *in* $\mathbf{y}$. While the exact value of $\mathbf{y}$ should remain secret, the underlying MLWE structure allows an attacker to approximate $\mathbf{y}$ through $\mathbf{z}$. If a `ptr` appears in $\mathbf{z}$, the attacker infers its presence within $\mathbf{y}$ and confirms this by observing DMP activations. Successful confirmation reveals partial knowledge of $\mathbf{s}_1$.

Our PoC consists of an offline and online signature collection phase. During the offline phase, the attacker sends m message to the server requesting signatures and collects m' pairs of $\{(\mathbf{z}, c), M\}$, where $\mathbf{z}$ contains a `ptr`. During the online phase, the attacker re-submits the collected m' messages to the server for signatures. The attacker can distinguish which pair $\{(\mathbf{z}, c), M\}$ causes the `ptr` to show up in $\mathbf{y}$ via DMP activations, and then derive a linear equation of $\mathbf{s}_1$. The attacker further uses the lattice reduction tool to recover $\mathbf{s}_1$ [59].

DMP-vulnerable subroutine in CIRCL Dilithium. The DMP-vulnerable subroutine is the $\mathbf{z} = \mathbf{y} + c\mathbf{s}_1$ in Algorithm 1 Sign. CIRCL uses an array of unsigned 32-bit integers to represent a polynomial. Every coefficient of $\mathbf{y}$ and $\mathbf{z}$ is stored as an unsigned 32-bit integer. We pick $\mathbf{y}$ as the AoP `a` from Section 5. The range of coefficients in $\mathbf{y}$ is $[-2^{17}, 2^{17}]$, and that of coefficients in $c\mathbf{s}_1$ is $[-78, 78]$.

Let's take the first two 32-bit coefficients of $\mathbf{y}$ ($\mathbf{y}[0][0]$, $\mathbf{y}[0][1]$) and $\mathbf{z}$ ($\mathbf{z}[0][0]$, $\mathbf{z}[0][1]$) as an example. Assume that $\mathbf{z}[0][1] \parallel \mathbf{z}[0][0]$ forms a valid 64-bit `ptr`, pointing to the same 4GByte region where $\mathbf{y}$ lives. If we break `ptr` into two 32-bit halves ($\texttt{ptr}_1 \parallel \texttt{ptr}_0$), then $\mathbf{z}[0][1] = \texttt{ptr}_1$ and $\mathbf{z}[0][0] = \texttt{ptr}_0$. We can derive the range of ($\mathbf{y}[0][0]$, $\mathbf{y}[0][1]$):

$$\begin{aligned} \mathbf{y}[0][1] &= \mathbf{z}[0][1] - c\mathbf{s}_1[0][1] \in [\texttt{ptr}_1 - 78, \texttt{ptr}_1 + 78] \\ \mathbf{y}[0][0] &= \mathbf{z}[0][0] - c\mathbf{s}_1[0][0] \in [\texttt{ptr}_0 - 78, \texttt{ptr}_0 + 78] \end{aligned} \quad (5)$$

The takeaway from Equation (5) is that if $\mathbf{z}[0][1] \parallel \mathbf{z}[0][0]$ is a `ptr`, $\mathbf{y}[0][1] \parallel \mathbf{y}[0][0]$ might also be a `ptr`!

To elaborate, we know $\mathbf{z}[0][1] \parallel \mathbf{z}[0][0]$ forms a `ptr`. If we want $\mathbf{y}[0][1] \parallel \mathbf{y}[0][0]$ to also form a `ptr`, we only need $\mathbf{y}[0][1] = \mathbf{z}[0][1]$ or $c\mathbf{s}_1[0][1] = 0$. The value of $\mathbf{y}[0][0]$ is less important because $c\mathbf{s}_1[0][0]$ is small, variations in which will only cause $\mathbf{y}[0][1] \parallel \mathbf{y}[0][0]$ to map to the same or an adjacent cache line as `ptr`. As a result, $\mathbf{z} = \mathbf{y} + c\mathbf{s}_1$ is DMP-vulnerable. If the attacker sets $\mathbf{y}$ as the AoP `a` from Section 5, they can learn $c\mathbf{s}_1[0][1] = 0$ by observing DMP activations. The same idea applies to all other coefficients of $\mathbf{y}$ and $\mathbf{z}$.

Offline and Online signature collection In the offline phase, the attacker sends m random messages for signatures. Recall that $\mathbf{z}$ is a length-4 vector of 256-degree polynomials. The attacker collects m' pairs of $\{(\mathbf{z}, c), M\}$ where for an $i \in [0, 3]$ and an even $j \in [0, 255]$, $\mathbf{z}[i][j+1] \parallel \mathbf{z}[i][j]$ forms a `ptr`, which lives in the same 4GByte region as $\mathbf{y}$.[21]

In the online phase, the attacker re-submits the m' messages collected offline. If the attacker observes a DMP activation, the attacker can deduce that $\mathbf{y}[i][j+1] = \mathbf{z}[i][j+1]$, and derive one linear equation of $\mathbf{s}_1$: $c\mathbf{s}_1[i][j+1] = 0$. After gathering at least 876 linear equations, the attacker uses the lattice reduction tool to recover $\mathbf{s}_1$ [59].

In [25], we discuss more details about our PoC including a theoretical bound of m and m', and how to loose some conditions above for the practicality of the PoC.

Experimental result. In our PoC, we request $m = 4 \times 10^9$ messages during the offline collection phase. We parse the signatures and collect $m' = 3 \times 10^5$ ones with the property that $\mathbf{z}[i][j+1] \parallel \mathbf{z}[i][j]$ forms a `ptr`. In the online phase, resubmitting the m' messages, we observe a Prime+Probe latency of 772 ± 152 ticks when the message triggers the DMP, compared to 657 ± 106 ticks when it does not. To minimize false positives, we accept a message as triggering the DMP only after observing 10 consecutive positive signals. The entire experiment takes 10 hours. An additional 5 hours are spent on lattice reduction to extract the full secret key. More details about compound eviction set generation and noise tolerance for CIRCL Dilithium are in Appendix B.

[20] CIRCL: Cloudflare's Interoperable Reusable Cryptographic Library https://github.com/cloudflare/circl/

[21] Both base addresses of $\mathbf{z}$ and $\mathbf{y}$ are 64-bit aligned, so that entries at even indexes are 64-bit aligned as well.

8 Countermeasures

This paper demonstrates that information disclosure through the Apple m-series DMP is significantly greater than previously believed, and puts constant-time cryptography at risk. A drastic solution would be to completely disable the DMP. However, as doing so will incur heavy performance penalties and is likely not possible on M1 and M2 CPUs,[22] in this section we discuss alternative defensive approaches.

Using Efficiency Cores. As pointed out by Augury [84], the DMP does not activate on code running on Icestorm cores. Thus, a sensible short-term security posture is to run all cryptographic code on Icestorm cores. This strategy is simple, general, and does not require user code changes. Yet, it is brittle because any future Apple part could silently enable the DMP on Icestorm cores. Finally, restricting cryptography to run on Icestorm cores will likely incur a significant performance penalty.

Blinding. An alternative solution is to apply cryptographic blinding-like techniques. For example, by instrumenting the code to add/remove masks to sensitive values before/after being stored/loaded from memory. These ideas could be applied in different ways depending on the sensitive program. For instance, in our attack on Diffie-Hellman Key Exchange, one can generate a random number to mask the secret key for every key exchange [45]. The major downside of this approach is that it requires potentially DMP-bespoke code changes to every cryptographic implementation, as well as heavy performance penalties for some cryptographic schemes.

Ad-Hoc Defenses. Finally, one can imagine point defenses that interfere with specific steps in the attack. For example, changing victims to better validate inputs or scheduling policies to forbid co-location [70]. The downside of these approaches is that they are ad-hoc and leave the root cause (the DMP) unaddressed.

Hardware Support. Longer term, we view the right solution to be to broaden the hardware-software contract to account for the DMP. At a minimum, hardware should expose to software a way to selectively disable the DMP when running security-critical applications. This already has nascent industry precedent. For example, Intel's DOIT extensions specifically mention disabling their DMP through an ISA extension [3]. Longer term, one would ideally like finer-grain control, e.g., to constrain the DMP to only prefetch from specific buffers or designated non-sensitive memory regions.

9 Conclusions

In this paper we showed that DMPs pose a significant security threat to modern software, breaking a wide variety of state-of-the-art cryptographic implementations. At a high level, if the attacker has the ability to secret-dependently write a pointer to memory, the DMP enables it to learn partial or complete information about that secret. While we demonstrate end-to-end attacks on four cryptographic implementations, more programs are likely at risk given similar attack strategies. Given our findings that DMPs also exist on the Apple M2/M3 and Intel 13th Generation CPUs, the problem seemingly transcends specific processors and hardware vendors and thus requires dedicated hardware countermeasures.

[22] We observe that setting the data independent timing (DIT) [1] bit disables the DMP behavior on M3, which is not the case with M1 and M2.
